Important note: Medicine is an ever-changing science undergoing continual development. Research and clinical experience are continually expanding our knowledge, in particular our knowledge of proper treatment and drug therapy. Insofar as this book mentions any dosage or application, readers may rest assured that the authors, editors, and publishers have made every effort to ensure that such references are in accordance with the state of knowledge at the time of production of the book.

Nevertheless, this does not involve, imply, or express any guarantee or responsibility on the part of the publishers in respect to any dosage instructions and forms of applications stated in the book. Every user is requested to examine carefully the manufacturers' leaflets accompanying each drug and to check, if necessary in consultation with a physician or specialist, whether the dosage schedules mentioned therein or the contraindications stated by the manufacturers differ from the statements made in the present book. Such examination is particularly important with drugs that are either rarely used or have been newly released on the market. Every dosage schedule or every form of application used is entirely at the user's own risk and responsibility. The authors and publishers request every user to report to the publishers any discrepancies or inaccuracies noticed. If errors in this work are found after publication, errata will be posted at www.thieme.com on the product description page.

Some of the product names, patents, and registered designs referred to in this book are in fact registered trademarks or proprietary names even though specific reference to this fact is not always made in the text. Therefore, the appearance of a name without designation as proprietary is not to be construed as a representation by the publisher that it is in the public domain.

This book, including all parts thereof, is legally protected by copyright. Any use, exploitation, or commercialization outside the narrow limits set by copyright legislation without the publisher's consent is illegal and liable to prosecution. This applies in particular to photostat reproduction, copying, mimeographing or duplication of any kind, translating, preparation of microfilms, and electronic data processing and storage.

Of all the blessings I have received, the most important is the encouragement and love of the smartest person I know—my dear Peg—and three very impressive young men, Anthony, James, and Matthew. Without their love and support, I could never have completed this book, and it is to them that I dedicate this work.

Foreword

As a specialty, otolaryngology–head and neck surgery covers a diverse set of clinical problems, most of which can be managed by a general otolaryngologist. It seems that most practicing otolaryngologists prefer certain aspects of our field and frequently concentrate their practice in one or several of these areas. Some of the more complicated problems within otolaryngology–head and neck surgery require additional subspecialization and training, advanced equipment, and/or specialized facilities to obtain the best outcomes. For medical students, and even colleagues in other fields, it is frequently difficult to appreciate the breadth of the specialty. For residents and fellows, it can be intimidating to consider the mastery of otolaryngology-head and neck surgery.

The editors of Total Otolaryngology–Head and Neck Surgery have successfully created a single volume covering all aspects of our specialty, in an accessible format that is well organized and beautifully illustrated. The book is organized into sections which include Emergency Management, General Otolaryngology, Head and Neck Surgery, Facial Plastic Surgery, Pediatric Otolaryngology, Laryngology, Rhinology and Otology. The chapters are concise and efficient, containing the most relevant information. Illustrations within the

text are easy to understand, while clinical pictures clearly demonstrate the underlying clinical condition. Many chapters also contain algorithms and tables to help provide quick overview of the accompanying text. Recommended reading lists are also included, which refer the reader to the most important references on a specific topic.

Total Otolaryngology–Head and Neck Surgery provides a framework for understanding the extent and depth of our field. This format provides important context for those trying to master the field and serves as a great reference, especially for practitioners who are focused on other areas of the specialty who need an update about advances in other aspects of the specialty. Congratulations to Dr. Sclafani and his coeditors on creating an up-to-date, well-illustrated, and comprehensive resource covering otolaryngology–head and neck surgery, which will aid in the training of future residents and fellows and serve as an excellent reference for practicing otolaryngologists.

Ronald B. Koppersmith, MD, FACS
Texas ENT and Allergy
College Station, Texas

Preface

Otolaryngology-head and neck surgery has developed as a specialty in recognition of the highly focused attention necessary to fully comprehend and master the intricate anatomic and physiologic relationships of the structures located between the thoracic inlet and the foramen magnum. Our specialty originally developed out of a need to manage the intricacies of this area of the body, but as the depth of our knowledge grew, subspecialties within the discipline branched off. Often, it may seem that we are a collection of otologists, neurotologists, head and neck oncologists, laryngologists, pediatric otolaryngologists, rhinologists, facial plastic surgeons, and general otolaryngologists. There are times when, as a group, we seem to speak different dialects of a common tongue.

The true otolaryngologist-head and neck surgeon, however, is well-versed in the broad spectrum of the field and, if not an expert, can certainly understand the issues managed by other subspecialists. The facial plastic surgeon performing microtia repair should understand the issues faced by the otologist in providing aural rehabilitation to the patient; the pediatric otolaryngologist appreciates the implications of airway surgery on the development of voice and speech; the rhinologist may encounter malignant disease involving the

anterior skull base and may coordinate treatment with the head and neck oncologic surgeon. Probably, most commonly and most important, the practicing general otolaryngologist is faced with the dilemma of deciding which patients and disease can be safely and appropriately handled in a general hospital and which should be referred to trusted subspecialty colleagues.

The need to pursue continuing education and to maintain board certification in the field is evident. This text is designed to provide full and comprehensive coverage of the breadth of our field in a concise, yet thorough way. The authors who have contributed to this book have distilled their topics into the most pure and concentrated forms, so that the reader is presented with practical information on these topics as concisely as possible. Illustrations have been limited to only those which illustrate key topics of the each chapter. Chapter highlights are provided in “Roundsmanship.” Selected readings have been provided for more in-depth detail for the reader interested in a specific topic. This text should serve as a concise yet practical review and reference textbook for anyone interested in the full scope of otolaryngology-head and neck surgery.

–APS

Acknowledgements

Heartfelt thanks are offered to all of the colleagues who have contributed chapters to this textbook; their generosity in sharing their expertise and knowledge to create a comprehensive textbook is truly humbling. The outstanding illustrations were drawn by Jill Gregory and Courtney McKenna, who seemed to understand intuitively the important concepts to be conveyed in each illustration. Additional thanks is offered to the editorial staff of Thieme Publishers, especially Timothy Hiscock and J. Owen Zurhellen, for their assistance in the writing of this book.

I have been fortunate to have had many special mentors (including several of the authors in this book) in my personal journey through otolaryngology, including Hyun Cho, MD,

Peter Schindler, MD, Richard Bellucci, MD, Robert Eberle, MD, and John Conley, MD, who in their own individual ways nurtured my development in otolaryngology.

Very special thanks and recognition are offered to Claude Douge, MD, and the late Paul Chodosh, MD, for providing me with true role models of the “total otolaryngologist.” These men showed me that the practice of otolaryngology requires not only a complete fund of knowledge, but an inquisitive nature, a willingness to think “outside the box” and to challenge thoughtfully the status quo, and the dedication to serve as the patient’s strongest advocate. These physicians, above all, taught me to always keep the patient foremost.

Department of Otolaryngology

Harvard Medical School

Brigham and Women's Hospital

Director

Brigham and Women's Hospital Voice Center

Boston, Massachusetts

John A. Carucci, MD, PhD
 Chief, Mohs Micrographic and Dermatologic Surgery
 Section of Dermatologic Surgery
 Ronald O. Perelman Department of Dermatology
 New York University Langone Medical Center
 New York, New York

Edwin K. Chan, MD
 Attending Physician
 Department of Otolaryngology and Head and Neck Surgery
 New York Eye and Ear Infirmary of Mount Sinai
 New York, New York

Pat Colley, MD
 Department of Otolaryngology
 New York Eye and Ear Infirmary of Mount Sinai
 New York, New York

Jennifer S. Collins, MD
 Medical Director
 Gramercy Allergy and Asthma
 Attending Physician
 Department of Allergy and Immunology
 Mount Sinai-Beth Israel Medical Center
 New York, New York

Amy L. Cooper, MS, CCC-SLP
 Director of Speech Pathology
 New York Eye and Ear Infirmary of Mount Sinai
 New York, New York

Maura K. Cosetti, MD
 Assistant Professor of Otolaryngology and Neurosurgery
 Department of Otolaryngology-Head and Neck Surgery
 Louisiana State University School of Medicine
 Shreveport, Louisiana

David J. Crockett, MD
 Department of Pediatric Otolaryngology–Head and Neck
 Surgery
 Arizona Otolaryngology Consultants
 Phoenix Children's Hospital
 Phoenix, Arizona

Seth H. Dailey, MD
 Chief of Laryngology
 Associate Professor
 Division of Otolaryngology
 Department of Surgery
 University of Wisconsin Hospital and Clinics
 Madison, Wisconsin

E. Ashlie Darr, MD
 Clinical Instructor
 Department of Otolaryngology and Laryngology
 Harvard Medical School
 Boston, Massachusetts

Clare Dean, MD
 Department of Otolaryngology
 New York Eye and Ear Infirmary of Mount Sinai
 New York, New York

Robert Deeb, MD
 Senior Staff Surgeon
 Department of Otolaryngology–Head and Neck Surgery
 Henry Ford Health System
 Detroit, Michigan

Robin A. Dyleski, MD
 Assistant Professor of Otolaryngology
 Chief of Pediatric Otolaryngology
 Department of Otolaryngology–Head and Neck Surgery
 Loma Linda University Medical Center
 Loma Linda, California

Michele M. Gandolfi, MD
 Department of Otolaryngology
 New York Eye and Ear Infirmary of Mount Sinai
 New York, New York

Christopher R. Gilbert, DO, MS
 Assistant Professor of Medicine
 Bronchoscopy and Interventional Pulmonology
 Department of Medicine, Division of Pulmonary, Allergy,
 and Critical Care
 Penn State College of Medicine–Milton S. Hershey Medical
 Center
 Hershey, Pennsylvania

Stacey L. Halum, MD, FACS
 Research Professor
 Department of Speech and Hearing Sciences
 Purdue University
 West Lafayette, Indiana

Louis B. Harrison, MD, FASTRO
 Chair
 Department of Radiation Oncology
 Senior Member
 H. Lee Moffitt Cancer Center and Research Institute
 Tampa, Florida

Tina Qingxin He, MD
 Attending Physician
 Department of Otolaryngology
 New York Eye and Ear Infirmary of Mount Sinai
 New York, New York

David Henry Hiltzik, MD
 Director
 Department of Otolaryngology–Head and Neck Surgery
 Staten Island University Hospital
 New York Head and Neck Institute
 Northshore LIJ Healthcare System
 Staten Island, New York

Ajay Hira, MD, MBA
 Radiologist
 Lake Medical Imaging and Vascular Institute
 Leesburg Regional Medical Center
 Leesburg, Florida

Ronald A. Hoffman, MD, MHCM
 Director
 Ear Institute
 New York Eye and Ear Infirmary of Mount Sinai
 Professor of Otolaryngology–Head and Neck Surgery
 Icahn School of Medicine of Mount Sinai
 New York, New York

Robert Hong, MD, PhD
 Attending Physician
 Michigan Ear Institute
 Farmington Hills, Michigan
 Assistant Professor
 Department of Otolaryngology
 Wayne State University
 Detroit, Michigan

Amanda Hu, MD, FRCSC
 Assistant Professor
 Department of Otolaryngology–Head and Neck Surgery
 Drexel University College of Medicine
 Philadelphia, Pennsylvania

Kenneth S. Hu, MD
 Associate Professor of Radiation Oncology
 Department of Radiation Oncology

New York Medical College
Valhalla, New York

1 Head and Neck Emergencies

Stimson P. Schantz, Jean-Paul Azzi, and James Azzi

1.1 Introduction

The head and neck contain a multitude of vital structures in proximity. It is therefore vital to identify those pathologies and insults that may require emergent treatment in order to prevent death or permanent disability. This chapter outlines some of the possible etiologies, organized by anatomical structure, and will serve to provide a framework for the management of head and neck emergencies.

1.2 Oral Cavity and Oropharynx Emergencies

- Post-tonsillectomy hemorrhage
 - Eschar sloughs off tonsillar fossa 7 to 10 days postoperatively
 - Suction clots from tonsillar fossa; bleeding may minimize or stop as bleeding vessel allowed to retract
 - If bleeding continues, start intravenous (IV) line and administer fluids
 - Obtain stat hemoglobin and hematocrit
 - Pressure packing, hemostatic agents
 - If unsuccessful, take to operating room (OR)
- Infections
 - Ludwig angina
 - Bilateral cellulitis involving fascial spaces of floor of mouth
 - Neck swelling and induration, drooling, respiratory distress
 - Upward displacement of tongue
 - Potential rapid airway compromise
 - Awake tracheotomy to protect airway
 - Drainage of submental space through external skin incision, IV antibiotics
 - Peritonsillar abscess
 - Unilateral otalgia, odynophagia, uvular deviation, trismus, drooling, “hot potato” voice; potential airway compromise
 - Intraoral incision and drainage with culture
 - Antibiotics

1.3 Neck Emergencies

- Postoperative complications
 - Hematoma
 - Neck swelling, pain, dyspnea, stridor
 - Remove bandaging, open surgical incision at bedside if airway compromise
 - Manage in OR if signs of active expansion
 - Thyroid storm
 - Tremor, nausea, altered mental status, progression to coma.
 - Tachycardia, cardiac arrhythmia, hyperthermia
 - Administer β -blockers, propylthiouracil (PTU), sodium iodide, steroids
- Severe symptomatic hypocalcemia
 - Administer cooled IV fluids, place cooling blanket
 - Circumoral paresthesias, tetany, seizures, mental status changes, laryngospasm
 - Chvostek sign (tapping on the face anterior to tragus and below zygomatic arch elicits ipsilateral facial twitching)
 - Trousseau sign (inflating blood pressure cuff for several minutes elicits wrist, metacarpophalangeal, and thumb flexion, interphalangeal hyperextension)
 - QT prolongation, cardiac arrest
 - Administer IV calcium gluconate (1 g over 10 minutes; if still symptomatic, infuse at 1 to 2 mg/kg/h until symptoms resolve)
- Deep space neck infection
 - Fascial compartments adjacent to deep musculature act as potential spaces
 - Spread from oral cavity, dentition, pharynx, salivary glands, sinuses, or temporal bone
 - Fever, chills, neck swelling, posterior pharyngeal swelling, pain, referred ear pain, dysphagia, trismus, torticollis
 - Culture throat, blood, sputum, aspirate
 - Computed tomography, anteroposterior (AP) and lateral neck radiographs
 - Manage airway
 - Oxygen saturation monitoring
 - Tracheotomy tray at bedside
 - Surgical drainage, broad-spectrum antibiotics
 - If *Actinomyces israelii* identified on histology, penicillin for 6 to 12 months
 - Complication: mediastinitis
 - Severe dyspnea, chest pain, fever
 - Chest X-ray (mediastinal widening)
 - Aggressive drainage, IV antibiotics
 - Complication: Lemierre syndrome
 - Thrombosis of internal jugular vein
 - Complication: carotid artery rupture
 - Bleeding from nose, mouth, or external auditory canal
 - Ipsilateral Horner syndrome
 - Cranial nerve IX, X, XII palsies
- Penetrating neck trauma
 - Unstable
 - Hypotensive shock, not responsive to fluid resuscitation
 - Airway, breathing, circulation (ABC)
 - Large-bore IV lines with fluids and blood running
 - Proximal and distal control of bleeding major vessels
 - Emergent exploration
 - Stable, zone I
 - Angiography
 - Consider swallow studies, direct laryngoscopy, bronchoscopy, and esophagoscopy
 - Stable, zone II
 - Symptomatic: surgical exploration
 - Asymptomatic: 48-hour observation
 - Stable, zone III
 - Angiography
 - Regular intraoral examinations

- Consider swallow studies, esophagoscopy, and direct laryngoscopy

1.4 Trachea and Esophagus Emergencies

- Tracheal foreign body
 - Persistent, nonproductive cough.
 - Transient episodes of respiratory distress
 - Inspiratory and expiratory stridor
 - Unequal breath sounds on auscultation
 - Early: obstructive emphysema, hyperinflation, distant breath sounds
 - Later: atelectasis, prominent breath sounds
 - Most often right main bronchus
 - Chest radiograph
 - Hyperaerated lung (mediastinal shift away, flattening of hemidiaphragm)
- Esophageal foreign body
 - AP and lateral chest X-rays
 - Frequently at cricopharyngeal area
 - Potential for aspiration
 - Rigid esophagoscopy
 - Rule out esophageal injury (observe for several hours before feeding)
- Caustic ingestion
 - Lye
 - Liquefying necrosis
 - Prevent development of stricture
 - Antibiotics
 - Steroids
 - Serial dilations
- Atelectatic lung (mediastinal shift toward, elevation of hemidiaphragm)
 - Rigid bronchoscopy

2 Otologic Emergencies

Christopher J. Linstrom and Michele M. Gandolfi

2.1 Introduction

Otologic emergencies include foreign bodies in the ear, certain infections, trauma that can destroy ear structure, and idiopathic pathologies that cause hearing loss. This chapter is meant to be a guide for the initial assessment and management of major otologic emergencies.

2.2 External Auditory Canal Foreign Body

Certain foreign bodies do require emergent attention, such as a button battery. These can cause liquefaction necrosis and erosion of the ear in a short time.

□ Evaluation

- History
 - Object known or unknown
 - Duration
 - Otolgia
 - Hearing loss
 - Vertigo
 - Otorrhea
 - Pruritus
- Physical examination
 - External auditory canal: otorrhea, edema, necrosis
 - Tenderness
 - Tympanic membrane integrity
- Testing
 - Audiogram if tympanic membrane injured and test immediately available

□ Treatment

- Caustic foreign bodies like batteries are a true emergency and must be removed as soon as possible.
- A foreign body is best removed with a looped cerumen curet fashioned as an angled hook to get behind the foreign body and pull it forward. An alligator can also be used to grasp soft foreign bodies. Irrigation lavage should not be used for beans or seeds that can expand in the external auditory canal when exposed to water.
- Antibiotics/anti-inflammatory eardrops can be given if the external auditory canal is abraded/bleeding or if there is a visible perforation. Water precautions are also necessary in this case.
- If hearing impairment persists after removal, consider audiogram.

2.3 Malignant Otitis Externa

A potentially life-threatening osteomyelitis of the skull base that commonly affects elderly diabetic or immunocompromised patients. The most common pathogens are *Pseudomonas aeruginosa*, *Staphylococcus aureus*, and rarely *Aspergillus* and *Proteus*.

□ Evaluation

- History
 - Multiple-weeks course of severe otitis externa in an immunocompromised patient that is not responsive to the typical medical therapy of steroid/antibiotic drops and oral antibiotics
 - Severe otalgia
 - Pruritus
 - Decreased hearing due to edema of the external auditory canal
 - Foul-smelling discharge
 - Fever is rare
 - Typically, a gradual progression of disease, with waxing and waning of symptoms possible
- Physical examination
 - Granulation tissue along the tympanomastoid suture line
 - Possible cranial nerve neuropathies (cranial nerves VII, IX, X, XI)
 - Exudate in the external auditory canal with edema
- Testing
 - Culture of external auditory canal debris/granulation tissue with a calcium alginate swab
 - Complete blood cell count (CBC) for white blood cells and erythrocyte sedimentation rate (ESR)
 - Computed tomography (CT) to document extent of disease
 - Initial bone scan with technetium Tc 99 m, a sensitive but nonspecific test that may stay positive for months
 - Gallium 67 scintigraphy is more specific. Used to monitor resolution of disease during treatment every 4 to 6 weeks

□ Treatment

- Prolonged intravenous (IV) antibiotic treatment (6 to 12 weeks); often two-drug therapy is used (e.g., third-generation cephalosporin plus a quinolone)
- Follow-up cultures to make sure appropriate antibiotics are used, starting with broad-spectrum antibiotics
- Fastidious débridement of external auditory canal. Clinical examination and gallium scans to assess improvement
- Surgical intervention for intratemporal or extratemporal abscesses
- A normal external auditory canal is not a sensitive indicator of resolution. Gallium scan is more sensitive

2.4 Complications of Acute Otitis Media

2.4.1 Acute Mastoiditis/Subperiosteal Abscess

Acute mastoiditis typically occurs when there is contiguous spread of an acute otitis media to the mastoid portion of the temporal bone. *Streptococcus pyogenes* (group B β -hemolytic) is the most common cause of acute mastoiditis. Other species include *Streptococcus pneumoniae*, *Haemophilus influenzae*, *P. aeruginosa*, and anaerobes.

□ Evaluation

- History
 - Onset of symptoms
 - Prior antibiotic course
 - Improvement of symptoms
 - Any other associated symptoms suggesting extracranial/intratemporal disease, such as the following:
 - Headache
 - Fever/chills
 - Retro-orbital pain
 - Diplopia
 - Cranial nerve paresis/paralysis
 - Photophobia
 - Altered mental status/drowsiness
- Physical examination
 - Retroauricular pain
 - Ear protrusion due to postauricular tenderness to palpation and edema
 - Bulging tympanic membrane with hyperemia and middle ear serous/purulent effusion
 - Weber and Rinne tests consistent with a conductive hearing loss
 - Neck stiffness, Kernig sign, Brudzinski sign
- Testing
 - CBC
 - CT of temporal bone to evaluate extent of disease, degree of mastoid osteitis and abscess formation (IV contrast should be used whenever an abscess is suspected)
 - Audiogram
 - Culture of middle ear effusion if tympanocentesis or myringotomy performed

□ Treatment

- If no mastoid abscess formation (coalescence) seen on CT, then begin with nonsurgical treatment.
- Noncoalescent mastoiditis can be treated with myringotomy and drainage of middle ear and culture.
- Before culture results, empiric therapy is begun with a second-generation cephalosporin or an antipseudomonal aminopenicillin IV.
- Subsequent antibiotics should be culture-directed.
- After symptoms resolve, oral antibiotics should continue for 10 to 14 days.
- If no clinical improvement is noted after 24 to 48 hours of antibiotic therapy, mastoidectomy should be considered.
- Indications for surgical intervention
 - Coalescent mastoiditis on CT scan
 - Clinical nonresponsiveness after 24 to 48 hours of IV antibiotics
 - Significant abscess (subperiosteal, cervical, occipital, or temporal)
 - Suspected intracranial extension
- Surgery
 - Coalescent mastoiditis: simple mastoidectomy to the level of the mastoid antrum with wound drainage
 - Extratemporal abscess formation: incision and drainage
 - Additional mastoidectomy if accompanied by coalescent mastoiditis or if the abscess fails to respond to incision and drainage and antibiotics.

2.4.2 Petrous Apicitis

The internal auditory canal divides the petrous apex into anterior and posterior compartments. The anterior compartment is then divided into the peritubal and apical regions. Petrous apicitis can develop rapidly as a consequence of acute otitis media and mastoiditis. Chronic petrositis evolves as a complication of chronic serous otitis media. It can be found in asymptomatic patients on radiographic imaging. For etiology, see Acute Mastoiditis (above).

□ Evaluation

- History
 - Deep pain
 - Symptoms similar to those of mastoiditis
 - Persistent aural discharge after mastoidectomy
 - Suboccipital headache and/or retro-orbital pain
- Physical examination
 - Pain as a result of trigeminal nerve involvement, and sixth nerve involved as it enters the Dorello canal.
 - Gradenigo syndrome: petrositis associated with retro-orbital pain, sixth nerve palsy, and persistent otorrhea.
- Testing
 - CT of the temporal bone: clouding of the petrous apex region with varying degrees of erosion.
 - Magnetic resonance (MR) imaging: when intracranial extension is suspected.

□ Treatment

- Noncoalescent petrositis managed with culture-directed IV antibiotics obtained during myringotomy.
- Indications for surgical intervention
 - CT reveals coalescence; symptoms and clinical signs such as fever, leukocytosis, and otorrhea fail to respond to IV antibiotics.
 - A significant abscess, especially an intracranial abscess, exists. Consultation with a neurosurgeon is frequently useful to help manage the associated intracranial complications.

2.5 Auricular Trauma

Whether the patient has a simple laceration, avulsion, or blunt trauma, treatment is needed immediately. Injuries may be physical (lacerations, avulsions, or blunt trauma) and/or thermal (burns, frostbite).

□ Evaluation

- History
 - Mechanism
 - Agent
 - Timing
- Physical examination
 - Presence of all structures of auricle, pieces missing
 - Viability of tissue
 - Foreign bodies in wound
 - Signs of infection

□ Treatment

- Lacerations
 - Cleaning and débridement (only of devitalized tissue), irrigation with sterile saline

- Three-layer suturing of cartilage/perichondrium, skin on both sides of auricle
 - Absorbable suture to close perichondrium (5–0 or 6–0 Polyglactin 910; DemeTech, Miami Lakes, FL)
 - Nonabsorbable sutures to close skin (5–0 or 6–0 nylon)
- Prophylactic antibiotic treatment: ciprofloxacin, amoxicillin/clavulanate
- Avulsions
 - Cleaning and débridement
 - Can require complex closure requiring staging, flap reconstruction
 - Superficial defects of the skin may be repaired with the use of vascularized skin flaps based on postauricular skin. This works well in the presence or absence of the perichondrium. Careful attention is paid to provide a flap of non–hair-bearing skin. Full-thickness skin grafts are generally not recommended for the helical rim.
 - Small helical rim defects may be amenable to chondrocutaneous advancement flaps, especially if the defect is smaller than 2 cm.
 - For defects larger than 2 cm, a staged tube flap from the postauricular skin may be necessary.
 - For large avulsions, isolate cartilage from avulsed segment. Incise temporal scalp at the superior border of the auricular remnant. Suture medial skin of auricular remnant to inferior temporal skin edge. Place avulsed cartilage in a temporal pocket dissected above the incision, and suture the avulsed cartilage to the remnant cartilage with Polyglactin 910 suture. Close the superior temporal skin edge to the lateral skin of the auricular remnant. After 6 to 8 weeks, elevate temporal skin and cartilage, skin grafting the medial side of the reattached cartilage.
 - Prophylactic antibiotic treatment as above
 - Mastoid dressing to protect ear
- Hematomas
 - Incision and drainage
 - Incision through the perichondrium under the helix just within the scaphoid fossa along the length of the hematoma. If the hematoma is located within the conchal bowl, the incision can be made on the conchal side of the anti-helix. Drain the hematoma and irrigate the pocket with sterile saline.
 - Apply a pressure dressing created from soft red rubber catheters on either side of the scaphoid fossa that are sutured together through the auricle with 4–0 nylon.
 - Reevaluation every 24 to 48 hours for the next 3 to 4 days
 - Prophylactic antibiotics for 7 to 10 days
- Burns
 - Determine extent and depth of injury.
 - Fluid resuscitation for patient
 - Tetanus prophylaxis
 - Wound care and observation
 - Topical antibiotics
 - No pressure applied
- Frostbite
 - Bring patient to warm environment as soon as possible.
 - Warm auricle in water bath at 38 to 42°C slowly (pain control needed, as rewarming can be very painful).
 - Delayed surgical débridement only if necessary

2.6 Sudden Idiopathic Sensorineural Hearing Loss

Idiopathic sudden sensorineural hearing loss usually happens abruptly or rapidly and progressively over minutes, hours, or a few days. It is defined as 30 dB or more of sensorineural hearing loss over at least three contiguous audiometric frequencies occurring within 3 days or less. Possible causes include infection (measles, mumps, rubella, HIV infection, herpes, toxoplasmosis, syphilis, meningococcal infection, cryptococcal infection, Lyme disease); autoimmune disease (lupus, Wegener granulomatosis, polyarteritis nodosa, Cogan syndrome, relapsing polychondritis, ulcerative colitis); vascular disease (diabetes, vertebral artery insufficiency, sickle cell disease); neurologic disease (multiple sclerosis, pontine ischemia); neoplastic disease (acoustic neuroma, metastasis to internal auditory canal); trauma (perilymph fistula, barotrauma, otologic surgery); and iatrogenic causes (ototoxins).

□ Evaluation

- History
 - Time course (treatment most successful within first 2 weeks of hearing loss)
 - Associated symptoms (tinnitus, vertigo, aural fullness, otalgia, cranial neuropathies)
- Physical examination
 - Signs of infection
 - Evaluation for trauma
 - Cranial nerve paresis/paralysis
- Testing
 - Audiogram
 - CT of temporal bone (if trauma, congenital deformity suspected)
 - MR imaging with gadolinium to evaluate internal auditory canal and cerebellopontine angle for mass
 - Electroneurography (ENG)/videonystagmography (VNG) when associated with vertigo
 - Laboratory testing
 - CBC with differential
 - ESR
 - Fluorescent treponemal antibody-absorbed (FTA-ABS) or rapid plasma reagin (RPR)
 - Thyroid function testing
 - Lipid profile
 - Antinuclear antibody (ANA)
 - HIV testing
 - Fasting glucose

□ Treatment

- Steroids
 - Systemic: prednisone 60 to 80 mg daily for 7 days (1 mg/kg/d), then begin slow taper.
 - Intratympanic injections: superior–posterior quadrant injections 1 to 2 times a week with audiograms between injections to monitor improvement, up to 3 to 4 injections
 - Dexamethasone 0.4 to 0.7 mL of 24 mg/mL
 - Methylprednisolone 0.4 to 0.7 mL of 62.5 mg/mL
 - Antiretrovirals (acyclovir 1 g 2 times daily for 5 to 7 days)

- Diuretics and salt restriction if Meniere disease suspected (hydrochlorothiazide/triamterene 50 mg daily)
- Medical management of suspected underlying cause (diabetes, hypothyroidism, hyperlipidemia)

2.7 Idiopathic Facial Nerve Paralysis

Idiopathic facial paralysis (Bell palsy) is the most common cause of acute facial paralysis, with an incidence of 15 to 40 per 100,000 per year. Possible causes include infection (herpes type 1, herpes zoster [Ramsay Hunt syndrome], mononucleosis, mumps, Lyme disease, severe complicated otitis media, malignant otitis externa); autoimmune disease (Guillain-Barré syndrome, myasthenia gravis, sarcoidosis, Wegener granulomatosis); congenital syndromes (Melkersson-Rosenthal syndrome [unilateral facial palsy, facial edema, fissured tongue] and Mobius syndrome [bilateral facial and abducens palsies]); neoplasms; and trauma.

□ Evaluation

- History
 - Time course
 - Associated symptoms: dysgeusia, hyperacusis, decreased lacrimation, facial hypesthesia
 - Exposure to pathogen/toxin
- Physical examination
 - Cutaneous vesicles in external auditory canal and conchal bowl with otalgia; cochlear and vestibular symptoms (Ramsay Hunt syndrome)
 - Complete otolaryngic examination
 - Cranial nerve examination (House-Brackmann classification)
- Testing
 - Nerve excitability test (NET) and electroneuronography (ENOG) should not be done in the first 3 days.
 - ENOG: 90% or greater degeneration of compound muscle action potentials (CMAPs) suggests poor recovery and is an indication for surgical exploration and decompression. ENOG should be performed daily until nadir is reached.
 - NET: 2.0- to 3.5-mA difference between sides suggests unfavorable prognosis.
 - Electromyography (EMG) measures motor unit potentials (MUPs) and may be useful in first 3 days. MUPs in 4 to 5 groups in first 3 days associated with return of function in more than 90% EMG is good for assessing reinnervation potential of the muscle 2 to 3 weeks after onset of paralysis. Polyphasic potentials are seen in regeneration, while fibrillation potentials portend a poor prognosis.
 - Imaging: MR imaging is performed in cases of progression of palsy over 3 weeks, recurrent palsy, facial hyperkinesias, cranial neuropathies.

□ Treatment

- Medical
 - Prednisone (1 mg/kg) divided into 3 daily doses for 10 days with a 10-day taper afterward
 - Antiretrovirals
 - Acyclovir 800 mg 5 times a day for 10 days

– Valacyclovir more effective for Ramsay Hunt syndrome

- Surgical
 - Decompression from mastoid to geniculate ganglion if ENOG shows more than 90% degeneration of CMAPs

2.8 Temporal Bone Trauma

Temporal bone fracture is a frequent manifestation of head trauma. In the adult population, approximately 90% of temporal bone fractures are associated with concurrent intracranial injuries and 9% with cervical spine injuries. Motor vehicle accidents are the cause of 31% of temporal bone fractures; other causes include physical assaults, falls, motorcycle accidents, pedestrian injuries, bicycle accidents, and gunshot wounds. Two different classification systems are in use. Fractures are often mixed and oblique and do not fit into one classification.

□ Etiology

- Longitudinal fractures comprise 80% of all temporal bone fractures. They are frequently caused by a lateral force over the mastoid or temporal squama, usually produced by temporal or parietal blows. Typically spare otic capsule and run anterolateral to otic capsule.
- Transverse fractures comprise 20% of all temporal bone fractures. They are usually caused by a frontal or parietal blow but may result from an occipital blow. Typically run into otic capsule, damaging cochlear and semicircular canals.

□ Evaluation

- History
 - Etiology of trauma
 - Direction of impact
 - Time course
 - Associated symptoms (tinnitus, vertigo, hearing loss)
- Physical examination
 - Glasgow Coma Scale score
 - Associated injuries
 - Battle sign
 - Bloody or clear otorrhea
 - Cranial nerve palsy/paralysis
 - Tympanic membrane perforation
- Testing
 - High-resolution CT of temporal bone; evaluate fracture site
 - Eventual audiogram (when feasible)
 - Eventual VNG/ENG (when feasible)
 - NET/ENOG/EMG if facial nerve involved

□ Classification

- Longitudinal (80%)
 - Conductive hearing loss due to ossicular chain disruption at the incudostapedial joint. Hemotympanum and external auditory canal fractures also possible. Approximately 20% of these patients have temporary/delayed facial nerve injury, usually in the horizontal segment.
 - Cerebrospinal fluid (CSF) otorrhea common but temporary
 - Tympanic membrane perforation common
 - Less intense vertigo
- Transverse (20%)
 - Severe sensorineural hearing loss

- Vertigo common and intense
- Facial nerve injury in 50% which is usually permanent, severe, and early in onset
- Occasional CSF otorrhea
- Rare to have a tympanic membrane perforation

□ Treatment

- Medical: a patient with delayed facial paralysis is managed conservatively with 10 to 14 days of systemic corticosteroids unless medically contraindicated.
 - Surgical: dependent on facial nerve status
- A patient with complete paralysis of immediate onset undergoes initial testing with the Hilger nerve stimulator between days 3 and 7. If ability to stimulate nerve is not lost, patients are observed.
 - If ability to stimulate nerve is lost within 1 week, or more than 90% degeneration on ENOG occurs within 2 to 3 weeks, then facial nerve decompression is offered to the patient.
 - Surgical exploration may also be indicated for a CSF fistula that lasts longer than 14 days and does not resolve with conservative management.

3 Pediatric ENT Emergencies

Robin A. Dyleski and Moustafa Mourad

3.1 Airway Foreign Body

Assess respiratory status, patency of airway, and ability to move air, as indicated by crying or speaking. If the patient is not exchanging air well, emergent airway control is required. Nonsurgical management includes the Heimlich maneuver or bedside direct laryngoscopy and endotracheal intubation followed by transfer to the operating room (OR) for further management/removal of the foreign body. Surgical management (rarely needed in children, especially young children) includes tracheotomy or cricothyroidotomy. For a patent airway, proceed with evaluation of the patient (Heimlich maneuver is contraindicated).

□ Evaluation

- History
 - Was the aspiration witnessed?
 - Type of foreign body, if known
 - Duration of symptoms
 - Dyspnea, labored breathing
 - Dysphagia
 - Drooling
 - Cough
 - Pain
 - Ability to cry/speak
 - History of tracheoesophageal or bronchial abnormalities
 - Previous treatment for symptoms (i.e., nonresolving stridor during treatment of croup, recurrent pneumonia, recurrent bronchitis)
- Physical examination
 - Mental status
 - Presence of stridor
 - Inspiratory: glottic, subglottic, or supraglottic obstruction
 - Expiratory: subglottic or bronchial obstruction
 - Biphasic: glottic obstruction
 - Asymmetric breath sounds
 - Respiratory distress: paradoxical breathing, cyanosis, use of accessory muscles, low oxygen saturation
 - Wheezing, especially “unilateral” wheezing

□ Management

- High clinical suspicion of airway foreign body
 - Witnessed aspiration episode with coughing/choking
 - Asymmetric breath sounds
 - Loss of voice or vocal changes
 - Wheezing, especially if unilateral
 - Stridor
- Nondiagnostic history and physical examination with medium to low clinical suspicion of airway foreign body
 - Chest X-ray shows indirect evidence of airway obstruction
 - Hyperinflation of one lung
 - Atelectasis
 - Bronchiectasis due to long-standing chronic bronchial obstruction
 - Soft-tissue neck X-ray (usually lateral and anteroposterior [AP])

- Computed tomography (CT): infrequently used but may be helpful in the event that clinical suspicion remains high but plain radiography is nondiagnostic.
- Definitive treatment
 - Rigid bronchoscopy in operating room with foreign body retrieval
 - Flexible bronchoscopy is not advised when there is strong evidence for a foreign body. The flexible bronchoscope working channel is too small to permit use of appropriate forceps to grasp the object in young children. Flexible bronchoscopy is a useful diagnostic tool for the patient who arrives already intubated with a questionable history of foreign body aspiration. If a foreign body is seen, then rigid bronchoscopy for foreign body removal under general anesthesia is recommended. Only very small foreign bodies may be able to be removed with flexible bronchoscopy.

3.2 Esophageal Foreign Body

□ Evaluation

- History
 - Describe object (blunt, sharp, disk battery)
 - Duration of ingestion (<24 hours vs >24 hours)
 - Symptoms
 - Dysphagia
 - Odynophagia
 - Drooling
 - Vomiting
 - Chest pain
 - History of gastrointestinal abnormalities such as prior tracheoesophageal fistula or esophageal stenosis
 - Intake/nutritional status (assess need for intravenous [IV] hydration)
- Physical examination
 - Respiratory status
 - Mental status
 - Complete cardiovascular, pulmonary, and abdominal examination
- Testing
 - Chest X-ray: AP and lateral
 - Avoid barium swallow because barium will interfere with subsequent endoscopy

□ Management

- Blunt-edged foreign body (not a battery)
 - If foreign body located at lower esophageal sphincter, patient may be monitored for spontaneous passage with follow-up radiographs 24 hours after ingestion.
 - Thoracic inlet or midesophageal area, esophagoscopy (flexible or rigid) with general anesthesia (for airway protection)
- Sharp-edged object
 - Rigid esophagoscopy with foreign body removal. If possible, the sharp portion of the foreign body may be placed within the lumen of the esophagoscope in order to protect the esophageal mucosa.

- Alkaline disk battery
 - A chest X-ray is often able to distinguish between coins and disk batteries by the appearance of the edge of the object; disk batteries appear to have a “ring” around the edge, raising suspicion that the object is a battery.
 - Indications for immediate endoscopic retrieval
 - Any battery in esophagus
 - Battery larger than 15 mm in stomach
 - Battery smaller than 15 mm in stomach that has failed to pass within 48 hours or patient becomes symptomatic (abdominal pain, nausea, vomiting, or fevers)
- Esophagoscopy considerations
 - Esophagoscopy for foreign body should always be performed under general anesthesia for airway protection.
 - Always have pediatric bronchoscopy set up and available during esophagoscopy because of risk for loss of object into airway during retrieval.
 - After removing the foreign body, reinsert the esophagoscope to examine the site of impaction and also check for second foreign body.
 - Consider steroids and prophylactic antibiotics if significant edema noted at site of impaction.

3.3 Croup

□ Evaluation

- History
 - Age: typically younger than 5 years old
 - Sudden onset
 - Barking cough
 - Hoarseness
 - Fevers variable
- Physical examination
 - Alertness of child
 - Stridor, usually high pitched and inspiratory
 - Wheezing
 - Signs of impending respiratory distress
 - Accessory muscle use
 - Cyanosis
 - Paradoxical breath
 - Chest retractions
 - Complete cardiovascular and pulmonary examination
- Testing
 - Anterolateral chest X-ray: steeple sign indicates subglottic narrowing.
 - Oxygen saturation (pulse oximetry) and in severe cases arterial blood gas

□ Management

- Mildly symptomatic, with stable respiratory status and adequate hydration
 - Supportive home care
 - Humidification of air: cool mist
- Moderately symptomatic with moderately labored breathing
 - Intramuscular dexamethasone
 - Nebulized racemic epinephrine
- Severely symptomatic, acute respiratory distress
 - Emergency supportive respiratory care including treatment with dexamethasone and nebulized racemic epinephrine

- If respiratory distress continues or progresses, endotracheal intubation is necessary. Use of endotracheal tube 0.5 to 1.0 mm smaller than normal size for patient age.

3.4 Epiglottitis

Several hours, history of high fever, stridor, difficulty swallowing, drooling, muffled voice, and difficulty breathing. Patients may present in the “sniffing position” or with the neck flexed and head extended.

Typically patients have no cough, in contrast to those with croup. The diagnosis is typically based on clinical examination and history. Radiographs may be used showing an edematous epiglottis (“thumb print” sign) and obliteration of the vallecula (vallecula sign). Most cases of epiglottitis are diagnosed clinically, and ultrasound is emerging as a noninvasive and accurate method of diagnosis.

□ Evaluation

- History
 - Acute onset is typical
 - Dysphagia, drooling
 - Increasing respiratory distress
 - Acute onset of high fever; up to 40°C is common
- Physical examination
 - Posture: sitting up with head thrust forward, “tripod position”
 - Drooling
 - Respiratory status
 - Accessory muscles
 - Paradoxical breathing
 - Chest retractions
 - Cyanosis
 - Mental status (obtunded patients at high risk for acute respiratory failure, requiring airway to be secured)
 - Complete cardiopulmonary examination

□ Management

- Maintain a high index of suspicion
 - Avoid upsetting patient; do not separate patient from parent/caregiver, minimize situations that might induce crying.
 - Transport immediately to OR for evaluation and treatment if patient is in respiratory distress.
 - Have emergent tracheostomy tray open and available in OR.
 - Direct laryngoscopy and intubation
 - Intubate with endotracheal tube or use rigid bronchoscope
 - Consider percutaneous transtracheal jet ventilation if epiglottitis is too edematous to visualize the true vocal cord.
 - Culture and sensitivity of epiglottitis after airway is secured
- Treatment and monitoring
 - Intensive care unit setting for both intubated and nonintubated patients
 - Antibiotic coverage of *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Staphylococcus pyogenes*
 - Third-generation cephalosporin
 - Amoxicillin/clavulanate

- Epiglottal edema should be monitored with flexible laryngoscopy.
- Extubation typically possible after antibiotic treatment for 48 to 72 hours
- Corticosteroid use controversial

3.5 Stridor with Respiratory Distress

□ Etiology

- Foreign body
- Infectious
 - Epiglottitis/supraglottitis
 - Croup
 - Retropharyngeal abscess
- Mechanical
 - Subglottic stenosis
 - Vocal cord palsy
 - Airway edema
- Congenital
 - Airway anomalies such as laryngomalacia and tracheomalacia
 - Vascular malformations
- Neoplasm
 - Laryngeal papillomatosis

□ Evaluation

- History
 - Age
 - Duration
 - Onset
 - Dysphagia
 - Dyspnea
 - Is fever present?
 - Birth history, especially prematurity; mechanical ventilation; intracranial, neck, or chest surgical intervention
- Physical examination
 - Alertness of patient
 - Cyanosis: presence or absence of congenital cardiac disease is important
 - Accessory muscle use: indicates degree of respiratory effort needed
 - Chest retractions, sternal retractions
 - Paradoxical breathing
 - Full head and neck examination, including flexible laryngoscopy
 - Full cardiopulmonary examinations, including neck auscultation for location of loudest stridor
 - Abdominal examination
 - Vital signs including continuous pulse oximetry, respiratory rate
- Testing
 - Laboratory data
 - Arterial or venous blood gas: unusual to require except in most severe cases or intubated cases
 - Complete blood cell count (CBC)
 - Blood electrolytes and metabolic panel
 - Plain radiographs
 - AP and lateral chest X-rays

- AP and lateral neck X-rays
- Barium esophagram (if suspect involvement of esophagus)
- CT with contrast: may show vascular anomalies, compressions due to neoplastic masses, presence of pneumonia.
- Magnetic resonance (MR) imaging, MR angiography: may allow improved delineation between neoplastic and vascular causes.

□ Management

- Determine need for emergent airway management on the basis of the respiratory distress and the diagnosis.
 - Intubation
 - Tracheostomy
 - Cricothyroidotomy
 - Percutaneous transtracheal jet ventilation
- Treat underlying cause of respiratory condition.

3.6 Post-tonsillectomy Hemorrhage and Other Oropharyngeal Bleeding

3.6.1 Emergent Management

Assess the need for emergent resuscitation. Assess airway: if bleeding is severe and there is a compromised airway and hemodynamic instability, then pack oral cavity after oral endotracheal intubation, tracheotomy, or cricothyroidotomy.

Assess circulation; if hemodynamically unstable, then secure two large-bore peripheral IV lines and administer bolus fluids by weight. Type and cross match, obtain CBC, and assess for possible transfusion. Prepare the patient for emergent return to OR to control and stop bleeding.

3.6.2 Nonemergent Management

□ Evaluation

- History
 - Vital signs: monitor oxygen saturation, heart and respiratory rates, blood pressure
 - Time and date of procedure, timing of postoperative bleeding
 - Onset/duration/quantity of bleeding
 - Personal or family history of bleeding or easy bruising: possible undiagnosed coagulopathy or use of medications (nonsteroidal anti-inflammatory drugs) impairing platelet function
 - Fever
 - Recent oral intake, dehydration status
- Physical examination
 - Signs and symptoms of acute blood loss
 - Complete cardiopulmonary examination
 - Oral cavity
 - Determine if there is localizable area of active bleeding.
 - Assess for presence of clots
 - Is the patient still bleeding?

□ Management

- Notify OR for possible OR need to control post-tonsillectomy hemorrhage.

- If no gross acute/active bleed, but evidence of old clotted blood, then consider in older patients to gargle with 50:50 hydrogen peroxide and water solution, then reassess oral cavity.
- If localizable area of bleeding
 - Attempt to cauterize with silver nitrate (only in older, highly cooperative patients).
 - If bleeding does not stop or patient does not tolerate, take to OR for examination under anesthesia and electrocautery.
- Admit patient to observe for recurrence of bleeding.

3.7 Retropharyngeal Abscess

□ Evaluation

- History
 - Precedent upper respiratory infection
 - Fever
 - Dysphagia/poor oral intake (in infants)
 - Limitation of neck range of motion, either from side to side or up and down; may mimic meningitis symptoms
 - Shortness of breath or stridor
 - Sore throat
 - Cough
 - Neck swelling
- Physical examination
 - Vital signs
 - Neck lymphadenopathy
 - Posterior pharyngeal swelling/bulge
 - Torticollis
 - Stridor
 - Drooling
 - Agitation
 - Presence of tonsillar or peritonsillar exudates
- Testing
 - Laboratory data
 - CBC
 - Blood cultures
 - Oral exudate culture
 - Imaging: lateral neck X-ray
 - Widening of the retropharyngeal soft tissues and prevertebral space
 - Gas–fluid levels in abscess cavity
 - Foreign body: while most retropharyngeal abscesses are from suppurated retropharyngeal lymph nodes, a foreign body may be the etiology.
 - Imaging: CT with IV contrast
 - Used in setting of nondiagnostic radiographs but high clinical suspicion
 - Demonstrates typical rim enhancement when abscess present
 - Allows diagnosis of extent of abscess into the lower neck/upper thoracic area (allows differentiation between retropharyngeal abscess and prevertebral space abscess)

□ Management

- Emergent intubation or surgical airway, as indicated
- Supplemental oxygen, if needed
- IV fluids
- IV antibiotics

- Operative drainage
- Most retropharyngeal abscesses are transoral
 - Use mouth gag for exposure to the posterior pharyngeal wall
 - Injection of lidocaine with epinephrine in the proposed vertical incision site (low on the abscess for enhanced drainage after incision)
 - Incise the mucosa vertically (about a 1-cm incision), then using a tonsil clamp, bluntly enter the abscess cavity (spreading vertically between the muscle fibers).
 - Sample of abscess contents for Gram stain, culture, and sensitivity
 - No closure of incision needed
 - May begin feeding with clear liquids after operation.

3.8 Soft Palate Lacerations and Other Oropharyngeal Injuries

□ Evaluation

- History
 - Mechanism of injury
 - Fall from seated position or while running at maximum speed
 - Grade mild, moderate, or severe size of laceration
 - Neurologic complaints: if present then need vascular surgery consultation.
 - Fever
 - Torticollis
 - Neck pain
 - Dysphagia
 - Drooling
 - Chest pain
- Physical examination
 - Primary survey: assess airway, breathing, and circulation (ABC) after trauma and possible need for emergent intubation and volume resuscitation.
 - Secondary survey in the stable patient
 - Wound assessment and characterization, including location of the laceration (midline vs lateral soft palate/lateral pharyngeal wall area)
 - Neurologic examination
 - Neck auscultation over carotid artery (e.g., carotid bruit)
 - Examination of teeth (fracture, subluxation, avulsion)
 - Examination of tongue
 - Assess for trismus and drooling (e.g., infection)
 - Assess for neck crepitus and subcutaneous air
- Testing
 - Laboratory data
 - CBC (indicated only in cases of severe bleeding)
 - Blood cultures and C-reactive protein if an infection is suspected
 - Imaging: plain radiographs of chest and neck
 - Pneumomediastinum.
 - Retropharyngeal widening
 - Foreign bodies
 - Imaging: CT angiogram of chest and neck
 - The test of choice
 - Demonstrates thrombus and/or dissection of carotid artery from a blunt or penetrating injury

- Imaging: MR angiography (limited use because of need for anesthesia in young children)
- Imaging: carotid artery angiography
 - Gold standard for internal carotid artery imaging
 - Risk for stroke with carotid artery angiography
 - Reserved for children with neurologic findings, severe mechanism of trauma, evidence of internal carotid artery (ICA) injury with other imaging

□ Management

- Primary survey in severe trauma
 - Assess need for airway stabilization (endotracheal intubation vs surgical airway)
 - Assess need for volume resuscitation
 - Cervical spine immobilization
 - Do not alter or remove protruding objects
- For high-risk injury (high-force trauma, such as motor vehicle accident)
 - Angiography
 - Endoscopy
 - Surgical exploration
- For moderate-risk injury (retained oropharyngeal object)
 - Hospital admission
 - CT angiography (or less commonly MR angiography)
 - If concerning findings on CT angiography for ICA injury (ICA abnormality, subcutaneous air near ICA, or disruption of

ICA sheath), proceed to carotid artery angiography. For ICA injury (e.g., intimal tear), consider vascular surgery consultation.

- If CT angiography or MR angiography indicates non-ICA injury, then
 - Local oral cavity wound care
 - Discharge home with close monitoring for development of fevers, neurologic paresis, neck stiffness, torticollis, dysphagia, or dyspnea. Can be considered only in patients with extremely reliable parents.
 - May admit to hospital for 24 to 48 hours for serial neurologic examinations.
- For low-risk injury (superficial laceration, midline lacerations)
 - Local wound care
 - Discharge home with close follow-up
- Wound care
 - Wounds smaller than 2 cm (e.g., puncture wounds) do not require surgical wound closure.
 - Indications for operative repair
 - Palatal flaps
 - Avulsed tonsils
 - Retained or protruding foreign body
 - Gross contamination
 - Tetanus prophylaxis
 - IV/oral empiric antibiotics

4 Facial Plastic and Reconstructive Surgery Emergencies

Grigorly Mashkevich

4.1 Facial Trauma

4.1.1 General

- Initial evaluation
 - “ABC”: airway, breathing, and circulation.

Vascular access with two large-bore intravenous (IV) lines.

- Protection of the cervical spine (Philadelphia collar); plain X-rays to rule out cervical spine fracture
- Stabilization of vital signs in the emergency room setting.
- Secondary survey
 - Examination of wounds
 - Head and neck radiography: computed tomography (CT) of the facial bones for suspected fractures, plain or CT angiography of the neck for penetrating trauma or suspected vascular injuries.
 - Assess potential for central nervous system, ophthalmic injury; consult other services when appropriate.

4.1.2 Facial Fractures

General

- Radiographic evaluation with thin-cut, noncontrast CT of the maxillofacial region
- Preoperative ophthalmologic evaluation when appropriate to rule out intraocular injuries before any manipulation of the frontal, orbital, or maxillary regions.
- Delayed (up to 5 to 10 days) fracture repair to allow reduction of tissue edema, improve surgical access, and diminish intraoperative bleeding.
- Open reduction with internal rigid fixation is the optimal solution for most facial fractures.

Frontal Sinus Fracture

- Radiographic evaluation with CT to assess anterior and posterior tables of the frontal sinus.
- Surgical repair depending on the degree of table displacement and comminution.
- Consider neurosurgical consultation, especially if posterior wall violated.

Nasal Fracture

- Preliminary assessment should be followed by more detailed secondary evaluation in 4 to 6 days once acute edema has partially subsided.
 - Minimal bony displacement: observation with secondary reconstruction 2 to 3 months later if necessary.
 - Clinically apparent bony displacement: closed reduction with external cast stabilization within 10 to 14 days; secondary reconstruction 2 to 3 months later if necessary.

Orbital Fracture

- Palpate orbital rims for step-off deformities.
- Assess extraocular motion.
- Assess globe position (enophthalmos/exophthalmos).
- Assess sensory function.
- Assess stability of medial canthus.
- Medial orbital fracture
 - Consider naso-orbito-ethmoid (NOE) fracture.
- Infraorbital rim fracture
 - Consider associated orbital floor fracture.
- Orbital floor fracture
 - Repair in cases of enophthalmos and radiographic evidence of orbital content displacement into the maxillary sinus.
 - Exploration of orbital floors with comminution of more than half of the total surface area.
- Lateral orbital rim fracture
 - Consider zygomaticomaxillary complex (ZMC) fracture.
 - Treat as indicated.
- Maxilla and mandible fracture
 - Soft diet
 - Empiric antibiotics
 - Cold compresses (edema reduction in preparation for surgery)
 - Restoration of proper occlusion via maxillomandibular fixation (MMF) is the most important consideration during reduction of fractures involving this region.

Temporal Bone Fracture with Facial Nerve Paralysis

- CT of temporal bone
- Electroneurography (ENOG)
- Stable patients: consider surgical exploration and nerve repair.
- Unstable patients: steroids to reduce nerve inflammation, followed by reassessment at a later date.

4.2 Lacerations of the Face

4.2.1 Skin and Soft Tissue

- Tetanus protocol
- Clean wounds
 - Within 12 hours of injury
 - Layered primary closure
 - More than 12 hours after injury
 - Antibiotics and delayed primary closure
- Grossly contaminated wounds or any evidence of pus or cellulitis
 - Wound care and packing, followed by delayed repair.

4.2.2 Bites

- Empiric antibiotics
- Uninfected wounds
 - Animal bite: rabies protocol, consider primary closure
 - Human bite: HIV and hepatitis protocols, wound care, delayed primary closure
- Grossly contaminated wounds or any evidence of pus or cellulitis: wound care and packing, followed by delayed repair

4.3 Facial Nerve Paralysis

- Operating room for exploration and repair (optimal time frame for repair is within 3 days, during which time distal nerve ends can still be stimulated).

4.4 Parotid Duct Injury

- Operating room for exploration and repair
 - Clean ductal laceration without tissue loss: direct suture repair over a stent.
 - Ductal loss: segmental replacement with an interposition vein graft sutured over a stent
 - Intraparotid ductal injury: watertight closure of parotid fascia, botulinum toxin A injection to extinguish salivary production

4.5 Penetrating Neck Wounds

- Vascular imaging (including CT angiography)
 - Surgical repair versus embolization for vascular injuries
- Evaluation of aerodigestive tract injury
 - Surgery in appropriate cases

4.6 Hematomas: Septal and Auricular

- Incision and drainage
- External splinting for apposition of separated tissues
- Insertion of small drain (short segment of a sterile rubber band)

4.7 Postoperative Emergencies

4.7.1 Rhinoplasty/Nasal Surgery

Toxic Shock Syndrome

- Early recognition is key!
 - Early: postoperative fever, facial flushing
 - Later: hypotension and cardiovascular collapse
- Remove nasal packing.

- Broad-spectrum antibiotics
- Fluids, cardiovascular support, and intensive care monitoring

4.7.2 Blepharoplasty

Bleeding/Intraorbital Hematoma

- Lateral canthotomy and cantholysis, performed urgently at bedside.
- Removal of any nasal packing, intermittent globe massage
- Stat ophthalmologic evaluation to monitor pressure and vision
- Stress dose of IV corticosteroids
- Mannitol (1 to 2 g/kg IV over 30 minutes)
- Operating room for wound exploration

4.7.3 Facelift

Hematoma

- Small: aspiration and pressure dressing, with possible drain placement
- Medium: open incision and express clots, place drain
- Large or expanding: operating room for wound exploration

Facial Nerve Paralysis

- Observe for several hours until local anesthetic wears off.
- Consider exploration depending on the index of suspicion.

4.7.4 Microvascular Reconstruction

Venous Obstruction

- Examination: engorged and bluish skin paddle, rapid capillary refill, “water hammer” Doppler signal, rapidly flowing dark blood on pricking of the skin paddle
 - Operating room for exploration of anastomosis and flap vasculature
 - Leech therapy in partially obstructed flaps

Arterial Obstruction

- Examination: pale skin paddle, absent capillary refill, absent Doppler signal, absent or significantly delayed blood flow on pricking of the skin paddle
 - Operating room for exploration of anastomosis and flap vasculature

4.7.5 Tissue Expansion

- Expander exposure
 - Early: remove the expander
 - Late: continue expansion and use expanded tissue for reconstruction.

5 Rhinologic Emergencies

Steven David Schaefer

5.1 Epistaxis

- Initial evaluation

Assess general appearance of patient.

- Obtain vital signs as warranted.
- Obtain brief history to permit focusing on the site and potential cause of hemorrhage.
- Initial control of hemorrhage
 - Manually compress the lower half of nose or use a nose clip to reduce anterior hemorrhage. If bleeding is controlled, maintain compression continuously for 15 minutes before checking for cessation of bleeding. Compressing the upper nose or nasal bones will not affect hemorrhaging.
 - Clear the nose of blood clots with suction and/or gentle nose blowing.
 - Spray the nose with a vasoconstrictive agent, such as oxymetazoline (Afrin; Merck Consumer Care, Cleveland, TN).
 - Continue manual compression of the lower nose while preparing to perform anterior rhinoscopy with a nasal speculum, or preferably with a nasal endoscope.
 - Place cotton pledgets, approximately 0.5 x 3 to cm long, along the floor of the nose and, if possible, at the site of bleeding.
 - If the site of hemorrhage is in the posterior third of the nose, consider a transpalatal injection of the sphenopalatine artery.
- Inspection of the nose
 - Perform rhinoscopy with a 0-degree nasal endoscope. If an endoscope is not available, a nasal speculum and a bright headlight will permit visualization of the anterior nose.
- Control of anterior epistaxis
 - Cauterize site of minor bleeding with silver nitrate or chromic acid.
 - Avoid chemical cauterization in patients with abnormal wound healing, such as those with lupus. In such patients, the cauterization site will become necrotic and rehemorrhage; instead, place a dissolvable agent that will facilitate clotting, such as Gelfoam (Pfizer, New York, NY), at the bleeding site.
 - Anterior nasal packing is reserved for anterior epistaxis refractory to the above measures. Place the nasal pack along the floor of the nose and against the site of hemorrhage. Vaseline gauze should be progressively layered along the floor of the nose until the site of bleeding is compressed. Commercially available packs, such as Merocel (Medtronic, Minneapolis, MN), are simpler to use but require the same careful attention to placement. Do not shove something in the nose and expect it to control hemorrhage.
 - Avoid nonbiodegradable nasal packing in patients with impaired wound healing. Biodegradable products such as Gelfoam or oxidized cellulose (Surgicel; Johnson & Johnson, New Brunswick, NJ) should be applied in the same way as other forms of nasal packing. Overall, such products are preferable because they do not require removal in 3 to 4 days, as do the nonbiodegradable nasal packs.

- Place the patient on broad-spectrum antibiotics to avoid sinusitis.
- Control of posterior epistaxis
 - Reserve posterior nasal packing for identifiable bleeding sites or failure to control hemorrhage with anterior packing.
 - Posterior packing must tamponade the choana and sphenopalatine artery. A commercial nasal balloon or a Foley catheter is placed into the posterior nose and inflated with saline. The balloon must be pulled forward and a clamp placed over the anterior aspect of the device. Cotton gauze is placed between the clamp and the nasal ala to prevent necrosis of the nose.
 - Most patients with posterior nasal packing should be hospitalized to monitor respiratory function and oxygen saturation, and many require oxygen by face mask.
 - Place the patient on broad-spectrum antibiotics to avoid sinusitis.
 - After 2 days of nasal packing, patients with persistent hemorrhage should be considered for either endoscopically directed electrocautery, intranasal ligation of the sphenopalatine artery, or arterial embolization of the internal maxillary artery.

5.2 Iatrogenic Cerebral Spinal Fluid Rhinorrhea

- Acute, intraoperative cerebrospinal fluid (CSF) rhinorrhea
 - Immediately obtain careful hemostasis within the nose by placement of cottonoids at all bleeding sites and consider bipolar electrocautery as indicated.
 - Identify the site of CSF rhinorrhea and inspect the integrity of the bony skull base, dura, and brain. Intracranial hemorrhage requires neurosurgical consultation. Low-volume venous bleeding on the cortex can be temporarily mitigated by direct placement of neurosurgical cottonoids, and if it is available and the surgeon has the proper skills, bipolar electrocautery is useful.
 - After hemostasis has been obtained, the 1 cm or more of mucous membrane surrounding skull base defect should be removed. This will later permit adhesion of the graft to the bony skull base.
 - A watertight seal should be obtained by intrathecal grafting. Although many grafting materials are available, fat is the easiest and most reliable graft. One continuous piece of abdominal or ear lobule fat measuring several times the size of the dural defect is placed intrathecally. Approximately 25% of the fat should protrude into the nasal side of the dura to help anchor the graft.
 - After placement of the fat graft, the anesthesiologist should perform a Valsalva maneuver to raise the intracranial pressure, and the surgeon should observe the defect for persistent CSF rhinorrhea. A properly placed graft should provide a watertight seal.

- A second graft may be placed intranasally along the bony skull base. Mucous membrane or various commercial products are excellent grafts and can be made to adhere to the skull base with tissue glues. The graft should be applied only to the exposed bone of the skull base to permit optimal adherence.
- Biodegradable or dissolvable packing, such as Gelfoam, is applied to the underlay or intranasal graft to further secure it. As most iatrogenic fistulas occur in the roof of the ethmoid sinus, the packing should fill only part of this sinus. If possible, any packing requiring removal should be avoided because its removal may dislodge the graft.
- Intraoperatively, an intravenous (IV) broad-spectrum antibiotic should be administered to prevent meningitis.
- Patients should avoid straining or other activities that increase intracranial pressure, and they should be made aware of the signs of meningitis.
- Patients should avoid flying for 6 weeks.
- Late or post-sinus surgery CSF rhinorrhea
 - Post-sinus surgery CSF fistulas should be repaired as soon as recognized.
 - Patients should be informed of the signs of meningitis and should avoid flying, nasal cleaning, nose blowing, and nasal lavage. Antibiotics should be considered with concurrent acute sinusitis.
 - Post-sinus surgery meningitis with or without CSF rhinorrhea should alert the physician to a communication between the subarachnoid space and the nose. Potential fistulas may cease after meningitis and later recur.
 - High-resolution coronal 2-mm computed tomographic (CT) images are helpful in identifying or confirming the site of the fistula. Contrast CT cisternography can be helpful if the site of the fistula is questionable, provided the patient has active rhinorrhea. In Europe, intrathecal hypodense fluorescein (10 mg/mL) is employed to endoscopically visualize fistulas.
 - In fistulas that are more than several weeks old, 3 days of lumbar drainage may be considered to divert the excessive CSF produced to compensate for the rhinorrhea. If lumbar drainage is employed, 1 to 2 mL of hypodense fluorescein can be placed intrathecally via the drain. The fluorescein enhances identification of the fistula site and intraoperatively ensures the detection of post-grafting rhinorrhea.
 - Repair of the fistula and post-hospitalization care are the same as outlined for acute injuries.

5.3 Complications of Acute Sinusitis

- Etiology of acute sinusitis complications
 - The proximity and venous drainage of the sinuses may result in the spread of infections to the orbit and brain.
 - Obstruction of the drainage pathways of the sinuses, or masses or tumors of the sinuses, may first present as eye or brain complications. Spread of infection to the orbit is more common from ethmoid sinusitis, and to the brain or epidural space from frontal and sphenoid infections. Maxillary sinusitis may be secondary to dental infections.
- Orbital complications of acute sinusitis
 - The periosteum of the orbit (periorbita) initially confines the extension of infection from the sinuses into the orbit.
 - Preseptal (anterior to the septum orbitale) infections present with swelling of the eyelids and a minimal chemosis and injection of the conjunctivae.
 - Preseptal infections are initially treated with broad-spectrum oral antibiotics, with IV antibiotics reserved for more aggressive infections or in compromised patients. Ophthalmology consultation is indicated.
 - Subperiosteal abscesses of the orbit arise from direct extension of the sinus infection into the subperiosteal space between the periorbita and the bony walls of the orbit. Such infections are not within the orbit proper and do not involve the extraocular muscles, fat, or globe. Ethmoid sinusitis is the most common etiology of such infections. Patients present with variable degrees of proptosis due to displacement of the orbital contents by the abscess.
 - Subperiosteal abscess requires surgical drainage and broad-spectrum antibiotics. Surgical drainage includes ethmoidectomy or sinusotomy (drainage) of the involved sinus. Subperiosteal abscess arising from ethmoid sinusitis can be drained into the ethmoid cavity by removal of the lamina papyracea endoscopically at the time of ethmoidectomy, or externally via a Lynch incision. Subperiosteal abscesses involving the superior orbit are approached through direct incision over the abscess or orbitotomy. Management should be in conjunction with ophthalmology.
 - Intraorbital cellulitis or abscesses result from the progression of infection from the sinuses through the periorbitae. Involvement of the extraocular muscles presents as diplopia, with proptosis resulting from the mass effect of the abscess.
 - Visual acuity and intraocular pressure must be monitored. As pressure rises, retinal perfusion is compromised, leading to potential blindness and requiring urgent care.
 - Intraorbital abscesses are treated by IV broad-spectrum antibiotics and incision and drainage of the orbit (orbitotomy). Management should be in conjunction with ophthalmology.
 - Localization of infection and/or abscess to the superior orbital fissure presents as loss of extraocular movement as the third, fourth, and sixth cranial nerves are compromised.
 - Treatment is urgent and the same as for intraorbital infections because both processes have the same etiology and simply differ in localization.
 - Management should be in conjunction with ophthalmology.
 - Loss of vision and afferent pupillary defect (Marcus Gunn pupil, or positive swinging flashlight test) implies compromise of the optic nerve between the retina and the optic chiasm.
 - In conjunction with ophthalmology, management focuses on relieving pressure or infection involving the optic nerve.
 - Cavernous sinus involvement is heralded by contralateral visual or ocular movement findings.
 - Treatment consist of IV antibiotics with prevention and/or amelioration of cavernous sinus thrombosis.
- Intracranial complications of acute sinusitis

- The proximity of the ethmoid, frontal, and sphenoid sinuses to the intracranial cavity permits direct extension of infection and/or abscesses to the meninges, epidural space, cavernous sinus, internal carotid artery, and optic nerve.
 - Treatment is urgent and is directed toward the site of infection. Symptoms vary with the site of infection. CT or magnetic resonance imaging is useful in identifying abscesses, thrombosis of the dural sinuses, and evidence of increased intracranial pressure.
 - A complete neurologic examination, including assessment of the cranial nerves, deep tendon reflexes, and abnormal posturing on sensory stimulation, often helps to localize the site and severity of infection or abscess.
 - Prior treatment with oral antibiotics may mask signs of meningitis (lack or minimal evidence of meningeal tenderness, papilledema, confusion, lethargy, and cranial neuropathies).
- Lumbar puncture must be wisely employed and can precipitate brainstem herniation in the setting of increased intracranial pressure. When appropriate, lumbar puncture should be performed to diagnose meningitis, and bacteria/fungus should be obtained for culture.
- Broad-spectrum antibiotics are employed and vary with the age and nature of the infection. For example, patients after neurologic or sinus procedures have a higher incidence of *Staphylococcus aureus* and pneumonia infections.
- Abscesses require drainage by neurosurgery.
- Hematogenous spread to the subarachnoid space and brain
 - Depending on the site of infection, diagnosis and management are similar to those for the site of infection.
 - Timing of the drainage of brain abscess depends on the neurologic consequences of the abscess and its maturity (cerebritis vs mature abscess).

6 Laryngologic Emergencies

Philip A. Weissbrod

6.1 Introduction

Integral to breathing, swallowing, protection of the airway, and phonation, the larynx is a vital component of the upper respiratory tract. This chapter will serve to outline possible etiologies and provide a framework for the management of laryngologic emergencies.

6.2 Acute Upper Airway Obstruction

Obstruction can occur for many reasons at different levels of the upper airway, including the oral cavity, pharynx, larynx, and trachea. Often, a careful history and physical examination can point to a clear etiology and anatomical location. Management consists of establishing a safe, secure airway and reversing the underlying cause. Severe airway compromise is best managed in a controlled setting, such as the operating room, intensive care unit, or trauma bay, before patient decompensation.

□ Etiology

- Anaphylaxis
- Angioedema
- Autoimmune
 - Amyloidosis
 - Sarcoidosis
 - Wegeners granulomatosis
- Foreign body
- Granulation tissue
- Granulomatosis
- Hemorrhage
 - Postsurgical
 - Traumatic (intraluminal vs extraluminal/compressive)
- Infectious
 - Deep neck space infection
 - Ludwig angina
 - Peritonsillar abscess
 - Respiratory papillomatosis
 - Retropharyngeal abscess
 - Supraglottitis/epiglottitis
- Neoplasm
- Neurologic
 - Bilateral vocal fold paralysis
- Stenosis.
- Trauma
 - External trauma.
 - Intubation-related trauma.
- Other
 - Laryngospasm.
 - Laryngomalacia/tracheomalacia
 - Paradoxical vocal fold motion

□ Evaluation

- History
 - Allergy history

- Cough
- Duration of symptoms
- Dysphagia
- Dyspnea
- Fever/chills
- Hoarseness
- Odynophagia
- Pain
- Recent intubation for airway trauma
- Physical examination
 - Vital signs
 - Stridor: noisy respiration
 - Inspiration: localizes to glottis and above
 - Biphasic: localizes to glottis or subglottis
 - Expiration: localizes to subglottis and below
 - Observed patient discomfort/anxiety
 - Mental status change
 - Examination of the head and neck with a focus on the airway column from nose to lungs to locate and grade the obstruction
 - Observe for signs of respiratory fatigue: shallow, rapid respiration; supraclavicular retractions; recruitment of accessory respiratory muscles; paradoxical breathing; intercostal retractions.
 - Chest and neck auscultation
 - Flexible laryngoscopy: while performing fiber-optic examination, it is important to avoid stimulation of the pharynx and larynx to prevent laryngospasm, which can precipitate a clinical decompensation.
- Testing
 - Arterial blood gas
 - CT scan (if there is concern for abscess, framework injury, or tumor)

□ Treatment

- Determine site/level of obstruction and reverse the cause.
- Control airway distal to obstruction by either endotracheal intubation or surgical airway if warranted by the severity and location of obstruction.
- Nonsurgical airway management
 - Mask ventilation
 - Continuous positive airway pressure (CPAP)/bilevel positive airway pressure (BiPAP)
 - Laryngeal mask airway (LMA)
 - Endotracheal intubation
 - Macintosh or Miller blade
 - Rigid laryngoscope
 - Fiber-optically assisted
 - Rigid bronchoscope
 - Observation in intensive care unit or emergency department setting.
 - When appropriate, consider treatment with
 - Steroids
 - Antibiotics
 - Racemic epinephrine
 - Heliox

- Surgical airway management
 - Cricothyroidotomy.
 - Tracheotomy.
 - Cricothyroid puncture
 - During emergent surgical airways, placement of the airway below the second ring is ideal to avoid trauma to the larynx and subglottis; however, this is a lifesaving measure, and securing the airway is the priority.

6.3 Laryngeal Blunt Trauma

The management of blunt laryngeal trauma is dictated by the extent of injury to cartilaginous structures and mucosa. Care must be taken not to exacerbate a tenuous airway during the diagnostic process.

□ Etiology

- Clothesline injury
- Motor vehicle accident
- Strangulation

□ Evaluation

- History
 - Dyspnea
 - Hoarseness/aphonia
 - Hemoptysis
 - Mechanism of injury
 - Odynophagia
 - Pain
- Physical examination
 - Stridor
 - Dysphonia
 - Respiratory fatigue
 - Blunting of thyroid ala
 - Crepitus
 - Neck ecchymosis
 - Tenderness
- Flexible laryngoscopy (note the following if present)
 - Airway narrowing
 - Ecchymosis/hematoma
 - Edema
 - Mucosal or vocal fold laceration
 - Vocal fold immobility
 - Exposed cartilage
- Testing
 - Computed tomography: look for fracture (displaced, non-displaced)

□ **Treatment.** Treatment is dictated by the category of injury (types I, II, III, IV). Initial management should determine if the patient is in respiratory extremis or in danger of compromise. If at risk for obstruction, regardless of subtype, emergent tracheotomy or cricothyroidotomy should be considered as the first step in management without endotracheal intubation if it can be avoided. Laryngeal injury can be missed because of intubation before examination. In the presence of significant laryngeal trauma, injuries to the esophagus are frequent and can be missed. Esophagrams or rigid/flexible esophagoscopy should be performed, especially for zone I penetrating injuries.

- Type I
 - Diagnostic criteria: patients have no airway compromise, soft-tissue injury only (including mucosal abrasions, hematomas, small lacerations)
 - Management
 - Medical: close observation, no oral intake, serial fiber-optic examination
- Type II
 - Diagnostic criteria: patients with possible airway compromise, moderate soft-tissue laceration or tearing, nondisplaced or minimally displaced cartilaginous framework fracture
 - Management
 - Medical: close observation, steroids, humidified oxygen, voice rest, antireflux medication, esophagram
 - Surgical: possible tracheotomy, direct laryngoscopy, esophagoscopy
- Type III
 - Diagnostic criteria: displaced or unstable laryngeal fractures, significant mucosal or vocal fold lacerations, and/or intraluminal cartilage exposure
 - Management
 - Surgical: awake tracheotomy, direct laryngoscopy, open reduction with internal fixation, repair of mucosal lacerations, esophagoscopy
- Type IV
 - Diagnostic criteria: similar but more severe injuries than type III
 - Management
 - Surgical: same as type III but with placement of laryngeal stent for support of cartilaginous fractures, mucosal repairs, and exposed cartilage

6.4 Laryngeal Penetrating Trauma

Penetrating trauma to the neck can be life-threatening. The initial evaluation should be dictated by patient stability. If a patient is hemodynamically unstable from a neck injury, immediate exploration is indicated. As many as one-third of patients with vascular injury from penetrating trauma are asymptomatic. Otherwise, diagnostic modality and management are dictated by the location of the injury.

□ Etiology

- Low-velocity injury (e.g., stab wounds, broken glass)
- High-velocity injury (e.g., gunshot wounds, shrapnel)

□ Evaluation

- History
 - Dysphagia
 - Hematemesis
 - Hemoptysis
 - Hoarseness
 - Nerve weakness or paralysis
 - Odynophagia
 - Pain
- Physical examination
 - Bruits
 - Examine for both entry and exit wounds when applicable.

- Hematoma
- Hemorrhage
- Impaired mental status (potential vascular injury)
- Neurologic deficits
- Respiratory obstruction/compromise
- Subcutaneous emphysema
- Stridor
- Unequal pulses
- Surgical exploration and imaging is not indicated for injuries that do not pierce the platysma.
- Testing and treatment for zone I injury
 - Inferior border: sternal notch
 - Superior border: inferior border of cricoid
 - Obstacles to surgical access: sternum, clavicles
 - Structures at risk: brachiocephalic artery and vein, internal jugular vein, common carotid artery, subclavian artery and vein, vertebral artery, trachea, esophagus, vagus nerve, phrenic nerve, brachial plexus, recurrent laryngeal nerve, thoracic duct, thyroid, lung apex, spinal cord. In penetrating trauma, zone I injuries carry the highest mortality rate.
 - Testing/management: angiography vs CT angiogram, esophagram/esophagoscopy
- Testing and treatment for zone II injury
 - Inferior border: inferior border of cricoid
 - Superior border: angle of mandible
 - Structures at risk: internal jugular vein; common, external, and internal carotid artery; vertebral artery; trachea; larynx; pharynx; hypopharynx; vagus nerve; submandibular gland; phrenic nerve; accessory nerve; hypoglossal nerve; marginal mandibular nerve; spinal cord
 - Testing/management: somewhat controversial. If symptomatic, surgical exploration is indicated. If asymptomatic, consider surgical exploration vs angiography or CT angiogram.
- Testing and treatment for zone III injury
 - Inferior border: angle of mandible
 - Superior border: skull base
 - Obstacles to surgical access: mandible, mid face
 - Structures at risk: internal jugular vein, vertebral artery, internal carotid artery, branches of the external carotid artery, pharynx, parotid gland, facial nerve, cranial nerves, spinal cord
 - Testing/management: angiography vs CT angiogram
- Treatment points
 - If unstable (shock or evolving stroke), then consider immediate exploration.
 - Initially, bleeding should be controlled with direct pressure.
 - Manipulation and probing of the site of injury and removal of penetrating objects should be avoided until in a controlled environment and large-bore intravenous lines have been secured.
 - Surgical consultations
 - Vascular surgery for complex repair of the carotid system
 - Thoracic surgery for low zone I vascular injuries

- Neurosurgery for high zone III injuries that may require craniotomy for control
- Interventional neuroradiology for zone III vascular injuries that may benefit from embolization or stenting

6.5 Voice Emergencies

Vocal emergencies, although not life-threatening, can pose significant risk to those who use their voice for vocation. Untreated vocal emergencies are capable of causing significant scarring of the vocal folds or polyp formation, leading to decreased vibratory capacity and ultimately chronic voice alterations.

□ Etiology

- Hemorrhage (often associated with sudden voice changes that occur during vocal strain, coughing, vomiting)
- Vocal fold tear
- Severe laryngitis (bacterial, fungal, or viral)
- Upper respiratory infections

□ Evaluation

- History
 - Pain with phonation
 - Smoking history
 - Sudden onset versus progressive
 - Voice change
 - Vocal hygiene
 - Preexisting symptoms of chronic laryngitis
 - Upcoming vocal demands/performance obligations
- Physical examination
 - Dysphonia
 - Flexible laryngoscopy
 - Videostroboscopy if available

□ Treatment

- Voice rest
- Supportive care (hydration, mucolytics, general rest, cessation of smoking)
- Treatment of underlying causative, contributing, or exacerbating factors
- Voice therapy after acute phase
- Avoidance of laryngeal irritants
- When indicated, consider
 - Antibiotics
 - Antifungals
 - Corticosteroids (oral or intramuscular)
 - Proton pump inhibitors
- Avoid blood-thinning agents
- Identify pending vocal engagements to determine how quickly the restoration of normal voice is needed. This will affect the aggressiveness of therapy and establish the need to cancel pending engagements.

7 Emergency Airway Management and Tracheotomy

Adam S. Jacobson and Joseph J. Rousso

7.1 Introduction

Airway control is the most critical component of emergency patient care and accordingly is the first step in cardiopulmonary resuscitation. Emergency airway management requires quick and decisive action, and a functional knowledge of anatomical landmarks. There are several methods of accessing the airway in both the emergent and controlled settings, including endotracheal intubation, cricothyrotomy, and tracheotomy.

7.2 Incidence of Disease

Several pathologic processes result in the need for airway management. The most common reason for tracheotomy and tube placement is respiratory ventilation for longer than 1 to 2 weeks.

7.3 Terminology

The term airway generally refers to the route of air passage from the upper aerodigestive tract into the tracheobronchial tree. The airway can be compromised anywhere along this route. A keen understanding of the airway anatomy allows the practitioner to have a clearer picture of interventions and procedures that can be used to access the airway.

Tracheotomy is a surgical opening made directly into the trachea, below the cricoid cartilage. Cricothyrotomy is a surgical opening through the cricothyroid membrane, which lies between the thyroid and cricoid cartilages.

7.4 Applied Anatomy

Inspired air enters the nasal cavity, where it is warmed and humidified. It continues through the nasopharynx, oropharynx, and endolarynx to enter the trachea via the subglottis, below the true vocal cords.

The anterior neck has palpable landmarks that assist in finding an entry point for a surgical airway. The sternal notch and cricoid cartilage serve as excellent indicators of the midline, the expected location of the normal trachea in its longitudinal course. The thyroid cartilage, often referred to as the Adam's apple, is typically a prominent surface landmark that reliably protects the structures of the deeper endolarynx. Below the thyroid cartilage lies the cricoid cartilage. The cricoid cartilage is the most important landmark in tracheotomy because it lies immediately above the superior tracheal rings.

In the emergent setting, in which exposure is not ideal, palpable anterior cervical landmarks are the most valuable tool available to the surgeon. When the neck is palpated, the first palpable prominence above the sternal notch typically represents the cricoid cartilage. The second, more superior and larger palpable prominence represents the thyroid cartilage. The slight indentation or valley between these two prominences represents the cricothyroid membrane, the entry point for emergent cricothyrotomy.

7.5 Disease Process

7.5.1 Etiology and Pathogenesis

Airway complications can arise from several causes, including trauma, anaphylaxis, cardiopulmonary arrest, infection, toxic exposure, congenital, neurologic insult, hypoventilation, and many others.

7.5.2 Natural History and Progression

In the hemodynamically unstable patient with acute obstruction, the airway must be secured immediately because anoxia results in death within 4 to 5 minutes. In the hemodynamically stable patient or the patient whose airway is secured, further evaluation can be afforded. Patients who are endotracheally intubated are at risk of several complications, including tracheal and laryngeal stenosis; the risk increases with prolonged intubation.

7.5.3 Potential Complications

Damage to the airway can lead to dysphonia, stridor, difficulty breathing, and potentially death.

7.5.4 Disease Grading

Airway grading systems are not generally used for the assessment of surgical airways.

However, thinner individuals with a full range of neck extension and palpable cricoid and thyroid cartilages are considered favorable surgical candidates.

The simplest and most common method of endotracheal intubation assessment is the Mallampati classification, which indicates how much of the posterior pharynx can be visualized with the mouth fully opened. The Mallampati system divides patients into four classes. Class I indicates full visualization of the pillars, fauces, soft palate, and uvula and is considered predictive of a relatively uncomplicated intubation. On the other end of the spectrum, class IV indicates visualization of the hard palate only because of a large tongue obscuring the view and is predictive of a difficult endotracheal intubation.

7.6 Medical Evaluation

7.6.1 Presenting Complaints

The presentation of a patient in respiratory distress can be highly variable. The presentation can range from a conscious patient who complains of "throat tightness" to an unconscious patient who is unable to be ventilated. Stridor, drooling, rapid breathing, shallow breathing, decreasing oxygen saturation, tachycardia, tongue swelling, dysphonia, globus sensation, and facial fractures are all signs of possible or pending loss of airway and should be assessed with urgency.

7.6.2 Acute Evaluation in the Unconscious Patient

Initial evaluation in the unconscious patient should include a chin lift and rapid assessment of breathing, with care taken not to manipulate the cervical spine in a trauma setting. After it has been established that the airway is compromised, further considerations should include the mechanism of injury, site of obstruction, overall hemodynamic stability, and possible immediate interventions. From the moment the patient arrives at a medical setting, a cardiac monitor with a functional pulse oximeter and large-bore intravenous access must be in place.

7.6.3 Acute Evaluation in the Conscious Patient

The urgency of airway evaluation should not be ignored in the conscious patient as several factors can lead to immediate instability. After the initial and secondary survey, the focused history should include an assessment of allergen exposure, medications, timing and onset of symptoms, mechanism of injury, associated symptoms, substance use, and medical and surgical histories.

Stridor is a very important symptom that may be elicited by the patient history and/or a sign that may be found on physical examination. The characteristics of the patient's stridor can give the physician a preliminary impression as to the level of anatomical disturbance. Inspiratory stridor is indicative of a disturbance at the level of the larynx, whereas expiratory stridor suggests obstruction more distally in the tracheobronchial tree. Biphase stridor is a symptom of a glottic or subglottic cause of respiratory distress.

7.6.4 Physical Examination

A complete physical examination is invaluable in the clinician's decision-making process. Assessment of the neurologic status should include a Glasgow Coma Scale score. Examination of the head and neck, with complete evaluation of the eyes, ears, nose, throat, and face, is necessary, with particular attention given to traumatic injury. Furthermore, a dedicated head and neck examination should include thorough and careful neck palpation to evaluate for masses that could be causing airway compression. A cardiac and pulmonary examination should then be performed, with attention to respiratory effort and the use of accessory muscles of respiration. If the patient is stable, visualization of the endolarynx and airway via fiberoptic endoscopy is appropriate and extremely useful when available.

7.6.5 Laboratory Studies and Imaging

Imaging studies, particularly noncontrast computed tomography, present the physician with further information as to the structural integrity of the upper aerodigestive structures in patients who are sufficiently stable to undergo the tests. Arterial blood gas values assist in identifying the source of respiratory distress.

7.6.6 Differential Diagnosis

Several pathologic processes can present similarly to acute airway distress. Anxiety disorder can manifest as panic attacks, which often present with respiratory distress. The associated hyperventilation further aggravates the patient's sense of choking and impending doom.

Paradoxical vocal fold movement is another pathologic entity that in severe cases can manifest with acute respiratory distress and be mistaken for asthma.

Acute airway distress can have several causes. Any source of anatomical disruption or obstruction of the airway can lead to respiratory distress. Tumors, masses, traumatic injury, and foreign bodies at any level of the pharynx, larynx, or trachea can lead to profound respiratory difficulty. Direct compression of the airway from an extratracheal mass, such as an anaplastic thyroid carcinoma or thyroid goiter, can have grave airway consequences. True vocal cord immobility, particularly when bilateral, can lead to nearly complete airway obstruction.

7.7 Treatment

7.7.1 Endotracheal Intubation

Endotracheal intubation is the first step of achieving airway control in the acute setting.

Rapid-sequence intubation is the method of choice when time permits. This consists of preoxygenation with 100% oxygen via a non-rebreather mask for several minutes. If ventilation is necessary, bag gently while cricoid pressure is applied. The administration of either midazolam 0.2 mg/kg or etomidate 0.3 mg/kg can be used for induction in the hemodynamically stable patient. A paralytic, such as succinylcholine, can then be administered for easier access into the oral airway and will take effect within 30 seconds. Finally, the endotracheal tube is placed and secured. If the endotracheal tube cannot be placed, the patient should be ventilated with a bag valve mask. If the orotracheal intubation is unsuccessful, other options must quickly be considered. Nasotracheal intubation with visualization via the use of a fiber-optic nasopharyngoscope is helpful in obtaining a difficult airway. However, nasotracheal intubation is challenging and requires an experienced practitioner.

Complications of endotracheal intubation can be differentiated into immediate and postprocedural. Immediate complications include esophageal intubation, main bronchus intubation, tooth damage, mucosal tears, laryngospasm, and traumatic disarticulation or laceration of endolaryngeal structures. Post-intubation complications include subglottic stenosis, pneumothorax, vocal cord granuloma, vocal cord paralysis, and tracheal edema.

7.7.2 Surgical Treatment: Cricothyrotomy

Cricothyrotomy is the procedure of choice for emergency establishment of an airway in a patient who is unable to be intubated. The procedure consists of identifying the cricothyroid membrane as a slight indentation in the skin inferior to the

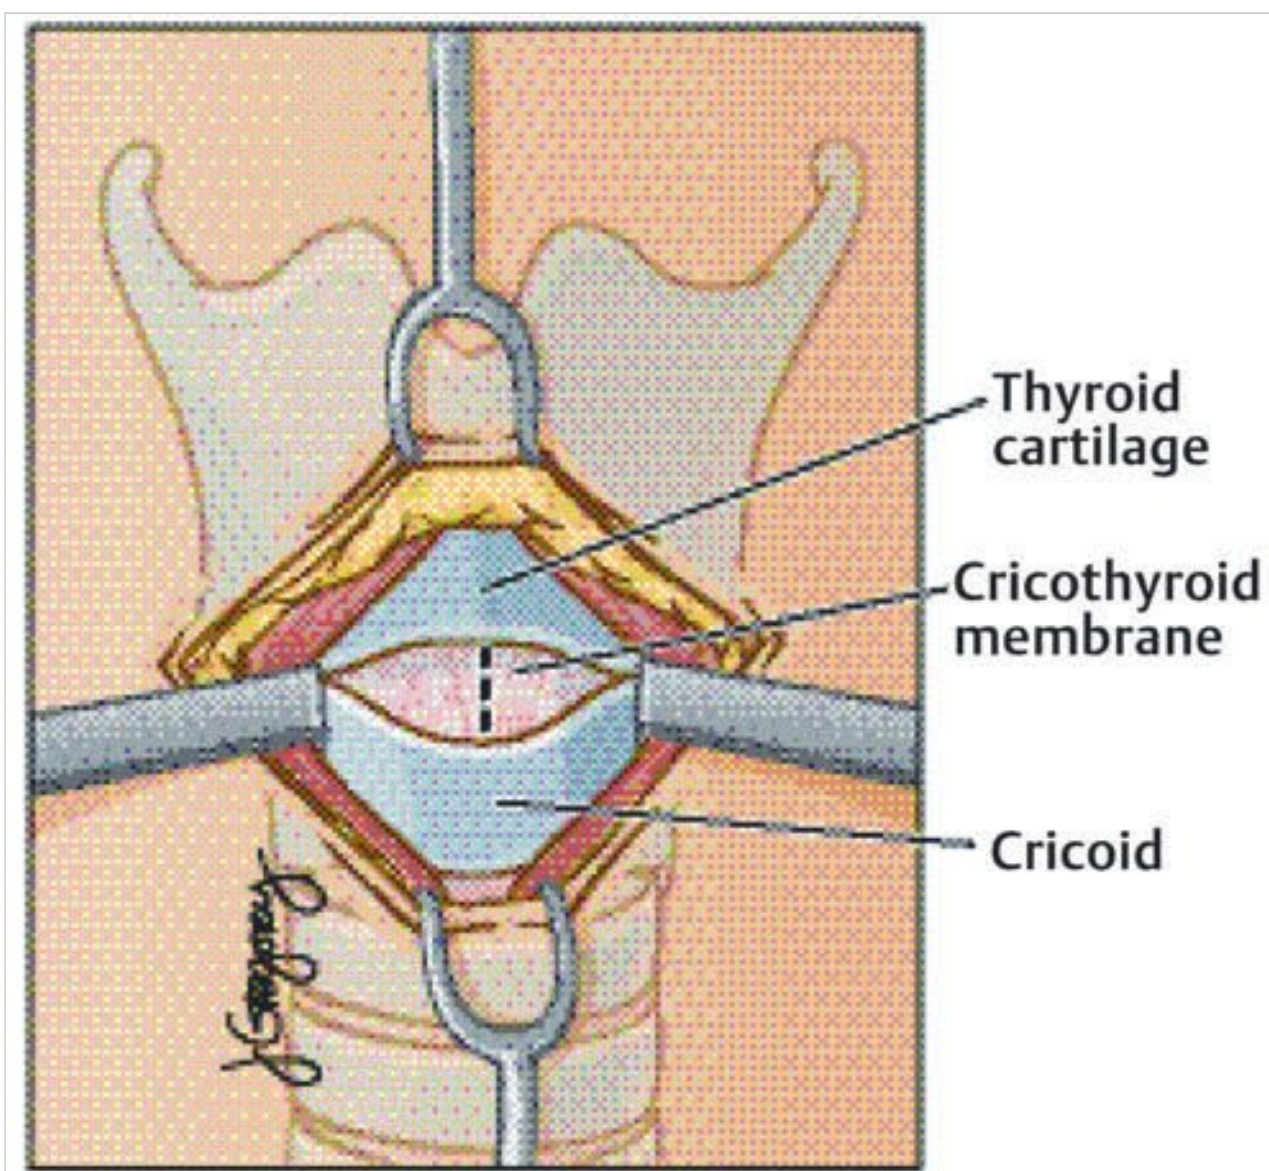

Fig. 7.1 The surgical landmarks for cricothyrotomy.

laryngeal prominence. The membrane is relatively superficial without any overlying large vessels or fascial layers, allowing easy access. A vertical skin incision is made from the thyroid cartilage to below the cricoid cartilage to increase exposure and minimize hemorrhage by avoiding the vertically coursing anterior jugular veins. Continuous palpation is necessary to feel the location of the cricothyroid membrane. Once the membrane is found, a stab wound is made and extended horizontally, and a small endotracheal tube or tracheotomy tube is placed. □ Fig. 7.1 demonstrates the anatomical landmarks for cricothyrotomy.

The major complication associated with cricothyrotomy is the increased rate of subglottic stenosis that occurs in comparison with tracheotomy. Therefore, it is recommended that cricothyrotomy be converted to formal elective tracheotomy as soon as safely possible.

7.7.3 Surgical Treatment: Needle Cricothyrotomy

A variation of a formal cricothyrotomy performed in dire emergencies is the needle cricothyrotomy. A large-gauge needle with a cannula is inserted into the cricothyroid membrane until air can be aspirated with the attached syringe. The cannula is then inserted into the airway and attached to a supply of oxygen. This allows the patient to be oxygenated for a short time, but the removal of carbon dioxide is not adequate and acidosis may ensue rapidly.

7.7.4 Surgical Treatment: Tracheotomy

Tracheotomy is a reliable procedure for access into the trachea. The modern procedure was described by Dr. Chevalier Jackson in 1909. Tracheotomy can be performed in the emergent setting (“slash trach”) when other methods of airway control are not attainable. However, the majority of tracheotomies are performed electively under general anesthesia.

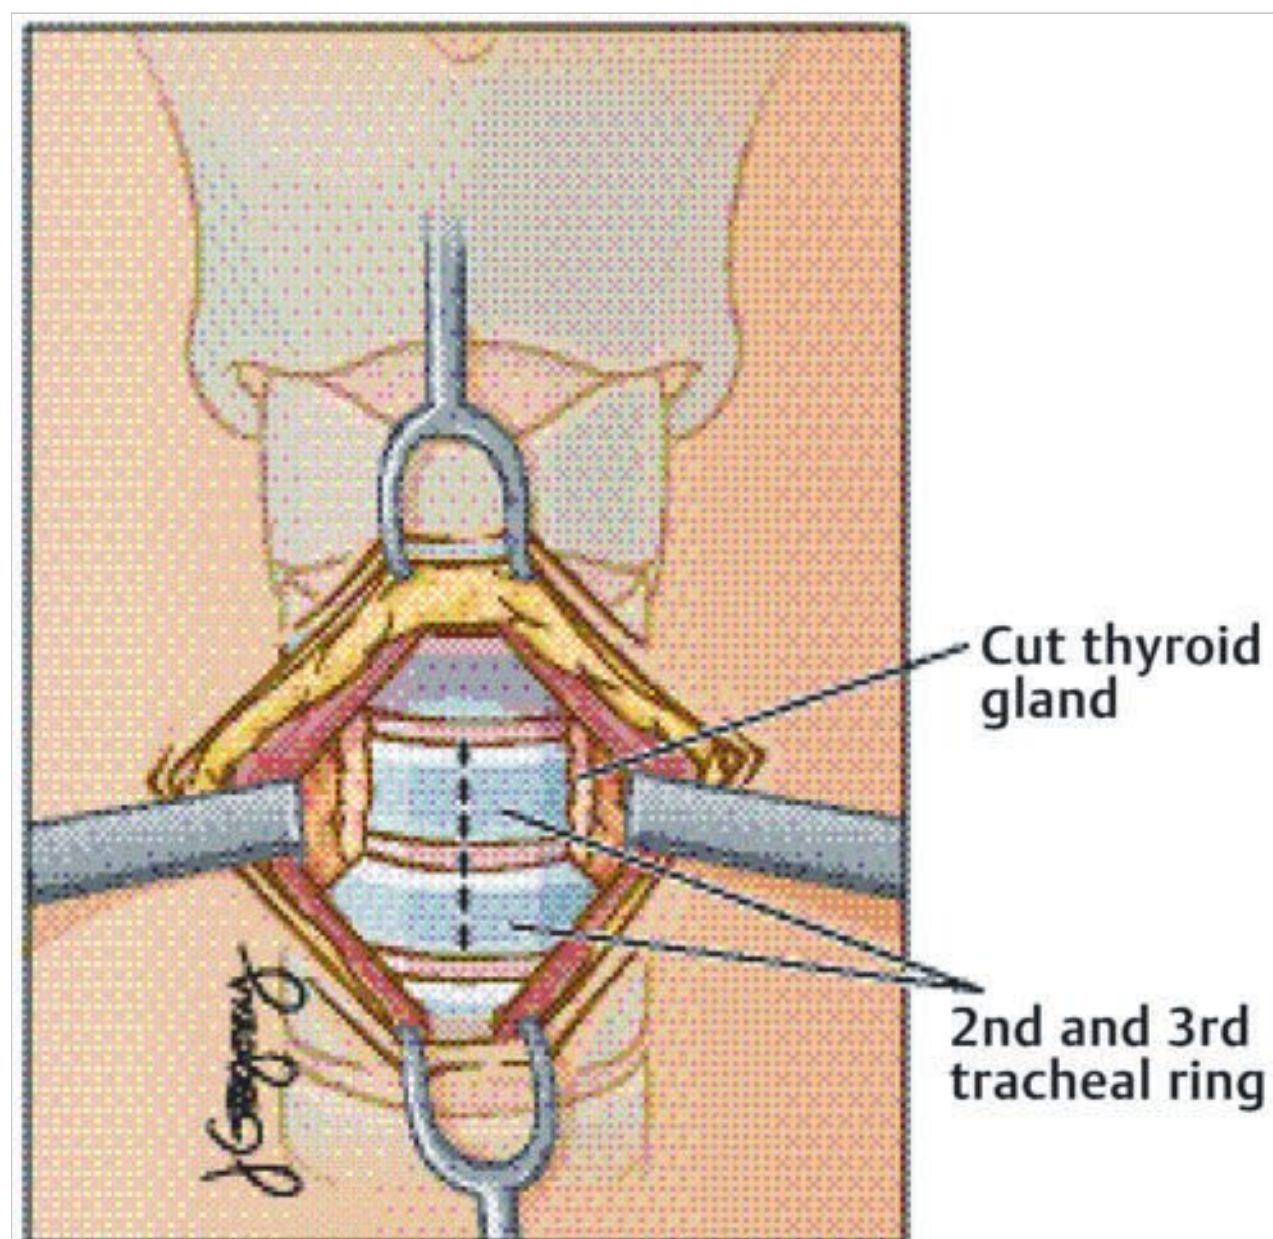

Fig. 7.2 The surgical landmarks for tracheotomy.

There is some discrepancy as to the preferred skin incision for an elective tracheotomy (vertical vs horizontal), although the consensus is that an emergent tracheotomy must have a vertical incision. □ Fig. 7.2 demonstrates the appropriate surgical landmarks for a tracheotomy. The incision should be placed below the cricoid cartilage, with anticipation of placing the tube between the third and fourth tracheal rings.

The incision is taken down below the platysma until the strap muscles are visualized. The strap muscles are separated at the midline raphe and retracted to reveal the isthmus of the thyroid. At this point, the isthmus can be retracted superiorly or transected to expose the underlying trachea. A window is made in the anterior wall of the trachea, with care taken not to insert the blade deeply enough to rupture the cuff of the endotracheal tube. A tracheal dilator is then inserted into the lumen of the trachea and the window expanded. At this point, the anesthesiologist is asked to deflate the cuff and slowly pull back the endotracheal tube until it lies immediately above the tracheotomy site. It is important that the endotracheal tube remain in the trachea at this point, in the event that the tracheotomy tube cannot be easily positioned through the window and into the trachea; should this occur, the endotracheal tube can be advanced below the tracheotomy site and the patient ventilated while the tracheotomy exposure is improved to allow easier placement of the tracheotomy tube. A cuff-tested and prepared tracheotomy tube (□ Fig. 7.3) is then inserted into the lumen of the trachea. Auscultation of the lungs and end-tidal carbon dioxide detection are used to confirm placement of the tracheotomy tube into the trachea. Furthermore, a flexible fiber-optic endoscope can be placed through the tracheotomy tube to visually confirm placement. The endotracheal tube is then completely removed, and the tracheotomy tube is sutured into place and a tracheotomy tie placed around it for additional security.

In the first 24 hours after tracheotomy, the patient should be treated with the same level of urgency as a patient with pending respiratory distress. Postoperatively, the patient should be

Fig. 7.3 A tracheotomy tube with the components labeled.

admitted to an observation unit with continuous cardiac and pulse oximeter monitoring and placed on humidified oxygen to prevent acute tracheal crust formation. The tracheotomy tube obturator should be kept by the bedside in an obvious but secure place. Any possible concerns that arise in these patients should be addressed immediately because tracheotomy tube replacement in a fresh surgical airway is extremely difficult. Suctioning should be performed frequently but only to the distal tip of the tube because excessive suctioning the tracheal lumen can cause irritation, granulation, and stenosis or erosion. If acute obstruction of the tracheotomy tube occurs, the inner cannula should be removed immediately and cleaned before it is replaced.

If the tracheotomy tube is displaced or falls out of place, the inner cannula should be removed and replaced by the obturator. The tracheotomy tube should be replaced immediately by manipulating it through the stoma. If the stoma has closed and the original tube cannot be passed, a smaller tracheotomy or endotracheal tube should be placed through the stoma. This can be facilitated (especially in patients expected to be difficult to reintubate, such as those with severe kyphosis or an obese neck) by the placement of stay sutures through the anterior trachea at the time of surgery that are taped to the patient's neck; these stay sutures are gently pulled laterally to aid in opening the tracheotomy track. If these measures do not allow fast access into the airway, the patient should be ventilated with a bag mask, and orotracheal intubation may be necessary. It is important to remember that a surgical airway does not necessarily preclude orotracheal intubation, if it becomes necessary.

As a rule of thumb, it takes about 7 days for a safe, well-formed track to form between the skin and the tracheal opening. Therefore, absolutely no unnecessary manipulation of a tracheotomy tube should be done until this time. Furthermore,

a new tracheotomy tube should remain secured with sutures as well as a tracheotomy tube tie. At postoperative day 7, the sutures can be removed. There is discrepancy between the timing and necessity of the first tracheotomy tube change. Some practitioners will routinely change the tracheotomy tube at postoperative day 7 for hygienic purposes, whereas others feel that this is unnecessary and unsafe. If the patient originally required a cuffed tracheotomy tube for ventilation purposes, the tracheotomy tube should be changed to an uncuffed one as soon as possible, as long as the tract is well formed. This prevents cuff-related tracheal ulceration, necrosis, and granulation tissue, which may otherwise result. If the patient is to have the tracheotomy tube in place for a long time, it should be replaced every 1 to 3 months. The peristomal skin should be cleansed meticulously to avoid irritation and breakdown from tracheal secretions.

Operative complications include injury to the esophagus, recurrent laryngeal nerves, and great vessels. Furthermore, pneumothorax, anesthetic complications, and perforation of the posterior tracheal wall can rarely occur intraoperatively. Postoperative complications include innominate artery erosion, tracheoesophageal fistula, tracheal stenosis, infection, and persistent stoma. The most severe complication that may arise from the placement of any form of surgical airway is death, most often resulting from tube displacement or hemorrhage. Complications in emergency tracheotomies are two to five times more frequent than when tracheotomy is done as an elective procedure.

7.8 Prognosis

After the airway has been secured, the patient's prognosis depends on overall hemodynamic stability and concomitant medical conditions.

Postoperative care of the surgical airway is vital to avoiding further airway complications. Frequent suctioning and pulmonary toilet prevent crusting and secretion buildup in the patient with a fresh tracheotomy. A patient with a tracheotomy tube should always have an obturator at the bedside to assist in timely replacement if the tracheotomy tube comes out of place.

7.9 Roundsmanship

- The airway is the physician's first priority in resuscitating a patient.
- Basic comprehension of the airway anatomy and cervical landmarks is vital to securing an airway in an unstable patient.
- The urgency of airway evaluation should not be ignored in the conscious patient as several factors can lead to immediate instability.
- Endotracheal intubation is the first step in accessing an airway in the emergent setting.
- If there is an immediate need for a surgical airway in the emergency setting, cricothyrotomy should be performed.
- Tracheotomy is a reliable procedure for airway access that is most successful when performed electively in a controlled setting.

8 Head and Neck Anatomy

Ameet R. Kamat and Edward J. Shin

8.1 Face

8.1.1 Muscles of the Face

The facial muscles are subcutaneous, some in a plane continuous with the superficial muscular aponeurotic system (SMAS). Their unique attachments with the skin, fascia, and bone allow for a variety of facial expressions. The muscles of facial expression are all derived from the second pharyngeal arch and are innervated by the seventh cranial nerve (the facial nerve).

Muscles of the Forehead

The anterior belly of the occipitofrontalis muscle is known as the frontalis. It arises from the epicranial aponeurosis posteriorly and attaches to the skin of the eyebrows anteriorly without a bony attachment. It is responsible for elevating the brow and producing transverse wrinkles. The cutaneous attachment of the procerus muscle is continuous with frontalis and arises from the upper nasal dorsum. It is responsible for transverse forehead wrinkles over the bridge of the nose. The corrugator supercilii muscle arises from the nasal bones and orbital part of the orbicularis oculi and connects to the skin of the brow. It is responsible for oblique wrinkles of the bridge of the nose.

Muscles of the Mouth, Lips, and Cheeks

Several muscles allow the human mouth to exercise a myriad of movements. The sphincter of the mouth is the orbicularis oris muscle, with fibers that encircle the mouth and lie within the lip. The muscle is responsible for mouth narrowing (as during whistling) and lip tightening (as during speech and mastication). The buccinator muscle works in conjunction with the orbicularis to hold the cheeks against the molar teeth during mastication and whistling. It arises from the pterygomandibular raphe posteriorly and extends to the alveolar processes of the maxilla and mandible. The zygomaticus major and minor muscles originate from the zygomatic arch, insert on the skin of the nasolabial fold, and act to retract the upper lip. The levator labii superioris and levator labii superioris alaeque nasi are more medial and elevate the lip, as well. The depressor anguli oris originates from the mandibular border lateral to the mental nerve and everts the lower lip. The platysma muscle is broad and thin, lying in a subcutaneous plane. It arises inferiorly from the deltoid and pectoralis fascia to extend superiorly to the lower border of the mandible, where it is continuous with the SMAS. The platysma tenses the skin, depresses the mandible, and contributes to inferior retraction of the chin and lower lip.

Muscles around the Orbit

The orbicularis oculi is responsible for closing the eye gently during blinking and squinting, and also for wrinkling the forehead. Its fibers wrap around the eye concentrically, attaching to the medial orbital margin and palpebral ligament. It is divided into three parts: preseptal, pretarsal, and orbital.

8.1.2 Arteries of the Face

The face is known for its abundant blood supply with extensive anastomosis. The major arterial supply is from the facial artery, the fourth branch of the external carotid artery. After branching, the facial artery courses deep to the submandibular gland, then along the inferior border of the mandible in a superficial plane just deep to the platysma until it ascends over the mandible anterior to the masseter muscle attachment. It then travels superomedially, crossing the maxilla and buccinator muscle and finally ending at the medial canthus in an anastomosis with the dorsal nasal branch of the ophthalmic artery. During this ascent, it gives off the superior and inferior labial arteries, which supply the lips and nose. Distal to the superior labial artery, the facial artery is known as the angular artery (□ Fig. 8.1).

The superficial temporal, occipital, transverse facial, and posterior auricular arteries also supply lateral or superior portions of the face, mainly the scalp. They also originate from the external carotid artery.

8.1.3 Veins of the Face

The retromandibular vein is formed by the union of the superficial temporal and maxillary veins. It runs deep and posterior to the ramus of the mandible, through the parotid gland, deep to the facial nerve. The anterior retromandibular vein and facial vein join to become the common facial vein, with subsequent drainage into the internal jugular vein. The posterior retromandibular vein joins with the posterior auricular vein to become the external jugular vein. The facial vein communicates with the superior ophthalmic vein near the medial canthus, with possible drainage into the cavernous sinus.

8.1.4 Nerves of the Face

Motor Innervation

All of the muscles of facial expression are innervated by the facial nerve (cranial nerve VII). The facial nerve exits the cranium through the stylomastoid foramen between the mastoid tip and styloid process. Before entering the parotid gland, it gives off the posterior auricular nerve, which passes posterosuperiorly towards the ear to supply both the occipital belly of the occipitofrontalis muscle and the posterior auricular muscle. The facial nerve then enters the parotid gland and divides into five terminal branches at the pes anserinus. The temporal branch courses superiorly over the zygomatic arch to supply the frontalis and orbicularis oculi muscles. The zygomatic branch further divides into several branches that supply the inferior orbicularis oculi. The buccal branch courses anteriorly to supply the buccinator muscle and orbicularis oris. The mandibular branch leaves the parotid at its inferior border, then crosses the mandible deep to the platysma within the submandibular gland fascia to innervate the depressor anguli oris. The cervical branch courses inferiorly to supply the platysma muscle. Other than the muscles of facial expression, the facial nerve is responsible for innervation

Fig. 8.1 Arteries of the face.

of the posterior belly of the digastric muscle and of the stylohyoid and stapedius muscles (□ Fig. 8.2).

Sensory Innervation

The trigeminal nerve (cranial nerve V) is the primary sensory nerve of the face. Cranial nerve V has three branches after leaving the trigeminal ganglion: the ophthalmic nerve (V_1), maxillary nerve (V_2), and mandibular nerve (V_3). V_1 and V_2 are entirely sensory, whereas V_3 contains motor fibers for the muscles of mastication and smaller muscles. The ophthalmic nerve is the smallest and most superior of the three divisions. After leaving the trigeminal ganglion, it enters the orbit via the superior orbital fissure and divides into three terminal branches: nasociliary nerve, frontal nerve, and lacrimal nerve. These nerves supply the nose (via the external nasal nerve and infratrochlear nerve) and the skin of the forehead and upper eyelid (via the lacrimal, supratrochlear, and supraorbital nerves). The maxillary nerve is the intermediate division of the trigeminal ganglion and exits the cranium via the foramen rotundum to enter the pterygopalatine fossa. It gives off branches to the pterygopalatine ganglion and zygomatic nerve before passing into the infraorbital foramen. Before exiting the foramen as the cutaneous infraorbital nerve, it gives off the zygomaticotemporal and zygomaticofacial nerves. It is responsible for sensation of the

skin of the temple, upper cheek, lower eyelid, upper lip, maxillary teeth, and mucosa of the maxillary sinus. The mandibular nerve is the most inferior and largest division of the trigeminal ganglion and exits the cranium via the foramen ovale. Its sensory branches include the auriculotemporal, buccal, and inferior alveolar nerves, which supply the lower portion of the face. The auriculotemporal nerve arises from two roots that pass around the middle meningeal artery, through the parotid gland, to the temporal region. It conveys secretomotor fibers to the parotid and sensation to the auricle, external auditory canal, and temporal skin. The buccal and inferior alveolar nerves supply the cheek, buccal gingiva, skin of the chin, lower lip, and labial gingiva (□ Fig. 8.3 and □ Fig. 8.4).

8.2 Nasal Cavity and Paranasal Sinuses

8.2.1 Nasal Cavity

The nasal cavity is entered anteriorly through the nares and posteriorly from the nasopharynx through the choanae. The roof of the nasal cavity is narrow anteriorly, widens intermediately, and narrows posteriorly. The floor of the nose is formed by the palatine bone and maxilla. The medial wall is formed by

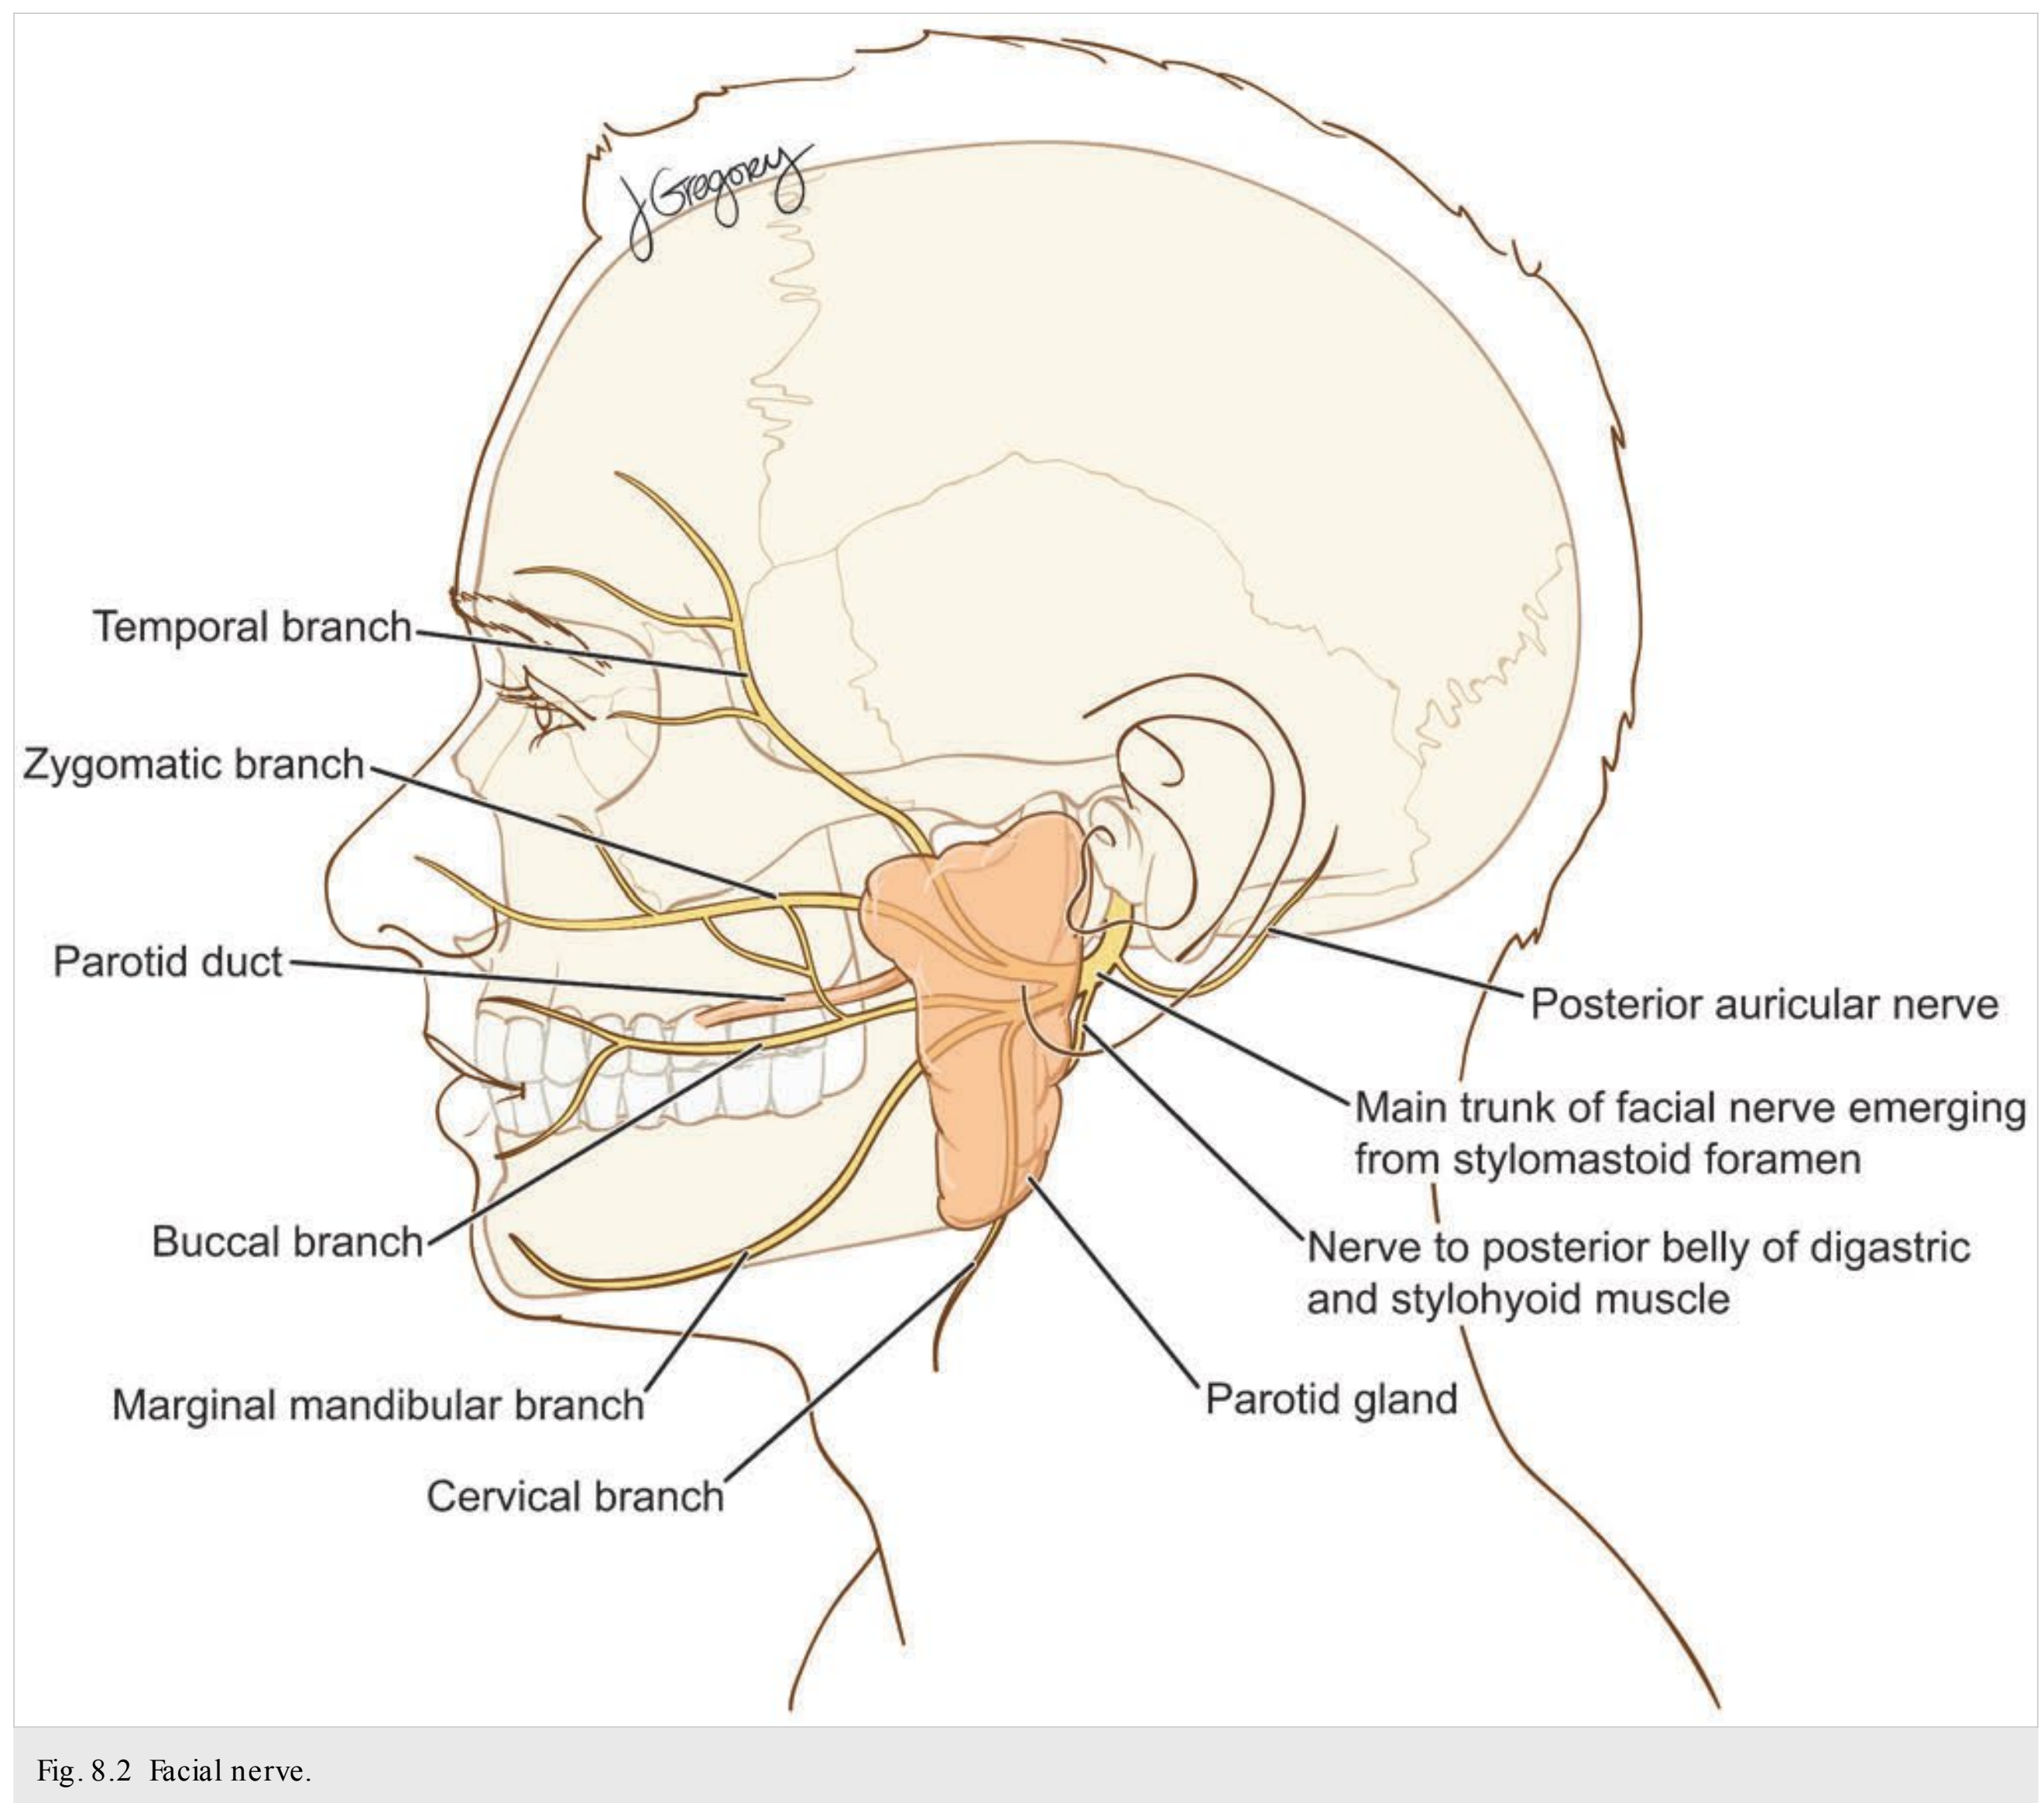

Fig. 8.2 Facial nerve.

the bony and cartilaginous nasal septum. The lateral wall is most intricate, consisting of three bony projections, each covered in respiratory mucosa. These conchae, also called turbinates, are most important for the structures lateral and inferior to them. The inferior turbinate is a separate bone and plays an important role in the nasal cycle, given the abundance of vascular sinusoids within its substance. The nasolacrimal duct opens inferolateral to the inferior turbinate in the inferior meatus. The middle turbinate is part of the ethmoid bone and is important as a landmark in endoscopic sinus surgery. Lateral to the middle turbinate, the bulla ethmoidalis is found bulging from the lateral wall. Inferior to this bulge rests an opening known as the hiatus semilunaris, which leads laterally into the ethmoid infundibulum. The frontal, maxillary, and anterior ethmoid sinus air cells also empty into this space. The superior turbinate contains both respiratory epithelium and olfactory mucosa along its upper surface. Posterosuperior to the superior concha lies the sphenothmoidal recess, into which drain the sphenoid and posterior ethmoid cells.

8.2.2 Paranasal Sinuses

The paranasal sinuses are air-filled continuations of the nasal cavity and are typically named for the bone within which they exist. They are lined by ciliated respiratory epithelium, which allows them to pass secretions into a designated ostium for entrance into the nasal cavity. The frontal sinus lies between the anterior and posterior tables of the frontal bone and is not present at birth; it is usually detectable only after the age of 6 years. Each frontal sinus drains into a frontonasal duct that empties into the ethmoid infundibulum. The ethmoid sinus is actually made up of several smaller cells that pneumatize the ethmoid bone between the nasal cavity and orbit. The lateral wall of the ethmoid cells is an extremely thin bone known as the lamina papyracea. The ethmoid sinus is divided into anterior and posterior ethmoid air cells by the posterior bony attachment of the middle turbinate to the medial orbit, known as the basal lamella. The sphenoid sinuses are located in the body of the sphenoid bone and can be divided unevenly by a bony

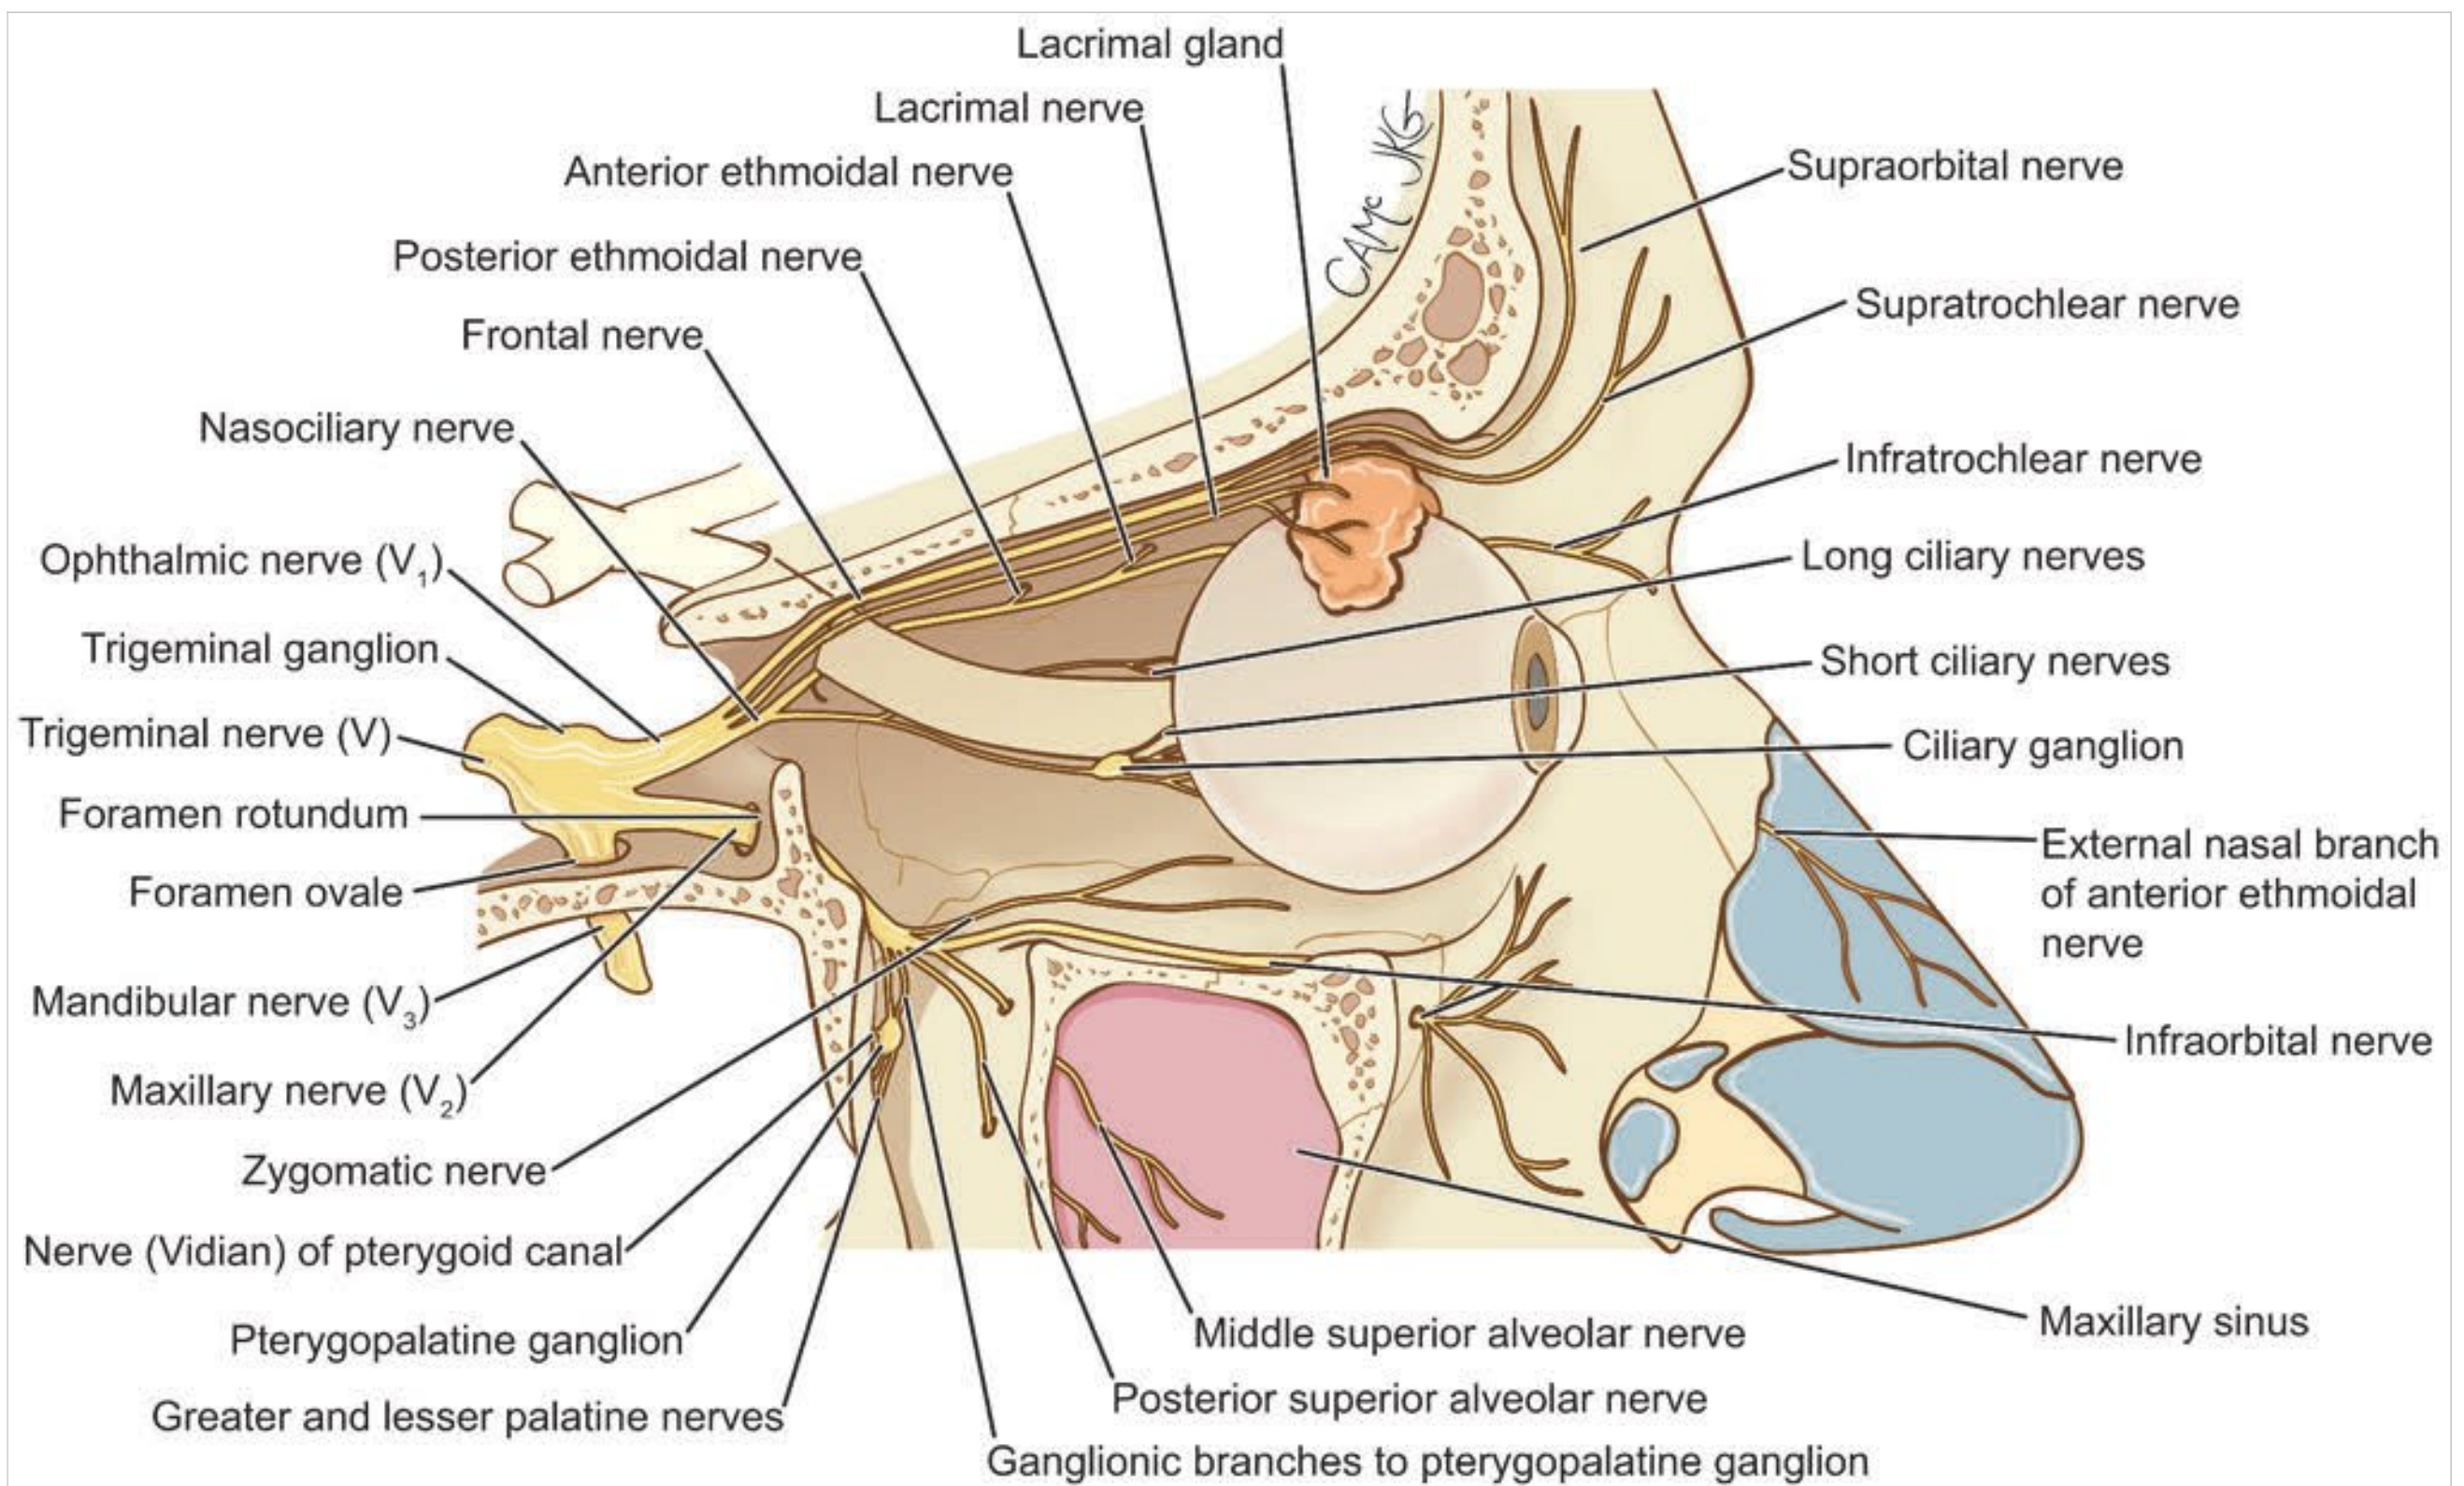

Fig. 8.3 Trigeminal nerve: first and second divisions.

Fig. 8.4 Trigeminal nerve: third division.

septum. The sphenoid is bordered posteriorly by the sella turcica and laterally by the cavernous sinus (with associated nerves), optic chiasm, and internal carotid arteries. The maxillary sinuses are the largest sinuses. They are located within the maxilla below the orbit and above the alveolus.

8.2.3 Arteries and Veins of the Nasal Cavity and Paranasal Sinuses

The arterial supply of the nasal cavity comprises four main divisions. First, the sphenopalatine artery (branch of the internal

maxillary artery) enters the nasal cavity on the lateral wall behind the middle turbinate via the sphenopalatine foramen. Once entering the nose, it typically divides into two branches supplying the posterior and lateral portions of the nasal cavity along with the septum. The anterior and posterior ethmoidal arteries are branches of the ophthalmic artery from the internal carotid system. They supply the superior and lateral nasal wall along with the superior concha and septum. The greater palatine artery is a branch of the internal maxillary artery that supplies the floor of the maxillary sinus. The superior labial branch of the facial artery supplies the anterior nasal cavity, including both lateral wall and septum. Anteriorly along the septum, the vessels anastomose to form the Kiesselbach plexus, the most common site for anterior epistaxis.

The venous drainage of the nose is through a rich plexus deep to the nasal mucosa that ultimately drains into the sphenopalatine, facial, and ophthalmic veins. These vessels are important for both thermoregulation and humidification.

8.2.4 Sensory Innervation

The anterosuperior part of the nasal cavity is innervated by the anterior and posterior ethmoidal branches of the nasociliary nerve (V_1). The posteroinferior and lateral part is innervated by the maxillary nerve (V_2). The septum is also innervated by the maxillary nerve (V_2) via the nasopalatine branch. The frontal sinuses are innervated by branches of the supraorbital nerve (V_1). The ethmoid and sphenoid sinuses are innervated by anterior and posterior ethmoidal branches of the nasociliary nerve (V_1). The maxillary sinuses are innervated by the anterior, middle, and posterior superior alveolar nerves, which are branches of the maxillary nerve (V_2).

8.3 Salivary Glands

8.3.1 Parotid Gland

The parotid gland lies between the ramus of the mandible and the temporal bone landmarks of the external auditory canal and mastoid tip. Anteriorly, it is found superficial to the masseter muscle, and posteriorly, it rests over the sternocleidomastoid muscle. Medially, the parotid gland can extend as deep as the pharyngeal wall. It is incompletely surrounded by parotid gland fascia, a continuation of the superficial or investing layer of deep cervical fascia. The parotid duct, or Stenson duct, passes over the masseter muscle, runs in close proximity to the buccal branch of the facial nerve, pierces the buccinator muscle, and empties into the oral cavity opposite the second maxillary molar. Within the parotid gland are several important structures. The facial nerve divides the parotid into superficial and deep lobes. The external carotid artery divides into its terminal branches—the superficial temporal and internal maxillary arteries—within the parotid gland. The retromandibular vein is formed from the union of the superficial temporal and maxillary veins within the gland. It travels deep to the facial nerve before dividing into anterior and posterior branches.

8.3.2 Submandibular Gland

The submandibular gland lies within the submandibular triangle of the neck, below the mylohyoid muscle and superior to the anterior and posterior digastric muscle. It is covered by the investing layer of deep cervical fascia, which also contains the marginal mandibular branch of the facial nerve. The submandibular duct, or Wharton duct, which arises from the portion of the gland that lies between the mylohyoid and hyoglossus muscles, travels anteriorly to open lateral to the frenulum in the anterior portion of the floor of the mouth behind the incisors. As it travels in a lateral to medial direction, the lingual nerve is found to loop under the duct. The arterial supply for the gland is the submental artery.

8.3.3 Sublingual and Minor Salivary Glands

The sublingual glands are located within the submucosal layer of the floor of the mouth between the mandible and the genio-glossus muscle. There are numerous small sublingual ducts that open in the floor of mouth. The arterial supply of the sublingual glands comes from the sublingual and submental arteries. Minor salivary glands lie within the submucosal layer of the oral cavity, oropharynx, nasopharynx, and hypopharynx.

8.3.4 Parasympathetic Innervation

Parotid Gland

The preganglionic fibers begin in the medulla at the inferior salivatory nucleus. They travel along the glossopharyngeal nerve into the tympanic plexus (Jacobson nerve), then course through the lesser superficial petrosal nerve through the foramen ovale to synapse on the otic ganglion. From here, postganglionic parasympathetic fibers travel along the auriculotemporal nerve (branch of V_3) to reach the parotid gland.

Submandibular and Sublingual Glands

The preganglionic fibers begin in the pons at the superior salivatory nucleus. They travel along the facial nerve, then course with the chorda tympani nerve to join the lingual nerve. The fibers synapse on the submandibular ganglion, located near the submandibular gland. From here, postganglionic parasympathetic fibers travel to the submandibular gland directly and to the sublingual gland via branches of the lingual nerve.

8.4 Thyroid Gland

The thyroid gland is located deep to the sternohyoid and sternothyroid, anterior and lateral to the trachea, approximately midway between the sternal notch and thyroid cartilage. It consists of two lobes, which meet over the trachea to form an isthmus, usually over the second and third tracheal rings. The thyroid is surrounded by its own fibrous capsule, which is just deep to the visceral layer of the pretracheal layer of the deep cervical fascia. In approximately half of individuals, a small

amount of thyroid tissue, known as a pyramidal lobe, extends superiorly from the isthmus or either lobe. The thyroid gland is supplied by the superior and inferior thyroid arteries, and occasionally by a thyroid ima artery. Venous drainage is typically from the superior, middle, and inferior thyroid veins. The important structures that lie immediately around the thyroid gland include the four parathyroid glands; these lie deep to the thyroid lobes and the paired recurrent laryngeal nerves, which course in the tracheoesophageal groove to reach the larynx (□ Fig. 8.5).

8.5 Parathyroid Glands

The parathyroid glands usually lie external to the thyroid capsule on the medial half of the posterior surface of the each thyroid lobe. The superior parathyroid glands, which have a more reliable position, can usually be found at the level of the inferior border of the cricoid cartilage, approximately 1 cm superior to the entrance of the inferior thyroid artery into the thyroid gland. The inferior parathyroid glands, which are more unpredictable, are usually near the inferior pole of the thyroid lobe, approximately 1 cm inferior to the entrance of the inferior thyroid artery into the thyroid gland. Most people have four parathyroid glands; however, approximately 5% have more than four glands. In addition, the position of each parathyroid gland can be quite variable. The superior parathyroid glands arise from the fourth branchial pouch and descend with the thyroid gland, so they may be directly embedded within the thyroid gland. They can also be located in a retroesophageal, retropharyngeal, or retrolaryngeal position. The inferior parathyroid glands arise from the third branchial pouch with the thymus, so they can be located in the anterior mediastinum or within the thyroid. The parathyroid glands are supplied primarily by the inferior thyroid artery. The venous drainage is through the parathyroid veins, which empty into the thyroid venous plexus.

8.6 Oral Cavity

The oral cavity begins anteriorly at the lips and extends posterosuperiorly to the junction of the hard palate and soft palate, and posteroinferiorly to the circumvallate papillae of the tongue. The mylohyoid muscle forms the floor, and the buccinator muscles border the oral cavity laterally. The oral cavity can be broken down into several subsites, which include the lips, buccal mucosa, alveolar ridge, retromolar trigone, hard palate, oral tongue, and floor of the mouth.

8.6.1 Oral Tongue

The anterior two-thirds of the tongue develop separately from the posterior one-third. Whereas the anterior two-thirds are covered with foliate, filiform, and fungiform papillae, the posterior one-third is mostly lymphoid tissue.

Muscles of the Oral Tongue

The tongue itself is actually a mass of muscles covered by mucous membrane. The muscles of the tongue do not act in

isolation; rather, a collaboration of many muscles gives the tongue its unique versatility. The musculature can be divided into intrinsic and extrinsic muscles. In general, the extrinsic muscles, such as the genioglossus, hyoglossus, styloglossus, and palatoglossus muscles, alter the position of the tongue. The intrinsic muscles, including the superior and inferior longitudinal, transverse, and vertical muscles, alter the shape of the tongue. The genioglossus contributes most of the bulk of the tongue and is responsible for protrusion, depression, and deviation of the tongue. The hyoglossus, acting with its attachment to the hyoid bone, is responsible for depression and retraction. The styloglossus, acting with its attachment to the styloid process, retracts and elevates the tongue. In conjunction with the genioglossus muscle, the styloglossus allows curling of the tongue sides to create a trough during swallowing. The palatoglossus arises from the palatine aponeurosis and acts more to depress the palate than to elevate the posterior tongue during swallowing.

Vasculature of the Oral Tongue

The arterial supply to the oral tongue comes mainly via branches of the lingual artery from the external carotid artery. The main branches include the dorsal lingual, deep lingual, and sublingual arteries. The lingual artery is unique in that it courses medial to the hyoglossus muscle rather than lateral like most of the other vessels and nerves. The venous drainage is mainly through the dorsal and deep lingual veins.

Innervation of the Tongue

Sensory innervation of the tongue is divided into general sensation and special sensation or taste. General sensation of the anterior two-thirds of the tongue is provided by the lingual nerve, a branch of the mandibular nerve (V_3). The posterior one-third and circumvallate papillae are supplied by the lingual branch of the glossopharyngeal nerve. For special sensation (taste), the anterior two-thirds is supplied by the chorda tympani nerve, a branch of the facial nerve. The posterior one-third of taste sensation is supplied by the glossopharyngeal nerve. All the muscles of the tongue except the palatoglossus muscle derive their motor innervation via the hypoglossal nerve or cranial nerve XII.

8.6.2 Floor of the Mouth

The floor of mouth is formed primarily from the mylohyoid and geniohyoid muscles. The mylohyoid extends from the anterior portion of the hyoid bone to the inner surface of the mandible. Its contraction elevates the hyoid bone, floor of the mouth, and tongue during swallowing and speaking. The sublingual gland and a portion of the submandibular gland lie above the mylohyoid muscle. The lingual nerve enters the oral cavity medial to the third mandibular molar. It initially lies superior and lateral to the submandibular duct but subsequently dives inferior then medial to the duct. The hypoglossal nerve enters the oral cavity lateral to the hyoglossus muscle then superior to the mylohyoid muscle below the submandibular duct.

Fig. 8.5 Posterior aspect of the visceral compartment of the neck.

Table 8.1 Structures that pass into the pharynx between the pharyngeal constrictors

Gaps between pharyngeal constrictors	Structures that pass to the pharynx
Skull base to superior constrictor	Levator palatini muscle, eustachian tube, ascending pharyngeal artery
Superior to middle constrictor	Stylopharyngeus muscle, stylohyoid ligament, glossopharyngeal nerve
Middle to inferior constrictor	Superior laryngeal branch of superior thyroid artery, internal branch of superior laryngeal nerve
Below inferior constrictor	Inferior laryngeal branch of inferior thyroid artery, recurrent laryngeal nerve

Innervation of Floor of the Mouth and Rest of Oral Cavity

The lingual nerve (V_3) supplies sensation to the floor of mouth, lingual aspect of the lower alveolar ridge, and mucosa of the lip. The buccal nerve (V_3) supplies sensation to the buccal mucosa and buccal margin of the upper and lower alveolar ridges. The infraorbital nerve (V_2) carries sensation for the upper lip mucosa and the most anterior part of the upper oral cavity. The mental nerve (V_3) supplies the mucosa of the lower lip and the most anterior portions of the lower oral cavity. Motor innervation to the floor of the mouth muscles (mylohyoid and anterior belly of the digastric) is by the mandibular nerve (V_3). The geniohyoid is innervated by the cervical roots from C1 carried by the hypoglossal nerve.

8.7 Pharynx

The pharynx lies posterior to and communicates with the nasal cavity, oral cavity, and larynx. It extends from the skull base to the inferior border of the cricoid cartilage anteriorly and the inferior border of the C6 vertebra posteriorly. Posteriorly, the pharynx is bordered by the buccopharyngeal fascia and retropharyngeal space. This fascia and space allow the pharynx to move along the vertebral column. The buccopharyngeal fascia is continuous with the pretracheal layer of deep cervical fascia inferiorly. The pharynx is made up of mucosa (either ciliated columnar or stratified squamous) and pharyngeal muscles.

8.7.1 Muscles of the Pharynx

The muscles of the pharynx consist of an inner longitudinal layer and an outer circular layer. The inner muscular layer mainly consists of the palatopharyngeus, stylopharyngeus, and salpingopharyngeus muscles. These muscles are responsible for elevation of the larynx and shortening of the pharynx during swallowing and speaking. The outer circular layer consists of the three pharyngeal constrictor muscles: superior, middle, and inferior. The muscles are bordered internally by the strong pharyngobasilar fascia and externally by the thin buccopharyngeal fascia. The pharyngeal constrictor muscles contract involuntarily and in a sequential fashion to propel food into the esophagus. The superior constrictor originates from the pterygoid hamulus and pterygomandibular raphe. The middle constrictor originates from the stylohyoid ligament and hyoid bone. The inferior constrictor originates from the thyroid and cricoid cartilages. Posteriorly, the pharyngeal muscles insert into the median raphe of the pharynx. The muscles overlap so that the inferior fibers of one muscle are inside the superior fibers of the next (□ Fig. 8.5). This allows food to be propelled more

efficiently. The structures that must pass between the pharyngeal constrictors to reach the pharynx are detailed in □ Table 8.1 and □ Fig. 8.6.

8.7.2 Innervation of the Pharynx

The nerve supply to the pharynx, motor and most sensory, derives from the pharyngeal plexus. The pharyngeal plexus is made up of branches of the glossopharyngeal nerve (IX), vagus nerve (X), maxillary nerve (V_2), and postganglionic sympathetic fibers from the sympathetic trunk. Motor fibers from the cranial root of the accessory nerve are carried by the vagus nerve via pharyngeal branches to supply all the pharyngeal muscles except the stylopharyngeus (IX) and tensor veli palatini (V_3). Sensory innervation of the upper part of the nasopharynx is derived from the maxillary nerve (V_2). Sensory innervation of the rest of the nasopharynx, oropharynx, and hypopharynx is derived from the glossopharyngeal nerve. The piriform sinus sensory innervation is primarily from the vagus nerve through the internal branch of the superior laryngeal nerve.

8.7.3 Nasopharynx

The nasopharynx is the posterior extension of the nasal cavities through the choanae to the level of the soft palate. The roof and posterior wall of the nasopharynx lie inferior to the body of the sphenoid bone. The lateral wall of the nasopharynx is marked by the torus tubarius, a bulge created by the cartilage of the eustachian tube. Extending inferiorly from the medial end of the eustachian tube is a vertical fold of mucous membrane known as the salpingopharyngeal fold. Posterior to the torus tubarius and the salpingopharyngeal fold is a slitlike lateral projection known as the pharyngeal recess or fossa of Rosenmüller. Posteriorly and superiorly lie the adenoids, part of the Waldeyer ring.

8.7.4 Oropharynx

The oropharynx is bounded by the soft palate superiorly and the superior border of the epiglottis inferiorly. Anteriorly, the oropharynx extends to the sulcus terminalis and includes the posterior one-third of the tongue. The posterior one-third of the tongue is continuous with the epiglottis via the vallecula formed by the three glossoepiglottic folds. The lateral walls of the oropharynx are marked by the palatine tonsils, which reside between the tonsillar pillars, palatoglossus, and palatopharyngeus muscles. The blood supply to the tonsil is via branches of the lingual, facial, ascending pharyngeal, and internal maxillary arteries. The soft palate is composed of muscle that allows depression, elevation, and contraction during swallowing and phonation. The

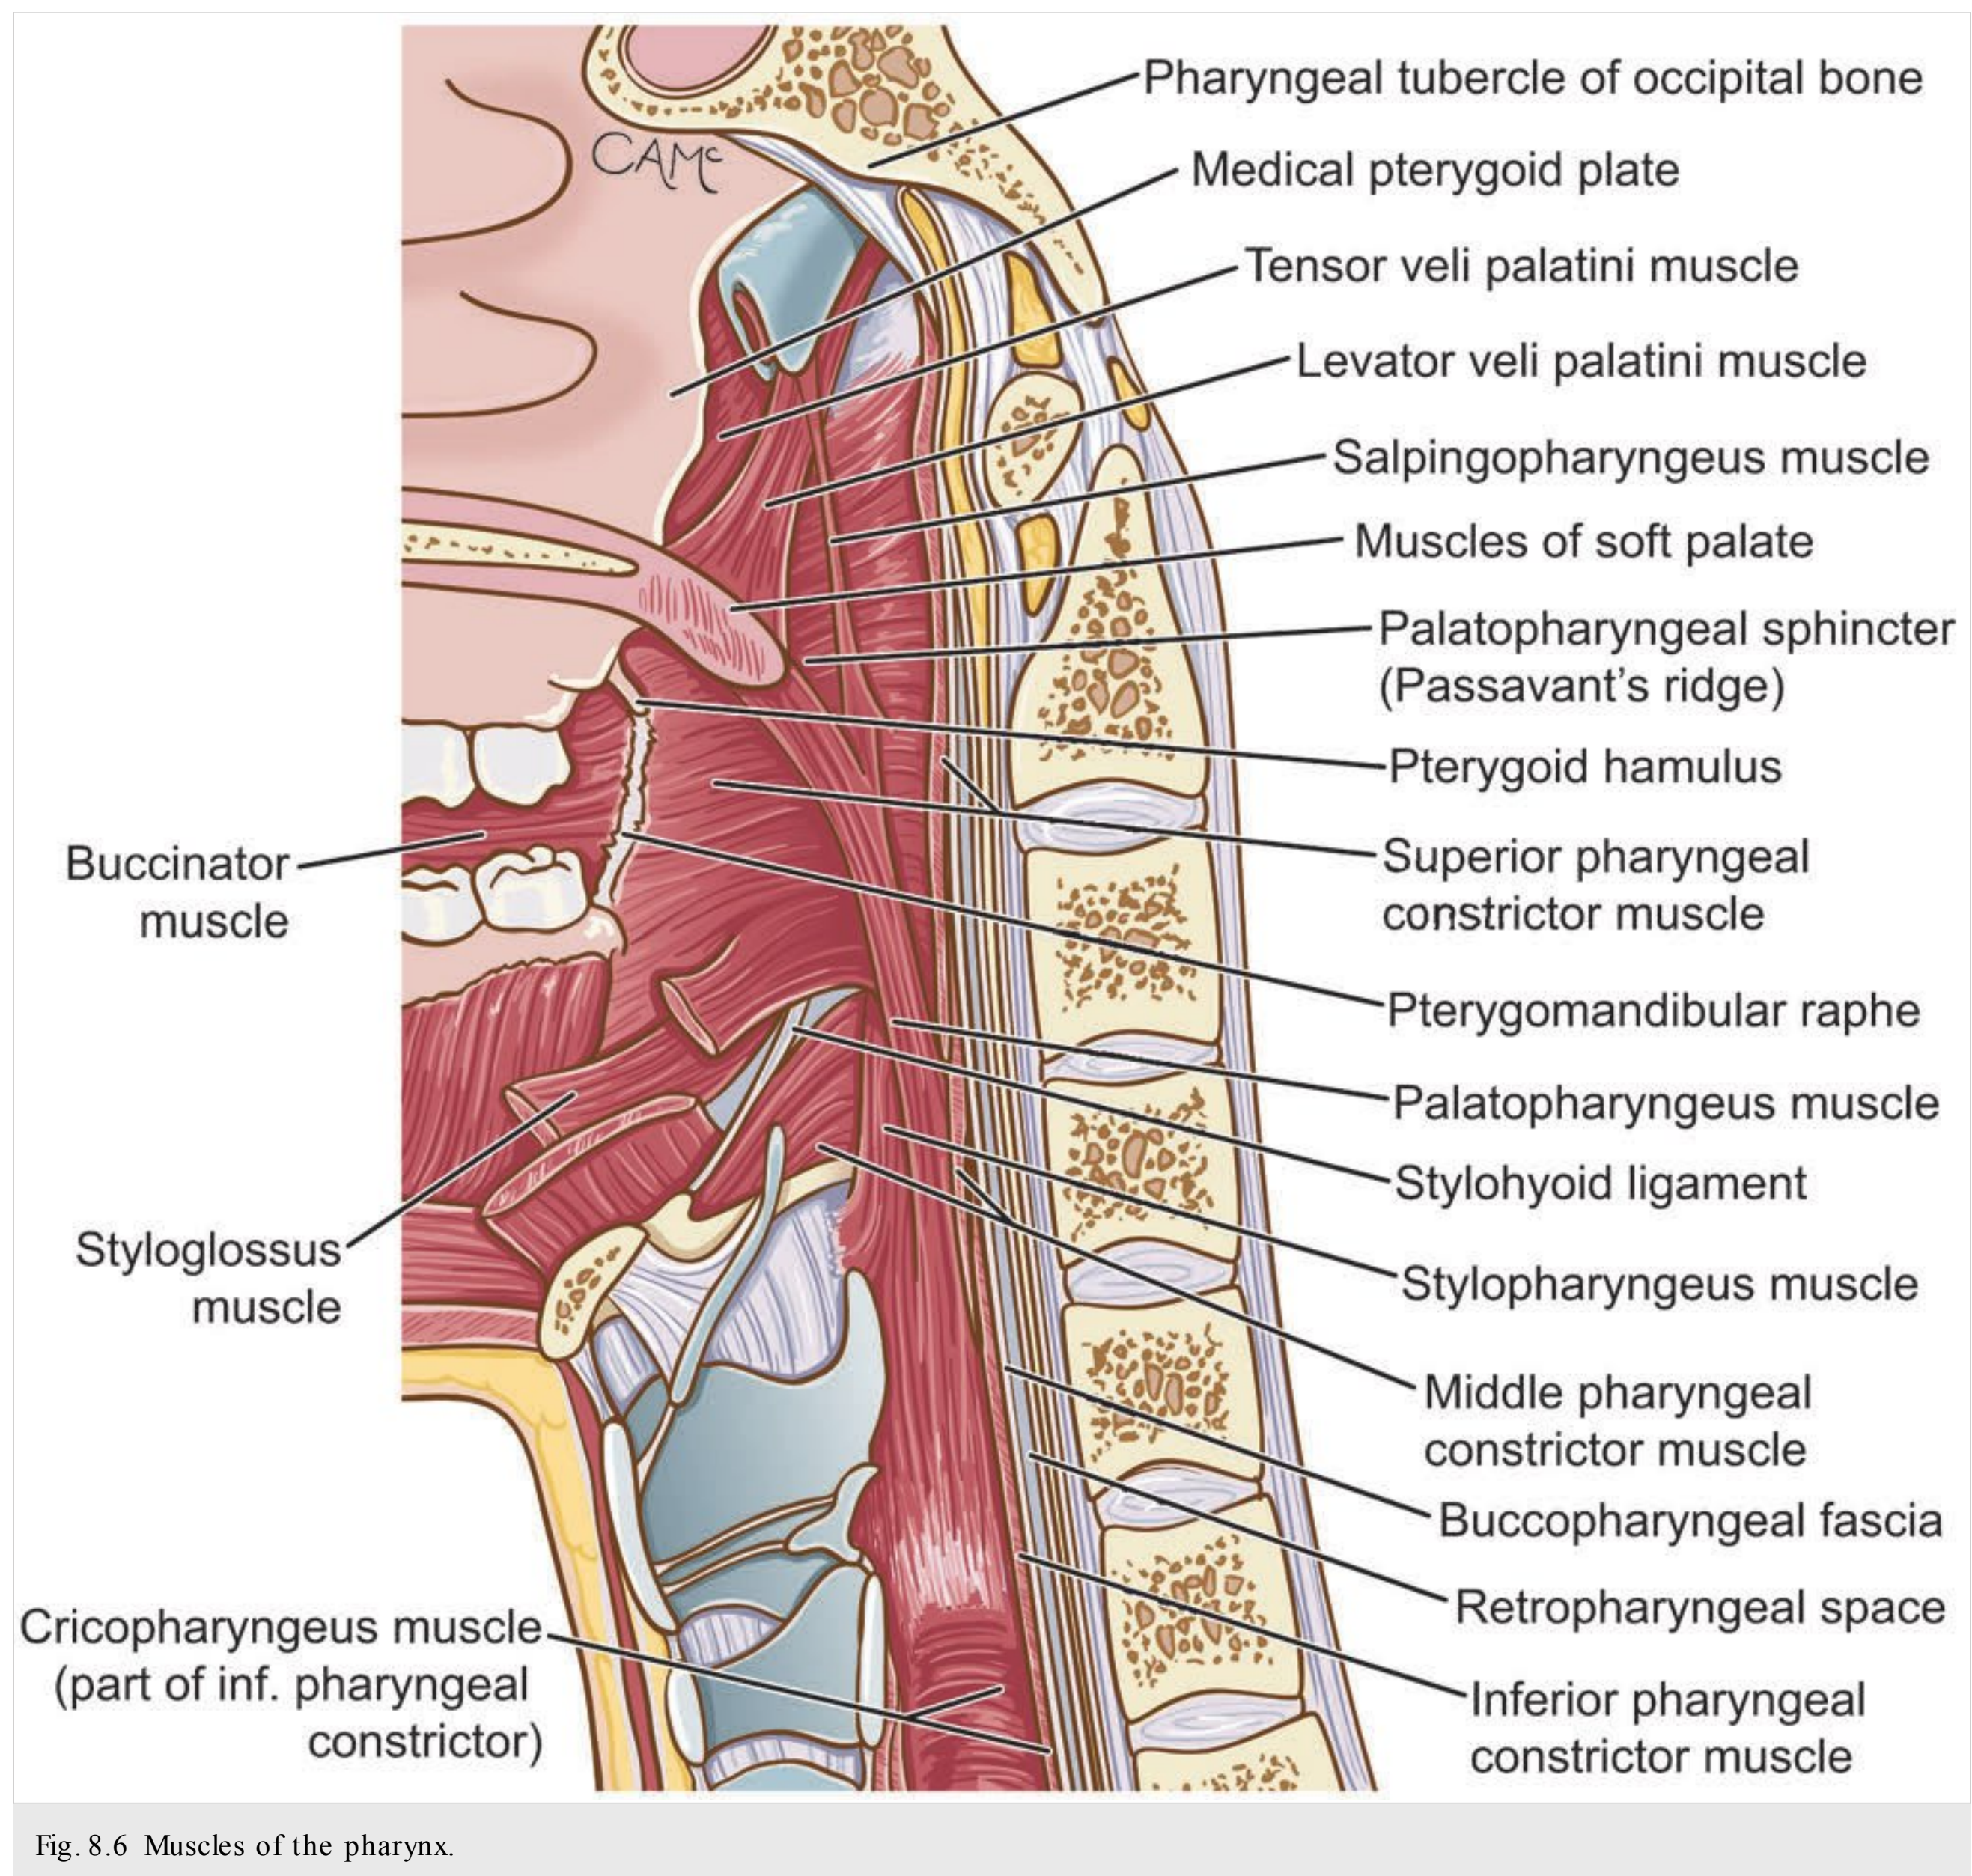

Fig. 8.6 Muscles of the pharynx.

tensor veli palatini arises from the scaphoid fossa of the medial pterygoid plate and descends in the nasopharynx and nasal cavity to attach to the palatine aponeurosis. It is responsible for tensing the soft palate and opening the eustachian tube. The levator veli palatini muscle arises from the petrous portion of the temporal bone and passes between the superior and middle constrictors to attach to the palatine aponeurosis. It functions to elevate the soft palate during swallowing. The palatoglossus muscle arises from the palatine aponeurosis and extends inferiorly to attach to the side of the tongue. It is responsible for elevating the posterior part of the tongue and depressing the soft palate. The palatopharyngeus muscle arises from the palatine aponeurosis and hard palate and attaches to the longitudinal layer of lateral pharyngeal wall. It functions to tense the soft palate and pulls the pharyngeal wall superiorly, anteriorly, and medially during swallowing. The musculus uvulae arises from the posterior nasal

spine and palatine aponeurosis. It functions to shorten and elevate the uvula. The blood supply to the soft palate is mainly from the ascending palatine branches of the facial artery and palatine branches of the internal maxillary artery.

8.7.5 Hypopharynx

The hypopharynx is a continuation of the oropharynx and lies posterior and lateral to the larynx. It extends from the superior border of the epiglottis and pharyngoepiglottic folds to the inferior border of the cricoid cartilage. Its posterior and lateral walls are formed by the middle and inferior pharyngeal constrictors. The piriform sinus is a small pyramid-shaped depression on either side of the larynx, separated by the aryepiglottic folds. Laterally, the piriform sinus is bordered by the medial surface of the thyroid cartilage and thyrohyoid membrane.

Table 8.2 Intrinsic laryngeal muscles

Muscle	Attachments	Functions
Posterior cricoarytenoid muscle	Muscular process of the arytenoid, posterior surface of cricoid lamina	Sole vocal fold abductor
Lateral cricoarytenoid muscle	Muscular process of the arytenoid, cricoid arch (anterior)	Adducts vocal folds
Thyroarytenoid muscle	Muscular process of the arytenoid, posterior surface of thyroid cartilage	Decreases length and tension of vocal folds
Vocalis muscle (part of thyroarytenoid)	Vocal process of the arytenoids, vocal ligaments	Fine control of vocal fold tension
Interarytenoid muscle	Between the bodies of the two arytenoids	Adducts vocal folds
Cricothyroid muscle	Inferior margin and inferior horn of thyroid cartilage, anterior part of cricoid cartilage	Stretches and tenses vocal folds

8.8 Larynx

The larynx lies in the anterior neck at the level of the bodies of the C3 to C6 vertebrae. It extends internally from the superior border of the epiglottis to the inferior border of the cricoid cartilage. It is continuous with the trachea below the cricoid cartilage and with the hypopharynx through the laryngeal inlet. The supraglottis extends from the epiglottis to the apex of the laryngeal ventricle between the two infoldings of mucous membrane, the false (vestibular) and true vocal folds. The glottis extends from the apex of the laryngeal ventricle to 1 cm inferiorly. The space between the true vocal folds is known as the rima glottidis. Each wedge-shaped vocal fold is made up of squamous epithelium, superficial lamina propria, vocal ligament, and vocalis muscle. The subglottis begins 1 cm below the laryngeal ventricle and extends to the inferior border of the cricoid cartilage. Phonation and airway protection are mediated through a variety of muscles tethered to laryngeal cartilages.

8.8.1 Laryngeal Cartilages

The laryngeal skeleton consists of nine cartilages joined by ligaments and membranes. The thyroid, cricoid and epiglottic cartilages are singular while the arytenoid, corniculate, and cuneiform cartilages are duplicated bilaterally. The thyroid cartilage is the largest of these and is made up of two laminae that join in the midline to form the laryngeal prominence. The superior border of the thyroid cartilage attaches to the hyoid bone by the thyrohyoid membrane. It attaches inferiorly to the cricoid cartilage by the cricothyroid membrane and cricothyroid joint. The cricoid cartilage is a complete ring of cartilage that lies below the thyroid cartilage. It is made up of a tall posterior lamina and a shorter anterior arch. The arytenoid cartilages are pairs of three-sided pyramids that articulate with the posterior lamina of the cricoid cartilage. Each cartilage has an apex superiorly that articulates with the corniculate and cuneiform cartilages, an anterior vocal process that forms the posterior margin of the vocal fold, and a lateral muscular process where the posterior and lateral cricoarytenoid muscles attach.

8.8.2 Muscles of the Larynx

The muscles of the larynx can be divided into extrinsic and intrinsic muscles. The extrinsic muscles include the suprahyoid

and infrahyoid muscles. The suprahyoid muscles include the mylohyoid, stylohyoid, geniohyoid, and digastric muscles. They act together to elevate the hyoid and larynx during swallowing and phonation. The infrahyoid muscles include the omohyoid, sternohyoid, sternothyroid, and thyrohyoid muscles. They act together to depress the hyoid and larynx. The intrinsic laryngeal musculature is detailed in □ Table 8.2.

8.8.3 Vasculature of the Larynx

The superior thyroid artery with its superior laryngeal branch supplies the superior part of the larynx and cricothyroid muscle. The inferior thyroid artery with its inferior laryngeal branch supplies the inferior part of the larynx. Laryngeal veins accompany the arteries to drain to the internal jugular vein or left brachiocephalic vein (□ Fig. 8.7).

8.8.4 Innervation of the Larynx

Sensory innervation for the larynx above the vocal folds is carried by the internal branch of the superior laryngeal nerve of the vagus nerve. The sensory innervation below the level of the vocal folds is carried by the recurrent laryngeal nerve of the vagus nerve. Motor innervation for all intrinsic laryngeal musculature except the cricothyroid muscle is by the recurrent laryngeal nerve of the vagus nerve. The cricothyroid muscle is innervated by the external branch of the superior laryngeal nerve of the vagus nerve.

8.9 Neck

The neck extends from the inferior border of the mandible and skull base to the clavicles inferiorly. It is divided into anterior and posterior triangles by the sternocleidomastoid muscle and into smaller triangles by the omohyoid and digastric muscles. The anterior triangle is bordered by the anterior border of the sternocleidomastoid muscle laterally, the inferior margin of the mandible superiorly, and the clavicle inferiorly. The posterior triangle is bordered by the posterior margin of the sternocleidomastoid muscle medially, the anterior margin of the trapezius muscle laterally, the skull base superiorly, and the clavicle laterally (middle one-third). The anterior and posterior triangles can be subdivided into smaller triangles (□ Table 8.3).

Fig. 8.7 Anterior aspect of the visceral compartment of the neck.

8.9.1 Fascia of the Neck (□ Fig. 8.8 and □ Fig. 8.9)

Superficial Cervical Fascia

The superficial cervical fascia is a thin layer of connective tissue that separates the dermis from the investing layer of the deep cervical fascia. Within this layer run cutaneous blood vessels and nerves surrounded by subcutaneous fat. Anterolaterally, it envelops the platysma muscle.

Deep Cervical Fascia

The deep cervical fascia consists of three fascial layers: investing, pretracheal, and prevertebral. All three layers come together to form the carotid sheath around the common carotid arteries, internal jugular vein, and vagus nerve.

Investing (Superficial) Layer of Deep Cervical Fascia

The investing fascia lies below the superficial cervical fascia and surrounds the entire neck. It splits to form deep and superficial layers to invest the trapezius, sternocleidomastoid, submandibular glands, and parotid glands. Superiorly, the investing layer attaches to the superior nuchal line, mastoid process, zygomatic arches, mandible, hyoid bone, and spinous processes of the vertebrae. Inferiorly, it attaches to the manubrium of the sternum, the clavicles, and the spines of the scapulae.

Pretracheal Layer of Deep Cervical Fascia

The pretracheal layer is in the anterior part of the neck and is further divided into a visceral layer and a muscular layer. The visceral layer encloses the thyroid gland, trachea, and

Table 8.3 Neck triangles

Triangle	Borders	Contents
Posterior triangle		
Occipital	Trapezius, posterior border of sternocleidomastoid, inferior belly of omohyoid muscle	External jugular vein, posterior branches of cervical plexus, accessory nerve, trunks of brachial plexus, transverse cervical artery, occipital artery, lymph nodes
Supraclavicular	Inferior belly of omohyoid muscle, posterior border of sternocleidomastoid, clavicle	Third part of subclavian artery, suprascapular artery, lymph nodes
Anterior triangle		
Submental	Midline, anterior belly of digastric muscle, hyoid bone	Small veins en route to anterior jugular vein, lymph nodes
Submandibular or digastric	Mandible, anterior and posterior bellies of digastric muscle	Submandibular gland, hypoglossal nerve, mylohyoid nerve, facial artery (deep to submandibular gland) and vein (superficial to submandibular gland)
Carotid	Anterior border of sternocleidomastoid, posterior belly of digastric muscle, superior belly of omohyoid muscle	Carotid sheath (common carotid artery, internal jugular vein, vagus nerve), external carotid artery and branches, hypoglossal nerve, superior ansa cervicalis, accessory nerve, thyroid, larynx, pharynx, lymph nodes
Muscular	Superior belly of omohyoid muscle, anterior border of sternocleidomastoid, midline	Sternohyoid, sternothyroid, thyroid and parathyroid glands

Fig. 8.8 Sagittal view of neck fascial compartments.

Fig. 8.9 Axial view of neck fascial compartments.

esophagus. It is continuous with the buccopharyngeal fascia of the pharynx. The muscular layer encloses the infrahyoid muscles and forms the tendons that divide the anterior and posterior bellies of the digastric and the inferior and superior bellies of the omohyoid.

Prevertebral Layer of Deep Cervical Fascia

The prevertebral layer envelops the vertebral column and paraspinal musculature. It extends from the skull base to the T3 vertebra.

8.9.2 Muscles of the Neck

The superficial muscles of the neck include the platysma, sternocleidomastoid, and trapezius muscles. The platysma lies in the subcutaneous tissue to cover the anterolateral portion of the neck. Its fibers originate from the fascia covering the deltoid and pectoralis major muscles inferiorly. Superiorly, the platysma extends over mandible to blend with the fascial muscles and SMAS while leaving an anterior gap for the larynx. It acts to tense the skin and depress the mandible. The sternocleidomastoid is a straplike muscle that attaches superiorly to the mastoid process of the temporal bone and superior nuchal line. Inferiorly, it divides into two heads—sternal and clavicular (middle third)—which are named for their attachments. Each sternocleidomastoid muscle acts independently to flex and rotate the

head and neck so that the ear approaches the shoulder and the chin faces the opposite side. Acting together, the sternocleidomastoid muscles can flex the head and protrude the chin. The trapezius muscle is large triangular muscle located in the posterolateral aspect of the neck and thorax. Superiorly and medially, the trapezius attaches to the superior nuchal line, ligamentum nuchae, spinous processes of C7 to C12, and lumbar and sacral spinous processes. Inferiorly and laterally, the trapezius attaches to the lateral third of the clavicle, acromion, and spine of the scapula. It acts to elevate (superior fibers), retract (middle fibers), and rotate (inferior fibers) the shoulder via the scapula.

The muscles of the posterior triangle include the splenius capitis, levator scapulae, and scalene muscles. The scalene muscles (anterior, middle, and posterior) attach to the cervical spine and first rib. The roots of the brachial plexus and subclavian artery pass between the anterior and middle scalene muscles. The subclavian vein and phrenic nerve pass anterior to the anterior scalene (□ Fig. 8.10).

8.9.3 Vasculature of the Neck

Arteries

The main arteries of the neck originate at the arch of the aorta. The three main branches are the left common carotid, left subclavian, and brachiocephalic arteries. The brachiocephalic artery gives rise to the right subclavian and common carotid

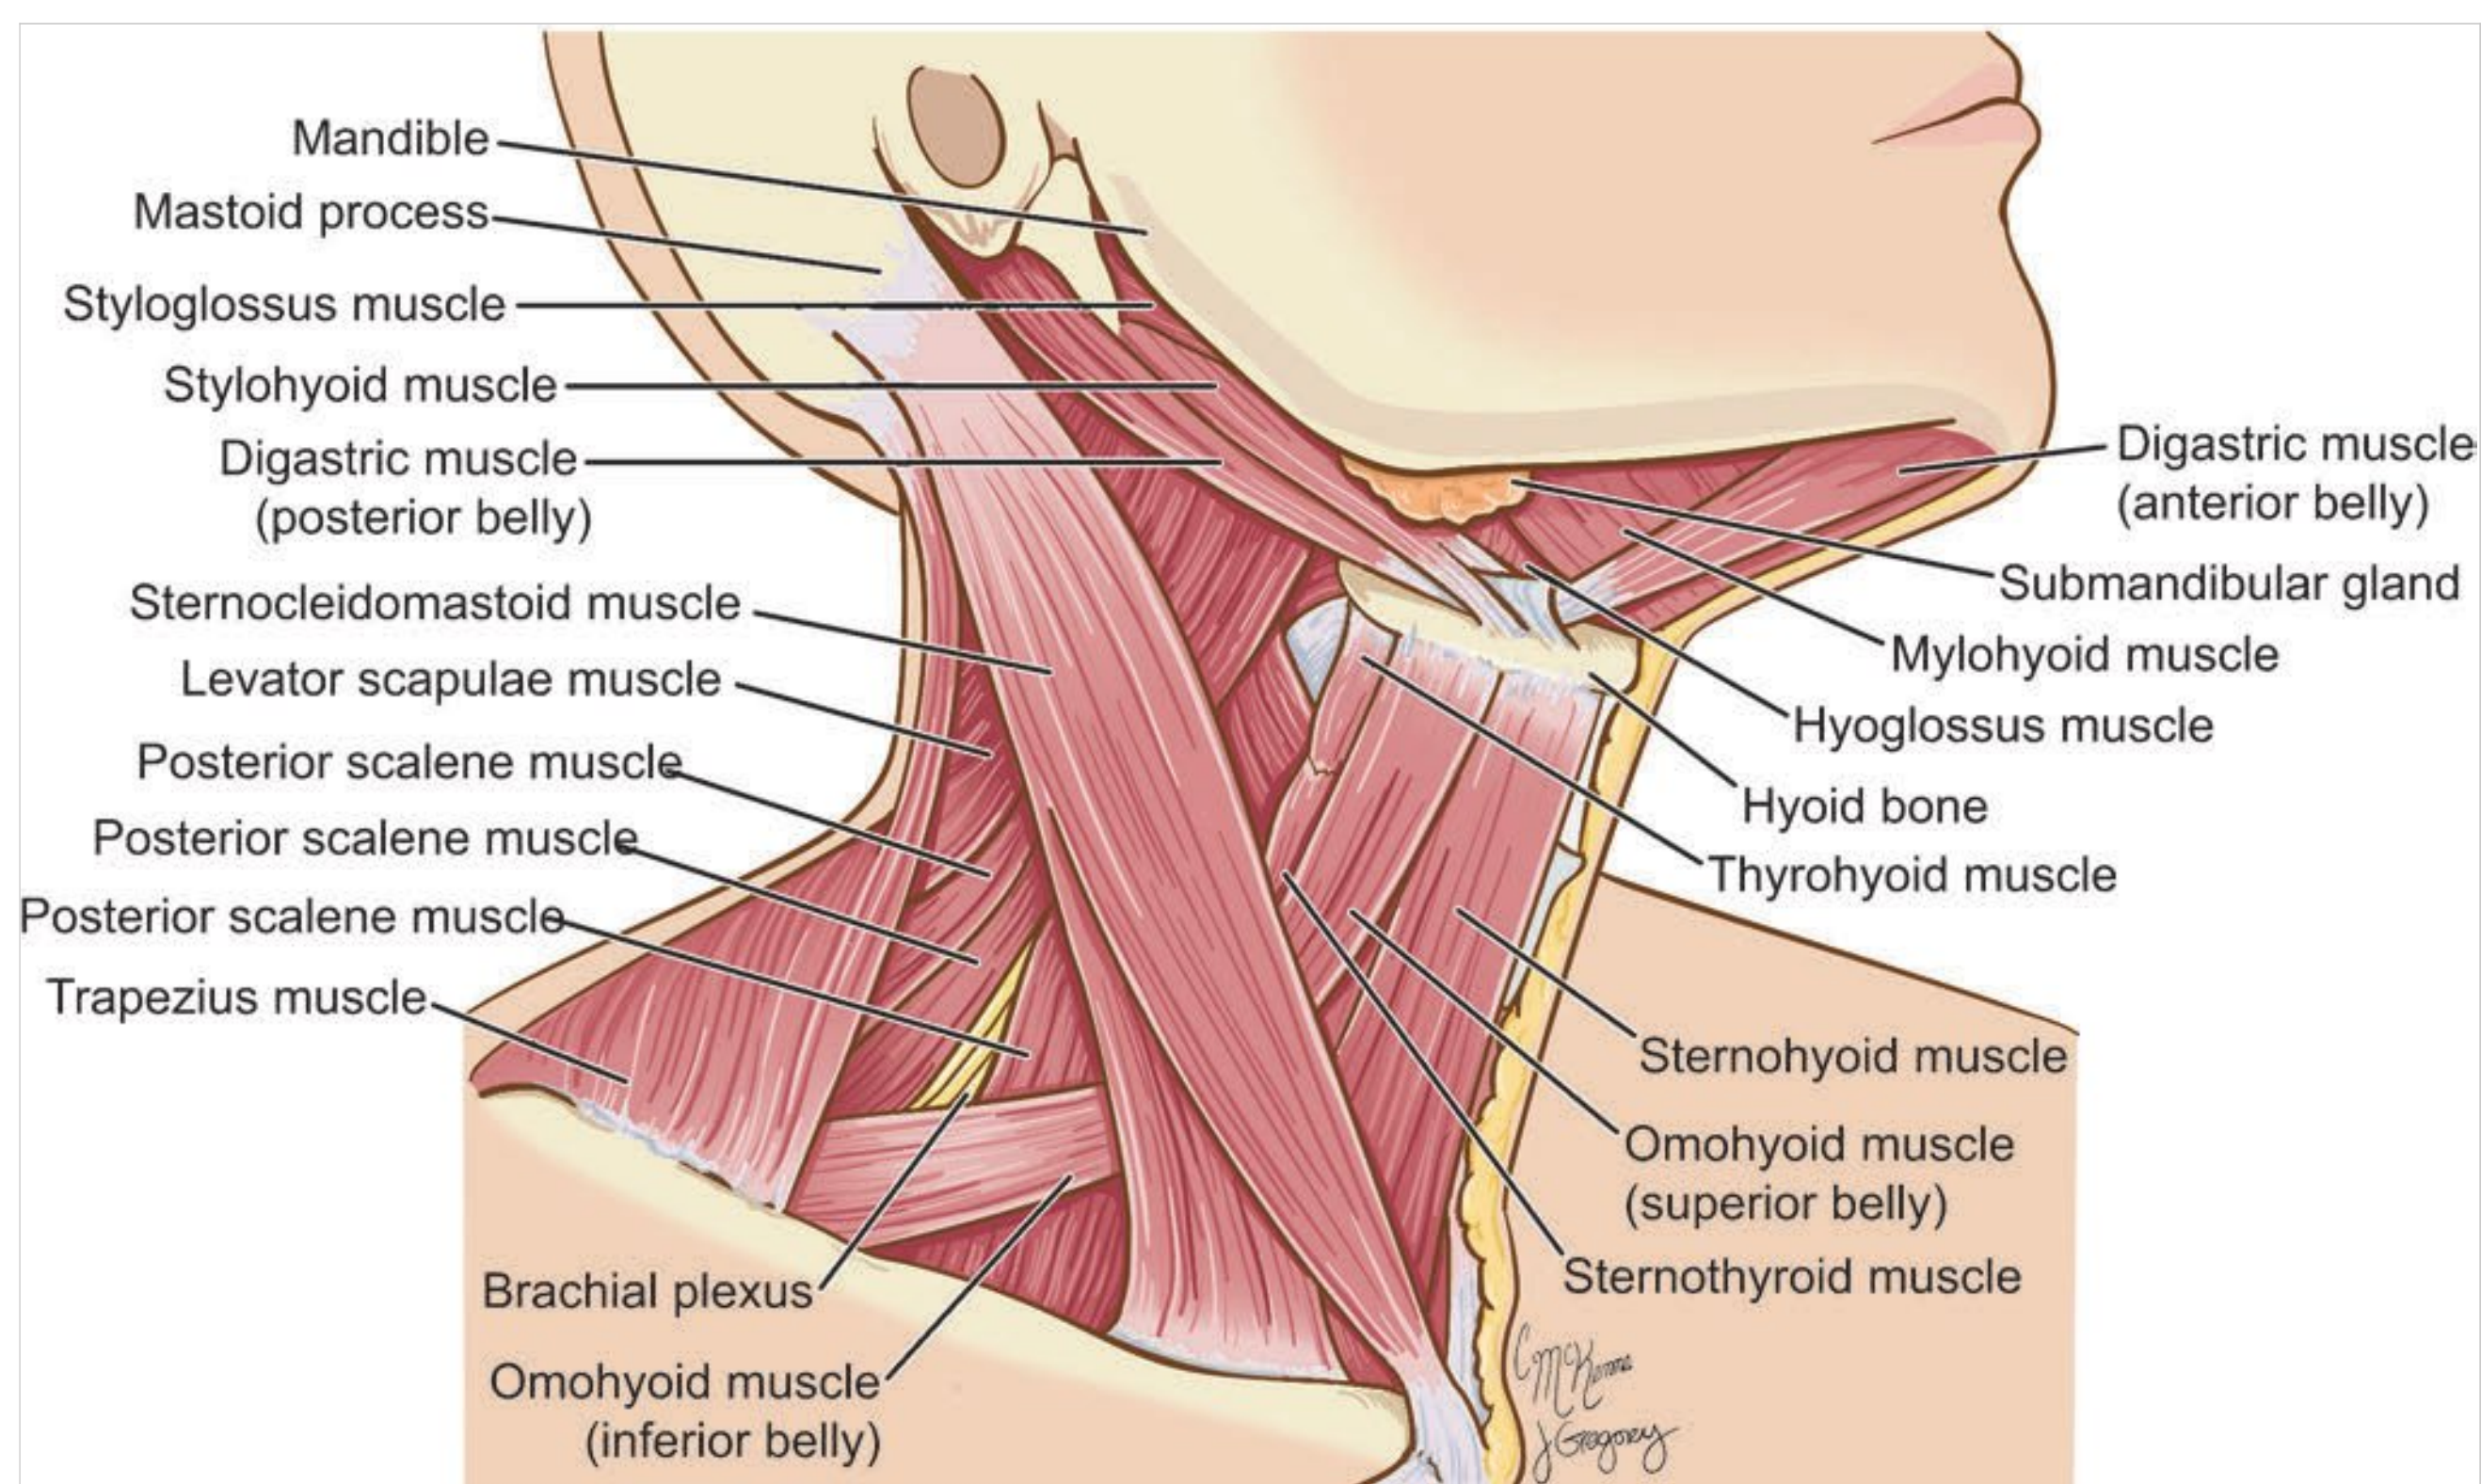

Fig. 8.10 Muscles of the neck.

arteries. The common carotid arteries course superiorly in the neck to approximately the level of the thyroid cartilage before dividing into the internal and external carotids. The internal carotid artery has no branches in the neck. It enters the skull through the carotid canals to supply the brain and orbital structures. A slight dilatation in the proximal portion of the internal carotid artery, the carotid sinus, contains blood pressure sensors. The carotid body, which lies at the bifurcation, has chemoreceptors sensitive to changes in oxygenation. The external carotid artery runs posterosuperiorly in the neck behind the mandible and anterior to the auricle before dividing into its two terminal branches: the maxillary and superficial temporal arteries. The branches of the external carotid artery and their distribution are detailed in □ Table 8.4 and □ Fig. 8.11.

The subclavian arteries supply the limbs, neck, and brain. In the neck, the four main branches include the vertebral artery, internal thoracic artery, thyrocervical trunk, and costocervical trunk. The vertebral artery arises from the first part of the subclavian and ascends along the scalene and longus muscles before entering the foramina of the transverse processes of C1 to C6 to enter the cranium via the foramen magnum. It is the main supply to the posterior part of the brain and brainstem. The internal thoracic artery passes into the thorax to supply the anterior chest wall and abdominal wall. The thyrocervical trunk has three main branches: the inferior thyroid artery (supplies thyroid), transverse cervical artery (supplies trapezius), and suprascapular artery (supplies scapula). The costocervical trunk arises from the posterior aspect of the second part of the

Table 8.4 Branches of the external carotid artery

Branch	Structures supplied
Superior thyroid	Supplies upper thyroid; superior laryngeal branch pierces thyrohyoid membrane to supply superior larynx
Ascending pharyngeal	Supplies pharynx
Lingual	Passes behind posterior edge of hyoglossus to supply tongue and floor of mouth
Facial	Passes deep to submandibular gland over the mandible to supply face
Occipital	Supplies scalp and back of head
Posterior auricular	Passes behind auricle to supply scalp
Superficial temporal	Crosses zygomatic arch, passes anterior to auricle to supply scalp
Internal maxillary	Passes medially into infratemporal fossa with several branches supplying deep face structures

subclavian to supply the first two intercostal spaces and the posterior deep cervical muscles.

Veins

The venous drainage of the neck is similar to the arterial supply in that each artery usually has a corresponding vein. For details, please refer to the section on venous drainage of the face.

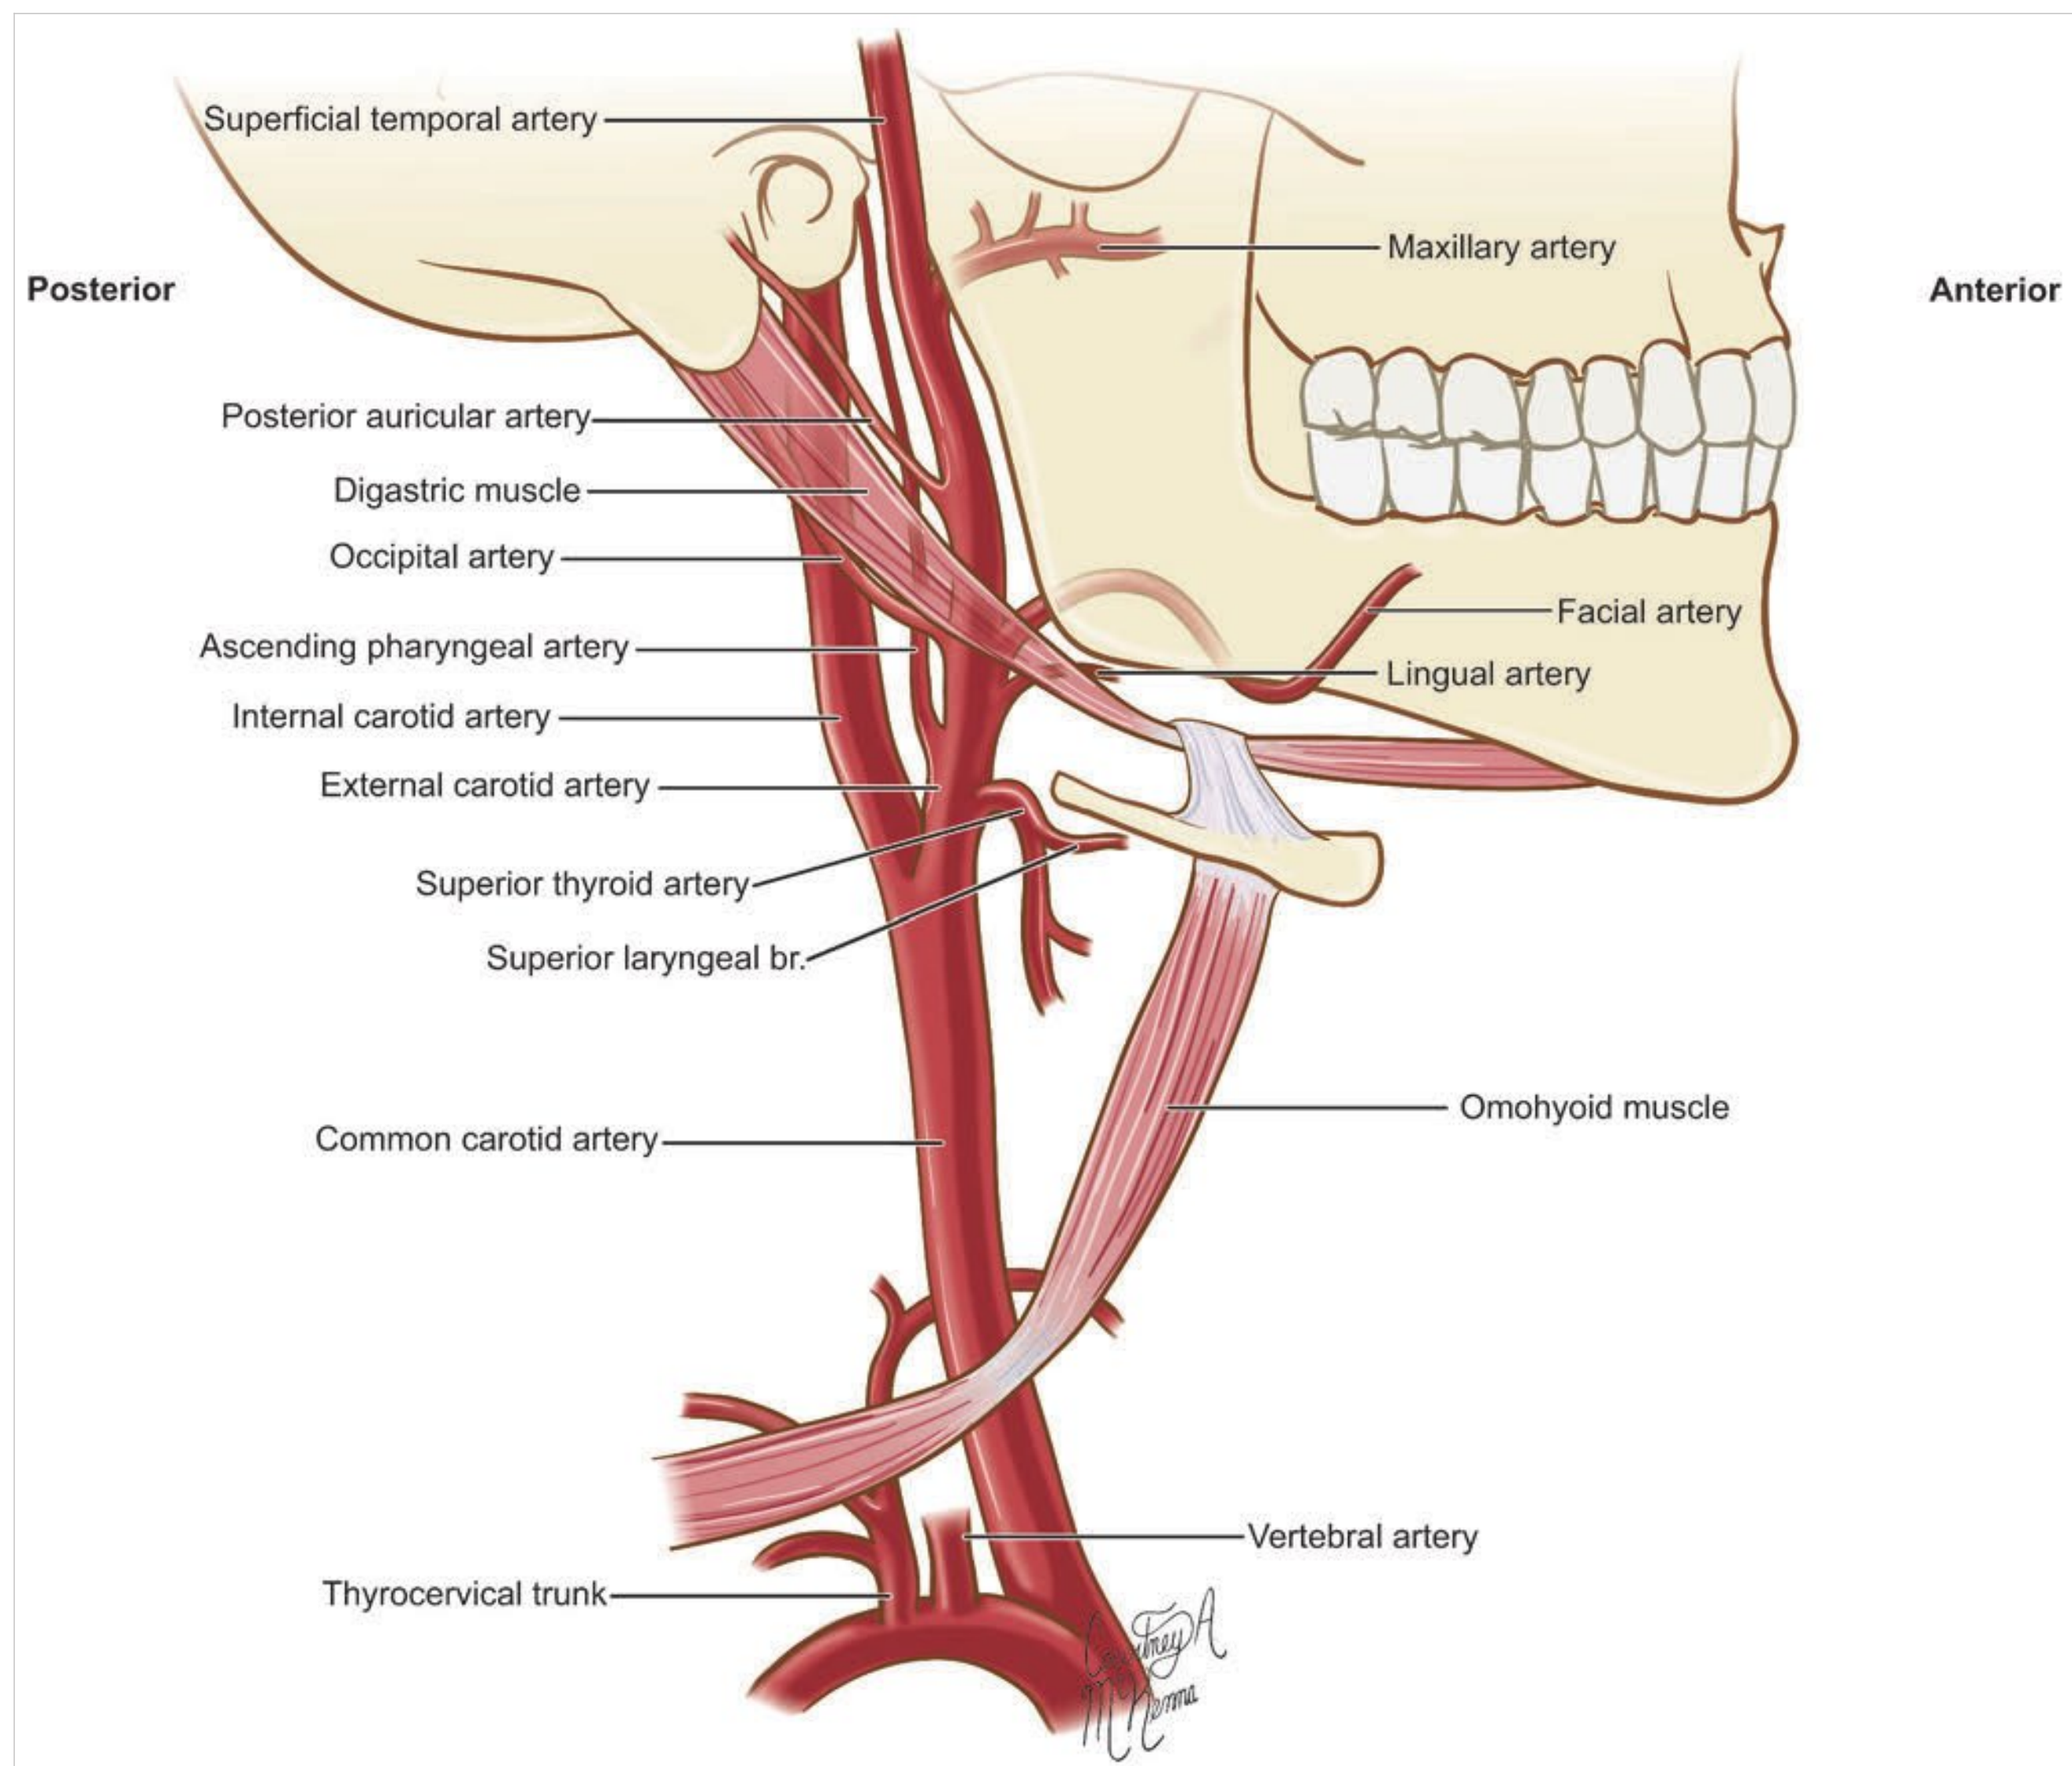

Fig. 8.11 Branches of the external carotid artery.

8.9.4 Innervation of the Neck

(□ Fig. 8.12)

Sensory Innervation

The anterior skin of the neck is supplied by various cutaneous branches originating from the ventral rami of the cervical spinal nerves (C2-C4) that form the cervical plexus. The posterior skin is supplied by cutaneous branches of the dorsal rami (C2-C5). Named branches include the greater auricular nerve, transverse cervical nerve, supraclavicular nerve, and lesser occipital nerve.

Motor Innervation

The sternocleidomastoid muscle and trapezius muscle are supplied by the spinal accessory nerve (XI), whereas the paraspinal muscles are supplied by direct branches of the cervical plexus. The mylohyoid and anterior belly of the digastric are supplied by the mandibular nerve (V₃), whereas the stylohyoid and posterior

belly of the digastric are supplied by the facial nerve. The infrahyoid muscles are supplied by branches of the ansa cervicalis.

Vagus Nerve

The vagus nerve exits from the cranium via the jugular foramen and descends in the neck within the carotid sheath in the posterior angle between the common carotid artery and internal jugular vein. The right vagus nerve then passes anterior to the first part of the subclavian artery and posterior to the brachiocephalic vein to enter the thorax. The left vagus nerve passes between the common carotid and subclavian arteries and posterior to the sternoclavicular joint. The vagus nerve contains both sensory and motor fibers, with several branches to the larynx, pharynx, and heart. In addition, the vagus provides sensory innervation to the external ear and meninges. The branches to the larynx include the superior laryngeal nerve and recurrent laryngeal nerve. The superior laryngeal nerve, after

Fig. 8.12 Innervation of the upper neck and pharynx.

leaving the vagus, divides into an internal and an external branch. The internal branch pierces the thyrohyoid membrane to supply sensation to the larynx above the vocal cords. The external branch passes inferiorly to supply motor innervation to the cricothyroid muscle. The recurrent laryngeal nerve travels in the tracheoesophageal groove on either side of the neck and carries motor and sensory fibers, as described previously. The right recurrent nerve, after branching from the vagus, loops inferior to the right subclavian artery at the T1–T2 level. The left recurrent nerve, after branching from the vagus, loops inferior to the aortic arch at approximately the T4–T5 level.

Phrenic Nerve

The phrenic nerves form superficial to the anterior scalene muscles, mainly from the ventral rami of cervical spinal roots C3 to C5. They descend into the thorax in the prevertebral fascia overlying the scalene muscles between the subclavian arteries and veins. Each provides both sensation and motor innervation to its respective half of the diaphragm.

Sympathetic Trunk

The cervical sympathetic trunk lies medial to the carotid sheath within the prevertebral layer of deep cervical fascia. There are three sympathetic ganglia—superior, middle, and inferior—which receive presynaptic sympathetic fibers from the superior

thoracic spinal nerves and associated white rami communicantes through the sympathetic trunk. The superior sympathetic ganglion lies at the skull base, the middle lies at the level of the cricoid cartilage, and the inferior lies at the level of the first rib. Postsynaptic sympathetic fibers leave the ganglion to pass onto cervical spinal nerves or direct visceral nerves or to run with arteries to their destination. Branches to the head and viscera of the neck run with the vertebral, internal, and external carotid arteries.

8.10 Orbit

The orbit is a pyramid-shaped bony cavity with four walls and an apex. The superior wall is formed by the frontal bone, which separates it from the anterior cranial fossa. Farther posteriorly, near the apex, the superior wall is formed by the lesser wing of the sphenoid bone. The medial wall is formed primarily from the ethmoid bone, along with smaller parts of the frontal, lacrimal, and sphenoid bones. The lateral wall is formed by the frontal process of the zygomatic bone and greater wing of the sphenoid. The inferior wall is formed by the maxilla, zygomatic, and palatine bones. The apex of the orbit lies within the lesser wing of the sphenoid just medial to the superior orbital fissure. The contents of the orbital fissures are detailed in □ Table 8.5. The orbit contains the eyeball (globe), optic nerve, ocular muscles, fascia, nerves, vessels, orbital fat, lacrimal gland (which lies

Table 8.5 Orbital fissures

Orbital fissure	Contents
Superior	Cranial nerves III, IV, V ₁ , and VI; superior ophthalmic vein; superior orbital vein; orbital branch of middle meningeal artery; sympathetic fibers
Inferior	Infraorbital nerve and zygomatic nerves (V ₂), infraorbital artery and vein, parasympathetics to lacrimal gland, inferior ophthalmic vein
Optic canal	Optic nerve, ophthalmic artery, central retinal vein

Table 8.6 Muscles of the orbit

Muscle	Origin and insertion	Innervation	Action
Levator palpebrae superioris	Lesser wing of sphenoid, anterosuperior to optic canal to tarsal plate and skin of upper eyelid	Oculomotor (III) nerve, sympathetic fibers (superior tarsal muscle)	Elevates upper eyelid
Superior rectus	Common tendinous ring to sclera	Oculomotor (III) nerve	Elevates, adducts, and rotates eyeball medially
Inferior rectus	Common tendinous ring to sclera	Oculomotor (III) nerve	Depresses, adducts, and rotates eyeball laterally
Medial rectus	Common tendinous ring to sclera	Oculomotor (III) nerve	Adducts eyeball
Lateral rectus	Common tendinous ring to sclera	Abducens (VI) nerve	Abducts eyeball
Superior oblique	Body of sphenoid to sclera deep to superior rectus after its tendon passes through a fibrous ring laterally	Trochlear (IV) nerve	Abducts, depresses, and rotates eyeball medially
Inferior oblique	Anterior part of orbital floor to sclera	Oculomotor (III) nerve	Abducts, elevates, and rotates eyeball laterally

superorlaterally), and lacrimal sac. The muscles of the orbit are detailed in □ Table 8.6.

8.10.1 Innervation of the Orbit

Sensory Innervation

The sensory innervation of the orbit is derived primarily from the lacrimal, frontal, and nasociliary branches of the ophthalmic nerve (V₁). The lacrimal nerve carries sensation for the lateral aspect of the upper eyelid. It also carries secretomotor fibers for the lacrimal gland from the zygomatic nerve (V₂). The frontal nerve runs superiorly in the orbit to divide into the supraorbital and supratrochlear nerves, giving sensation to the skin of the forehead. The nasociliary nerve passes superomedially to the eyeball, providing sensation to the nasal cavity, external nose, ethmoid and sphenoid sinuses, lacrimal sac, eye, and cornea. The optic nerve enters the orbit through the optic canal and is surrounded by meninges. Visual stimuli from the retina are transmitted through the optic nerve.

Autonomic Innervation

The preganglionic parasympathetic fibers, which innervate the sphincter pupillae muscle and ciliary muscle, originate at the Edinger-Westphal nucleus. The fibers travel along the oculomotor nerve to synapse on the ciliary ganglion. From here, the postsynaptic fibers travel along short ciliary nerves of the nasociliary nerve (V₁) to reach the musculature. Contraction of the sphincter pupillae constricts the pupil, whereas contraction of the ciliary muscle relieves tension on the suspensory ligaments of the lens, increasing its power. The preganglionic sympathetic

fibers, which innervate the dilator pupillae and superior tarsal muscles, originate in the thoracic spinal cord. The fibers travel along the sympathetic trunk and synapse in the superior sympathetic ganglion. From here, the postsynaptic fibers travel along the internal carotid artery to reach the orbit. The fibers then travel along the long ciliary nerves of the nasociliary nerve (V₁) to reach the dilator pupillae. The fibers also travel along the ophthalmic artery to reach the superior tarsal muscle. Contraction of the dilator pupillae dilates the pupil, while contraction of the superior tarsal muscle elevates the upper eyelid.

8.11 Pterygopalatine Fossa

The pterygopalatine fossa is a small pyramid-shaped space just inferior to the apex of the orbit between the posterior maxilla and the pterygoid process. It connects laterally with the infratemporal fossa through the pterygomaxillary fissure, medially with the nasal cavity through the sphenopalatine foramen, and inferiorly with the oral cavity through the palatine canal. Anterosuperiorly, it connects with the orbit through the inferior orbital fissure. Posterosuperiorly, it connects with the middle cranial fossa through the foramen rotundum and vidian canal. The pterygopalatine fossa contains the third part of the internal maxillary artery and its branches, maxillary nerve (V₂), vidian nerve, and pterygopalatine ganglion.

8.11.1 Maxillary Artery

The maxillary artery enters the pterygopalatine fossa through the pterygomaxillary fissure, where it lies anterior to the

Table 8.7 Muscles of the infratemporal fossa

Muscles	Attachments	Innervation	Actions
Temporalis	Floor of temporal fossa to coronoid process and anterior border of mandibular ramus	Mandibular (V ₃) nerve	Elevates and retracts mandible
Masseter	Inferior border of zygomatic arch to lateral surface of mandibular ramus and coronoid process	Mandibular (V ₃) nerve	Elevates and protrudes mandible
Lateral pterygoid	Superior head: greater wing of sphenoid Inferior head: lateral surface of lateral pterygoid plate to neck of mandible, articular disk and capsule of temporomandibular joint	Mandibular (V ₃) nerve	Protrudes mandible and depresses chin, side-to-side movements
Medial pterygoid	Deep head: medial surface of lateral pterygoid plate Superficial head: maxillary tuberosity to medial surface of ramus of mandible	Mandibular (V ₃) nerve	Elevates and protrudes mandible

pterygopalatine ganglion. Here, it gives off various branches that follow the similarly named branches of the maxillary nerve (V₂). These branches include the posterior superior alveolar artery, descending palatine artery, infraorbital artery, and sphenopalatine artery. The sphenopalatine artery divides into posterior lateral nasal branches and posterior septal branches.

8.11.2 Maxillary Nerve

The maxillary nerve enters the pterygopalatine fossa through the foramen rotundum. It then gives off the zygomatic nerve, which further divides into the zygomaticofacial and zygomaticotemporal nerves. These nerves supply sensation to the lateral part of the cheek and temple.

Secretomotor fibers to the lacrimal gland are also carried on the zygomaticotemporal nerve. Within the fossa, the maxillary nerve also gives off two pterygopalatine nerves that carry sensory fibers that pass through the pterygopalatine ganglion without synapsing to supply the nose, palate, tonsil, and gingiva. These sensory nerves include the greater and lesser palatine nerves, which travel through the palatine canal. The maxillary nerve then passes through the inferior orbital fissure, becoming the infraorbital nerve.

8.11.3 Autonomic Innervation

The preganglionic parasympathetic fibers of the vidian nerve originate from the facial nerve by way of the greater superficial petrosal nerve. After synapsing at the pterygopalatine ganglion, postsynaptic fibers join branches of the maxillary nerve to reach the mucus-secreting glands of the nasal cavity, paranasal sinuses, and palate. Postganglionic parasympathetic fibers also travel along the zygomaticotemporal nerve and its communicating branch to the lacrimal nerve to supply secretomotor fibers to the lacrimal gland. The preganglionic sympathetic fibers of the vidian nerve originate in the thoracic spinal cord before synapsing in the superior cervical ganglion. Postganglionic sympathetic fibers then travel along the internal carotid artery, where they branch off to become the deep petrosal nerve. After passing through the vidian canal, these fibers join branches of the maxillary artery.

8.12 Infratemporal Fossa

The infratemporal fossa lies deep to the zygomatic arch and ramus of the mandible. It is posterior to the maxilla, lateral to the lateral pterygoid plate, anterior to the mastoid and styloid process, and inferior to the greater wing of the sphenoid bone. The medial pterygoid muscle attachment to the mandible marks its inferior extent. The infratemporal fossa contains the inferior part of the temporal muscle, lateral and medial pterygoid muscles, maxillary artery and branches, mandibular nerve (V₃) and branches, otic ganglion, and pterygoid venous plexus. The muscles of the infratemporal fossa are detailed in □ Table 8.7.

8.12.1 Maxillary Artery

The maxillary artery is a terminal branch of the external carotid artery that gives off several branches as it courses through the infratemporal fossa. It passes either medial or lateral to the lateral pterygoid muscle before exiting the fossa through the pterygomaxillary fissure. The lateral pterygoid muscle divides the maxillary artery into three parts, the first two of which lie within the infratemporal fossa. Important branches of the first part include the middle meningeal artery, which courses superiorly, splitting the auriculotemporal nerve to enter the cranium via the foramen spinosum, and the inferior alveolar artery, which supplies the mandible, gingiva, and teeth. Important branches of the second part include the deep temporal arteries, pterygoid arteries, masseteric arteries, and buccal arteries.

8.12.2 Mandibular Nerve

The mandibular nerve, as described earlier, enters the infratemporal fossa through the foramen ovale. Here, it divides into both motor and sensory branches. The branches include the auriculotemporal nerve, inferior alveolar nerve, lingual nerve, and buccal nerve. The otic ganglion lies just inferior to the foramen ovale medial to the mandibular nerve.

9 The Complete Otolaryngology Physical Examination

James Azzi, Jean-Paul Azzi, Anthony P. Sclafani, and Edward J. Shin

9.1 Introduction

The proper evaluation and treatment of patients presenting to an otolaryngologist–head and neck surgeon require a thorough and complete history and physical examination. Establishing rapport with the patient is essential. Greet the patient with eye contact and a smile. Explain your role on the medical team, what you plan to do, and why you plan to do it. When patients are at ease and you have gained their trust, the evaluation can be the most productive.

Although a complete otolaryngologic examination should be performed on all patients, a thorough medical history is essential in determining the key portions of the examination. It is important to listen to patients and to guide them to a thorough description of their complaint, without interrupting them. As with any medical evaluation, a complete past medical/surgical history, a list of medications and any allergies to medications, social and family histories, and a review of systems will aid the clinician in making the correct diagnosis.

9.2 General Appearance

While donning gloves, observe the patient for any obvious abnormalities, noting behavior as well as physical appearance. For example, a gait disturbance may suggest cerebellar dysfunction, or brown stains on the teeth may signify heavy tobacco use. Next, evaluate the skin of the head and neck. Pay particular attention to areas that receive significant sun exposure. These include the nose, ears, scalp, and the back of the neck. Look for any irregular lesions that may indicate malignancy.

9.3 Face

Evaluate the patient for any facial asymmetry, paresis, or paralysis. Use the American Academy of Otolaryngology–Head and Neck Surgery facial nerve grading system or the House-Brackmann classification (□ Table 9.1) to grade the severity of dysfunction. Palpate the face for any deformities or bony

Table 9.1 House-Brackmann scale of facial paralysis

Grade	Facial movement
I. Normal	Normal function
II. Mild dysfunction	Eye with complete closure, forehead and mouth with some asymmetry
III. Moderate dysfunction	Eye with complete closure, forehead and mouth with slight movement
IV. Moderately severe dysfunction	Eye with incomplete closure, no forehead movement, asymmetry of mouth with maximal effort
V. Severe dysfunction	Eye with incomplete closure, no forehead movement, mouth with slight movement
VI. Complete paralysis	No movement

irregularities. In patients with a history of trauma, pay particular attention to the periorbital areas, zygomatic arches, and dorsum of the nose, palpating any bony step-offs. Tap above and below the orbits to evaluate the frontal and maxillary sinuses; tenderness in these areas may indicate sinusitis. The temporomandibular joint is evaluated by placing two or three fingers anterior to the external auditory canal and having the patient open and close the mouth. Tenderness, clicking, or grinding may indicate temporomandibular joint dysfunction.

9.4 Neck

In the evaluation of the neck, the normal midline structures, including the trachea and the hyoid, thyroid, and cricoid cartilages, should be identified. With the examiner standing behind the seated patient, the cartilages of the larynx are palpated. The examiner places both thumbs behind the patient's neck and the remaining four fingers of each hand in the paratracheal grooves. Gentle alternating finger pressure should move the larynx to and fro; a fixed larynx is highly suspicious for malignant disease. The thyroid is located inferior to the cricoid cartilage and lateral to the trachea. While the patient swallows, each thyroid lobe rises and can be palpated separately. Any enlargement or nodule should be noted.

Systematically palpate levels I through VI of the neck (□ Fig. 9.1) to assess for adenopathy. Any large lymph node (>1 cm) or hard fixed lesion, especially in a patient with a history of tobacco use and/or alcohol abuse, warrants further investigation and a thorough mucosal examination of the upper aerodigestive tract. Alternatively, in the setting of fevers, night sweats, and weight loss, a diagnosis of lymphoma should be entertained.

Level I is defined by the body of the mandible, the anterior belly of the digastric muscle, and the stylohyoid muscle. Level I can be further subdivided into IA and IB. Level IA includes the submental nodes. Level IB contains the submandibular nodes. Level II contains the jugulodigastric lymph nodes and extends from the base of the skull to the hyoid bone, anterior to the sternocleidomastoid muscle. Levels IIA and IIB are located medial and lateral to the spinal accessory nerve, respectively. Level III begins superiorly at the level of the inferior hyoid bone and ends inferiorly at the level of the cricoid cartilage. The jugulodigastric nodal chain can be followed inferiorly to level IV, which extends from the cricoid to the clavicle. Levels III and IV are bordered anteriorly by the sternohyoid muscle and posteriorly by the lateral sternocleidomastoid muscle. Level V includes the lymph nodes from the lateral sternocleidomastoid muscle to the anterior trapezius muscle. Finally, level VI is defined by the hyoid superiorly, the sternal notch inferiorly, and the common carotid arteries laterally.

9.5 Ears

The auricle is examined for appropriate size, shape, definition, and location. The preauricular area is inspected for skin tags

Fig. 9.1 Diagram of levels of the neck.

and pits; the postauricular area is also examined, especially for swelling, discoloration, or lesions. In the setting of acute otitis media, it is important to visually and manually inspect for mastoiditis. If mastoiditis is complicated by a subperiosteal abscess, the ear will often protrude. Postauricular ecchymosis, or the Battle sign, may indicate trauma and possible temporal bone fracture.

To evaluate the external auditory canal and tympanic membrane, use a pneumatic otoscope with the largest possible speculum to create an airtight seal without traumatizing the canal skin. The auricle is grasped and retracted posteriorly and superiorly to straighten the canal. The speculum is advanced beyond any hair in the external auditory canal but should not be passed into the bony portion of the external auditory canal. The fifth finger of the hand holding the otoscope is used to stabilize the hand against the patient's temple (□ Fig. 9.2). This is particularly important when children, who may make sudden movements, are examined. If cerumen is obstructing visualization of the tympanic membrane, it is removed by suction, curet, or irrigation.

Tenderness, otorrhea, or edema can signal infection. Acute otitis externa typically will present with tenderness on examination, particularly with tragal manipulation. The external auditory canal will be edematous and may also contain purulent debris. Fungal otitis externa may present with white or brown spores in the external auditory canal. If the patient is diabetic or immunocompromised, be aware of the increased risk for malignant otitis externa, which presents with granulation tissue at the junction of the bony and cartilaginous portions of the canal. The external auditory canal may be narrowed by nodular growth, which may represent an osteoma or exostoses. A history of cold water exposure, such as with surfers, increases

Fig. 9.2 Proper hand positioning in examination of the ear. The fifth finger of the hand holding the otoscope is braced against the temple, while the opposite hand draws the auricle posteriorly to straighten the external auditory canal.

the likelihood of exostoses. If severe, this narrowing can increase the risk for acute otitis externa.

The tympanic membrane (□ Fig. 9.3) is inspected and all anatomical landmarks identified; any abnormalities should be documented. The mobility of the tympanic membrane is assessed with a pneumatic otoscope by gently insufflating air and observing the movement of the membrane. This will be effective, however, only if the speculum creates a seal with the external auditory canal, as described above. Common causes of immobility include improper use of the otoscope, perforation,

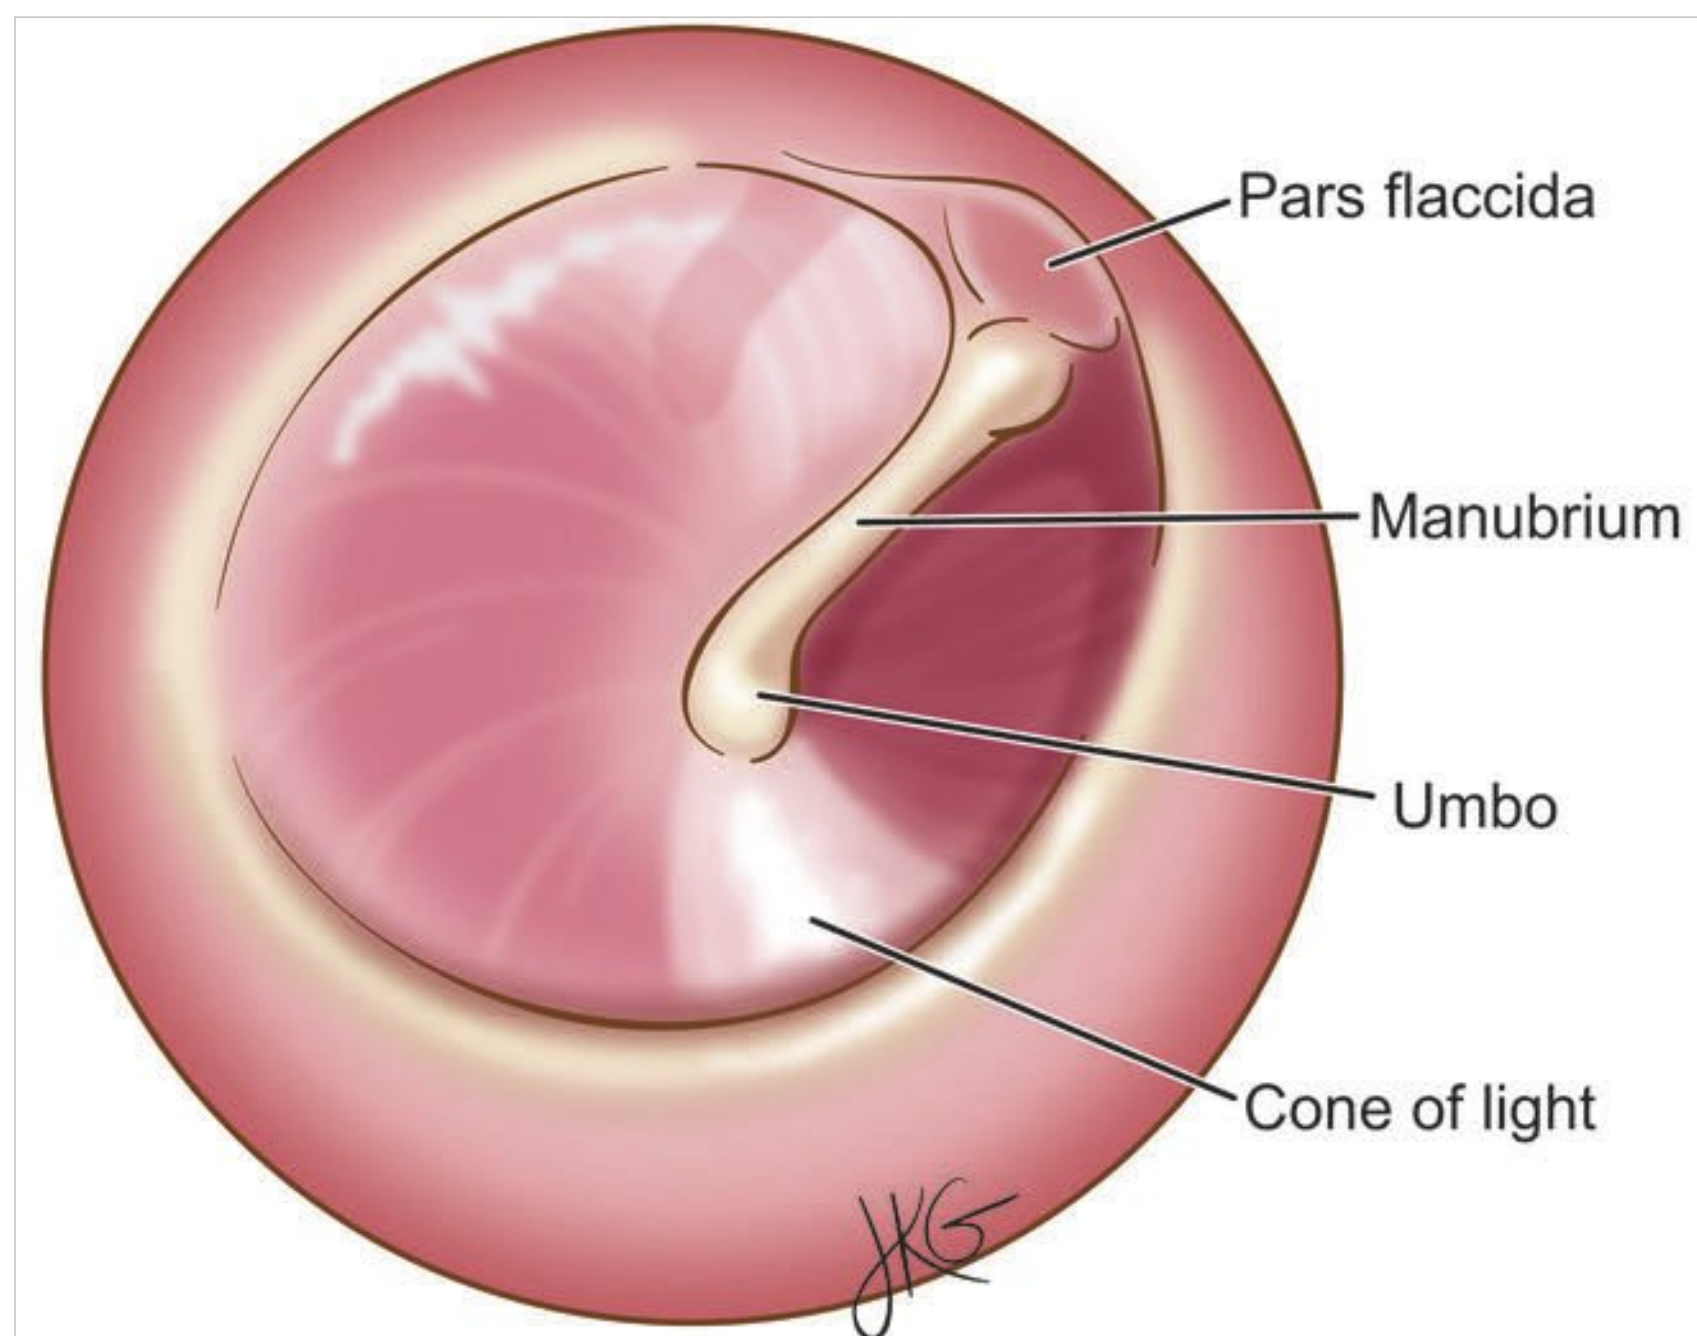

Fig. 9.3 Diagram of the right tympanic membrane.

and middle ear fluid. Significantly better outward than inward movement of the tympanic membrane is suggestive of eustachian tube dysfunction. Masses, discolorations, or other abnormalities of the tympanic membrane are evaluated and described according to location by quadrant. Extension of any abnormality into the middle ear is carefully evaluated, and the visible margins of any lesions are described.

Basic tuning fork testing is best done in a quiet room, and the results are always reported with the frequency tested. To perform the Weber test, place a vibrating (512 or 1,024 Hz) tuning fork on the center of the patient's forehead. (Alternatively, the fork can be placed between the patient's central incisors). The patient is asked in which ear the sound is perceived as louder or if it is equal bilaterally. A lateralized Weber test may indicate ipsilateral conductive hearing loss or contralateral sensorineural hearing loss. The Weber test should be documented as "negative" for midline responses and as either "right" or "left" for lateralization.

To perform the Rinne test, a vibrating tuning fork is first placed over the mastoid process (bone conduction) and then held 2 to 3 cm from the external auditory canal (air conduction); the patient is asked which sound is perceived as louder. A conductive loss will cause the sound to be louder over the mastoid process. This is referred to as "Rinne negative." When the air conduction is louder than bone conduction, this is referred to as "Rinne positive." If the two positions have the same intensity, then this is referred to as "Rinne equal."

9.6 Oral Cavity, Oropharynx, and Nasopharynx

The oral cavity and oropharynx (□ Fig. 9.4) are examined with an adequate light source (preferably a headlight to free both hands). The lips, dentition, and gums are evaluated, with

attention paid to dental occlusion, masses, or lesions that may require further investigation. The dorsal and ventral tongue, as well as the sides of the tongue and floor of the mouth, are examined by asking the patient to elevate and move the tongue from side to side. Palpate the lateral tongue and the floor of the mouth, and examine the buccal mucosa and hard palate. Bimanual palpation, with one finger of one hand in the oral cavity and oropharynx and the other hand on the corresponding areas of the external neck, can aid in palpating deeper lesions of the floor of the mouth and base of the tongue.

The posterior tongue, soft palate, tonsillar pillars, and vallecula are examined. Two tongue depressors are used to fully manipulate and expose all areas to be visualized (□ Fig. 9.5). The tonsils are graded on a scale from 1+ to 4+ (1+ indicated tonsils barely visible in the tonsillar fossae and 4+ indicates tonsils that "kiss" in the midline). The nasopharynx can then be examined with a warm nasopharyngeal mirror suspended just behind and below the uvula while the tongue is depressed with a tongue blade for wider exposure. A flexible fiber-optic endoscope can also be used and may provide a superior examination. The patency of the posterior choanae should be assessed, and any obstruction from polyps or adenoid hypertrophy should be noted. The eustachian tube orifices should be unobstructed, and the posterior wall of the nasopharynx should be smooth and without masses.

9.7 Nose, Nasopharynx, and Larynx

9.7.1 Anterior Rhinoscopy

The anterior portions of the nasal cavity are easily evaluated with a nasal speculum and light source (□ Fig. 9.6). Note any abnormal findings, such as a deviated septum or boggy,

Fig. 9.4 Diagram of the oral cavity and oropharynx.

Fig. 9.5 With two tongue depressors, the cheeks are held laterally to fully visualize the entire oral cavity.

edematous turbinates. Visualization can be improved by spraying a mist of nasal decongestant (oxymetazoline or phenylephrine) in the nose. An unobstructed nasal cavity should allow visualization of palatal elevation by anterior rhinoscopy while the patient pronounces the sound of the letter K.

9.7.2 Endoscopic Examination

When indicated by history or physical examination, endoscopy can be performed to better visualize suspected pathologic processes. A topical anesthetic and decongestant (see Box Dr. Chodosh's Topical Airway Anesthetic/Decongestant Solution (p.47)) is applied to both sides of the nose before endoscopy to ensure patient comfort during the examination.

Dr. Chodosh's Topical Airway Anesthetic/Decongestant Solution

- Lidocaine 1%
- Phenylephrine
- Peppermint oil

9.7.3 Nasal and Nasopharyngeal Endoscopy

The nose and nasopharynx can be evaluated with either a rigid or a flexible endoscope. Suctioning, biopsy, and manipulation are far simpler when a rigid endoscope is used. Generally, it is easier to pass the scope close to the floor of the nose, and each

Fig. 9.6 Proper hand positioning during anterior rhinoscopy. The nasal speculum blades should be oriented vertically and the hand stabilized on the nasal tip with the index finger.

side is examined from anterior naris to nasopharynx. The size and color of the inferior and middle turbinates and middle meatus are noted, as are any polyps, crusting, purulent debris, or masses in these areas. The septum is inspected, again by examining the color and quality of the mucosa, as well as verifying septal integrity and assessing septal deflections, curvatures, and spurs.

The nasopharynx is examined by advancing the flexible endoscope beyond the posterior choanae on one side and turning the tip as needed to allow adequate assessment of the entire nasopharynx. The posterior and lateral nasopharyngeal walls, fossae of Rosenmüller, and eustachean tube orifices should all be evaluated and any masses, mucosal abnormalities, or adenoidal vegetation/hypertrophy noted.

9.7.4 Laryngoscopy

Ideally, indirect laryngoscopy should be performed on all patients. The seated patient leans forward with the chin slightly elevated (in a “sniffing” position), while the examiner sits just to the side of the patient. The examiner gently holds the patient’s outstretched tongue with a gauze pad and places a warm laryngeal mirror to elevate the soft palate and uvula (□ Fig. 9.7).

The patient is asked to say EEE, and the vocal folds should be observed for brisk symmetric movement and complete glottis closure during phonation. The piriform sinuses are better dilated for inspection while the patient pronounces a long-A sound. The vallecula, lingual and laryngeal surfaces of the epiglottis, aryepiglottic folds, arytenoid cartilages, and post-cricoid area should all be visualized; all should be smooth-surfaced, nonerythematous, and without masses or ulcerations.

Fig. 9.7 Proper form for indirect laryngoscopy.

Table 9.2 Cranial nerves

Cranial nerve	Function
I	Sense of smell
II	Visual acuity and visual fields
III	Extraocular movements
IV	Superior oblique muscle
V	Corneal reflex and sensation to the face
VI	Lateral rectus muscle
VII	Motor and symmetry of facial muscles
VIII	Auditory and vestibular function
IX	Gag reflex and soft palate
X	Vocal fold mobility, gag reflex, and soft palate
XI	Sternocleidomastoid, trapezius muscles
XII	Tongue movement and symmetry

The examination of patients with a strong gag reflex, or of patients who otherwise cannot tolerate indirect laryngoscopy, can be facilitated by spraying the oropharynx and tongue with a topical anesthetic. For patients who still cannot tolerate the mirror examination or in whom a more prolonged evaluation of the hypopharynx and larynx is necessary, flexible nasopharyngolaryngoscopy can be performed. The endoscope is introduced transnasally and passed into the nasopharynx; at this point, it is advanced beyond the soft palate as the patient gently inspires. While the same structures are inspected, the tip of the scope can be manipulated into the vallecula or piriform sinus for improved visualization. In compliant and well-anesthetized patients, the tip of the endoscope can be advanced to (and sometimes through) the glottis inlet to view the upper trachea.

Any significant erythema or edema (especially in the hypopharynx or larynx) warrants further investigation and airway control. Patients with laryngopharyngeal reflux may complain

of hoarseness, globus sensation, throat irritation, and cough. They commonly have edema and erythema of various portions of the supraglottis and hypopharynx; however, the most common finding is erythema of the posterior larynx and diffuse pachydermia of the pharyngeal walls. As patients with infections, systemic diseases, or mass lesions may present with similar complaints, a thorough evaluation is warranted.

9.8 Cranial Nerves

Finally, perform an abbreviated neurologic examination, with particular attention given to the cranial nerves (□ Table 9.2). Focal deficits may be suggestive of an underlying mass lesion or neurologic process requiring further work-up including, but not limited to, imaging and consideration of neurologic and/or ophthalmologic consultation.

9.9 Roundsmanship

- A thorough otorhinolaryngologic examination includes a detailed history and a complete head and neck examination.

- The otorhinolaryngologic examination should proceed in a structured and orderly fashion to avoid overlooking any portion of the examination.
- Resting the fifth finger of the hand holding an otoscope against the patient's temple braces the otoscope and prevents inadvertent injury if the patient (especially a child) moves suddenly.
- Warming mirrors prevents fogging during indirect nasopharyngoscopy or laryngoscopy.

10 Radiology of the Head and Neck

Hasit Mehta and Ajay Hira

10.1 Introduction

Imaging plays a large role in the noninvasive diagnosis of head and neck pathology. In the following two chapters, we will briefly review the various imaging modalities available, as well as the relevant radiologic anatomy and pathology.

10.2 Imaging Modalities

10.2.1 Radiography

Radiographs are the oldest and most basic imaging modality. X-rays were discovered in 1895 by Wilhelm C. Roentgen, who produced the first X-ray (of his wife's hand) in the same year. Radiographs (better known as X-rays or plain films) have historically been the primary imaging modality for the diagnosis of head and neck pathology. In the past three decades, radiography has largely been replaced by computed tomographic, ultrasound, and magnetic resonance imaging. Radiography is performed by exposing a region of the body to ionizing radiation (X-rays); the X-rays are differentially absorbed or transmitted to varying degrees by the imaged body structures (depending on the density of the structures imaged). A detector (digital or film) placed in line with the X-ray generator and behind the imaged body part registers the transmitted X-rays and creates the radiograph. The radiograph contains varying shades of gray; the whitest structures represent the densest body structures (which attenuate the most X-rays), such as bone, and the darkest structures on the radiograph represent the least dense structures, such as air in the aerodigestive tract or lungs. The ability to detect pathology depends primarily on the density, size, and location of the pathologic process. Radiography is still in use (□ Table 10.1), but its application in otolaryngology is primarily in the emergency department for quick evaluation of the upper aerodigestive tract, particularly in the pediatric population for the rapid evaluation of epiglottitis and croup (given the lower radiation exposure than with CT). Other clinical uses include exclusion of foreign body, evaluation of the upper airway (frontal and lateral views), and quick evaluation of the orbits, paranasal sinuses, and maxillofacial structures when other imaging modalities are unavailable (□ Fig. 10.1). Virtually all

other former indications of radiography have been replaced by alternative imaging modalities.

10.2.2 Computed Tomography

Computed tomography, better known as CT scanning, has revolutionized noninvasive head and neck imaging. CT has replaced radiography as the primary imaging modality for most acute head and neck pathology. A CT machine consists of a ringlike structure with multiple X-ray generators and detector arrays. The patient is placed on a movable gantry that traverses the center of the CT scanner; as the computer-controlled gantry moves the patient through the CT scanner, the X-ray generator and detector elements rotate around the patient, acquiring a large helical data set. Substantial computational hardware is necessary both to acquire and to post-process the data stream. The data set is analyzed with a variety of algorithms, traditionally filtered back projection, although currently more complex iterative methodology is used to produce the cross-sectional tomographic images from the data stream (□ Fig. 10.2). Current modern CT scanners are capable of extremely high-resolution image acquisition and routine helical image acquisition, allowing three-dimensional/volumetric reconstruction (□ Fig. 10.3) from the single data set. The helical data set is then post-processed by the CT technologist and/or radiologist to produce representative cross-sectional images in any plane (□ Fig. 10.4). The fundamentals of CT and radiography are similar; CT images are also primarily dependent on the attenuation of X-rays by body structures, measured quantitatively in Hounsfield units. Qualitatively, denser structures will appear whiter on a CT image. The CT image can be viewed at various window widths and levels to accentuate various spectra of density. The three-window width and levels that would be typically used by the otolaryngologist include soft-tissue, bone, and lung window and level presets (□ Fig. 10.5). Each of these presets accentuates different spectra of density.

CT of the head and neck can be performed with and/or without iodinated intravenous (IV) contrast material. IV contrast material is radiodense and produces a white appearance on the CT image because of its radiodensity. It can be administered to allow detailed imaging of the vascular compartment.

Table 10.1 Advantages and disadvantages of radiography

Advantages	Disadvantages
Inexpensive	Poor evaluation of submucosal lesion/mass
Quick	Ionizing radiation
Readily available, even in underserved regions	Variability with positioning of patient
Interpretation by non-radiology, non-ENT physicians possible	Poor assessment of salivary and endocrine glands
Medium-size and portable units available	Generally diminished sensitivity and specificity for detection of lesions compared with newer imaging modalities
> Abbreviation: ENT, ear, nose, and throat.	

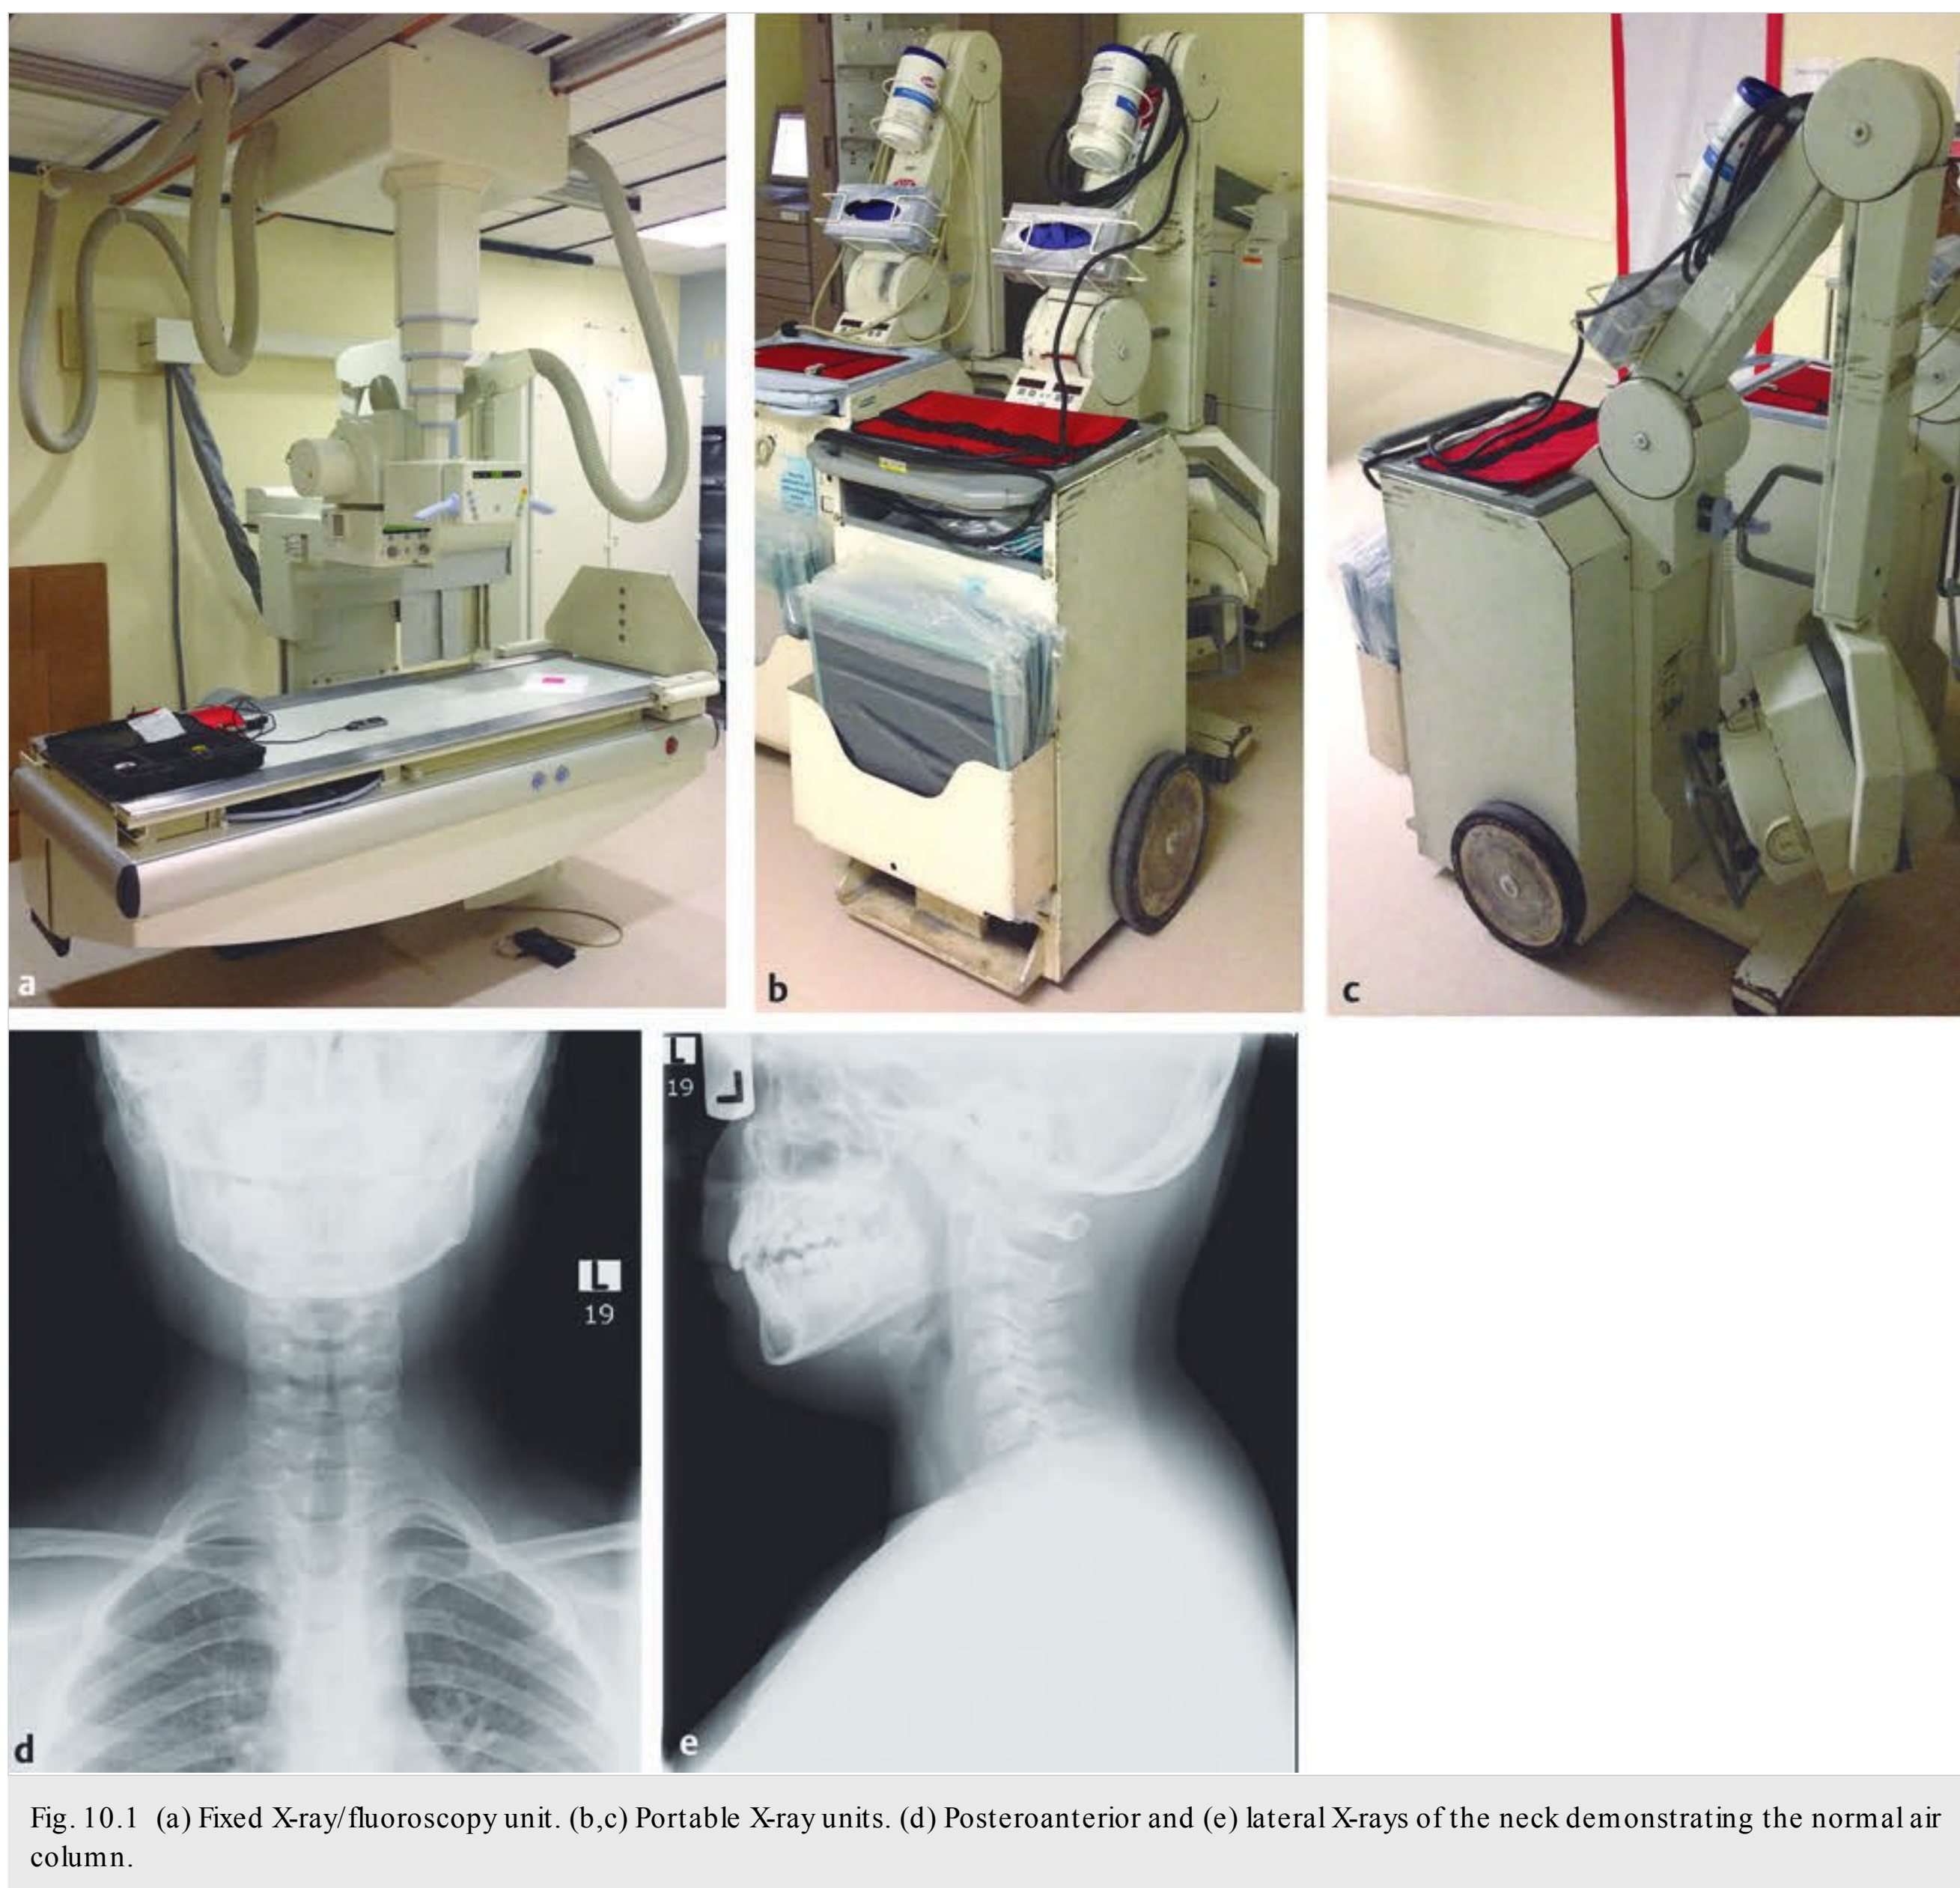

Fig. 10.1 (a) Fixed X-ray/fluoroscopy unit. (b,c) Portable X-ray units. (d) Posteroanterior and (e) lateral X-rays of the neck demonstrating the normal air column.

Additionally, contrast can help accentuate various pathologic processes, which may cause pooling of contrast either from hyperemia or tissue breakdown. Its application can dramatically improve the sensitivity of CT when administered in the appropriate setting. The primary limitations to the use of contrast material are renal dysfunction, cross reactivity with certain medications, and allergic reaction to contrast media. Various guidelines exist to screen patients at risk for contrast-induced nephrotoxicity, and premedication regimens are available. Contrast is typically indicated in the evaluation of head and neck neoplasms and most head and neck infections. It is not routinely necessary in the evaluation of the paranasal sinuses or temporal bone unless there is a suspicion of neoplasm or large soft-tissue extension of infection.

CT of every compartment of the head and neck is in active clinical use worldwide. It is the imaging modality of choice for

acute head and neck pathology, including trauma, acute infection, airway obstruction, and foreign body evaluation. It is the most sensitive examination to evaluate fine bony detail. CT is also an important adjunct in the evaluation of head and neck neoplasms. It is the imaging modality of choice for evaluation of the paranasal sinuses and is a critical component in planning for functional endoscopic sinus surgery. Three-dimensional reconstructions allow the pre- and postoperative assessment of complex trauma and reconstruction. CT is also routinely used for the minimally invasive image-guided biopsy of head and neck lesions (□ Table 10.2).

10.2.3 Ultrasonography

Medical ultrasonography came into use around the period of World War II after advances made during wartime research.

Fig. 10.2 (a) Axial soft-tissue window of the neck at the level of the hyoid and piriform sinuses on computed tomographic scan. (b) Axial bone window at the level of the maxillary sinuses demonstrating bony septal deviation to the right.

Fig. 10.3 Computed tomographic data can be reformatted to produce a three-dimensional image of selected tissue. (a) Frontal and (b) left oblique three-dimensional bone surface reconstructions of facial structures. Note fractures at the left infraorbital rim, zygomaticomaxillary suture/zygomatic arch, zygomaticofrontal suture, and orbital floor (asterisks).

Ultrasound uses sound waves that are beyond the range of human hearing. Sound waves are generated by a piezoelectric transducer probe (□ Fig. 10.6), and echoes are reflected back to the probe depending on the echotexture of the tissue being ex-

amined. A grayscale anatomical image representative of the tissue being imaged is generated. The time of the returning echo depends on the depth of the structure. The intensity of the returning sound wave encodes the brightness of the pixel on the

generated image; more echogenic structures reflect more ultrasound energy and appear brighter on the image than do less echogenic structures. Typically bright (echogenic) structures include bony structures and calcifications. Muscle and soft tissue have intermediate echogenicity and are typically varying shades of gray. Fluid, gas, and aqueous material are extremely hypoechoic and thus very dark gray to black on the ultrasound image. Modern ultrasonography equipment can generate two-dimensional anatomical images in real time (□ Fig. 10.7) and provide three-dimensional image acquisition and flow-

Fig. 10.4 Coronal projection computed tomographic scan of the patient in □ Fig. 10.3.

dependent velocity measurements within vascular structures (□ Fig. 10.8).

Ultrasound is a rapid, noninvasive imaging technique that does not use ionizing radiation. This makes ultrasound an ideal imaging modality in the pediatric population. Ultrasound offers significant advantage in the pediatric population because imaging can routinely be obtained without sedation. Modern ultrasound equipment has evolved to the point of including extremely portable and mobile units that can be used in nearly any clinical environment. Some units are so small that they can be battery operated and carried in a handheld unit by a physician or technologist. However, the current typical medical-grade diagnostic ultrasound unit is of medium size, on wheels, and portable to most locations within a hospital or clinical setting. Ultrasound offers excellent soft-tissue detail for superficial lesions. In the head and neck, it is a primary imaging modality for evaluation of the thyroid gland, as well as evaluation of soft-tissue masses and infections of the neck in children. However, ultrasound typically cannot provide images of deep structures such as the aerodigestive tract, and radiography is still the imaging modality of choice for epiglottitis and croup. Real-time ultrasound imaging is also used for the image-guided intervention/biopsy of head and neck lesions typically performed by the otolaryngologist, radiologist, or pathologist (□ Table 10.3).

10.2.4 Magnetic Resonance Imaging

Magnetic resonance (MR) imaging is a complex imaging modality that leverages the unique properties of the nucleus of an atom. Atoms have a magnetic field that is related to their nuclear spin. These nuclear magnetic fields will align with a strong, externally applied magnetic field. The atoms are then subjected to electromagnetic energy, which they can absorb. This boosts them to an excited state, and they subsequently release the energy as they return to a ground state. The energy is detected and formed into images with complex pulse sequences and image generation. The MR scanner consists of a large tubular structure that contains an extremely powerful, liquid helium-cooled superconducting magnet. Additionally, a series of radio-frequency coils are present within the tubular structure, as well as coils placed on the patient's body in the region of

Fig. 10.5 Different details can be highlighted on a computed tomographic scan by selecting different windows. Coronal image of the neck, with images presented in (a) soft tissue, (b) bone, and (c) lung window widths and levels.

Table 10.2 Advantages and disadvantages of computed tomography

Advantages	Disadvantages
Excellent fine bony detail	Ionizing radiation exposure
Very good soft-tissue delineation	Moderately expensive
Cross-sectional imaging allows excellent detection of submucosal lesions and other lesions that may not be seen with endoscopy	Prone to artifact
Fast imaging modality, thus moderately impervious to motion artifact	Relatively more complex to interpret
Excellent delineation of airway	Large, complex imaging unit; typically fixed immovable imaging system
	Readily available in most developed nations but not necessarily in developing nations

Fig. 10.6 Ultrasound (a) unit and (b) probe.

imaging interest. These coils generate radio-frequency energy to agitate species of atoms in precise computer-controlled patterns. The energy absorbed and emitted is also captured by the coils and processed by the computer system to generate MR images. MR imaging allows exceptional soft-tissue delineation and excellent delineation of deep structures. Various pulse sequences can be used to accentuate certain tissues. The major sequences used in head and neck imaging include T1-weighted sequences (□ Fig. 10.9), T2-weighted sequences (□ Fig. 10.10), and fat-suppressed T2-weighted or STIR (short tau inversion recovery) pulse sequences (□ Fig. 10.11). T1 imaging may be performed with or without contrast material. T1-weighted imaging is most useful for imaging lesions that enhance, such as neoplasm and infection. Fat is extremely bright on T1 imaging and typically is suppressed during contrast administration to allow

a more sensitive detection of enhancement (□ Fig. 10.12). T2-weighted pulse sequences are fluid-sensitive and allow the visualization of edema and fluid-containing structures, including congenital cystic lesions of the head and neck.

MR imaging is the imaging modality of choice to evaluate soft tissues of the head and neck. It offers excellent delineation of the deep and superficial fascial planes of the neck. There are limitations to its use in patients with implanted metallic devices and/or foreign bodies, and these patients need to be assessed on a case-by-case basis. Additionally, MR imaging contrast agents may be contraindicated in patients with end-stage renal failure because of the risk for nephrogenic systemic fibrosis. MR imaging is not a primary modality used in the imaging of the paranasal sinuses and temporal bone because of the lack of free protons in calcium and air, which limits the ability to

Fig. 10.7 Ultrasound image of thyroid gland. The plus signs indicate the thickness of the isthmus, which continues bilaterally to the lobes.

generate MR signal, although it can be used as an adjunct imaging technique to evaluate for soft-tissue and perineural spread of disease (□ Table 10.4).

10.2.5 Positron Emission Tomography and Positron Emission Tomography–Computed Tomography

Positron emission tomography (PET) is unique in that it is a physiologic imaging modality and not strictly anatomical. A PET-CT unit consists of a large tubular imaging structure similar in appearance to a CT or MR imaging unit. Within the tubular structure are the components of both a CT scanner and a PET scanner. Typically, the patient is placed on the computer-controlled gantry, and a whole-body CT scan of the patient is performed, typically in less than 1 minute. Subsequently, the patient is slowly moved through the scanner over a period of approximately 30 minutes while the PET imaging portion of the examination is performed. The two imaging data sets are co-registered on a dedicated imaging workstation and interpreted by the radiologist.

In order to generate the PET image, the patient is injected with an IV dose of a radioactive material (radioactive tracer). The most commonly administered radiopharmaceutical agent is fluorodeoxyglucose F 18 (^{18}F -FDG). This agent is produced in a cyclotron near the imaging facility. With a half-life of

approximately 1,010 minutes, the agents are usually ordered the day before an examination and delivered to the imaging facility on the day of examination. The ^{18}F -FDG is injected and taken up from the vascular compartment by GLUT receptors in cells in a similar fashion to glucose. Once in the cells, the ^{18}F -FDG undergoes phosphorylation to ^{18}F -FDG-6-phosphate by hexokinase; the ^{18}F -FDG-6-phosphate is trapped in the cells and when measured can be an indirect indicator of the relative rate of glucose metabolism in the cells in the imaged tissue. The injection is given approximately 1 hour before imaging to allow time for tissue uptake of the radioactive tracer. Neoplastic processes tend to exhibit markedly elevated glucose utilization and thus take up more ^{18}F -FDG.

^{18}F undergoes radioactive positron decay (one proton decays into a neutron, with the release of a positron in the process). This positron will collide with its antimatter counterpart, an electron, in short order. The collision process (annihilation) of the electron and positron converts their mass into energy in the form of two 511-keV photons, which travel away from each other in opposite directions. The two photons are detected by scintillator detectors in the PET scanner via coincidence detection. The greater the number of photons emitted by the tissue, the more intense the image will appear. The amount of activity may be semiquantified with a standardized uptake value (SUV). SUV is the amount of activity in a measured region of interest that has been normalized for the injected dose and ratio of body weight to surface area. As a ratio, it is a unitless measure

Fig. 10.8 The intensity and direction of blood flow in the thyroid gland can be assessed with ultrasound.

Table 10.3 Advantages and disadvantages of ultrasound imaging

Advantages	Disadvantages
Low cost, readily available	Low spatial resolution (“fuzzy” image)
Extremely portable imaging units; ability to perform scans in nearly any environment on any patient	Poor evaluation of deep structures of the head and neck
No ionizing radiation	Highly dependent on skill of ultrasonographer, which reduces test reproducibility compared with other imaging modalities
Excellent evaluation of the thyroid, parotid, and submandibular glands	Inadequate evaluation of the aerodigestive tract
Real-time imaging modality ideal for image-guided interventional procedures	

and should be used with caution because it is prone to error if all variables are not properly considered. The imaging data set can be constructed into a three-dimensional image and can be fused with the CT data set (□ Fig. 10.13).

PET-CT imaging offers the best of two worlds: high-spatial-resolution anatomical CT imaging and excellent physiologic PET imaging to maximize the detection and staging of head and neck carcinoma. It is the imaging modality of choice for staging and following the treatment of head and neck carcinoma. PET-CT has greater sensitivity and specificity than MR imaging in the staging of head and neck neoplasm and is the imaging modality of choice for staging for nodal involvement. PET-CT is also excellent in the detection of a treatment response after head

and neck resection and/or chemoradiation. PET-CT is of critical value in the detection of recurrent head and neck neoplasm and is especially useful for detecting distant metastasis. Local recurrence detection is more difficult because of uptake in inflammatory tissue in the postoperative bed; however, CT and MR imaging have similar drawbacks. If the PET scan is negative, a recurrence is unlikely, whereas a positive PET scan may necessitate a biopsy to distinguish granulation/scar tissue from recurrence.

Interestingly, PET-CT is not useful for distinguishing benign from malignant salivary gland neoplasms as both have similar uptake of ^{18}F -FDG (□ Table 10.5).

Fig. 10.11 Coronal fat-suppressed T2-weighted magnetic resonance image of the neck.

10.3 Imaging Anatomy

10.3.1 Skull Base

Temporal Bone

Middle Ear

The middle ear comprises three principal components: the epitympanum (above the level of the tympanic membrane and extending to the tegmen tympani, which separates it from the

middle cranial fossa); the mesotympanum (at the level of the tympanic membrane); and the hypotympanum (below and medial to the tympanic membrane). The tympanic membrane attaches superiorly to the scutum, which is a sharp bony excrescence that is best seen on coronal images. The tympanic membrane will be seen as a thin wispy structure on CT. The tegmen tympani, or roof of the middle ear, is also best visualized on coronal imaging. It is a very thin structure, and close attention to its integrity is essential during the imaging of infectious, traumatic, and neoplastic processes of the middle ear. Erosion/

Fig. 10.12 (a) Axial and (b) coronal contrast-enhanced T1 image with fat suppression of the neck.

Table 10.4 Advantages and disadvantages of magnetic resonance imaging

Advantages	Disadvantages
No ionizing radiation	Long imaging time
Excellent soft-tissue and spatial resolution	Prone to artifact
Excellent delineation of soft tissue and perineural spread of disease	Confined imaging location/claustrophobia
	Extremely complex and expensive imaging modality
	Significant expertise needed to perform and interpret examination
	Limited availability
	Large fixed imaging unit

disruption of the tegmen may provide direct access to the central nervous system/intracranial compartment.

The Prussak space, just medial to the scutum, lies between the scutum and ossicles and is normally aerated. This is especially important because soft tissue seen on CT imaging in this space should raise the possibility of a cholesteatoma. All aerated structures in the middle ear are typically very dark on CT imaging. Any alteration in the uniformity of the dark black appearance suggests opacification of these spaces, possibly indicating infection, such as otitis media, or a mass lesion, such as cholesteatoma or other neoplasm. The scutum is best visualized on coronal imaging and should taper to sharp point (□ Fig. 10.14a). Blunting or erosion of the scutum with opacification of the middle ear is a sine qua non of acquired cholesteatoma.

The malleus, incus, and stapes are evaluated well with thin-section CT imaging. The head of the malleus articulates with the incus. On imaging, the malleus and incus are frequently described as having an “ice cream on cone” appearance, with the malleus making up the ice cream portion and the incus the cone (□ Fig. 10.14b). This is especially important in the setting of trauma because ossicular disruption is often visualized as a

loss of this classic “ice cream on cone” appearance. The lenticular process of the incus articulates with the head of the stapes. The stapes has a horseshoe appearance on imaging and comprises an anterior and posterior crus and footplate. The footplate covers the oval window. A quick way to ensure that CT imaging of the middle and inner structures is technically adequate is to determine whether you can easily and reliably identify the footplate of the stapes. This usually requires thin-section images that are less than 1 mm in thickness.

Within the middle ear, two muscles deserve special mention because these can be visualized on imaging. The tensor tympani muscle is seen extending along the eustachian tube and inserts onto the manubrium of the malleus. The stapedius muscle originates from the pyramidal eminence, an osseous mound that is found within the hypotympanum and attaches to the head of the stapes.

Inner Ear

The principal components of the inner ear include the cochlea and the vestibular apparatus. The cochlea, semicircular canals,

Fig. 10.13 A positron emission tomographic–computed tomographic (PET-CT) scan can provide anatomical detail and show the physiologic activity of tissues. (a) Three-dimensional volume-rendered image of the entire PET data set. This is shown in anteroposterior view but can be rotated on the workstation. (b) Axial PET image and (c) axial PET-CT fused image through the abdomen. PET-CT fusion clearly shows fluorodeoxyglucose F 18 excreted in the renal collecting system (normal), without a renal mass. The PET data (shown in color) are fused onto the CT image with a three-dimensional workstation.

Table 10.5 Advantages and disadvantages of positron emission tomography–computed tomography (PET-CT)

Advantages	Disadvantages
Physiologic and anatomical imaging	High dose of ionizing radiation
Fusion of CT improves spatial resolving power limitations of PET imaging	Significant expertise is needed to properly interpret examination
Excellent for staging and postoperative evaluation of head and neck carcinoma	Time-consuming examination, both in preparation and scan time
	Limited availability, large scanner, and requirement to be near cyclotron for production of radioactive tracer
	Confined imaging location/claustrophobia
	Very expensive
	Large, fixed imaging unit

and vestibule comprise the bony labyrinth. The cochlea has two and a half turns (apical, middle, and basal). The modiolus is the bony central portion of the cochlea seen on imaging. The lateral, superior, and posterior semicircular canals converge on the vestibule and are crucial for propagating information involved in balance. The cochlea and vestibular apparatus are very well visualized with CT and MR imaging. CT of the tem-

poral bone is integral in the evaluation of congenital malformations of the inner ear. Additionally, multiplanar reconstructions of the temporal bone allow excellent evaluation of the semicircular canals for dehiscence. The vestibular aqueduct is an important inner ear anatomical structure that is well visualized on thin-section CT scans and can be reliably assessed for enlargement.

Fig. 10.14 (a) Coronal view through the external auditory canal shows a sharply defined scutum, head, and long process of the malleus; an air-filled Prussak space; ventilated mastoid air cells; an intact tegmen tympani; and 1.5 turns of the cochlea. (b) Another coronal view of the scutum (s), tympanic membrane (tm), mastoid air cells (m), tegmen tympani (tt), and cochlea (c). The incudomalleolar joint is seen between the tegmen and the tympanic membrane.

External Ear

The external auditory canal is bound anteriorly by the glenoid fossa and posteriorly by the mastoid air cells and extends medially to the tympanic membrane. The external auditory canal, meatus, and auricle are well visualized on routine CT imaging. CT allows excellent characterization of associated anomalies of the ossicles, inner ear, and facial nerve canal in cases of external ear anomalies.

Facial Nerve

The facial nerve is a complex cranial nerve that spans numerous anatomical compartments and spaces. The primary modalities used to image the facial nerve include CT and MR imaging. There are three primary components of the facial nerve: visceral motor component/parasympathetic component (autonomic control to the lacrimal, submandibular, and sublingual glands); branchial motor component (innervation to the muscles of facial expression); and special sensory component (taste from the anterior two-thirds of the tongue). The visceral motor and branchial motor components arise from nuclei within the brainstem at the pontine tegmentum. The root entry zone and cisternal segments of the facial nerve can be well visualized with high-resolution T2-weighted balanced fast field imaging of the brain stem. Cranial nerves VII and VIII (including the superior and inferior vestibular divisions and cochlear division) can be identified with high-resolution imaging. This is of importance during an evaluation for vestibular schwannoma or congenital aplasia of the cochlear nerve. Imaging of the proximal intracranial segments of cranial nerve VII and VIII is best done at high-field-strength, 3-tesla MR imaging. The motor fibers of the facial nerve course ventrally and laterally at the cerebellopon-

tine angle to exit as the more anterior nerve. The canalicular segment of the facial nerve is located in the anterior superior quadrant of the internal auditory canal. The facial nerve has a complex path in the temporal bone that is poorly visualized on MR imaging. However, the bony facial nerve canal is well visualized on CT scan of the temporal bone. The geniculate ganglion of the facial nerve may be visualized on MR imaging. On contrast-enhanced MR imaging of the facial nerve, no enhancement should be seen in the pre-geniculate portions of the facial nerve, but normal enhancement may be seen in the post-geniculate segments of the facial nerve because of the extensive perineural blood supply. Enhancement in the pre-geniculate portions of the facial nerve is suggestive of neuritis or neoplasm. The facial nerve exits the temporal bone at the stylomastoid foramen, which is best visualized on coronal and axial CT scans. The facial nerve then courses anteriorly into the parotid gland, running superficial to the retromandibular vein and dividing into peripheral branches, many of which cannot be resolved with current imaging technology.

Sinuses

It is prudent to discuss the sinonasal apparatus in terms of drainage pathways, centered on the ostiomeatal complex serving as the common pathway for drainage of the anterior ethmoid, frontal, and maxillary sinuses, with the sphenoethmoidal recess serving to drain the posterior ethmoid and sphenoid sinuses. The ostiomeatal complex comprises the maxillary sinus os, the uncinate process, the infundibulum, and the hiatus semilunaris, with drainage into the middle meatus. The cilia within the maxillary sinus serve to steer drainage toward the superomedial ostium within the sinus. A bony extension, the uncinate process, projects superiorly from the superomedial

Fig. 10.15 Coronal view through the nose and sinuses, showing normal structures: maxillary sinus (ms), ethmoid sinus air cells (es), middle turbinate (mt), inferior turbinate (it), septum (s), uncinete process (asterisk), and inferior meatus (im). The middle meatus is located between the uncinete process and the middle turbinate, whereas the ethmoid infundibulum is located lateral to the uncinete process.

maxillary sinus wall. Lateral to the uncinete process, the hiatus semilunaris is the half-moon-shaped entry to the infundibulum, the trough lateral to the uncinete process, through which mucus drains into the middle meatus and eventually to the back of the nasal cavity. The osseous structures of the ostiomeatal unit are best assessed on coronal reformatted CT scans of the paranasal sinuses. The various bony landmarks and details are well appreciated on routine CT of the paranasal sinuses with coronal reconstructions (□ Fig. 10.15).

The lateral attachment of the middle meatus to the medial orbit is termed the basal lamella and serves as the anatomical landmark dividing the anterior from posterior ethmoid air cells. The air cell lying just superior to the infundibulum is termed the ethmoid bulla. The frontal sinuses, as do the anterior ethmoid air cells, drain directly to the middle meatus via the frontal recess. The sphenoid sinuses and posterior ethmoid air

cells drain via the superior meatus and the sphenoidal recess.

Ethmoid air cells of specific interest include agger nasi cells, Onodi cells, and Haller cells. Agger nasi cells are ethmoid air cells anterior and lateral to the frontal recess; they can obstruct frontal sinus outflow. Onodi cells are ethmoidal air cells that extend into the posterior orbit or sphenoid bone. Haller cells are anterior ethmoid air cells that are seen inferior to the orbit and extend into the maxillary sinus; they also can obstruct outflow.

The nasal cavity comprises the superior, middle, and inferior turbinates. Imaging of the nasal passage is straightforward. One must remain aware of nasal cycling, with alternating mucosal hyperemia in the nasal passages. This can lead the inexperienced imager to overcall nasal mass lesions. A simple rule of thumb in the evaluation of the nasal passages is that if a rim of air (no matter how thin) can be traced around the nasal mucosa, there is a low likelihood of a space-occupying mass lesion, and any asymmetry can be attributed to nasal cycling. Below the inferior turbinate, one finds the opening for the nasolacrimal duct, originating from the lacrimal sac; the bony canal for the nasolacrimal duct can often be identified on coronal images. The septum serves to divide the right and left nasal cavities and comprises an anterior cartilaginous portion and a posterior bony portion.

10.3.2 Head and Neck Mucosal Surfaces

Nasopharynx

The nasopharynx is bound by the mucosal surface that lies above the soft and hard palate. Posterolaterally, the eustachian tube orifice can be found. On either side of the eustachian tube are the tensor veli palatini and levator veli palatini. Deep to the mucosa of the nasopharynx, the buccopharyngeal fascia and pharyngobasilar fascia serve to prevent the spread of disease to the retropharyngeal and parapharyngeal spaces. Additionally, lymph nodes and minor salivary glands are found throughout the nasopharynx. The nasopharynx is well imaged with either CT or MR imaging. A rudimentary evaluation of the nasopharynx can be made with radiography. Close attention to the mucosa and submucosal fat planes may allow early detection of nasopharyngeal carcinoma. MR imaging may be particularly sensitive to evaluate for neoplasm. Sagittal reformatted images are a key component in the evaluation of the nasopharynx.

Oral Cavity

The lips, buccal and gingival surfaces, hard palate, anterior two-thirds of the tongue, and floor of the mouth comprise the oral cavity. The lingual space is the area between the mylohyoid muscle and the hyoglossus muscle; the lingual nerve and hypoglossal nerve and the sublingual gland are located in this space. The mylohyoid muscles define the floor of the mouth. The submandibular gland is found within the floor of the mouth and drains via the Wharton duct. Below the mylohyoid muscles, one finds the submental space. Determining the exact spaces involved by pathology is especially important because this greatly affects surgical approach. The oral cavity is an extremely difficult space to image. This is primarily because of extensive artifact that is generated by dental amalgam, and streak artifact on

CT scan will diminish its sensitivity and specificity. MR imaging results in magnetic susceptibility artifact, which appears as dark black holes on the image. These artifacts make evaluation of the oral cavity extremely challenging. A detailed history and any information from the physical examination help the interpreting radiologist to “read through the artifact.”

Oropharynx

As in the oral cavity and nasopharynx, minor salivary glands are found in abundance within the oropharynx. The imaging modality of choice for most oropharyngeal lesions is CT or MR imaging. The exception to this would be the evaluation of epiglottitis and croup in pediatric patients, in whom radiography is the first imaging modality typically employed because of its accessibility, speed, and relatively low radiation exposure.

Hypopharynx

The hypopharynx is most typically attended to on imaging when there is extension of squamous cell carcinoma to this region. It is well assessed with multiplanar CT or MR imaging. PET-CT can be very useful in evaluating the degree of neoplasm extension to the hypopharynx.

Larynx

The larynx is subdivided into the supraglottis, glottis, and subglottis. The cricoarytenoid joint is the marker for the level of the true vocal fold; however, this is often difficult to visualize. Another marker that is used is the paraglottic space, found lateral to the laryngeal mucosa, which contains fat at the false vocal fold level but contains muscle at the true vocal fold level. Again, multiplanar CT and MR imaging are the typical imaging modalities of choice in evaluating the larynx.

10.3.3 Soft Tissues of the Neck

Parapharyngeal Space

The prestyloid parapharyngeal space is readily identified on CT. This region is bound posteriorly by the carotid space, laterally by the parotid space, anteriorly by the masticator space, anteromedially by the oropharynx, and posteromedially by the retropharyngeal space. This area contains fat, lymphatics, small branches of the external carotid artery, and the mandibular nerve. However, this area is especially important in placing pathology into the various spaces of the neck by determining the displacement of the parapharyngeal fat. For example, a mass within the masticator space will displace the parapharyngeal fat posteromedially, whereas a mass from the parotid gland will displace the parapharyngeal fat anteromedially. This point will continue to be illustrated throughout the following sections. Lesions in the parotid space can be visualized very clearly with CT or MR imaging techniques. The axial imaging plane is usually the most useful plane for visualizing the parapharyngeal space.

Carotid Space

This space is also known as the post-styloid parapharyngeal space and extends the entire length of the neck. It contains the

carotid artery, internal jugular vein, cranial nerves IX through XII, and the sympathetic nerve plexus, as well as lymph nodes, which are found throughout its course. Lesions originating within the carotid space will displace the parapharyngeal fat anteriorly. The carotid space is best evaluated with multiplanar CT or MR imaging. Axial and sagittal planes allow the best visualization and delineation of this space.

Parotid Space

The parotid space contains the parotid gland, cranial nerve VII, and branches of cranial nerve V, as well as vasculature including external carotid artery branches and the retromandibular vein. The deep portion of the parotid gland extends through the stylomandibular tunnel, found between the mandibular ramus and the digastric and sternocleidomastoid muscles. Most of the gland is superficial to the masseter muscle and the mandible. The Stensen duct drains the parotid gland passing over the masseter muscle and then pierces the buccinator muscle before terminating within the buccal mucosa. The parotid gland is relatively superficial and amenable to excellent visualization with ultrasound, CT, or MR imaging modalities. Lesions within the parotid gland are best characterized with CT or MR imaging; however, many solid lesions may require biopsy or surgical resection because the specificity of imaging in the delineation of benign versus malignant neoplasm of the parotid gland is poor.

Masticator Space

The muscles of mastication, including the temporalis and masseter muscle as well as the medial and lateral pterygoid muscles, are contained by the superficial layer of the deep cervical fascia in the masticator space. The mandibular ramus is centrally located in the masticator space and contains the inferior alveolar nerve, which traverses the masticator space. Other contents include branches of the mandibular division of the trigeminal nerve and the inferior alveolar vein and artery. The buccal space is often included in a discussion of the masticator space because of its close physical proximity to the masticator space and its lack of true fascia boundaries. The masticator space is ideally imaged with CT or MR imaging. The axial and coronal imaging planes are the most useful orientations to appreciate the relevant anatomy and spread of disease.

10.4 Roundsmanship

- Emergent imaging of the head and neck frequently will involve one of two entities: infection or airway obstruction. Contrast-enhanced CT of the neck is the examination of choice to evaluate for acute head and neck infection in most cases and will also adequately assess the airway. In the pediatric population, one may consider radiography to evaluate and exclude epiglottitis because of the decreased radiation dose.
- Reviewing your imaging studies with your interpreting radiologist will likely greatly improve the accuracy of the interpretations and allow the highest-quality medical care for your patients. Do not hesitate to consult your radiologist frequently. Head and neck imaging is challenging, even for many experienced neuroradiologists, and feedback from the

ordering otolaryngologist often leads to the most accurate interpretations.

- Be aware of radiation doses and possible side effects of IV contrast material when ordering imaging of the head and neck. If there is a risk–benefit question, always consult your radiologist.
- Remember that image-guided (CT or ultrasound) percutaneous needle biopsy of deep lesions of the head and neck is a service that is available at many institutions.

11 Radiographic Imaging of Common Clinical Presentations in Otolaryngology–Head and Neck Surgery

Hasit Mehta and Ajay Hira

11.1 Introduction

The radiologic imaging of a number of disorders of the head and neck can be highly distinctive and often diagnostic. A number of clinical scenarios and the characteristic radiologic

appearance of each are described below. The reader is referred to the previous chapter for more detailed discussions of the various imaging modalities available.

Fig. 11.1 Coronal computed tomography (CT) through the temporal bone demonstrates marked diastasis of the left incudomalleolar joint, compatible with ossicular dislocation. This is the appearance of the “ice cream scoop” falling off the “cone.” The partially visualized right incudomalleolar joint demonstrates a tight joint space and no diastasis. CT of the temporal bone (with coronal and axial thin sections) is the ideal imaging modality to make this diagnosis.

Fig. 11.2 Axial (a) and coronal (b) computed tomographic scans of the temporal bone demonstrate extensive otomastoiditis with associated petrous apicitis. There is erosion of the many septa within the mastoid air cells, as well as erosion into the middle cranial fossa. In this situation, magnetic resonance imaging of the brain would be useful to evaluate for possible intracranial extension of an infectious process.

Fig. 11.3 (a) Axial and (b) coronal projections through the temporal bone. The scutum is sharp. There is a 2-mm ovoid soft-tissue-density lesion noted above the left tympanic membrane that may be contiguous with the tympanic membrane, compatible with a small primary congenital cholesteatoma. In another patient, (c) axial and (d) coronal views show a 4-mm ovoid soft-tissue mass in the left middle ear medial to the left ossicular chain, in close proximity to the expected location of the long process of the incus and stapes. These findings are compatible with congenital cholesteatoma. Other diagnoses to consider include facial nerve schwannoma (although there is no evidence of expansion of the bony facial nerve canal) and glomus tympanicum. Correlation with direct examination is useful. In another patient, soft tissue in the left middle ear and mastoid associated with bony erosion on (e) axial and (f) coronal computed tomographic scans is more suggestive of acquired cholesteatoma.

11.2 Disorders of the Ear

11.2.1 Ossicular Discontinuity

(□ Fig. 11.1)

The diagnosis of traumatic ossicular dislocation is best visualized on thin-section computed tomographic (CT) scans of the temporal bone. Ossicular dislocation is often seen with traumatic temporal bone fracture. Ossicular injury and conductive hearing loss are more commonly seen with longitudinal and longitudinal oblique fractures of the temporal bone than with posterior transverse fractures of the temporal bone, which may present with sensorineural hearing loss. The most common ossicular dislocation is dislocation of the incudomalleolar joint.

The incudomalleolar joint is a true joint with a joint capsule and is best visualized on high-resolution axial CT scans of the temporal bone. Diastasis of the head of the malleus and short process of the incus is characteristic of incudomalleolar dislocation and may also be appreciated on coronal imaging. Incudostapedial ossicular dislocation is less common and more difficult to visualize. This is typically best seen with coronal high-resolution sagittal imaging of the temporal bone. Careful attention must be given to the long process of the incus and the head of the stapes. Often, in the acute traumatic setting, with extensive blood product and debris within the middle ear, the diagnosis of ossicular dislocation may not be made. Follow-up CT of the temporal bone after resolution of the acute traumatic injury may be useful in this case. Occasionally, portions of the incus,

Fig. 11.4 Noncontrast thin-section computed tomographic (CT) scans of the temporal bone in the (a) axial and (b) coronal planes demonstrate small regions of lucency within the temporal bone just anterior to the oval window bilaterally in the region of the fissula ante fenestram, right greater than left. This finding is typically seen in early fenestral otosclerosis. The remainder of the otic capsule appears spared. (c) Axial CT scan demonstrating radiolucent appearance about the cochlea, giving the appearance of an extra turn about the left cochlea. (d) Axial magnetic resonance image demonstrates enhancement around the left cochlea. Both of these imaging findings are characteristic of cochlear otosclerosis.

malleus, and stapes may be completely disrupted, with free-floating bone fragments in the middle ear; close attention to the osseous structures on coronal, axial, and sagittal planes is necessary to make this diagnosis.

11.2.2 Chronic Ear Disease, Mastoiditis, and Cholesteatoma (□ Fig. 11.2)

Chronic otitis media demonstrates soft-tissue accumulation in the middle ear and mastoid cavities. Often, the ossicles are surrounded by a dense, sometimes calcific soft-tissue mass; bone erosion may be seen. The normal septa of the mastoid cavity may be broken down, creating a large central cavity filled with soft tissue. The disease can spread into an aerated petrous

apex. Potential erosion into the middle cranial fossa should be examined.

Acquired cholesteatomas are collections of keratinous debris that lead to infection and inflammation. Soft tissue will be seen within the middle ear cavity, and erosive change can involve the mastoid air cells and inner ear structures. The most common type of cholesteatoma is the acquired pars flaccida subtype. The pars flaccida subtype begins in the Prussak space, between the scutum and the incus. On CT, soft tissue is seen within the Prussak space. This by itself is a nonspecific finding. However, larger lesions will be accompanied by osseous erosion, which is very characteristic of acquired cholesteatomas and can lead to ossicular chain disruption and erosion of the scutum. The more uncommon pars tensa subtype will begin

Fig. 11.5 (a,b) Axial and (c) coronal computed tomographic scans of the temporal bone demonstrate an extensive, high-density deposition within the membranous labyrinth. This may present with sensorineural hearing loss, often secondary to a traumatic or infectious insult to the inner ear. (d) Axial high-resolution T2 images through the region of the internal auditory canals demonstrate a paucity of expected endolymph in the right membranous labyrinth, compatible with labyrinthine ossification. In severe cases, the cochlear nerve may be small.

with soft tissue within the posterior mesotympanum medial to the ossicles. The scutum is usually spared, unlike in the pars flaccida subtype. Extension of a cholesteatoma into the mastoid air cells is common. Additional complications include semicircular canal fistulas, erosion of the tegmen tympani, and dehiscence of the tympanic segment of the facial nerve. Noncontrast CT of the temporal bones is the imaging test of choice to assess for the aforementioned findings. Magnetic resonance (MR)

imaging can also be utilized to demarcate a nonenhancing cholesteatoma from enhancing granulation tissue, but this is generally unnecessary, with cholesteatomas appearing hypointense on T1, of intermediate intensity on T2, and nonenhancing. Congenital cholesteatomas (□ Fig. 11.3) develop because epidermal rests reside in the middle ear cleft embryologically. These are typically more anteriorly located and may not have the same degree of bony erosion as acquired cholesteatomas.

Fig. 11.6 The imaging of superior semicircular canal dehiscence requires high-resolution, thin-section (1-mm or smaller interval) temporal bone imaging; additionally, oblique multiplanar reformatted images are useful in demonstrating the entire course of the superior semicircular canal to adequately detect dehiscence. This image is an oblique coronal view through the inner ear structures. The roof of the left superior semicircular canal is dehiscence into the left middle cranial fossa, with marked demineralization.

Fig. 11.8 Axial T1 images through the cerebellopontine angle region (a) before and (b) after contrast demonstrate curvilinear enhancement involving the most distal segment of the right internal auditory canal and extending to the labyrinthine and geniculate segments of the right facial nerve, which appear enlarged. Portions of the horizontal segment of the right facial nerve also appear enlarged in a tapered fashion. This configuration is characteristic of facial nerve schwannoma. Other etiologies that could have a similar appearance include metastatic disease and lymphoma. Facial neuroma/schwannoma may occur along any segment of the facial nerve. The geniculate ganglion is often involved. The symptomatology depends on which segment of the facial nerve is involved. In distinguishing between facial schwannoma and other etiologies, expansion of the facial nerve canal is highly suggestive of facial schwannoma, excluding inflammatory neuritis. When the lesion enters the internal auditory canal and cerebellopontine angle, it may be indistinguishable from vestibular schwannoma.

Fig. 11.7 Noncontrast computed tomographic scan of the temporal bone in the (a) axial, (b) coronal, and (c) sagittal planes demonstrates a large, destructive mass lesion involving the petrous portion of the left temporal bone. The mass extends to the clivus, involving portions of the basisphenoid. The lesion is centered in the region of the petroclival synchondrosis, characteristic of an aggressive skull base chondrosarcoma. Typically, these lesions contain extensive calcified chondroid matrix in a ring-and-arc type of pattern; however, this patient's lesion demonstrates minimal intratumoral calcified matrix, making the diagnosis more difficult. This diagnosis should be included in the differential of a large expansile lesion with regions of mixed osseous structures within the lesion. Other diagnoses to consider include metastatic lesions, plasmacytoma, petrous apex cholesteatoma, and chordoma.

Fig. 11.9 Axial T1 postcontrast magnetic resonance imaging through the region of the cerebellopontine angle demonstrates a large enhancing lesion that extends from the internal auditory canal through the internal auditory meatus/porus acusticus into the cerebellopontine angle. The appearance of this lesion is that of an ice cream cone (with the scoop of ice cream melting off into the cerebellopontine angle) and is characteristic of vestibular schwannoma. With a large canal-to-cerebellopontine angle schwannoma, it is impossible to distinguish between vestibular and facial schwannoma. Schwannomas typically enhance homogeneously, although when they are large, the central portions may demonstrate heterogeneous enhancement, as in this case. Differential considerations include meningioma, lymphoma, and metastatic disease.

Fig. 11.10 Postcontrast T1-weighted (a) axial and (b) coronal images of the brain demonstrate canicular enhancement of the right facial nerve extending to the labyrinthine segment as well as the geniculate ganglion. The differential diagnosis for this finding primarily includes facial nerve schwannoma, neuritis (e.g., Bell palsy), and metastatic cranial nerve lesion. Inflammatory processes, such as sarcoidosis or Lyme disease, may also present with cranial nerve enhancement. However, this patient was known to have lymphoma, which can present with cranial nerve enhancement. Additionally, more cephalic images demonstrated asymmetric abnormal enhancement of the right trigeminal nerve, compatible with lymphomatous involvement of cranial nerve V. Computed tomography of the temporal bones may be useful to differentiate cranial nerve mass lesions (e.g., schwannoma) from neuritis because a mass lesion typically will demonstrate remodeling and enlargement of the osseous structures when the mass is large enough.

Fig. 11.11 (a) Soft-tissue and (b) bone axial window computed tomography (CT) is the imaging modality of choice for choanal atresia. Thin-section CT of the maxillofacial region as well as maximum-intensity-projection reconstructions may be obtained to evaluate more completely the nasal passage and nasal choanae. In this case, the posterior nasal cavity is narrow, with bony atresia of the left choana and a small membranous component inferiorly. The vomer is enlarged asymmetrically, left greater than right. The left maxillary sinus is rotated laterally. There is no significant air–fluid level in the nasal passage. These findings are typical for left choanal atresia.

11.2.3 Otosclerosis/Otospongiosis

Fenestral otospongiosis is more common than cochlear otosclerosis. Young and middle-aged patients often present with progressive conductive or with mixed conductive and sensorineural hearing loss. Often, symptoms and findings are bilateral. In fenestral otospongiosis, radiographic findings begin at the anterior margin of the oval window, which is called the fissula ante fenestram. On CT, this begins as a hypoattenuating focus at the fissula ante fenestram (□ Fig. 11.4a, b). However, with time, this often spreads to involve the additional margins of the oval and round windows. Over time, or in cochlear otosclerosis, demineralization can involve the middle and basal turns of the cochlea, resulting in an apparent double ring or halo appearance of hypoattenuation surrounding the cochlea (□ Fig. 11.4c, d). In the late healing phase, new bone or increased sclerosis will be seen along the oval and round windows. MR imaging, often not needed in the evaluation, may demonstrate subtle enhancing foci within the medial portions of the middle ear in the regions of the oval and round windows.

11.2.4 Labyrinthine Ossificans (□ Fig. 11.5)

Following trauma, infection, or inflammation, the activation of fibroblasts or osteoblasts may result in fibrosis or ossification within the cochlea. Most commonly, this follows meningitis in young children, resulting in bilateral sensorineural hearing loss. Less commonly, the semicircular canals or vestibule can be involved. On CT, dense sclerosis of the labyrinthine portion of the cochlea is seen. On T2 MR imaging, low-intensity foci will be

seen within the fluid-filled spaces of the inner ear, most often the cochlea. This can be seen as an apparently increased size of the modiolus, which is normally of low signal intensity on T2-weighted sequences.

11.2.5 Superior Semicircular Canal Dehiscence (□ Fig. 11.6)

Semicircular canal dehiscence is best imaged with thin-section CT of the temporal bone. The coronal or paracoronal imaging plane is usually the best for evaluating the semicircular canal. To diagnose semicircular canal dehiscence on imaging, one must note extreme demineralization and thinning of the bony covering of the semicircular canal measuring 2 mm or greater, typically the superior posterior semicircular canal. If the region of dehiscence is less than 2 mm, it may represent a normal anatomical variant, with thinning rather than complete dehiscence of the bony covering of the semicircular canal. Semicircular canal dehiscence may present with vestibular disturbance. Typically, the region of dehiscent or thinned bone measures 2 to 5 mm. Semicircular canal dehiscence may also be visualized with high-resolution T2 MR imaging, typically with an internal auditory canal protocol of the brain.

11.2.6 Temporal Bone Chondrosarcoma (□ Fig. 11.7)

Chondrosarcoma is included within the differential of skull base neoplasms and will be found off midline, most often at the petro-occipital fissure. CT is important in the evaluation of skull

Fig. 11.12 Sinusitis. (a) Acute sinusitis. Axial noncontrast computed tomographic (CT) scan of the paranasal sinuses demonstrates an air–fluid level in the right maxillary paranasal sinus with a bubbly stranding at the medial aspect of the air–fluid level. These findings are suggestive of acute sinusitis. (b,c) Chronic sinusitis. Axial noncontrast CT scans through the paranasal sinuses demonstrate complete opacification of the maxillary paranasal sinuses. Severe bony hypertrophy, sclerosis, and thickening noted about the maxillary paranasal sinuses are compatible with chronic sinusitis, which is most easily appreciated on the axial image provided in (b) bone window width and level. Inspection of the maxillary paranasal sinus using (c) soft-tissue window demonstrates hyperdensity in the central portion of the opacified maxillary paranasal sinuses, which may represent inspissated secretions or fungal sinusitis change.

base masses and will best demonstrate the chondroid tumor matrix, which helps in distinguishing this tumor from other lesions involving the skull base. Chondroid matrix has been described as arclike or ringlike calcifications, or it may be amorphous, appearing as osteoid matrix that demonstrates cortical and medullary elements. The masses appear aggressive and will

result in bone destruction and expansion. On MR imaging, the tumor will demonstrate low signal intensity on T1 and high signal on T2. Calcifications will appear dark on T1- and T2-weighted sequences. Enhancement will be heterogeneous on CT and MR imaging.

Fig. 11.13 Silent sinus syndrome. (a) Note the small left maxillary sinus with thickening of the lateral wall of the left maxillary sinus. There is associated enlargement of the left orbital contents. (b,c) Note the lateral position of the left uncinat process with narrowing of the infundibulum. These patients may present with enophthalmos and involution of the maxillary sinus after occlusion of the infundibulum. Coronal computed tomography is the ideal imaging modality to make this diagnosis.

Fig. 11.14 (a) Coronal and (b,c) axial computed tomographic scans through the paranasal sinuses demonstrate extensive paranasal sinus opacification, particularly involving the right ethmoid and maxillary paranasal sinuses. There is associated extensive soft-tissue swelling and collection from the right medial canthus region to the soft tissues overlying the right nasal bridge, as well as both pre- and postseptal right orbital cellulitis. These findings are typical of sinusitis with the complication of Pott's puffy tumor and associated soft-tissue abscess. This patient subsequently underwent magnetic resonance imaging of the brain. (d) A soft-tissue abscess is seen in the right frontal to periorbital soft tissues. Multiplanar imaging of the brain demonstrates extensive intracranial extension of this infectious process with associated dural hyperemia (d), compatible with meningitis and associated subdural phlegmon/early empyema, as well as extensive edema within the right greater than left frontal lobes, compatible with cerebritis (e,f). This entity can lead to rapid central nervous system deterioration and death, particularly if there is thrombophlebitis of the intracranial cortical veins and/or intracranial dural venous sinuses.

11.3 Lesions of the Central Nervous System

11.3.1 Internal Auditory Canal Lesions (□ Fig. 11.8 and □ Fig. 11.9)

Schwannomas of the facial nerve may arise anywhere along the course of the nerve. Given the proximity of the nerve to the vestibulocochlear nerve, patients will present with hearing loss more often than facial nerve palsy. On noncontrast temporal bone CT, expansion of the bony facial nerve canal will be seen. On MR imaging, nodularity of the facial nerve will be seen best visualized on thin-section, high-resolution T2-weighted images. However, fat-saturated T1-weighted imaging will demonstrate the extent of the mass most clearly (see □ Fig. 11.8). It is important to realize that the facial nerve can demonstrate enhancement normally distal to the anterior genu. However, the facial nerve should never demonstrate enhancement within the cisternal (cerebellopontine angle), meatal (internal auditory

canal), and extracranial segments. Enhancement can be seen with a facial nerve schwannoma, perineural spread of another head and neck malignancy, or inflammation associated with idiopathic facial paralysis (Bell palsy).

Often, enhancing masses will be seen at the cerebellopontine angle. Diagnostic considerations for these masses include schwannomas, epidermoid cysts, meningiomas, arachnoid cysts, and metastasis, to name a few. Schwannomas on imaging will be avidly enhancing, similar to a meningioma or metastasis. However, enhancement and the mass will extend into the porus acusticus, unlike a meningioma, which will often demonstrate a dural tail of enhancement. Furthermore, a schwannoma will have a dumbbell appearance, with the waist of the mass at the porus acusticus, and will also expand the porus acusticus. Epidermoid and arachnoid cysts, on the other hand, will not enhance. Arachnoid cysts will follow the signal intensity of cerebrospinal fluid on all sequences, and epidermoid cysts will demonstrate restricted diffusion, evident as high signal on diffusion-weighted imaging and decreased signal on apparent diffusion coefficient (ADC) maps.

Fig. 11.15 Postcontrast axial images through the maxillofacial region (a) demonstrate extensive cellulitis and phlegmon in the left premaxillary tissues extending to the left nasal soft tissues. Additionally, abutting the left anterior maxilla there is a well-demarcated ovoid abscess (asterisk). A more cephalic image (b) demonstrates an ovoid hypoenhancement (asterisk) in the left cavernous sinus, consistent with left cavernous sinus thrombosis. Close attention to the cavernous sinus is necessary because this lesion can rapidly lead to death from sepsis or overwhelming intracranial central nervous system infectious involvement.

11.3.2 Central Nervous System Lymphoma (□ Fig. 11.10)

Central nervous system (CNS) lymphoma can be separated into two major categories: primary CNS lymphoma and metastatic CNS lymphoma. For the purposes of this text, metastatic intracranial lymphoma will be briefly discussed. Metastatic intracranial lymphoma can involve any portion of the CNS structures; however, it is typically seen as a dural or leptomeningeal lesion. Metastatic CNS lymphoma may also affect peripheral nerves. MR imaging of the brain with contrast is the best imaging modality to evaluate for CNS lymphoma. CNS lymphoma is a great imaging mimicker and may appear in any fashion; however, multiple T2 isointense to hypointense lesions with avid enhancement are typical of CNS lymphoma. On the CT scan, lymphoma may be hyperdense because of its low cytoplasmic-to-nuclear ratio. When CNS lymphoma involves the dura, meninges, and cranial nerves, the primary differential considerations vary depending on the location. For the purposes of this text, when enhancement is seen about the trigeminal nerve, facial nerve, or vestibulocochlear nerve, one must consider the possibility of metastatic lymphoma as well as other etiologies, including a peripheral nerve sheath tumor from a phakomatosis such as neurofibromatosis or a primary peripheral nerve sheath tumor such as schwannoma. Other neoplastic processes may metastasize to the cranial nerves, such as breast or lung carcinoma. These neoplasms also have a propensity for leptomeningeal and dural spread with CNS metastases. The other major category of disease processes that may present with cranial nerve enhancement includes inflammatory or infectious processes that result in neuritis, such as Bell palsy or Lyme disease. Typically, these lesions do not have a masslike appearance.

11.4 Disorders of the Nose and Paranasal Sinuses

11.4.1 Choanal Atresia (□ Fig. 11.11)

Choanal atresia is a narrowing of the posterior nasal apertures. Patients will present with respiratory distress during feeding, especially if the stenosis is bilateral. High-resolution noncontrast CT is used to characterize the stenosis and to assess for membranous or osseous obstruction. Before imaging, it is important to suction secretions from the nasal cavity. The choana will measure less than 0.34 cm, and the vomer will be thickened to more than 0.23 cm. Either soft tissue or bone may be seen obstructing the posterior choana. Additionally, the posterior walls of the maxilla may be bowed medially.

11.4.2 Sinusitis

Imaging may play a role in acute sinusitis in the setting of medically refractory sinusitis or when there is clinical concern for spread to adjacent orbital or cranial structures. Noncontrast CT of the paranasal sinuses is the typical modality of choice to evaluate for acute paranasal sinus disease. If there is a high degree of clinical suspicion for concomitant spread of infection into the orbit or cranial vault, MR imaging with and without contrast may be obtained. The imaging hallmark of acute sinusitis is an air–fluid level within a paranasal sinus, oftentimes seen with strandy or bubbly secretions, as well. These findings are most easily appreciated in the maxillary sinus. It may be difficult to appreciate an air–fluid level within the ethmoid and frontal paranasal sinuses because of their relatively small size. Mucosal thickening and polypoid lesions within the paranasal

Fig. 11.16 Extensive opacification with hyperdensity and stippled calcifications is seen on computed tomographic scans (a–c) and sagittal T2 magnetic resonance (MR) imaging (d) within the entirety of the visualized right maxillary, ethmoid, sphenoid, and frontal sinuses. There is associated expansion and thinning of the sinus walls, including the posterior lateral wall of the right maxillary sinus, right lamina papyracea, and entire sphenoid sinus. On T2 axial MR imaging (e), thickened, inspissated secretions in the expanded right ethmoid sinuses are hypointense and can be missed. Although this lesion may appear to the inexperienced imager to mimic a neoplastic aggressive mass lesion, these findings are suggestive of chronic allergic fungal sinusitis in the correct clinical setting.

sinuses may mimic an air–fluid level. Conversely, nearly complete opacification of any of the paranasal sinuses with fluid may mimic a large polypoid lesion.

Imaging in the setting of sinusitis is often nonspecific. Radiologic reports will focus on descriptive comments regarding location, configuration, and the magnitude of mucosal thickening and opacification. In the differentiation of chronic from acute sinusitis, attention must be turned to the bony confines of the paranasal sinuses. With long-standing chronic paranasal sinus disease, there is often a periosteal reaction and thickening of the bony confines of the affected paranasal sinus. This may be termed mucoperiosteal thickening. The bony confines may become extremely thick and hyperdense. When chronic sinusitis is suspected, CT of the paranasal sinuses may be obtained to evaluate for anatomical variants of the paranasal sinuses that may predispose to the development of chronic sinusitis. CT is the imaging modality of choice to evaluate for chronic sinusitis because it allows the most complete assessment of the bony confines of the paranasal sinuses. Attention to the soft-tissue

window when the paranasal sinuses are examined is important to evaluate for hyperdense paranasal sinus disease. On MR imaging, the appearance of secretions and the sinuses is related to the proteinaceous content of the secretions. In general, as the protein content increases, the appearance will become more intense on T1-weighted imaging and less intense on T2-weighted imaging; however, as the secretions become more solid or mineralized (as in fungal sinusitis), their appearance can be dark on T1- and T2-weighted imaging and can thus mimic an aerated sinus. If hyperdense material is appreciated in the paranasal sinuses, one must exclude fungal sinusitis. Other etiologies for hyperdense paranasal sinus disease are inspissated secretions, blood product, or hyperdense mass lesion.

The location of the mucosal thickening, as well as the presence of any anatomical variants, is essential in planning sinus surgery. Often, sinonasal disease is categorized into a number of patterns, including infundibular, ostiomeatal complex, sphenoidal recess, sporadic, polyposis, frontal recess, and dental source. In the infundibular pattern, disease is limited to

Fig. 11.17 (a) Coronal bone and (b) soft-tissue window computed tomographic scans demonstrating opacification of the left maxillary sinus with polypoid extension into the middle meatus and posterior nose without significant bone erosion, consistent with an antrochoanal polyp.

Fig. 11.18 (a) Axial and (b) coronal noncontrast computed tomographic scan of the paranasal sinuses demonstrates paranasal sinus opacification (most prominent in the right maxillary sinus), mucosal thickening, and partial opacification. There is a large polypoid component extending into the right nasal passage with extensive destruction of the right middle nasal turbinates and portions of the right inferior nasal turbinate. These findings suggest an aggressive polypoid lesion, and the extensive osseous destruction suggests malignant degeneration. Tissue pathology was consistent with a squamous cell carcinoma arising from an inverted papilloma.

the maxillary sinus, with obstruction of the ostium. In the ostiomeatal complex pattern, disease is often variable but involves the sinuses that drain via the ostiomeatal complex (anterior ethmoid, maxillary, and frontal sinuses). In the sphenoidal recess pattern, disease involves the sphenoid sinus and posterior ethmoid air cells. The sporadic pattern is, as the name implies, more random in appearance and cannot be classified by a specific drainage pattern. The sinonasal polyposis pattern is characterized by polypoid-appearing lesions within

the sinuses. The frontal recess pattern is characterized by occlusion of the frontal recess, resulting in disease within the ipsilateral frontal sinus. The dental source pattern is characterized by maxillary disease, with lucent, cystic-appearing lesions involving the maxillary teeth (□ Fig. 11.12 and □ Fig. 11.13).

Moreover, care should be taken to evaluate for potential complications of sinusitis. The visualized brain parenchyma should be carefully assessed to evaluate for the presence of an epidural or subdural abscess (□ Fig. 11.14). This will appear as a

Fig. 11.19 (a) Contrast-enhanced computed tomographic scan of the maxillofacial region demonstrates a large, hyperenhancing soft-tissue mass arising from the region of the right sphenopalatine foramen that involves the right anterolateral nasopharyngeal wall and extends into the right nasal passage. (b,c) There is associated extension into the pterygopalatine fossa with mild osseous erosion of the base of the right pterygoid plate. The findings are compatible with juvenile nasopharyngeal angiofibroma. These lesions are often treated with endovascular embolization before surgical resection to aid hemostasis. (d) Note the large, extremely hypodense ovoid collection in the anterior right nasal passage; this represents hemostatic packing material and a balloon tamponade catheter.

hyperdense fluid collection resulting in mass effect and displacement of the underlying brain parenchyma. If contrast was administered, enhancement of the dura will make the empyema more conspicuous. On MR imaging, diffusion weighted sequences, if obtained, will demonstrate increased signal, indicating empyema. In the setting of ethmoid disease, infection will often spread to the adjacent orbit.

Additionally, in the setting of contrast administration, evaluation of the cavernous sinuses is important to evaluate for the presence of thrombosis. A thrombosed cavernous sinus will demonstrate enlargement, and a hypodense clot may be seen on CT (□ Fig. 11.15). Secondary signs of cavernous sinus thrombosis include engorgement of the ipsilateral superior ophthalmic vein. On MR imaging, evaluation of the cavernous sinus for

Fig. 11.20 Left nasopharyngeal carcinoma. (a) On T1 precontrast imaging, the lesion is isointense to muscle, but (b,c) it is hyperintense to muscle on postcontrast T2 imaging with fat suppression. The mass lesion is centered in the left nasopharynx with effacement of the left fossa of Rosenmüller and the left eustachian tube. These structures are preserved in the uninvolved right nasopharynx.

thrombosis is best performed with routine contrast-enhanced sequences. High-resolution three-dimensional gradient-echo sequences may be employed after the administration of contrast to interrogate the cavernous sinus. Alternatively, imaging performed with a sellar protocol allows evaluation of the cavernous sinus. It is important to note that MR venography will not allow adequate evaluation of the cavernous sinuses.

Allergic fungal sinusitis results in the opacification and expansion of multiple sinuses. On imaging, this can appear very aggressive, with diffuse involvement resulting in bony remodeling and apparent cortical thinning or erosion (□ Fig. 11.16a–c). However, centrally within the sinuses, hyperdense secretions will be seen. On MR imaging, as described above, signal characteristics are variable depending on the proteinaceous content of the secretions. Typically, these secretions are hypointense on T2 sequences and variable on T1 sequences (□ Fig. 11.16d, e).

11.4.3 Antrochoanal Polyp (□ Fig. 11.17)

An antrochoanal polyp is an inflammatory polyp arising from the maxillary sinus antrum and herniating through the maxillary os into the nasal cavity. It is most often found in adolescents and young adults, who present with unilateral nasal obstruction. On imaging, the lesion is dumbbell-shaped, bridging the maxillary sinus and nasal passage and expanding the maxillary ostium. On CT, the mass will be of low density and demonstrate peripheral enhancement. Depending on the water or mucoid content, the mass will be of low intensity on T1 and of high intensity on T2. Of course, this can vary depending on the protein content of the lesion. Enhancement will be peripheral, as on CT.

11.4.4 Inverting Papilloma

Papillomas are most often centered in the middle meatus and may result in obstructive sinonasal disease. On CT, a soft-tissue

mass with nonspecific characteristics will be seen (□ Fig. 11.18a, b). Calcifications will often be seen within the mass. On MR imaging, the mass will demonstrate isointensity on T1 and T2 sequences. The enhancement pattern has been described as curvilinear or “cribriform.” It is important to note that squamous cell carcinoma often coexists with inverting papillomas.

11.5 Disorders of the Pharynx

11.5.1 Juvenile Nasal Angiofibroma

A juvenile nasal angiofibroma is a benign, highly vascular, locally aggressive tumor typically affecting young male adolescents, who present with nasal obstruction and recurrent epistaxis. On imaging, the mass will enhance intensely and often originates from the sphenopalatine foramen or the pterygopalatine fossa (□ Fig. 11.19a, b). It is important to look for local spread of the mass. Common locations of local spread include the paranasal sinuses (most commonly the sphenoid sinus), or the tumor may spread via the pterygopalatine fossa, vidian canal, or foramen rotundum to extend into the orbit or infratemporal fossa, or intracranially. This is especially important to recognize to ensure proper surgical planning for a complete resection.

On CT, the mass is isodense to muscle and demonstrates marked enhancement (□ Fig. 11.19c,d). The mass does demonstrate locally aggressive features, and imaging will show bony remodeling and destruction, including bowing of the nasal septum and posterior wall of the maxillary sinus and enlargement of the pterygopalatine fossa. As mentioned above, the mass is found within the nasal cavity; however, local spread must be evaluated thoroughly. MR imaging will demonstrate a heterogeneous mass that is isointense to skeletal muscle on T1-weighted and of intermediate to high intensity on T2-weighted images. Flow voids, often described as having a “salt and pep-

Fig. 11.21 Magnetic resonance (MR) imaging with (a) T1 precontrast, (b) T1 postcontrast, and (c) T2 with fat saturation sequencing of a right floor of mouth squamous cell carcinoma (SCCa) with extension and destruction of the right mandibular body. The neoplasm extends beyond the mandible into the right masticator space. MR imaging and CT are the best modalities to evaluate the extent of local disease in SCCa; positron emission tomography–computed tomography (PET-CT) is the imaging modality of choice for staging SCCa for both regional and distant metastasis.

Fig. 11.22 (a) Axial postcontrast computed tomographic (CT) scan demonstrating a sialolith in the distal right submandibular duct. There is associated dilatation and likely infection within the right submandibular duct. (b) There are enlargement and enhancement of the right submandibular gland, compatible with sialadenitis (c). Note the small reactive lymph nodes at the right IB level. CT is the imaging modality of choice for the evaluation of salivary stone disease. If there is concern for very small stones, CT may be performed before and after contrast to avoid mistaking a small enhancing branch of the external carotid artery for a sialolith.

per” appearance, are often seen throughout the mass, illustrating its increased vascularity. Local extension is best evaluated with fat-saturated postcontrast imaging.

Before surgery, these patients will often be embolized to reduce intraoperative blood loss. On catheter angiography, the tumor will demonstrate a prominent capillary blush and is most often fed via branches of the internal maxillary and ascending pharyngeal arteries. Endovascular embolization is often accomplished with the use of particles. Alternatively, tumor emboliza-

tion may be accomplished percutaneously with the use of liquid embolic agents such as n-butyl cyanoacrylate (Onyx; eV3, Irvine, CA).

11.5.2 Cancer of the Pharynx

Most malignancies involving the mucosal surfaces of the head and neck are squamous cell cancer. The role of imaging is not to provide a histologic diagnosis, but rather to define the extent of

Fig. 11.23 Pleomorphic adenoma of the deep lobe of the left parotid gland. These lesions are usually smooth and ovoid in shape, with relatively homogeneous enhancement. (a) They have low intensity on T1, (b) enhance brightly with contrast, and (c) may have extremely high T2 signal, as in this case, which increases the specificity of the diagnosis of pleomorphic adenoma. The T1 signal varies depending on the presence of protein and/or blood products within the lesion. Larger lesions demonstrate a lobulated appearance and more heterogeneous enhancement. Computed tomography is adequate in sensitivity for the detection of parotid adenoma; however, its specificity is not as high as that of magnetic resonance imaging. Ultrasound should be used with caution because lesions in the deep lobe of the parotid may not be well visualized.

Fig. 11.24 Left parotid mucoepidermoid carcinoma. (a) T1 precontrast image shows a tumor arising from the deep lobe of the parotid gland and invading the left masticator space. (b) Image with contrast enhancement. (c) T2 signal abnormality extends to the left mandibular ramus, indicative of osseous extension, with likely perineural extension along the inferior alveolar nerve. Note the infiltration and involvement of the left pterygoid musculature.

disease to better stage the malignancy and aid in making treatment-related decisions. Squamous cell carcinoma is generally isodense to muscle on CT, isointense to muscle on T1-weighted images, and mildly hyperintense on T2-weighted images, and it will demonstrate modest enhancement. However, background enhancement of lymphoid tissue will often limit detection. The key to detection and defining extent is to be mindful of the fat planes and fatty architecture normally present within the muscles and spaces of the neck.

For example, replacement of the fat (bright on T1) in front of the prevertebral musculature may suggest invasion, making carcinoma potentially unresectable. Muscle invasion can also be suggested by increased T2 signal within the muscle or nodular

enhancement of the muscle itself. Another example is the use of fat to determine tumor spread at the eustachian tube orifice. The levator veli palatini and tensor veli palatini normally have an abundant amount of striated fat within the muscle bellies; if these areas are involved in spread of disease, this fatty architecture will be lost (□ Fig. 11.20a–c).

Osseous invasion is also important to assess with imaging. Cortical involvement can be seen on CT as cortical thinning or destruction. On T1 MR imaging, cortex is normally hypointense. This linear hypointense signal will be lost if there is tumoral invasion. Medullary involvement is depicted well on MR imaging. The normal marrow is bright on T1 sequences and will become hypointense when involved with tumor. Bright signal

Fig. 11.25 (a,c,e) T1-weighted axial and (g) sagittal and (b,d,f) T2 fat-suppressed axial views of a patient with massive lymphadenopathy, which biopsy proved to be lymphoma. (h) More often, reactive lymph nodes are characterized by more modest enlargement and uniformity.

following gadolinium and hyperintense signal on T2 images are less specific evidence of medullary involvement with malignancy (□ Fig. 11.21).

11.6 Disorders of the Salivary Glands

11.6.1 Sialolithiasis and Sialadenitis (□ Fig. 11.22)

Imaging is often performed to evaluate for sialadenitis and assess for underlying stones. Radiography may be employed to

detect large radiopaque stones. CT with or without contrast can be utilized to evaluate for obstructing stones resulting in upstream ductal dilatation with or without accompanying gland inflammation. On CT, a stone will be visualized as a hyperdense focus found within or along the draining ducts (□ Fig. 11.22a), most often of the submandibular or parotid glands. Contrast allows better resolution of the soft tissues, as well as better evaluation for microabscesses, which may form within the gland. However, contrast does decrease sensitivity for the detection of small stones, which like contrast appear hyperdense. On imaging, glandular swelling, reticulation of the overlying subcutaneous fat, and skin thickening are signs of inflammation (□ Fig. 11.22b, c). MR imaging can demonstrate similar findings,

Fig. 11.26 (a–d) Multiple axial postcontrast computed tomographic scans through the region of the mandible demonstrate an ovoid, hypodense, peripherally enhancing abscess along the buccal surface of the distal body extending to the angle of the right mandible. There is associated extensive soft-tissue swelling and cellulitic change with phlegmon in the surrounding soft tissues. Additionally, reactive right greater than left cervical chain lymphadenopathy is present, with a markedly enlarged, partially enhancing right station IIA cervical chain lymph node.

with edema and inflammation best seen on T2 sequences with fat saturation. Stones will be visualized on T1 or T2 sequences as hypointense foci. Ultrasound can demonstrate a swollen gland and intra- and extraductal dilatation. However, stone detection is very operator-dependent. In general, contrast-enhanced CT is sufficient and offers optimized stone detection as well as the detection of complications.

11.6.2 Salivary Gland Masses

Salivary gland masses have considerable overlap on imaging, with most benign or malignant tumors appearing isodense to muscle on CT, and many malignant tumors can have bright signal on T2 sequences. Additionally, the margin of the lesion can be well defined or infiltrative in benign or malignant settings. Thus, imaging is focused on location so that appropriate decisions can be made in terms of surgical approach.

Pleomorphic adenomas are the most commonly seen tumor within the parotid gland. These masses are isodense to muscle on CT and of low signal intensity on T1 sequences

(□ Fig. 11.23a), demonstrate avid enhancement following the administration of gadolinium (□ Fig. 11.23b), and are very bright on T2-weighted images (□ Fig. 11.23c). Occasionally, calcifications and cysts can be seen within pleomorphic adenomas. Warthin tumors are the most common bilateral tumors within the parotid gland. These tumors are dark on T1 sequences but can be very heterogeneous on T2-weighted images.

Mucoepidermoid carcinoma is the most common malignant tumor of the parotid gland (□ Fig. 11.24). Low-grade mucoepidermoid carcinomas can have very bright signal on T2 sequences, whereas higher-grade tumors can be of low signal intensity. Adenoid cystic carcinoma is the most common malignant tumor of the submandibular, sublingual, and minor salivary glands. As with mucoepidermoid carcinoma, signal intensity on T2 sequences is highly variable. However, unlike mucoepidermoid carcinoma, adenoid cystic tumors have a propensity for perineural spread, so particular attention must be paid to cranial nerves V and VII. Other malignant tumors of the salivary glands include metastatic lesions, lymphoma, squamous cell carcinoma, and adenocarcinoma.

Fig. 11.27 (a) Axial and (b) coronal postcontrast computed tomographic scans through the neck demonstrate an ovoid homogeneous cystic lesion located posterior to the submandibular gland, medial to the left sternocleidomastoid muscle and anterolateral to the left carotid sheath. The appearance and location of this lesion are characteristic of a second branchial cleft cyst, with a typical appearance of homogeneous hypodensity and a thin, smooth wall (unless infected). Alternate diagnoses in the differential include submandibular gland neoplasm/cyst, venous or lymphatic malformation, abscess, and necrotic lymph node.

11.7 Disorders of the Neck

11.7.1 Lymph Nodes (□ Fig. 11.25)

Lymph nodes within the neck have designated levels and are described elsewhere. Lymph nodes are isodense to muscle on CT and isointense to muscle on T1-weighted images. Nodes are well seen in patients with abundant fat. Nodes are normally hyperintense on T2-weighted images obtained with fat saturation. The fatty hilum is not always seen on imaging but when seen portends benignity. In the setting of infection, lymph nodes will often demonstrate avid reactive enhancement. Suppurative lymph nodes (in the setting of tuberculosis, fungal disease, or staphylococcal infections) will look like abscesses, demonstrating hypoattenuation on CT and hyperintensity on T2 sequences with ring enhancement. However, necrotic lymph nodes may also be seen in the setting of head and neck malignancy (even occult lesions), and lymph nodes larger than 1 cm in greatest short-axis diameter should be considered pathologic.

11.7.2 Deep Neck Infections (□ Fig. 11.26)

Imaging within the deep spaces of the neck is centered upon localizing pathology to a certain space in the neck. For example,

localization of a lesion to the carotid or masticator space will greatly aid the differential diagnosis. However, certain lesions, such as infiltrative neoplasms and infections, can be trans-spatial. Many infections within the extramucosal spaces of the head and neck have a dental origin; other possible etiologies for infection include antecedent trauma, often minor.

Infection is often evaluated within the emergency department setting with the use of CT. Phlegmonous changes on CT will demonstrate loss of the expected fat planes and architecture within the deep spaces of the neck. Secondary signs of infection include enlarged enhancing lymph nodes within the ipsilateral neck, which are reactive in nature. Sometimes, these lymph nodes may become necrotic secondary to superinfection. However, squamous cell cancer can also present with necrotic lymphadenopathy. Clinical data, including signs of infection, are especially important in making a proper diagnosis. Pharyngitis and tonsillitis may be visualized on CT, but imaging is not routinely performed in this setting unless there is concern for a complication such as abscess formation.

Abscesses will demonstrate fluid attenuation higher than that of water and a peripheral rim of enhancement following contrast administration. On MR imaging, signal characteristics will include low to higher signal intensity on T1 sequences (depending on the proteinaceous content of fluid), high signal on T2 sequences, and peripheral enhancement following gadoli-

Fig. 11.28 Postcontrast computed tomographic scans in the (a) axial, (b) coronal, and (c) sagittal planes demonstrate a left paramedian ovoid cystic lesion deep to the infrahyoid muscles and abutting the undersurface of the left hyoid bone. These imaging characteristics are most suggestive of a thyroglossal duct cyst. Included in the differential diagnosis are venous or lymphatic malformations and necrotic lymph node. The uniformity and lack of multiloculation, as well as the anterior location, make the lymphatic malformation a less likely diagnosis.

nium administration. Diffusion sequences are especially helpful because abscess will demonstrate high signal intensity on diffusion-weighted images with low signal on ADC maps, in keeping with restricted diffusion. Imaging can also aid in localizing a source such as an infected tooth. Osteomyelitis or osteonecrosis of the mandible is often seen in conjunction with dental infections. It is especially important to identify infection within the retropharyngeal space, or the so-called “danger space.” Infection in these locations allow a conduit into the mediastinum. Moreover, close inspection of the carotid space is important to exclude thrombosis and secondary thrombophlebitis.

11.7.3 Branchial Cleft Cyst (□ Fig. 11.27)

The second branchial cleft cyst is the most commonly encountered branchial cleft remnant. It arises from incomplete closure of the cervical sinus of His, which is an ectodermal pit that arises from the second through fourth branchial clefts. It is most commonly found along the angle of the mandible and along the carotid sheath and most often lies posterolateral to the submandibular gland and anteromedial to the sternocleidomastoid muscle. The lesion has signal characteristics classic for cysts:

Fig. 11.29 (a) Ultrasound of the thyroid gland demonstrating a large right thyroid mass of mixed echogenicity, later proven on biopsy to be papillary thyroid carcinoma. T, trachea. Magnetic resonance images of the neck including (b) sagittal T1, (c,d) axial T1, (e,f) axial T2 fat-suppressed, and (g) axial and (h) coronal T1 fat-saturated postcontrast pulse sequences demonstrate the large carcinoma of the right thyroid, with extensive enlarged ipsilateral lymph nodes.

hypointense on T1 and hyperintense on T2 with thin peripheral enhancement and attenuation similar to that of fluid or possibly slightly hyperdense to water on CT. If infected, the wall may become thick and then become indistinguishable from necrotic or infected lymphadenopathy. As mentioned, differential diagnostic considerations for second branchial cleft cysts include cystic or necrotic lymphadenopathy and lymphatic malformations. However, lymphatic malformations are more often found posterior to the sternocleidomastoid muscle or may be trans-spatial within the neck, and they are often multilocular, containing fluid–fluid levels indicating intralésional hemorrhage.

11.7.4 Thyroglossal Duct Cyst (□ Fig. 11.28)

Thyroglossal duct cysts are remnants of the thyroglossal duct, which forms along the pathway of descent of the thyroid gland from the foramen cecum to the thyroid bed. Most are found at the level of the hyoid bone or within the infrahyoid neck. Most,

but not all, are found within the midline. With that said, some can be seen embedded within the musculature. The relationship with the hyoid bone is important to recognize because the hyoid bone will be resected during the Sistrunk procedure. Imaging characteristics follow those of cysts—namely, fluid attenuation on CT, low intensity on T1-weighted images, and high intensity on T2-weighted images. If there is proteinaceous debris within the cyst, then high intensity can be seen on T1-weighted images. If the cyst is superinfected, enhancement of the cyst wall can be seen. Carcinoma is rare; however, it does occur in fewer than 1% of cases.

11.7.5 Thyroid Nodules (□ Fig. 11.29)

Sonography remains an important tool to evaluate thyroid nodules. However, the vast majority of detected nodules are benign. Nodules can vary in shape, echogenicity, and internal architecture. Specific characteristics that have been associated with malignancy include nodules that have a solid component, are hypoechoic, contain microcalcifications, are taller than wide on

Fig. 11.30 (a) Axial, (b) coronal, and (c) sagittal postcontrast computed tomographic scans of the neck demonstrate an avidly enhancing, mixed-density lesion in the right carotid sheath splaying the right internal and external carotid arteries. This is best demonstrated on (d) magnetic resonance (MR) angiography, which shows marked splaying of the internal and external carotid arteries. The lesion demonstrates multiple early-filling arterial vessels. The finding is characteristic of paraganglioma/carotid body tumors. These can occur anywhere along the sympathetic chain. Typically, on imaging these lesions demonstrate a smooth contour with extensive enhancement because of their high vascularity. There may be a salt-and-pepper appearance on MR imaging due to the extensive flow voids. Catheter angiography will show extensive tumoral blush. This case is unique because there are multiple metastatic lesions (including an upper thoracic lesion resulting in thoracic spinal cord compression) seen on (e) sagittal T1 and (f) T2 images. The spinal lesions were histopathologically proven metastatic paraganglioma lesions.

transverse views, and have irregular margins. As the number of worrisome characteristics increases, the risk for malignancy increases. Nodules that are photopenic on iodine nuclear scans have a 20% risk of malignancy.

11.7.6 Paragangliomas

Carotid body tumors (□ Fig. 11.30) arise from chemoreceptor cells derived from the primitive neural crest. These masses arise at the carotid bulb and splay the internal and external carotid arteries apart from each other. This is well seen on sagittal projections and helps distinguish these slowly growing vascular masses from schwannomas, which do not splay the internal and external carotid arteries. The masses are generally unilateral but can be bilateral in certain inherited conditions, such as

succinate dehydrogenase enzyme deficiency, multiple endocrine neoplasia, and Von Hippel-Lindau syndrome.

On CT, the mass will be isodense to muscle and demonstrate avid contrast enhancement. On MR imaging, the mass will be isointense to muscle on T1-weighted images and hyperintense on T2 and will demonstrate avid enhancement. Once again, as with other vascular head and neck tumors, a “salt and pepper” appearance on unenhanced MR images will be seen, with the flow voids representing the “pepper” and hemorrhage or slow flow representing the “salt.” On angiography, a strong contrast blush will be seen, indicating the vascular nature of the mass. Before resection, embolization with particles is often used to limit blood loss during surgery.

Glomus jugulare and glomus vagale tumors may also be seen within the carotid space. However, glomus vagale tumors will

Fig. 11.31 (a–c) Multiple magnetic resonance images demonstrate fusiform enlargement of the lower right sternocleidomastoid muscle, suggestive of fibromatosis colli. However, given the presence of mild peripheral T2 hyperintensity and heterogeneous postcontrast enhancement, infectious myositis should also be considered. If further evaluation is necessary, fine needle aspiration may be performed. Signal abnormality and enhancement are confined to the sternocleidomastoid muscle, making malignant neoplasm (such as rhabdomyosarcoma) less likely.

Fig. 11.32 (a,b) Radiographs of the soft tissue of the neck in this patient with prior tracheotomy demonstrate a suggestion of narrowing of the subglottic trachea at the level of the thyroid cartilage; however, this is poorly visualized because of the confluence of shadows and the limitations of radiography. The irregular contour is in better appreciated on a lateral as opposed to a frontal projection. Subsequent computed tomography (CT) of the neck without contrast was performed. (c) Axial and (d) coronal images, as well as (e–g) three-dimensional surface-shaded minimal-intensity-projection reconstructions, were performed to demonstrate and more clearly visualize the stenosis of the trachea at the level of the patient's presumed prior tracheostomy, with narrowing of the trachea by approximately 40 to 50%. There is also a slightly patulous appearance of the trachea distal to the stenosis and possible air trapping within the lungs. This entity and associated findings are much more clearly visualized on CT than on radiography in many cases.

not splay the internal and external carotid arteries but rather will displace the carotid arteries anteriorly and the jugular vein posteriorly. Additionally, these tumors are generally found about 2 cm below the jugular foramen and thus are much higher than carotid body tumors. Glomus jugulare tumors may extend into the carotid space; however, they also involve the skull base and jugular foramen. Erosion of the jugular spine is common, and a permeative destruction pattern is often seen on CT.

Glomus tympanicum originates from glomus cells in the cochlear promontory. Imaging characteristics are similar to those of other paragangliomas; however, location within the middle ear is the distinguishing feature of these masses. Clinical symptoms include a retrotympanic mass and pulsatile tinnitus. CT will demonstrate the characteristic location of these lesions along or about the cochlear promontory. Enhancement characteristics are generally visualized only with MRI; however, this is generally unnecessary if the clinical presentation and CT features are characteristic.

Indium-111 octreotide nuclear medicine scintigraphy will demonstrate increased activity with paragangliomas. Additionally, distant metastases can be evaluated utilizing whole body imaging. However, false negative scans do exist, especially for smaller lesions and lesions which do not express the proper somatostatin receptors.

11.7.7 Fibromatosis Colli (□ Fig. 11.31)

Fibromatosis colli is a focal thickening and fibrosis of the sternocleidomastoid muscle, thought to be secondary to birth trauma. On imaging, thickening and fusiform enlargement of the sternocleidomastoid muscle are seen. On MR imaging, the muscle may be slightly hypoattenuating to other muscle and will be hypointense and hyperintense on T2-weighted images. It is important to recognize that changes will involve only the muscle, and adjacent tissues will lack inflammatory change.

11.7.8 Acquired Airway Stenosis

Acquired intrinsic airway stenosis is most often secondary to prolonged intubation or prior tracheostomy. Additional causes of intrinsic stenosis include prior trauma, laryngeal carcinoma, granulomatous diseases, inflammatory conditions involving the tracheal cartilage, tracheopathia osteochondroplastica, and prior radiation. Extrinsic compression secondary to thyroid malignancy and lymphadenopathy can also result in compression of

the trachea. Thin-section CT allows accurate characterization of the length of stenosis, assessment of abnormal soft tissue, and assessment of calcification, which can provide clues to possible etiologies. Irregular posterior tracheal wall calcifications may be seen with amyloidosis, whereas tracheopathia osteochondroplastica will have regular-appearing calcifications that spare the posterior wall. Other etiologies, such as sarcoidosis, relapsing polychondritis, and Wegener granulomatosis, will usually not calcify. Three-dimensional images can be reformatted, and virtual bronchoscopy can allow luminal evaluation of the stenosis. One of the few current indications for radiography of the soft tissue of the neck is evaluation of the airway for patency (□ Fig. 11.32a, b), in addition to evaluation of pediatric epiglottitis and croup. CT, with or without three-dimensional surface-shaded minimal-intensity-projection reconstructions, may be more helpful in planning surgery (□ Fig. 11.32c–g).

12 General Anesthesia and Anesthetic Considerations for Otolaryngologic Surgery

Jason G. Lai and Andrew M. Malinow

12.1 Introduction

The anesthetic management of a patient undergoing surgery of the head, neck, ear, nose, or throat challenges the anesthesiologist to develop an anesthetic plan that will accommodate the needs of the surgeon, anesthesiologist, and patient. Optimally formulated before the surgical procedure and in consultation with the surgeon, the anesthetic plan should always allow modification to meet the ever-changing requirements encountered in the operating room. Just as a surgical procedure is divided into a series of steps, so is the delivery of a general anesthetic (see Box Steps of the Delivery of General Anesthesia). (p. 89)

Steps of the Delivery of General Anesthesia

1. Preoperative evaluation
2. Patient preparation
3. Induction of anesthesia
4. Airway management
5. Maintenance of anesthesia
6. Emergence from anesthesia
7. Recovery from anesthesia

12.2 Steps of the Delivery of General Anesthesia

12.2.1 Preoperative Evaluation

During the preoperative evaluation, the anesthesiologist:

- Summarizes the patient's general health, including new or ongoing medical conditions, allergies, and current medications. Patients presenting for otolaryngologic surgery often have a history of heavy smoking, alcohol abuse, obstructive sleep apnea, chronic upper respiratory tract infections, or chronic obstructive pulmonary disease, as well as a high incidence of coronary artery disease, hypertension, and chronic renal insufficiency. All of these factors impact the formulation of the anesthetic plan for each patient in an attempt to minimize perioperative morbidity and mortality.
- Performs a complete physical examination, focusing not only on the pulmonary and cardiovascular systems but also especially on the airway in an attempt to uncover anatomy that may make manual ventilation and the placement of a tracheal tube difficult. The steps of asking the patient to open the mouth and then assessing the visible anatomical structures have been widely adopted by anesthesiologists to determine the possibility of a difficult airway. The Mallampati classification system (□ Table 12.1 and □ Fig. 12.1) has been developed to correlate the visual oropharyngeal anatomy, seen during a preoperative evaluation, with visualization of the glottic

aperture during direct laryngoscopy. Evaluation of the oropharynx is accomplished with the patient sitting upright, with the head in the neutral position, the mouth open as widely as possible, and the tongue protruded maximally. Other anatomical features that are often noted on preoperative examination include the patient's ability to actively flex the neck to achieve a "sniffing" position and the ability to anteriorly protrude the mandible ("upper lip bite"); both of these maneuvers are important in the process of direct laryngoscopy. A large tongue (relative to the capacitance of the oral cavity), protruding incisors, a small mandible, and a restricted mouth opening may all contribute to the inability of the anesthesiologist to visualize the glottic aperture during direct laryngoscopy.

- Requests and evaluates appropriate laboratory tests and studies (e.g., complete blood cell count, serum chemistries, coagulation studies, electrocardiogram, chest radiography, pulmonary function tests, echocardiography, myocardial stress test) to assess acute and chronic medical conditions as well as positive findings from the physical examination.
- Discusses with the patient any previous personal or familial adverse reactions to general anesthetics (e.g., allergies, family history of malignant hyperthermia), the available anesthetic options, and the relative risks and benefits of each.
- Obtains the patient's informed consent for anesthesia.
- Provides preoperative instructions as to medications to take or avoid on the day of surgery, and when to discontinue eating and drinking to reduce the risk for pulmonary aspiration, especially during the induction of and emergence from general anesthesia.
- Formulates an anesthetic plan that takes into consideration the proposed surgery, patient's medical condition, requirements of the surgeon, and wishes of the patient.

Once the preoperative evaluation is completed, the patient is assigned an American Society of Anesthesiologists (ASA) physical status (□ Table 12.2). Among anesthesiologists, as well as other members of the perioperative team, the ASA physical status communicates anesthetic risk more efficiently than any individual patient characteristic. The ASA classification system ranges from physical status 1 through 6. The suffix "E" is added to the physical status for patients undergoing emergency surgery.

Table 12.1 Mallampati classification

Class	Visible oropharyngeal structures
I	Soft palate, fauces, uvula, tonsillar pillars
II	Soft palate, fauces, uvula
III	Soft palate, base of the uvula
IV	Hard palate only

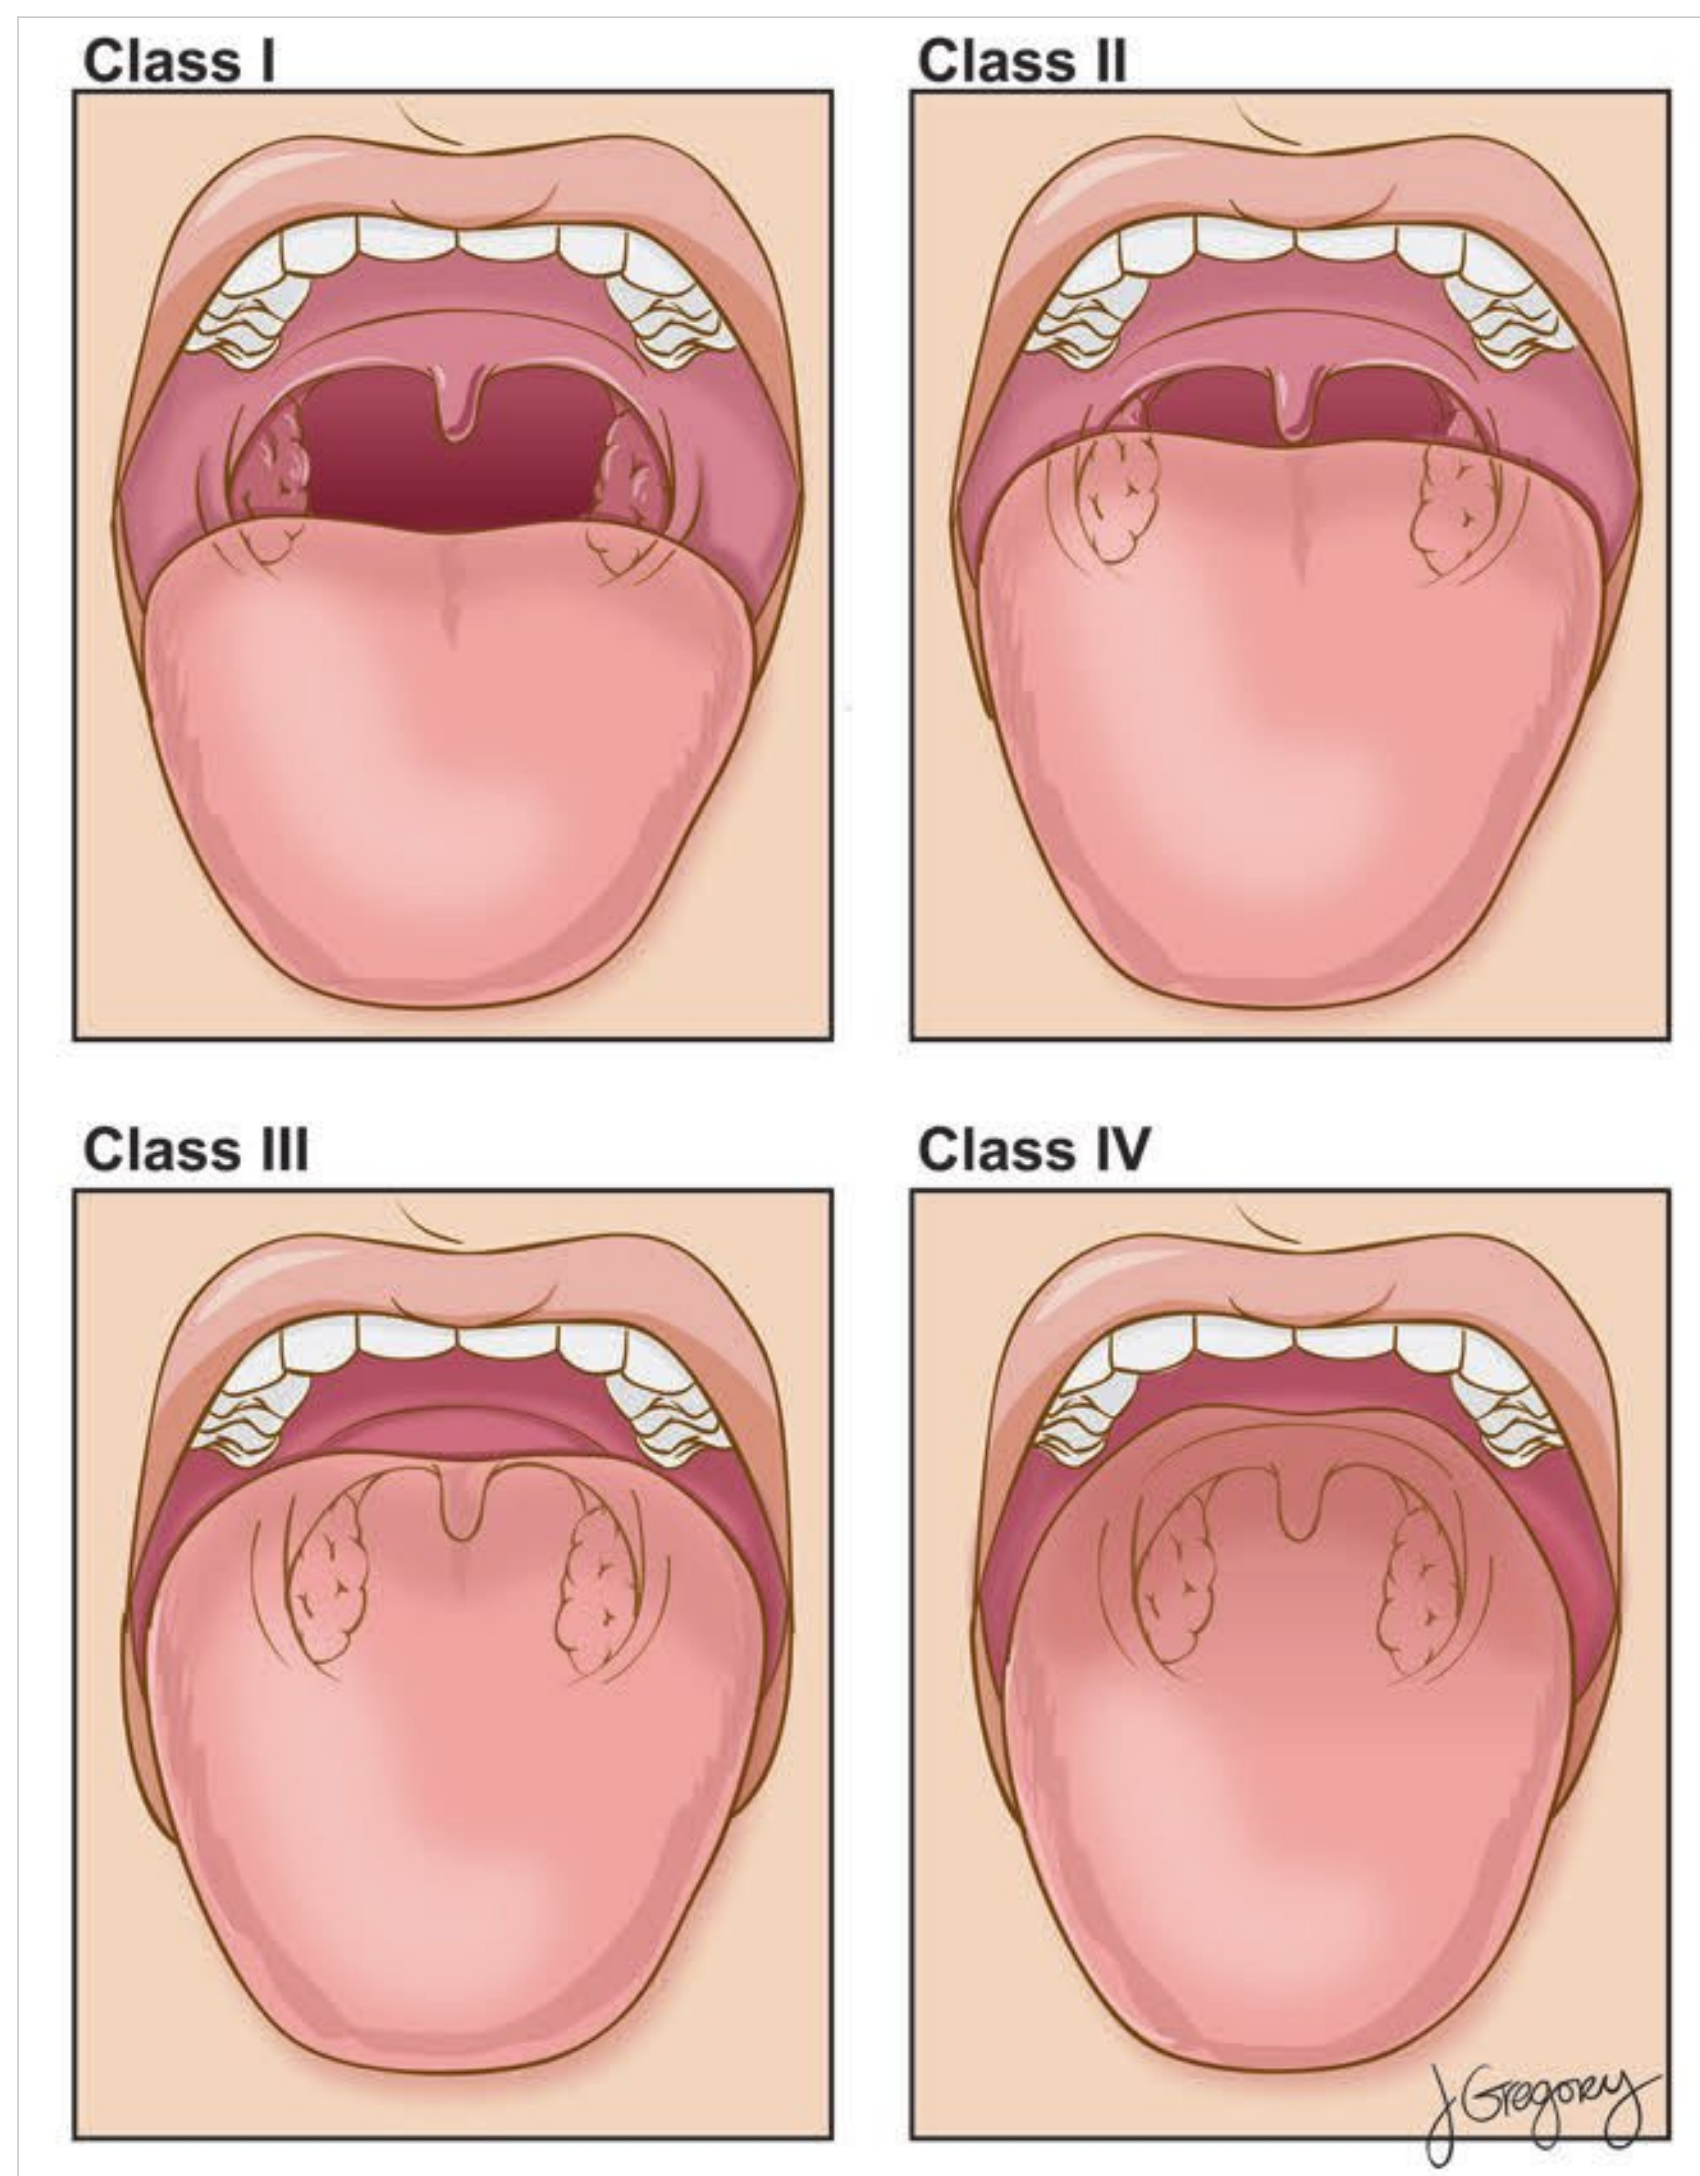

Fig. 12.1 Mallampati classification.

Table 12.2 American Society of Anesthesiologists classification of physical status

Class	Description
1	Normal, healthy patient
2	Patient with mild systemic disease that results in no functional limitations (e.g., hypertension, smoking, diabetes without complications)
3	Patient with severe systemic disease that results in functional limitations but is not incapacitating (e.g., diabetes with vascular complications, stable angina, previous myocardial infarction, pulmonary disease that limits activity)
4	Patient with incapacitating systemic disease that is a constant threat to life (e.g., congestive heart failure; unstable angina; advanced pulmonary, renal, or hepatic dysfunction)
5	Moribund patient who is not expected to survive without the operation (e.g., ruptured abdominal aneurysm, pulmonary embolus, head injury with increased intracranial pressure)
6	A brain-dead patient whose organs are being removed for donor purposes

12.2.2 Patient Preparation

In the preoperative holding area, initial preoperative preparation begins with measurement of the vital signs, confirmation of nil per os status, placement of a peripheral intravenous (IV) line, and review of the anesthetic plan with the patient. Most, but not all, patients are given an “anxiolytic” dose of an IV sedative (e.g., midazolam). Larger, “sedative” doses of these

medications should be avoided in patients with obstructive sleep apnea and patients with symptoms of upper airway obstruction. Premedication with an antisialagogue (e.g., glycopyrrolate, atropine), which improves the surgical exposure, is beneficial before endoscopy or surgery in the oral cavity.

After transferring the patient into the operating room and before inducing anesthesia, the anesthesiologist will attach

appropriate monitors (e.g., electrocardiogram leads, noninvasive blood pressure cuff, pulse oximeter) and confirm that the peripheral IV line is “in situ” and patent.

12.2.3 Induction of Anesthesia

Before the surgeon can make an incision, the patient must enter an anesthetic state in which he or she has no awareness, feeling, or response to surgical stimuli. Induction of this anesthetized state begins with preoxygenation, during which the patient is allowed to breathe 100% oxygen through an anesthesia face mask attached to a breathing circuit. Oxygen thus replaces most of the nitrogen contained in the patient’s lungs and lessens the chance of hypoxemia during the apnea associated with anesthetic induction. Loss of consciousness is then achieved with IV injection of induction agents, inhalation of anesthetic vapors (especially in children), or a combination of both (vide infra).

12.2.4 Airway Management

After the patient loses consciousness, the anesthesiologist will most often attempt to “open the airway” by lifting the chin and then ventilate the patient’s lungs by manually applying positive pressure via the anesthesia machine circuit bag and mask. Once the airway is deemed “open” (e.g., observation of rise and fall of the chest with ventilation, detection of end-tidal carbon dioxide, auscultation of breath sounds), the immediate maintenance of anesthesia usually continues with the use of inhaled anesthetics, delivered to the lungs most commonly by tracheal intubation.

In certain patients, the anesthesiologist will instead choose to insert a laryngeal mask airway (LMA). The LMA consists of a wide-bore tube whose proximal end is connected to a breathing circuit and distal end is attached to an elliptical, inflatable cuff. Once properly placed in the patient’s posterior oropharynx, the cuff is inflated to form a low-pressure seal around the glottic structures, providing a patent airway for ventilation.

Via the tracheal tube or the LMA, either the patient can spontaneously ventilate or the anesthesiologist can apply positive-pressure (usually manual) ventilation. The cuff on the tracheal tube creates a mechanical barrier, separating the distal trachea and main bronchi from the upper airway, which is potentially soiled with contents aspirated from the stomach or with blood/infection from surgery on the airway. Therefore, a tracheal tube provides a more “secure” airway than the LMA in preventing aspiration.

Designed as a compromise between a face mask and tracheal tube, the LMA has enjoyed a quarter century of novel application in the modern practice of anesthesiology. Routinely used to maintain ventilation under anesthesia, the LMA has also become a lifesaving adjunct routinely used (and suggested by ASA protocols) by anesthesiologists in any patient for whom manual bag and mask ventilation is ineffective and whose trachea cannot be intubated. Once effective (and lifesaving) ventilation and oxygenation have been established, the LMA can be used as a conduit for blind or even fiber-optic bronchoscope-guided insertion of a tracheal tube.

The otolaryngologic surgical patient often presents with difficult airway management problems, including the following: certain anatomical characteristics (e.g., decreased cervical spine

range of motion, large tongue, receding jaw); history of stridor and hoarseness (e.g., airway narrowing and possible vocal cord dysfunction); history of neck surgery, trauma, or radiation therapy; history of difficult intubation; and infections (e.g., epiglottitis, retropharyngeal abscess, Ludwig angina). Neoplastic growths anywhere within the upper airway may achieve significant size with little evidence of airway obstruction in the non-anesthetized patient. However, airway compression can occur with the use of sedative medication, the induction of anesthesia, and the use of muscle relaxants. Moreover, these tumors are often friable, leading to unexpected hemorrhage. Attempts at tracheal intubation can induce hemorrhage and edema, causing severe compromise of the airway. In addition, patients with head and neck cancer often have had previous surgery or radiation therapy; these treatments may further impair airway management by decreasing tissue compliance and adversely affecting neck range of motion and mouth opening. Abscesses in the upper airway may be of sufficient size to mimic neoplasms, presenting the same problems of airway distortion, compression, and compromise. An additional problem is the potential for the abscess to rupture spontaneously or during tracheal intubation, potentially obscuring the anesthesiologist’s view during laryngoscopy and causing pneumonia.

Radiologic evaluation of the airway (e.g., plain films of the trachea and larynx, computed tomography, and magnetic resonance imaging studies of the airway) may identify anatomical distortion and aid the anesthesiologist in developing a logical plan for “securing” the airway. If difficult upper airway management is anticipated, then an awake fiber-optic intubation of the trachea or even a tracheostomy under local anesthesia may be indicated.

In a patient with a Le Fort III fracture, nasotracheal intubation risks the introduction of foreign material from the nasopharynx into the subarachnoid space and the consequent development of meningitis. More importantly, nasotracheal intubation risks the introduction of the tracheal tube into the substance of the brain, causing direct mechanical trauma. Even positive-pressure bag and mask ventilation is contraindicated; the increase in volume and pressure of inhaled gas within the nasopharynx can force foreign material or air into the skull. In such patients, the airway is most often “secured” after tracheostomy with local anesthesia.

Several methods have successfully been used to provide oxygenation and ventilation during endoscopy (e.g., laryngoscopy, microlaryngoscopy, esophagoscopy, bronchoscopy). Most commonly, the trachea is intubated with a small-diameter (4.0 to 6.0 mm) tracheal tube through which conventional positive-pressure ventilation is administered. The advantages of intubation include protection against aspiration, the ability to administer inhalational anesthetics, and the ability to continuously monitor end-tidal carbon dioxide. When a tracheal tube is used, caution must be exercised during head and mouth gag manipulation; the tracheal tube may be inadvertently obstructed, disconnected, dislodged, or advanced into a main bronchus.

In some cases, tracheal intubation may interfere with the surgeon’s visualization or performance of the procedure. An alternative approach to this is an intermittent-apnea technique, in which periods of ventilation with 100% oxygen by face mask, small catheter, or tracheal tube alternate with periods of apnea, during which time the surgery is performed. The duration of

apnea, usually 2 to 3 minutes, is routinely determined by the peripheral oxygen saturation as measured by a pulse oximeter. Hypoventilation with hypercarbia and pulmonary aspiration are risks of this technique.

Jet ventilation is a more sophisticated technique of ventilation employing a manual jet ventilator connected to a side port of the laryngoscope. During inspiration, a high-pressure source of oxygen (but not volatile anesthetic) is directed through the glottic opening, entraining room air into the lungs; expiration is passive through the patent upper airway. It is important to constantly monitor chest wall motion and to allow sufficient time for exhalation so as to avoid air trapping and barotrauma. Jet ventilation is advantageous because it provides an unobstructed operating field and increased safety with laser use (vide infra); however, it poses an increased risk for gastric aspiration and distension, pneumomediastinum, pneumothorax, and hypoventilation.

12.2.5 Maintenance of Anesthesia

Once the airway has been established, most often the anesthesiologist chooses to continue the anesthesia by allowing the patient to inhale an anesthetic, thereby maintaining the state of unconsciousness and providing amnesia and analgesia. Maintenance of anesthesia can also be (totally or partially) achieved with IV anesthetics; an alternative to inhaled anesthetics sometimes is a necessity for certain procedures (e.g., oxygenation via intermittent-apnea or jet ventilation techniques; vide supra).

During the maintenance of anesthesia, the anesthesiologist

- Delivers inhaled anesthetic gases or IV anesthetic agents at levels that provide adequate depth of anesthesia for the surgical stimuli.
- Injects narcotic drugs, as needed, to lessen the requirement for inhaled/IV anesthetic agents and to provide analgesia during the emergence and recovery phases of anesthesia.
- Injects neuromuscular blocking drugs to maintain muscle paralysis, if required.
- Injects other drugs, if indicated (e.g., antibiotics, antiemetic agents).
- Monitors cardiorespiratory parameters, temperature, and urine output; intervenes with adjustments to the anesthetic technique (e.g., ventilator settings) or injects medication (e.g., vasopressors) when necessary.

12.2.6 Emergence from Anesthesia

As the surgery nears completion, the anesthesiologist executes the plan for emergence from anesthesia, transforming the patient's state from comatose and unresponsive to awake and alert. The usual emergence sequence routinely includes

- Reversal of any residual neuromuscular blockade with combinations of anticholinesterase and anticholinergic drugs so that the patient will have full muscle strength upon awakening.
- Discontinuation of the inhaled or IV anesthetics while the patient is allowed to breathe 100% oxygen.
- Extubation of the trachea after the patient has demonstrated adequate respiratory function and when full protective laryngeal reflexes return. In patients with reactive airway disease (e.g. asthma), a "deep" extubation may be warranted to minimize the risk for bronchospasm and laryngospasm.

- Monitoring of cardiorespiratory parameters.
- Continued administration of oxygen by face mask or nasal cannula after extubation and during transfer to the postanesthesia care unit (PACU).

Although never 100% possible, "smooth" emergence from anesthesia is the anesthesiologist's goal. Straining, bucking, or coughing during emergence will cause an increase in venous pressure that may lead to postoperative bleeding, disruption of delicate suture lines, and/or dislodgement of tympanic membrane graft following tympanoplasty. A "smooth" emergence will also minimize laryngospasm and the need for positive-pressure ventilation by face mask, particularly after nasal cosmetic surgery, when the nose is unstable and the application of a face mask is undesirable.

Excessive upper airway bleeding, edema, or pathology may preclude tracheal extubation in the operating room. If edema is a concern at the time of tracheal extubation, then the tracheal tube may be removed over a tube changer, gum elastic bougie, or fiber-optic bronchoscope, leaving a guide in case the tube needs to be immediately replaced. Even the spontaneously ventilating patient is often transported while breathing supplemental oxygen in an attempt to avoid hypoxemia if a period of hypoventilation occurs before admission to the PACU.

12.2.7 Recovery from Anesthesia

After leaving the operating room, the patient is admitted to the PACU, where the anesthesiologist is available for consultation and emergency airway management. In the PACU, the anesthesiologist commonly manages postoperative pain, nausea and vomiting, and cardiorespiratory compromise (e.g., hypoxemia, hypoventilation, hypertension, hypotension, tachyarrhythmias, bradyarrhythmias).

12.3 Anesthesia during Laser Surgery of the Airway

Laser light offers the surgeon excellent precision and hemostasis with minimal postoperative edema or pain; yet, it also introduces major hazards into the operating room. General precautions include evacuation of toxic fumes from tissue vaporization because these may have the potential to transmit microbacterial disease. All operating room personnel should wear eye protection gear, and the patient's eyes should be taped shut.

The greatest fear during laser airway surgery is a tracheal tube fire. This can be avoided by using a technique of ventilation that does not involve a flammable tube or catheter, such as intermittent-apnea or jet ventilation. However, some surgical procedures require a tracheal tube because of the expected duration of the case, location of the lesion, or preexisting lung problems that might warrant airway pressures unattainable with jet ventilation. In these cases, a tracheal tube resistant to laser ignition is used.

Nitrous oxide as well as oxygen supports combustion. If a volatile agent is chosen to maintain anesthesia, then consideration should be given to using a mixture of air/oxygen or helium/oxygen to decrease the inspired oxygen concentration, thus minimizing the risk for an airway fire. Cuffed tracheal tubes can be

Table 12.3 Levels of sedation/analgesia and general anesthesia

Function/structure affected	Minimal sedation (anxiolysis)	Moderate sedation/analgesia (conscious sedation)	Deep sedation/analgesia	General anesthesia
Responsiveness	Normal response to verbal stimulation	Purposeful response to verbal or tactile stimulation	Purposeful response following repeated or painful stimulation	Unarousable even with painful stimulus
Airway	Unaffected	No intervention required	Intervention may be required	Intervention required
Spontaneous ventilation	Unaffected	Adequate	May be inadequate	Frequently inadequate
Cardiovascular function	Unaffected	Usually maintained	Usually maintained	May be impaired

inflated with methylene blue–dyed sterile saline; not only would a laser-induced rupture of the cuff be readily detectable, but the spark might be extinguished by the saline before an airway fire occurred.

If an airway fire occurs, then ventilation is discontinued, and the tracheal tube is disconnected from the breathing circuit and removed from the patient. Saline is poured into the pharynx to absorb heat, and the airway is suctioned before ventilation resumes with 100% oxygen. The trachea is then reintubated with a new tube and the airway is examined by bronchoscopy. Complications of airway fires include airway edema, inhalation injury caused by heat and smoke, tracheal and laryngeal granulation tissue formation, and airway stenosis.

12.4 Intravenous Sedation and Analgesia

Sedation and analgesia comprise a continuum of states ranging from minimal sedation to general anesthesia (□ Table 12.3). As an anesthetic technique, IV sedation and analgesia is attractive because it does not routinely involve supporting ventilation or manipulation of the airway, although chin lift, jaw thrust, or even insertion of a nasopharyngeal or oral airway may be required. IV sedation and analgesia, along with injection of local anesthetic by the surgeon, usually produces fewer physiologic perturbations than general anesthesia, making it an especially useful anesthetic technique for patients undergoing facial plastic surgery procedures (e.g., rhinoplasty, blepharoplasty, rhytidectomy). The drugs most commonly injected during IV sedation and analgesia include incremental doses or continuous infusions of benzodiazepines (e.g., midazolam), opioids (e.g., fentanyl, remifentanyl), and sedative–hypnotics (propofol, dexmedetomidine, ketamine).

12.5 Analgesics

Pain control is an essential part of perioperative management. Two common classes of drugs used to provide analgesia are opioids and nonsteroidal anti-inflammatory drugs (NSAIDs). Commonly used opioids include morphine, hydromorphone, methadone, fentanyl, alfentanil, sufentanil, and remifentanyl; side effects of opioids include respiratory depression, nausea, vomiting, constipation, biliary spasm, and pruritus.

NSAIDs are commonly used to treat postsurgical pain and work by inhibiting cyclooxygenase and the production of other

Table 12.4 Antiemetic medications

Antiemetic medication class	Examples
Serotonin (5-HT ₃) antagonists	Ondansetron, granisetron
Dopamine (D ₂) antagonists	Metoclopramide, prochlorperazine
H ₁ antagonists	Diphenhydramine
Antimuscarinics	Scopolamine
Corticosteroids	Dexamethasone

chemical mediators of inflammation. Side effects of NSAIDs include gastrointestinal ulceration, inhibition of thromboxane synthesis and platelet aggregation, renal dysfunction, and hypersensitivity reactions. Ketorolac is an IV NSAID commonly used in clinical anesthesia.

12.6 Postoperative Nausea and Vomiting

Postoperative nausea and vomiting (PONV) is a common side effect caused by both anesthetic medications and the surgical procedure. During surgery, blood from the upper airway may passively drain into the stomach. The placement of a throat pack or suctioning of the stomach with an orogastric tube at the conclusion of surgery therefore may attenuate the severity of PONV. Minimizing the use of opioids and/or nitrous oxide while ensuring adequate IV hydration may also help decrease the incidence of PONV. The routine use of antiemetic medications has also significantly reduced the incidence of PONV (□ Table 12.4).

12.7 Drugs for the Induction of Anesthesia

12.7.1 Intravenous Drugs

Thiopental, propofol, etomidate, and benzodiazepines exert their effects through specific interactions with γ -aminobutyric acid (GABA), the principal inhibitory neurotransmitter in the central nervous system. Ketamine exerts its anesthetic properties through antagonism of the excitatory N-methyl-D-aspartate (NMDA) receptor (□ Table 12.5).

Table 12.5 Intravenous drugs for the induction of anesthesia

Intravenous anesthetic	Pros	Cons
Thiopental	Excellent brain protection, potent anticonvulsant, inexpensive	Myocardial depression, vasodilation, histamine release, possible precipitation of porphyria in susceptible patients
Propofol	Prevents nausea/vomiting; rapid, clear-headed recovery if used as sole anesthetic agent to maintain anesthesia	Myocardial depression; vasodilation; pain on injection; supports bacterial growth, which limits duration of safe use after it has been drawn up in a syringe; expensive
Etomidate	Intravenous anesthetic with fewest myocardial effects	pain on injection, adrenal suppression, myoclonus, nausea, vomiting
Ketamine	Minimal depression of cardiorespiratory system; analgesic and amnestic properties; can be given intravenously, orally, rectally, or intramuscularly	Dissociative anesthesia with postoperative dysphoria and hallucinations, increases intracranial pressure and intraocular pressure, increases airway secretions
Benzodiazepines (midazolam, diazepam)	Minimal depression of cardiorespiratory system; anticonvulsant, anxiolytic, sedative, and amnestic properties; reversible with flumazenil	Slow onset of unconsciousness, delayed awakening, pain on injection (diazepam)

Table 12.6 Inhalational drugs for the induction of anesthesia

Inhaled agent	Pros	Cons
Isoflurane	Inexpensive; renal, hepatic, coronary, and cerebral blood flow preservation	Relatively long time to onset/offset, irritating to airway so cannot be used for inhalation induction
Desflurane	Extremely rapid onset/offset	Expensive, stimulates catecholamine release, irritating to airway so cannot be used for inhalation induction
Sevoflurane	Extremely rapid onset/offset, nonirritating to airway so can be used for inhalation induction	Theoretical potential for renal toxicity from inorganic fluoride metabolites
Nitrous oxide	Extremely rapid onset/offset, nonirritating to airway so can be used with sevoflurane for inhalation induction	Diffuses freely into gas-filled spaces (bowel, pneumothorax, middle ear); increases pulmonary vascular resistance; nausea, vomiting; combustible

12.7.2 Inhalational Drugs

Inhaled agents fall into two categories: volatile anesthetics and nitrous oxide (□ Table 12.6). Volatile anesthetics (e.g., isoflurane, desflurane, sevoflurane) are liquids at room temperature, and a vaporizer is required to convert the liquids to gases, which are then delivered to the patient through the anesthesia breathing circuit.

Nitrous oxide is a gas of low anesthetic potency that is commonly used in combination with volatile anesthetic agents to reduce the amount of volatile anesthetic required. The relative insolubility of nitrous oxide compared with nitrogen can cause the expansion of closed, air-filled compartments in the body, with adverse effects such as rupture of alveolar blebs (causing a pneumothorax) or further expansion of an existing pneumothorax. To avoid pressure-related disruption of the repair or displacement of the graft during tympanoplasty, nitrous oxide is discontinued before tympanic membrane graft placement.

In some circumstances, the anesthesiologist may choose to induce anesthesia by a purely inhalational method. The inhalation of pleasant-smelling sevoflurane is well tolerated by children, leading to a rapid and smooth loss of consciousness. Once the patient is anesthetized, the anesthesiologist can then painlessly and more easily insert an IV catheter for the remainder of the anesthetic.

12.7.3 Neuromuscular Blocking Drugs

Neuromuscular blocking drugs can be classified depending on whether or not they depolarize the postsynaptic membrane of the neuromuscular junction. Succinylcholine is the depolarizing neuromuscular blocking drug routinely used. Injected IV, succinylcholine works rapidly, although briefly, to produce conditions suitable for tracheal intubation. Common side effects noted after the injection of succinylcholine include skeletal muscle fasciculations (with resultant myalgia, increased intraocular pressure, and increased intracranial pressure) and hyperkalemia. Uncommon side effects after the injection of succinylcholine include malignant hyperthermia in genetically sensitive patients and prolonged paralysis in patients with abnormal or absent plasma cholinesterases.

Nondepolarizing neuromuscular blocking drugs (e.g., rocuronium, vecuronium, cisatracurium) bind competitively at the acetylcholine receptors in the neuromuscular junctions of striated muscle. Therefore, the blockade can be reversed by using anticholinesterase drugs (e.g., neostigmine, edrophonium), which increase the amount of acetylcholine present at the neuromuscular junction. Anticholinergic agents (e.g., glycopyrrolate, atropine) must be administered immediately before the reversal drugs to prevent profound muscarinic-mediated vagal effects on the cardiovascular system (e.g., bradycardia).

Table 12.7 Steps of Emergency Therapy for Malignant Hyperthermia

1	Call for help.
2	Discontinue administration of volatile anesthetics and succinylcholine.
3	Hyperventilate the patient with 100% oxygen at flows of 10 L/min or more.
4	Administer dantrolene 2.5 mg/kg; repeat every 5 minutes until signs of malignant hypertension are reversed; up to 30 mg/kg may be necessary.
5	Administer bicarbonate 1 to 2 mEq/kg to treat metabolic acidosis.
6	Institute cooling measures (e.g., gastric lavage, cooling blankets, cold intravenous solutions).
7	Administer inotropes and antiarrhythmic agents as necessary to treat dysrhythmias.
8	Treat hyperkalemia with: hyperventilation, calcium, bicarbonate, and glucose/insulin.
9	Promote urine output (2 mL/kg/h) with aggressive fluid therapy; mannitol and furosemide may also be required.
10	Monitor temperature, urinary output, electrolytes, glucose, blood gases, end-tidal carbon dioxide, and coagulation studies.
11	Consider invasive monitoring of arterial blood pressure and central venous pressure.
12	If necessary, consult on-call physicians at the 24-hour MHAUS (Malignant Hypertension Association of the United States) hotline: 1-800-MH-HYPER.

Adequate muscle relaxation is often necessary to prevent swallowing during intraoral procedures and facilitate surgical exposure. However, in some surgical procedures (e.g., parotidectomy), nerve monitoring is used to identify and preserve specific nerves; therefore, neuromuscular blockade is contraindicated.

12.8 Recognition and Treatment of Malignant Hyperthermia

Susceptibility to malignant hyperthermia is inherited in an autosomal-dominant pattern. In genetically susceptible individuals, all of the volatile anesthetic agents as well as succinylcholine are capable of triggering malignant hyperthermia, a disorder of intracellular calcium regulation in skeletal muscle. Administration of a triggering agent(s) leads to a sudden release of calcium from the sarcoplasmic reticulum. The intense and sustained muscle contraction that follows results in signs of hypermetabolism, including tachycardia, metabolic acidosis, hypercarbia, hypoxemia, hyperthermia, ventricular dysrhythmias, hyperkalemia, rhabdomyolysis, muscle rigidity (even in the presence of neuromuscular blockade), and tachypnea in the spontaneously breathing patient. As soon as malignant hyperthermia is suspected, all triggering anesthetics are discontinued and the patient is hyperventilated with 100% oxygen. The IV injection of dantrolene, which inhibits calcium release from the sarcoplasmic reticulum, reverses the metabolic reaction taking place in the muscle cells by stabilizing intracellular calcium metabolism. In addition, adequate hydration, active diuresis, correction of metabolic abnormalities, cardiac monitoring, and active cooling are all part of the immediate management of this life-threatening condition (see Table □ Table 12.7 Steps of Emergency Therapy for Malignant Hyperthermia). The Malignant Hyperthermia Association of the United States (MHAUS) is

a valuable clearinghouse for information about the familial inheritance, recognition, management, and patient follow-up of this disease and maintains a hotline (1-800-MH-HYPER) for health care providers to call with urgent questions.

12.9 Roundsmanship

- The goal of anesthesia is to provide the desired combination of analgesia, amnesia, and optimal operating conditions while ensuring physiologic homeostasis.
- Careful preoperative assessment of the patient and a cooperative relationship between the surgeon and anesthesiologist will improve the operative outcome, especially in more complex cases.
- The equipment and personnel required for an emergency tracheostomy must be immediately available when a difficult airway is being managed.
- If there is a chance of postoperative edema involving structures that could obstruct the airway, the patient should be carefully observed in the postanesthesia care unit or even remain intubated until a trial of spontaneous ventilation, perhaps around a deflated cuff, can be attempted.
- The earliest signs of malignant hyperthermia are tachycardia, hypercarbia, and muscle rigidity. Hyperthermia may be a late development.

13 Infectious Diseases of the Oral Cavity, Pharynx, and Larynx

E. Ashlie Darr and Edward J. Shin

13.1 Oral Cavity

The oral cavity extends from the skin–vermillion border to the junction of the hard and soft palate and includes the buccal mucosa, superior and inferior alveolar ridges and teeth, retromolar trigone, hard palate, floor of the mouth, and oral tongue. The normal oral flora consists of approximately 100 million organisms per milliliter of saliva, with 700 species of organisms represented. Odontogenic infections typically result from commensal oral flora; however, primary pathogens, such as herpes simplex viruses, *Candida albicans*, and human papillomavirus, may also lead to oral cavity infectious disease.

13.1.1 Odontogenic Infections

Odontogenic infections include dental caries, periapical abscesses, pulpitis, gingivitis, and periodontal disease. These infections are typically polymicrobial, with a large percentage of obligate anaerobes comprising the microflora. More than 80% of cultivated organisms consist of *Streptococcus*, *Peptostreptococcus*, *Veillonella*, *Lactobacillus*, *Corynebacterium*, and *Actinomyces* species, with *Streptococcus mutans* particularly notable for its role in dental caries. Commensal flora must be able to adhere to tooth or mucosal surfaces, evade mechanical disruption, penetrate tissues, and survive host responses in order to become pathogenic. Odontogenic infections have the potential for hematogenous dissemination to the heart and prosthetic devices, and they may provide a nidus for deep neck space infections. Broad-spectrum antibiotics with good coverage against gram-positive and aerobic organisms are appropriate therapy.

13.1.2 Oral Candidiasis

Candida may lead to infections on the mucosal surfaces of the upper aerodigestive tract. *Candida albicans* is most commonly identified as the causative organism; however, *Candida tropicalis*, *Candida glabrata*, and *Candida krusei* may also cause disease. Oral candidiasis is characterized by white curdlike material on mucosal surfaces that can usually be scraped off with a tongue blade to reveal a friable, painful, erythematous base. The white material is a pseudomembrane consisting of keratin, sloughed epithelium, food debris, leukocytes, and bacteria. Oral mucosal candidiasis may be found in association with angular cheilitis. Diagnosis is usually based on the history and physical examination; however, a potassium hydroxide preparation or Gram stain of a specimen scraped from the mucosa will reveal hyphae, pseudohyphae, and yeast forms. Oral candidiasis represents an opportunistic infection associated with poor cellular immunity, especially in patients whose CD4+ cell counts fall below 200 to 300/mm³. As such, it occurs most commonly in patients with cancer or AIDS, although it may also develop in asthmatic patients using inhaled steroids who are otherwise healthy. In the latter, the infection usually resolves spontaneously without the patient discontinuing the inhalant. For all

other patients, treatment consists of triazole antifungals, although resistance to fluconazole is a developing problem.

13.1.3 Oral Herpes Simplex

Human herpes simplex virus type 1 is the most common cause of oral and oropharyngeal ulcerative lesions, with 600,000 new cases per year diagnosed in the United States. The virus is most commonly transmitted by contact with individuals who have active primary or recurrent disease. Infection is caused by viral attachment to the mucosal cell surface, where it undergoes endocytosis, replicates, and ultimately causes cell lysis. This releases viral particles and clinically leads to the formation of vesicles. Human herpes simplex virus type 1 is also taken up by neurons, where it becomes latent and will later replicate when recurrent infection is provoked. Diagnosis is primarily clinical, although viral culture, vesicle content analysis, and serum antibody titers may be used to confirm or follow disease. Multilobulated viral inclusion particles called Tzanck cells are pathognomonic.

Primary herpetic gingivostomatitis is characterized by the onset of tenderness and erythema of the oral and often oropharyngeal mucosal surfaces, followed by an eruption of small vesicles with inflammatory borders that quickly degenerate to ulcerative lesions. The onset of symptoms occurs 5 to 7 days after contact with an infected individual. Signs and symptoms are usually self-limited and resolve within 7 to 14 days with supportive treatment. Recurrent or “secondary” episodes of oral herpes simplex are caused by reactivation of the virus within dermatome-specific ganglia, leading to a prodromal period of altered sensation over the affected area followed by vesicular eruption. This occurs most commonly in the form of herpes labialis. The small vesicles may coalesce and persist for 1 to 2 days, after which ulceration and crusting may occur. Healing usually occurs within 5 to 7 days, and scarring is uncommon in immunocompetent individuals. Treatment with systemic antiviral agents is not required for most cases of oral herpes simplex; however, topical docosanol or penciclovir creams may be used to halt viral replication during labial recurrences.

13.2 Pharynx

The pharynx is subdivided into the nasopharynx, oropharynx, and hypopharynx and extends from the base of the skull to the esophageal inlet. The region predominantly affected by pharyngitis is the oropharynx, which extends from the junction of the soft and hard palate to the base of the tongue.

13.2.1 Bacterial Pharyngitis

Pharyngitis is inflammation of the pharynx, which presents as sore throat and involves predominantly the oropharynx. In adults, only 5 to 10% of cases of pharyngitis are caused by a

Fig. 13.1 (a) Normal lateral neck X-ray. 1, Epiglottis; 2, hyoid; 3, nasopharynx; 4, oropharynx; 5, maxillary sinus; 6, mastoid air cells. (b) Lateral neck X-ray in patient with epiglottitis. 7, Enlarged epiglottis; 8, thickened aryepiglottic folds; 9, cricoid cartilage; 10, esophagus; 11, trachea; 12, laryngeal ventricle.

bacterial infection. In children, the numbers of cases of bacterial pharyngitis are slightly higher, at 30 to 40%. The most common cause of bacterial pharyngitis in adults is group A β -hemolytic *Streptococcus pyogenes*, a gram-positive coccus that occurs in pairs and chains. Inflammation typically involves the soft palate, tonsillar pillars, posterior pharyngeal wall, and tonsils, which may be swollen and covered with a gray–white exudate. The oropharyngeal tissues are erythematous, the breath is foul-smelling, and soft palate petechiae may be present. Other signs and symptoms may include fever, anorexia, cervical lymphadenitis, odynophagia, and malaise. Rapid antigen tests or throat culture are used for diagnosis. Although the disease is usually self-limited within 3 to 7 days, treatment is recommended to decrease the odds of contagion and the development of rheumatic fever. Other possible sequelae of infection include scarlet fever, post-streptococcal glomerulonephritis, and distant infection due to hematogenous bacterial spread. Penicillin is the mainstay of treatment, and erythromycin or clindamycin may be used in penicillin-allergic patients. Other bacterial causes of pharyngitis include group C and G streptococci and *Arcanobacterium haemolyticum*. *Neisseria gonorrhoeae* may be sexually transmitted and cause pharyngitis concomitantly with genital infection.

13.2.2 Vincent Angina

Vincent angina is an acute necrotizing pharyngitis caused by *Spirochaeta denticulata* and the fusiform bacillus *Borrelia vincentii* (*Treponema vincentii*). These organisms similarly cause a form of gingivostomatitis known as trench mouth. Vincent angina presents with sore throat, high fever, and cervical lymphadenopathy, as well as a deep, friable ulcer of the tonsil that easily bleeds. Diagnosis is made by pharyngeal swab culture of tonsillar exudates. Appropriate antibiotic therapy includes penicillin or clindamycin, with resolution of infection occurring typically within 7 to 10 days.

13.3 Larynx

The larynx extends from the tip of the epiglottis superiorly to the inferior border of the cricoid cartilage. In general, infectious processes affecting the mucous membranes of the oral cavity and pharynx, such as mucocutaneous candidiasis, mucositis, and herpes simplex virus lesions, can also affect the mucosal surfaces of the larynx. A few unique infectious diseases of the larynx deserve special mention.

13.3.1 Epiglottitis (□ Fig. 13.1)

Epiglottitis is bacterial cellulitis of the epiglottis, which causes supraglottic edema and can rapidly lead to upper airway obstruction. The disease has become rare since the development of the vaccine for *Haemophilus influenzae* type B, which was formerly the causative agent in more than 90% of cases. Today, the most common cause is group A β -hemolytic streptococci, although other organisms have been reported. The importance of epiglottitis lies in its potential for airway obstruction within hours and thus the need for prompt diagnosis and management.

The most common clinical signs of epiglottitis are fever and difficulty breathing. The classic description is the child with inspiratory stridor, retractions, severe sore throat, drooling, and dysphagia who may be sitting in a tripod or sniffing position to maximize airflow through an obstructed larynx. Diagnosis is made by direct visualization of the supraglottis in a controlled environment such as the operating room, where emergent airway interventions can take place in the event of complete obstruction due to further edema or laryngospasm. Although epiglottitis can be confirmed by the presence of the classic “thumbprint” sign on lateral neck X-ray, this study is not encouraged in a patient with potential airway compromise, and pharyngeal examination and other manipulations that may lead to obstruction should be avoided. In the operating room,

Fig. 13.2 Laryngeal papilloma. Intraoperative photograph of an intubated larynx with bilateral vocal fold papillomas.

cultures from the surface of the epiglottis, alongside blood cultures, should be sent. Ceftriaxone, cefotaxime, or ampicillin/sulbactam are appropriate initial antibiotic choice, and therapy should be further tailored based on culture results and clinical improvement. Extubation may be performed when epiglottic edema is adequately decreased as visualized by flexible or direct laryngoscopy or after a positive endotracheal tube leak test. Extubation can usually be achieved at 48 hours. Oral antibiotics should be continued to complete a 7- to 10-day course once peroral intake is accomplished.

13.3.2 Recurrent Respiratory Papillomatosis

Recurrent respiratory papillomatosis (□ Fig. 13.2) is characterized by recurrent benign squamous papilloma of the aerodigestive tract caused by human papillomavirus types 6 and 11. Recurrent respiratory papillomatosis is the most common benign laryngeal neoplasm in children and the second most common cause of hoarseness in childhood. Two forms are known: an aggressive, juvenile form and a less aggressive adult-onset form, although disease in adults can also be aggressive. The disease primarily affects the larynx, where it may lead to airway compromise and the requirement for tracheotomy. Disease may also occur in the oral cavity, trachea, and bronchi. Recurrent respiratory papillomatosis affects patients of all ages and is notoriously difficult to treat because of spreading throughout the aerodigestive tract and recurrences that necessitate multiple surgeries. The course of the disease is variable, with some patients achieving full remission and others requiring lifelong treatment.

Human papillomavirus is a double-stranded DNA virus that infects epithelial cells, leading to the formation of benign or malignant neoplasms. To date, more than 100 types of human

papillomavirus are known. Human papillomavirus infects mucosal basal layer stem cells, where it may become latent or actively express proteins that lead to cellular proliferation. The lesions of recurrent respiratory papillomatosis appear histologically as finger-like projections of squamous epithelium over a fibrovascular core. Grossly, recurrent respiratory papillomatosis exhibits a cauliflower-like appearance, with white or pink sessile or pedunculated projections. These lesions have low malignant potential.

The mechanism of transmission has not been fully elucidated, but most cases are thought to involve vertical transmission from mothers with genital condylomas during transit through the birth canal. The most common presenting symptom is hoarseness, followed by inspiratory or biphasic stridor. Diagnosis is made by history and physical examination with nasopharyngolaryngoscopy or direct laryngoscopy. Various methods of surgical treatment have been described. Popular methods of microlaryngoscopic treatment include lesion excision with cold instruments, carbon dioxide laser ablation, and microdebridement. Adjuvant therapies are indicated for patients with rapid regrowth, with multiple-site disease, or requiring more than four surgeries per year. These include systemic therapies, such as interferon- α , ribavirin, acyclovir, and retinoids, as well as intralesional therapies such as cidofovir. Photodynamic therapy involves injection of a photosensitizing drug that is concentrated within papillomas, followed by argon pump dye laser ablation. This also shows potential as an effective therapeutic option.

13.3.3 Acute and Chronic Infectious Laryngitis

Most cases of acute laryngitis are caused by viral upper respiratory infections and are characterized by dysphonia and/or hoarseness. These symptoms may occur in association with sore throat, odynophagia, postnasal drip, malaise, cough, and other manifestations of upper respiratory illness. The most common agents include rhinoviruses, parainfluenza viruses, respiratory syncytial virus, adenoviruses, and influenza virus. Inhalation of humidified air and voice rest are recommended treatment, which is supportive.

Chronic laryngitis of infectious etiology may be caused by a variety of bacterial and fungal agents that commonly produce hoarseness or dysphonia, recurrent throat clearing, sensation of postnasal drip, or recurrent episodes of sore throat lasting for at least 3 months. Laryngeal tuberculosis, once a common sequela of severe pulmonary tuberculosis, now typically occurs in the absence of pulmonary disease. Examination of the larynx may reveal nonspecific inflammatory changes, superficial ulcerations, or exophytic lesions affecting any area of the larynx. Protein purified derivative testing is usually positive, and most patients do not have evidence of pulmonary infection on chest X-ray. Diagnosis is made by culture of sputum and/or laryngeal lesions, and treatment is medical. Fungal causes of chronic laryngitis include candidiasis, histoplasmosis, blastomycosis, cryptococcosis, and coccidioidomycosis. Diagnosis is made by clinical history and biopsy and culture of laryngeal lesions. Treatment is culture-based antibiotic therapy.

13.4 Roundsmanship

- Odontogenic infections typically result from commensal oral flora; however, primary pathogens, such as herpes simplex viruses, *Candida albicans*, and human papillomavirus, may also lead to oral cavity infectious disease.
- Multilobulated viral inclusion particles called Tzanck cells are pathognomonic for herpes simplex virus infection.
- In adults, only 5 to 10% of cases of pharyngitis are caused by a bacterial infection.
- Because of vaccination, the most common cause of epiglottitis is group A β -hemolytic streptococci.

14 Antimicrobial Therapy for Head and Neck Infections

E. Ashlie Darr and Edward J. Shin

14.1 Antibacterial Agents

(□ Table 14.1)

14.1.1 Penicillins

Penicillins (PCNs) are a group of antibiotics that share a β -lactam ring and function by binding irreversibly to PCN-binding proteins in bacterial cell walls, leading to osmotic lysis and cellular death.

Natural Penicillins

Members of this class include oral penicillin V and parenteral formulations (e.g. aqueous, crystalline, procaine, and benzathine penicillin G).

Clinical Uses

The natural penicillins are active against *Streptococcus pyogenes* (group A β -hemolytic), most strains of *Streptococcus pneumoniae*, *Treponema pallidum*, *Actinomyces*, and some oral anaerobes. They are inactivated by a variety of enzymes produced by gram-negative and oral anaerobic organisms collectively known as β -lactamases, as well as by penicillinase produced by *Staphylococcus aureus*. Another mechanism of resistance is the

alteration of PCN-binding proteins by certain strains of staphylococci and *S. pneumoniae*.

Penicillinase-Resistant Penicillins

Agents in this category include methicillin, oxacillin, cloxacillin, dicloxacillin, and nafcillin.

Clinical Uses

These agents are active against most forms of *S. aureus*, except for methicillin-resistant *S. aureus* (MRSA). They remain active against most streptococcal and pneumococcal infections. Nafcillin is metabolized by the liver, making it a good choice in patients with renal impairment. Among the oral agents in this group, dicloxacillin attains the highest blood concentrations.

Aminopenicillins

These include amoxicillin and ampicillin.

Clinical Uses

These agents are effective against certain gram-negative organisms, such as *Proteus*, *Haemophilus influenzae*, and *Escherichia coli*. They are inactivated by β -lactamases and are ineffective against *S. aureus*.

Table 14.1 Antibacterial agents

Class	Activity against	Adverse effects
Penicillins	Most streptococci, pneumococci, <i>Staphylococcus aureus</i> (except methicillin-resistant <i>S. aureus</i>)	Rash, gastrointestinal upset
Cephalosporins	Staphylococci, streptococci, and some gram-negatives	Rash, gastrointestinal upset
Macrolides	Gram-positive cocci, some upper respiratory gram-negatives	Nausea, abdominal cramping, elevated liver function tests
Clindamycin	Gram-positives and most anaerobes	Pseudomembranous colitis
Tetracyclines	Chlamydia, <i>Mycoplasma</i> , <i>Borrelia burgdorferi</i> (Lyme disease)	Nausea, photosensitivity, tooth enamel discoloration in children
Fluoroquinolones	<i>Pseudomonas</i> , some gram-positives	Nausea, central nervous system disturbances, rashes, phototoxicity
Vancomycin	Gram-positives, including methicillin-resistant <i>S. aureus</i>	Red man syndrome, nephrotoxicity, ototoxicity
Daptomycin	Gram-positives, including methicillin-resistant organisms	Skeletal muscle effects, gastrointestinal disturbances, increased liver function tests
Metronidazole	Anaerobes and some protozoa	Nausea, disulfiram-like reactions to alcohol, dysgeusia
Aminoglycosides	Gram-positive and gram-negative aerobes	Nephrotoxicity, ototoxicity
Mupirocin	Gram-positives, including methicillin-resistant <i>S. aureus</i>	Local itching, burning
Rifampin	Mycobacteria, combination therapy for methicillin-resistant <i>S. aureus</i>	Orange discoloration of body fluids, hepatitis, rash
Sulfonamides	Gram-positives and gram-negatives; some resistant <i>S. aureus</i>	Cholestatic jaundice, bone marrow suppression, severe hypersensitivity reactions
Oxazolidinones	Gram-positives, drug-resistant <i>S. aureus</i> and streptococci	Diarrhea, nausea, headaches, thrombocytopenia
Streptogramins	Resistant <i>S. aureus</i> strains	Arthralgias, myalgias, increased liver function tests

Augmented Penicillins

Members include amoxicillin/potassium clavulanate (Augmentin; Dr. Reddy's Laboratories), ampicillin/sulbactam (Unasyn; Pfizer), piperacillin/tazobactam (Zosyn; Pfizer), and ticarcillin/potassium clavulanate (Timentin; GlaxoSmithKline).

Clinical Uses

These agents combine a penicillin with an inactivator of β -lactamase. This confers effectiveness against *H. influenzae*, *M. catarrhalis*, anaerobes, and certain staphylococci (although not MRSA). Additionally, Timentin and Zosyn may be used to treat *Pseudomonas aeruginosa* infections. Ticarcillin and piperacillin, without the addition of β -lactamases, are not active against gram-positive bacteria.

Adverse Effects

Rashes occur in approximately 5% of patients using penicillins; however, this reaction recurs in only 50% of patients who go on to use the drug a second time. Anaphylaxis occurs in 0.05% of patients and is considered a contraindication to further penicillin use. Other potential adverse effects include interstitial nephritis, anemia, and leukopenia. Patients requiring prolonged high-dose therapy (for longer than 2 weeks) should be monitored with weekly serum creatinine levels and blood counts. Augmentin commonly produces unwanted gastrointestinal side effects. Amoxicillin, when taken in the setting of infectious mononucleosis, causes a maculopapular rash in 65 to 90% of patients. This is not indicative of a true PCN allergy. Oral PCNs, except for amoxicillin, are destroyed by gastric acid and should therefore be taken on an empty stomach. Any patient reporting a history of serious PCN allergy should undergo skin testing or desensitization before PCN use.

14.1.2 Cephalosporins

Cephalosporins are another family of β -lactam antibiotics, which are classified as first-, second-, third-, and fourth-generation. As a general rule, first-generation cephalosporins have the greatest activity against gram-positive organisms, whereas fourth-generation cephalosporins have the greatest activity against gram-negative species.

First-Generation Cephalosporins

These include cephalexin (Keflex; Shionogi) and cefazolin (Ancef, GlaxoSmithKline; Kefzol, Eli Lilly).

Clinical Uses

These agents are active against staphylococci, streptococci, and community-acquired species of *Proteus*, *Klebsiella*, and *E. coli*. They have limited activity against other enteric gram-negative organisms and anaerobes. Cefazolin is commonly used for its antistaphylococcal activity in surgical prophylaxis for infection at skin incision sites.

Second-Generation Cephalosporins

Members in this category include cefuroxime (Ceftin; GlaxoSmithKline), cefprozil (Cefzil; Bristol-Myers Squibb), and cefaclor (Ceclor; Eli Lilly).

Clinical Uses

These agents have slightly more activity than first-generation cephalosporins against gram-negative bacteria such as *Proteus*, *Klebsiella*, *Neisseria* species, and *Moraxella catarrhalis*. They have slightly less activity against gram-positive organisms.

Third-Generation Cephalosporins

These include cefpodoxime (Vantin; Pfizer), ceftriaxone (Rocephin; Genentech), ceftazidime (Fortaz; Covis Pharmaceuticals), cefdinir (Omnicef; Abbott Laboratories), and cefotaxime (Claforan; Sanofi-Aventis).

Clinical Uses

These agents are less active against *S. aureus* than the earlier generations, but they usually inhibit streptococci and have expanded coverage against gram-negative organisms. Ceftriaxone has good activity against pneumococci, *H. influenzae*, and *Neisseria meningitidis*, and it also effectively crosses the blood-brain barrier, making it a popular choice for treating meningitis as well as intracranial or intraorbital complications of sinusitis and otitis media. It is also useful for treating pharyngeal gonorrhea. Cefpodoxime and cefdinir are commonly used in treating acute otitis media and sinusitis because of their enhanced gram-positive activity relative to the other third-generation drugs. None of the oral cephalosporins are active against PCN-resistant pneumococci.

Fourth-Generation Cephalosporins

Cefepime (Maxipime; Elan Pharmaceuticals) is the only fourth-generation cephalosporin. It has the best activity of the cephalosporins against *P. aeruginosa* and thus may be used as a non-ototoxic and non-nephrotoxic alternative to aminoglycosides. It is effective against other often-resistant gram-negatives, such as *Enterobacter* and *Citrobacter*, as well as *S. aureus* and pneumococci.

Adverse Effects

Because of the molecular structural similarity between cephalosporins and PCNs, patients with a history of anaphylaxis after PCN use should not take cephalosporins. However, only 5 to 10% of patients who have a history of PCN rashes will develop a rash with cephalosporins. Mucocutaneous candidiasis or *Clostridium difficile*-induced pseudomembranous colitis may result from overgrowth of yeast or bacteria, respectively, primarily because of the broad-spectrum activity of cephalosporins. Ceftriaxone is associated with biliary sludging, especially in patients receiving total parenteral nutrition. Like PCNs, cephalosporins have been reported to cause interstitial nephritis, anemia, and leukopenia, and prolonged use indicates appropriate serologic monitoring.

14.1.3 Other β -Lactams

These include the carbapenems—imipenem (Primaxin; Merck), meropenem (Merrem; AstraZeneca), and ertapenem (Invanz; Merck)—and aztreonam (Azactam; Bristol-Myers Squibb), which is a monobactam.

Clinical Uses

Aztreonam is active only against aerobic gram-negative rods, such as *P. aeruginosa*. It has no known cross-reactivity with PCNs or cephalosporins and can therefore be used in PCN-allergic patients. Carbapenems are effective against most gram-positive, gram-negative, and anaerobic organisms, as well as against *P. aeruginosa* (except ertapenem). They are important antibiotics for polymicrobial and resistant bacterial infections.

14.1.4 Macrolides and Ketolides

Macrolides include erythromycin, azithromycin (Zithromax; Pfizer), and clarithromycin (Biaxin; AbbVie). Ketolides, such as telithromycin (Ketek; Sanofi-Aventis), are macrolide derivatives that have enhanced activity against *S. pneumoniae*. Both groups exert their antibacterial activity by binding to 50S subunits on bacterial ribosomes.

Clinical Uses

These agents are effective against respiratory infections caused by *Legionella*, *Mycoplasma*, *Chlamydia*, *Corynebacterium diphtheriae*, *Bordetella pertussis*, and susceptible streptococci. They are sometimes used to treat sinusitis and streptococcal pharyngitis, although less expensive and equally effective alternatives are available. Macrolides and ketolides are relatively ineffective against *H. influenzae*.

Adverse Effects

Erythromycin may cause nausea and vomiting and elevation of hepatic enzymes with prolonged use. Erythromycin and clarithromycin are inhibitors of cytochrome P-450, which may lead to increased levels of oral anticoagulants, theophylline, and other medications. Macrolides and ketolides can additionally prolong cardiac QT intervals, especially when used with other potentiating drugs.

14.1.5 Clindamycin

Clindamycin (Cleocin; Pfizer) works by inhibiting bacterial protein synthesis.

Clinical Uses

Clindamycin is highly active against most anaerobes, including most *Bacteroides fragilis*, as well as gram-positive organisms, including many strains of PCN-resistant pneumococci and MRSA. It penetrates well into abscess cavities and bone, making it ideal for the treatment of osteomyelitis and deep neck space abscesses caused by oral or dental infections.

Adverse Effects

Oral clindamycin may cause nausea or vomiting and should be taken with meals. It is also the most commonly implicated antibiotic in pseudomembranous colitis. Patients who develop diarrhea while taking clindamycin should immediately discontinue the medication. Pretreatment with metronidazole for several days before clindamycin is administered is sometimes employed to decrease the risk for colitis.

14.1.6 Tetracyclines

Tetracyclines include doxycycline, tetracycline, and minocycline. They exert bacteriostatic activity by binding to the 30S subunit of bacterial ribosomes, thus inhibiting protein synthesis. Tigecycline (Tygacil; Pfizer) is a derivative of minocycline.

Clinical Uses

Tetracyclines are popularly used to treat acne. They are also used as prophylaxis against traveler's diarrhea and against upper respiratory infections caused by *Legionella*, *Mycoplasma*, and *Chlamydia*. They may be used in Lyme disease and Rocky Mountain spotted fever. Oral preparations may relieve the pain of aphthous ulcers and may be effective against other oral infections, such as Vincent angina. Tigecycline is useful in skin infections with gram-positive bacteria, including MRSA, and is not susceptible to the tetracycline resistance mechanisms that commonly render other members of this class ineffective.

Adverse Effects

Tetracyclines are notable in causing brownish discoloration of teeth if taken during enamel formation and thus should not be given to pregnant or nursing women or to children younger than 10 years of age. Tetracyclines may also promote sunburn and esophagitis. Minocycline may cause transient vertigo.

14.1.7

Chloramphenicol

Chloramphenicol is effective against most gram-positives, including many PCN-resistant staphylococci, most anaerobes, and most gram-negatives. *Pseudomonas* and PCN-resistant streptococci are, however, not susceptible. Chloramphenicol readily crosses the blood-brain barrier. It is notable for causing bone marrow suppression, which can be fatal, and thus its use is reserved for life-threatening infections in patients who cannot tolerate alternatives. Chloramphenicol may also cause the "gray baby syndrome" in fetuses and neonates and thus should not be given during pregnancy.

14.1.8 Fluoroquinolones

This class includes ciprofloxacin (Cipro; Bayer HealthCare), levofloxacin (Levaquin; Janssen), gatifloxacin (Zymar; Allergan), gemifloxacin (Factive; Merus Labs International), and moxifloxacin (Avelox; Bayer HealthCare). Quinolones are broad-spectrum antibiotics that function by inhibiting bacterial DNA gyrase, which blocks DNA synthesis.

Clinical Uses

Members of this class are effective against most gram-negative infections, including those caused by *P. aeruginosa*. Topical preparations are thus commonly used in the treatment of otitis externa. They also have moderate activity against gram-positive organisms, *S. pyogenes*, and PCN-resistant pneumococci, as well as *H. influenzae*, *M. catarrhalis*, *Legionella*, and other atypicals. Of the quinolones, only moxifloxacin has significant activity against anaerobes.

Adverse Effects

Nausea, drowsiness, rashes, and photosensitivity are the most common adverse effects associated with fluoroquinolone use. Fluoroquinolones also may induce the prolongation of cardiac QT intervals. Pediatric and age-related arthropathy may also occur, so these agents should not be used in pregnant or lactating women and should be discontinued in patients who develop joint pain or tendinitis.

14.1.9 Vancomycin

Vancomycin (Vancocin; ViroPharma) is a parenteral antibiotic best known for its effectiveness against strains of resistant bacteria, including MRSA, PCN-resistant pneumococci, and enterococci, although resistant strains have emerged. It functions by interfering with gram-positive bacterial cell wall synthesis. Vancomycin may cause nephrotoxicity and/or ototoxicity, especially when administered together with aminoglycosides. Red man syndrome is upper body flushing and erythema caused by histamine release, which may occur with rapid vancomycin infusion. Because of its unique ability to combat highly resistant organisms, vancomycin should be used only in cases of severe infections that cannot be controlled with other medications.

14.1.10 Daptomycin

Daptomycin is a parenteral agent that works by inserting itself into the bacterial cell membrane, causing depolarization and cellular death. It is used to treat MRSA and methicillin-resistant *S. epidermidis* infections as a once-daily alternative to vancomycin. Its principal adverse effect is elevation of creatine phosphokinase levels and associated myopathy.

14.1.11 Metronidazole

Metronidazole (Flagyl; Pfizer) is active against anaerobes and some protozoa by promoting the accumulation of toxic metabolic byproducts. Metronidazole crosses the blood–brain barrier well and may be used to treat antibiotic-induced colitis. In the head and neck, metronidazole is useful in treating oral infections, or it may be employed in treating sinusitis, deep neck space infections, and chronic otitis media when used concomitantly with agents that have aerobic and gram-positive activity. Adverse effects include a disulfiram-like reaction with alcohol consumption and dysgeusia.

14.1.12 Aminoglycosides

Members of this class include gentamicin, tobramycin, amikacin, neomycin, and streptomycin. They interfere with the bacterial translation of messenger RNA into protein by binding to ribosomes. Aminoglycosides are effective against aerobic gram-positive and gram-negative bacteria, such as *P. aeruginosa*, and have a synergistic effect when used with PCNs, cephalosporins, or vancomycin. Resistance to one aminoglycoside does not necessarily imply resistance to the others in the group. Neomycin is a component of certain topical preparations used in the treatment of otitis externa; however, *P. aeruginosa* is often resistant. Gentamicin and tobramycin nasal irrigations may be used as antipseudomonal treatments in patients with cystic fibrosis. The use of aminoglycosides is limited by clinically significant oto- and nephrotoxicity. Because of its ototoxic effects, gentamicin has been used as a transtympanic therapy for refractory Meniere disease.

14.1.13 Mupirocin

Mupirocin (Bactroban; GlaxoSmithKline) is a topical ointment used to treat nasal carriers of *S. aureus*. It may be mixed with saline spray for deeper nasal penetration. It has a unique molecular structure and thus has no allergic cross reactivities.

14.1.14 Rifampin

Rifampin is most commonly used to treat mycobacterial infections; however, it is also active against *S. aureus* and *S. epidermidis* (including MRSA), streptococci, pneumococci, anaerobes (including *Bacteroides fragilis*), *Neisseria*, *H. influenzae*, and *Legionella*. Unless used for prophylaxis, rifampin should not be used as monotherapy because of the rapid resistance that may occur during treatment. Rifampin concentrates well in nasopharyngeal secretions and thus is useful for nasal carriers of *Neisseria* or *H. influenzae*. When combined with mupirocin, it is helpful in eradicating the *S. aureus* carrier state. Rifampin causes orange discoloration of body fluids and may be hepatotoxic or nephrotoxic. It potentiates cytochrome P-450, which may lead to decreased serum levels of other medications.

14.1.15 Sulfonamides

Sulfonamides, such as sulfamethoxazole, are rarely used as monotherapeutic agents because of increases in resistance. Currently, sulfamethoxazoles are effective against about 75% of *H. influenzae* strains but are ineffective against most other respiratory pathogens. Trimethoprim/sulfamethoxazole (Bactrim; AR Scientific) produces a synergistic effect that is useful in treating *S. aureus* infections, including MRSA infections. It has also been used as adjuvant therapy in Wegener granulomatosis and in the treatment of *Pneumocystis carinii* infection.

14.1.16 Oxazolidinones

Linezolid (Zyvox; Pfizer) is an alternative to vancomycin for the treatment of MRSA infections and can even be used for

infections with vancomycin-resistant strains of both *S. aureus* and enterococci. Unlike vancomycin, it is available in both parenteral and oral forms. At present, this medication is highly expensive. It may adversely lower platelet levels or lead to hypertension in those concomitantly using decongestant medications.

14.1.17 Streptogramins

Quinupristin/dalfopristin (Synercid; Pfizer) is a streptogramin. Streptogramins have a structure and function similar to those of macrolides. Synercid was developed to treat resistant gram-positive infections, such as those caused by MRSA, vancomycin-resistant enterococci (*Enterococcus faecium*, but not *Enterococcus faecalis*), and resistant pneumococci. It may cause arthralgias.

14.2 Antifungals

14.2.1 Amphotericin B

Amphotericin B (Amphotec; Alkopharma USA) is a broad-spectrum antifungal effective against systemic mycotic infections, including those caused by *Candida*, *Mucor*, and *Aspergillus*. It functions by interfering with fungal plasma membranes. Intravenous infusion is notable in producing several unpleasant side effects, including fevers, rigors, nausea/vomiting, hypotension, and tachypnea; however, lipid formulations may decrease these symptoms. Amphotericin B may also cause anemia or nephrotoxicity, both of which are reversible.

14.2.2 Triazoles

Triazoles interfere with ergosterol synthesis and are fungistatic. Fluconazole (Diflucan) is used in local and disseminated candidal infections and is a second-line agent against *Cryptococcus*. Unlike fluconazole, voriconazole (Vfend) and itraconazole (Sporanox) are effective against *Aspergillus*. Nausea, diarrhea, and rash are the most common adverse effects, although hepatotoxicity can be severe. Liver function tests should be monitored weekly. Voriconazole and itraconazole can both potentiate the effects of other medications, such as cyclosporin, warfarin, and digoxin, so serum levels should be monitored. Voriconazole may also produce visual disturbances, which are reversible.

14.2.3 Flucytosine

Flucytosine (Ancobon) may be used to treat *Candida* or *Cryptococcus* infection or as combined therapy with amphotericin B for *Aspergillus* infection. It may be taken orally and is better tolerated than amphotericin B, although resistance frequently develops during treatment. It may cause reversible bone marrow suppression.

14.2.4 Candins

Caspofungin (Cancidas) is a parenteral candin that may be used in refractory aspergillosis or candidal infections. It is relatively

well tolerated, although it may cause flushing, fever, or a rash with infusion and may be hepatotoxic when used with cyclosporine.

14.2.5 Nystatin

Nystatin (mycostatin) is a topical preparation that is used for oropharyngeal and cutaneous candidiasis (thrush). No significant adverse effects or medication interactions are associated with its use.

14.3 Antivirals

14.3.1 Antiherpetic Agents

These drugs include acyclovir (Zovirax; GlaxoSmithKline), valacyclovir (Valtrex; GlaxoSmithKline), famciclovir (Famvir; Novartis), and penciclovir (Denavir; New American Therapeutics). They function as nucleotide analogues that inhibit DNA synthesis. Acyclovir is effective against herpes simplex and herpes zoster and comes in topical, oral, and intravenous forms. It may be used as prophylaxis against herpes simplex attacks; however, it functions only during the active phase of the viral life cycle, and thus recurrences can be expected. It may cause a nephropathy, especially in those with preexisting poor renal function. Valacyclovir is taken orally and is converted to high serum levels of acyclovir. It is effective in decreasing the symptoms associated with herpes simplex labialis attacks when taken within the first 2 hours of symptom onset. Some physicians treat idiopathic facial paralysis (Bell palsy) with antiherpetic agents because of the possibility of a viral cause.

14.3.2 Anti-influenza Agents

Amantadine (Symmetrel; Endo Health Solutions) and rimantidine (Flumadine; Forest Pharmaceuticals) block the entry of influenza A virus into cells. They are ineffective against influenza B. These agents are used within 48 hours of symptom onset and are continued for 7 to 10 days. They may be used as prophylaxis for patients who have been exposed but are known to be immune, or for patients in nursing homes or hospital staff during epidemics. Side effects include gastrointestinal distress or central nervous system symptoms, such as dizziness and confusion. Zanamivir (Relenza; GlaxoSmithKline) and oseltamivir (Tamiflu; Genentech) are both neuraminidase inhibitors that are effective against both influenza A and influenza B. Both may decrease symptom severity and illness duration when taken within 36 hours of initial symptom onset. Zanamivir is a dry inhalant that may cause nasal irritation or bronchospasm in patients with asthma, as well as gastrointestinal discomfort and headaches. Oseltamivir may cause nausea, vomiting, diarrhea, headaches, and dizziness.

14.4 Roundsmanship

- Rashes occur in approximately 5% of patients using penicillins; however, this reaction recurs in only 50% of patients who go on to use the drug a second time. Any patient report-

ing a history of serious PCN allergy should undergo skin testing or desensitization before PCN use.

- Because of its unique ability to combat highly resistant organisms, vancomycin should be used only in cases of severe infections that cannot be controlled with other medications.
- The use of aminoglycosides is limited by clinically significant oto- and nephrotoxicity. Because of its ototoxic effects, gentamicin has been used as a transtympanic therapy for refractory Meniere disease.

15 Evaluation and Management of Deep Neck Space Infections

Craig E. Berzofsky and Zhenqing Brett Wu

15.1 Introduction

Understanding the anatomy of the head and neck is important in the discussion of deep neck space infections. It is the relationship between the major structures in the neck and the fascial compartments that allows the infections to form and disseminate. The interconnecting lymphatic drainage of these areas also provides a means for infectious spread. The infections develop from tonsillitis, pharyngitis, trauma, and iatrogenic events. The incidence of deep neck space infections has dramatically decreased since the advent of antibiotics. However, delayed treatment of deep neck space infections can result in severe morbidity and mortality by causing respiratory distress, mediastinitis, vascular thrombosis/rupture, and cranial neuropathy.

15.2 Spaces and Infections

The deep cervical spaces can be divided into those existing above the hyoid bone, below the hyoid bone, and across the hyoid bone extending the entire length of the neck (□ Fig. 15.1).

The spaces above the hyoid bone are the buccal, masticator, submandibular/sublingual, parotid, peritonsillar, and parapharyngeal spaces. The buccal space extends from between the teeth, buccal mucosa, and buccinator muscles medially; the superficial layer of the deep cervical fascia and muscles of facial expression laterally and anteriorly; and the mandible, parotid gland, and masseter and lateral and medial pterygoid muscles posteriorly; it contains the retromaxillary (buccal) fat pad. Infections here are usually odontogenic in origin and often arise from bicuspid and molar teeth.

The masticator space is surrounded by the superficial layer of deep cervical fascia extending from the skull base to the angle of the mandible. This space contains the muscles of mastication, mandibular nerve, ramus and body of the mandible, and pterygoid venous plexus. The source of infection is also typically odontogenic.

The parotid space is contained in the superficial layer of deep cervical fascia, which splits to envelop the parotid gland, lymph nodes, and branches of the facial nerve.

Abscess of this space may be multiloculate because of the septa from the superficial layer of the deep cervical fascia.

Peritonsillar space infections are associated with tonsillitis. This is a potential space between the tonsillar capsule and the palatoglossus, palatopharyngeus, and superior constrictor muscles.

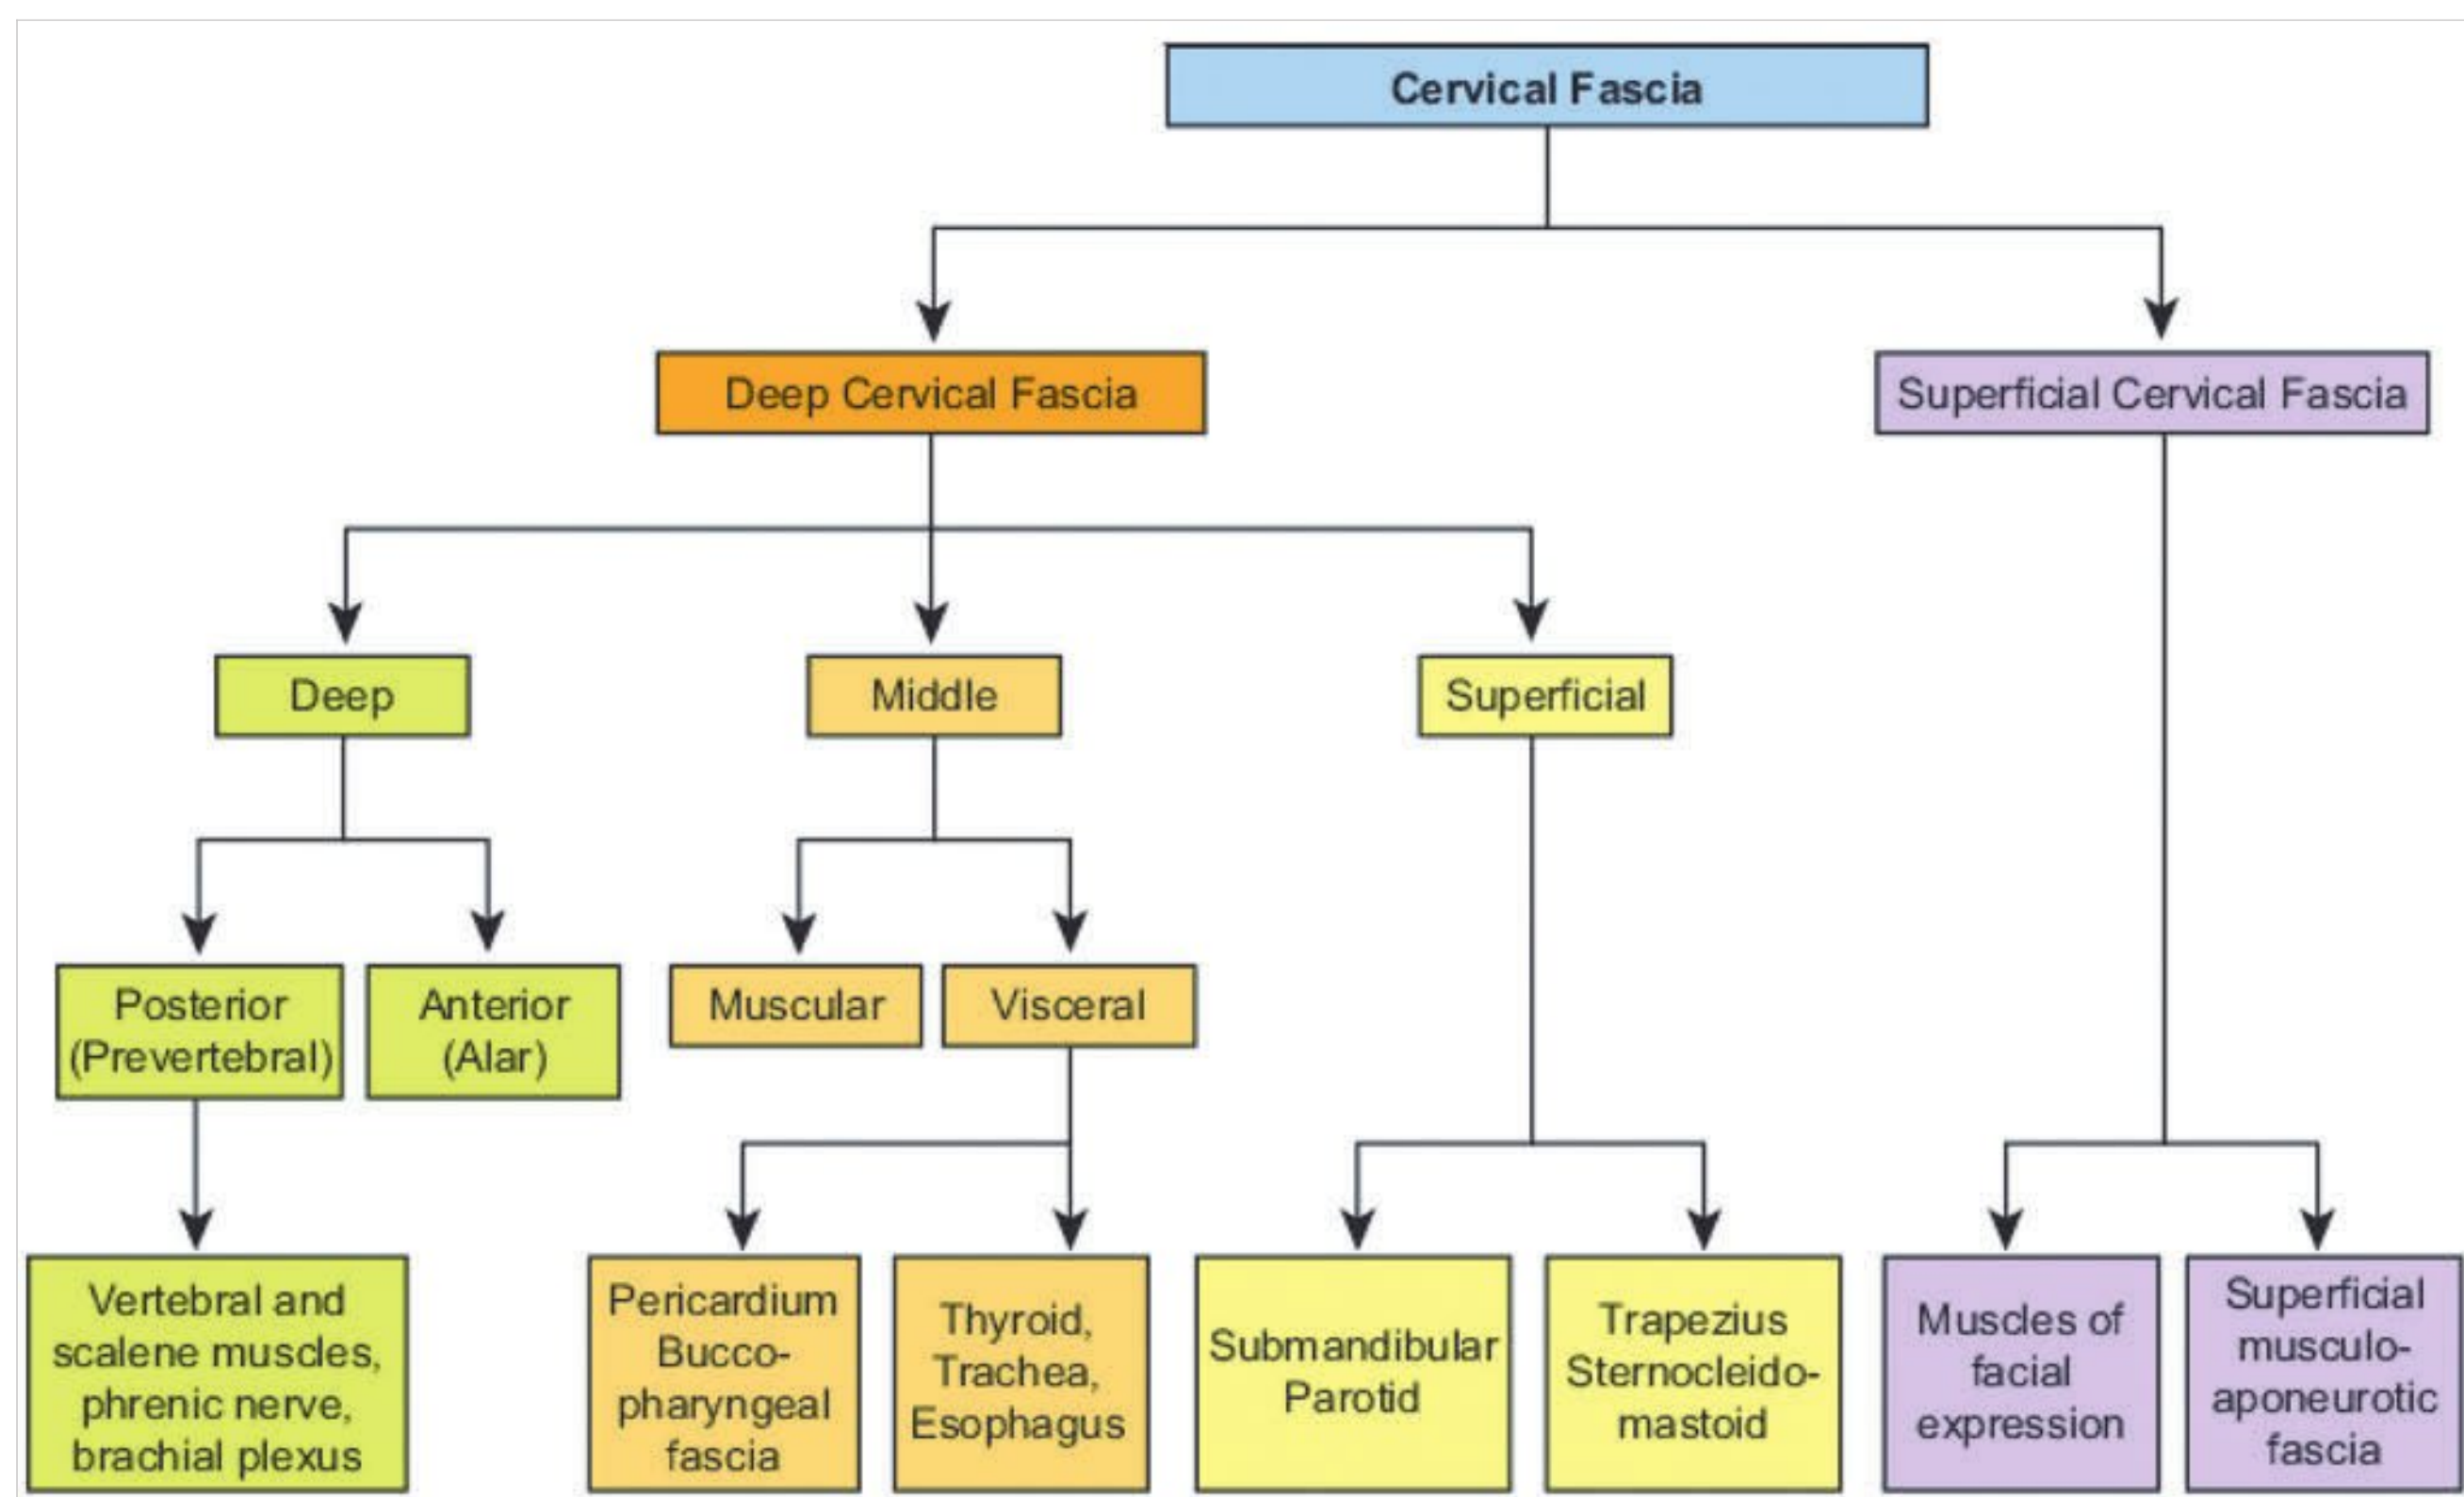

Fig. 15.1 Fascial layers and associated structures and spaces. The carotid sheath is made of superficial and deep cervical fascia.

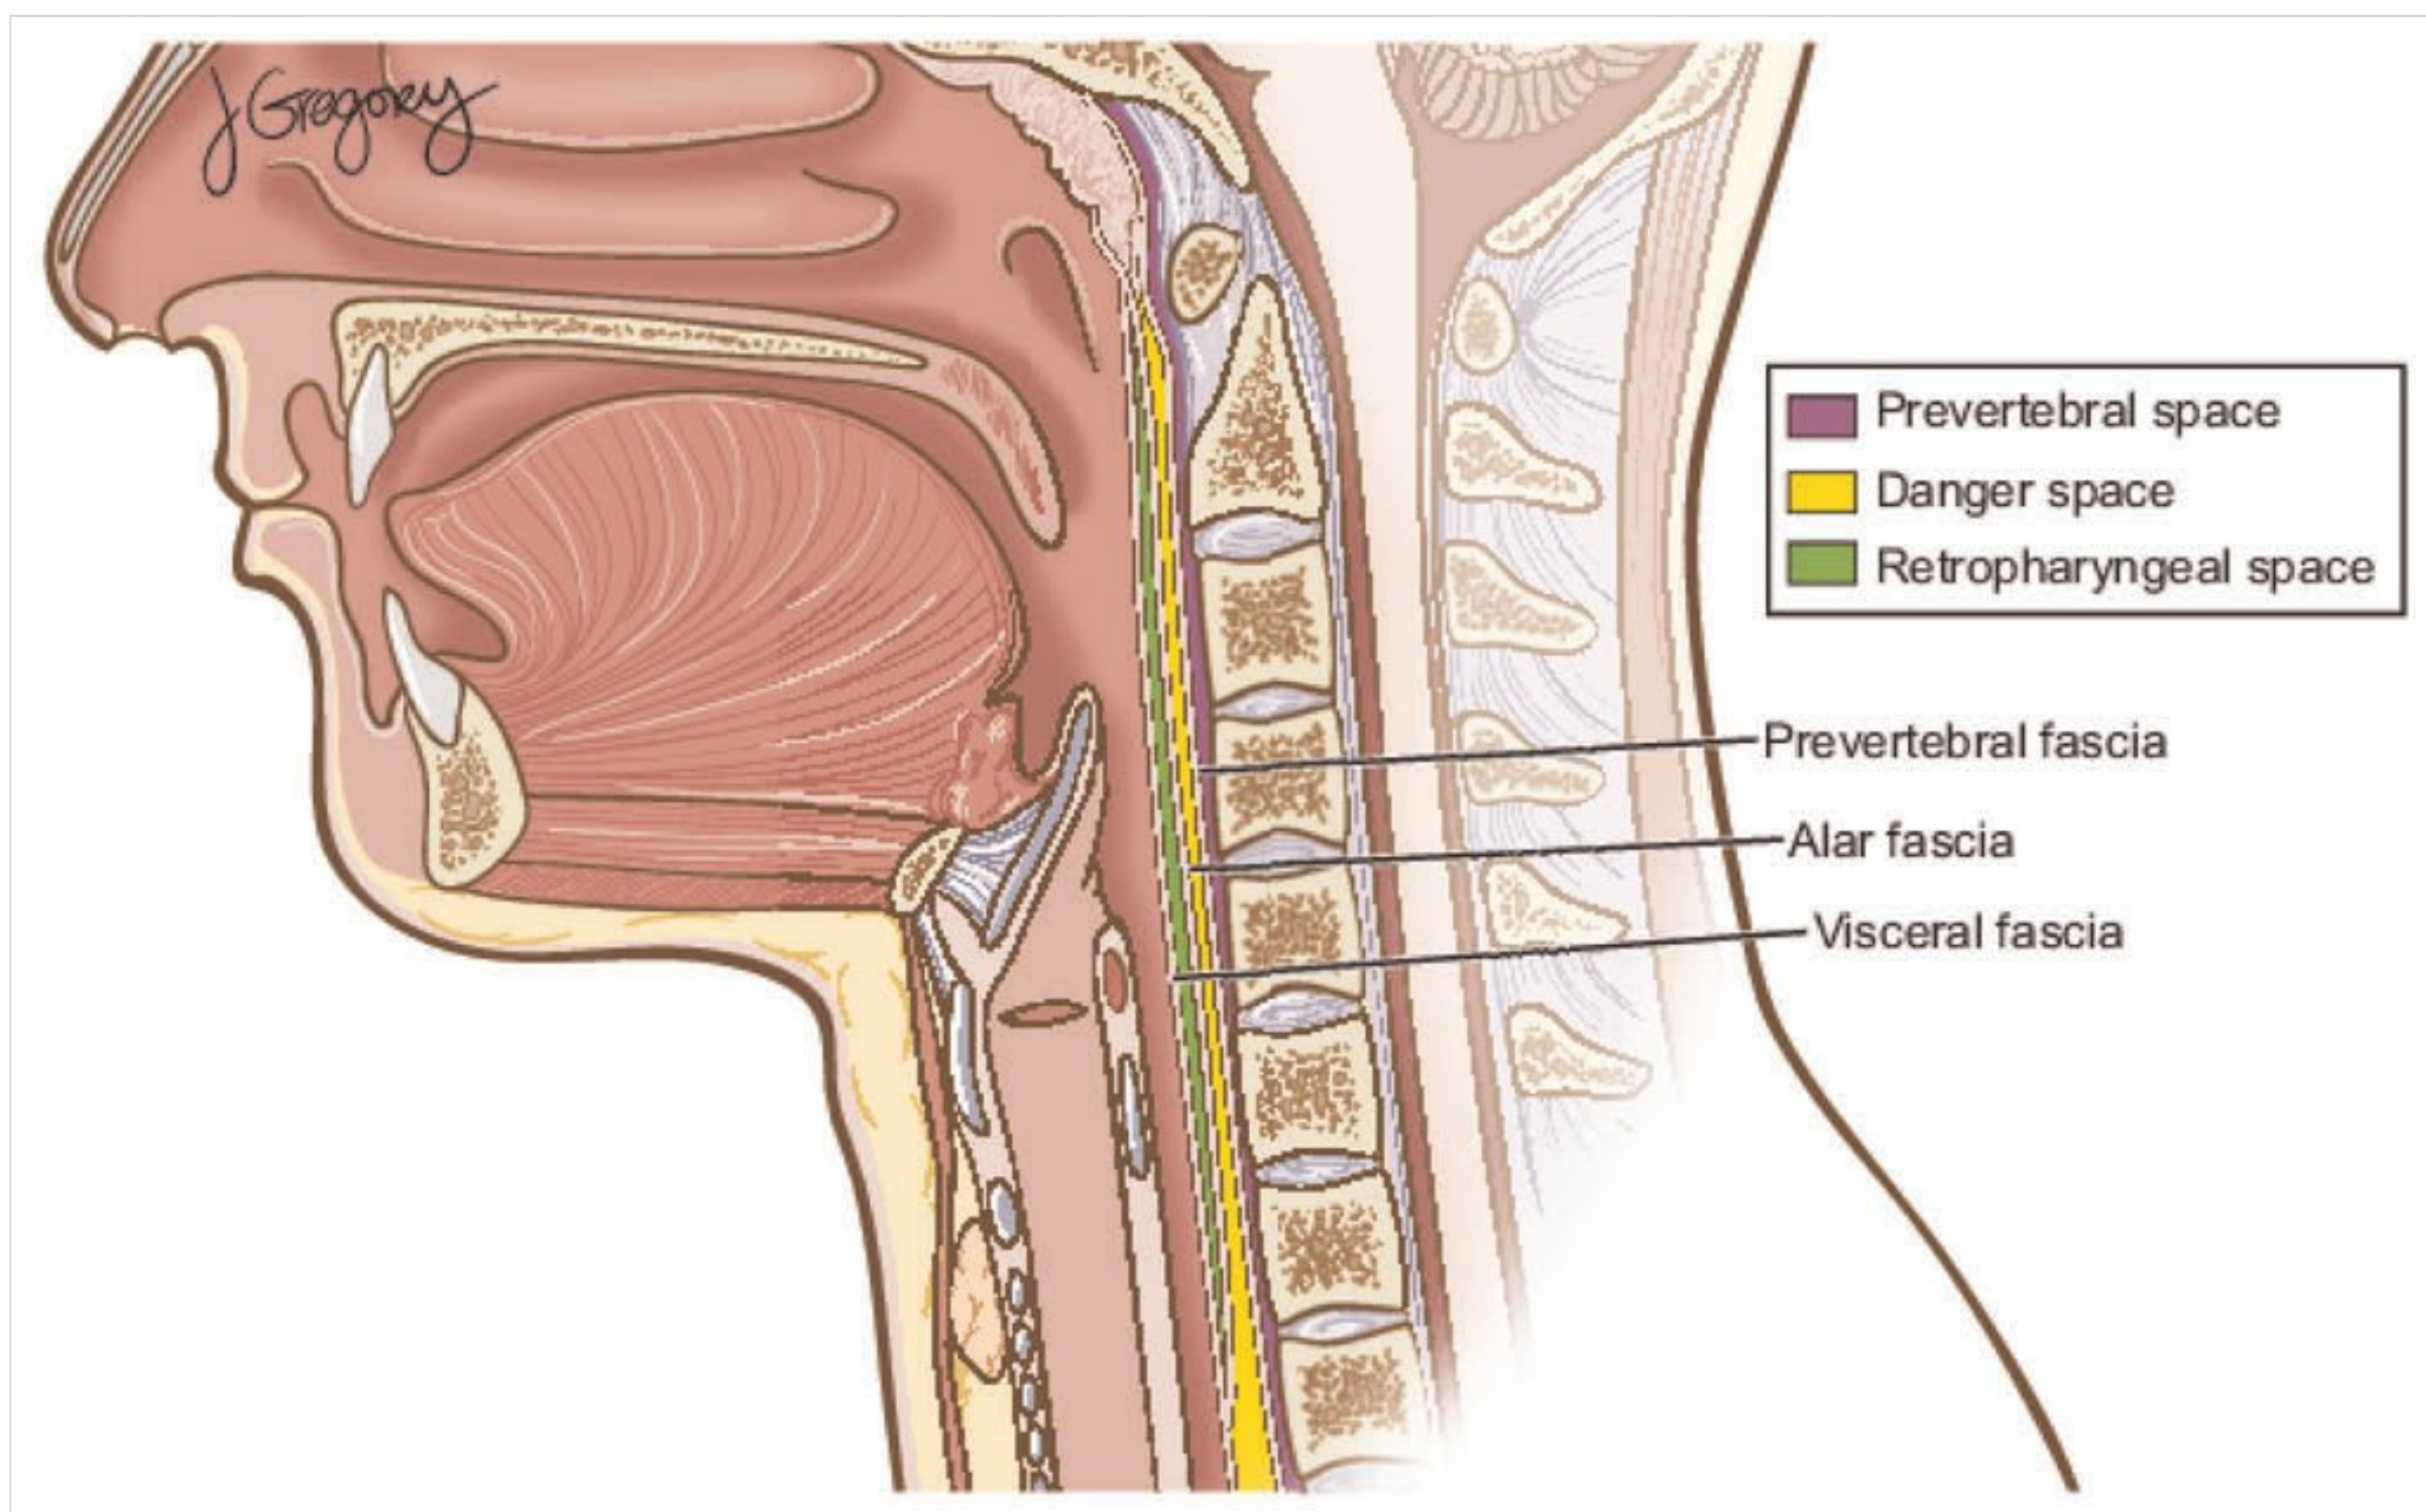

Fig. 15.2 Sagittal view of the deep neck spaces and fascial layers extending through the neck.

The submandibular and sublingual space is bordered by the mandible, floor of the mouth, superficial layer of the deep cervical fascia, and parapharyngeal space. The mylohyoid muscle originates from the mandibular line of the inner cortex of the mandible and separates the submandibular space below from the sublingual space above. Dental infections anterior to the second molar (above the mandibular line) usually result in sublingual space infections. Infections of the second and third molars (below the mandibular line) usually cause submandibular space infection and readily spread to the parapharyngeal space posteriorly.

The lateral pharyngeal or parapharyngeal space extends from the skull base to the hyoid bone. It is bounded by the ramus of the mandible, parotid, pterygoid muscles, and superior pharyngeal constrictors. It is divided into prestyloid and poststyloid compartments. The prestyloid space contains fat, the internal maxillary artery, and branches of the trigeminal nerve. The poststyloid space contains the carotid artery; internal jugular vein; cranial nerves IX, X, and XI; and the sympathetic chain. Because of its proximity to the peritonsillar, submandibular, masticator, and parotid space, the parapharyngeal space is readily involved.

The visceral space is the only space existing solely below the hyoid bone. It is bounded by the pharyngeal constrictors laterally and the alar fascia posteriorly. As the name suggests, it contains the pharynx, larynx, esophagus, trachea, and thyroid. Foreign body, trauma, and iatrogenic events are usually the causes of infections in this space.

The spaces that extend the entire length of the neck are the retropharyngeal space, danger space, and prevertebral space (□ Fig. 15.2). The retropharyngeal space exists between the visceral division of the middle layer of the deep cervical fascia and the alar division of the deep layer of the deep cervical fascia. Between the alar and prevertebral divisions of the deep cervical fascia is the danger space. Clinically, infections in both these spaces typically arise from the nose, sinuses, and nasopharynx. They have the potential of causing mediastinitis by virtue of their location. The prevertebral space is posterior to the prevertebral division of the deep layer of the deep cervical fascia and contains the longus colli muscle. Infections here may travel farther below the diaphragm to the coccyx.

It is important to realize that although the fascial layers and spaces have distinct names and separate borders (□ Fig. 15.3), infectious processes may readily spread through the boundaries. A simple manageable infection may become life-threatening unless prompt evaluation and treatment are instituted.

15.3 The Disease Process

15.3.1 Etiology

The etiology of deep space cervical infections varies widely. Parkscar and Har-El reported that 43% of the infections are dental in origin, while the second most common cause is intravenous (IV) drug injection (12%). Other causes noted were pharyngotonsillitis, mandible fracture, skin infection, tuberculosis,

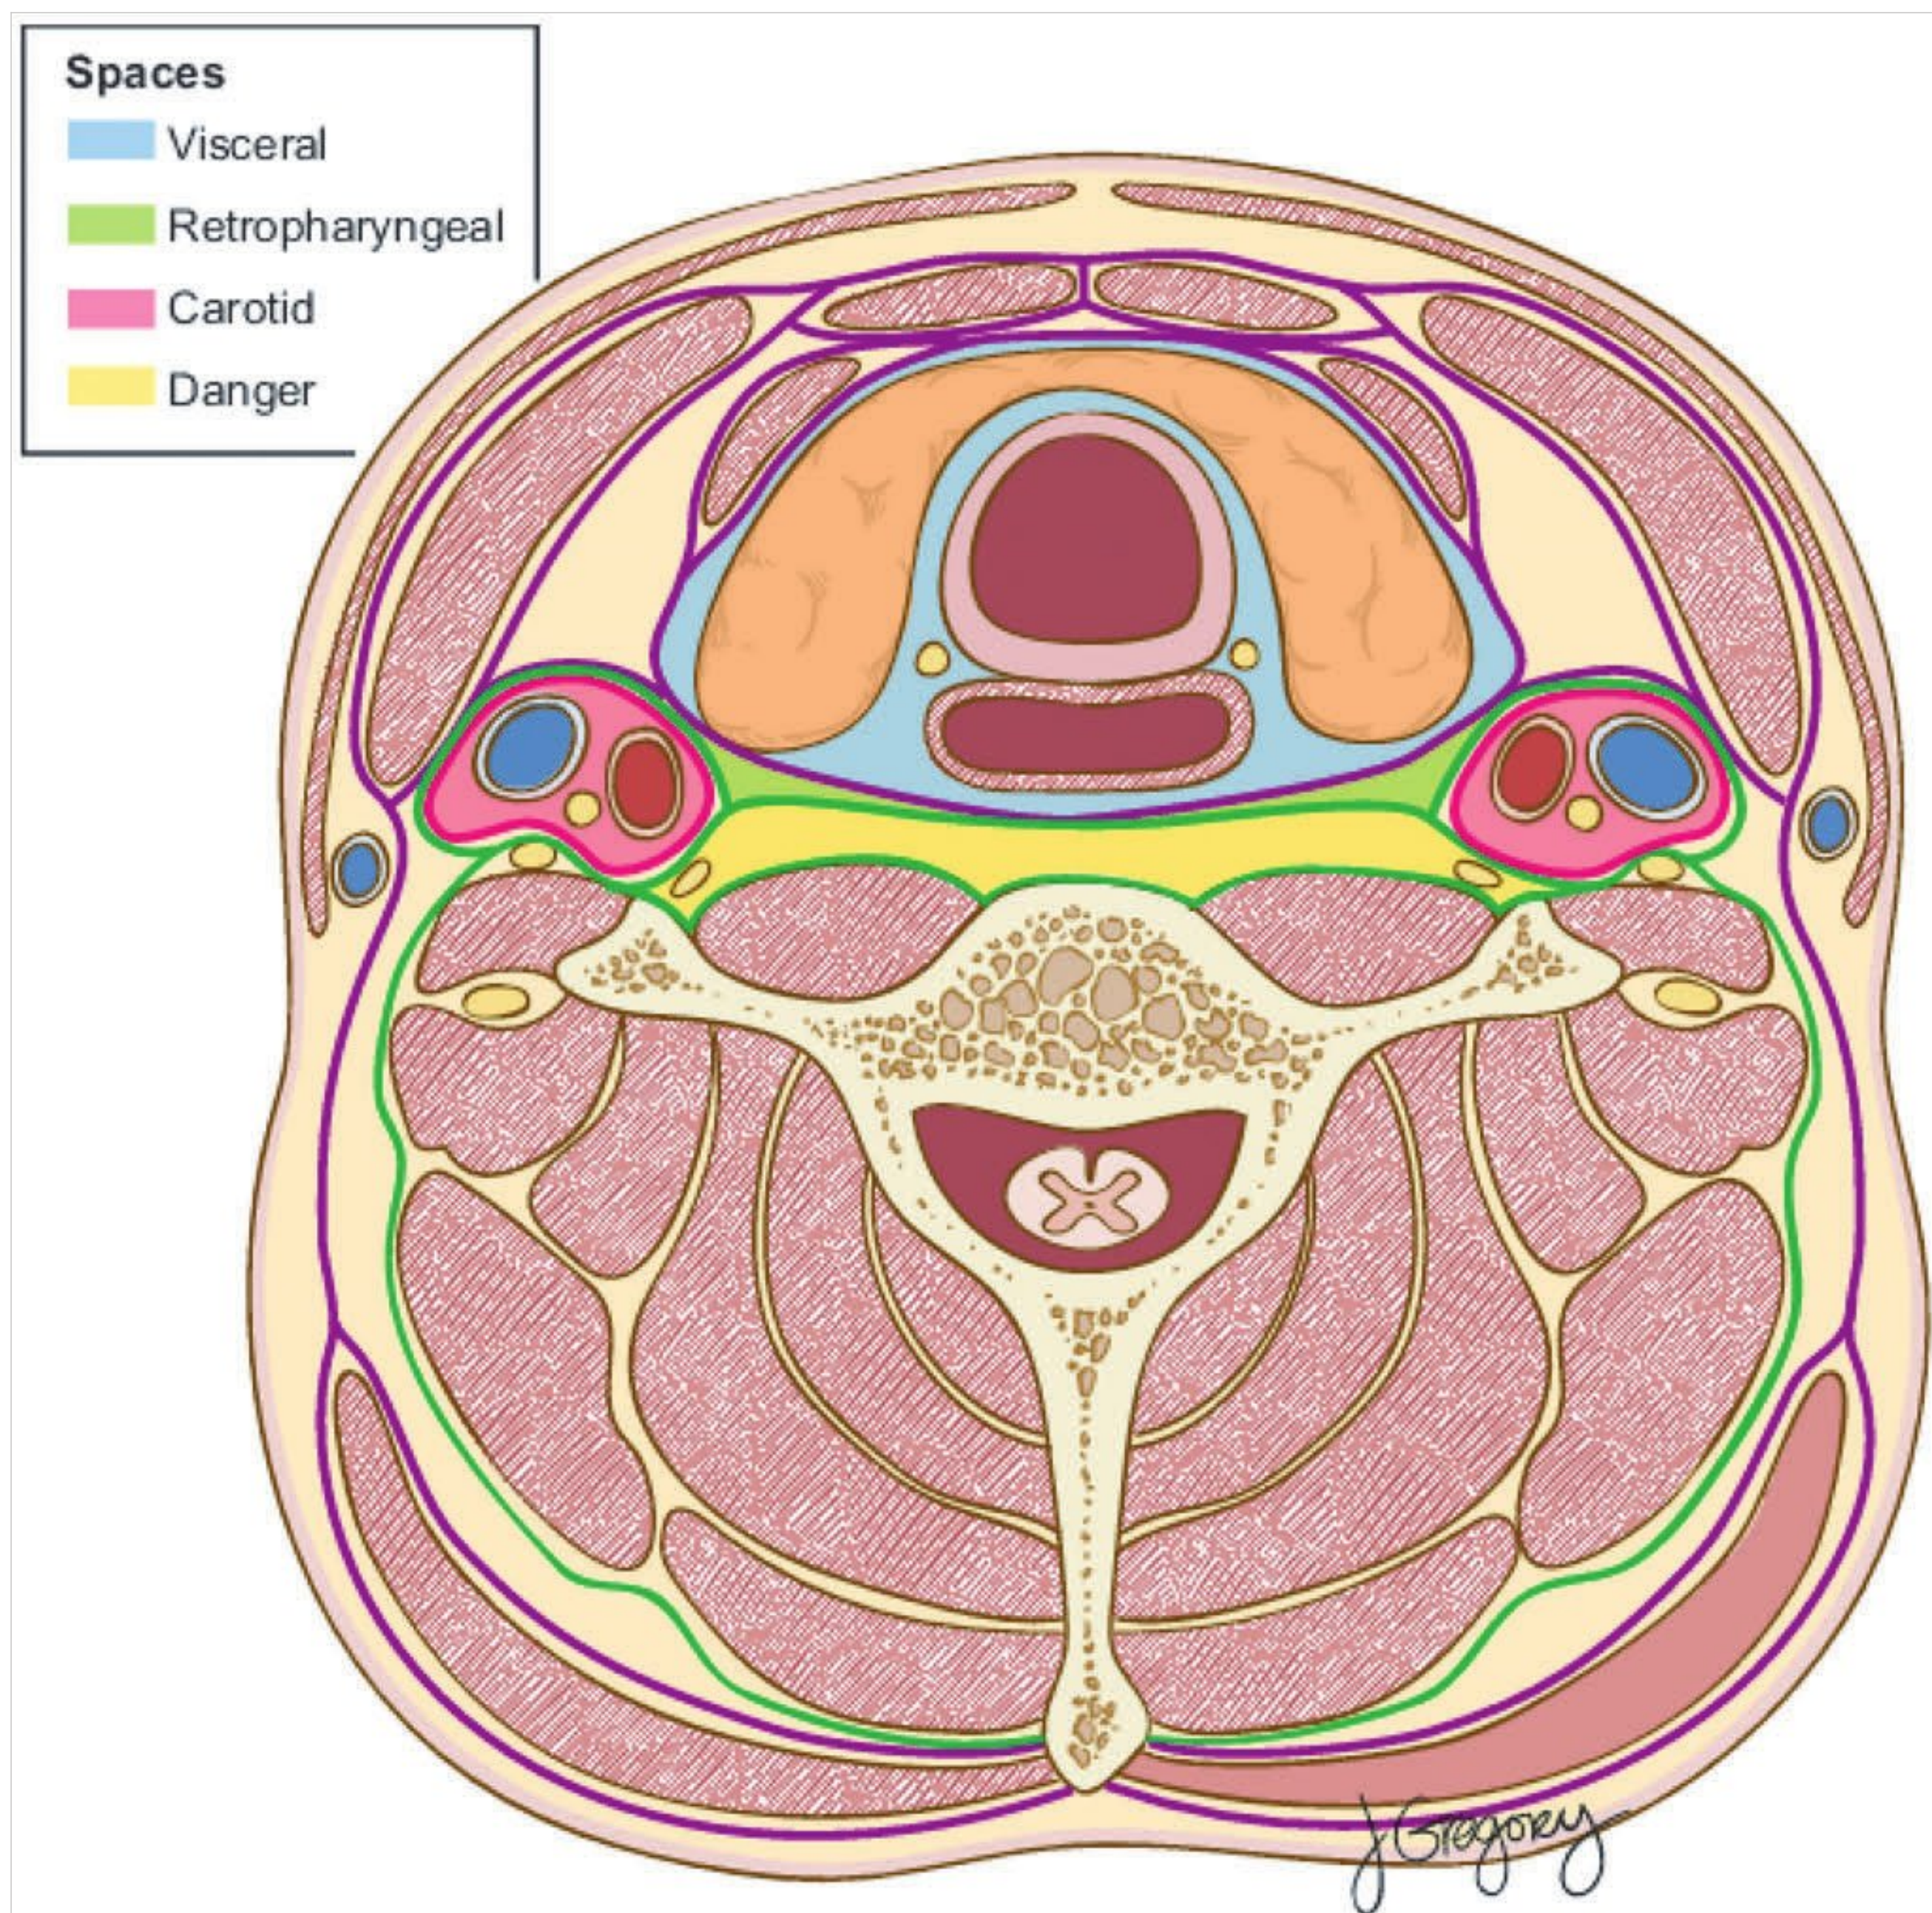

Fig. 15.3 Axial view through the lower neck demonstrating the fascial layers and deep neck spaces.

foreign body, trauma, peritonsillar abscess, sialolithiasis, and parotitis, together comprising the other 45% of infections.

15.3.2 Microbiology

Most of the deep space neck infections are polymicrobial in origin. Several studies have examined the culture results from these patient populations. The most commonly cultured bacteria are *Streptococcus viridans*, *Staphylococcus epidermidis*, *Staphylococcus aureus*, *Bacteroides* species, and β -hemolytic streptococci. Anaerobes were cultured in 35% of the infections. Gram-negative organisms were present in fewer than 4% of infections.

15.3.3 Potential Complications

Infections in each of these areas can lead to complications that can cause significant morbidity and mortality. The most urgent complication of deep neck space infection is airway compromise. Ludwig angina deserves special discussion. It is an extension of dental infection in the sublingual space. It is associated with necrotizing cellulitis, causing swelling of the floor of the mouth and base of the tongue. Airway compromise and death ensue if the condition is not promptly treated. Many of these patients require emergent airway establishment via tracheotomy followed by incision and drainage of the involved space.

Other notable entities include danger space and retropharyngeal space infections. The predominantly loose areolar tissue in these spaces affords little resistance to the spread of infection. The rapid development of mediastinitis may prove fatal.

Neurologic complications can occur through the irritation and compression of involved nerves, such as the cranial nerves and the sympathetic chains in the poststyloid compartment of the parapharyngeal space. They can also occur through the extension of infections from adjacent deep neck spaces. Pott abscess, for example, is a result of mycobacterial infectious extension posteriorly from a vertebral body.

Vascular compromise and septicemia can occur when the infection extends into the carotid sheath. Involvement of the internal jugular vein can lead to Lemierre syndrome, with associated pulmonary septic emboli. Carotid artery rupture preceded by sentinel bleeding is another feared complication with significant morbidity and mortality.

15.4 Medical Evaluation

15.4.1 Presenting Complaints

The presenting complaint for patients depends on the location of the infection. Systemic symptoms include fever, chills, pain, and loss of appetite. Symptoms and signs specific to the deep cervical spaces are listed in □ Table 15.1. When these patients are interviewed, it is important to obtain an accurate history of any recent infections, surgeries, dental care, or traumatic events. It is also important to gather a past medical history and social history, especially those pertaining to the immune status of the patient, such as HIV disease, diabetes, and IV drug use.

15.4.2 Physical Findings

A comprehensive head and neck examination should be performed. Special attention should be paid to any areas with edema, tenderness, and limitation of muscular or neural functions, which will help determine the deep neck space involved. Routine examination of the dentition will shed light on possible sources of infection in quite a number of cases. Trismus is a common finding in many of these deep neck space infections. Dyspnea is typically a significant finding, and the stability of the airway should be ensured before the patient is sent for any testing. Localized, tense swelling of the neck can help indicate the origin and location of a deep neck infection.

15.4.3 Testing

Diagnosing deep neck space infections may be obvious or require various imaging modalities. Maintaining a high index of suspicion is important. The patient should initially have a complete blood cell count, basic metabolic panel, coagulation profile, and blood and abscess cultures. When accessible, a fine needle aspiration can be performed at the bedside to obtain such a culture.

Imaging is usually performed in these patients to either localize or determine the presence of an abscess. Several studies have looked at the efficacy of different imaging modalities for this purpose. The original imaging modality because of its ease of use and low expense is the lateral neck X-ray. It is frequently used in retropharyngeal abscess. The results can be affected by head positioning, but the standard measurements for retropharyngeal soft-tissue thickness are 7 mm at C2 and 14 mm in children and 22 mm in adults at C6. A Panorex image can be

Table 15.1 Signs and symptoms of deep neck space infections

Space	Presenting symptoms	Clinical findings
Buccal	Cheek swelling, trismus	Gingival and/or buccal erythema and edema, facial edema and thickening of cheek, posterior teeth tenderness (usually the third molar)
Submandibular/sublingual	Submandibular/submental pain, oral dysphagia, odynophagia	Bulging of floor of mouth, restriction of tongue movement, submandibular/submental edema
Masticator	Trismus, cheek swelling, cheek pain, toothaches	External or internal cheek enlargement, trismus, posterior teeth tenderness (usually the third molar)
Parotid	Trismus, parotid pain	Swelling at angle of jaw, Stensen duct papillae, edema with or without pus drainage, trismus
Peritonsillar	Trismus, “hot potato” voice, dysphagia, drooling	Uvula deviation, soft palate swelling, tonsil displacement
Parapharyngeal	Prestyloid: trismus Poststyloid: neural compressive symptoms of cranial nerves IX, X, and XI and sympathetic chain	Prestyloid: swelling of angle of mandible, lateral displacement of pharyngeal wall and tonsil Poststyloid: swelling of posterior pharyngeal wall, cranial nerve and sympathetic chain deficits
Visceral	Dyspnea, dysphagia, hoarseness	Swelling and erythema of hypopharynx, subcutaneous emphysema, airway compromise
Carotid	Tenderness deep to sternocleidomastoid, torticollis to the opposite side, septicemia	Cyclic spiking fevers, septic hypotension and organ failure, neural deficits (cranial nerve X), carotid blowout
Retropharyngeal/danger	Dyspnea, dysphagia, odynophagia, neck pain and stiffness	Bulging of posterior pharyngeal wall, asymmetric enlargement of the neck masses, stridor
Prevertebral	Similar to those of retropharyngeal/danger space	Torticollis, decreased range of motion of the neck, neural involvement from compression of the cervical nerves

valuable in abscesses of dental origin. Proper dental evaluation and treatment can be promptly initiated.

Further testing is performed with computed tomography (CT) with IV contrast and magnetic resonance imaging. CT is by far the more commonly performed procedure given that it is rapid, widely available, and relatively inexpensive. An area of low density with a ring of enhancement on a contrast CT scan is diagnostic of abscess. Knowing the location, size, and relationship of the infection to surrounding structures is invaluable in the treatment of the disease. The extent of deep neck space infections may be underestimated in 70% of patients by physical examination, underscoring the importance of CT in aiding the evaluation of these patients.

15.5 Treatment

15.5.1 Initial Treatment

The patient's breathing should be assessed immediately; after the airway is secured, the circulation is assessed with blood pressure and physical signs of dehydration. Because of the incidence of dysphagia and sepsis, the patient may present with hypovolemia and shock. IV fluids are required for volume expansion. Occasionally, pressors may be necessary. Any metabolic derangement is corrected at the same time.

The initial treatment of deep neck space infections is the same for all patients, which is establishment a patent airway. Many of these patients can present with stridor due to soft-tissue swelling around the airway. This is further exacerbated by the frequent presence of trismus. Patients may require oro-tracheal or nasotracheal intubation; tracheotomy should be performed expeditiously if oral or nasal intubation cannot be performed. When dealing with a retropharyngeal abscess, the clinician must take special care to avoid rupturing the abscess during intubation. A Trendelenburg position may prevent aspiration.

15.5.2 Secondary Treatment

Once the patient is stabilized, attention is turned to treating the infection. In principle, cellulitis is managed with antibiotics, but abscesses require drainage combined with antibiotics. Sometimes, patients with a small abscess are given time to respond to IV antibiotics before surgery is pursued. In selected pediatric patients with retropharyngeal and parapharyngeal abscesses, antibiotics alone can achieve clinical resolution in many cases.

Conservative treatment with antibiotics is geared toward empiric coverage with antibiotics having broad-spectrum activity and β -lactamase resistance until cultures determine the causative organisms. The most common empiric antibiotics are clindamycin, ampicillin/sulbactam, cefuroxime, amoxicillin/clavulanate, metronidazole, and penicillin. These are used alone or in combination to cover the most common causative organisms. When a clinical response is observed, the parenteral antibiotics are usually continued for 48 hours before oral antibiotics are given.

If conservative antibiotic treatment fails, surgical drainage becomes necessary. Surgery usually requires incision and drainage followed by copious irrigation and placement of a drain.

Abscess cultures must be obtained to direct postoperative antibiotic therapy.

The surgical approach is different depending on the location of the abscess. However, the general surgical principle of an adequate exposure is key to evacuating an abscess without compromising the surrounding vital structures.

Buccal and peritonsillar infections can be accessed and drained through the oral cavity and allowed to drain freely. Buccal space abscesses can be drained through a mucosal incision above the Stenson duct, followed by blunt dissection of the buccinator muscle fibers and penetration of the buccopharyngeal membrane. Peritonsillar abscesses can be drained by incising the soft palate just above the superior tonsillar pole and bluntly dissecting the space above the tonsil with a fine curved clamp. Alternatively, peritonsillar abscesses can be aspirated with a 21-gauge needle. Care must be taken to avoid deep needle insertion into the peritonsillar space because of the proximity of the internal carotid artery. Parapharyngeal space abscesses are approached through a transcervical incision to allow identification and protection of the neurovascular structures. Submandibular/sublingual abscesses can be approached and drained through the oral cavity or an external incision. This is usually determined by the location of the abscess relative to the mylohyoid; abscesses superior to the mylohyoid can be drained through the oral cavity, whereas those inferior and posterior are drained through an external incision.

Retropharyngeal, danger, and prevertebral space abscesses can be drained through either an external or internal approach. This is determined by the extent of the infection. Localized infection can be drained intraorally with the patient intubated and in a Trendelenburg position. When the infection is large and life-threatening, a transverse cervical approach is used.

Treating immunocompromised patients with deep neck space infections requires a heightened suspicion for the involvement of atypical agents. *Pseudomonas*, methicillin-resistant *Staphylococcus aureus*, and fungal and mycobacterial agents must be included in the differential of offending organisms. Mycobacterial tuberculosis should be treated medically, not surgically, because of the increased risk for draining fistula after open surgical treatment.

15.5.3 Postoperative Care

Postoperatively, antibiotics are adjusted according to the culture results. Patients typically improve expeditiously, and surgical drains can be slowly advanced and removed as each patient's progress allows. Large abscess cavities sometimes require irrigation with saline. Lack of a response to the therapy should prompt a close examination for the persistence or reaccumulation of an abscess. Repeat imaging and drainage should be attempted.

15.5.4 Complications

Even after surgery, the airway should be closely monitored, as extrinsic compression and tissue edema take time to resolve. An endotracheal or tracheotomy tube is maintained until after a patent airway is confirmed with endoscopy. The aspiration of purulent fluid may have occurred before or during surgery,

which can lead to pneumonia. Mediastinal extension with the development of mediastinitis is often preceded by unexplained tachycardia and fever. Chest X-ray shows a characteristic mediastinal widening. A thoracic surgery consultation should be sought promptly for possible drainage.

Other complications include internal jugular vein thrombosis with septic emboli, carotid rupture, and neurologic deficits of the involved cranial nerves and sympathetic chain. Necrotizing cervical fasciitis has a high morbidity and mortality rate due to a rapid, aggressive invasion of fascia and tissue with ensuing necrosis. Surgical débridement, parenteral antibiotics, and hyperbaric oxygen are usually indicated.

15.6 Roundsmanship

- In treating patients with deep neck space infections, airway control is the most important initial treatment decision.
- CT scan is the best imaging modality due to its cost, ease of access and diagnostic purposes.

- Treatment of deep neck space infections includes a combination of appropriate antibiotic and drainage.
- Antibiotics should be started empirically and specified to cultured bacteria, which is usually polymicrobial.

16 Evaluation and Management of Hearing Loss in Adults

Tina Qingxin He

Hearing loss affects approximately 28 million Americans. The prevalence increases with age, and it is estimated that a third of people age 65 and older have a significant hearing loss. Hearing loss can cause a major problem with communication, thereby affecting education, employment, and relationships.

16.1 Classification of Hearing Loss

Hearing loss is generally divided into three broad categories: conductive hearing loss (CHL), sensorineural hearing loss (SNHL), and mixed hearing loss. CHL is caused by an obstruction in the transmission of sound as the sound waves pass from the air through the auricle into the inner ear (□ Fig. 16.1). The most common etiologies of CHL are cerumen impaction and middle ear infections. Conditions that alter ossicular stiffness, such as otosclerosis, produce predominantly low-frequency hearing loss, whereas changes in the mass of middle ear structures classically produce high-frequency deficit.

16.1.1 Selected Etiologies of Conductive Hearing Loss

- Congenital anomalies of the external and middle ear may be hereditary or sporadic in presentation and either syndromic or nonsyndromic. Patients usually present with a history of hearing loss since birth. Examples include aural atresia, microtia, and ossicular malformation.
- Foreign bodies of the external auditory canal and cerumen are common presentations of CHL. These can be easily removed if the patient is cooperative, the foreign body is small, and adequate tools are available. A microscope should be used

Fig. 16.1 Audiogram of mild conductive hearing loss with an air-bone gap. ANSI, American National Standards Institute.

when possible to prevent injury to the external auditory canal and tympanic membrane. In an uncooperative patient with a large occluding foreign body, removal of the foreign body under anesthesia may be the safest treatment.

- Inflammatory/infectious processes are one of the most common causes of CHL.
 - Otitis externa, either acute or chronic, is one of the most common problems causing CHL. Acute otitis externa can be caused by bacterial, viral, or fungal infections. The most common pathogens in acute otitis externa include *Pseudomonas aeruginosa*, *Staphylococcus*, and *Proteus*. Cleaning of the external auditory canal under the microscope and treatment with appropriate medication are usually all that is required. In cases of severe acute otitis externa in which the canal is extremely edematous, an ear wick is placed in the canal for several days to expand the canal and facilitate the administration of antibiotic drops deep into the canal. Necrotizing otitis externa (malignant otitis externa) is a rapidly progressive, potentially life-threatening infection involving the skin, cartilage, and bone surrounding the external auditory canal. This disease is usually found in elderly immunocompromised patients. *P. aeruginosa* is the most common causative agent. Hospitalization for the administration of intravenous antibiotics or prolonged oral antibiotics may be necessary for treatment.
 - Acute and chronic otitis media. The sequelae of chronic otitis media, including tympanic perforation, ossicular erosion, and tympanosclerosis, are major causes of hearing loss.
 - Cholesteatoma is an epidermal inclusion cyst of the middle ear and/or mastoid. It may be congenital or acquired. The cholesteatoma contains desquamated debris from keratinizing squamous epithelial lining. The expansion of a cholesteatoma can cause bone erosion of the ossicles and otic capsule.
- Trauma
 - Trauma to the auricle or external auditory canal is common. Poorly protected by surrounding structures, the external ear is vulnerable to blunt, sharp, and thermal injury. For example, athletes in sports such as boxing frequently present with auricular hematoma or laceration. Trauma can also result from frostbite or burn injuries.
 - The most common locations for traumatic tympanic membrane perforation are the anterior-inferior and posterior-inferior quadrants. Tympanic membrane perforation can be the result of a penetrating injury or blunt trauma. Whereas penetrating injury tends to present with a linear perforation, blunt trauma tends to present with a larger stellate defect.
 - Injury to the middle ear and temporal bone is much less common and requires much more intense force of trauma. The middle ear and temporal bone are protected by dense bones. Therefore, injuries to the middle ear and temporal bone rarely present in isolation; instead, temporal bone fractures are frequently the result of a motor vehicle accident, and patients may present with a constellation of injuries involving other major systems. Longitudinal temporal

bone fractures account for 70 to 90% of temporal bone fractures, are associated with bleeding from the external canal, and present with conductive hearing loss. SNHL is relatively uncommon in patients with longitudinal skull fractures.

Transverse temporal bone fractures result from more severe occipital injury and present with SNHL and hemotympanum.

- Otosclerosis is a disease of the bone causing fixation of the stapes footplate in the oval window. Otosclerosis presents as progressive CHL in an otherwise normal-looking ear. It is an autosomal-dominant hereditary disease with variable penetrance and expression that affects more women than men.
- Neoplasms. Carcinomas and benign tumors of the external auditory canal and temporal bone are uncommon. Squamous cell carcinoma is by far the most common malignant tumor of the external auditory canal, followed by basal cell carcinoma and adenoid cystic carcinoma. Carcinomas of the external auditory canal usually occur in older individuals.
- Systemic diseases
 - Wegener granulomatosis is a granulomatous disease associated with necrotizing vasculitis. It primarily affects the upper and lower respiratory tracts and kidneys. When the granulomatous process involves the eustachian tube, it will present as serous otitis media with CHL. Involvement of the inner ear will cause rapidly progressive SNHL.
 - Sarcoidosis commonly manifests with cough. Chest X-ray shows bilateral hilar adenopathy. Involvement of the temporal bone may cause facial, auditory, or vestibular nerve dysfunction.
 - Tuberculosis can rarely cause otitis media and tympanic membrane perforations. Patients who have this disease may present initially with painless multiple small perforations of the tympanic membranes that progress to form large tympanic membrane perforations. Otologic involvement occurs as a result of hematogenous or lymphatic spread to the middle ear.

SNHL is caused by problems involving sound processing after sound waves reach the inner ear (□ Fig. 16.2). SNHL can occur at the level of the cochlea, cochlear nerve, central auditory pathways, or cerebral cortex centers. Noise exposure and presbycusis are the leading causes of SNHL.

16.1.2 Selected Etiologies of Sensorineural Hearing Loss

- Presbycusis is age-related hearing loss. This may affect more than 30% of persons older than 65 years of age. Patients commonly present with bilateral symmetric high-frequency SNHL and poor speech discrimination.
- Hereditary disorders. These can be divided into syndromic and nonsyndromic forms of hereditary hearing loss. An estimated 70 to 80% of cases of hereditary hearing loss are nonsyndromic. Although most cases of hereditary hearing loss present at birth, some persons inherit a tendency to develop hearing loss later in life. Some examples of syndromes associated with hereditary hearing loss include Waardenburg syndrome, Alport syndrome, and Usher syndrome.

Fig. 16.2 Audiogram of sensorineural hearing loss in the left ear. ANSI, American National Standards Institute.

- Inner ear and temporal bone anomalies. Inner ear anomalies are classified as either membranous or combined membranous and osseous. These anomalies usually present as profound SNHL in children. In the case of large vestibular aqueduct syndrome, the SNHL can present in adulthood as progressive deterioration with a propensity for the sudden development of SNHL after head trauma.
- Infectious disorders
 - Labyrinthitis
 - Herpes zoster oticus or Ramsay Hunt syndrome is caused by reactivation of the varicella-zoster virus during a period of immunosuppression many years after the primary infection, which manifests as chickenpox. The cause appears to be a recrudescence of a latent varicella-zoster virus infection of the geniculate ganglion. The initial presentation includes painful vesicles on the pinna or along the external auditory canal. This is followed by facial paralysis in a couple of days. Auditory and vestibular symptoms develop in approximately 25% of these patients. The diagnostic work-up should include a Tzanck smear.
 - Serous and bacterial suppurative labyrinthitis generally presents with sudden severe SNHL and acute vertigo. The hearing loss is usually permanent, but the vertigo may improve with treatment.
 - Chronic otitis media and cholesteatoma. Paparella et al showed that in patients with chronic otitis media, permanent SNHL may result from the passage of toxic substances through the round window. When a large cholesteatoma expands to the otic capsule, it may result in SNHL, presumably secondary to suppurative labyrinthitis.
 - Syphilis can be classified as congenital or acquired. In congenital syphilis, hearing loss occurs in approximately one-third of patients. In acquired syphilis, the middle ear may be affected in late latent and tertiary forms. The symptoms may be sudden SNHL, fluctuating hearing loss, episodic vertigo, or progressive hearing loss and tinnitus. Ootosyphilis can often be associated with the Hennebert sign and the

Tullio sign. The Hennebert sign is a positive fistula test in the absence of middle ear disease. The Tullio sign is vertigo and nystagmus elicited with exposure to a loud sound. A definitive diagnosis of syphilis requires a positive finding of *Treponema pallidum* on serology.

- Lyme disease. *Borrelia burgdorferi* is the offending organism in Lyme disease. Facial nerve paralysis is the most common otologic manifestation. Auditory and vestibular manifestations such as SNHL, sudden hearing loss, and positional vertigo are less common.
- Meningitis. This is a known etiology of acquired severe-to-profound SNHL.
- Pharmacologic toxicity
 - Aminoglycosides appear to affect the function of hair cells, some causing eventual cell death.
 - Loop diuretics alter metabolism in the stria vascularis. Hearing loss due to loop diuretics may be reversible.
 - Salicylates and aspirin may cause reversible SNHL. On discontinuation of the medication, hearing returns to normal within 72 hours. Ototoxicity due to nonsteroidal anti-inflammatory drugs is rare.
- Meniere disease is of unknown etiology. It results in endolymphatic hydrops and presents with episodic low-frequency SNHL, aural fullness, vertigo, and tinnitus. The hallmark of this disease is its variability and unpredictability. It is bilateral in 30 to 50% of cases.
- Systemic disease
 - Paget disease of bone is of unknown etiology. New bone formation or remodeling of temporal bone can cause hearing loss, tinnitus, and mild vestibular dysfunction.
 - Multiple sclerosis. Between 4 and 10% of patients with multiple sclerosis develop SNHL.
 - Wegener granulomatosis. When Wegener granulomatosis involves the ear, it usually causes CHL. Rarely, this disease involves the inner ear to cause SNHL.
- Neoplasm
 - Acoustic neuroma. This is a benign vestibular schwannoma that may account for 10% of patients who present with sudden SNHL.
- Trauma
 - Noise trauma is one of the most common adult hearing problems encountered. It is also one of the more easily preventable causes of SNHL. An estimated 10 million Americans have noise-induced hearing loss. The primary sites of damage are the inner hair cells and outer hair cells of the organ of Corti, with the outer hair cells most affected in the initial stages of hearing loss.
 - Labyrinthine injury can result from severe trauma to the head. Longitudinal temporal bone fractures mostly present with CHL but can also present with high-frequency SNHL. Transverse temporal bone fractures, however, almost always result in a complete loss of auditory and vestibular function.
 - Acquired perilymphatic fistula can result from barotrauma or as a complication of ear surgery. The fistula can occur at either the round or oval window. When barotrauma is the inciting etiology, the presenting history is acute hearing loss immediately following heavy lifting, straining, flying, or underwater diving. The fistula test may yield a positive Hennebert sign.
- Vascular disorders

- Migraine. This is a common disorder that usually presents with headaches and an associated visual aura. Of patients with basilar migraine, 30 to 45% have been found to have low-frequency SNHL.

Mixed hearing loss is a combination of CHL and SNHL. It is often caused by a combination of the above etiologies.

16.2 Evaluation of Hearing Loss

When a new patient with hearing loss is evaluated, it is important to obtain a thorough history and physical examination before moving on to the audiogram.

16.2.1 History

Questions that should be asked in the work-up of hearing loss:

1. Age at onset.
2. Circumstances surrounding onset.
3. Unilateral or bilateral hearing loss.
4. Severity and speed of progression.
5. Duration of complaint; patients with sudden SNHL require a stat audiogram and need to be treated immediately.
6. Associating symptoms: tinnitus, vertigo, aural fullness, pain, otorrhea, or autophony.
7. Other ear-related history, including noise exposure, previous ear infections, and ear surgeries.
8. Personal and medical history, current medications, surgical history, social history, past head trauma, and exposure to ototoxic agents.
9. Family history of hearing loss.

16.2.2 Physical Examination

In addition to a complete head and neck examination, a thorough evaluation of the external and middle ear is essential. Keep in mind that patients with SNHL often have completely normal examinations. The removal of any obstructing foreign body or cerumen is absolutely essential. Many beginners make the mistake of looking for the light reflex only on the tympanic membrane. Make sure that the entire tympanic membrane is visualized. Some diseases can involve only a small portion of the tympanic membrane. For example, a middle ear cholesteatoma can manifest as a flattened crust on the posterior–inferior quadrant of the tympanic membrane. The mobility of the tympanic membrane is then checked with a pneumatic otoscope to determine the presence of retraction or fluid in the middle ear. In addition, an operating microscope can be useful for the removal of foreign bodies and for more detailed examination of the middle ear.

The Weber and Rinne tests can be performed to identify the side of hearing loss and to confirm the audiometric results. The Weber test is done by placing a vibrating tuning fork in the mid-portion of the forehead and asking the patient which side he or she can hear more clearly. A normal Weber response occurs when the sound is heard equally in both ears or across the forehead. If the sound seems louder in one ear, this can indicate CHL in the ear with the louder response or SNHL in the contralateral ear. The Rinne test response is normal when the air

conduction sounds louder than the bone conduction. The 512- and 1,024-Hz tuning forks are typically used for this purpose. A patient who has a recent history of acute pressure changes, such as a scuba diver, would benefit from a fistula test.

16.2.3 Audiometry

Audiometric testing is essential to verify and quantify the degree of hearing loss. Air conduction, bone conduction, speech audiometry, and tympanometry are the basic tests included in the audiogram. Speech audiometry, in addition to determining the nature of the SNHL, can provide prognostic information regarding the potential benefits of amplification. Tympanometry is essential for verifying any CHL and can confirm a retracted, stiff, or perforated tympanic membrane. Acoustic reflex testing can provide additional clues to the etiology of hearing loss. Auditory brainstem response (ABR) is useful for evaluating a retrocochlear etiology or for evaluating adult patients who are unable to respond to a normal audiogram. In offices where an audiologist is not readily available, therefore, the audiogram is ordered for a future date unless a sudden SNHL is suspected; in this case, the audiogram needs to be performed immediately so that the patient can be treated as soon as possible.

16.2.4 Laboratory Testing

For CHL, blood work is usually unnecessary; however, in unilateral or sudden SNHL, this can help determine the etiology in certain cases. The most useful test is the fluorescent treponemal antibody absorption (FTA-ABS) test.

16.2.5 Radiographic Testing

Most patients with CHL do not require radiographic examinations. Noncontrast computed tomography (CT) of the temporal bone can be used to visualize the middle ear and the mastoid. This can be useful for complicated middle ear pathology or persistent CHL despite treatment. On the other hand, CT is less useful in an adult with SNHL unless the hearing loss is congenital or secondary to recent trauma. Magnetic resonance imaging with gadolinium is used in patients with asymmetric or sudden SNHL to evaluate for a cerebral or retrocochlear cause of the hearing loss.

16.3 Treatment of Hearing Loss

16.3.1 Conductive Hearing Loss

Treatment of the underlying etiology is necessary to improve hearing loss. Some conditions are very easy to treat, such as cerumen impaction, acute ear infection, and foreign body, but others are much harder to correct. For conditions such as chronic serous otitis media, otosclerosis, tympanosclerosis, tympanic membrane perforation, canal stenosis, and ossicular chain abnormality, surgical intervention can be very beneficial. When surgery is discussed, the alternative of amplification with hearing aids must be presented. Patients with CHL have high speech discrimination scores and will experience significant improvement with hearing aids without the risks of surgery.

16.3.2 Sensorineural Hearing Loss

Most cases of SNHL are not reversible. The primary exception is sudden SNHL. This is defined as unilateral hearing loss not attributable to known causes that occurs in less than 3 days. Two-thirds of the patients recover to nearly normal hearing levels spontaneously and many improve with high-dose systemic corticosteroid treatment. Otherwise, treatment options for SNHL are limited. Even when the etiology of the hearing loss is corrected, the damage to the cochlea and auditory pathway is often permanent.

There are measures to mitigate the effects of SNHL on a patient's quality of life. Amplification devices such as hearing aids and assistive listening devices for telephones and televisions are a few examples. A hearing aid may be beneficial for patients with SNHL. When hearing aids are recommended, patient motivation and the perceived degree of handicap must be considered. Hearing aids have many limitations. Poor sound quality, discomfort, and the frequent need for battery change and cleaning are just a few of the common complaints. Many patients choose not to wear amplification simply because the social stigma of having a hearing aid. Many patients with SNHL have poor speech discrimination scores. Because hearing aids do not significantly improve speech discrimination, they often derive limited benefit. For patients with unserviceable hearing even with hearing aids, cochlear implantation should be considered.

16.4 Roundsmanship

- Conductive hearing loss is caused by an obstruction in the transmission of sound as the sound waves pass from the air through the auricle into the inner ear. Sensorineural hearing loss is caused by problems involving sound processing after the sound waves reach the inner ear. Mixed hearing loss is a combination of conductive and sensorineural hearing loss.
- Patients with hearing loss should be questioned about the timing and circumstances surrounding the onset of hearing loss, as well its progression and any associated symptoms of tinnitus, vertigo, aural fullness, otalgia, otorrhea, and autophony.
- The recent onset of sudden sensorineural hearing loss necessitates an audiogram as soon as possible.

17 Evaluation and Management of Otolgia

Michele M. Gandolfi and Christopher J. Linstrom

17.1 Introduction

Ear pain, or otalgia, reflects either localized otologic pathology (primary otalgia) or a problem within a periauricular or more distant source (referred otalgia) due to the complex sensory innervation of the ear. The physical examination usually reveals the source of the pain. Not uncommonly, however, a patient may have ear pain but no identifiable pathology within the ear, and the clinician should expand the differential diagnosis to include causes of referred otalgia. The source of otalgia can be as proximal and obvious as an acute otitis externa or as distant and occult as a laryngeal mass. The evaluation of patients with otalgia is aided by a detailed understanding of the innervation of the ear and knowledge of potential causes. Comprehension of the anatomy underlying shared neural pathways and the potential causes of referred otalgia arising from distant sites enables the physician to reach a diagnosis.

Sensory afferents from the trigeminal, facial, glossopharyngeal, and vagus nerves and the cervical plexus supply the auricle, periauricular region, external canal, and middle ear. All of these afferents can cause localized ear pain that is misleading; these nerves innervate distant sites that can harbor the culpable pathology. For example, the auriculotemporal branch of the mandibular division of the trigeminal nerve provides sensation to the tragus, anterior pinna, anterior lateral surface of the tympanic membrane, and anterosuperior external auditory canal. The vagus nerve similarly provides sensation to the larynx, hypopharynx, trachea, esophagus, and thyroid gland. The Arnold nerve (auricular branch of the vagus nerve) provides sensation to the concha, inferoposterior external auditory canal, tympanic membrane, and postauricular skin. Sensory innervation to the oropharynx, tonsils, and tongue base is provided by the glossopharyngeal nerve. The Jacobson nerve (tympanic branch of the glossopharyngeal nerve) provides sensation to the medial surface of the tympanic membrane, mucosa of the middle ear, eustachian tube, and mastoid air cells. The cervical roots C2 and C3 provide sensation to the postauricular region via the great auricular nerve. The facial nerve innervates the skin of the lateral concha and antihelix, lobule, mastoid, posterior external auditory canal, and posterior portion of the tympanic membrane. Pathology related to the distribution of these nerves can refer pain back to their afferent destination of innervation, leading to referred otalgia (□ Fig. 17.1).

17.2 Differential Diagnosis

Otolgia can be separated into two types: primary and referred. Primary otalgia arises from local or regional pathology. The ear itself is the source of the pathology. Sources of primary otalgia include acute otitis externa, cerumen impaction, foreign body, inflammation or infection of the auricle, ear trauma, eustachian tube dysfunction, otitis media, and mastoiditis. Otolgia may be referred to the ear from pathology in an adjacent area, such as temporomandibular joint dysfunction, periauricular lymphadenopathy, and scalp or neck infections. Even more distant

sources should be suspected in cases of referred otalgia, such as periodontal or dental disease, parotitis, sinusitis, thyroiditis, tonsillitis, laryngitis, and hiatal hernia with gastroesophageal reflux. Referred pain is a manifestation of pathology in any region of the head and neck that shares a neural pathway with the temporal bone and periauricular region. In the initial assessment, examination of the ear indicates whether the otalgia is local or regional in origin. If the ear examination is completely normal, it is helpful to discern the exact focus of pain and redirect the physical examination to other areas that share neural pathways with the ear.

Referred otalgia is related to the wide distribution of the nerves that innervate the auricular area. The trigeminal nerve has a wide sensory distribution. Infection and neoplasms within the nasal cavity or paranasal sinuses, particularly the sphenoid or maxillary sinuses, can cause irritation of the vidian nerve. Nasopharyngeal surgery, neoplasms, and infections in this region are common sources of referred otalgia. In children, erupting dentition is the most common cause of referred ear pain. Similarly, an impacted molar in an adult may cause symptoms of ear pain. Dental malocclusion resulting in temporomandibular joint dysfunction can cause referred ear pain from masticator muscle spasms. A history of excessive gum chewing, malocclusion, and bruxism may suggest this diagnosis.

The facial nerve can be involved in referred ear pain in cases of geniculate neuralgia, Bell palsy, and herpes zoster oticus. The ear pain of herpes zoster oticus can occur even in the absence of a significant vesicular eruption, making the diagnosis even more difficult. The otalgia associated with Bell palsy frequently occurs before the onset of facial paralysis. The glossopharyngeal and vagus nerves can transmit referred ear pain as a result of pathology originating from anywhere within the upper aerodigestive tract. The glossopharyngeal nerve can be stimulated by pathology in the pharynx, such as tonsillitis, post-tonsillectomy inflammation, peri-tonsillar abscess, and neoplasms. Lingual tonsillitis and impacted foreign bodies within the tongue can also cause otalgia. Eagle syndrome (□ Fig. 17.2) consists of ear pain secondary to stretching and irritation of the glossopharyngeal nerve resulting from elongation of the styloid process. Glossopharyngeal neuralgia is similar to trigeminal neuralgia. The pain is sharp and lancinating in quality; it originates in the tongue base, soft palate, or tonsillar fossa and radiates to the ear. Neoplasms within the larynx and esophagus have long been recognized as causes of referred otalgia. Ulcerations, foreign bodies, and reflux also can be seen in a similar manner. Chronic or subacute inflammation of the thyroid gland may cause referred ear pain through stimulation of the vagus nerve.

17.3 Evaluation: History, Physical Findings, and Testing

In order to define the specific etiology of otalgia, a thorough history is necessary, with detailed attention to the onset and duration of pain, quality of the ear pain, alleviating and exacerbating factors, and associated symptoms, such as fever, weight

Fig. 17.1 Sources of referred otalgia. (a) The sensory innervation of the ear and periauricular area is from multiple nerves, including branches from cranial nerves V, VII, IX, and X, as well as C2 and C3 rootlets. (b) Multiple areas in the head and neck share sensory innervation with the ear. CN, cranial nerve.

loss, tinnitus, hearing loss, pruritus, vertigo, aural fullness, and other sources of pain. A careful initial examination of ear and pneumatic otoscopy (to test the movement of the tympanic membrane and see if this illicit any new symptoms) can help distinguish sources of referred pain. Fiber-optic nasopharyngolaryngoscopy should be performed to evaluate the pharynx and larynx if laryngitis, gastroesophageal reflux, or a mass is suspected because of associated symptoms. In patients with a significant history of tobacco and/or alcohol use, a mass in the oral cavity or laryngopharynx should be sought. Adults with a

unilateral middle ear effusion detected on otoscopy should be presumed to have a nasopharyngeal mass until it has been proved otherwise by fiber-optic nasopharyngoscopy. A complete inspection of the nasopharynx, oral cavity, mandible, pharynx, larynx, and neck should be completed to find the source of otalgia.

If mastoiditis is suspected, computed tomography (CT) of the temporal bone without contrast is necessary to evaluate the extent of disease. If there is any suspicion of coalescent mastoiditis, a CT with contrast should be ordered. Audiography and

Fig. 17.2 Eagle syndrome from elongation of the styloid process or elongation of stylohyoid ligament.

electronystagmography/videonystagmography (ENG/VNG) should be ordered to evaluate the cause of otalgia if symptoms of hearing loss, tinnitus, or vertigo are also present. Magnetic resonance (MR) imaging or CT with contrast of the area involved should be ordered if any local head and neck masses are detected on examination.

17.4 Treatment

Infections such as acute otitis media, pharyngitis, and tonsillitis can be treated with broad-spectrum antibiotics such as amoxicillin, amoxicillin/clavulanate, or in the penicillin-allergic patient clindamycin to cover the more common head and neck pathogens, such as *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Moraxella catarrhalis*. If referred pain from a local site is suspected, treatment should be focused on the source. A patient with external tenderness over the temporomandibular joint, malocclusion, clicking, and teeth grinding should be referred to a dentist or oral surgeon who treats temporomandibular joint disease. In patients in whom an X-ray reveals an elongated styloid process, surgical shortening of the process can help relieve symptoms if other sources are ruled out. If nasal

congestion or sinusitis is the cause of otalgia, treatment with antibiotics and nasal decongestants can help alleviate the symptoms. A unilateral peri-tonsillar abscess can also cause otalgia (although otalgia is not the most significant symptom in these cases). The peri-tonsillar abscess should be drained and the appropriate antibiotics should be given based on cultures and a steroid taper prescribed if there are no contraindications (immunocompromised, pregnancy etc.). Parotiditis can also cause otalgia, and the local infection should be treated with antibiotics, sialagogues, and massage. If a mass is found as a potential source, biopsy of the mass must be done; appropriate management and subspecialist referral should be based on the pathology results.

Otalgia is a vague symptom that can be the result of an extremely wide array of pathology. The physician must use the details of the patient's history and associated symptoms, as well as the physical examination findings, to tease out possible etiologies. In order to do so, a thorough knowledge of the innervation pathways that provide sensation to the ear is necessary. Localizing the pathology to a nearby anatomical structure is important for the treatment and resolution of referred otalgia. Diagnostic work-up and testing can help the physician discern whether audiography, electronystagmography, videonystagmography, CT, MR imaging, X-ray, fiber-optic nasolaryngoscopy, or other further studies are necessary.

17.5 Roundsmanship

- There are two types of otalgia. In primary otalgia, the ear is the direct source of pain, whereas in referred otalgia, the complex afferent innervations of the ear are the source.
- Intricate knowledge of the afferent innervation of the ear is necessary to discover the source of referred otalgia. Any location that shares innervation with the ear through branches of the trigeminal, facial, glossopharyngeal, or vagus nerve can be the source.
- Ear infections, sinusitis, tonsillitis, temporomandibular joint disorder, odontogenic sources, Bell palsy, nasopharyngeal mass, neck mass, or even thyroiditis can cause otalgia. A detailed documentation of associated symptoms is important to diagnose the cause of otalgia.
- A detailed history and physical examination with focused testing are helpful in determining the etiology of otalgia.

18 Obstructive Sleep Apnea

Gene Ukrainsky and Boris Sagalovich

18.1 Introduction

Sleep is an essential part of our normal physiology. Profound changes occur during sleep, all of them part of the body's normal physiology. Although the exact nature and reason for sleep are not known, interruption of the physiologic processes and normally occurring sequences in sleep leads to a variety of pathologic conditions.

18.2 Incidence of Disease

Obstructive sleep-disordered breathing is probably one of the most common sleep-related disorders and includes obstructive sleep apnea (OSA). OSA is defined by the presence of the polysomnographic findings of upper airway obstruction and OSA syndrome, which is a combination of OSA, defined as presence of more than 5 upper ventilatory events per hour, and clinical symptoms.

In one of the most comprehensive studies undertaken, 24% of men and 9% of women had sleep-disordered breathing, defined as an apnea-hypopnea index (AHI) of 5 or higher. The prevalence of obstructive sleep-disordered breathing increases with age. Sleep apnea is characterized by partial or complete obstruction of the upper airway leading to episodic hypoxia, hypercapnia, and ultimately arousal with increased ventilatory effort. The arousals lead to sleep fragmentation and disruption of the normal sleep architecture. It is this disruption in the sleep architecture, as well as the tissue vibration and abnormal cardiovascular response during the hypoxic episodes, which explains patients' symptoms as well as the pathologic consequences of obstructive sleep-disordered breathing.

18.3 Terminology

Apnea is the cessation of airflow lasting 10 seconds or longer.

Hypopnea is a decline of at least 50% in airflow from baseline, associated with an electroencephalogram (EEG)-defined arousal or with a 4% drop in oxygen saturation.

A respiratory effort-related arousal is an arousal caused by an obstructive respiratory event.

The apnea-hypopnea index (AHI) is the sum of the number of apneic and hypopneic episodes per hour.

The respiratory disturbance index (RDI) may be synonymous with the AHI or may be a combination of the AHI and respiratory effort-related arousal.

18.4 Pathophysiology

Sleep is a reversible state of disengagement and unresponsiveness to the surrounding environment. It is subdivided into non-rapid eye movement (NREM) sleep and rapid eye movement (REM) sleep. NREM sleep is further subdivided into three stages that parallel the depth of the sleep continuum. NREM

sleep can be thought of as a period with relatively diminished brain activity, as demonstrated by brain waves registered on the EEG. REM sleep, by contrast, is characterized by EEG activation, muscle inactivity, and episodic bursts of rapid eye movements. It is not surprising, then, that most apneic episodes in adults occur during this stage of sleep, during which relative muscle atonia predominates. Abnormal upper airway structure is mostly responsible for obstructive sleep-disordered breathing. In children, this abnormality is most often caused by adenotonsillar hypertrophy. In adults, multiple anatomical and physiologic abnormalities along the upper airway can contribute to obstructive sleep-disordered breathing. It is useful to think of the upper airway as a series of conduits with both static and dynamic components. The dynamic components of upper airway collapse are tissue mass, tissue elasticity, and neuromuscular tone and airflow influencing airway diameter. The static determinants of airway size are the fixed skeletal and soft-tissue configuration of the nasal cavity, nasopharynx, oropharynx, and hypopharynx. Dilating forces reduce the potential for airway collapse as a result of increased negative inspiratory pressures. Hence, any decrease in neuromuscular tone increases the chance of airway collapse. Obesity (because of the increased fat deposition around the neck), upper airway soft-tissue hypertrophy (seen in adenotonsillar hypertrophy), and retrognathia increase extraluminal pressure and make upper airway collapse more likely.

Fujita classified the patterns of obstruction according to anatomical location (□ Table 18.1).

Nasal obstruction contributes to upper airway obstruction; however, it is not a sole cause but rather a contributor to OSA. Nasal obstruction contributes to increased upper airway resistance, and open-mouth breathing decreases the efficiency of the upper airway dilator muscles and promotes collapsibility of the upper airway.

18.5 Medical Evaluation

18.5.1 Presenting Complaints

Patients with OSA are rarely fully aware of the severity of their sleep-disordered breathing. Rather, a bed partner frequently insists on the evaluation. On questioning, however, patients with OSA will often have many of the symptoms listed in the Box Symptoms of Obstructive Sleep Apnea (p. 120).

Table 18.1 Fujita classification of airway obstruction

Type	Site of obstruction
I	Retropalatal area only
II	Retropalatal and retrolingual areas
III	Retrolingual area only

Symptoms of Obstructive Sleep Apnea

- Restless sleep
- Loud snoring
- Observed episodes of choking or gasping
- Excessive daytime sleepiness
- Morning fatigue
- Memory loss
- Gastroesophageal reflux disease
- Decreased libido and impotence
- Nocturnal sweating
- Depression

18.5.2 Physical Examination and Clinical Findings

The most common symptoms of OSA syndrome are fatigue and hypersomnolence. One of the most useful tools routinely used as a self-assessment for OSA is the Epworth Sleepiness Scale (□ Table 18.2).

During the office visit of a patient with suspected OSA, it is important to measure the patient's height, weight, blood pressure, and neck circumference. More than 70% of adults with OSA are obese. Note the general body habitus and any facial characteristics, which may suggest the presence of retrognathia or maxillary hypoplasia. Keep in mind that daytime fatigue and loss of energy are the presenting symptoms of many medical conditions; these can both mimic and coexist with OSA. Patients with hypertension, cardiovascular disease, obesity, or diabetes mellitus should be screened for the presence of OSA.

Evaluate for specific signs of nasal obstruction: external or internal nasal valve collapse, nasal septal deviation, turbinate hypertrophy (mucosal or bony enlargement), sinusitis, polypoid nasal disease, and adenoid hypertrophy. The oropharynx

should be carefully examined. Note the type of dental occlusion; compared with persons who have a normal skeleton relationship, patients with class II occlusion are predisposed to OSA because the anatomical position of the tongue base may be displaced backward.

Cephalometric radiographs, although seldom used, may be very helpful in identifying underlying skeletal abnormalities. Note the size of the tongue, size of the tonsils, and length of the soft palate. An elongated soft palate, relative macroglossia, and tonsillar hypertrophy may give examiner a clue to the presence of sleep apnea and help to formulate treatment plan.

We use the Friedman classification to document and convey the relationships between the tongue, soft palate, and lateral pharyngeal wall as seen on direct intraoral examination (□ Fig. 18.1 and □ Table 18.3). This classification allows an accurate and uniform description of the clinical findings and facilitates the development of a treatment plan.

Flexible endoscopy should be performed with the patient in both a sitting and a supine position; the latter allows visualization of the position of the tongue base against the epiglottis with the patient in a resting position. The Müller maneuver is performed during flexible nasopharyngoscopy. With the patient in a seated position and the tip of the endoscope positioned in the nasopharynx, the patient is asked to inhale against a closed mouth and nose. The negative pressure generated allows the examiner to observe palatal and lateral pharyngeal wall collapse.

This maneuver, together with other gathered information, can give examiner a clue to the major site of obstruction. There are several other examination techniques whose effectiveness has been clearly documented in the research setting but that are less widely used in clinical practice, including magnetic resonance imaging, drug-induced sleep video endoscopy, and somnofluoroscopy. All of these have been shown in clinical studies to be useful for planning surgical intervention; however, the technical difficulties and relative expense associated with these tests preclude their widespread use in clinical practice.

Nocturnal polysomnography has become the criterion standard in the diagnosis and treatment of OSA since it was first described in 1974 by Holland. Polysomnography provides objective data on sleep and respiratory status. Information gathered in the study includes pulse oximetry, electrocardiography, airflow, respiratory effort, extremity and submental electromyography, nasal and oral airflow, electro-oculography, and EEG evidence of arousal. After the information is gathered, it is then interpreted by a sleep physician. Nocturnal polysomnography gives precise information about the presence of sleep-disordered breathing and allows one to differentiate OSA from other sleep-related disorders. In a split-night study, a variation of nocturnal polysomnography, the first half of the night is devoted to standard polysomnography and the second part of the night is devoted to continuous positive airway pressure (CPAP) titration. In the interest of cost containment, other, less costly home studies have gained widespread acceptance as diagnostic tools. These studies usually measure overnight oxygen levels and respiratory effort. Studies have shown a good concordance between home-based polysomnography and studies obtained in the sleep ambulatory setting for the diagnosis of OSA. The main advantage of home-based studies is convenience for the patient

Table 18.2 Epworth Sleepiness Scale

Situation	Chance of dozing ^a
Reading	
Watching TV	
Sitting in a public place	
Driving a car, stopped at a traffic light	
As a passenger in a car for an hour without a break	
During a quiet time after lunch without alcohol	
Lying down to rest when circumstances permit	

^aTo derive the score, points are assigned according to the patient's answer for each situation and then totaled. 1, slight chance of dozing; 2, moderate chance of dozing; 3, high chance of dozing. Epworth score <8, normal; Epworth score >10, suspicion of sleep apnea.

Fig. 18.1 Friedman classification of tongue position.

Table 18.3 Friedman classification

Friedman class	Tongue position	Tonsil size
I	1 or 2	+3 or +4
II	1 or 2	0, +1, or +2
	3 or 4	+3 or +4
III	3 or 4	0, +1, or +2
IV	Body mass index >40	

and reduced costs. However, they fail to diagnose other sleep disorders that might be present together with OSA.

18.6 Potential Disease Complications of Obstructive Sleep Apnea

OSA, if left untreated, can lead to severe medical consequences. It is implicated in excessive daytime sleepiness and impaired mood, as well as impaired neurocognitive function. In one

study, OSA was implicated as a causal factor in motor vehicle accidents. The prevalence of gastroesophageal reflux disease is much higher in patients with OSA than in the general population. OSA is an independent risk factor for the development of insulin resistance, and it is believed to lead to pulmonary and systemic hypertension. Mortality is increased in patients with an AHI higher than 20.

18.7 Nonsurgical Treatment of Obstructive Sleep Apnea

Studies have documented significant improvement in the quality of life in individuals treated for OSA. The treatment of OSA should be tailored to the individual needs of the patient. Planning should include a consideration of the severity of the disease, the patient's weight and body habitus, medical comorbidities, and social demands. Often, weight reduction alone can significantly decrease or alleviate OSA.

The gold standard in the medical treatment of OSA is CPAP. After a diagnosis of sleep apnea, the patient is brought back to the sleep center and a second nocturnal polysomnography is

performed while the patient uses a CPAP machine at various airway pressures. The pressure of the air applied acts to prevent collapse of the airway and, based on monitoring, is adjusted to the optimal minimal setting at which the recorded parameters normalize and apneic and hypopneic episodes disappear. The use of the CPAP machine alleviates most, if not all, of the medical sequelae of OSA. The most significant problem associated with CPAP use is compliance, which remains relatively low. Many patients are unable to tolerate the fit of the mask on the face or the rush of pressurized air, or they simply view it as a socially unacceptable treatment.

In general, the higher the positive airway pressure required to alleviate the obstruction, the less tolerable patients find CPAP treatment. To improve compliance with CPAP treatment, bilevel positive airway pressure (BiPAP) and autoadjustable positive airway pressure have been developed. These modalities deliver lower expiratory pressures and higher inspiratory pressures. Although the devices may be beneficial for individual patients, they have not been shown to improve overall compliance with the treatment. In recent years, oral appliances have gained widespread popularity in the treatment of snoring and mild to moderate OSA. The oral appliances are designed to shift the mandible forward, thereby increasing the diameter of the posterior oropharyngeal airway. They are usually composed of interlocking plastic molds that are placed on the maxillary and mandibular dentition so that the mandibular arch is in the protrusive position. Patients using dental appliances have a much higher compliance rate than those using CPAP devices.

18.8 Surgical Treatment of Obstructive Sleep Apnea

In 1981, Fujita and colleagues introduced uvulopalatopharyngoplasty (UPPP) as a surgical treatment option for patients with OSA. Together with tonsillectomy, UPPP is a procedure designed to alleviate oropharyngeal airway obstruction by removing redundant palatal and pharyngeal tissues. Despite its widespread use, the overall success rate of this procedure for all patients is less than 50% emphasizing the need for the use

of a staging system and stepwise approach in the treatment of OSA. Available surgical procedures may be subdivided into four groups (□ Table 18.4).

When a surgical treatment is chosen, it is necessary to take into consideration the patient's body mass index (BMI), severity of disease, tolerance of medical treatment, age, medical comorbidities, and anatomical sites of obstruction. The Friedman classification is a useful tool for determining the extent of surgical intervention necessary to achieve a good result. Patients with a low BMI, mild OSA, or snoring with obstruction limited to one anatomical site may be excellent candidates for an in-office procedure such as injection snoreplasty, palatal implants (designed to stiffen the soft palate and reduce the noise caused by palatal vibration with injection of a sclerosing agent or placement of a synthetic implant, respectively), or radio-frequency tongue base reduction. Most often, there are multiple sites of anatomical obstruction, so that several surgical procedures are required to achieve a successful outcome. It is essential to discuss the possibility of multiple procedures with the patient preoperatively, and to ensure that the patient realizes that the definition of surgical success most often used in the surgical literature is an RDI of less than 20 with at least a 50% improvement in the RDI; most studies of CPAP define success as an RDI of less than 5.

A patients undergoing surgery should meet the following criteria: has a BMI below 30; is noncompliant with or refusing medical therapy; is medically stable to undergo surgical procedures; $5 < \text{AHI} < 14$; has upper airway resistance syndrome.

Planning for OSA surgery requires multidisciplinary approach. The anesthesiology team must be aware of the patient's difficult airway and potentially difficult intubation; often, when tongue base and hypopharyngeal procedures are needed, nasal intubation is helpful. Postoperative edema may compromise airway patency. Surgery in the hypopharyngeal area increases the risk for airway compromise; the patient should be counseled about the possibility of temporary tracheotomy. All patients should use CPAP in perioperative period because it has been clearly shown to reduce postsurgical airway compromise and the risk for postobstructive pulmonary edema (POPE). Admission to an intensive care unit for observation should be considered for patients who undergo multilevel surgical

Table 18.4 Types of surgical intervention for obstructive sleep apnea

Nasal surgery	Palatal surgery	Tongue base/hypopharyngeal procedures	Secure airway
Septoplasty	Injection snoreplasty	Lingual tonsillectomy	Tracheotomy
Inferior turbinate reduction	Palatal pillar implants	Radio-frequency reduction of tongue base	
Reconstruction of the nasal valve	Tonsillectomy	Midline posterior glossectomy	
Endoscopic sinus surgery to relieve obstruction from polyps	Uvulopalatopharyngoplasty and its variations	Hyoid myotomy and suspension	
Adenoidectomy	Transpalatal advancement pharyngoplasty	Tongue base suspension suture	
		Mandibular osteotomy and genioglossal advancement	
		Maxillomandibular osteotomy and advancement	

procedures. In trained hands, these surgical procedures can be quite safe, but temporary postoperative dysphagia is the rule. Bleeding may occur, either in the immediate postoperative period or 1 to 1.5 weeks after surgery. Nasopharyngeal reflux of liquids or, conversely, nasopharyngeal stenosis can occur after these surgeries.

18.9 Prognosis

It is essential to discuss the possibility of multiple procedures with the patient preoperatively, and to ensure that the patient realizes that the definition of surgical success most often used in the surgical literature is an RDI of less than 20 with at least a 50% improvement in the RDI; most studies of CPAP define success as an RDI of less than 5.

18.10 Roundsmanship

- Up to 24% of men and 9% of women have sleep-disordered breathing, defined as an apnea–hypopnea index (AHI) of 5 or higher.
- The prevalence of obstructive sleep-disordered breathing increases with age.
- Apnea is the cessation of airflow lasting 10 seconds or longer. Hypopnea is a decline of at least 50% in airflow from baseline, associated with electroencephalographically defined arousal or with a 4% drop in oxygen saturation.
- The AHI is the sum of the number of apneic and hypopneic episodes per hour. The respiratory disturbance index (RDI) may be synonymous with the AHI or may be a combination of the AHI and respiratory effort–related arousal.

- The gold standard for the medical treatment of obstructive sleep apnea (OSA) is continuous positive airway pressure (CPAP).
- Surgical success is most often defined in the surgical literature as an RDI of less than 20 with at least 50% improvement in the RDI; most studies of CPAP define success as an RDI of less than 5.

19 Head and Neck Manifestations of Systemic Diseases

Edwin K. Chan

19.1 Introduction

The head and neck region is often the window into a disease process occurring throughout the rest of the body. The first clue for a clinician in diagnosing many systemic diseases may be revealed during the head and neck examination. Therefore with this in mind, otolaryngologists should approach their evaluation of the head and neck in a “global” manner, while general practitioners and physicians from other fields cannot neglect the head and neck evaluation before drawing up their differential diagnoses. This chapter reviews noninfectious inflammatory diseases that manifest in the head and neck and focuses on some of the more significant conditions in this category (□ Table 19.1).

19.2 Wegener Granulomatosis

19.2.1 Pathogenesis

This systemic granulomatous disease may have an autoimmune in etiology and causes a vasculitis affecting the upper and lower respiratory tracts (chronic bronchitis) and kidneys (glomerulonephritis).

19.2.2 Types

- Limited form has only pulmonary involvement.
- Systemic form has pulmonary and renal involvement.

19.2.3 Histology

Necrotizing granulomas, multinucleated giant cells, and vasculitis of the upper/lower respiratory tracts and kidneys.

19.2.4 Head and Neck Presentation

Affects predominantly Caucasians.

Sinonasal

Chronic sinusitis is the most common head and neck manifestation of the disease; saddle nose deformity is due to severe septal perforation, epistaxis, nasal obstruction.

Otologic

Chronic serous otitis media, conductive hearing loss.

Laryngeal

Laryngeal ulcers, subglottic stenosis.

Oral

Mucosal ulcers, “strawberry” gingiva.

Ocular

Conjunctivitis, uveitis, keratitis.

19.2.5 Work-up

The most specific blood test is c-ANCA (antineutrophil cytoplasmic autoantibodies, cytoplasmic). Renal and/or pulmonary biopsies are most specific, showing necrotizing glomerulonephritis and vasculitis respectively. Nasal biopsy is frequently nondiagnostic, showing only nonspecific inflammation. Multiple nasal biopsies on the edges of the ulcers yield a higher success rate in finding the specific features of necrotizing granulomas and vasculitis. The erythrocyte sedimentation rate (ESR), urinalysis, blood urea nitrogen (BUN)/creatinine levels, and a chest X-ray may aid in the diagnosis.

19.2.6 Treatment

Immunosuppressive therapy with corticosteroids, cyclophosphamide, and/or methotrexate. Trimethoprim/sulfamethoxazole may be considered to prevent relapse and treat limited disease.

19.3 Sarcoidosis

19.3.1 Pathogenesis

This is a systemic granulomatous disease with an unknown etiology that affects the head and neck region and is also characterized by pulmonary, dermatologic, hepatic, renal, cardiac, osseous, and neurologic involvement.

19.3.2 Histology

Noncaseating epithelioid granulomas, giant cells, accumulation of T cells and mononuclear macrophages.

19.3.3 Head and Neck Presentation

Affects predominantly African-Americans and females.

Lymphatic

Cervical lymphadenopathy is the most common head and neck finding.

Sinonasal

“Cobblestoning” of the nasal mucosa, epistaxis, and dry crusting.

Laryngeal

Causes submucosal lesions that affect primarily the supraglottis. The epiglottis is the most commonly affected region of

the larynx, and the aryepiglottic folds, false vocal folds, and subglottis are affected in descending order of frequency. The true vocal folds are rarely affected. Hoarseness due to vocal fold paralysis has been reported with this disease process.

Salivary Glands

An asymptomatic parotid mass may be part of a spectrum of symptoms in uveoparotid fever (Heerfordt disease), an extrapulmonary form of sarcoidosis that also causes uveitis, facial nerve palsy, sensorineural hearing loss, and fever.

19.3.4 Work-up

Most commonly presents when a chest X-ray incidentally reveals hilar adenopathy. Blood work may show an increased angiotensin-converting enzyme (ACE) level, abnormal liver function tests, and hypercalcemia. The electrocardiogram (EKG) may reveal an arrhythmia. Enlarged cervical lymph nodes, abnormal nasal mucosal lesions, laryngeal lesions, parotid masses, and subcutaneous nodules (Darier-Roussy nodules) found in the skin can be readily biopsied. Biopsy of any affected region may show the noncaseating granulomas.

19.3.5 Treatment

Systemic corticosteroids for exacerbations of pulmonary disease. Localized lesions may be treated with topical/injectable steroids, and supraglottic lesions are excised only if they are causing obstructive symptoms. Asymptomatic lesions are only monitored.

19.4 Lupus Erythematosus

19.4.1 Pathogenesis

A deposition of antibodies and immune complexes (type III hypersensitivity) underlies this autoimmune disease.

19.4.2 Histology

Inflammation and degeneration of the dermal–epidermal junction. Deposits of immunoglobulins (IgG and C3) in a bandlike pattern are seen in the subepithelial layer on direct immunofluorescence.

19.4.3 Types

Discoid Lupus Erythematosus

The least aggressive form of the disease that affects only superficial tissue and does not have visceral involvement.

Head and Neck Presentation

Affects predominantly affects young women.

Oral

Aphthous ulcers, superficial bullae, erythematous plaques with surrounding lacy, white strands.

Cutaneous

Raised erythematous plaques with hypopigmented edges and resultant alopecia and scarring.

Work-up

This is a clinical diagnosis because the antinuclear antibody (ANA) test and lupus erythematosus (LE) cell test are negative. Biopsy of the lesions may show immunoglobulin deposition on the basement membrane on immunofluorescence.

Treatment

Topical steroids and strict sunscreen use/avoidance of sun exposure.

Subacute Cutaneous Lupus Erythematosus

A mild systemic form of the disease with the same head and neck presentation as discoid lupus erythematosus but with cutaneous papulosquamous lesions that do not cause scarring. The diagnosis is also made from the clinical history and physical. Results of ANA, Sjögren syndrome A antibody (SS-A [anti-Ro]), and Sjögren syndrome B antibody (SS-B [anti-La]) blood tests are inconsistent.

Systemic Lupus Erythematosus

The most severe systemic form of the disease with widespread visceral involvement including polyarthritis, glomerulonephritis, anemia, pulmonary fibrosis, and endocarditis.

Head and Neck Presentation

Affects predominantly young women.

Oral

Similar to that of discoid lupus erythematosus.

Cutaneous

In addition to the lesions found in discoid lupus erythematosus, a pathognomonic malar “butterfly” rash is often present.

Laryngotracheal

Perichondritis of the laryngeal and tracheal cartilage and thickening of the vocal folds cause neck/throat pain and hoarseness, respectively.

Sinonasal

Nasal dryness, crusting, and septal perforation.

Otologic

Tinnitus with or without sensorineural hearing loss.

Work-up

Tests for nonspecific markers such as ANA, SS-A (anti-Ro), and SS-B (anti-La) are typically positive. Tests for specific markers such as anti–double-stranded (anti-DS) DNA and Sm antigen are positive. LE tests are typically positive, and positive immu-

Table 19.1 Noninfectious systemic diseases of the head and neck

	Pathophysiology	Histology	Symptoms and physical findings	Work-up	Treatment
Wegener granulomatosis	Vasculitis of the upper/lower respiratory tracts ± kidneys	Necrotizing granulomas, multinucleated giant cells	“Saddle nose,” septal perforation, sinusitis, “strawberry gingiva,” otitis media, subglottic stenosis	Positive c-ANCA, nasal biopsy, pulmonary/renal biopsy most diagnostic	Corticosteroids, immunosuppressants, trimethoprim/sulfamethoxazole may be considered
Sarcoidosis	Idiopathic granulomatous disease	Noncaseating granulomas	Cervical lymphadenopathy, epistaxis, nasal crusting, supraglottic submucosal lesions, parotid mass	Elevated ACE levels, biopsy of affected area	Corticosteroids
Lupus erythematosus	Type III hypersensitivity	IgG and C3 immunoglobulin deposition in subepithelium and basement membrane	Oral ulcers, cutaneous plaques, malar rash, nasal dryness, septal perforation, tinnitus ± sensorineural hearing loss in systemic form	Systemic form: positive ANA, SS-A (anti-Ro), SS-B (anti-La), anti-DS DNA, Sm antigen; positive LE test	Anti-inflammatories, corticosteroids, immunosuppressive agents
Sjögren syndrome	Autoimmune polyclonal B-cell activation affecting exocrine glands	Periductal exocrine gland lymphoid infiltration	Ocular, nasal, and oral dryness; fissuring of the tongue; parotitis, submandibular gland enlargement	Positive ANA, SS-A (anti-Ro), SS-B (anti-La), RF; minor salivary gland biopsy; Schirmer test	Topical eye and oral treatments, punctal plugging, pilocarpine hydrochloride
Relapsing polychondritis	Autoimmune inflammation of cartilage with high levels of glycosaminoglycans	Perichondrial infiltration with inflammatory cells	Auricular erythema/edema sparing lobule, saddle nose deformity, laryngeal collapse/stenosis	Elevated antibodies to type II collagen	Corticosteroids, nonsteroidal anti-inflammatory drugs, immunosuppressants, tracheotomy if airway collapse/stenosis
Langerhan cell histiocytosis	Idiopathic infiltration of dendritic cells (Langerhan cells) and histiocytes (macrophages) in affected tissue	Birbeck granules, CD1A- and S100-positive	Osteolytic bone lesions of the skull/mandible, mastoiditis, otitis media, gingival ulcers, alopecia, proptosis	Biopsy of a lesion (skin most accessible)	Excision of localized lesions, corticosteroids and chemotherapy for disseminated disease
Behçet disease	Idiopathic vasculitis, likely autoimmune, triggered by an infectious event; triad of aphthous ulcers, uveitis, and genital ulcers	Lymphocytic vasculitis with neutrophilic infiltrate, thrombotic clotting	Aphthous ulcers, uveitis, dysphagia, dysarthria, hearing loss	Elevated ESR, C-reactive protein; pathergy test	Topical oral steroids, sucralfate, and tetracycline for oral lesions; systemic corticosteroids and immunosuppressants for generalized disease
Cogan syndrome	Autoimmune reaction to a common antigen found in both the cornea and inner ear	Hydropic findings similar to those of Meniere disease, lymphocytic infiltration of cornea	Episodic vertigo; fluctuating hearing loss, tinnitus, and aural fullness; interstitial keratitis	Slit lamp examination, audiography and ENG	Systemic corticosteroids and immunosuppressants
Rheumatoid arthritis	Inflammatory disease affecting peripheral joints	Granulomatous lesions of the skin with small-vessel vasculitis, lymphocytic infiltration of synovium	Trismus, temporomandibular joint tenderness, hoarseness, conductive hearing loss	Elevated ESR, RF; audiogram; fiberoptic laryngoscopy; biopsy of cutaneous lesions	Corticosteroids, nonsteroidal anti-inflammatory drugs, DMARDs
Scleroderma	Autoimmune small-vessel vasculitis and fibrosis	Collagen deposition in affected tissue, smooth-muscle atrophy	“Pursed lip” appearance, gastroesophageal reflux, dysphagia, hoarseness, sicca syndrome	Positive ANA, barium esophagram, minor salivary gland biopsy	Proton pump inhibitors, corticosteroids, nonsteroidal anti-inflammatory drugs
Dermatomyositis/polymyositis	Autoimmune vasculopathy and myopathy of striated muscle	Inflammatory infiltrate in muscle and perivascular regions	Heliotrope rash, “shawl” sign, weakness in flexing neck, dysphonia, dysphagia	Elevated CK, LDH, AST, and ANA; barium swallow; biopsy of affected muscle	Proton pump inhibitors, systemic corticosteroids, immunosuppressants, IVIG

Table 19.1 continued

	Pathophysiology	Histology	Symptoms and physical findings	Work-up	Treatment
Giant cell (temporal) arteritis	Idiopathic vasculitis of medium-size and large arteries	Panarteritis, neovascularization, fragmentation of internal elastic lamina	Headache, jaw and tongue claudication, temporal tenderness, anosmia, dysphagia, hoarseness, vertigo, sensorineural hearing loss, amaurosis fugax	ESR, C-reactive protein, alkaline phosphatase elevated; temporal biopsy the gold standard test	Systemic corticosteroids
Churg-Strauss syndrome	Allergic granulomatous disease of small and medium-size vessels	Necrotizing granulomas with central eosinophilic core, giant cells	Nasal polyposis, nasal obstruction, sinusitis, allergic rhinitis	Eosinophilia on bloodwork, ESR and C-reactive protein elevated, p-ANCA positive, biopsy of involved tissue	Systemic corticosteroids
Kawasaki disease	Vasculitis, possibly infectious in origin, affecting predominantly medium-size vessels	Necrosis of smooth muscle causing aneurysms, fibrosis, and stenosis of vessels	Cervical lymphadenopathy, conjunctival injection, “strawberry tongue”	Elevated WBC count, ESR, C-reactive protein, cardiac enzymes (with myocardial infarction); EKG; CXR; echocardiogram	IVIg, salicylates/aspirin, close cardiovascular monitoring

Abbreviations: ACE, angiotensin-converting enzyme; ANA, antinuclear antibody; AST, aspartate aminotransferase; anti-DS, anti-double-stranded (DNA); c-ANCA, antineutrophil cytoplasmic autoantibody, cytoplasmic; CK, creatine kinase; CXR, chest X-ray; DMARD, disease-modifying antirheumatic drug; EKG, electrocardiogram; ENG, electroneurography; ESR, erythrocyte sedimentation rate; IVIG, intravenous immunoglobulin; LDH, lactic dehydrogenase; LE, lupus erythematosus; p-ANCA, antineutrophil cytoplasmic autoantibody, perinuclear; RF, rheumatoid factor; SS-A, Sjögren syndrome A antibody; SS-B, Sjögren syndrome B antibody; WBC, white blood cell.

no fluorescence testing of lesions may aid in the diagnosis. Complete blood cell count, urinalysis, and electrocardiography may detect other visceral involvement.

Treatment

Nonsteroidal anti-inflammatory drugs, corticosteroids, and immunosuppressive agents are used to control inflammation.

19.5 Sjögren Syndrome

19.5.1 Pathogenesis

This is an autoimmune systemic disease initially presenting with head and neck symptoms. Autoimmune destruction of the exocrine gland parenchyma with resultant atrophy, periductal lymphocytic infiltration, and polyclonal B-cell activation occurs with this disease process.

19.5.2 Histology

Foci of interstitial periductal lymphocytic infiltration of affected exocrine glands.

19.5.3 Types

1. Primary: disease is not associated with another autoimmune connective tissue disorder.
2. Secondary: disease is associated with another autoimmune connective tissue disorder, most commonly rheumatoid arthritis or systemic lupus erythematosus.

19.5.4 Head and Neck Presentation

Found primarily in peri- and postmenopausal women and may be the second most common autoimmune disease after rheumatoid arthritis. Sjögren syndrome can rarely progress to a non-Hodgkin lymphoma.

Ocular

Dry eyes most commonly described as a gritty or sandy sensation in the eyes, keratoconjunctivitis sicca, filamentary keratosis (mucinous threads adhering to damaged portions of the ocular surface).

Oral

Dry mouth manifested with dental caries, oral candidiasis, angular cheilitis, dysphagia, dysphonia, and/or dysgeusia. The oral examination reveals erythema and fissuring of the tongue with loss of papillae.

Sinonasal

Nasal dryness, epistaxis.

Salivary Glands

Bilateral parotitis with intermittent parotid swelling, but with atrophy occurring in advanced disease, submandibular gland enlargement may also occur.

19.5.5 Work-up

Positive SS-A (anti-Ro) and SS-B (anti-La), ANA, and rheumatoid factor blood tests. Polyclonal hypergammaglobulinemia on serum electrophoresis is often seen, and loss of a previous positive finding and/or development of a monoclonal gammopathy may indicate development of a lymphoma. Minor salivary gland biopsy from the inner lip showing lymphocytic infiltrates is the most definitive test. Sialography of the parotid gland shows a globular pattern of contrast collections throughout the gland described as an “apple tree appearance.” The Schirmer test evaluates tear production by placing a strip of filter paper on the lower conjunctiva; a definitively positive result is less than 5 mm of wetting after 5 minutes (>15 mm after 5 minutes is normal).

19.5.6 Treatment

Ocular dryness is treated with artificial tears, nighttime gels, cyclosporine drops, humidifiers, glasses with moisture shields, and plugging of the lacrimal puncta. Dry mouth is treated with artificial saliva, frequent sips of water throughout the day, a humidifier, and pilocarpine hydrochloride to stimulate saliva production.

19.6 Relapsing Polychondritis

19.6.1 Pathogenesis

A rare autoimmune condition causing inflammation of the cartilage and tissue containing high concentrations of glycosaminoglycans. Polyarthritides, pulmonary function compromise, renal disease, cardiac valve compromise, vascular aneurysms, and cutaneous nodules have been associated with the disease.

19.6.2 Histology

Perichondrial infiltration of inflammatory cells causing cartilage destruction and fibrosis.

19.6.3 Head and Neck Presentation

Occurs most frequently in Caucasians.

Otologic

Auricular chondritis in a relapsing pattern is the most common presenting symptom (erythema and edema of the auricle, sparing the lobule); conductive hearing loss caused by stenosis of the external auditory canal, eustachian tube chondritis, and/or serous otitis media; proposed vasculitis of the internal auditory artery may cause vestibular injury and sensorineural hearing loss.

Ocular

Ocular inflammation is most commonly manifested as episcleritis and scleritis.

Sinonasal

Nasal chondritis causing saddle nose deformity.

Oral

Aphthous ulcers are common.

Laryngotracheal

Chondritis of the laryngotracheal framework occurs more frequently in females, sometimes causing obstruction due to vocal fold paralysis, airway edema, airway collapse, and airway stenosis.

19.6.4 Work-up

Elevated antibodies to type II collagen (found in cartilage and the vitreous humor of the eye) is the most specific test; nonspecific tests include elevated ESR and C-reactive protein. Biopsy of cartilaginous structures is not performed unless necessary for diagnosis because of the possibility of infection and potential cosmetic deformity. Electrocardiogram, echocardiogram, chest X-ray, pulmonary function tests, urinalysis, and BUN/creatinine may detect the effect of the disease outside the head and neck region.

19.6.5 Treatment

Corticosteroids, nonsteroidal anti-inflammatory drugs, immunosuppressive chemotherapeutic agents. In patients with acute airway compromise, intubation may exacerbate the airway distress due to laryngotracheal edema and stenosis. Tracheotomy is the treatment of choice in securing the airway in these patients.

19.7 Langerhans Cell Histiocytosis (Histiocytosis X)

19.7.1 Pathogenesis

Infiltration and proliferation of eosinophils, T cells, dendritic cells (Langerhans cells), and histiocytes (macrophages) in the affected tissue without a primary cause.

19.7.2 Histology

Birbeck granules (which show a “zipper pattern”) in the dendritic cells are pathognomonic. Nonspecific features include granulomatous lesions with a background of eosinophils, T cells, dendritic cells (Langerhans cells), and histiocytes (macrophages). CD1A- and S100-positive.

The disease occurs more frequently in Caucasians, and the incidence is higher among males.

19.7.3 Types

Eosinophilic Granuloma (Localized Form)

Head and Neck Presentation

Occurs in children 5 to 15 years old.

Osseous

Solitary, monostotic calvarial osteolytic bone lesion presenting with bone pain; can be found in mandible and also present with loose teeth.

Ocular

Periorbital osseous lesions may cause periorbital edema and proptosis.

Otologic

Mastoid involvement can cause chronic otitis media, mastoiditis, tympanic membrane perforations, external canal polyps, and facial paralysis.

Oral

Gingival erosions with bleeding.

Dermatologic

Scalp disease can cause scaling of the scalp with patchy lesions leading to alopecia; usually not pruritic, but may be tender.

Hand-Schüller-Christian Disease (Intermediate, Chronic, Disseminated Form)

Head and Neck Presentation

Occurs in children 2 to 10 years old. Classic triad of diabetes insipidus, exophthalmos, and polyostotic lesions, particularly of the skull. This disease has otologic, oral, and dermatologic findings similar to those of eosinophilic granulomas. It also may affect the lungs, liver, spleen, and lymph nodes.

Letterer-Siwe Disease (Severe, Acute, Disseminated Form)

Occurs in children younger than 2 years old. Presents with fever, anemia and thrombocytopenia, hepatomegaly and splenomegaly, and pulmonary infiltrates.

Head and Neck Presentation**Osseous**

Osteolytic lesions are not common.

Otologic

The mastoid may be involved, causing chronic otitis media, otorrhea, postauricular edema, external canal polyps, and conductive hearing loss.

Lymphatic

Cervical lymphadenopathy may be present.

Work-up

Laboratory studies include complete blood cell count with differential, liver function tests, coagulation studies, and urine osmolality testing to rule out diabetes insipidus. Radiologic studies

include chest X-ray and skeletal survey. Biopsy of a lesion (skin lesion is the most accessible) will establish the diagnosis.

Treatment**Localized/Single-Organ Disease**

Monostotic bone lesions may be treated by curettage/excision. Polyostotic bone lesions can be treated with systemic steroids.

Skin lesions may be treated with topical steroids, and localized lymph node involvement can be addressed with excision.

Chemotherapy and radiation therapy are reserved for large lesions that may be causing severe pain, are difficult to access, or involve vital structures.

Disseminated/Multiple-Organ Disease

Systemic chemotherapy (methotrexate, vinblastine, etoposide) with or without systemic corticosteroids is standard. Diabetes insipidus is treated with desmopressin acetate. Rapidly progressive disease that is refractory to other treatment modalities may be treated with a bone marrow transplant for salvage.

19.8 Behçet Disease

19.8.1 Pathogenesis

The classic triad of symptoms includes recurrent oral aphthous ulcers, genital ulcers, and uveitis. However, this is a complex, multisystem disease affecting the skin; eyes; joints; cardiovascular, gastrointestinal, and urologic systems; kidneys; lungs; and central nervous system. The condition is an idiopathic vasculitis with a likely autoimmune component triggered by an infectious event

19.8.2 Histology

Lymphocytic vasculitis with a neutrophilic infiltrate; thrombotic clotting due to a hypercoagulable state may also be present. The histologic findings are nonspecific.

19.8.3 Head and Neck Presentation

The disease occurs predominantly in the Middle East, in particular Turkey, and in Asia, with a higher incidence especially in people of Japanese background. The gender prevalence depends on the country, but the disease is more prevalent in females in the United States.

Oral

Aphthous and herpetic lesions are the most common presenting symptom.

Ocular

Uveitis and retinal vasculitis causing blurry vision, scleral injection, eye pain, excessive lacrimation, photophobia, and possible blindness if the ocular symptoms develop early in the disease course. The ocular symptoms usually follow the oral symptoms.

Pharyngoesophageal

Dysphagia due to oropharyngeal and esophageal ulcers and neurologic impairment of the swallowing mechanism.

Otologic

Acute deafness due to neuro-otologic impairment.

Laryngeal

Speech difficulties due to neurologic impairment.

19.8.4 Work-up

Diagnosis is based on the clinical symptom and findings. Laboratory results show an elevated inflammatory state (elevated ESR, C-reactive protein, leukocytosis). Pathergy test: mild skin trauma induces the formation of an erythematous papule/pustule after 1 to 2 days.

19.8.5 Treatment

Topical steroids, tetracycline swish and swallow solutions and sucralfate for limited oral ulcerations, and systemic steroids for severe mucocutaneous disease. Immunosuppressive and immunomodulating agents such as azathioprine, colchicine, sulfasalazine, cyclosporine, and cyclophosphamide are indicated for more pervasive disease. Proper consultations as needed: surgery for possible gastrointestinal bleeds or perforation, neurosurgery for central nervous system thrombotic or aneurysmal events, cardiothoracic surgery for major vessel aneurysms/thrombosis, ophthalmology, dermatology, urology, gastroenterology, neurology, and nephrology.

19.9 Cogan Syndrome

19.9.1 Pathogenesis

Classic triad of nonsyphilitic interstitial keratitis, fluctuating vertigo/sensorineural hearing loss with tinnitus, and an associated autoimmune vasculitic condition (usually a large-vessel vasculitis). Autoimmune in etiology, likely in reaction to a common antigen found in both the cornea and inner ear.

19.9.2 Histology

Hydropic findings similar to those of Meniere disease in the inner ear, lymphocytic infiltration of the cornea with neovascularization.

19.9.3 Head and Neck Presentation

Predominantly in young adults and Caucasians.

Otologic

Symptoms similar to those of Meniere disease, with episodic vertigo, fluctuating sensorineural hearing loss associated with tinnitus, and possible aural fullness.

Ocular

Interstitial keratitis causing eye pain, redness, excessive lacrimation, blurry vision, and photophobia.

19.9.4 Work-up

Slit lamp examination reveals the anterior chamber findings of interstitial keratitis. Audiogram reveals a sensorineural hearing loss preferentially in the low and high frequencies. Electroneurography and rotary chair testing show a vestibular weakness.

19.9.5 Treatment

Systemic corticosteroids and immunosuppressants (azathioprine, cyclophosphamide).

19.10 Rheumatoid Arthritis

19.10.1 Pathogenesis

Systemic inflammatory disease affecting peripheral joints.

19.10.2 Histology

Neovascularization of synovium with lymphocytic infiltration. Rheumatoid skin nodules are characterized by a small-vessel vasculitis and granulomatous lesions.

19.10.3 Head and Neck Presentation

Female predominance with a high incidence in certain Native American populations.

Maxillofacial

Bilateral temporomandibular joint tenderness and swelling, trismus.

Laryngeal

Hoarseness due to cricoarytenoid joint inflammation/ankylosis.

Otologic

Conductive hearing loss due to ossicular chain fixation.

19.10.4 Work-up

Radiologic studies of the temporomandibular joint may show condyle erosion at the articular surface and obliteration of the joint space. Laryngoscopy may reveal arytenoid edema, impaired mobility of the vocal folds, and cricoarytenoid joint fixation. Rheumatoid nodules may appear on the vocal folds (bamboo nodules). Computed tomographic scan of the neck may show a soft-tissue swelling of the cricoarytenoid joint. Audiogram may show a conductive hearing loss. Laboratory studies show an elevated rheumatoid factor, ESR, and/or C-reactive protein. Biopsy of cutaneous nodules may be helpful in the diagnosis.

19.10.5 Treatment

Nonsteroidal anti-inflammatory drugs, glucocorticoids, and disease-modifying antirheumatic drugs (DMARDs): methotrexate, sulfasalazine, gold salts, penicillamine.

19.11 Scleroderma (Progressive Systemic Sclerosis)

19.11.1 Pathogenesis

A triad of processes including autoimmune activation causes a small-vessel vasculitis and progressive fibrosis due to excessive collagen deposition; smooth-muscle atrophy occurs in the gastrointestinal tract.

19.11.2 Histology

Extensive fibrosis of the skin and affected organs with collagen deposition, possible inflammatory infiltrates, and small-vessel vasculopathy with microthrombi.

19.11.3 Head and Neck Presentation

Cutaneous

Tight, fibrotic facial skin with thinning of the lips and reduction in the oral aperture (“pursed lip” appearance).

Esophageal

Gastroesophageal reflux (due to a patent lower esophageal sphincter); dysphagia from disease infiltration anywhere along the gastrointestinal tract but classically the lower two-thirds of the esophagus due to smooth-muscle involvement; oropharyngeal and esophageal cancers are more common in these patients.

Ocular and Oral

Xerostomia and dry eyes as part of a sicca syndrome may be present.

Laryngeal

Hoarseness due to gastroesophageal reflux or laryngeal fibrosis.

19.11.4 Work-up

Laboratory studies are positive for ANA. Barium swallow may show a dilated esophagus but incompetent lower esophageal sphincter (to distinguish from achalasia). Esophageal manometry will show normal upper esophageal pressures but the incompetent lower esophageal sphincter. pH probe studies can confirm the gastroesophageal reflux. Minor salivary gland biopsy will show extensive fibrosis but without the lymphocytic infiltrate seen in Sjögren syndrome.

19.11.5 Treatment

Gastroesophageal reflux precautions, proton pump inhibitors, nonsteroidal anti-inflammatory drugs, and corticosteroids

may be considered. There are no FDA-approved therapies for scleroderma.

19.12 Dermatomyositis/Polymyositis

19.12.1 Pathogenesis

An autoimmune inflammatory vasculopathy and myopathy of striated muscle. When both skin and muscle are affected, it is termed dermatomyositis, and when only muscle is involved, it is called polymyositis. An inflammatory infiltrate is present in muscle and around vessels.

19.12.2 Histology

An inflammatory infiltrate is present in muscle (interfascicular in dermatomyositis and intrafascicular in polymyositis) and around vessels; affected skin has an inflammatory infiltrate at the dermal–epidermal basement membrane.

19.12.3 Head and Neck Presentation

More common in women.

Cutaneous

In dermatomyositis, the heliotrope rash—a reddish brown to purple discoloration around the eyelids with periorbital edema—is pathognomonic; an erythematous rash is prominent in the head and neck, sometimes in a V-shaped distribution on the neck (“shawl” sign); a psoriatic scalp dermatitis may lead to alopecia.

Musculoskeletal

Weakness in the neck flexors.

Pharyngoesophageal

Dysphonia and dysphagia are caused by oropharyngeal and esophageal striated muscle weakness (upper third of the esophagus).

19.12.4 Work-up

Blood work illustrates elevated creatine kinase (CK), lactic dehydrogenase (LDH), aspartate aminotransferase (AST), and ANA levels.

Radiologic studies may include a barium swallow showing esophageal dysmotility, and magnetic resonance imaging of an affected muscle may show an inflammatory myopathy. Electromyography of an affected muscle may be performed. Biopsy of an affected muscle reveals the histologic findings.

19.12.5 Treatment

Reflux precautions, systemic corticosteroids, immunosuppressive cytotoxic agents, intravenous immunoglobulin (IVIG).

19.13 Giant Cell (Temporal) Arteritis

19.13.1 Pathogenesis

Giant cell arteritis is the most common idiopathic vasculitis; it is a chronic vasculitis of medium-size and large arteries that causes concentric intimal hyperplasia of the vessel walls.

19.13.2 Histology

The intima, media, and adventitia of the vessel wall are affected (panarteritis); inflammation in the endothelium at the intima-media junction as well as the adventitia leads to neovascularization; giant cells may be present; fragmentation of the internal elastic lamina is often seen.

19.13.3 Head and Neck Presentation

Found predominantly in the elderly and more common in women and Caucasians. Headache is the most common presenting symptom.

Cutaneous

Erythema of the skin with facial pain and, if severe, necrosis of the skin.

Maxillofacial

Jaw claudication is pathognomonic; trismus, temporomandibular joint pain, tooth and gingival pain, tenderness over the scalp/temporal region.

Nasal

Edematous and inflamed nasal mucosa, anosmia.

Oropharyngeal

Dysphagia caused by edematous and inflamed oropharyngeal mucosa, necrotic lesions of the oral mucosa, tongue claudication due to ischemia, glottic ulcerations, ageusia.

Laryngeal

Hoarseness.

Otologic

Otalgia, tinnitus, vertigo, sensorineural hearing loss; lymphadenopathy and tonsillar hypertrophy may be present; salivary gland enlargement.

Ocular

Blindness is one of the most severe complications of the disease. Amaurosis fugax is the transient sensation of a “shade coming over the eye.”

19.13.4 Work-up

Blood work includes elevated C-reactive protein and ESR (acute phase reactants), elevated alkaline phosphatase, normocytic normochromic anemia.

Temporal artery biopsy is the gold standard diagnostic test.

19.13.5 Treatment

Systemic corticosteroids are the first-line therapy.

19.14 Churg-Strauss Syndrome

19.14.1 Pathogenesis

An allergic granulomatous disease of small to medium-size vessels; closely related to Wegener granulomatosis. Six criteria (four or more criteria are highly sensitive and specific) for the disease include the following:

1. Asthma.
2. Eosinophilia of more than 10% in the peripheral blood.
3. Paranasal sinusitis.
4. Pulmonary infiltrates.
5. Histologic evidence of vasculitis with eosinophilic infiltrate.
6. Polyneuropathy.

19.14.2 Histology

Necrotizing granulomas with a central eosinophilic core and surrounding giant cells and macrophages; these findings are seen predominantly in the lungs.

19.14.3 Head and Neck Presentation

Sinonasal

Allergic rhinitis, nasal polyposis, chronic sinusitis, nasal obstruction.

19.14.4 Work-up

Blood work may illustrate the eosinophilia mentioned above and anemia. Elevated ESR and C-reactive protein are often present. BUN and creatinine and an abnormal urinalysis may indicate glomerulonephritis. Patients with this disease are often positive for p-ANCA (antineutrophil cytoplasmic autoantibodies, perinuclear).

Radiologic studies include chest X-ray to evaluate pulmonary involvement.

Tissue biopsy of an involved organ (lung, skin, muscle, nerve, kidneys) aids in the diagnosis.

19.14.5 Treatment

Systemic corticosteroids usually control the disease process.

19.15 Kawasaki Disease

19.15.1 Pathogenesis

Vasculitis that may be infectious in origin; it is most severe in medium-size vessels but may affect vessels of all calibers; the most common cause of acquired cardiac disease in children, followed by acute rheumatic fever.

19.15.2 Histology

Necrosis of smooth-muscle cells leads to splitting of the internal and external laminae, causing aneurysms. Fibrosis and stenosis of vessels subsequently occur as well, possibly leading to thrombosis and complete occlusion. Myocardial infarctions may occur and are due to coronary artery aneurysms and thrombosis.

19.15.3 Head and Neck Presentation

Most common in children younger than 4 years old and of Asian descent (Japanese in particular).

Systemic/Cutaneous

Fever and generalized erythematous, desquamating rash.

Ocular

Conjunctival injection.

Lymphatic

Cervical lymphadenitis; lymph nodes larger than 1.5 cm, not responsive to antibiotics.

Oral

Mucositis of the lips leading to fissuring and oropharyngeal erythema, “strawberry tongue” (glossal erythema and prominent papillae).

19.15.4 Work-up

Blood work includes elevated white blood cell count and acute phase reactants (ESR, C-reactive protein); elevated cardiac enzymes with myocardial infarction.

The EKG may show signs of myocarditis or infarction; chest X-ray and echocardiography to evaluate cardiac disease.

19.15.5 Treatment

The mainstay of treatment is IVIG, salicylates/ aspirin, and close cardiovascular monitoring.

19.16 Roundsmanship

- Multiple findings and symptoms across different areas of the head and neck should make the physician consider putting a systemic etiology higher on the list of differential diagnoses.
- A preliminary blood work-up that includes acute phase reactants, such as the erythrocyte sedimentation rate and C-reactive protein level, may be useful in diagnosing an inflammatory autoimmune disease presenting in the head and neck of a patient.

20 Epidemiology of Head and Neck Cancers

Guo-Pei Yu and Stimson P. Schantz

20.1 Oral Cavity and Pharyngeal Cancers

20.1.1 Epidemiology

Almost all oral and pharyngeal cancers are squamous cell carcinomas with similarities in epidemiology, treatment, and prognosis. Oral cavity cancer is the 11th most common cancer in the world in terms of number of cases, while pharyngeal cancer ranks 20th. Oral and pharyngeal cancer, considered together, is the sixth most common form of cancer in the world. About 389,000 new cases occurred in the world in 2000, two-thirds of which were in developing countries. The rates of oral and pharyngeal cancer vary among countries. The highest incidence is observed in Australia, France, Hungary, South America (Brazil), and southern Africa, while the lowest incidence is seen in Mexico and Japan. Oral and pharyngeal cancers are responsible for about 200,000 deaths worldwide each year.

According to the estimates by the American Cancer Society, there were about 35,310 new cases (25,310 in men and 10,000 in women) of oral cavity cancer (22,900) and pharyngeal cancer (12,410) and about 7,590 people (5,210 men and 2,380 women) who died of these cancers in the United States in 2008. These cancers account for nearly 2.5% of all malignancies.

Of all squamous oral and pharyngeal cancers (excluding salivary gland and nasopharyngeal cancers), oral cavity cancers account for nearly 88% and pharyngeal cancers about 12%. In addition, most squamous oral cavity cancers occur in the tongue (43.1%), tonsillar fossa (23.4%), lip (9.1%), and floor of the mouth (7.8%). The rest occur on the gums, palate, and unspecified parts of mouth (□ Table 20.1).

Oral and pharyngeal cancers can occur in young people. Of all patients, adults younger than 40 years of age account for 2.9% and those younger than 50 account for 16.2%. The incidence of oral and pharyngeal cancers increases with age and reaches a peak at the ages of 70 to 79 years. The incidence declines after

80+ years except in women, in whom the incidence continues to rise (□ Fig. 20.1). The incidence of oral and pharyngeal cancers is higher in men than in women, and the female-to-male ratio is 2:7 for oral cancer and 3:4 for pharyngeal cancer, respectively.

The incidence of oral cavity and pharyngeal cancers has gradually decreased over the past 30 years in the United States. The incidence of oral cavity cancer decreased 18.8% (from 8.7 per 100,000 to 6.5 per 100,000), and that of pharyngeal cancer decreased 44% (from 1.8 to 1.0 per 100,000; □ Fig. 20.2). In contrast to that of other oral cancers, however, the incidence of tongue cancer increased nearly 60% in American adults younger than 40 years of age during the same period. The increase continued until 1985, after which the incidence remained stable.

When patients with newly diagnosed oral and oropharyngeal cancers are carefully examined, about 15% will have another cancer in a nearby area, such as the larynx, esophagus, or lung. Of those who attain a complete cure of oral or oropharyngeal cancer, about 10% will develop a second cancer in one of these organs.

20.1.2 Risk Factors

Smoking and alcohol consumption are the major risk factors for oral and pharyngeal cancers. They are independent risk factors but produce a synergistic effect when combined. Smoking is estimated to be responsible for 41% of oral and pharyngeal cancers in men and 15% in women worldwide. In addition, both smoking and drinking account for approximately three-fourths of all oral cancers in the United States. Compared with non-smokers, heavy smokers have a 4- to 10-fold increased risk after adjustment for alcohol intake. After control for smoking, moderate drinkers have a 3-fold increased risk for oral cancer, and heavy drinkers have an 8- to 9-fold increased risk. The combination of heavy smoking and drinking results in a greater than 35-fold excess risk. The significant decrease in cigarette smoking is considered a major factor responsible for the decreases in oral and pharyngeal cancers in the United States.

Smokeless tobacco use is another risk factor in some populations; it is associated with relative risks for oral cancers and oral leukoplakia as great as that for cigarette smoking. Among users of snuff, cancerous lesions typically arise at the site where smokeless tobacco, or quid, is held in contact with the buccal mucosa or gingiva. Chewing quid containing betel leaves and lime is thought to contribute to the majority of cases in parts of India and Southeast Asia. However, the rate of smokeless tobacco use is still relatively low in the United States.

Although tobacco use and alcohol consumption are considered major risk factors for oral and pharyngeal cancers, heritable familial factors may also play a role. Some studies have found a significantly higher proportion of cancer within the families of patients with oral and pharyngeal cancer (risk 3-fold higher than the risk in families of noncancer controls). The familial aggregation seems to be associated with defective DNA repair capability. After adjustment for potentially confounding factors, including tobacco and alcohol consumption, patients with both a family history of cancer and mutagen sensitivity

Table 20.1 Number of squamous oral cavity cancers by subsites, excluding cancers of the salivary glands and nasopharynx

Sites	Number	Percentage
Tongue	2,123	43.1
Tonsils	1,153	23.4
Lip	447	9.1
Floor of mouth	383	7.8
Gum	237	4.8
Palate	219	4.5
Other/unspecified parts of mouth	360	7.3
All oral cavity cancers	4,922	100.0

Source: Data are from the Surveillance Epidemiology and End Results program, 2006, which covers 17 cancer registry areas of the United States.

Fig. 20.1 Age-specific incidence of oral cavity and pharyngeal cancer, all races, Surveillance Epidemiology and End Results (SEER), 17 registry areas, 2006. The numbers in parentheses are age-adjusted incidence per 100,000.

Fig. 20.2 Age-adjusted incidence of oral and pharyngeal cancers by time, Surveillance Epidemiology and End Results (SEER), 17 registry areas, 2006.

have a 7-fold or higher risk for oral and pharyngeal cancers in comparison with normal controls. The finding indicates the importance of genetic influence in the causation of the disease.

Oral human papillomavirous (HPV) infection is an additional risk factor for oral and pharyngeal cancers. Two types of HPV (types 16 and 18) seem to be the most carcinogenic and show a close correlation with TP53 mutation. Overall estimates of HPV infection for oral neoplastic tissues are variable, ranging from 14 to 91%. Oral squamous carcinoma has an approximately 4-fold higher expression of HPV than normal oral mucosa. In addition, tumors of the oropharynx (in particular tonsillar tissue) have been found to be three times more likely to be HPV-positive than tumors at other sites in the head and neck. However, the exact relationship of HPV infection and carcinoma in the mouth and the role of cofactors are unknown. A low intake of fruits and vegetables is known to significantly increase the risk for oral and pharyngeal cancers.

20.2 Nasopharyngeal Cancer

20.2.1 Epidemiology

Nasopharyngeal cancer is a very rare malignancy in North America, Europe, and many regions of Asia, including Japan and Korea, where the incidence is less than 1 per 100,000. This cancer, however, is extremely common in southern regions of China, Southeast Asia, and North Africa. In Guangdong of China and in Hong Kong, the incidence of nasopharyngeal cancer is more than 20 per 100,000.

In 2002, roughly 80,000 new cases of nasopharyngeal cancer were diagnosed worldwide, and the estimated number of deaths exceeded 50,000. There are about 2,000 new cases each year in the United States. Most nasopharyngeal cancers are of the keratinizing type in the United States, whereas in Southeast Asia the undifferentiated type is most common.

Nasopharyngeal cancer can occur in people younger than 40 years of age, suggesting a possible exposure to a common agent in early life. Young patients account for about 16% of all patients. The incidence of nasopharyngeal cancer increases with age, but the age peak is different in different races. In high-risk Asian Americans, the age peak is at 50 to 59 years, whereas in low-risk non-Asian Americans, the peak is at 60 to 69 years. The incidence of nasopharyngeal cancer is 2- to 3-fold higher in men than in women (□ Fig. 20.3).

The incidence in descendants of Chinese who emigrate to the United States is significantly lower than that in native Chinese, but the rate remains six times higher than that in Caucasian Americans and African-Americans. Similarly high incidence rates have been observed among Chinese emigrants to the United Kingdom and Australia. The incidence risk for nasopharyngeal cancer seems to decrease with a longer duration of residence in Western nations.

The incidence of nasopharyngeal cancer has been high in Southeast Asia for several decades. However, the incidence of this cancer has declined gradually in Hong Kong since the 1970s, in Taiwan since the 1980s, and in Singapore Chinese since the late 1990s. A similar trend of decline has been noted in the United States between 1975–1979 and 2005–2006, during which time the incidence of the disease decreased 20% in whites, 38% in blacks, and 28% in other persons of races, such as Asians, Pacific Islanders, and Native Americans.

20.2.2 Risk Factors

Epstein-Barr virus (EBV) infection is a highly likely cause of nasopharyngeal cancer, and it distinguishes nasopharyngeal cancer from other oral cancers. EBV infection is a cause of the undifferentiated form of nasopharyngeal cancer recognized by International Agency for Research on Cancer (IARC). Many epidemiologic studies have observed that antibody titers and neutralizing antibodies against EBV-specific DNase are much higher among patients with nasopharyngeal cancer than among controls. In general, biopsy specimens of the undifferentiated form of this cancer are all EBV-positive and monoclonal

with regard to this virus. Specimens of severe dysplasia or carcinoma in situ of the nasopharynx are positive for EBV. However, the relationship between EBV infection and nasopharyngeal cancer is not entirely understood. An unexplainable fact is that all adults in areas of endemicity are infected with the virus, yet only a very small proportion of people develop nasopharyngeal cancer. In addition, it is unclear whether higher titers of EBV are a cause of or are caused by nasopharyngeal cancer—that is, whether EBV passively infects nasopharyngeal cancer cells or plays an active role in malignant transformation.

The intake of salt-preserved fish and other food is another risk factor. In southern China, boat-dwelling fishermen and their families consume a great deal of salted fish and other preserved foods, and the incidence of nasopharyngeal cancer in these people is extremely high. Traditionally, salted fish is used to wean infants in the Cantonese population, in which the incidence of nasopharyngeal cancer is as high as 20 per 100,000. The carcinogenic potential of salt-preserved fish is supported by experiments in rats, which develop malignant nasal and nasopharyngeal tumors after the consumption of salted fish. Salted fish contains varying amounts of volatile nitrosamines and bacterial mutagens. So far, however, the association of salt-preserved fish with nasopharyngeal cancer risk has not been proved by prospective studies.

Other suspected risk factors for nasopharyngeal cancer include genetic background; occupational exposures to fumes, dusts, or chemicals; low intake of fresh fruits and vegetables; tobacco smoking; use of herbal medicines; and previous chronic respiratory tract diseases. The familial aggregation of nasopharyngeal cancer has been widely reported. The risk is about 4- to 8-fold higher among first-degree relatives of patients with nasopharyngeal cancer than in those without a family history. Occupational exposure to wood dusts, fumes, or chemicals has also been noted to increase the risk for nasopharyngeal cancer. Individuals exposed to wood dust for 10 years or longer had an adjusted relative risk of 2.4; the risk was highest for those first exposed before the age of 25 years and in those seropositive for EBV.

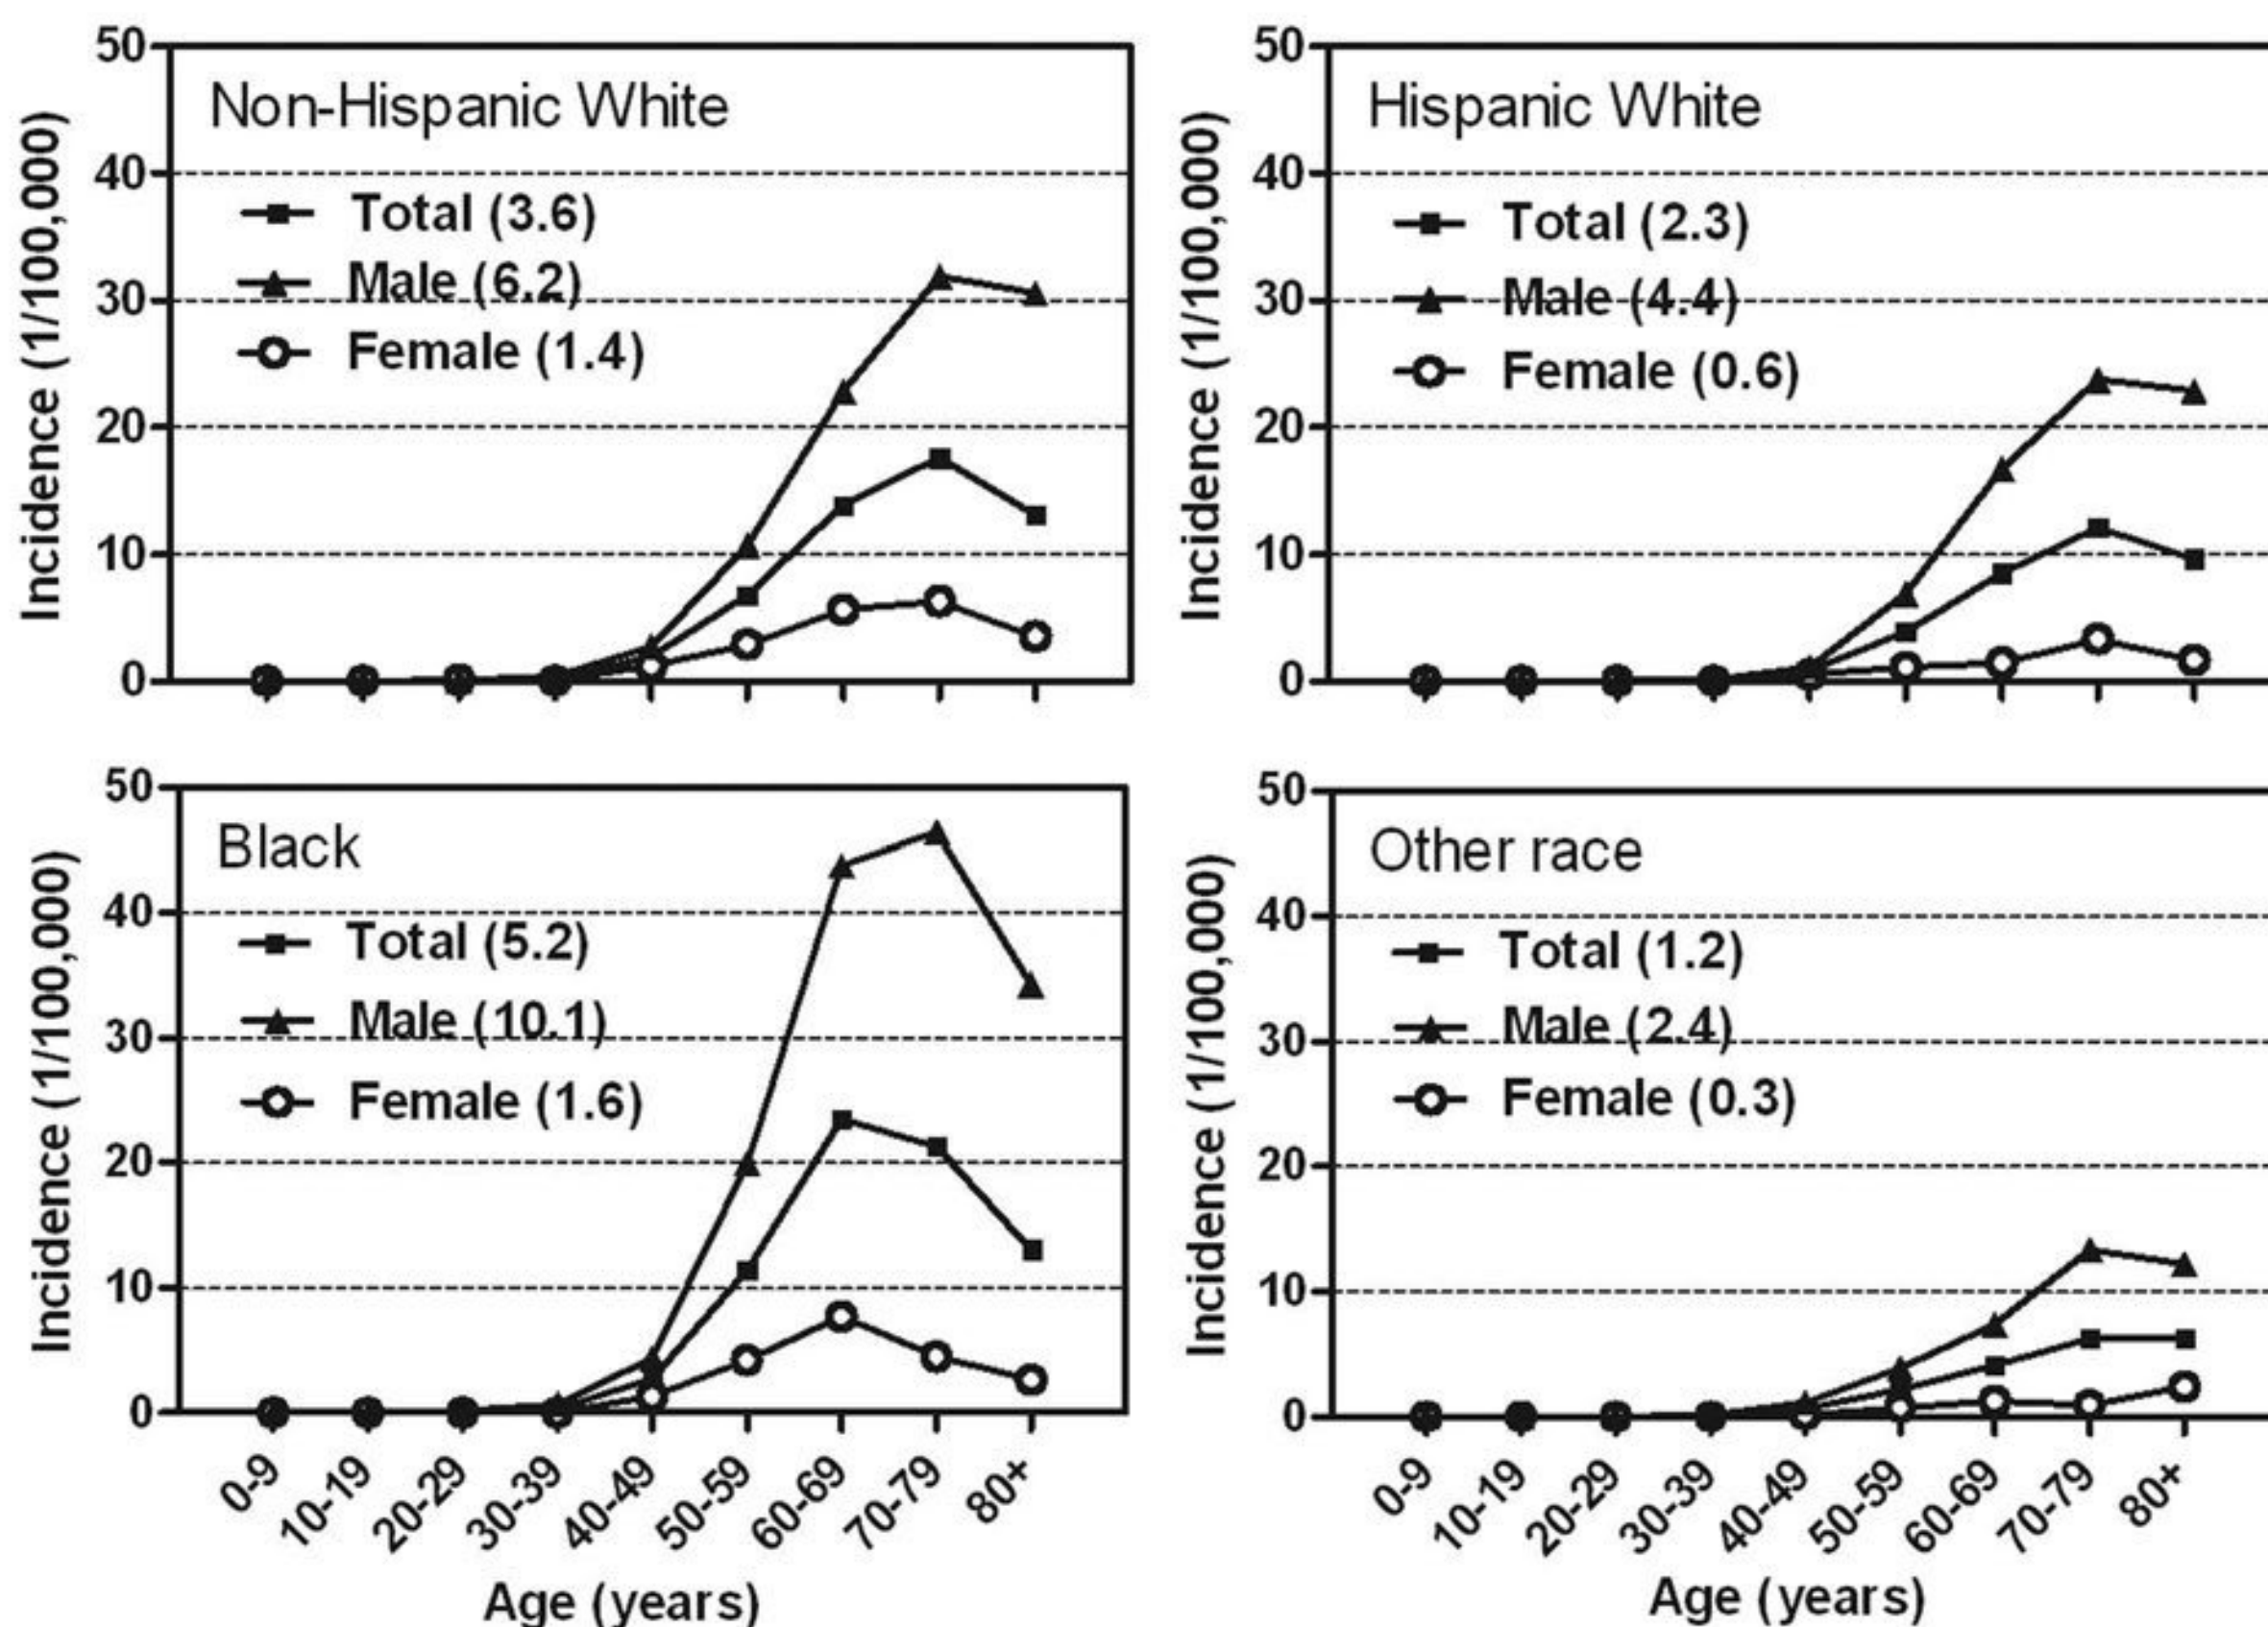

Fig. 20.4 Age-specific incidence of laryngeal cancer by race, Surveillance Epidemiology and End Results (SEER), 17 registry areas, 2006. The numbers in parentheses are age-adjusted incidence per 100,000.

20.3 Laryngeal Cancer

20.3.1 Epidemiology

More than 90% of cancers of the larynx are squamous cell carcinoma, and the majority originate from the supraglottic and glottic regions of the organ. Laryngeal cancer accounts for approximately 1 to 2% of all new cancer diagnoses, and its incidence varies by country. The incidence of laryngeal cancer is high in southern and central Europe, southern Brazil, Uruguay, and Argentina, whereas it is low in Southeast Asia and central Africa. A total of 140,000 new cases were diagnosed worldwide in 1990, of which 120,000 were in men. In the United States, the estimated number of new cases was 12,250 in 2008; 3,670 died of this disease.

Laryngeal cancer has an incidence pattern similar to that of cancers of the mouth and throat, occurring more often in men than in women, and more often in blacks than in whites. Rates among men range from a low of 2.4 per 100,000 in Asians, Pacific Islanders, and Native Americans to a high of 10.1 per 100,000 in blacks; rates for non-Hispanic whites and Hispanics are intermediate (6.2 per 100,000 and 4.4 per 100,000, respectively). Laryngeal cancer is much less common in women, with rates ranging from 0.3 per 100,000 in Asians, Pacific Islanders, and Native Americans to 1.6 per 100,000 in blacks. The male-

to-female ratios of disease incidence are 8:1 for Asians, Pacific Islanders, and American Indians; 7:1 for Hispanics; 6:1 for blacks; and 4:1 for non-Hispanic whites (□ Fig. 20.4).

Laryngeal cancer is uncommon in patients younger than 40 years. The incidence of laryngeal cancer increases with age but decreases after the age of 70 years. The age-related peak incidence is as high as 46 per 100,000 in blacks, whereas it is about 32 per 100,000 in non-Hispanic whites, 22 per 100,000 in Hispanics, and 12 per 100,000 in other races.

As shown in □ Fig. 20.5, the age-adjusted incidence of laryngeal cancer significantly decreased between 1975–1979 and 2005–2006 in all racial groups (35% decrease in whites, 27% decrease in blacks, and 44% decrease in other racial populations). The incidence also significantly decreased with time in persons of all ages except for those 80+ years of age. The magnitude of decrease varies by age, with larger decreases in younger age groups.

20.3.2 Risk Factors

As with cancers of the mouth, throat, and lung, smoking is the major cause of laryngeal cancer. Cigarette smokers have almost a 10-fold greater risk for laryngeal cancer than nonsmokers do, and risk increases with increased cigarette smoking. The smoking-related risk is also affected by alcohol use; the risk is highest

Fig. 20.5 Time trend of incidence of laryngeal cancer by race and by age, Surveillance Epidemiology and End Results (SEER), 17 registry areas, 2006.

among heavy smokers who are also heavy users of alcohol. The effect of tobacco is stronger for glottic than for supraglottic cancers. There is also a beneficial effect of quitting smoking. In addition, the effect of alcohol is stronger for supraglottic tumors than for tumors in other sites.

Additional risk factors for laryngeal cancer are occupational exposures to sulfuric acid, nickel, and asbestos; the link to sulfuric acid is best established. Occupational risk factors account for only a small fraction of all cases of laryngeal cancer.

HPV infection is also found to be associated with laryngeal cancer. Patients with laryngeal papillomatosis (associated with HPV-6 and HPV-11 infection) have an increased risk for laryngeal cancer. Herpes simplex virus type 1 is another virus with a possible causal role in laryngeal cancer.

20.4 Salivary Gland Cancer

20.4.1 Epidemiology

Salivary gland cancer is a rare malignancy, with an incidence rate of 1.5 per 100,000 people and 4,313 new cases in 2006 in the United States. Salivary gland cancer accounts for about 16% of all oral cavity cancers (squamous and nonsquamous). In contrast to other malignancies, salivary gland cancer shows very little international variation in incidence.

Fig. 20.6 shows the incidence of salivary gland cancer among different races. The incidence is highest in non-Hispanic whites (1.6 per 100,000), whereas it ranges from 1.0 to 1.2 in other races. The incidence of salivary gland cancer increases

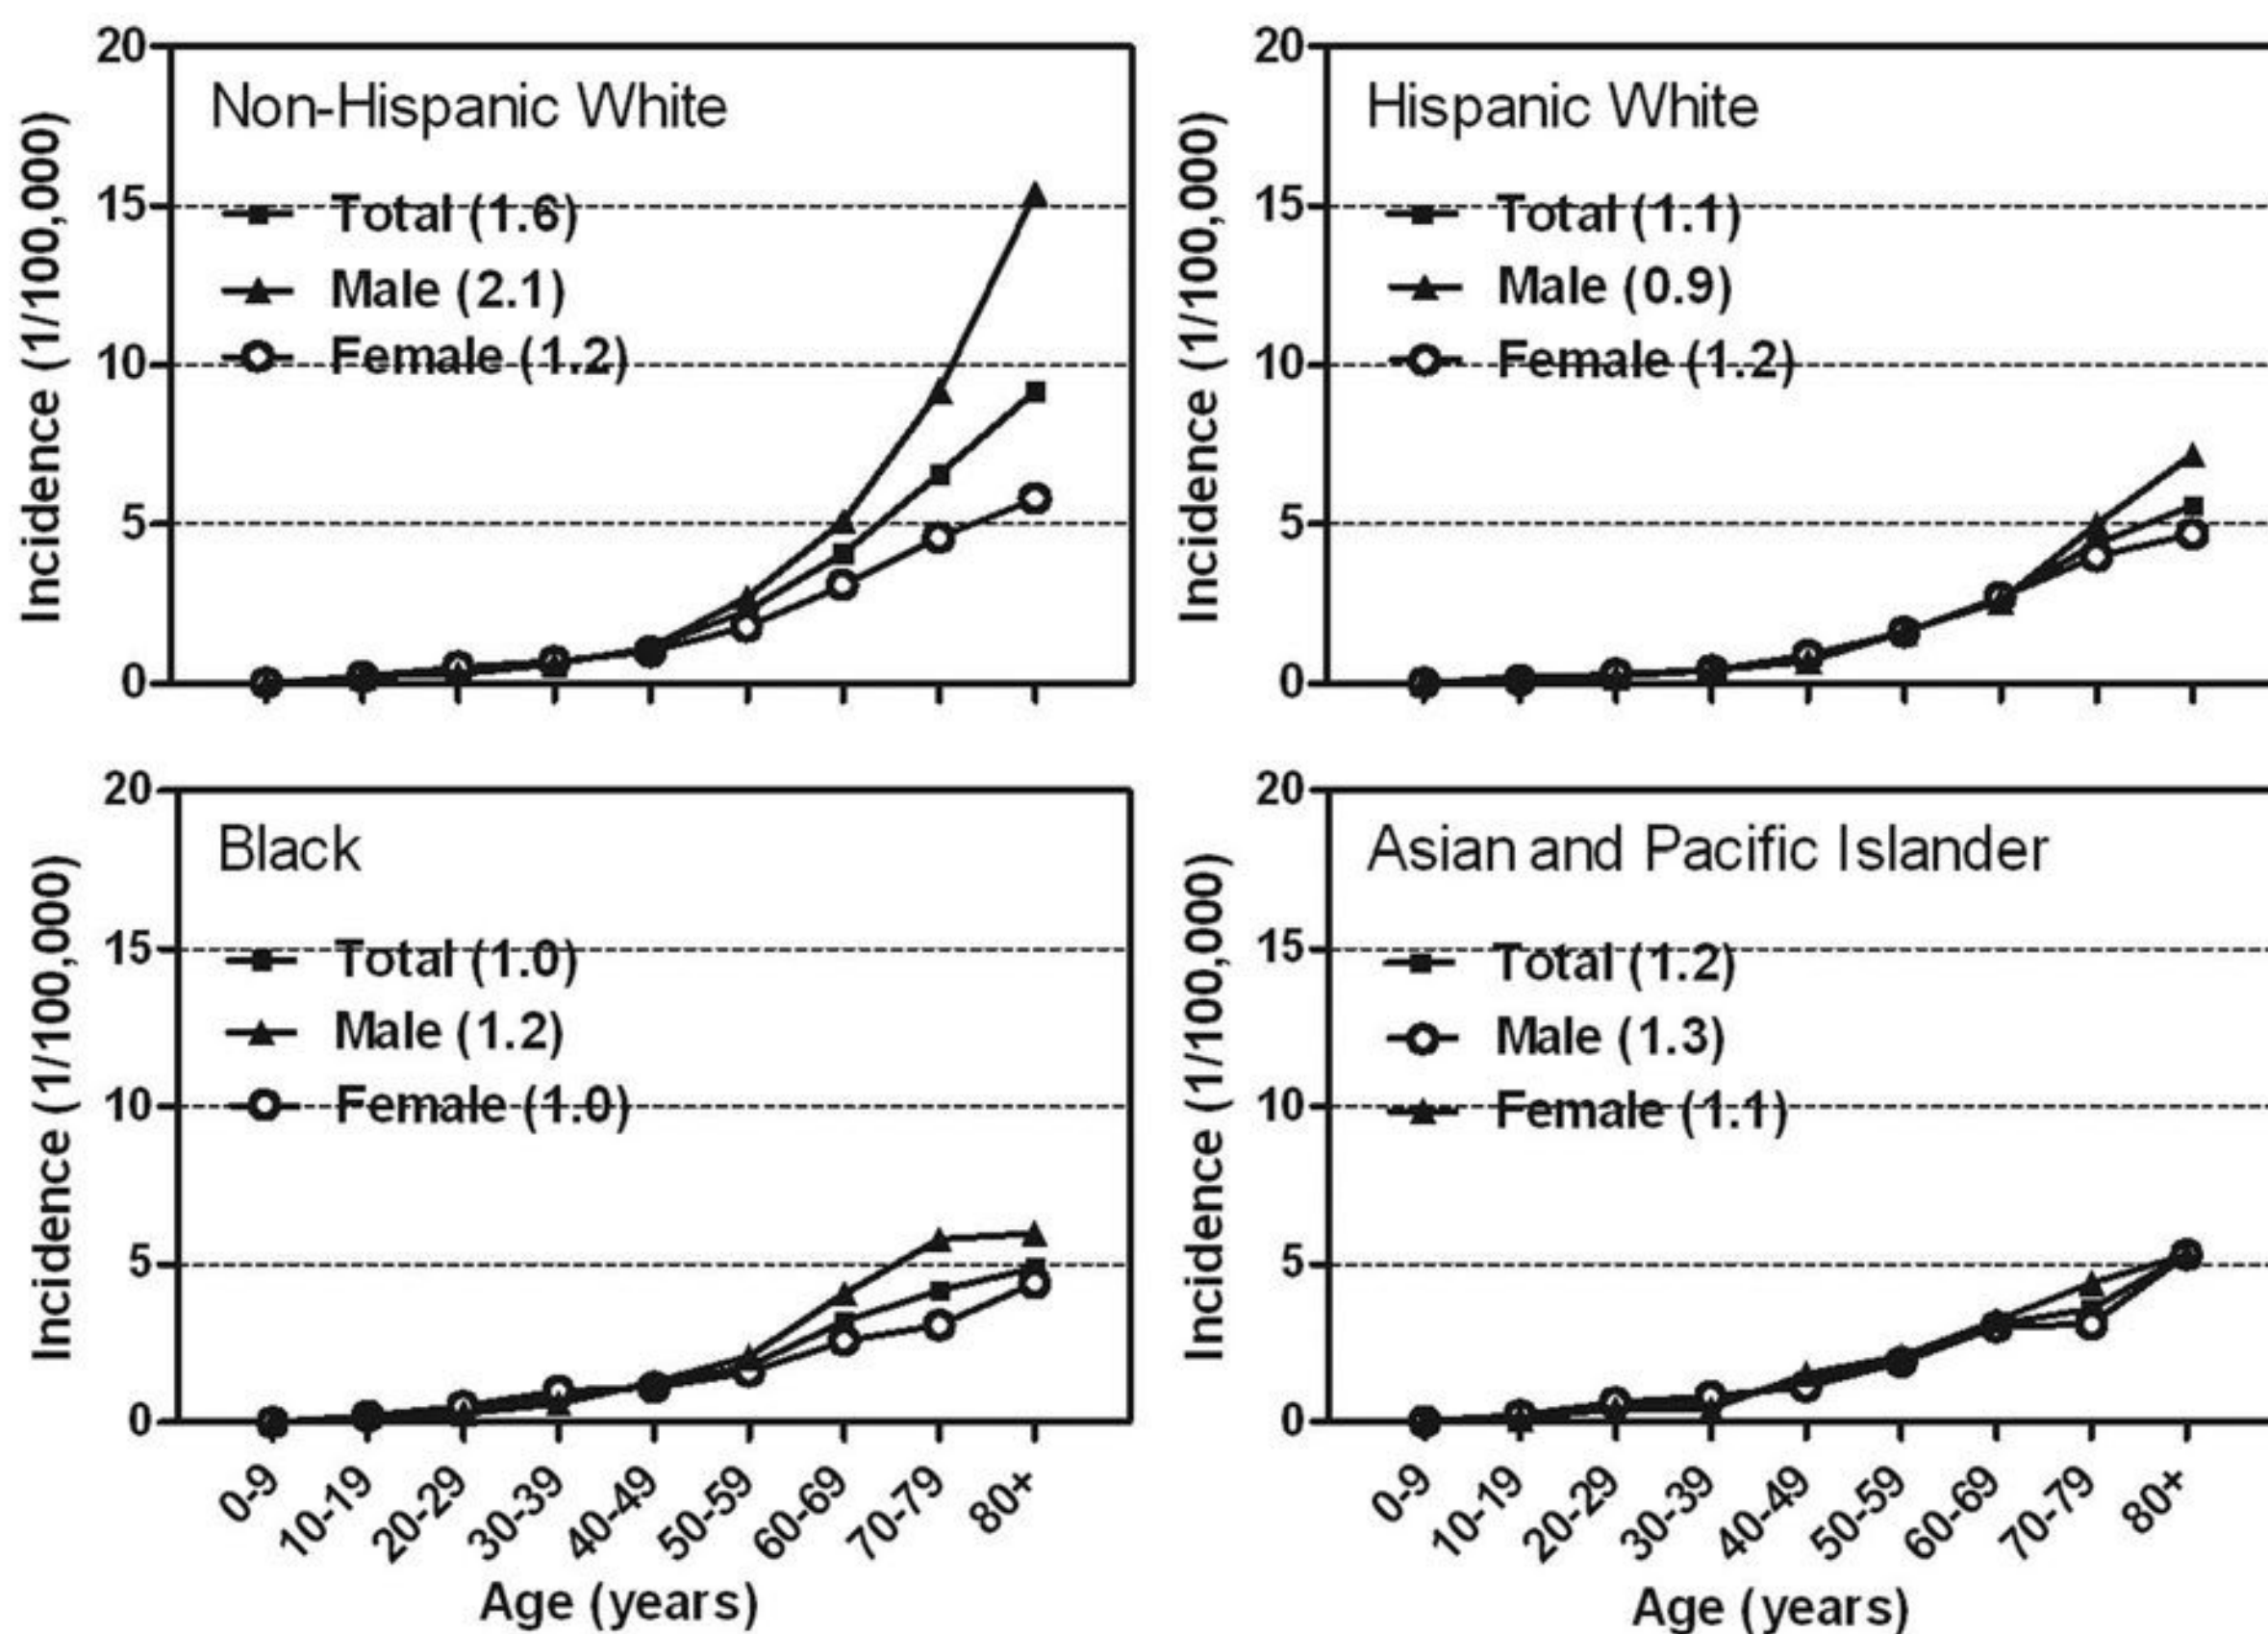

Fig. 20.6 Age-specific incidence of salivary gland cancer by race, Surveillance Epidemiology and End Results (SEER), 17 registry areas, 2006. The numbers in parentheses are age-adjusted incidence per 100,000.

with age. However, the age patterns of incidence differ between non-Hispanic whites and other racial populations; among people younger than 60 years old, the age patterns are similar in non-Hispanic whites and other races. However, the incidence of salivary gland cancer increases nearly 5 times (in non-Hispanic white males) and 2 times (in non-Hispanic white females) in persons 60 to 80 years old. Non-Hispanic male whites have a nearly 2 times higher incidence than non-Hispanic female whites, but there is no similar sex difference among other racial populations except for people who are 60 years of age or older.

The incidence of salivary gland cancer has increased 30 to 40% in the past 25 to 30 years in the United States in all ages and races (□ Fig. 20.7). This trend has also been noted in other countries. The reasons for this increase are not well understood.

20.4.2 Risk Factors

Exposure to radiation is a well-established risk factor for salivary gland cancer. Strong evidence comes from the excess risk for salivary gland cancer among survivors of atomic bomb attacks. Additional evidence comes from the findings of exposure to prior dental radiography and therapeutic radiation, workplace exposure to certain radioactive substances, and exposure to ultraviolet B radiation.

Other risk factors for salivary gland cancer include smoking; alcohol drinking; EBV, HPV, and AIDS virus infections; certain occupational exposures; family history; low intake of vegeta-

bles; and cell phone use. However, the association of these risk factors with salivary gland cancer is relatively weak and sometimes controversial. For instance, smoking and heavy alcohol drinking are associated with a 1-fold higher risk for salivary gland cancer, whereas the risks of both factors are more than 2-fold higher when they are associated with other oral and pharyngeal cancers. As for viral association, EBV is found to be associated with lymphoepithelioma-like carcinoma of the salivary gland only among Asian patients. In addition, HPV does not appear to be associated with second cancers of the salivary gland. In occupational exposures, a high risk for salivary gland cancer has been observed among hairdressers and those working in beauty shops, indicating a possible hazard from dyes, sprays, and other inhaled chemicals. Moreover, an increased risk is also observed among workers who are exposed to nickel alloy dust or silica dust. However, these occupation-related links are still inconclusive because of the rarity of salivary gland cancer in those occupational populations. Although one study reported an increased risk for parotid gland tumors among heavy cell phone users, the link has been not proved by other studies.

20.5 Thyroid Cancer

20.5.1 Epidemiology

Thyroid cancer accounts for 2.6% of all malignancies. In the United States, 37,340 new cases of thyroid cancer were estimated

Fig. 20.7 Time trend of incidence of salivary gland cancer by race and by age, Surveillance Epidemiology and End Results (SEER), 17 registry areas, 2006.

in 2008, of which 28,410 were in women and 8,930 in men. About 1,590 people (910 women and 680 men) died of thyroid cancer in 2008. Thyroid cancer is one of the five most common cancers occurring among women ages 15 to 44 years. Most thyroid cancers are papillary (85%); the rest are follicular (9.6%), medullary (2.0%), or anaplastic (0.7%) (Table 20.2).

Thyroid cancers occur in all age groups (Fig. 20.8). Whereas the incidence of most other cancers increases markedly with age, the incidence of papillary thyroid cancer is highest in female adults 40 to 59 years of age and then decreases sharply as age increases. The age-related peak incidence of papillary tumor occurs later in males than in females. The incidence rates of other histologic types of thyroid cancer increase with age and reach a peak in the eighth decade.

In the United States, the highest age-adjusted incidence rate for thyroid cancer occurs in non-Hispanic whites (9.5 per

Table 20.2 Distribution of histologic type of thyroid cancer, all races, Surveillance Epidemiology and End Results (SEER), 17 registry areas, 2006

Histology	Number	Percentage
Papillary	7,042	85.1
Follicular	795	9.6
Medullary	163	2.0
Anaplastic	60	0.7
Others	215	2.6
Total	8,275	100.0

Source: Data are from the Surveillance Epidemiology and End Results program, 2006, which covers 17 cancer registry areas of the United States.

Fig. 20.8 Age-specific incidence by type of thyroid cancer, all races, Surveillance Epidemiology and End Results (SEER), 17 registry areas, 2006.

100,000) and Filipinos (9.3 per 100,000), whereas the lowest rates are seen in Native Americans (4.4 per 100,000) and African-Americans (5.0 per 100,000); moderate rates are noted in Asians and Pacific Islanders (8.6 per 100,000), Hispanic whites (7.7 per 100,000), and Chinese (5.5 per 100,000).

Thyroid cancer, mainly papillary thyroid cancer, has been increasing since the 1940s. The increase is characterized by continuity in time and significance in magnitude. From 1973 to 2006, the incidence of papillary thyroid cancer increased more than 2-fold in the United States (age-adjusted rates of 2.7 per 100,000 in 1973 and 9.4 per 100,000 in 2006). Medullary thyroid cancer showed a similar trend, but follicular and anaplastic thyroid cancers did not. The increase in papillary and medullary thyroid cancers has been observed in many other regions of the world, including Canada, the United Kingdom, Sweden, France, and Norway.

□ Fig. 20.9 shows that papillary thyroid cancers other than microscopic tumors and tumors 5 cm in size or larger increased in frequency between 1992–1996 and 2000–2004 in all racial/ethnic groups in the United States other than Native Americans Indians/Alaska Natives.

20.5.2 Risk Factors

Radiation exposure is a well-known risk factor for thyroid cancer. Its effect was initially recognized in the 1930s and 1940s, when X-rays were often used in the treatment of skin diseases

and other benign conditions, such as enlarged thymus or tonsils. Subsequently, an increased risk for thyroid cancer was observed in Japanese survivors of the atomic bomb, in persons exposed to fallout from atomic testing in the Marshall Islands, and in persons exposed to nuclear contaminations from the Chernobyl nuclear disaster. In general, the risk associated with X-rays is increased about 2- to 3-fold, but this increase rises to 10-fold or greater with exposure to nuclear radiation. In addition to therapeutic X-rays and nuclear radiation, some investigators also suspect that diagnostic X-rays (the most common human-made source of radiation exposure) may play a role in the occurrence of thyroid cancer. However, the effect of diagnostic X-rays remains controversial, and data appear weak.

Female hormones have been also considered a risk factor for thyroid cancer. Supporting evidence include that (1) females have 2- to 3-fold higher incidence of thyroid cancer than males; (2) the association is more pronounced for the papillary type than for the follicular type among young women; (3) the elevated levels of female hormones can promote thyroid hyperplasia; (4) pregnancy is associated with elevations in both estrogen and thyroid hormone levels; (5) pregnancy and early menopause appear to enhance the risk for thyroid cancer; and (6) risk is reduced for women who have never used oral contraceptives. However, the association between female hormones and thyroid cancer is still incompletely understood. For example, it remains unclear how female hormones influence thyroid carcinogenesis. In addition, there is no time consistency between

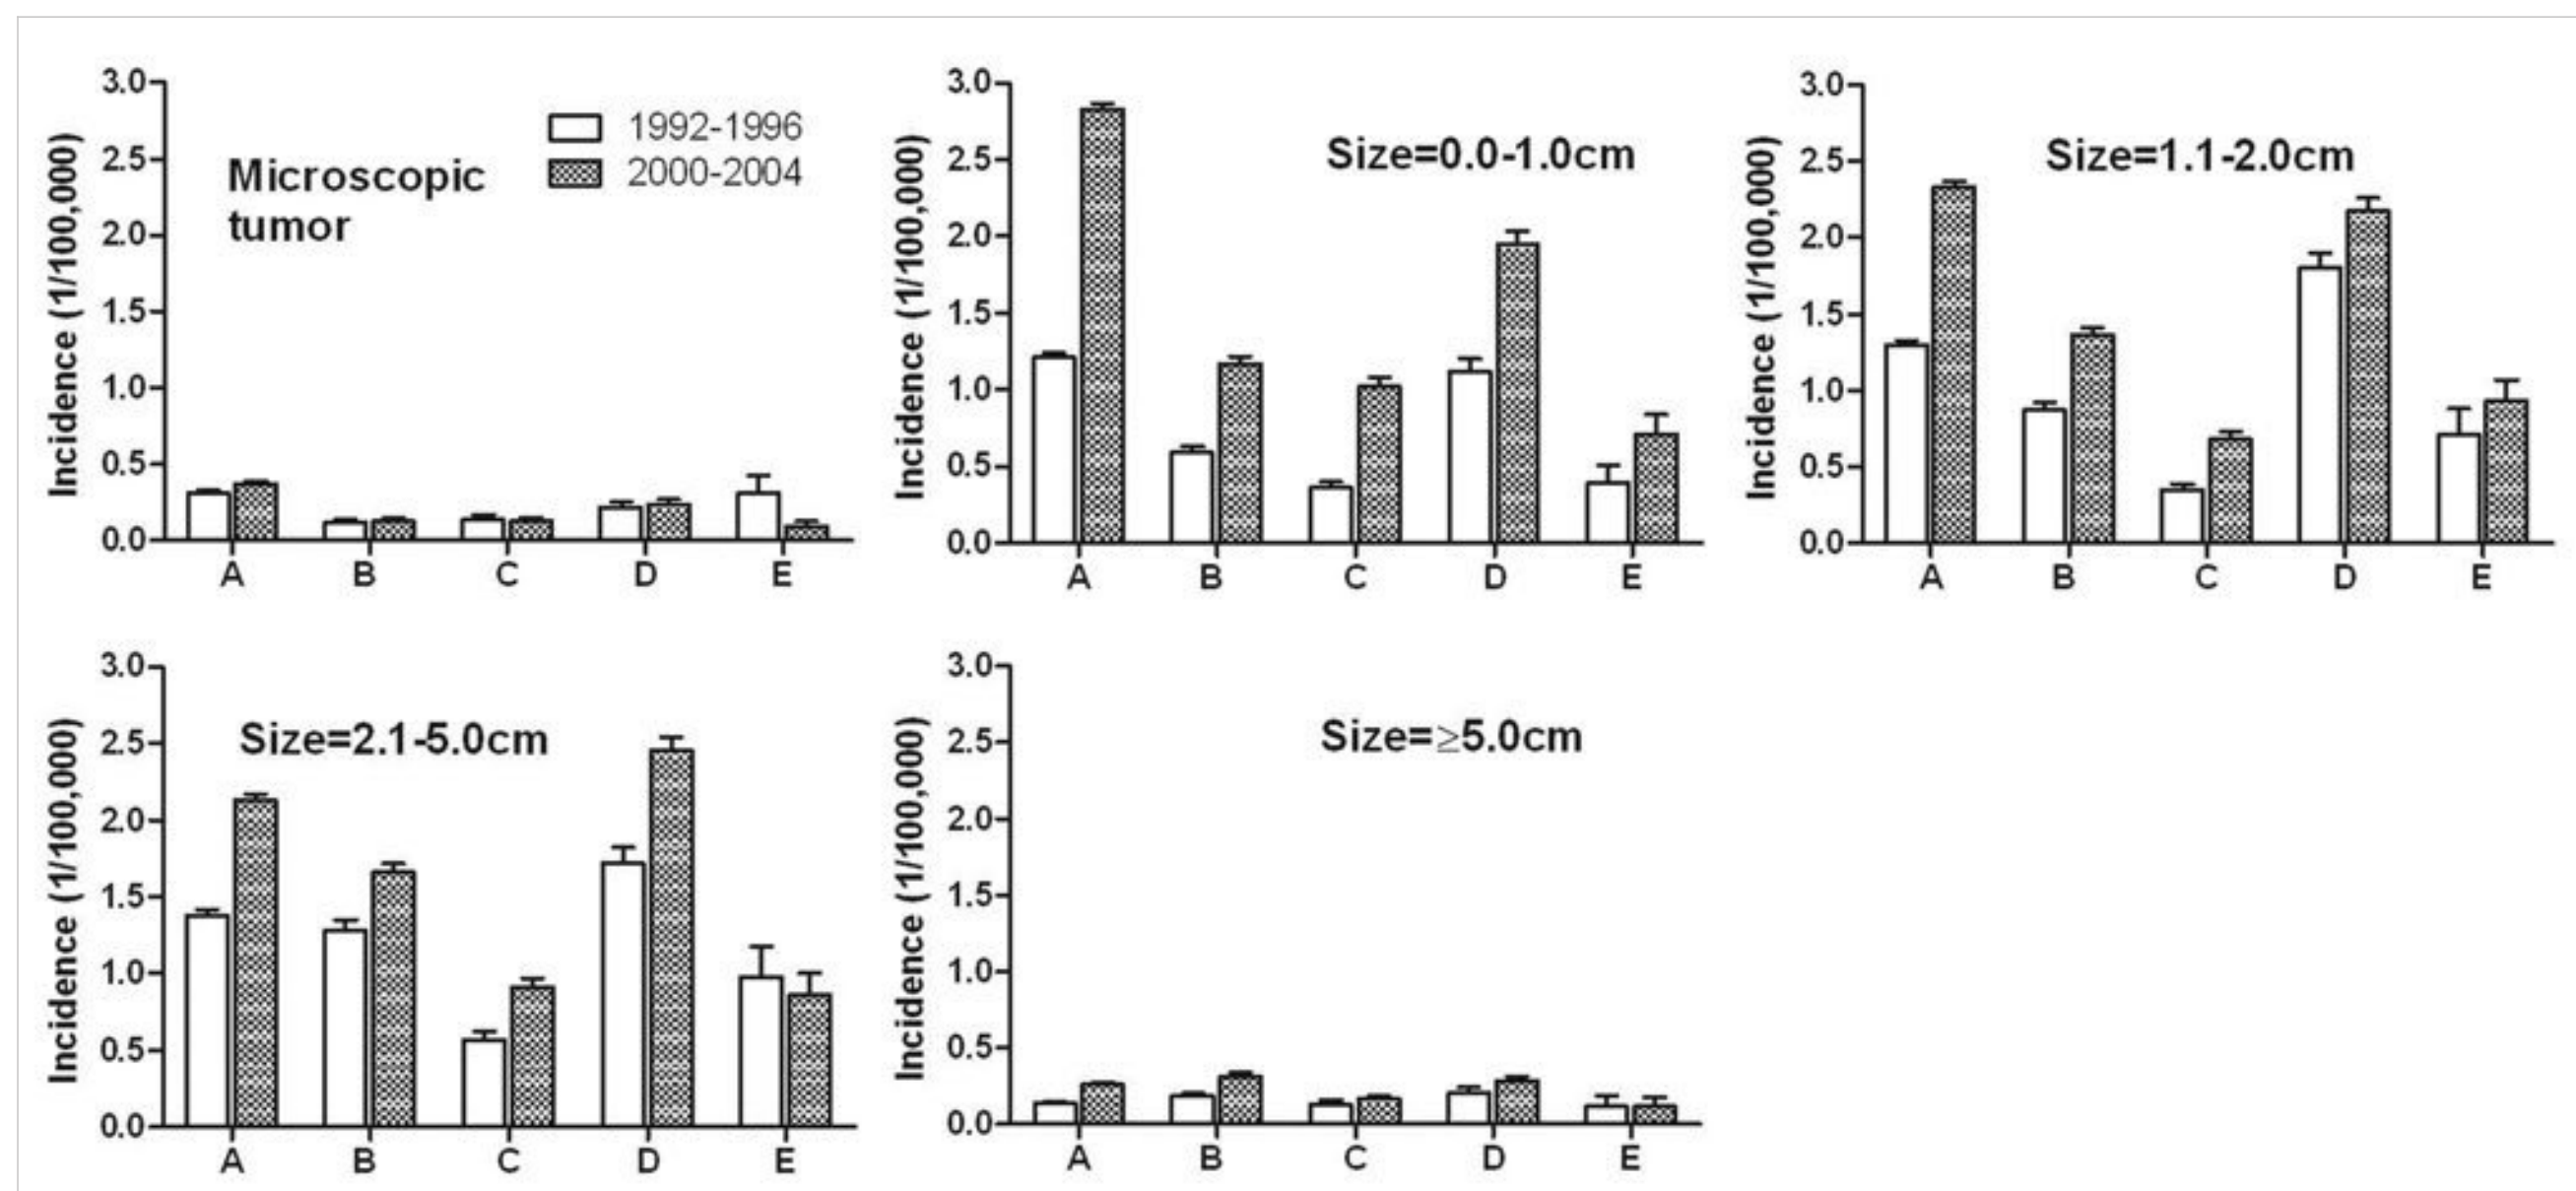

Fig. 20.9 Incidence of papillary thyroid cancer by race and two time periods: 1992–1996 and 2000–2004, Surveillance Epidemiology and End Results (SEER). A, non-Hispanic white; B, Hispanic white; C, black; D, Asian; E, American Indian/Alaska Native.

the increased use of female hormones and increased trend of thyroid cancer.

Iodine, which is essential in the synthesis of thyroid hormones, is an additional suspected risk factor for thyroid cancer. This is based on the positive correlation between either iodine deficiency (epidemic goiter) or iodine excess and the incidence and mortality of thyroid cancer. However, the findings also cannot explain the observed temporal trend of thyroid cancer. In general, iodine exposure is believed to have at most a weak effect on the risk for papillary thyroid cancer.

Cigarette smoking appears to have a protective effect for thyroid cancer; this may be a consequence of lowering the levels of endogenous thyroid hormones: thyroxine (T_4) and thyroid-stimulating hormone (TSH). In addition, smoking may have an anti-estrogenic effect.

Some have postulated that the increased incidence may be caused by enhanced diagnosis due to the increased use of new diagnostic techniques such as computed tomography, ultrasound, and fine needle aspiration biopsy. However, it is unlikely that new technologies would make a disease continuously increase year by year for decades. Second, many thyroid tumors can be detected by patients themselves when the tumor becomes symptomatic, including those tumors about 1 cm in size. Third, even though new diagnostic techniques can help find some subclinical tumors, the increase in cancer cases can be still explained by any of the following three scenarios: (1) Subclinical tumors do not increase, but diagnostic scrutiny increases; (2) subclinical tumors increase, but diagnostic scrutiny does not increase; and (3) both subclinical tumors and diagnostic scrutiny increase. Because one does not know whether there is a substantial increase in the number of nonlethal subclinical tumors hiding in the reservoir of the thyroid glands of the general population and whether the perceived increase via abnormal symptoms leads more patients to seek a clinical diag-

nosis, the possibility of a true increase of thyroid cancer cannot be excluded.

The thyroid is very sensitive to the stimulation of various factors. Because it is located superficially in the body, it may be more easily influenced by environmental carcinogenic factors. Suspected factors for the increased trend include the impact of nuclear fallout, increased use of hormone replacement therapy (HRT), increased use of diagnostic X-rays, and increased use of wireless phones. However, current data supporting the association of these factors with the increase of thyroid cancer are lacking. For instance, the incidence of thyroid cancer had already increased before nuclear fallout, and local atmospheric fallout is less likely to affect populations living in distant locations to the same degree. In addition, several large epidemiologic studies did not find any association between the use of exogenous estrogens and the risk for female thyroid cancer, and the factor of HRT cannot explain the increased trend of thyroid cancer in males. Although the increased uses of diagnostic X-rays and wireless phones are quite suspicious, evidence for both factors is lacking.

20.6 Roundsmanship

- Oral and pharyngeal cancer, considered together, is the sixth most common form of cancer in the world. Of all squamous oral and pharyngeal cancers (excluding salivary gland and nasopharyngeal cancers), oral cavity cancers account for nearly 88% and pharyngeal cancers about 12%. In addition, most squamous oral cavity cancers occur in the tongue (43.1%) and tonsillar fossa (23.4%). Smoking and alcohol consumption are the major risk factors for oral and pharyngeal cancers.
- Nasopharyngeal cancer is extremely common in southern regions of China, Southeast Asia, and North Africa. The incidence among the descendants of Chinese who emigrate to the

United States is significantly lower than that among native Chinese, but the rate remains six times higher than that among Caucasian Americans and African-Americans. Epstein-Barr virus infection is a cause of the undifferentiated form of nasopharyngeal cancer recognized by the International Agency for Research on Cancer (IARC). The intake of salt-preserved fish and other food is another risk factor. Other suspected risk factors for nasopharyngeal cancer include genetic background; occupational exposures to fumes, dusts, or chemicals; low intake of fresh fruits and vegetables; tobacco smoking; use of herbal medicines; and previous chronic respiratory tract diseases.

- More than 90% of cancers of the larynx are squamous cell carcinoma, and the majority originate in the supraglottic and glottic regions. Laryngeal cancer accounts for approximately 1 to 2% of all new cancer diagnoses and is more common in southern and central Europe, southern Brazil, Uruguay, and Argentina. It is seen less frequently in southeastern Asia and central Africa. As with cancers of the mouth, throat, and lung, smoking is the major cause of laryngeal cancer. Cigarette smokers have almost a 10-fold greater risk for laryngeal cancer than nonsmokers, and risk increases with as cigarette smoking increases. The smoking-related risk is also affected by alcohol use; the risk is highest among heavy smokers who are also heavy users of alcohol.
- Salivary gland cancer is a rare malignancy, with an incidence rate of 1.5 per 100,000 in 2006 in the United States. Exposure to radiation is a well-established risk factor for salivary gland cancer.
- Thyroid cancer accounts for 2.6% of all malignancies. Most thyroid cancers are papillary (85%), while the rest are follicular (9.6%), medullary (2.0%), and anaplastic (0.7%). Radiation exposure is a well-known risk factor for thyroid cancer.

21 Head and Neck Histopathology

Codrin E. Iacob

21.1 Introduction

The relation between surgeon and pathologist has been masterfully described by Dr. Lauren V. Ackerman in an early edition of his surgical pathology textbook: “A good surgeon has not only technical dexterity (a fairly common commodity), but also, more importantly, good judgment and personal concern for his patient’s welfare. The surgeon with a prepared mind and a clear concept of the pathology of disease invariably is the one with good judgment. Without this background of knowledge, he will not recognize specific pathologic alterations at surgery nor will he have a clear concept of the limitations of his knowledge, and therefore he will not know when to call the pathologist to help him. Without this basic knowledge, he may improve his technical ability but never his judgment. One might say that with him his ignorance is refined rather than his judgment.”¹

Rather than the memorization of specific microscopic images of certain pathologic processes, practicing head and neck surgeons are better served by an understanding of the general principles that guide tissue analysis in a pathology laboratory: the possibilities and limitations of tissue analysis; the advantages and possibilities of minimally invasive tissue examination techniques (e.g., fine-needle aspiration); the various special studies that can be conducted (e.g., microbiological cultures, frozen sections, molecular analysis of neoplastic tissues, conventional cytogenetics, molecular investigations for the identification of infectious agents, flow cytometry examinations, immunohistochemistry, histochemical techniques, immunofluorescence examinations, electron microscopy); the particulars of tissue submission (fresh, frozen, or fixed tissue); and the specific indications and time course of each test. Facing this vast and dynamic domain of laboratory analyses, head and neck surgeons can best help their patients by keeping in close contact

with their pathologists via preoperative, intraoperative, and postoperative communication in an effort to integrate all clinical, imaging, and laboratory information into a comprehensive diagnostic and treatment plan.

21.2 Fine Needle Aspiration

Simple and cost-effective, fine-needle aspiration (FNA) is used as a tool for the initial screening of lesions of the glands (thyroid, salivary, and lacrimal), lymph nodes, and any neoplasm of the head and neck. There are no contraindications to FNA, although patients with a bleeding diathesis may be more susceptible to the development of a local hematoma. FNA of malignant lesions is frequently performed, and the likelihood of tumor implantation along the needle tract is considered negligible. FNA is done by palpation or under ultrasound or computed tomographic (CT) guidance. Immediate assessment of the adequacy of sampling (generally six clusters of five to 10 diagnostic cells)² is desirable. If the sample is adequate, part of the fresh tissue sample may be used for other ancillary studies (microbiology cultures, flow cytometry, immunohistochemistry), whereas the procedure should be repeated in case of an insufficient first sample. Smears should be prepared immediately after the procedure and rapidly fixed in 95% alcohol to avoid air drying. Tissue remaining in the syringe should never be discarded because it usually is sufficiently cellular for a cell block (solid deposit of spun-down fluid that is fixed in formalin and then processed like a tissue sample) to be formed, allowing serial sectioning of the paraffin block and further histochemical or immunohistochemical staining. Correlation among the clinical, imaging, and morphological findings significantly raises the accuracy of FNA interpretation.

Fig. 21.1 Fine-needle aspiration biopsy of a goiter shows a flat sheet of benign follicular cells with a macrofollicular arrangement and hemosiderin-laden macrophages.

Fig. 21.2 This fine-needle aspiration biopsy is consistent with papillary carcinoma and demonstrates uniform, marked enlargement of nuclei with clear chromatin, irregular nuclear contours, nuclear grooves, and an intranuclear pseudoinclusion. Papillary carcinoma samples are usually hypercellular with solid or papillary architecture, enlarged nuclei with conspicuous nucleoli, and occasional intranuclear pseudoinclusions. Psammoma bodies (concentric calcium depositions), corresponding to sonographically identified microcalcifications, are very characteristic but rarely present in aspirates. Papillary carcinoma accounts for up to 80% of all thyroid malignancies

Fig. 21.3 Fine-needle aspiration biopsy of medullary carcinoma demonstrates round to elongated atypical nuclei with a stippled chromatin pattern (neuroendocrine type), occasional binucleation, and an intranuclear pseudoinclusion. Medullary carcinoma, a neuroendocrine malignancy arising from calcitonin-producing C cells of the thyroid, rarely has background amyloid.

Fig. 21.4 Hashimoto thyroiditis (chronic lymphocytic thyroiditis) can be diagnosed on fine-needle aspiration biopsy when cytologically bland follicular cells with focal pink granular cytoplasm (oncocytic metaplasia) and diffuse lymphocytic infiltration are noted; occasional multinucleated histiocytes are seen.

21.2.1 Fine Needle Aspiration of the Thyroid

FNA of the thyroid allows an assessment of the morphology of follicular cells and their nuclei, tissue architecture, colloid quality, and background (i.e., degenerative, inflammatory, neoplastic, necrotic). Benign follicular processes include follicular adenomas with macrofollicular architecture, as well as hyperplastic and colloid nodules in goiters. These are slowly growing lesions that can be clinically observed. They are all character-

Fig. 21.5 Fine-needle aspiration (FNA) biopsy specimen from a pleomorphic adenoma shows a cluster of cytologically benign myoepithelial cells and ductal epithelial cells in a myxoid background with spindle mesenchymal cells. Pleomorphic adenoma, basal cell adenoma (monomorphic adenoma), and myoepithelioma may appear similar on FNA.

ized by moderately cellular samples with abundant colloid, variously degenerative background, and tissue fragments disposed in flat sheets with predominantly macrofollicular architecture (□ Fig. 21.1). Suspicious follicular processes include follicular adenomas with a microfollicular growth pattern, follicular carcinomas, and follicular variants of papillary carcinomas, all of which yield hypercellular aspirates with microfollicular architecture, little or no colloid, and various tridimensional clusters; often, nuclear atypia is also present. Papillary carcinoma samples are usually hypercellular with solid or papillary architecture, enlarged nuclei with conspicuous nucleoli. Medullary carcinoma, a neuroendocrine malignancy, arises from calcitonin-producing C cells of the thyroid (□ Fig. 21.2 and □ Fig. 21.3).

Fig. 21.6 Warthin tumor on fine-needle aspiration biopsy consists of a flat sheet of benign epithelial cells with oncocytic metaplasia in a lymphocytic background.

Fig. 21.7 Fine-needle aspiration biopsy of a reactive lymph node shows predominantly small lymphocytes (mainly B cells) but also a range of other lymphocytes, including cells of germinal center origin (centroblasts and centrocytes); in addition, tingible body macrophages (containing irregularly staining debris resulting from phagocytosis) and follicular dendritic cells are encountered. Occasional immunoblasts and plasma cells from the paracortex or medulla may also be present.

Fig. 21.8 Granulomatous lymphadenitis on fine-needle aspiration biopsy (FNA) is characterized by a dense cluster of spindle histiocytes with abundant pink cytoplasm and focal lymphocytic infiltration with occasional multinucleated giant cells in a necrotic background. All reveal clusters of histiocytes. A diagnosis of granulomatous lymphadenitis, such as cat-scratch disease or mycobacterial lymphadenitis, by FNA should be followed by microbiology cultures of the aspirate. By contrast, sarcoidosis lacks necrosis and harbors well-formed, compact granulomas.

Fig. 21.9 Hodgkin lymphoma on fine-needle aspiration biopsy is diagnosed by the presence of Reed-Sternberg cells, which have a multilobed nucleus and prominent nucleoli, in a background of reactive lymphocytes. These cells are immunoreactive to CD30 and CD15.

Other malignancies, like poorly differentiated (insular) carcinoma, undifferentiated (anaplastic) carcinoma, lymphomas, and parathyroid tumors, can also be diagnosed on FNA, albeit with greater difficulty. The diagnosis of Hashimoto thyroiditis (chronic lymphocytic thyroiditis) can be made if bland follicular cells with focal pink granular cytoplasm (oncocytic metaplasia) and diffuse lymphocytic infiltration are noted (□ Fig. 21.4).

Subacute granulomatous thyroiditis (de Quervain thyroiditis) on FNA displays frequent multinucleated giant cell histiocytes and benign follicular cells. A correct diagnosis on FNA avoids unnecessary surgery in these patients. Rare pathologic thyroid processes like Riedel thyroiditis and black thyroid (seen with

the chronic use of tetracyclines, especially minocycline) are also rarely diagnosed on FNA.

21.2.2 Fine Needle Aspiration of the Salivary Glands

Chronic sialadenitis, frequently associated with sialolithiasis, usually shows acini and ductal epithelial cells with variable background lymphocytes. Salivary gland cysts (ranula and mucocele) show similar patterns of inflammatory cells in a proteinaceous background with more or less mucin. Pleomorphic adenoma is characterized by a cluster of cytologically benign

Fig. 21.10 Mantle cell lymphoma on fine-needle aspiration biopsy is characterized by monotonous, medium-size lymphocytes with vesicular nuclei and occasional conspicuous basophilic nucleoli.

Fig. 21.11 Diffuse large B-cell lymphoma on fine-needle aspiration biopsy is recognized by large pleomorphic lymphocytes with irregular nuclear contours, hyperchromatism, frequent mitoses, and a "dirty" background comprising lymphoreticular bodies (cellular debris caused by the high turnover of neoplastic cells).

Fig. 21.12 Rhinitis and sinusitis are mostly of viral origin but sometime complicated by superimposed bacterial infections. Chronic sinusitis with inflammatory polyps demonstrates a diffuse chronic inflammatory infiltrate and eosinophilic infiltrate accompanied by lamina propria edema, focal mucus retention cyst formation, thickening of the basement membrane, and an unremarkable surface epithelium.

Fig. 21.13 Sarcoidosis affects the upper respiratory tract, lungs, and mediastinal lymph nodes. Histologically, there are well-formed, non-necrotizing granulomas with compact epithelioid histiocytes and occasional giant cells; note the unremarkable surface epithelium of the respiratory tract with underlying normal mucous glands.

myoepithelial cells and ductal epithelial cells in a myxoid background with spindle mesenchymal cell (□ Fig. 21.5). By contrast, Warthin tumor displays a flat sheet of benign epithelial cells with oncocytic metaplasia in a lymphocytic background (□ Fig. 21.6).

FNA biopsies of adenoid cystic carcinoma are usually hypercellular, with monotonous basaloid cells harboring angulated hyperchromatic nuclei and scant cytoplasm; microcysts and hyaline globules are frequently present. In mucoepidermoid carcinoma, FNA samples show large amount of mucin, intermediate cells (smaller uniform cells), and epithelial cells with epidermoid differentiation (intercellular bridging). Acinic cell carcinoma is composed of acinar cells with granular eosinophilic cytoplasm and various degrees of nuclear atypia.

21.2.3 Fine Needle Aspiration of the Lymph Nodes (□ Fig. 21.7)

Acute lymphadenitis is characterized by excess neutrophils with scattered elements of a reactive lymphoid process; rarely, the etiologic agent (bacteria, fungi, or parasites) can also be identified (□ Fig. 21.8).

Kimura disease is characterized by a dense eosinophilic background with reactive lymphocytic features and prominent vasculature. Kikuchi lymphadenitis is a subacute necrotizing condition with a large number of histiocytes and a complete lack of neutrophils. Sinus histiocytosis with massive lymphadenopathy (Rosai-Dorfman disease) harbors a reactive lymphoid pattern with numerous large, epithelioid background histiocytes that

Fig. 21.14 Fungal disease of the sinonasal tract can be invasive (acute fulminant), noninvasive (mycetoma or “fungus ball”), or most frequently, as seen here, allergic. The specimen shows compact clusters of partially degenerated eosinophils, plasma cells, lymphocytes, cellular debris, and few spindled Charcot-Leyden crystals in a mucinous background. The inset shows fungal hyphae (Gomori methenamine silver stain).

Fig. 21.15 Fungus ball (mycetoma) demonstrates noninvasive, dense, compact groups of fungal hyphae with neighboring unremarkable mucinous gland (periodic acid–Schiff stain). Cultures are recommended for identification of the causative fungus.

Fig. 21.16 Rhinosporidiosis has numerous thick-walled cysts or sporangia with a diameter of 100 to 300 μm containing numerous endospores in the mucosal lamina propria with a chronic inflammatory reaction.

Fig. 21.17 Glial heterotopia, a congenital displacement of neuroglial tissue, can be found in the subcutaneous tissue of the nose (60%), in the upper nasal cavity (30%), and less frequently in the ethmoid sinus, palate, middle ear, tonsil, and pharyngeal area. Note the haphazardly distributed astrocytes with rare nucleolated large neurons in a generally fibrillary background (neuropil) and a fibrous reaction. An encephalocele is a developmental abnormality in which neuroglial tissue is present in the nasal cavity or middle ear and retains a connection to the central nervous system. Glial heterotopia and encephalocele both show a mixture of glial tissue, including astrocytes and neurons admixed with fibrovascular connective tissue, and are often distinguished by imaging studies only.

have specific immunohistochemical features (S-100–positive while CD1a- and Langerin-negative). Characteristically, foci of lymphocytes are engulfed in histiocytic cytoplasm (emperipolesis). Hodgkin lymphoma is diagnosed by the presence of Reed-Sternberg cells in a background of reactive lymphocytes (□ Fig. 21.9).

Small lymphocytic lymphoma displays monotonous small lymphocytes with hyperchromatic nuclei and slight nuclear contour angulation; elements of a reactive lymphoid process are typically absent. Mantle cell lymphoma is characterized by medium-size lymphocytes with vesicular nuclei (□ Fig. 21.10). Follicular lymphoma comprises cleaved cells (small, medium, or large). Aspirates of marginal zone B-cell lymphoma (MALT

lymphoma) contain small and intermediate-size lymphocytes with an increased number of monocytoid cells. Diffuse large B-cell lymphoma is identified by large pleomorphic lymphocytes with irregular nuclear contours, hyperchromatism and frequent mitoses (□ Fig. 21.11).

For peripheral T-cell lymphoma and anaplastic large cell lymphoma, immunologic investigation is required to identify their T-cell origin. Plasmacytoma and multiple myeloma can yield hypercellular aspirates composed of seas of atypical plasma

Fig. 21.18 Sinus histiocytosis with massive lymphadenopathy (Rosai-Dorfman disease) is an idiopathic disorder with significant lymphatic enlargement and secondary involvement of the nasal cavity, orbit, and other head and neck sites. Histologically, there are large infiltrating histiocytes (immunoreactive to CD68 and S-100 while CD1a- and Langerin-negative) with marked accompanying chronic inflammation in the mucosal lamina propria. Characteristically, the histiocytes show foci of emperipolesis (lymphocyte engulfment into histiocytic cytoplasm).

Fig. 21.19 Wegener granulomatosis is a systemic vasculitic process involving the upper and lower respiratory tract and kidneys. Note the vasculitis with complete vessel destruction and fibrinoid necrosis (center of image) surrounded by a granulomatous histiocytic reaction and eosinophilic infiltration.

Fig. 21.20 Inverted papilloma histologically displays multiple islands of multilayered stratified epithelium proliferating inward in the mucosal lamina propria; note the overlying unremarkable, thin, respiratory type of epithelium.

Fig. 21.21 Nasopharyngeal carcinoma, undifferentiated. Syncytial growth of undifferentiated malignant epithelial cells with indistinguishable cell borders and prominent nucleoli is seen. Nasopharyngeal carcinoma is most common in Southeast Asia and has a nearly constant association with Epstein-Barr virus. It affects both genders beyond the age of 30 years with a peak at 40 to 60 years. Its most frequent location is in the lateral wall of the nasopharynx (especially the fossa of Rosenmüller), followed by the superior posterior wall; it commonly presents with cervical metastases.

cells with binucleation, pleomorphic nuclei, and oftentimes visible nucleoli.

21.2.4 Fine Needle Aspiration of Cysts

Regardless of whether the source is a branchial cleft cyst, thyroglossal duct cyst, benign lymphoepithelial cyst of the parotid, or odontogenic cyst, these lesions as a group may show only non-specific benign epithelial cells in an inflammatory background on FNA, and the results of FNA should be always correlated with the clinical findings.

21.3 Tissue Pathology

21.3.1 Nasal Cavity, Paranasal Sinuses, and Nasopharynx

Infectious/Inflammatory/Anatomic/Idiopathic (□ Fig. 21.12 and □ Fig. 21.13)

Rhinitis and sinusitis are mostly of viral origin but sometime complicated by superimposed bacterial infections (□ Fig. 21.12). Sarcoidosis displays e well-formed, nonnecrotizing granulomas

Fig. 21.22 Nonkeratinizing (cylindrical cell) carcinoma has a ribbonlike growth of atypical epithelial cells lacking maturation (no keratin production); note invasion by pushing border next to mucous gland of respiratory epithelium.

Fig. 21.23 Sinonasal undifferentiated carcinoma is a highly aggressive malignancy that typically presents with locally extensive disease and is typically negative for Epstein-Barr virus. It displays undifferentiated epithelial cells in small nests, trabeculae, or sheets, with a high nuclear-to-cytoplasmic ratio, frequent mitoses, and large areas of necrosis. Despite aggressive management, this tumor has poor prognosis.

Fig. 21.24 Intestinal-type adenocarcinoma of sinus displays invading malignant epithelium with back-to-back irregular glands formed of columnar epithelial cells and occasional goblet cells with hyperchromatic nuclei. Inset shows nuclear labeling with CDX-2 immunohistochemical stain. Intestinal-type adenocarcinoma involves the ethmoid sinus (40%), nasal cavity (27%), and maxillary sinus (20%). Some of these tumors histologically simulate normal intestinal structures like Paneth cells, enterochromaffin cells, muscularis mucosae, and villi.

Fig. 21.25 Olfactory neuroblastoma (esthesioneuroblastoma) is a malignant neuroectodermal tumor arising from the olfactory membrane in the superior part of nasal cavity with intracranial and/or paranasal sinus extension. The tumors characteristically grow in the submucosa in circumscribed lobules or nests separated by richly vascularized fibrous stroma. Their cells harbor stippled nuclear chromatin ("salt and pepper") and scant cytoplasm. Some tumors show rosette formation (Homer-Wright pseudorosettes or Flexner-Wintersteiner real rosettes); some contain areas of necrosis. Based on the degree of differentiation, nuclear pleomorphism, necrosis, and mitotic activity, they are graded (patients with Hyam grades I and II tumors have better survival rates than those with Hyam grades III and IV tumors). The tumors are positive for neuroendocrine markers and negative for cytokeratin, and they display specific S-100-positive sustentacular cells at the periphery of tumor lobules.

with compact epithelioid histiocytes and occasional giant cells (□ Fig. 21.13). Tuberculosis of the nasal cavity and paranasal sinuses demonstrates poorly formed caseating granulomas with a prominent fibrous and chronic inflammatory reaction. Acid-fast bacilli can be identified with special stains at the periphery of necrotic areas. Rhinoscleroma is a chronic granulomatous disease endemic in Central and South America.³ It is caused by gram-negative *Klebsiella rhinoscleromatis* and affects primarily the nasal cavity and nasopharynx. The catarrhal phase has non-specific tissue changes consisting of numerous neutrophils and cellular debris. The subsequent granulomatous phase shows pseudoepitheliomatous hyperplasia of the overlying mucosa

with chronic inflammation that includes numerous macrophages with vacuolated cytoplasm (Mikulicz cells) containing *Klebsiella* organisms identifiable by special stains. The final phase is fibrotic with a few similar macrophages.⁴ Fungal disease of the sinonasal tract can be invasive (acute fulminant),

Fig. 21.26 Ectopic pituitary adenoma has polygonal, cytologically bland, small epithelial cells with distinct cell borders and various cytoplasmic tinctorial qualities. Ectopic pituitary adenomas arise in remnants of the embryonic adenohypophysis in the nasopharynx or sphenoid sinus. They contain polygonal epithelial cells that are positive for cytokeratin, neuroendocrine markers, and specific pituitary hormones.

noninvasive (mycetoma or “fungus ball”), or most frequently, allergic (□ Fig. 21.14, □ Fig. 21.15). Rhinosporidiosis has numerous thick-walled cysts (sporangia) containing numerous endospores in the mucosal lamina propria (□ Fig. 21.16).

Glial heterotopia, can be found in the subcutaneous tissue of the nose (60%), in the upper nasal cavity (30%), and less frequently in the ethmoid sinus, palate, middle ear, tonsil, and pharyngeal area (□ Fig. 21.17). Dermoid cyst, a developmental abnormality related to midline closure of the face, can be encountered in the bridge of the nose and rarely in the nasopharynx.⁵ It characteristically shows a cyst lined by epidermis with attached adnexal structures of the skin (hair follicles and/or sebaceous glands). Thornwaldt cyst is a cyst lined with ciliated epithelium located in the midline in the posterosuperior wall of the nasopharynx of young individuals.⁶ Sinus histiocytosis with massive lymphadenopathy (Rosai-Dorfman disease) is an idiopathic disorder with significant lymphatic enlargement and secondary involvement of the nasal cavity, orbit, and other head and neck sites (□ Fig. 21.18). Wegener granulomatosis is a systemic vasculitic process involving the upper and lower respiratory tract and kidneys (□ Fig. 21.19).

Fig. 21.27 Nasopharyngeal angiofibroma has thin-walled, irregular vascular spaces in a collagenized stroma with spindle-shaped and stellate fibroblasts. Nasopharyngeal angiofibroma is seen exclusively in young males, arises in the posterolateral nasal wall or nasopharynx, and demonstrates vascular proliferation in a fibrous stroma. The vessels are thin, slitlike, arborizing channels lined by endothelial cells and a discontinuous muscular layer. The rate of local recurrence can reach 20%

Fig. 21.28 Glomangiopericytoma (sinonasal-type hemangiopericytoma) is a sinonasal tumor demonstrating a proliferating perivascular myxoid phenotype, with ovoid nuclei, focal streaming, and neighboring irregular vascular spaces. It is a subepithelial unencapsulated tumor composed of closely packed cells growing in solid, fascicular, whorled, or storiform architecture with little intervening collagen and frequent branching vessels (staghorn vessels). It is immunoreactive to smooth-muscle actin, vimentin, and factor XIIIa but is specifically negative for CD34, Bcl-2, and CD99 (differing from soft-tissue-type hemangiopericytoma)

Pathologic features of Wegener granulomatosis include (1) mucosal ulceration with granulomas, (2) necrosis, and (3) vasculitis in the context of marked acute and chronic inflammation. Often, only some of these elements are present. Findings of necrosis, vasculitis, and granulomas are diagnostic if the patient has lung and/or kidney involvement. If two of these microscopic features are present, the biopsy is considered diagnostic only if both lungs and kidneys are involved; the diagnosis is considered probable if only one of lungs or kidneys is involved. In the presence of only one of the three microscopic features, the biopsy is considered suggestive if both lungs and kidneys are involved; it is considered suspicious if only one of lungs or kidneys is involved. Finally, if none of these microscopic features is identified, the biopsy is considered nonspecific even with clinical involvement of the lungs and kidneys.⁷ Antineutrophilic cytoplasmic antibodies in a cytoplasmic pattern against proteinase-3 (c-ANCA) are specific for Wegener granulomatosis, but 10 to 50% of patients can be ANCA-negative.

Neoplasms

Schneiderian papillomas are benign epithelial tumors of adults associated in part with human papillomavirus (HPV) infection; they can be multifocal but usually are unilateral; three variants

Fig. 21.29 Craniopharyngioma, usually a sellar tumor arising from Rathke pouch remnants, shows cords of multistratified squamous epithelium with nuclear peripheral palisading; note the compact accumulation of keratin (wet keratin) with focal dystrophic calcification.

Fig. 21.30 Irritation fibroma is a common submucosal response to trauma from teeth or dental prostheses and can be found on buccal, gingival, labial, or lateral tongue mucosa. It presents as a polypoid growth with a densely collagenized core covered by stratified squamous epithelium showing reactive changes. Gingival fibromatosis and drug-induced fibrous hyperplasia have wide areas of gingival tumefaction showing rather avascular fibrous hyperplasia with scant chronic inflammation.

Fig. 21.31 Oral focal mucinosis occurs in young adults and shows irregular submucosal collections of myxomatous loose connective tissue on the hard palate or gingiva. Note the submucosal interstitial accumulation of mucoid material (Alcian blue stain) and the unremarkable surface epithelium. Pyogenic granulomas arise on the gingiva, lip, or tongue and harbor neovascularization with a fibrous reaction and mixed acute and chronic inflammation.

Fig. 21.32 Oral osteoma is a compact lamellar bone proliferation with few haversian canals. Bony exostosis and osteomas are histologically similar dense lamellar bone lesions on the mandible or maxilla that are reactive and neoplastic, respectively. Torus palatinus/mandibularis is a proliferation of mature lamellar bone on the hard palate/mandible.

Fig. 21.33 Lingual osteoma (choristoma) is dense lamellar bone with occasional Haversian canals proliferating in lingual soft tissue; note the unremarkable overlying epithelium. Heterotopic ossification is a reactive bone-producing soft-tissue proliferation of muscle or other connective tissue (in the masseter or other facial muscles). Soft-tissue osseous and cartilaginous choristoma is a histologically normal tissue (bone or cartilage) arising in an unexpected location, such as lingual muscle.

Fig. 21.34 Fordyce granules consist of normal sebaceous units without hair follicle attachment, aberrantly present in oral mucosa, with or without surface communication.

Fig. 21.35 Granular cell tumor is frequently located in the tongue, but also in the larynx and trachea. It consists of poorly circumscribed collections of round to spindle cells with small nuclei and a large amount of granular cytoplasm (numerous cytoplasmic lysosomes) that is positive for periodic acid–Schiff and immunoreactive to S-100.

Fig. 21.36 Odontogenic tumors are derived from the tooth-forming apparatus. Ameloblastoma is a benign epithelial tumor of the enamel organ (producing dental enamel). Histologically, this tumor displays irregular islands of epithelium with characteristic palisading peripheral basal cells that have vacuolated cytoplasm and nuclei placed away from the basement membrane. The central epithelial cells are loosely arranged, with clear cytoplasm, and resemble stellate reticulum.

Fig. 21.38 Amalgam tattoo presents clinically as gray macules and is related to the epithelial implantation of heavy metal from dental filling material. Microscopically, dark brown or black particles are seen in the lamina propria with a haphazard and focally perivascular distribution.

are described.⁸⁹ Exophytic papillomas are found almost exclusively found on the nasal septum; they show papillary fronds with central fibrovascular cores and thick, nonkeratinizing squamous epithelium. Inverted papillomas (□ Fig. 21.20), probably the most frequent variant, affect the lateral nasal wall and sinuses (mostly maxillary) and display endophytic growth of similar nonkeratinizing squamous epithelium. Oncocytic papillomas (cylindrical cell papillomas), the least common type, are located similarly to inverted papillomas and are composed of multilayered columnar epithelial cells with eosinophilic and granular cytoplasm. Recurrence after surgical treatment is common because of incomplete initial excision. The rate of malignant transformation to squamous cell carcinoma reaches 11% in

Fig. 21.37 Squamous dysplasia. (a) Mild. Architectural and cytologic changes are limited to the lower third of the epithelium. (b) Moderate. Changes extend into the middle third of the epithelium. (c) Severe. Architectural and cytologic changes occupy more than two-thirds of the epithelium.

Fig. 21.39 Vocal fold polyps all harbor subepithelial myxoid, edematous, vascular, or hyaline changes in various proportions with a normal or mildly hyperplastic surface epithelium. Contact ulcers are posterior vocal fold lesions composed of granulation tissue with inflammatory infiltrates.

inverted and in oncocytic papillomas, whereas malignant change is unusual in exophytic papillomas.¹⁰

The 2005 World Health Organization (WHO) classification distinguishes several types of nasopharyngeal carcinoma: (1) squamous cell carcinoma (with features of conventional keratinizing squamous cell carcinoma); (2) nonkeratinizing carcinoma with two subtypes, differentiated (retaining intercellular bridges and distinct cell margins) and undifferentiated (with indistinct cellular margins and a syncytial growth pattern); and (3) basaloid squamous cell carcinoma (similar to the tumor encountered in the larynx, □ Fig. 21.21). The mainstay of treatment is radiotherapy.¹¹

Squamous cell carcinoma of the nasal cavity and paranasal sinuses is a rare tumor of adults arising in the maxillary sinus (60%), nasal cavity (12 to 25%), ethmoid sinus (10 to 15%), nasal

Fig. 21.40 Tonsillar cyst is lined by benign squamous epithelium with surrounding lymphoid hyperplasia.

Fig. 21.41 Laryngeal amyloidosis displays dense subepithelial amorphous deposits of congophilic material (orange color on Congo red stain) with apple green birefringence under polarized light examination.

Fig. 21.42 Laryngeal papillomatosis is associated with human papillomavirus infection. The recurrence rate after excision is high, but malignant transformation is uncommon. Histologically, multiple papillary structures with fibrovascular cores and a squamous epithelial covering with occasional koilocytes are seen.

vestibule (4%), and frontal and sphenoid sinuses (each 1%).¹² It rarely metastasizes but is locally destructive. The majority are conventional squamous cell carcinomas with recognizable cellular margins, intercellular bridges, and an intracellular and extracellular accumulation of keratin. They can be well differentiated (forming numerous keratin pearls), poorly differentiated (lacking keratin pools), or moderately differentiated (harboring a few keratin conglomerates). A minority of cases are nonkeratinizing (cylindrical cell, transitional cell, □ Fig. 21.22). Rarely, verrucous carcinomas, papillary squamous cell carcinomas, basaloid squamous cell carcinomas, spindle cell carcinomas, or adenosquamous carcinomas are encountered.

Lymphoepithelial carcinoma is a rare undifferentiated carcinoma with a prominent lymphoplasmacytic infiltrate that affects the nasal cavity and paranasal sinuses. It has a morphology similar to that of its nasopharyngeal counterpart and a strong association with the Epstein-Barr virus (EBV). It responds favorably

to radiotherapy. Sinonasal undifferentiated carcinoma is a highly aggressive malignancy that typically presents with locally extensive disease and is typically negative for Epstein-Barr virus (□ Fig. 21.23). Intestinal-type adenocarcinoma involves the ethmoid sinus (40%), nasal cavity (27%), and maxillary sinus (20%) (□ Fig. 21.24).

Sinonasal non-intestinal-type adenocarcinoma (low-grade adenocarcinoma) displays glandular or papillary architecture with a single layer of cuboidal epithelium and locally invasive features. A variant, nasopharyngeal papillary adenocarcinoma, may have morphologic similarities to papillary carcinoma of the thyroid and must be distinguished from the latter by its negative immunohistochemical reaction to thyroglobulin and thyroid transcription factor-1 (TTF-1). Small-cell neuroendocrine carcinoma is a high-grade malignant tumor arising in the superior and posterior nasal cavity and extending to the paranasal sinuses and/or nasopharynx. It is composed of sheets or nests of small to intermediate-size cells with a high nuclear-to-cytoplasmic ratio, hyperchromatic nuclei with nuclear molding, and numerous mitoses. Immunohistochemically, the cells show reactivity to neuroendocrine markers (synaptophysin, chromogranin, neuron-specific enolase) and cytokeratin. Extremely uncommon, carcinoids of the sinonasal tract have also been described.

Olfactory neuroblastoma (esthesioneuroblastoma) is a malignant neuroectodermal tumor arising from the olfactory membrane in the superior part of nasal cavity with intracranial and/or paranasal sinus extension (□ Fig. 21.25). Ectopic pituitary adenomas may arise in remnants of the embryonic adenohypophysis in the nasopharynx or sphenoid sinus. They contain polygonal epithelial cells that are positive for cytokeratin, neuroendocrine markers, and specific pituitary hormones (□ Fig. 21.26).

Mucosal malignant melanoma is a rare tumor of the sinonasal tract seen in elderly patients. As in any other location, melanoma is considered the great mimicker and presents in a wide variety of cell types (epithelioid, spindle, plasmacytoid, rhabdoid, and/or multinucleated cells). Specific immunohistochemical markers, such as S-100, HMB-45, Melan-A, and microphthalmia

Fig. 21.43 Squamous cell carcinoma of the larynx is characterized by invading irregular islands or malignant squamous epithelium with well-preserved intercellular bridges and intra- and extracellular keratin accumulation.

transcription factor, help distinguish it. Other infrequent neuroectodermal tumors are Ewing sarcomas/primitive neuroectodermal tumors and paragangliomas. Hemangioma is a benign vascular tumor arising in the nasal septum, turbinates, and sinuses and is composed of benign proliferating capillaries with intervening fibrous stroma.

Nasopharyngeal angiofibroma is seen exclusively in young males in the posterolateral nasal wall or nasopharynx. Local recurrence rate is high (□ Fig. 21.27).

Glomangiopericytoma (sinonasal-type hemangiopericytoma) is a subepithelial unencapsulated tumor composed of closely packed cells growing in solid, fascicular, whorled, or storiform architecture with little intervening collagen (□ Fig. 21.28), branching vessels (staghorn vessels).

Solitary fibrous tumor is rare in the sinonasal tract and is composed of spindle fibroblasts with a dense vascular pattern. Cells are positive for CD34 and Bcl-2 and generally lack smooth-muscle actin reactivity.¹³ Germ cell tumors of the sinonasal tract are rare. Mature teratoma shows a variable admixture of mature skin, skin appendages, neuroglial tissue, smooth muscle, bone, salivary glands, respiratory epithelium, and gastrointestinal epithelium. Ectodermal, mesodermal, and endodermal elements can be encountered in any distribution. Immature teratoma displays the same elements in their primitive, immature

variants, whereas teratoma with malignant transformation contains benign tissues of all three germinal layers and in addition a somatic malignancy, usually a carcinoma. If malignant epithelial and mesenchymal tissues are admixed, the tumor is called a teratocarcinoma. Craniopharyngioma, is usually a sellar tumor which arises from Rathke pouch remnants (□ Fig. 21.29).

21.3.2 Oral Cavity and Oropharynx

Infectious/Inflammatory/Anatomic/Idiopathic (□ Fig. 21.30, □ Fig. 21.31, □ Fig. 21.32)

Peripheral giant cell granulomas are pyogenic granulomas with a prominent osteoclast-type giant cell component arising exclusively from the periodontal ligament enclosing the root of a tooth. The same periodontal ligament can produce a peripheral ossifying fibroma, which is a fibrous proliferation with scattered islands of woven or lamellar bone, usually with abundant osteoblastic rimming. Lingual osteoma (choristoma) displays dense lamellar bone with occasional haversian canals proliferating in lingual soft tissue, (□ Fig. 21.33). Fordyce granules consist of normal sebaceous units without hair follicle attachment (□ Fig. 21.34)

The juxtaoral organ of Chievitz is composed of nests of epithelial cells with an organoid pattern and a squamoid appearance

Fig. 21.44 Verrucous carcinoma is a very well-differentiated variant of squamous cell carcinoma. Histologically evident is the proliferation of atypical squamous cells with prominent hyperkeratosis without granular layer formation, as well as cellular dysplasia and rare mitoses; note the pushing base of the carcinoma without basement membrane violation.

devoid of keratinization arising in the buccotemporal fascia on the medial aspect of the mandible. Lingual thyroid is a vestigial rest of thyroid tissue at the upper end of the thyroglossal duct. Congenital epulis is a submucosal collection of cytologically bland histiocyte-like cells with granular cytoplasm that are S-100–negative. Median rhomboid glossitis is an area of pseudoepitheliomatous hyperplasia on the dorsal tongue accompanied by chronic inflammation and fungal organisms. Palatal and gingival cysts of the newborn have the appearance of epidermoid cysts arising from epithelial remnants of deeply budding dental lamina during tooth development. Nasolabial cyst (nasolacrimal cyst) arises from remnants of the embryonic nasolacrimal duct at the base of the nostrils just above the periosteum and is lined by respiratory-type, stratified columnar or pseudostratified columnar epithelium. Nasopalatine duct cyst arises from vestiges of the embryonal nasopalatine duct connecting the oral and nasal cavities. It arises on the anterior midline hard palate and is lined by squamous or cuboidal epithelium.

Neoplasms

Granular cell tumor is frequently located in the tongue, but can also be found in the larynx and trachea (□ Fig. 21.35). Lipoma, a

mature adipose tissue tumor, can uncommonly be present in oral mucosa. Traumatic neuroma consists of moderately loose fibrovascular stroma admixed with irregular nerve fibers; it is usually related to tooth extractions or other forms of trauma. Mucosal neuroma is associated with multiple endocrine neoplasia syndrome and presents as multiple submucosal nodules composed of aggregates of nerves, often with thickened perineurium in a plexiform pattern. Palisaded encapsulated neuroma (solitary circumscribed neuroma) is a solitary, well-delineated nodule of proliferating Schwann cells (positive for S-100) with focal palisading nuclei and rare entrapped axons. Neurofibroma consists of a cellular proliferation of spindle Schwann cells with wavy nuclei and a variable amount of fibrous stroma with sparsely distributed axons.

Odontogenic tumors are derived from the tooth-forming apparatus. Ameloblastoma is a benign epithelial tumor of the enamel organ (□ Fig. 21.36).

Ameloblastic fibroma is a benign tumor harboring ameloblastic epithelial islands in a myxoid cell-rich stroma with stellate fibroblasts resembling embryonic tooth pulp. Malignant counterparts of these tumors are ameloblastic carcinoma, in which ameloblastic epithelium shows cellular atypia, mitoses, necrosis, and invasive features, and ameloblastic fibrosarcoma, in

Fig. 21.45 Basaloid squamous cell carcinoma has a predilection for the hypopharynx, piriform sinus, and supraglottis and has a more aggressive clinical course. It characteristically has nests of basaloid tumor cells with large, hyperchromatic nuclei and scant cytoplasm (basaloid features), often accompanied by central necrosis (comedo-type necrosis) alternating with areas of regular squamous cell carcinoma.

which a benign ameloblastic epithelium is admixed with a malignant ectomesenchymal component. Keratogenic odontogenic tumor (odontogenic keratocyst), mostly seen in the maxilla, is a cystic mass lined by parakeratinizing squamous epithelium with basal cells oriented away from the basement membrane and corrugated internal cystic surface.¹⁴

Epithelial Lesions

Squamous papillomas are benign epithelial tumors of the oral mucosa related to HPV infection. They have papillary architecture with central fibrovascular cores and a thickened squamous epithelial covering with some degree of keratinization. *Verruca plana*, also related to HPV infection, displays markedly thickened epithelium with hypergranulosis and hyperkeratosis including virally altered epithelial cells (koilocytes) in the upper layers; they are exophytic, showing epithelial folds, but no obvious papillary architecture is present. *Condyloma acuminatum* is caused by epithelial infection with HPV and displays short, blunt, rounded fronds of hyperplastic epithelium without keratinization and marked koilocytic changes. Focal epithelial hyperplasia is formed by multiple oral papillomas of buccal mucosa and tongue induced by HPV infection. *Keratoacanthoma* is

a keratinizing lesion of the mucosa of the skin and lip with rapid growth and clinically impressive craterlike center filled by hyperkeratosis. Histologically, there is a certain degree of squamous atypia without significant infiltrative features. *Hairy leukoplakia* is a well-demarcated verruciform hyperkeratotic plaque of the lateral tongue in HIV-positive patients related to EBV infection. Morphologically, the lesion displays superficial hyperkeratosis with parakeratosis and large collections of koilocytic intermediate cells with intracellular edema and basophilic viral nuclear inclusions. *Frictional keratosis* presents as a white hyperkeratotic line along the occlusal plane on buccal mucosa; it displays surface keratinization and mild inflammation. *Leukoedema* presents as bilateral semitranslucent gray or white plaques on buccal mucosa that typically have reticular streaks of thickened keratin with intracellular edema on microscopic examination. *White sponge nevus* shows white keratotic macules and plaques on buccal or labial mucosa with extensive and prominent intracellular edema in spinous layers on histologic evaluation. *Actinic cheilitis* is related to excessive sun exposure and consists of atrophic squamous epithelium with underlying solar elastotic degeneration of the lamina propria and chronic inflammation.

Fig. 21.46 Adenosquamous carcinoma displays invading islands of malignant epithelium with intercellular bridges (squamous cells) alternating with areas of columnar epithelial lining and mucin production (glandular differentiation), shown best with mucicarmine stain.

Squamous cell carcinoma is the most frequent malignancy of the upper aerodigestive tract. It affects adults of both genders with variable incidence rates worldwide according to local exposure to carcinogens (tobacco, alcohol, industrial pollution, and an unresolved role of HPV infection).

Oral cavity and laryngeal epithelial precursor lesions are clinically recognized as leukoplakia (well-delineated white elevated patch), erythroplakia (ill-delineated soft red patch), or a combination of the two, forming speckled leukoplakia. Although the histologic examination of leukoplakias frequently finds just hyperplasia of squamous epithelium, occasionally various degrees of dysplasia can be encountered. Erythroplakia most of the time harbors dysplastic changes and has a higher percentage of malignant transformation. Squamous cell dysplasia implies architectural changes (irregular stratification, loss of cellular polarity, increased mitoses, and dyskeratosis) and cytologic criteria (anisocytosis, nuclear pleomorphism, anisocytosis, cellular pleomorphism, nuclear hyperchromasia, and increased nuclear-to-cytoplasmic ratio). The 2005 WHO classification of precursor lesions distinguishes several categories:

- Squamous hyperplasia: increased number of spinous cells (acanthosis) and/or basal and parabasal cells (basal cell hyperplasia) with regular stratification and maturation
- Squamous dysplasia, mild

- Squamous dysplasia, moderate
- Squamous dysplasia, severe
- Squamous cell carcinoma in situ: full-thickness epithelial involvement with abnormal superficial mitoses and not yet recognizable invasion

Simple hyperplasia has a likelihood of undergoing malignant progression of less than 1% whereas severe dysplasia progresses to malignancy in 15 to 25% of cases¹⁵ (□ Fig. 21.37).

Inflammatory Epithelial Lesions

Lichen planus is an autoimmune mucositis with a subepithelial band of marked chronic inflammation and alterations of basal epithelial layers, including ballooning degeneration of epithelial cells and apoptotic single cells forming Civatte bodies. On immunofluorescence, there is a linear deposition of fibrinogen along the basement membrane.¹⁶ Inflammatory mucosal ulcerations show granulation tissue with prominent inflammation surrounded by erythematous hyperplastic epithelium. Dysplasia or squamous cell carcinoma needs to be ruled out by histologic investigation. Pemphigus vulgaris is a bullous autoimmune inflammatory condition of the oral mucosa with a characteristic fishnet pattern of intercellular immunoglobulin deposits and

Fig. 21.47 Chronic sclerosing sialadenitis shows atrophic salivary gland parenchyma with edema, fibrosis, and chronic inflammation. Sialadenitis can be acute suppurative or, more frequently, chronic. The latter is associated with sialolithiasis and displays morphologically various degrees of glandular atrophy, fibrosis, and chronic inflammation with occasional intraductal mineralized concretions (lithiasis).

immune complement deposits on immunofluorescent examination. Intraepithelial blistering is seen with sparing of the basal epithelial layer (suprabasal bullae).¹⁷ Mucous membrane pemphigoid, also an autoimmune mucositis, displays subepithelial blister formation and is characterized by immunoglobulin and complement deposits along the basement membrane. Amalgam tattoo presents clinically as gray macules and is related to the epithelial implantation of heavy metal from dental filling (□ Fig. 21.38).

Other pigmented epithelial lesions include oral melanotic macule, the mucosal equivalent of the freckle on the skin. It displays otherwise normal epithelium with a basal intraepithelial deposition of melanin pigment. Mucosal melanocytic nevus is likewise the mucosal counterpart of the skin nevus and consists of well-delineated subepithelial clusters of cytologically benign melanocytes. Oral melanocytic neuroectodermal tumor of infancy (retinal anlage tumor) is a congenital tumor derived from neural crest cells and is located in the oral cavity, other craniofacial sites, brain, skin, mediastinum, epididymis, uterus, and so on. Microscopically, it displays small neuroblastic cells and larger melanin-containing epithelial cells in a vascularized, dense fibrous stroma. Immunohistochemically, the tumor displays a polyphenotypic expression of neural, melanocytic, and epithe-

lial markers.¹⁸ Mucosal melanoma follows the same pattern described in the sinonasal mucosa.

21.3.3 Hypopharynx, Larynx, and Trachea

Infectious/Inflammatory/Anatomic/Idiopathic

Laryngeal tuberculosis, sarcoidosis, rhinosporidiosis, and rhinoscleroma have morphological changes identical to the ones described in the sinonasal location. Specific laryngeal infectious agents include *Treponema pallidum* (syphilis), *Actinomyces*, *Nocardia*, *Candida albicans*, *Coccidioides immitis*, *Paracoccidioides*, *Blastomyces*, *Cryptococcus*, *Histoplasma capsulatum*, cytomegalovirus, *Trichinella spiralis*, and others. Isolation of the etiologic agent requires a combined microbiological and histomorphologic effort.

Vocal fold polyps are characterized by subepithelial myxoid, edematous, vascular, or hyaline changes in various proportions with a normal or mildly hyperplastic surface epithelium (□ Fig. 21.39). Contact ulcers are posterior vocal fold lesions composed of granulation tissue with inflammatory infiltrates.

Fig. 21.48 Acquired immunodeficiency syndrome–related parotid gland cysts show multiple irregular lymphoepithelial islands with occasional lymphoepithelial cysts in a background of marked chronic inflammatory infiltrate.

Laryngeal cysts are of four categories: (1) laryngoceles, which are pulsion diverticula of the saccule (harbor full-thickness laryngeal wall structures, including respiratory-type epithelial lining); (2) saccular cysts, resulting from obstruction of the saccule (harbor mucus retention cysts that push on the thyrohyoid membrane and are analogous to the ones in the sinonasal tract); (3) ductal cysts (squamous, oncocytic, or tonsillar cysts), the most commonly encountered cysts, all mucin-filled and arising from minor salivary duct obstruction (squamous and oncocytic cysts are located in the glottis, ventricles, aryepiglottic folds, and epiglottis, whereas tonsillar cysts are located in the vallecula and show surrounding lymphoid hyperplasia, □ Fig. 21.40); (4) miscellaneous epithelial cysts (epidermal, dermoid, and branchial cleft cysts).¹⁹

Laryngeal amyloidosis displays dense subepithelial amorphous deposits of orange color on Congo red stain with apple green birefringence under polarized light examination (□ Fig. 21.41). Wegener granulomatosis, pemphigus vulgaris, and mucous pemphigoid are similar to the lesions of the oral cavity and sinonasal tract previously described.

Neoplasms

Laryngeal papillomatosis is associated with human papillomavirus infection, and demonstrates a high recurrence rate but low potential for malignant degeneration (□ Fig. 21.42). Squamous cell carcinomas of the larynx and hypopharynx account for 34% of upper aerodigestive tract carcinomas and are found (in decreasing frequency) in the supraglottis, glottis, hypopharynx, subglottis, and rarely the trachea.²⁰ Morphologically, these lesions range from well-differentiated tumors to poorly differentiated, undifferentiated, and spindle cell carcinomas, all with significant invasive features, especially perineurally, and lymphatic metastatic potential. The best outcome is noted with glottic tumors and the worst outcome with tumors in a hypopharyngeal, subglottic, or tracheal location. Several morphological features are of prognostic significance: involvement of the resection margins, lymphatic invasion (especially with extracapsular extension), perineural invasion, and invading front of the tumor (expansive pushing borders have a better prognosis, whereas infiltrative borders with isolated tumor islands at a distance from the main mass have a less favorable prognosis)²¹ (□ Fig. 21.43, □ Fig. 21.44, □ Fig. 21.45).

Fig. 21.49 Pleomorphic adenoma displays a proliferation of cytologically bland myoepithelial cells forming irregular nests in a myxoid mesenchymal background. The former component displays cuboidal, basaloid, squamous, spindle, plasmacytoid, or clear cells. The mesenchymal component shows myxoid changes, fibrosis, and rarely cartilaginous or osseous metaplasia. Recurrence after surgical treatment is encountered in 3.4% of cases after 5 years and in 6.8% after 10 years. Many recurrent pleomorphic adenomas are multifocal. Pleomorphic adenomas account for 60% of salivary gland neoplasms. Of these, 80% arise in the parotid gland, 10% in the submandibular gland, and 10% in minor salivary glands.

Papillary squamous cell carcinoma is frequently located in the supraglottis and has a better prognosis. It implies papillary architecture with a malignant squamous epithelial covering. Spindle cell carcinoma is most frequently present in the glottis and has a prognosis similar to that of regular squamous cell carcinoma. It is a biphasic tumor in which areas of regular squamous cell carcinoma alternate with sarcomatoid-appearing areas of spindle epithelial cells. Acantholytic squamous cell carcinoma, located in the hypopharynx and supraglottis, shows acantholytic detachments between squamous cells, creating the appearance of glandular differentiation. Adenosquamous carcinoma displays invading islands of malignant epithelium with intercellular bridges alternating with areas of columnar epithelial lining and mucin production (□ Fig. 21.46).

Rare lymphoepithelial carcinomas are identical to the similar entity of the sinonasal tract. Neuroendocrine tumors of the larynx are similar to the carcinoid, atypical carcinoid, and small cell carcinomas described in the sinonasal tract. Laryngeal paraganglioma is morphologically identical to the one described in the middle ear. Malignant melanomas of larynx follow the same pattern as their sinonasal counterparts.

21.3.4 Salivary Glands

Infectious/Inflammatory/Anatomic/Idiopathic

Salivary gland heterotopia is commonly encountered as an incidental finding and consists of morphologically unremarkable serous and mucous acini with occasional ducts. The most frequent location is intranodal (in cervical lymph nodes); an extranodal location is described as high heterotopia (mandible, ear, palatine tonsil, mylohyoid muscle, pituitary gland, and cerebellopontine angle) or low heterotopia (associated with the branchial pouches of the lower neck and thyroid gland).²² Polycystic (dysgenetic) disease is a rare developmental abnormality characterized by varying degrees of honeycombed cystic changes. Chronic sclerosing sialadenitis shows atrophic salivary gland parenchyma with edema, fibrosis, and chronic inflammation (□ Fig. 21.47).

The microscopic hallmark of Sjögren syndrome is a lymphocytic sialadenitis present in minor salivary glands (frequently biopsied in the lip), in major salivary glands, and in lacrimal glands. Morphologically, there is chronic inflammation with lymphoid hyperplasia and focal lymphoepithelial islands

Fig. 21.50 Warthin tumor (papillary cystadenoma lymphomatosum) accounts for 3.5% of all epithelial tumors of the salivary glands, is almost exclusively found in the parotid gland, and can be multifocal or bilateral. Morphologically, it displays a characteristic cystic and papillary configuration in which epithelial cells with oncocytic metaplasia (high number of intracytoplasmic mitochondria, seen as large amount of pink, granular cytoplasm) arranged in double layers and forming papillary structures alternate with areas of lymphoid hyperplasia. A low recurrence rate is seen after resection.

Fig. 21.51 Acinic cell carcinomas are malignant tumors, most commonly seen in the parotid gland, characterized by at least partial acinic differentiation (cytoplasmic zymogen secretory granules), as well as intercalated smaller cells and vacuolated and clear cells.

(compact clusters of epithelial and myoepithelial cells surrounded by inflammation). The risk for developing non-Hodgkin lymphomas is significantly higher in individuals with Sjögren syndrome than in age-matched control subjects. Mucocele and ranula show degenerative mucin-filled spaces without epithelial lining (mucus extravasation). Mucus retention cyst is an intraductal accumulation of mucin and is lined by stratified epithelium. Lymphoepithelial cyst is usually seen in major salivary glands and consists of a stratified squamous epithelial lining with surrounding lymphoid hyperplasia (□ Fig. 21.48).

Necrotizing sialometaplasia is a reactive process of minor salivary glands in the palate or other oropharyngeal sites in which squamous metaplasia reaches into glandular acini, mimicking infiltrative islands of a squamous malignancy. Lack of mitotic activity and nuclear atypia help distinguish it from a squamous cell carcinoma.

Neoplasms

Pleomorphic adenomas account for 60% of salivary gland neoplasms. Of these, 80% arise in the parotid gland (□ Fig. 21.49). Myoepitheliomas account for 1.5% of all tumors in salivary

Fig. 21.52 Mucoepidermoid carcinoma is the most common malignant salivary gland tumor. It has malignant epithelium in which mucinous cells alternate with areas of epidermoid differentiation (large cells with visible intercellular bridges and no complete maturation to keratin production). A three-tiered grading system has good correlation with clinical outcome.

Fig. 21.53 Adenoid cystic carcinoma accounts for approximately 10% of salivary gland malignancies. Histologically, a cribriform pattern with mucopolysaccharide-filled spaces is seen; note the monotony of the proliferating myoepithelial cells with angulated hyperchromatic nuclei and scant clear cytoplasm. Histologic grading correlates well with clinical outcome

glands and are composed of proliferating myoepithelial cells with spindle, epithelioid, or plasmacytoid features. They are less prone to recur than pleomorphic adenomas. Basal cell adenomas are rare benign tumors of proliferating epithelial and myoepithelial cells with a basaloid appearance and trabecular growth pattern. They are like pleomorphic adenomas in which there is no mesenchymal part. Recurrence after complete excision is rare.

Warthin tumor (papillary cystadenoma lymphomatosum) accounts for 3.5% of all epithelial tumors of the salivary glands, is almost exclusively found in the parotid gland, and can be multifocal or bilateral (□ Fig. 21.50).

Oncocytic adenoma (oncocytoma) is a rare salivary gland benign tumor composed of oncocytic epithelial cells that grow in a nesting and trabecular pattern. Canalicular adenoma frequently affects the upper lip and is composed of rows of columnar epithelial cells forming canaliculi. Sebaceous adenomas are benign salivary gland neoplasms with proliferating sebaceous units; some show intervening lymphoid tissue (sebaceous lymphadenomas). Ductal papillomas and cystadenomas are also rarely seen.

Acinic cell carcinomas are characterized by acinic differentiation, as well as intercalated smaller cells and vacuolated and

Fig. 21.54 Basal cell adenocarcinoma is the malignant counterpart of basal cell adenoma. These lesions have proliferating myoepithelial cells with frequent areas of ductal differentiation (epithelial and myoepithelial bilayering of lumina).

clear cells (□ Fig. 21.51). Mucoepidermoid carcinoma has malignant epithelium in which mucinous cells alternate with areas of epidermoid differentiation (□ Fig. 21.52). Adenoid cystic carcinoma accounts for approximately 10% of salivary gland malignancies and displays a cribriform pattern with mucopolysaccharide-filled spaces (□ Fig. 21.53).

Polymorphous low-grade adenocarcinoma arises mostly in the palate and is characterized by cytologic uniformity, histologic diversity, and an infiltrative growth pattern. Epithelial–myoepithelial carcinoma, a rare malignant tumor, shows bilayered ductlike structures with an inner layer of cuboidal epithelial cells and an outer layer of myoepithelial cells with clear cytoplasm. A rare malignant tumor is clear cell carcinoma (hyalinizing clear cell carcinoma) arising mostly in intraoral minor salivary glands. It shows a monomorphic clear cell population with a high glycogen content. Basal cell adenocarcinoma has proliferating myoepithelial cells with frequent areas of ductal differentiation (□ Fig. 21.54). Carcinoma ex pleomorphic adenoma is a mixed tumor in which the epithelial component has undergone malignant transformation (□ Fig. 21.55).

Sebaceous carcinoma and sebaceous lymphadenocarcinoma are rare malignant tumors with sebaceous differentiation. Oth-

er malignant tumors include cystadenocarcinoma, mucinous adenocarcinoma, oncocytic carcinoma, salivary duct carcinoma, adenocarcinoma not otherwise specified, carcinosarcoma, squamous cell carcinoma, small cell carcinoma, large cell carcinoma, and lymphoepithelial carcinoma.

21.3.5 Thyroid and Parathyroid Glands Infectious/Inflammatory/Anatomic/Idiopathic

Thyroglossal duct cysts are the most common cystic developmental abnormalities of the neck, arising along a tract in the anterior midline between the tongue and thyroid gland (□ Fig. 21.56). Subacute granulomatous thyroiditis (de Quervain thyroiditis) presents with neck pain following an upper respiratory tract viral episode. Microscopically, it presents as focal disruption of the thyroid follicles triggering a reactive chronic inflammation with granulomas and fibrosis. Palpation thyroiditis shows foci of histiocytic accumulation in disrupted thyroid follicles and is the result of frequent palpation of the thyroid gland. Hashimoto thyroiditis is characterized by lymphoplasmacytic infiltration of the thyroid parenchyma with focal lymphoid follicle

Fig. 21.55 Carcinoma ex pleomorphic adenoma is a mixed tumor in which the epithelial component undergoes malignant transformation, which can be only focally present and can be confined within the capsule of the benign tumor in which it arises. Note the large undifferentiated malignant epithelial cells (left side of image) arising in and invading the pleomorphic adenoma (right side of image).

formation. There is also reactive oncocytic changes in the thyroid epithelium Hashimoto thyroiditis is an autoimmune disorder affecting individuals with a genetic predisposition; it is associated with a variety of other autoimmune diseases (□ Fig. 21.57).

In Riedel thyroiditis, hyalinized fibrosis replaces the normal parenchyma and extends into adjacent soft tissues of the neck. The mild inflammatory component is usually mixed and is also associated with occasional foci of venulitis. Amyloidosis (amyloid goiter) is a rare condition characterized by the massive interstitial deposition of amorphous congophilic deposits (apple green birefringent under polarized light). Hyperplasia of the thyroid gland may be associated with hyperfunction (Graves disease), hypofunction (endemic goiter, dysmorphic goiter), or normal function (multinodular goiter).²³ Graves disease shows diffuse and symmetric enlargement of the thyroid gland, which is beefy red on cut surfaces. Microscopically, there is preservation of the normal lobular architecture; follicles appear small and irregular, contain pale-staining colloid, and display numerous papillary epithelial infoldings with basally placed nuclei.

Dysmorphic goiter is usually present early in childhood and morphologically shows diffuse or nodular hyperplasia with

irregular epithelial islands and foci of nuclear pleomorphism. Multinodular goiter (nontoxic, simple, adenomatoid, or colloid goiter) harbors asymmetric enlargement with incompletely encapsulated hyperplastic nodules undergoing partial degeneration with hemorrhage, calcification, fibrosis, cyst formation, and rarely ossification. There is variation in follicular size, areas of papillary hyperplasia, and occasional oncocytic changes (□ Fig. 21.58).

Neoplasms

Follicular adenomas are benign thyroid tumor that are completely encapsulated by a thin rim of fibrous tissue and retain follicular architecture (□ Fig. 21.59). Hyalinizing trabecular adenoma is another benign encapsulated tumor with a trabecular growth pattern and hyalinization. The proliferating follicular cells display nuclear enlargement and grooves; they are frequently misinterpreted as atypia or even papillary carcinoma on FNA biopsies.

Papillary carcinoma is the most common thyroid malignant tumor, typically presenting in adults; it is more common in

Fig. 21.56 Thyroglossal duct cysts, the most common cystic developmental abnormalities of the neck, arise along the anterior midline (mostly below and some above the hyoid bone, and very few in the tongue). Histologically, the cysts are lined by ciliated respiratory-type epithelium, squamous epithelium, or both and occasionally harbor attached vestiges of thyroid parenchyma.

women. Papillary carcinomas are usually diffusely invasive tumor and have high propensity for lymphatic invasion (□ Fig. 21.60). Follicular carcinoma is usually a solitary large mass with a thick fibrous capsule and normal follicular or microfollicular architecture; follicular cells can be seen penetrating the thick fibrous capsule of the tumor) (□ Fig. 21.61).

Poorly differentiated carcinoma (insular carcinoma) displays a solid growth pattern with poorly differentiated round epithelial cells, is highly invasive, and has metastatic potential. Undifferentiated (anaplastic) carcinoma is a rare and aggressive tumor harboring undifferentiated epithelial cells with areas of spindle cells, pleomorphic giant cells, or epithelioid cells. Distant metastases are usually present by the time of presentation. Medullary thyroid carcinoma arises from C cells (calcitonin-secreting cells) of the thyroid and is a neuroendocrine tumor; tumor cells are immunoreactive to calcitonin (□ Fig. 21.62).

Spindle cell tumor with thymuslike differentiation (SETTLE) and carcinoma showing thymuslike differentiation (CASTLE) are rare malignant tumors in which there is co-expression of cytokeratin and CD5 (T cell marker). Other malignant thyroid

tumors are squamous cell carcinoma, mucoepidermoid carcinoma, and mucinous carcinoma.

Parathyroid adenoma usually involves a single parathyroid gland, and are encapsulated neoplasms composed of solidly proliferating chief cells or oncocytes with clear cytoplasm forming solid and focally follicular arrangements without intervening adipocytes (□ Fig. 21.63). Rare lesions are parathyroid cysts that are lined by a single layer of compressed cuboidal epithelial cells and show groups of chief or oxyphilic cells in neighboring fibrous tissue. Parathyroid carcinoma is diagnosed based on infiltrative features including desmoplastic reaction to invasion; cytologically, it displays cells identical to those of parathyroid adenoma. Primary chief cell hyperplasia is characterized by hyperplasia of all four parathyroid glands accompanied by hyperparathyroidism. Approximately 75% of cases are sporadic, whereas the rest are part of multiple endocrine neoplasia syndromes. Morphologically, there is nodular growth of chief cells with a normal number of oncocytes and transitional oncocytic cells and preserved intraglandular adipocytes.²⁴

Fig. 21.57 Hashimoto thyroiditis harbors lymphoplasmacytic infiltration in the thyroid parenchyma with focal lymphoid follicle formation and surrounding reactive oncocytic changes in the thyroid epithelium (Hurthle cell metaplasia). Hashimoto thyroiditis is an autoimmune disorder affecting individuals with a genetic predisposition; it is associated with a variety of other autoimmune diseases, such as Graves disease, Sjögren syndrome, and rheumatic diseases. Patients with Hashimoto thyroiditis have a significant risk for the development of non-Hodgkin lymphomas; it is asserted that they also have a higher risk for the development of papillary carcinoma.

21.3.6 Soft-Tissue Tumors of the Head and Neck

Neoplasms

Juvenile hyaline fibromatosis is an extremely rare disorder characterized by the presence of subcutaneous tumorlike masses, predominantly in the head and neck. The nodules are composed of plump fibroblasts in a hyalinized collagen replacing normal tissues. Nuchal fibromas are benign, well-circumscribed but unencapsulated nodules in the posterior neck and upper back that harbor bundles of mature collagen with focal entrapment of nerve bundles, adipocytes, and skeletal muscle fibers. Desmoid-type fibromatosis shows poorly circumscribed soft-tissue masses composed of proliferating spindle cells with a uniform appearance in a collagenous background. Although no cytologic atypia or mitotic activity is seen, the lesion has infiltrative margins and is frequently incompletely excised, therefore showing a high recurrence rate. Dermatofibrosarcoma

Fig. 21.58 An adenomatoid goiter has a large variation of hyperplastic thyroid follicles with cytologically benign follicular cells.

Fig. 21.59 Follicular adenomas are benign thyroid tumors of adults that are completely encapsulated, usually by a thin rim of fibrous tissue, and retain follicular architecture (follicular differentiation) with a normal amount of colloid. A follicular adenoma has proliferating follicular cells (lower part of image) that are larger than normal follicular cells of the thyroid (upper part of image). The cells have moderately enlarged nuclei in comparison with the normal thyroid. No tumor capsule or vascular invasion is found. Variants of follicular adenomas include oncocytic adenoma (Hurthle cell adenoma), follicular adenoma with papillary hyperplasia, signet-ring cell follicular adenoma, mucinous follicular adenoma, lipoadenoma (with included groups of adipocytes), clear cell follicular adenoma, atypical adenoma, and follicular adenoma with bizarre nuclei.

protuberans arises in the dermis and subcutis on the trunk and proximal extremities, with a certain percentage affecting the head and neck.²⁵ It displays a dense cellular proliferation of spindle fibroblasts with a honeycomb pattern, infiltrative margins, and little mitotic activity; neoplastic cells are immunoreactive to vimentin and CD34 while usually factor XIIIa–negative. Adult fibrosarcomas are diffusely infiltrating malignant tumors of soft tissues that are highly cellular and show hyperchromatic spindle nuclei with frequent mitoses; the growth pattern is storiform or herringbone-like. Tumor size and depth of invasion are prognostically significant. Pleomorphic malignant fibrous histiocytoma (undifferentiated high-grade pleomorphic sarcoma) is an aggressive tumor, invading widely and metastasizing; it has a poor prognosis (□ Fig. 21.64).

Traumatic neuromas arise after trauma or surgery and are composed haphazardly arranged nerves and fibrous tissue. Neurofibromas and schwannomas are both benign tumors of

the nerve sheath. The former arise in the substance of a nerve and entrap nerve fibers within the mass, whereas the latter grow attached to a nerve and do not harbor nerve fibers within the mass. Both contain proliferating Schwann cells (immunoreactive to S-100) with scattered fibroblasts and perineurial cells (□ Fig. 21.65).

Perineuriomas are deep or superficially located soft-tissue nodules composed of small spindle cells. They derive from perineurial cells and are epithelial membrane antigen–positive while S-100–negative. Nuclear pleomorphism in a neurofibroma, a high degree of cellularity, increased mitotic activity, and tumor necrosis all suggest a malignant transformation (malignant peripheral nerve sheath tumor). Perineuriomas have an aggressive clinical course and metastatic potential. Lipomas are collections of mature adipocytes and are frequently encountered in the head and neck; surgical excision is curative. Spindle cell lipoma and pleomorphic lipoma are

Fig. 21.60 Papillary carcinoma of the thyroid shows predominantly papillary (solid or follicular areas possible) architecture of the neoplasm with multilayered malignant epithelial cells that have distinct cytologic features (nuclear clearing, nuclear grooving, conspicuous nucleoli, and occasional intranuclear pseudoinclusions) and atypia. Psammoma bodies (concentric calcium deposits) are very characteristic but rarely encountered. Papillary carcinoma is by far the most common thyroid malignant tumor; it manifests in adult life and shows a female predilection. Papillary carcinomas can be encapsulated but are usually diffusely invasive tumors that break through the thyroid capsule and have high propensity for lymphatic invasion. Microscopic foci of papillary carcinoma smaller than 1 cm are described as papillary microcarcinomas. Variants of papillary carcinoma have been described (follicular, oncocytic, clear cell, macrofollicular, solid, diffuse sclerosing, tall and columnar cell), all with similar clinical outcomes.

the ends of a common histologic spectrum; they are well-circumscribed soft-tissue masses of bland spindle cells with various adipocytic components and scattered multinucleated giant cells with radially arranged nuclei in a floret-like pattern. Lipoblastomas are benign pediatric tumors composed of mature and immature adipocytes, the latter corresponding to lipoblasts in various stages of development. The lipoblasts are usually very scarce. Well-differentiated liposarcoma, an intermediate malignant mesenchymal tumor, is composed of mature adipocytes with significant variation in cell size, focal adipocytic nuclear atypia, and hyperchromasia. Dedifferentiated liposarcoma shows areas of fibrosarcoma or pleomorphic malignant fibrous histiocytoma. Myxoid liposarcoma shows primitive, round to oval, nonlipogenic mesenchymal cells and various numbers of lipoblasts in a myxoid stroma. Pleomorphic liposarcoma harbors bizarre cells and lipoblasts. Papillary endothelial hyperplasia is an intravascular clot organization and recanalization of a thrombosed vessel after a traumatic event; it shows pseudopapillae lined by plump, reactive endothelial cells. Capillary hemangiomas are irregular proliferations of thin walled capillaries with bland endothelial cells (□ Fig. 21.66).

Kaposiform hemangioendothelioma is a locally aggressive, immature vascular neoplasm with a Kaposi sarcoma-like fascicular spindle cell growth pattern. Epithelioid hemangioendothe-

lioma is a vascular tumor that usually originates in a vessel. It shows centrifugal extension into neighboring soft tissue with partial vessel wall destruction by proliferating epithelioid endothelial cells with a low rate of mitotic activity and scattered nuclear pleomorphism. It is considered a vascular tumor of intermediate malignancy between hemangiomas and angiosarcomas. Angiosarcomas of the head and neck highly aggressive vascular tumors with metastatic potential and a high local recurrence rate (□ Fig. 21.67).

Leiomyomas are benign smooth-muscle tumors arising from pilar smooth muscles or the muscularis of blood vessels. They are typically not well circumscribed and harbor interlacing fascicles of lightly eosinophilic spindle cells with cigar-shaped nuclei. The cells are positive for smooth-muscle actin and desmin. Leiomyosarcomas are rare in the head and neck. Microscopically, they show increased cellularity, nuclear pleomorphism and hyperchromasia, and frequent mitoses. Deep-seated leiomyosarcomas have a more aggressive clinical course. Adult rhabdomyomas arise in the pharynx, oral cavity, tongue base, and larynx. They are benign lobulated tumors of striated muscle, display large polygonal or round cells with abundant eosinophilic cytoplasm, and are immunoreactive to muscle-specific actin, desmin, and myogenin. Rhabdomyosarcomas are malignant striated muscle tumors of childhood. Embryonal rhabdomyosarcomas show primitive cells in various stages of myogenesis. Alveolar rhabdomyosarcomas show predominantly primitive cells with a high nuclear-to-cytoplasmic ratio. Pleomorphic rhabdomyosarcomas, arising exclusively in adults, consist of undifferentiated round to spindle cells with frequent pleomorphic nuclei. Epithelioid sarcoma is a tumor of young adults that seldom involves the head and neck. It is composed of epithelioid and spindle cells with nuclear atypia and frequent tumor necrosis. The cells are characteristically positive for both vimentin and epithelial markers, like cytokeratin and/or epithelial marker antigen. Alveolar soft-part sarcoma is a malignant tumor of young adults involving the tongue and orbit most frequently. It characteristically shows an organoid growth pattern with thin, fibrous septation. The cells are polygonal and show sharp cell borders and large nuclei with prominent nucleoli. Occasionally, there are rhomboid or rod-shaped crystalline inclusions that are positive for periodic acid–Schiff. Synovial sarcoma affects young adults. On histologic examination, it can be biphasic (epithelial cells and spindle cells), monophasic (usually spindle cells alone), or poorly differentiated. Epithelial cells are immunoreactive to cytokeratins, while vimentin is present in the spindle cells. Soft-tissue type hemangiopericytoma rarely affects the head and neck (□ Fig. 21.68).

21.3.7 Bone Lesions of the Head and Neck

Neoplasms

Osteoma is a benign osseous tumor, almost exclusively present in head and neck, arising in the paranasal sinuses, mandible, bony part of the external auditory canal, and soft tissues (tongue, buccal mucosa, and nasal cavity); it is composed of a

Fig. 21.61 Follicular carcinoma has neoplastic follicular cells breaking through the thick fibrous capsule of the tumor (mushrooming capsular invasion). Follicular carcinoma accounts for 10 to 15% of thyroid malignancies. It is mostly a solitary large mass with a thick fibrous capsule and normal follicular or microfollicular architecture. Invasiveness is identified along its capsule (complete capsular penetration with spread into neighboring thyroid tissue) or in vessels (most distant metastases are blood-borne). Minimally invasive follicular carcinoma shows few foci of vascular and capsular invasion but retains the general shape of an encapsulated neoplasm; its prognosis is excellent. Widely invasive follicular carcinoma shows multiple areas of invasion such that the initial capsule of the tumor can barely be recognized; distant metastases are usually present by the time of presentation.

proliferation of compact lamellar bone with a reduced number of haversian canals. Histologically identical is exostosis, which involves larger areas of the external auditory canals bilaterally and is distinguished from osteoma on clinical grounds. Osteoid osteoma is a rare benign bone tumor of young adults arising in the cervical spine, mandible, maxilla, and various skull bones; it characteristically presents with pain relieved by salicylates. It shows a central nidus with a peripheral denser rim on radiologic examination; this is matched on histologic examination by a central nidus with new bone formation and active osteoblastic rimming followed by mature bone formation at the periphery and balanced osteoclastic and osteoblastic activity.

Osteosarcoma is rare in the head and neck; typically affecting the mandible, maxilla, skull bones, and rarely the vertebrae of adults (□ Fig. 21.69).

Chondroma is a benign cartilaginous tumor rarely seen in the skull base and other bones of the head and neck or in soft tissues. It shows lobules of hyaline cartilage with well-formed chondrocytes in unremarkable lacunae. Osteochondroma is a pedunculated benign tumor protruding from the parent bone that remains in direct continuity with the cortex of the affected bone; its distal part displays a cartilage covering. Chondroblastoma shows small, densely proliferating chondroblasts with well-defined borders and reniform nuclei with little mitotic activity. Chondrosarcoma can affect any area of

bone in the head and neck as well as the larynx in adults (□ Fig. 21.70).

The general grading system of sarcomas (based on differentiation, mitoses, and necrosis) correlates well with clinical

Fig. 21.62 Medullary thyroid carcinoma has neoplastic neuroendocrine cells with a stippled chromatin pattern (salt and pepper nuclei) and elongated, hyperchromatic nuclei, as well as amyloid deposition within the tumor and invasive features; note the unremarkable neighboring thyroid follicle. Medullary thyroid carcinoma arises from C cells (calcitonin-secreting cells), and the tumor cells are immunoreactive to calcitonin.

Fig. 21.64 Pleomorphic malignant fibrous histiocytoma (undifferentiated high-grade pleomorphic sarcoma) displays bizarre, pleomorphic cells growing in a fascicular or storiform pattern with marked nuclear hyperchromasia and frequent mitoses. It invades widely, metastasizes, and has a poor prognosis.

Fig. 21.63 Parathyroid adenoma usually involves a single parathyroid gland. The tumors are delicately encapsulated neoplasms composed of solidly proliferating chief cells or oncocytes with clear cytoplasm forming solid and focally follicular arrangements without intervening adipocytes; frequently, a rim of unremarkable parathyroid parenchyma is attached.

Fig. 21.65 Schwannoma is characterized by proliferating spindle Schwann cells with a fair amount of pink cytoplasm and indistinguishable cell borders; note the nuclear palisading around the acellular pink area (Verocay body).

Fig. 21.66 Capillary hemangiomas are irregular proliferations of thin-walled capillaries with bland endothelial cells in a loose collagenous stroma.

Fig. 21.67 Angiosarcomas demonstrate irregular and anastomosing vascular spaces with markedly pleomorphic endothelial cells and numerous atypical mitoses. The head and neck are the most common locations of cutaneous angiosarcomas. These are highly aggressive vascular tumors with metastatic potential and a high local recurrence rate.

Fig. 21.68 Soft-tissue type hemangiopericytoma exhibits dense, proliferating pericytes with mitotic activity. It harbors densely cellular elongated cells with numerous intervening vessels with focal staghorn branching; a high number of mitoses is linked to a more aggressive clinical course, but the criteria for malignancy are ill defined. The tumor cells are immunoreactive to CD34 and CD99. Soft-tissue type hemangiopericytoma is generally deep-seated but rarely affects the head and neck.

outcome.²⁶ Some show primitive areas with undifferentiated cells (mesenchymal chondrosarcoma). Chordoma of the head and neck, an intermediate-grade malignant tumor that recapitulates notochord histology, affects the clivus (most chordomas generally arise in the sacrococcygeal area). It shows multivacuolated, physaliferous cells in a mucinous stroma; the cells are immunoreactive to S-100, epithelial markers, and vimentin (□ Fig. 21.71).

Ossifying fibroma is an extraosseous neoplasm of fibrous tissue with central osteoid formation including some osteoclastic activity and mineralization. Aneurysmal bone cyst affects the mandible, maxilla, and midline bone structures of the head and neck in young adults (□ Fig. 21.72).

21.3.8 Hematopoietic Lesions of Head and Neck

Infectious/Inflammatory/Anatomic/Idiopathic

Mononucleosis lymphadenitis affects adolescents and young adults. If a histologic diagnosis is necessary (unsuccessful serologic investigation), the excised lymph node shows partially effaced lymphoid architecture, an expanded paracortical T-cell zone, and occasional immunoblasts. Human immunodeficiency lymphadenitis shows three distinct morphological patterns

Fig. 21.69 Osteosarcoma in the head and neck is rare and affects mandible, maxilla, skull bones, and rarely the vertebrae of adults. On microscopic examination, it shows malignant mesenchymal cells with osteoid formation (immature bone with incomplete Haversian system formation); in parallel, it can show fibroblastic, chondroblastic, or various mesenchymal differentiations. Seen here are trabeculae of woven bone with a single layer of osteoblastic rimming in a fibrous stroma.

Fig. 21.71 Fibrous dysplasia shows bone trabeculae with lamellar and woven bone, both devoid of osteoblastic rimming. It is well circumscribed and composed of bone replacement by fibroblastic stroma with irregular bone trabeculae arising directly from the fibrous tissue without the presence of osteoblasts. Fibrous dysplasia affects flat bones in the head and neck.

Fig. 21.70 Chondrosarcoma is characterized by irregularly distributed atypical chondrocytes with large, atypical, hyperchromatic nuclei and mitoses in irregular lacunae. Chondrosarcoma can affect any area of bone in the head and neck as well as the larynx in adults.

Fig. 21.72 Giant cell reparative granuloma (aneurysmal bone cyst) is a well-circumscribed, benign, variably cystic bone tumor with peripheral woven bone formation accompanied by osteoblastic rimming in a fibrous and focally hemorrhagic stroma with unevenly distributed multinucleated osteoclast-type giant cells. Note the neighboring bone trabeculae with reactive woven bone changes. It affects the mandible, maxilla, and midline bone structures of the head and neck in young adults.

based on stage of evolution. Pattern A displays enlarged lymph nodes with mildly disturbed lymphoid architecture and aggregates of monocytoïd cells. Pattern B shows follicle effacement with lymphocytic depletion and vascular hyperplasia. Pattern C shows hyalinized germinal centers with transfixing, collagen-ensheathed arterioles and extensive angiogenesis.²⁷ Cat-scratch lymphadenitis usually presents with unilateral matted lymphadenopathy showing necrotizing granulomas with central microabscesses (*Bartonella henselae*). Toxoplasma lymphadenitis reveals posterior cervical lymphadenopathy with well-preserved reactive lymphoid architecture, perifollicular and intra-follicular clusters of epithelioid cells, and patches of monocytoïd cells without granulomas or necrosis. Mycobacterial lymphadenitis presents as caseating necrosis with granulomas in which rare bacilli can be found on special stains (acid-fast bacilli) (□ Fig. 21.73). Sarcoidosis lymphadenopathy may be seen in multisystem sarcoidosis (□ Fig. 21.74). Kimura lymphadenopathy, is common in young Asian males, usually seen in the neck and periauricular areas (□ Fig. 21.75). Kikuchi lymphadenopathy, also seen predominantly in young Asians, can be found in unilateral cervical lymph nodes and generally resolves spontaneously (□ Fig. 21.76). Sinus histiocytosis with massive lymphadenopathy (Rosai-Dorfman disease) is generally seen in

Fig. 21.73 Mycobacterial lymphadenitis is defined by irregular areas of caseous necrosis delineated by granulomas in lymph nodes. Mycobacterium tuberculosis lymphadenitis, the most common type of extrapulmonary tuberculosis, usually affects multiple lymph nodes. Histologically, it presents as caseating necrosis with granulomas in which rare bacilli can be found on special stains (acid-fast bacilli).

Fig. 21.74 Sarcoidosis lymphadenopathy accompanies multisystemic sarcoidosis. Histologically, it displays non-necrotizing granulomas with well-preserved lymphoid architecture.

children and adolescents, presenting with massive generalized lymphadenopathy of long duration (□ Fig. 21.77).

Inflammatory pseudotumor shows enlarged, tumorlike lymph nodes and soft-tissue masses. It displays fascicles and whorls of spindle cells (fibroblasts and myofibroblasts) accompanied by vascular proliferation and moderate chronic inflammatory infiltration without evidence of monoclonality.

Neoplasms

Hodgkin lymphoma (classic type) shows four distinct variants. Nodular sclerosis Hodgkin lymphoma is the most common type in the United States and shows lymph node architecture effacement due to fibrosis. Lymphoid cells, with an eosinophilic background, harbor a large number of Reed-Sternberg cells and Hodgkin cells (immunoreactive to CD30 and CD15 but CD20-negative) (□ Fig. 21.78). Lymphocyte-rich Hodgkin lymphoma shows few Reed-Sternberg cells in a largely lymphocytic background. Mixed-cellularity Hodgkin lymphoma is the most common type in underdeveloped countries and shows mixed

features of the first two. Lymphocyte depletion Hodgkin lymphoma affects elderly patients and shows severe lymphocyte depletion and few Reed-Sternberg cells with a diffuse fibrillary background.²⁸ Nodular lymphocyte-predominant Hodgkin lymphoma shows a nodular growth pattern, usually focal architectural replacement, and scattered neoplastic lymphocytic/histiocytic cells, which are in fact CD20-positive but CD30- and CD15-negative neoplastic B lymphocytes. No Reed-Sternberg cells are present. Marginal zone B-cell lymphoma (MALT lymphoma) is a low-grade lymphoma of adults arising in lymph nodes or extranodally. It harbors monotonous monoclonal small lymphocytes with slight nuclear angulation, very few mitoses, and B phenotype (CD20-positive with frequent CD43 coexpression and light chain restriction). Small lymphocytic lymphoma affects elderly persons and displays monotonous small lymphocytes with hyperchromatic nuclei and slight nuclear contour irregularity (immunoreactive to CD20, CD23, and CD5) with complete effacement of lymphoid architecture. Occasional proliferation centers populated by prolymphocytes are present. Mantle cell lymphoma is clinically aggressive and displays monotonous,

Fig. 21.75 Histologically, Kimura lymphadenopathy shows preserved lymphoid architecture with scattered and diffuse eosinophilic infiltration in a background of capillary endothelial hyperplasia in lymph nodes. Kimura lymphadenopathy, common in young Asian males, shows predilection for the neck and periauricular areas.

medium-size lymphocytes with vesicular nuclei, conspicuous basophilic nuclei, and a fair amount of mitoses (immunoreactive to CD20, CD5, and cyclin D1). Follicular lymphoma has high incidence in Western countries and affects elderly persons. It can show partial or complete nodal involvement with a follicular or diffuse growth pattern. It comprises cleaved cells (immunoreactive to CD20, CD10, Bcl-2, and Bcl-6) that can be small or large corresponding to a low or high histologic grade of follicular lymphoma, respectively. Diffuse large B-cell lymphoma is the most common lymphoma in Western countries and is high-grade. It can be nodal or extranodal and harbors large B lymphocytes (positive for CD20 with variable staining for CD10 and Bcl-6) with a high mitotic count and tumor necrosis. Burkitt lymphoma is a high-grade B-cell lymphoma

affecting young adults (□ Fig. 21.79).

Myeloid sarcoma (extramedullary myeloid cell tumor) is the tissue counterpart of chronic myeloid leukemia in which circulating malignant myeloid cells (immunoreactive to CD13, CD15, CD33, CD43, and CD117) form tissue masses. Extranodal NK

(natural killer)/T-cell lymphoma, nasal type, and peripheral T-cell lymphoma are the most frequent T-cell lymphomas of the head and neck. They are high-grade and display various T-cell antigen deletions in neoplastic lymphocytes. Plasmacytoma is a proliferation of atypical plasma cells with a high mitotic rate (□ Fig. 21.80).

21.3.9 External, Middle, and Internal Ear

External Ear

Infectious/Inflammatory/Anatomic/Idiopathic

The most common congenital lesion of the external ear is the accessory tragus, which microscopically is a fragment of cartilage covered by unremarkable skin and subcutaneous tissue. Preauricular cysts and sinuses are derived from the first branchial arch and consist of spaces lined by squamous- or respira-

Fig. 21.76 Biopsied lymph nodes in Kikuchi lymphadenopathy display partially preserved lymphoid architecture with patchy areas of necrosis, nuclear debris, aggregates of histiocytes, apoptotic cells, and a total lack of neutrophils and eosinophils. Kikuchi lymphadenopathy, predominant in young Asians, affects cervical lymph nodes unilaterally and has a benign clinical course with spontaneous remission.

tory-type epithelium. Type I anomaly is cystic and entirely ectodermal, whereas type II also contains cartilage. Keloids are thick, irregular scars which grow beyond the limits of the original scar (□ Fig. 21.81).

Chondrodermatitis helicis nodularis affects the external ear and consists of ulcerations with granulation tissue, necrobiosis of underlying cartilage, and surrounding hyperplasia of skin.

Neoplasms

Squamous cell carcinoma is associated with actinic injury and consists of atypical squamous cells with intercellular desmosomes and various degrees of keratinization. It tends to invade widely into soft tissues and along perineural spaces. Basal cell carcinomas arise from the basal layer of the epidermis and invade the dermis as irregular nests of basaloid cells with peripheral palisading. Some variants have irregular borders and are difficult to completely excise by standard methods (□ Fig. 21.82). Malignant melanoma is characterized by nests of

melanocytes with atypical nuclei and conspicuous nucleoli forming basal epidermal nests and spreading into the upper layers of the epidermis. Melanocytes are immunoreactive to S-100, MART-1 (Melan-A), and HMB-45 (□ Fig. 21.83).

Undifferentiated epithelial cells with scant cytoplasm and large nuclei harboring stippled chromatin are seen in Merkel cell carcinoma, as are frequent mitoses, tumor necrosis, and dense core cytoplasmic granules (□ Fig. 21.84). Dermatofibroma is a benign tumor of skin composed of proliferating spindle fibroblasts, various amounts of deposited collagen, and intervening macrophages (□ Fig. 21.85). Nodular fasciitis is a reactive growth secondary to trauma. Histologically, nodular fasciitis presents with a loosely arranged proliferation of myofibroblasts harboring occasional mitoses in a hypocellular or myxoid background (□ Fig. 21.86).

Kaposi sarcoma is a low-malignancy mesenchymal neoplasm of skin and subcutaneous tissue, but also with wide spread visceral involvement; it is usually linked to immune deficiency.

Fig. 21.77 Sinus histiocytosis with massive lymphadenopathy (Rosai-Dorfman disease) affects children and adolescents, presents with massive generalized lymphadenopathy of long duration, and can have a self-limited clinical course. Lymph node biopsies show effacement of lymphoid follicles with marked dilatation of interfollicular sinuses by an accumulation of histiocytes (S-100 immunohistochemical stain). Cells are CD68- and S-100-positive while CD1a- and Langerin-negative, devoid of necrosis, and capable of engulfing lymphocytes (emperipolesis).

Microscopically, it displays irregular vascular spaces lined by atypical endothelial cells with a low rate of mitotic activity and extravasated erythrocytes. Tumor cells show nuclear immunoreactivity for human herpesvirus 8 (HHV-8).²⁹ Angiolymphoid hyperplasia with eosinophilia is a chronic inflammatory condition presenting with swelling of skin and subcutaneous soft tissues in the head and neck, especially in the periauricular area; microscopically, it shows proliferating capillaries and various degrees of lymphocytic infiltrate with numerous eosinophils. External auditory canal cholesteatoma is a keratin-filled pearly expansion usually located in the inferior aspect of the canal. Long-standing lesions can be erosive/destructive of bone. Ceruminoma (adenoma of ceruminous glands) derives from transformed apocrine sweat glands of the external auditory canal (□ Fig. 21.87).

Malignant tumors of the ceruminous glands can be adenocarcinomas (low- or high-grade) or have salivary gland tumor differentiation (adenoid cystic or mucoepidermoid carcinomas).

Middle Ear and Inner Ear

Infectious/Inflammatory/Anatomic/Idiopathic

Chronic otitis media, seen in all age groups, shows lymphoplasmacytic infiltration of the middle ear mucosa. Granulation tissue can be associated (forming aural polyps that hang into the external ear canal through tympanic perforations). Cholesterol granulomas are derived from intralesional bleeding. Fibrosis and calcification of the tympanic membrane can follow (tympanosclerosis), inflammation can affect the mastoid (chronic mastoiditis), and the tegmen can be eroded, allowing brain tissue to herniate into the middle ear (encephalocele).³⁰ Specific inflammatory processes of the nasal cavities and paranasal sinuses, like sarcoidosis, Wegener granulomatosis, tuberculosis, fungal infections, and others, can also occur. Cholesteatoma of the middle ear arises from retraction pockets of squamous epithelium in the tympanic membrane or from squamous metaplasia of the middle ear mucosa in long-standing inflammation and is histologically similar to its external auditory canal (□ Fig. 21.88).

Fig. 21.78 Classic Hodgkin lymphoma, nodular sclerosing variant demonstrates fibrous bands separating nodules; a few Reed-Sternberg cells are seen with background eosinophilic infiltration.

Neoplasms

Adenomas of the middle ear are benign epithelial proliferations of packed small glands with single layer of cuboidal or columnar cells (□ Fig. 21.89). The same epithelium can develop schneiderian-type papillomas of the middle ear (usually inverted papillomas), which are histologically identical to their nasal and paranasal sinus counterparts. Choristomas of the middle ear include salivary gland choristomas and glial heterotopias, in which benign salivary gland and glial tissue vestiges are found, respectively. Paraganglia are collections of neuroendocrine cells of neural crest origin that migrate during embryologic evolution in close association with cranial nerves, large vessels, and autonomic nerves and ganglia. We distinguish adrenal paraganglia (mainly secreting adrenalin) and extra-adrenal paraganglia, which can be sympathetic (mainly secreting noradrenalin) or parasympathetic (mainly secreting dopamine). Benign tumors derived from extra-adrenal paraganglia, all histologically identical, are found in decreasing order of prevalence at the bifurcation of the common carotid artery, middle ear, vagus nerve,

aortic arch, and other unusual locations, such as the larynx, orbit, cauda equina, nasopharynx, and others. The middle ear paragangliomas are most frequently attached to the jugular vein bulb (jugular paraganglioma) and less frequently to the tympanic nerve (branch of the glossopharyngeal nerve) in the area of the medial promontory wall (tympanic paraganglioma).³¹ Collectively, they are called jugulotympanic paragangliomas (□ Fig. 21.90).

Other benign tumors infrequently involving the middle ear are meningioma, schwannoma (acoustic neuroma; see □ Fig. 21.65), and lipoma of the internal auditory canal. Malignant tumors of the middle ear comprise squamous cell carcinomas, adenocarcinomas, and others. Considered to arise in the inner ear with possible secondary involvement of the middle ear is the endolymphatic sac tumor (aggressive papillary middle ear tumor), a neoplasm with low-grade malignant potential. It can occur sporadically but can also be associated with von Hippel-Lindau disease. On microscopic examination, it shows variable papillary, follicular, or glandular arrangement covered

Fig. 21.79 Burkitt lymphoma is characterized by monotonous malignant large B lymphocytes with frequent scattered macrophages (starry sky appearance). Burkitt lymphoma is a high-grade B-cell lymphoma affecting young adults. It harbors large neoplastic B cells (immunoreactive to CD20, CD10, and Bcl-6 with Epstein-Barr virus positivity); the large numbers of macrophages attest to the high turnover rate of neoplastic cells.

Fig. 21.80 Plasmacytoma is a proliferation of atypical plasma cells (immunoreactive to CD38 and CD138) with light- and heavy-chain restrictions, a high mitotic rate, and occasional necrotic foci with characteristic cartwheel nuclei, perinuclear hof (clearing at the nuclear concavity), and basophilic cytoplasm.

Fig. 21.81 Keloids are thick, extend beyond the limits of the original scars, and are raised with dense, irregular collagen bundles. The earlobes are frequently affected by keloid formation next to areas of piercing.

Fig. 21.82 Basal cell carcinoma displays invading islands of epithelial cells with large hyperchromatic nuclei and scant cytoplasm; note the connection to the basal layer of the epidermis (upper left corner). Basal cell carcinomas arise from the basal layer of the epidermis and invade the dermis as irregular nests of basaloid cells with peripheral palisading. Most are nodular and therefore easily excised; other variants (multifocal superficial and invading morphea type) have irregular borders and are difficult to completely excise by standard methods.

Fig. 21.83 Malignant melanoma is characterized by nests of melanocytes with atypical nuclei and conspicuous nucleoli forming basal epidermal nests and spreading into the upper layers of the epidermis. Malignant melanoma is one of the great mimics among neoplastic lesions; it can be pigmented or amelanotic, ulcerated or nodular, and histologically it displays an array of cytologic features ranging from large epithelioid cells to spindle and fusiform cells suggesting a mesenchymal lesion. Melanocytes are immunoreactive to S-100, MART-1 (Melan-A), and HMB-45. Proper margins of resection may be difficult to achieve on the skin of the external ear because of anatomical restrictions.

Fig. 21.84 Sheets of undifferentiated epithelial cells with scant cytoplasm and large nuclei harboring stippled chromatin are seen in Merkel cell carcinoma, as are frequent mitoses, tumor necrosis, and dense core cytoplasmic granules; note individual cell necrosis. Tumor cells react to neuroendocrine markers (synaptophysin, chromogranin, and CD56) and characteristically show paranuclear dotlike staining with CK-20 (a low-molecular-weight cytokeratin fraction).

Fig. 21.85 Dermatofibroma is a poorly circumscribed benign tumor of skin composed of proliferating spindle fibroblasts (factor XIIIa-positive and CD34-negative), various amounts of deposited collagen, and intervening macrophages.

by cytologically bland epithelial cells in a single row; temporal bone invasion or middle ear infiltration is described.

21.4 Roundsmanship

- FNA as a screening test for thyroid nodules can subcategorize them as benign or suspicious, effectively preventing

unnecessary surgery. A specific diagnosis may not always be possible.

- FNA as a screening test for salivary masses is efficient in distinguishing benign from malignant entities, thus facilitating preoperative planning.
- Submission of the FNA sample of a lymph node for flow cytometry analysis is essential if non-Hodgkin lymphoma is suspected; conversely, if Hodgkin lymphoma is high on the

Fig. 21.86 Nodular fasciitis is a reactive rapid growth linked to a traumatic event. It presents with a loosely arranged proliferation of myofibroblasts harboring occasional mitoses in a hypocellular or myxoid background; note the occasional nuclear pleomorphism of fibroblasts.

Fig. 21.87 Ceruminoma (adenoma of ceruminous glands) derives from transformed apocrine sweat glands of the external auditory canal. It is an unencapsulated subcutaneous glandular epithelial neoplasm with epithelial and myoepithelial cells (bilayered disposition) and an apocrine type of apical decapitation (apical snouting).

Fig. 21.88 Cholesteatoma of the middle ear arises from retraction pockets of squamous epithelium in the tympanic membrane or from squamous metaplasia of the middle ear mucosa in long-standing inflammation. Histologically similar to its external auditory canal counterpart, cholesteatoma of the middle ear shows an accumulation of flaky keratin with fragments of squamous epithelium.

Fig. 21.89 Adenomas of the middle ear are unencapsulated benign epithelial proliferations of closely packed small glands with single layer of benign cuboidal or columnar cells.

different differential diagnostic list, the entire sample should be saved for morphological examination.

- FNA of lymph nodes can reliably suggest a lymphoproliferative process and therefore justify an open biopsy (the gold standard for the histopathologic diagnosis of lymphoid lesions).
- The correlation of clinical, imaging, and cytologic findings is always desirable.
- In the head and neck, skin, epithelial, neural, respiratory, digestive, glandular, soft-tissue, bone, vascular, and lymphoid normal elements are combined in highly specialized

structures within a relatively small anatomical area. The complexity of the pathologic processes here is unparalleled by that in any other area of the human body.

- The number of head and neck neoplasms with concomitant features of several different structures is high.
- Frozen sections in melanocytic skin lesions should be limited to surgical resection margins; the main lesion should be examined on permanent sections only after appropriate fixation.
- Malignant skin lesions of head and neck can be excised with only limited oncologic margins, and they should be excised with frozen section assessment of the surgical resection margins.

Fig. 21.90 On microscopic examination, paraganglioma shows polygonal neuroendocrine cells proliferating in clusters (zellballen) with intervening fibrous septa and scattered, flattened sustentacular cells (positive for S-100 and glial fibrillary acidic protein).

22 The Role of Radiation Therapy in the Management of Head and Neck Cancer

Kenneth S. Hu and Louis B. Harrison

22.1 Introduction

Radiation therapy is an integral component in the treatment of head and neck tumors. Machine-generated X-rays were discovered by William Roentgen in 1895. The first radioactive isotope (radium) was discovered in 1899 by Marie Curie and was first applied in the treatment of head and neck cancer in the early 1900s. Radioactive isotopes continue to be useful today in the form of brachytherapy. Machine-generated high-energy X-rays are the mainstay of treatment for the majority of head and neck tumors. Early orthovoltage and superficial voltage machines were limited in application because of skin injury during the treatment of subcutaneous tumors. Not until the development of the high-energy linear accelerator in the 1960s could external beam radiation be integrated into the treatment of head and neck cancer without prohibitive skin toxicity. Simulation, computed tomography (CT)-based treatment planning, field shaping with motorized multiple-leaf collimators, and intensity modulation of radiation represent important advances that have allowed the highly conformal delivery of radiation, optimizing the therapeutic ratio by concentrating the radiation around the tumor while sparing adjacent normal tissue such as salivary glands, pharyngeal muscles, and cranial nerves. Current radiation delivery systems allow millimeter precision and simultaneous differential dosing to areas at variable levels of risk. Such high levels of conformality increase the ability to integrate radiation in a multidisciplinary manner to provide excellent locoregional control and focus on organ function preservation.

22.2 Radiobiology

Radiation works primarily by causing reproductive cell death such that tumors are unable to replicate. The target of treatment is the tumor DNA, in which free radical formation from ionizing radiation therapy causes permanent double-strand breakage. Normal tissues have a greater capacity than tumor cells to repair themselves after radiation exposure. Fractionation exploits the repair differential such that doses high enough to kill tumors but that spare the function and integrity of normal tissue are used. In general, radiation doses of 50, 60, and 70 gray (Gy) are required for elective treatment, microscopic residual disease, and gross tumor, respectively. Advanced stage T3 and T4 tumors usually require the concurrent addition of a radiation sensitizer during radiation therapy to achieve a high probability of tumor control. Head and neck squamous cell carcinomas have the unique characteristic of delayed accelerated tumor repopulation during radiation therapy, which makes the total treatment time a vital aspect of optimal radiation delivery. The phenomena of on-treatment repopulation and differential repair ability underlie the rationale for several altered fractionated radiation regimens proven to improve locoregional control. Shortening the duration of treatment with accelerated radiation regimens from a conventional time of 7 to 6 weeks or

less has yielded significant gains. Also, escalating the dose beyond the conventional dose of 70 up to 80 Gy with hyperfractionation and administering two treatments per day exploit the repair advantage of normal tissue over tumor such that long-term toxicity is no different but tumor control is improved.

22.2.1 General Approaches to Improving Locoregional Control with Radiation Therapy

Because of their location, cancers of the head and neck can severely impact speech, mastication, taste, swallowing, and cosmesis. Eradicating disease and preserving organ function are important goals of treatment. For early-stage disease, single-modality therapy is preferred, whereas a complex multidisciplinary evaluation is needed for locoregionally advanced disease. Important advances have been made, with altered fractionation and the incorporation of chemotherapy used to improve disease control. More recent advances include better targeting of tumor through improved imaging, radiation delivery, and biologic therapies. The preservation of quality of life and organ function is a crucial end point that guides the selection of an optimal treatment for individual patients.

22.2.2 Radiation Techniques and Particle Therapies

Multiple methods of delivering radiation therapy to optimize the therapeutic ratio have been developed. The mainstay of treatment has been with external beam techniques, which deliver photons generated by machine and shaped by blocks and collimation before the patient is treated. Brachytherapy is the direct placement of radioactive sources in the tumor and is most often used as a boost to augment a course of external beam radiation. Such an approach permits escalation of the dose to the primary site and decreased exposure of normal tissues to the dose.

External Beam Radiation

Two-Dimensional Technique

In the traditional two-dimensional technique, treatment fields are designed based on bony landmarks and wide margins up to 2 cm, with X-rays delivered to opposed lateral fields and a low anterior neck field. The target volume of the parallel opposed fields should include the primary site with margin plus draining lymph nodes of the upper neck, with a high match above the arytenoids for oropharynx lesions and a low match below the cricoid cartilage for laryngeal/hypopharyngeal lesions.

Radiation therapy has improved vastly from the initial use of orthovoltage/radium sources, block-shaped beams, and plain film-based imaging with large setup uncertainty to the use of

high-energy linear accelerators with dynamic leaf collimation and CT-based treatment planning with precise setup and immobilization. The evolution in treatment planning has allowed the better-targeted delivery of radiation, with sparing of the structures important for salivation, hearing, swallowing, and chewing. Additionally, nausea can be prevented.

Intensity-Modulated Radiation Therapy

Recent efforts to improve radiation dose conformality and reduce toxicity have been made with three-dimensional and intensity-modulated radiation therapy (IMRT) techniques to treat complex, irregularly shaped head and neck tumors. IMRT has generated tremendous enthusiasm because it allows exquisite dose conformality with sparing of adjacent organs. Each radiation field is divided into a number of beamlets with the aid of an intensity modulator and inverse treatment planning. The different beamlets are added to form a cumulative dose distribution tailored to the shape of the tumor and respecting designated normal tissue tolerance constraints. IMRT also offers the possibility of differential dosing to the elective nodal basin, high-risk nodal areas, and primary tumor sites with resultant modestly accelerated radiation.

Cancers of the oropharynx and nasopharynx are ideal sites for IMRT because the tumors often present in close proximity to sensitive normal tissues such as the parotid glands or involve the pharyngeal wall/retropharyngeal nodes close to the spinal cord. Locoregional control of 87 to 89% appears similar and possibly better than that achieved with conventional techniques based on initial single-institution series. IMRT regimens of 70 Gy in 33 or 35 fractions are well tolerated, even with concurrent chemotherapy (□ Fig. 22.1).

To date, the greatest benefit of IMRT in regard to toxicity has been the reduction of severe xerostomia compared with standard techniques. Eisbruch et al showed that stimulated salivary flow can be preserved if the mean dose to one parotid gland with IMRT is 26 Gy or less, with full recovery occurring up to 2 years after treatment. This is clearly an important advance because xerostomia is the primary quality-of-life complaint among long-term survivors of head and neck cancer treated with radiation.

IMRT may also be used to spare the cochlea, nausea center, constrictor muscles, carotid arteries, minor salivary glands of the oral cavity, submandibular gland, larynx, and pterygoid muscles.

Brachytherapy

Brachytherapy, or the implantation of radioactive seeds directly into the target volume, offers dose escalation to tumor and sparing of surrounding normal tissue by inverse-square attenuation, producing excellent dose conformality. Normal tissue toxicity is further lessened because the dose of external beam radiation is reduced, which is especially advantageous in those receiving concurrent chemotherapy.

Stereotactic Radiotherapy

Stereotactic radiation delivers highly focused radiation to tumors through the use of rigid immobilization techniques and non-coplanar beam arrangements. The foremost advantage of

stereotactic radiation is that it delivers a single (stereotactic radiosurgery [SRS]) or hypofractionated (stereotactic radiation therapy [SRT]) dose of radiation having an ablative effect on the tumor with submillimeter margins of precision, allowing much smaller treatment volumes. The potential benefit of SRT over SRS is that the multiple fractions allow the repair of normal tissue, with the increased possibility of organ function preservation, an important consideration when tumors are adjacent to the optic nerve pathways, brain, and spinal cord. Both techniques require the use of a stereotactic frame, which creates a highly accurate three-dimensional localizing system orienting the treatment planning system to the precise location of the target. Stereotactic radiation is delivered by either of two methods: (1) a gamma knife device, which comprises 201 independently controlled cobalt sources arranged in a helmet, or (2) a linear accelerator, with conversion accomplished via a specialized collimating device. Stereotactic radiation is best applied to tumors that are less than 4 to 5 cm in size and well delineated on CT, magnetic resonance (MR) imaging, or angiography. It is most often used as a boost after a course of external beam radiation or as salvage therapy. It has proved particularly useful in malignant tumors of the skull base and paranasal sinuses, as well as benign tumors such as paragangliomas, meningiomas, pituitary adenomas, vascular malformations, and acoustic neuromas.

Particle Therapy

Radiation with heavy particles, such as protons and neutrons, offers unique advantages in dose deposition. Protons deposit radiation close to the tumor, with radiation falling off dramatically posterior to the target in a Bragg peak distribution. This allows the exquisite control of dose deposition. Traditionally, protons have been used to treat uveal melanomas and chondrosarcomas of the skull base, as well as adenoid cystic carcinomas of the parotid and lacrimal glands. Neutrons offer the high particle treatment of tumors thought to be resistant to radiation and destroy tumors without reliance on oxygenation because of their high linear energy transfer properties. They have been most successfully used in the treatment in suboptimally resected adenoid cystic carcinomas.

Altered Fractionated Radiation

Altered fractionated radiation therapy attempts to improve tumor control either by accelerating radiation treatment to overcome tumor repopulation or by dose escalation with hyperfractionation to make use of the radiation repair advantage of normal tissues over tumor. Radiation therapy can be successfully accelerated by delayed concomitant boost or a Danish regimen of six conventional treatments per week, whereas dose escalation is best accomplished by hyperfractionation. Meta-analysis has indicated a survival advantage of hyperfractionation with dose escalation compared with conventional fractionation.

A landmark trial conducted by the Radiation Therapy Oncology Group (RTOG 90-03) compared the leading U.S. altered fractionated regimens for cancers, primarily stages III and IV head and neck cancers or stage II hypopharynx or base of tongue cancers. At 8 years of follow-up, the results showed that hyperfractionated radiation therapy and accelerated radiation

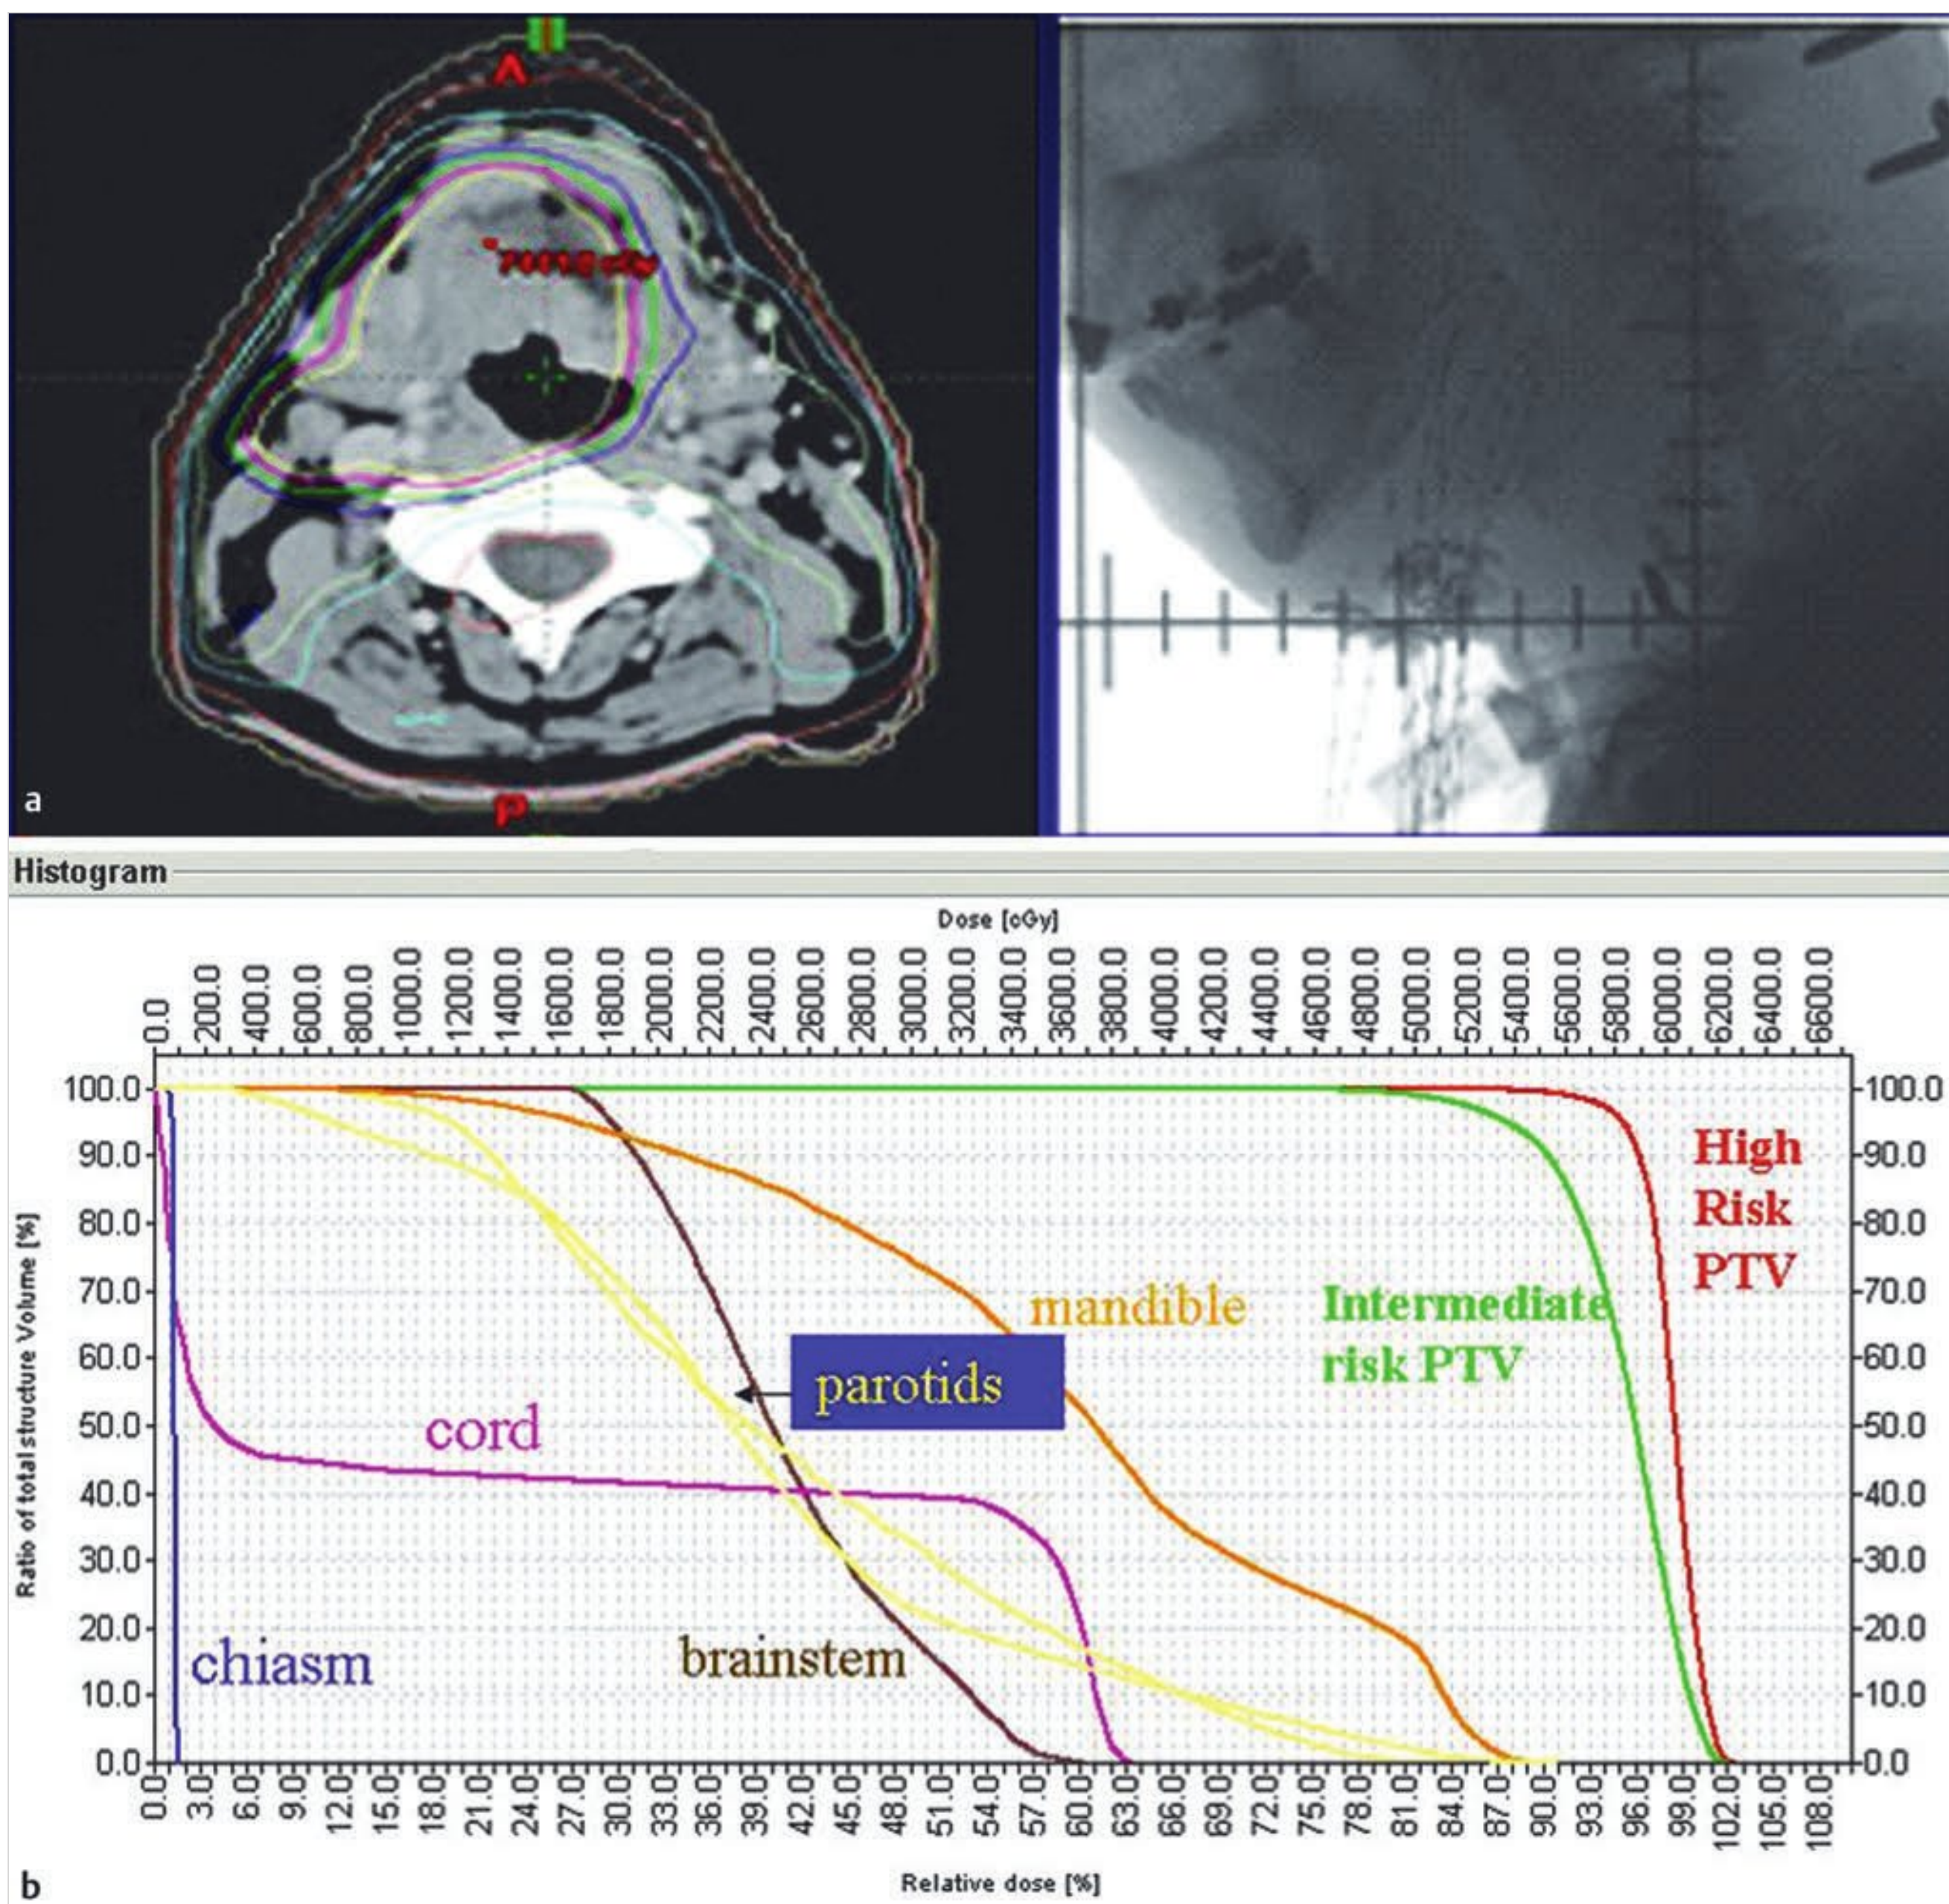

Fig. 22.1 (a) A 62-year-old man with a T2 N2b M0 base of tongue carcinoma treated with combined external beam radiation and concurrent chemotherapy, brachytherapy implant, and planned neck dissection. External beam radiation was delivered with intensity modulation in a reduced dose of 5,940 cGy to the involved primary site and nodes followed by a 20-Gy brachytherapy boost. (b) Dose–volume histogram demonstrating dose distribution from course of intensity-modulated radiation therapy.

by delayed concomitant boost improved locoregional control by 7 to 8% over conventional fractionation, with improved disease-free survival.

Concurrent Radiation and Chemotherapy

Numerous overviews demonstrate the advantage of adding chemotherapy to radiation. A meta-analysis by Monnerat et al concluded that concurrent chemotherapy offers an 8% survival benefit, induction chemotherapy a 2% benefit, and adjuvant therapy a 1% benefit. In general, there is a 10 to 20% improvement in locoregional control with concurrent chemotherapy.

The French Intergroup (GORTEC 94–01) Phase III randomized trial established concurrent chemoradiation as the standard treatment for locoregionally advanced oropharyngeal disease. Long-term follow-up demonstrated improved 5-year overall survival and disease-free survival and a locoregional control advantage with combined therapy (conventional radiation with three cycles of concurrent carboplatin/5-fluorouracil) over conventional radiation alone in patients with stage III and IV oropharyngeal carcinoma. Still, despite such intensive therapy, locoregional failure occurred in more than 50% of patients.

Chemotherapy Combined with Altered Fractionated Radiation

Efforts to further improve locoregional control and survival have explored combining concurrent chemotherapy with altered fractionated radiation because both approaches independently improve outcome for patients with head and neck cancer. The present challenge is to find the optimal chemoradiation regimen(s) that offer high rates of locoregional control and organ function preservation with acceptable morbidity and the possibility of integration with new biologic agents or additional chemotherapy.

The majority of Phase III trials show a benefit of the addition of concurrent chemotherapy to altered fractionated radiation with either hyperfractionation or delayed concomitant boost (DCB) compared with the same radiation regimen alone. Budach et al estimate a 2-year survival benefit of 12% with the addition of chemotherapy to either hyperfractionation or accelerated radiation.

Conventional versus Altered Fractionated Concurrent Chemoradiation

However, two recent randomized trials have shown no locoregional control or survival benefit of altered fractionated radiation over conventional fractionation in patients receiving concurrent chemoradiation. Thus, conventional fractionation is most commonly used in the setting of concurrent chemoradiation.

Role of Induction Chemotherapy

Induction chemotherapy has been used to reduce the tumor burden and increase the successful treatment of tumors with organ preservation therapy. This is particularly evident in patients with larynx and hypopharynx cancers. Multiple meta-analyses show only a minor survival benefit of induction chemotherapy. However, recent data show that the addition of docetaxel (Taxotere; Sanofi-Aventis) to induction chemotherapy with cisplatin/5-fluorouracil followed by radiation or concurrent chemoradiation improves survival and locoregional control.

A landmark trial randomized 202 selected patients with locally advanced hypopharyngeal cancer to radical resection with postoperative irradiation or to induction chemotherapy with two or three cycles of cisplatin/5-fluorouracil followed by conventional fractionated radiation (70 Gy for 7 weeks) if the patients had a clinical complete response after induction chemotherapy. At a median follow-up of 51 months, there was no statistical difference between the arms in rates of local and regional failure. At 5 years of follow-up, there was no significant survival difference (34% vs 29%). For all patients entered in the organ preservation arm, the 3-year organ preservation rate was 42%.

Most recently, the addition of docetaxel to induction cisplatin and fluorouracil (TPF) compared with induction PF alone increased larynx preservation. GORTEC 2000–01 randomized 220 patients with hypopharynx or larynx cancer for whom total laryngectomy would be required to either TPF or PF followed by conventionally fractionated radiation to 70 Gy. At a median follow-up of 35 months, larynx preservation at 3 years was

improved by about 10% such that three-quarters achieved organ preservation.

Other induction chemotherapy trials with TPF before radiation or concurrent chemoradiation showed an improvement in overall survival versus induction PF. However, the benefit of induction TPF in the setting of standard cisplatin-based concurrent chemoradiation has not been established, and its role in the treatment of head and neck cancer continues to be defined.

Biologic Therapy: C225

Epidermal growth factor receptor (EGFR) is commonly expressed in head and neck cancer cell lines. Ang reported in a study of a cohort of RTOG 90–03 patients that patients who had tumors expressing a higher than median level of EGFR had a greater risk for 2-year locoregional relapse, lower 2-year disease-free survival, and lower 2-year overall survival compared with patients who had tumors expressing lower than median or median levels of EGFR. No difference in distant metastases were noted between the two groups.

A pivotal Phase III trial reported by Bonner et al demonstrated the benefit of adding cetuximab (C225), a monoclonal antibody targeting EGFR, to radiation. In this trial, 424 patients with stage III or IV head and neck cancer (primarily of the oropharynx/hypopharynx) were randomized to 7 weeks of C225 plus radiation (conventional fractionation or altered fractionation) or to radiation alone. At a median follow-up of 38 months, C225/radiation was superior to radiation alone with respect to 2-year locoregional control, 2-year overall survival, and median overall survival. With regard to toxicity, the addition of C225, unlike the addition of concurrent chemotherapy or the acceleration of radiation, did not significantly increase grade 3 or 4 mucositis but was associated with increased rates of dermatitis and infusion reaction.

22.3 Role of Radiation Therapy in Specific Sites of Disease

Radiation therapy has been used preoperatively or postoperatively in the definitive treatment of head and neck squamous cell carcinomas in conjunction with curative-intent surgical resection, and also as radical treatment to avoid surgical extirpation in an attempt to maintain organ integrity and preserve organ function. The site-specific roles and treatment outcomes are summarized in the following paragraphs.

22.3.1 Oral Cavity

In general, primary surgery with radical resection and selective neck dissection is recommended for oral cavity cancer as single-modality therapy in stage I and II. Adjuvant radiation therapy should be considered in the presence of perineural or lymphovascular invasion or in cases with close margins.

For stage III and IV disease, radical resection with adjuvant radiation alone or concurrently with chemotherapy should be considered. Factors warranting consideration for radiation therapy include lymphovascular or perineural invasion, level IV nodal involvement, and the presence of multiple nodes. Risk factors warranting the incorporation of chemotherapy concur-

rently with radiation are positive margins at the primary site and extracapsular nodal extension. In high-risk patients receiving adjuvant radiation, the total treatment time from the day of surgery to the end of radiation therapy is best kept to 11 weeks or less.

For patients with locoregionally advanced tumors of the oral cavity tumors who are not candidates for resection, concurrent chemoradiation remains the standard. If definitive radiation therapy is considered, the integration of brachytherapy with external beam radiation has yielded excellent outcomes in patients with oral cavity tumors.

22.3.2 Oropharynx

Early-stage oropharyngeal carcinoma is often treated with a single modality. This can be either a surgical resection or radiation therapy. The decision between these two modalities often depends on the expertise of the treating center and also the expected functional outcome. Chemotherapy is rarely used in treating early-stage oropharyngeal cancer. The overall outcome for patients with early-stage disease is excellent, with a cure rate that often exceeds 90%. Conventionally fractionated radiation therapy alone controls the majority of early-stage oropharyngeal lesions but may be suboptimal for T2 base of tongue and posterior pharyngeal wall cancers. For tonsil cancers, several large single-institutional series have shown excellent local control after conventional fractionated radiation alone (1.8 to 2.0 Gy per dose over 6.5 to 7 weeks to doses of 65 to 70 Gy), approximating 80 to 90% for T1 to T2 lesions and 63% to 74% for T3 lesions.

Ipsilateral External Beam Radiation Therapy for Early-Stage Tonsil Cancer

In general, most lateralized T1 to T2 lesions in patients with an N0 or N1 neck can be treated with ipsilateral radiation fields. Lesions that cross the midline, extensively involve the tongue base or soft palate, or are associated with N2 or more advanced neck disease should receive comprehensive bilateral neck therapy. Such an approach minimizes irradiation to the contralateral salivary glands and reduces the incidence of xerostomia. Eisbruch et al demonstrated that patients treated unilaterally experience less xerostomia and have a better quality of life than do those treated with bilateral IMRT with contralateral parotid sparing.

Many early-stage soft palate and pharyngeal wall cancers are near midline, leaving bilateral neck and retropharyngeal nodes at risk. Therefore, external beam radiation therapy is often preferable because of comprehensive nodal coverage with high rates of control for T1 and T2 lesions, similar to those for tonsil cancers. Also, functional deficits after surgery, such as uvulopalatal insufficiency requiring prosthetic obturators to prevent reflux into the nasopharynx/nasal cavity, can be avoided. Large single-institution series show similarly high rates of local control after external beam radiation therapy alone.

Treatment of Locally Advanced Resectable Disease: Stages III and IV

Radiation alone provides less optimal rates of local control in patients with resectable T3 and T4 lesions or with advanced N2

and N3 neck disease (because of high rates of persistent disease after treatment) compared with combined treatment but may be considered in patients with intermediate-stage cancers (T1/T2 N1 or T3 N0). However, the majority of patients with oropharyngeal cancer will present with stage III or stage IV disease and do require a multimodality approach that combines chemotherapy, radiation therapy, and surgery. The choice of the modality to be used often depends on the treating team and its experience. The options include the following: (1) Surgery followed by radiation therapy or chemoradiation. (2) Concurrent chemoradiotherapy, which is considered by many to represent the standard of care in the treatment of patients with locally advanced oropharyngeal cancer. The agent most studied is bolus cisplatin at 100 mg/m² given every 3 weeks during radiation. Patients who cannot tolerate this dose and schedule of platinum can be treated with weekly chemotherapy with paclitaxel/carboplatin, cisplatin, or cetuximab. (3) Sequential induction chemotherapy followed by radiation therapy or concurrent chemoradiotherapy. The induction chemotherapy regimen that is most widely used is TPF, given every 3 weeks for a total of three cycles, followed by radiation alone or radiation with weekly carboplatin.

For patients with T4 or N3 disease, chemoradiation therapy or sequential induction chemotherapy followed by concurrent chemoradiotherapy is considered. Sequential chemoradiotherapy is preferable for this group of patients if they have good performance status because they have a worse prognosis than the group with resectable disease, with a cure rate of 25 to 40% at 5 years.

Human Papillomavirus–Related Oropharyngeal Carcinoma

Recently, infection with the human papillomavirus (HPV), especially HPV-16, has been identified as the predominant risk factor in the Western world for developing oropharyngeal cancer. It is currently estimated that 50 to 60% of cases of oropharyngeal cancer are related to HPV-16. The major characteristics of this entity are the following:

- Patients are about 10 years younger than those with smoking- or alcohol-related oropharyngeal cancer. Many patients with HPV-related oropharyngeal cancer are in their forties and early fifties.
- Patients are often nonsmokers and nondrinkers.
- Patients typically present with a small primary lesion and bulky lymphadenopathy.
- The pathology specimen often has a “basaloid” appearance.
- The prognosis is excellent. Patients with HPV-related oropharyngeal cancer, even those with locally advanced disease, have excellent survival, with a cure rate that often exceeds 85 to 90%. This has led to the development of clinical trials targeted specifically toward this patient population. Until those trials are completed, treatment should not be modified based on HPV status.

HPV status can be checked via fluorescent in situ hybridization (FISH) or polymerase chain reaction (PCR). Alternatively, p16 immunohistochemistry can serve as a surrogate for HPV infection and be used to assess HPV status. These tests are all performed on the surgical specimen. It is strongly recommended

that the HPV status of all patients with oropharyngeal cancer be assessed, given its prognostic implications.

Brachytherapy for Oropharyngeal Cancer

Brachytherapy has been a mainstay treatment for oropharyngeal cancers for decades, and excellent results have been reported. Brachytherapy, or the implantation of radioactive seeds directly into the target volume, allows escalation of the dose to the tumor and the sparing of surrounding normal tissue by inverse-square attenuation, producing excellent dose conformality. Normal tissue toxicity is further lessened because the dose of external beam radiation is reduced, which is especially important in those receiving concurrent chemotherapy.

Consistently excellent results with the use of this approach for base of tongue disease have been reported by multiple centers. Moreover, it has been demonstrated that such an approach improves the chance for swallowing preservation compared with conformal external beam radiation alone.

22.3.3 Nasopharynx

Nasopharyngeal carcinomas are located in a highly enriched lymphatic drainage area, which favors early regional spread to the retropharyngeal and cervical nodes (unilaterally and bilaterally). The primary tumor exists in an occult location with a propensity to invade the skull base, surrounding sinuses, nerves, and soft-tissue spaces before presenting clinically. Radiation therapy has been the mainstay treatment because it can cover the large areas of potential locoregional spread. Advances in radiation delivery with IMRT, imaging, integration of chemotherapy, standardization of an internationally agreed-upon staging system, multidisciplinary care, and scientific exchange have led to significant improvements in tumor control and quality of life.

In general, patients with early-stage tumors are amenable to treatment with radiation therapy alone with high rates of locoregional control, whereas those with T3 or T4 lesions or significant nodal disease require more intensive chemoradiation treatment because outcomes with radiation therapy alone have been associated with higher rates of locoregional failure and distant metastases.

Patients with early-stage disease account for fewer than 10% of all patients with nasopharyngeal cancer and may be treated with radiation therapy alone. Conventional fractionation and two-dimensional technique have shown generally good locoregional control rates for early-stage tumors but suboptimal outcomes for locoregionally advanced tumors. After conventional radiation, local control is obtained in 75 to 95% of T1/T2 tumors, compared with 44 to 80% of T3/T4 tumors. Improvement in early-stage disease control has been obtained by either dose escalation with brachytherapy or improved conformal technique. Moreover, with conformal techniques, improved preservation of salivary gland function, hearing, and overall quality of life has been demonstrated.

Although excellent outcomes are obtained in the treatment of early-stage disease with radiotherapy alone, 20 to 60% of patients with advanced-stage disease experience locoregional failure after radiotherapy only and high rates of distant metastases (50 to 70%), with 5-year overall survival rates of 28 to 56%

In the United States, the standard of care is concurrent chemoradiation with cisplatin chemotherapy and radiation followed by three cycles of adjuvant chemotherapy comprising 5-fluorouracil and cisplatin. The basis for such treatment is the landmark Phase III randomized Intergroup Study 0099, which demonstrated that compared with radiation alone, the addition of three cycles of CDDP (cis-diamminedichloroplatinum) to radiation therapy followed by adjuvant CDDP/5-fluorouracil improved 3-year locoregional control and decreased the incidence of distant metastases, which translated into an approximate 10% increase in 3-year progression-free and overall survival. In the chemoradiation arm, there was a higher incidence of grade 3/4 leukopenia and vomiting. Compliance with the planned regimen was compromised because only two-thirds of the patients were able to complete all three cycles of concurrent cisplatin, with an additional one-fourth able to complete two concurrent cycles. Only 60% of patients received two to three planned cycles of adjuvant chemotherapy. Alternative schedules used outside the United States have included weekly cisplatin (40 mg/m²) with radiation alone without adjuvant chemotherapy and induction chemotherapy followed by chemoradiation.

22.3.4 Hypopharynx

Patients with early-stage disease constitute about 25% of all those who present with hypopharyngeal cancers. Important goals in patients with T1 or T2 resectable disease are to obtain local control while optimizing swallowing and voice preservation, which can be accomplished with either conservation surgery or radiation therapy. Neck management is indicated even in patients with N0 disease, who will have a 30 to 40% risk for occult neck metastases.

Early-stage lesions, including T1 or low-bulk T2 hypopharyngeal squamous cell carcinomas, may be effectively treated with external beam radiation therapy, especially when the tumors are exophytic and do not involve the apex. Radiation has the advantage of sterilizing occult and early cervical metastases, obviating the need for nodal dissection. The local control rates for T1/T2 lesions treated with radiation therapy alone vary widely depending on the series, radiation technique/dose, patient selection factors, and neck staging. Taken together, local control varies from 47 to 90% and 5-year survival varies from 11 to 52%. In general, the best results have been obtained with conventional fractionation to doses higher than 65 Gy for T1 lesions and hyperfractionated radiation for T2 lesions in large single-institution series.

Primary resection is most often considered for advanced, bulky hypopharyngeal cancers because tumor control and organ preservation are suboptimal after nonsurgical therapy, and patients often have morbidity such as chronic aspiration due to the destruction of normal tissues by the tumor or treatment. In such a setting, total laryngectomy with partial or total pharyngectomy must be considered mandatory, followed by adjuvant radiation with or without chemotherapy.

For advanced-stage lesions, laryngopharyngectomy followed by postoperative radiation with or without chemotherapy is standard treatment. Small tumors with nodal involvement and nonbulky T3 lesions may be considered for management with radiation therapy and chemotherapy. In this setting, induction chemotherapy followed by radiation alone has been considered

Fig. 22.2 Early-stage glottic larynx cancer treated with opposed lateral fields in the two-dimensional technique. The top and bottom borders are positioned to account for larynx motion during treatment. Note that the lymph nodes were not electively treated. PTV, planning target volume.

as well as an alternative to concurrent chemoradiation in an effort to minimize long-term swallowing complications resulting from fibrosis. Patients who are to be considered for induction up front should be evaluated for a three-drug regimen with TPF because this improves the chance for organ preservation compared with two-drug therapy. The addition of docetaxel to PF increases larynx preservation. Standard concurrent treatment consists of three doses of cisplatin with 7 weeks of radiation therapy.

For selected patients with advanced hypopharyngeal tumors who have good laryngopharyngeal function, combined-modality therapy with primary chemoradiation may be considered. Radiation alone results in suboptimal rates of local control in patients with T3/T4 lesions or with advanced N2/N3 neck disease because of high rates of persistent disease. Induction chemotherapy followed by radiation therapy or concurrent chemoradiation is the best treatment option.

22.3.5 Larynx

Glottic Larynx

Early-stage vocal fold lesions are highly curable because they have a low propensity for nodal metastasis and can be managed with single-modality treatment. Surgery or radiation is considered for early-stage lesions, whereas most often a combination of chemotherapy, surgery, and radiation is considered for advanced lesions. For advanced lesions, multidisciplinary treatment is designed to maximize tumor cure, preserve organ function, address regional spread, and be tailored to the patient's comorbidities and preferences.

Radiation therapy without chemotherapy offers an excellent chance for tumor control and organ function preservation in early-stage disease. Current techniques use simple opposed lateral fields to treat the larynx, typically prescribing 63 to 65 Gy in 28 or 29 fractions over 5 1/2 weeks (□ Fig. 22.2). Treatment to the larynx alone without elective nodal coverage spares treatment of the major salivary glands, mandible, and oropharynx/oral cavity. The treatment time and total dose are important. The total duration of treatment is ideally less than 6 weeks. For patients with T2 lesions and impaired vocal cord mobility, a hyperfractionated radiation schedule can improve local control, albeit with increased acute toxicity. T2 lesions that invade areas of the supraglottic larynx may require elective nodal treatment. For T1 and T2 lesions, rates of local control are typically greater than 90% and 80% respectively.

Total laryngectomy followed by postoperative radiation therapy once represented the standard of care for advanced glottic laryngeal cancers. However, in the Department of Veterans Affairs (VA) Laryngeal Cancer Study, organ preservation was achieved in two-thirds of patients undergoing induction chemotherapy with three cycles of 5-fluorouracil/cisplatin followed by radiation without compromise of survival in comparison with the control arm of total laryngectomy and postoperative radiation. A subsequent landmark randomized intergroup trial of patients with primarily T2/T3 tumors compared the VA regimen with concurrent chemoradiation with high-dose cisplatin or radiation alone and demonstrated that concurrent chemoradiation is superior to the VA regimen in improving larynx preservation (from 75 to 88%) and represents the current standard of care. No difference in overall survival was noted among all three arms because of high surgical salvage rates.

Thus, for patients with good performance status, 7 weeks of daily radiation to deliver 70 Gy given concurrently with high-dose cisplatin at 100 mg/m² for three cycles is recommended. More intensive induction regimens consisting of three drugs (TPF) followed by radiation alone have also improved organ preservation and may serve as an alternative to concurrent chemoradiation. The two approaches have not been compared in a randomized setting for larynx cancers.

In debilitated patients who are unable to tolerate standard chemotherapy, other options include radiation therapy alone or radiation therapy with a biologic therapy consisting of a monoclonal antibody targeting the EGFR.

For patients undergoing radiation therapy alone, a course of altered fractionated radiation therapy may be considered with either hyperfractionation or accelerated radiation by delayed concomitant boost, based on the outcomes favoring these two schedules over conventional once-daily treatment reported in RTOG 90-03.

The patients excluded from the above studies had tumors that invaded cartilage and/or extended outside the larynx into soft tissues. For these patients, total laryngectomy followed by adjuvant radiation with possible concurrent chemotherapy is the standard treatment.

Supraglottic Larynx

Patients with tumors located in the supraglottic larynx, even early-stage tumors, require management of the neck because regional involvement is likely regardless of stage. The primary tumor can spread into the paralaryngeal space and cause vocal cord fixation, into the pre-epiglottic space with extension into the tongue base, through the thyroid cartilage into the soft tissues outside the larynx, and laterally into the hypopharynx.

T1/T2 lesions of the supraglottic larynx require management of the primary site with elective treatment of the draining lymph nodes at levels II through IV. Like early-stage vocal cord cancers, these tumors may be managed with single-modality therapy. Radiation consists of 66 to 70 Gy to treat the primary site and elective neck therapy to a dose of 50 to 54 Gy. With conventional technique, the superior aspects of the parotid glands may be spared, in addition to the superior constrictor muscles.

For patients who have advanced supraglottic cancers, chemoradiation is recommended if they have an appropriate performance status and good baseline laryngopharyngeal function, whereas primary resection followed by adjuvant radiation is recommended for patients who have disease with extralaryngeal spread or poor baseline function.

Subglottic Larynx

Tumors located under the vocal cords are rare and clinically difficult to visualize, even with endoscopy, requiring examination under anesthesia. Because of their occult nature, they often present as advanced lesions invading the trachea and soft tissues of the neck. Such tumors may spread to the inferior cervical nodal chains as well as the superior mediastinal nodes. Radiation therapy may be considered to cover the tumor and extensive lymphatic drainage area, whereas a combined a surgical approach may best for T4 lesions.

22.4 Toxicity of Radiation Therapy: Optimizing Patient Outcomes

The major sequelae of radiation therapy can be divided into acute and chronic side effects. These depend on total dose, fraction size, fractionation, prior or concomitant therapy (i.e., surgery or chemotherapy), and target volume. Mucositis is the major dose-limiting toxicity of radiation. Severe mucositis can result in treatment breaks, which can compromise locoregional control and cause infection in patients compromised by chemotherapy. Xerostomia is the most pervasive chronic side effect of radiation therapy (□ Table 22.1).

In order to optimize the chance for successful radiation therapy, patients must avoid smoking during treatment (smoking increases radiation resistance of the tumor) and be highly compliant with the radiation schedule, avoiding treatment delays totaling more than 5 days during the course of treatment, and they must be proactive with supportive measures to complete treatment. Patients should undergo a pretreatment evaluation with a speech/swallowing team, nutritionist, and pain management and psychosocial service team to help them cope with the acute and chronic effects of treatment. A pre-irradiation dental evaluation should include Panorex imaging, dental extractions if indicated, and provision of a fluoride tray, which may be useful for patients with fillings to wear during radiation therapy treatments as fillings may cause increased mucositis from radiation scatter.

22.4.1 Acute Side Effects

Patients usually begin to experience morbidity from radiation during the third week of treatment in the form of dermatitis, decreased mucus production, sore throat, hoarseness, dysphagia, fatigue, dysgeusia, and xerostomia. Rarely, within the first week of treatment, patients may develop a parotitis related to inspissated mucus from xerostomia. By the second half of the treatment, as symptoms intensify, most patients require creams/emollients for skin desquamation, mucolytics, narcotics for pain, antiemetics, and a change of diet soft solids and liquid nutritional supplements. Gastrostomy tube placement may be considered for patients not deemed strong enough to proceed through treatment, especially patients receiving concurrent chemoradiation. Patients may develop severe weight loss, which will impair their ability to heal and to complete treat-

Table 22.1 Complications of chemoradiation treatment

Complication	Incidence (%)
Dysgeusia	90
Chewing, eating difficulties	80
Xerostomia	78–95
Anorexia, weight loss, malnutrition	55–85
Dysphagia	40–65
Mucositis, stomatitis	35–75
Infection	14
Osteoradionecrosis	5–15

ment. It is important to minimize treatment breaks during therapy because impaired tumor control has been shown to occur, especially with treatment break days of more than 5 days.

22.4.2 Chronic Side Effects

Patients will recover for several weeks to several months after treatment and will typically be off medications by 4 to 6 weeks after treatment. Important long-term side effects include fibrosis of the neck and masticatory muscles, epilation, chondronecrosis, dysphagia, hypothyroidism, and xerostomia. Preventive swallowing exercises are important to minimize cricopharyngeal stricture and fibrosis of the swallowing muscles (which can lead to aspiration and feeding tube dependence). Dental decay and osteoradionecrosis may best be prevented by meticulous dental hygiene and avoidance of dental extraction/implantation.

22.5 Directions for Future Research

The RTOG-H5022 randomized trial will test whether the addition of C225 to concurrent chemoradiation consisting of accelerated radiation by delayed concomitant boost with two cycles of CDDP improves outcome versus concurrent chemoradiation alone.

Given the excellent outcomes achieved with present regimens in HPV-positive patients who have oropharyngeal cancer, multiple institutions and cooperative groups are exploring the possibility of treatment deintensification. Lower doses of radiation and fewer cycles of chemotherapy may be used to obtain similar results but decrease toxicity.

For patients who require treatment intensification because of very aggressive disease, several approaches have been explored including the addition of induction chemotherapy, escalation of radiation dose, such as the application of a brachytherapy boost and integration of biologic therapies to concurrent chemoradiation. Other approaches include identifying radioprotectants to decrease mucositis and improving radiation treatment techniques to preserve organ function and allow patients to complete treatment and maintain quality of life. For example, dysphagia-oriented IMRT is being studied to reduce the risk for long-term dependence on tube feeding after chemoradiation by decreasing the dose to structures important in swallowing, such as constrictor muscles.

Incorporating imaging characteristics and molecular profiling represent important efforts to further individualize treatment to find the right balance of treatment intensity so as to eradicate disease with tolerated doses that best maximize organ preservation and cosmesis.

22.6 Roundsmanship

- Radiation works primarily by causing reproductive cell death such that tumors are unable to replicate. The target of treatment is the tumor DNA, in which free radical formation from ionizing radiation therapy causes permanent double-strand breakage.
- Normal tissues have a greater capacity than tumor cells to repair themselves after radiation exposure. Fractionation ex-

ploits the repair differential by using doses that are high enough to kill tumors but that spare the function and integrity of normal tissue.

- In general, radiation doses of 50, 60, and 70 Gy are required for elective treatment, microscopic residual disease, and gross tumor, respectively.
- Head and neck squamous cell carcinomas have the unique characteristic of delayed accelerated tumor repopulation during radiation therapy. The phenomena of on-treatment repopulation and differential repair ability underlie the rationale for several altered fractionated radiation regimens proven to improve locoregional control. Shortening the duration of treatment and escalating the dose with hyperfractionation have yielded significant gains.

23 Diseases and Neoplasms of the Oral Cavity

Helen Yoo Bowne

23.1 Introduction

The oral cavity is the portal of entry for the aerodigestive tract, and its functions include taste, mastication, digestion of food, swallowing, and speech. Bordered anteriorly by the vermillion and posteriorly by the soft palate superiorly and circumvallate papillae inferiorly, the subunits of the oral cavity consist of the lips, buccal mucosa, upper and lower alveolar ridges, retromolar trigone, oral tongue (anterior two-thirds of the mobile tongue), hard palate, and floor of mouth (□ Fig. 23.1).

23.2 Applied Anatomy

The mucosa lining the oral cavity is largely squamous epithelium interspersed by 1,000 minor salivary glands. The minor salivary glands are concentrated in the hard and soft palate. The alveolar ridge is composed of the osseous alveolar process and overlying gingiva lined by mucosa. The floor of mouth mucosa is supported by the mylohyoid, geniohyoid, and genioglossus muscles. The sublingual gland and numerous minor salivary glands lie between the mucosa and these muscles.

The anterior two-thirds of the mobile tongue are lined by squamous epithelium. The dorsum of the tongue is also lined by fungiform, filiform, and circumvallate papillae. The intrinsic muscles of the tongue, which include the superior longitudinal, inferior longitudinal, vertical, and transverse muscles, are sepa-

rated at the midline by the median raphe, and their muscular functions produce speech and swallowing. The extrinsic muscles of the tongue (genioglossus, hyoglossus, styloglossus, and palatoglossus) also assist in the movement of the tongue backward, forward, upward, and downward.

The motor supply to the lips and cheek via the orbicularis oris and buccinator muscles is provided by the facial nerve. The hypoglossal nerve innervates the intrinsic and extrinsic muscles of the tongue. The muscles that control the movement of the mandible include the masseter, temporalis, and medial and lateral pterygoids, controlled by the second and third divisions of the trigeminal nerve. Sensory innervation of the oral cavity is supplied by the superior and inferior alveolar and lingual nerves (branches of second and third divisions of the trigeminal nerve). Taste is mediated by the innervation of the chorda tympani and secretomotor fibers to the submandibular salivary gland, which travel with the lingual nerve.

The vascular supply to the oral cavity consists of the branches of the external carotid artery. The lingual arteries supply the tongue, while facial arteries support the buccal mucosa and lips and the internal maxillary and inferior alveolar arteries supply the alveolar ridges. The lymphatics of the oral cavity drain to the submental, submandibular, and upper jugular–jugulodigastric lymph nodes. There is direct lymphatic drainage to the lower jugular lymph nodes from the tongue. The upper alveolar ridge and buccal mucosa also drain to buccinator lymph nodes.

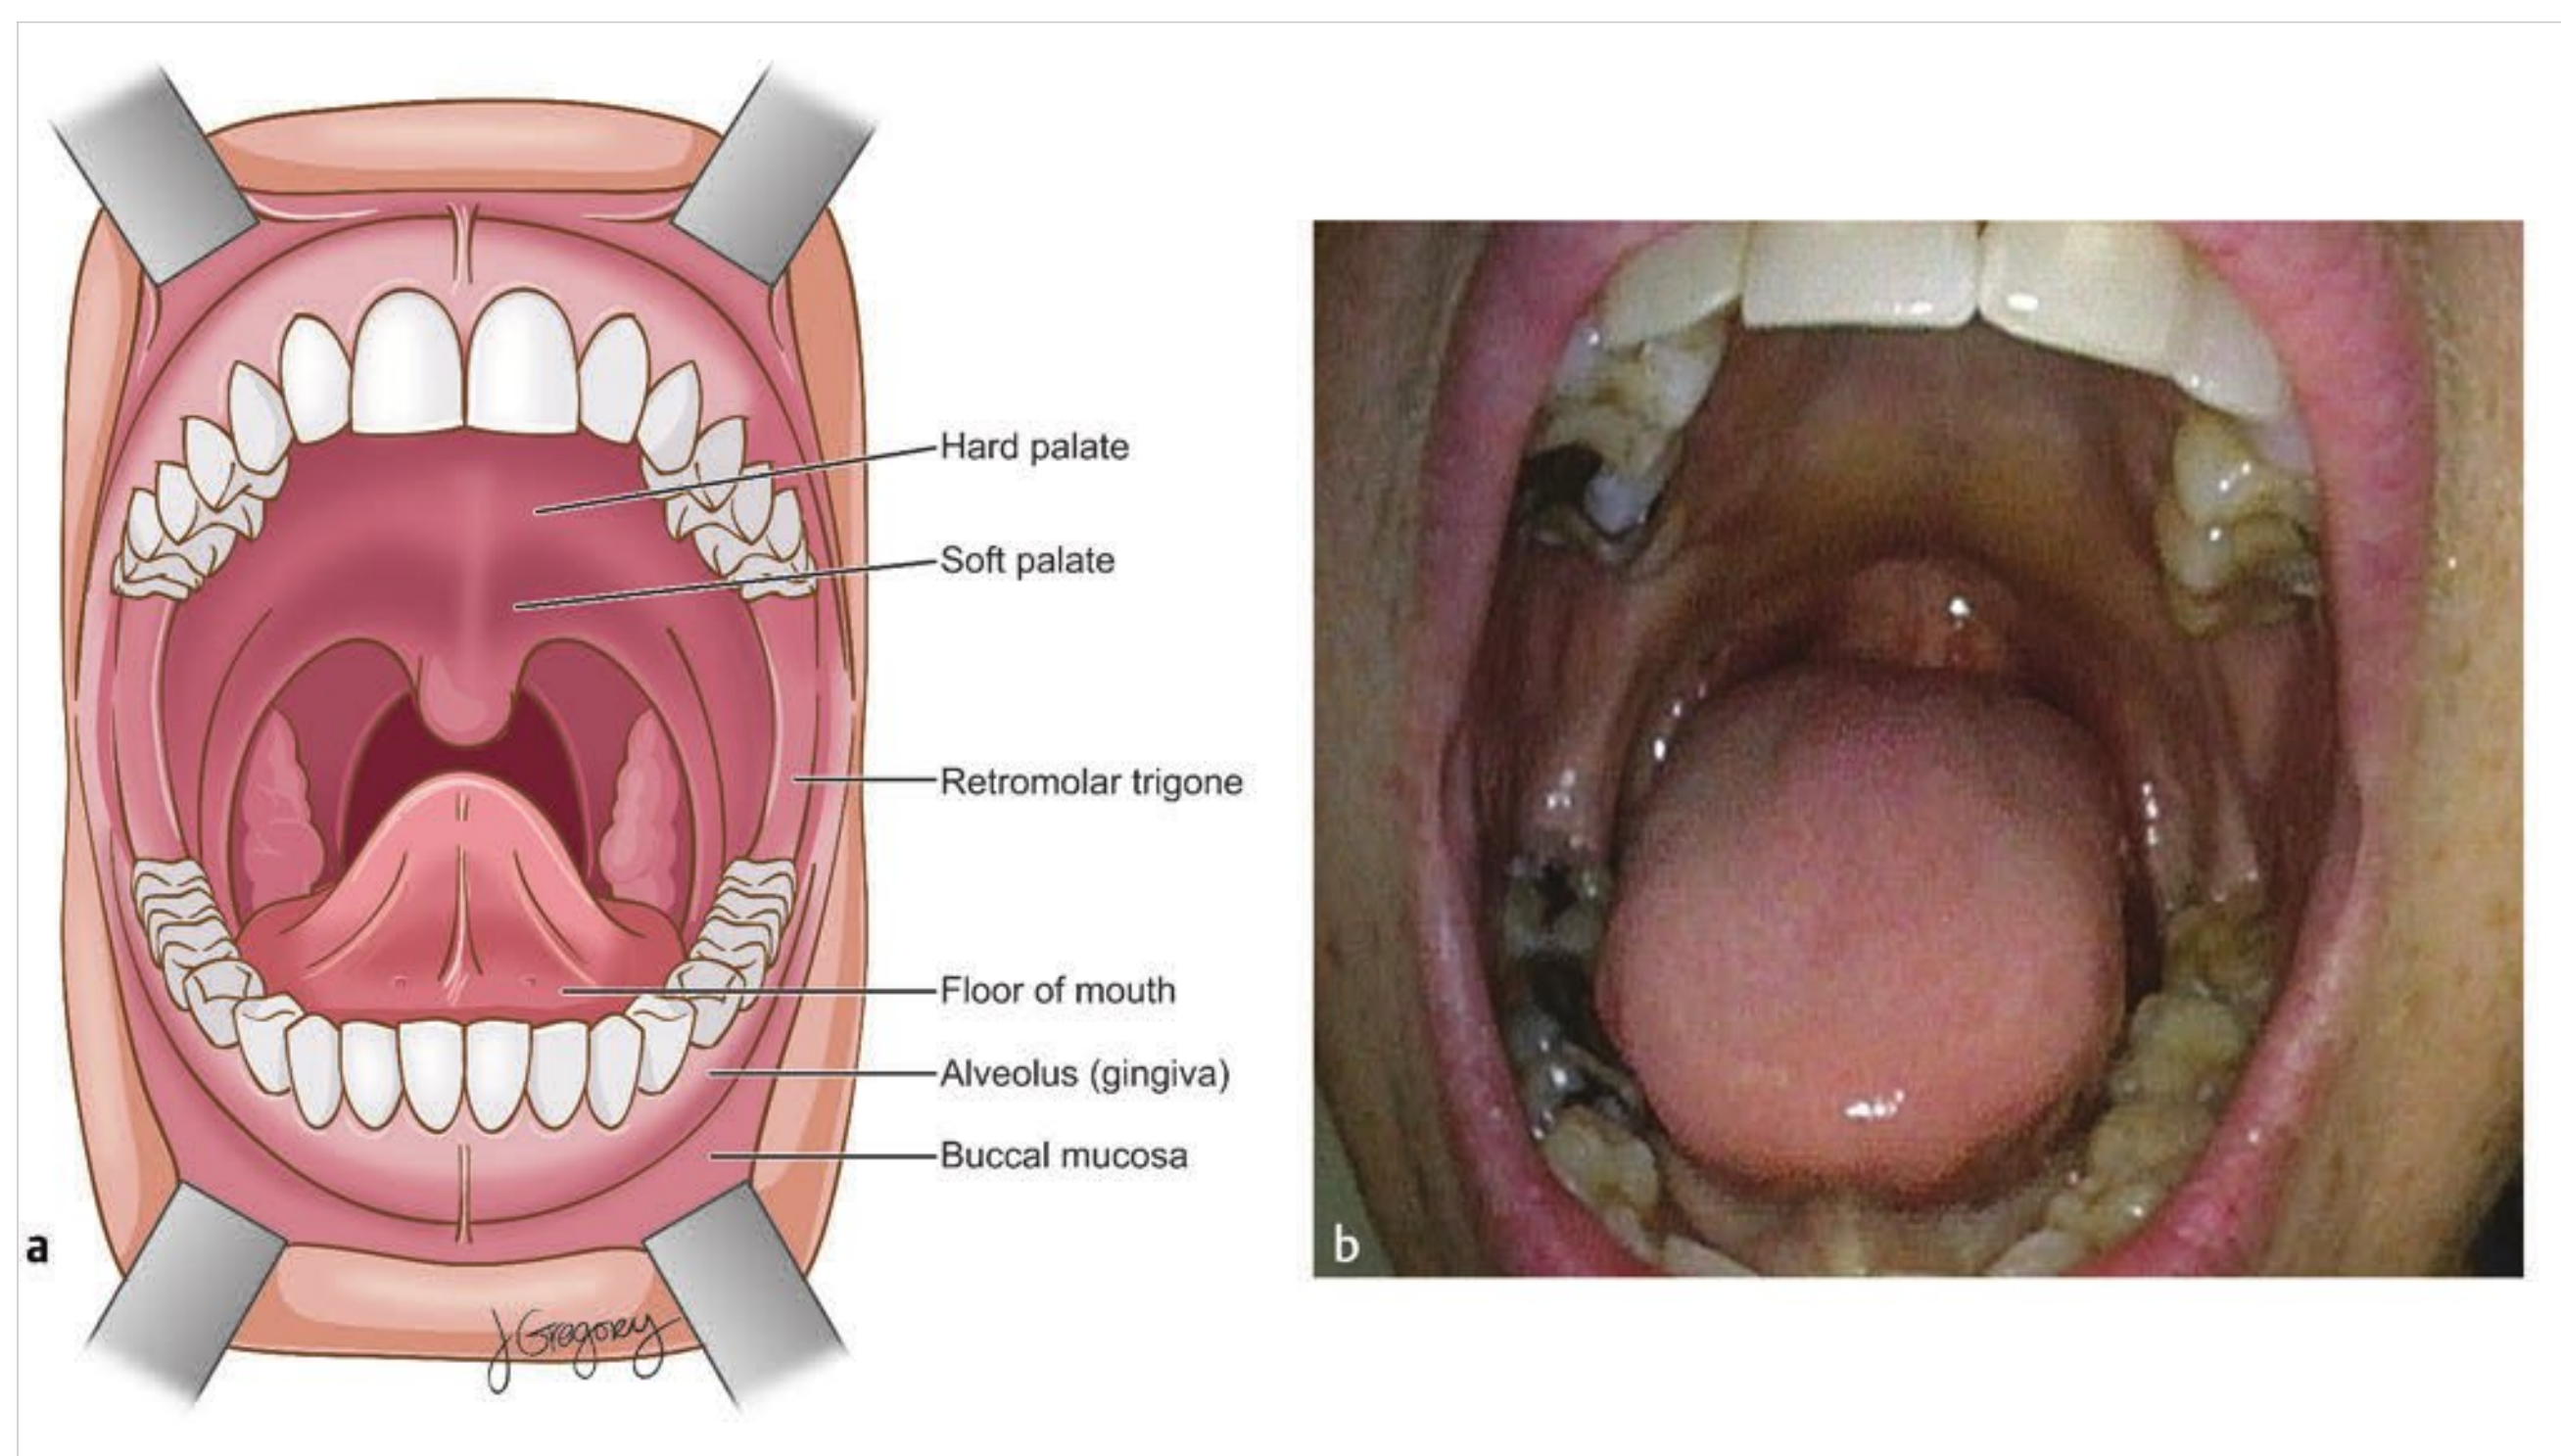

Fig. 23.1 (a) Drawing and (b) photo showing structures of the oral cavity, including the lip, alveolus (gingiva), hard palate, buccal mucosa, retromolar trigone, floor of mouth, and tongue.

23.3 Classification of the Disease Process

Diseases of the oral cavity may be classified into neoplastic and nonneoplastic processes. Benign and malignant neoplastic diseases may originate from the mucosa, salivary glands, or mesenchymal tissues, including bone, muscle, and fibroblastic tissues. Malignant neoplasms may be squamous cell carcinomas, adenocarcinomas, sarcomas, or other, less common cancers, such as mucosal melanomas, malignant peripheral nerve sheath tumors, or granular cell tumors. Benign neoplasms of the oral cavity may be pleomorphic or monomorphic adenomas, papillomas, fibromas, neurilemmomas, leiomyomas, pyogenic granulomas, benign melanonevi, or various benign odontogenic tumors. Nonneoplastic diseases consist of cysts (e.g., ranula and mucocele) and inflammatory conditions, which may be classified as (1) infections, (2) oral manifestations of systemic disorders, or (3) various medical conditions. Infectious diseases and head and neck manifestations of systemic disease affecting the oral cavity are covered in Chapter 13 and Chapter 19.

23.4 Malignant Neoplasms of the Oral Cavity

23.4.1 Incidence and Etiology

Oral cavity cancers account for 30% of all head and neck malignancies. Yearly, 22,000 new cases of oral cavity cancers (excluding lip cancers) are diagnosed, and oral cavity cancers are responsible for 6,000 to 7,000 deaths per year. The most common malignancy of the oral cavity is squamous cell carcinoma (95%). The most common location of carcinoma of the oral cavity is the oral tongue, followed by the floor of mouth. Risk factors associated with squamous cell cancer are the following: (1) tobacco exposure in any form (cigarettes, cigars, pipes, and chewing tobacco); (2) alcohol consumption (risk is increased when both tobacco and alcohol are consumed); (3) chewing betel quid (a common practice in south central Asia and Melanesia); and (4) infection with carcinogenic strains of human papillomavirus (HPV-16 and HPV-18), as well as sun exposure for lip carcinoma.

23.4.2 Pathogenesis

The carcinogenesis of squamous cell cancers is associated with mutagenic environmental exposure to tobacco, alcohol, betel products, and HPV, coupled with genetic susceptibility and predisposition. Progression to cancer is thought to occur in multiple steps, causing alterations in tumor suppressor genes and oncogenes. A variety of genetic changes have been reported in head and neck squamous cell carcinoma. They include p16 inactivation (70%) via deletion (predominantly) or promoter methylation and amplification, p53 mutation (50 to 80%), HPV integration (25% in oropharyngeal cancer), and epidermal growth factor receptor (EGFR) axis alteration (80 to 90%) via amplification, overexpression, and downstream activation.

Loss of 9p21 results in inactivation of the p16 gene, which inhibits cyclin-dependent kinase (CDK) involved in G1 cell cycle regulation, and inactivation of this protein enables cells to escape senescence. Loss of chromosome 9p21 occurs in the majority of invasive tumors and is also frequently present in dysplasia and carcinoma in situ. Loss of p16 appears to be necessary for the immortalization of keratinocytes.

When DNA damage is detected, p53 normally stops cell cycle progression. Loss of p53 function from mutations permits the progression of cancers from preinvasive to invasive lesions. A p53 mutation is prevalent in patients who smoke and drink alcohol. Squamous cell carcinoma induced by HPV-16 and HPV-18 is not associated with p53 mutations. Instead, the viral oncoprotein E6 promotes increased degradation of p53.

EGFR expression is normal in tissues of the dermis, gastrointestinal tract, and kidneys. However, dysfunction of this receptor occurs in 80 to 90% of head and neck squamous cell carcinomas. EGFR is related to multiple pathways controlling cellular proliferation, apoptosis, invasion, angiogenesis, and metastasis. There are numerous additional genetic alterations that play a role in carcinogenesis, proliferation, invasion, and metastasis. Research and technology advancement in the future will help elucidate and further clarify the pathogenesis of carcinoma and eventually lead to more specifically targeted therapies.

23.4.3 Natural History and Progression

Often, premalignant changes related to epithelial and subepithelial disturbances may appear as leukoplakia (white lesions; □ Fig. 23.2) or erythroplasia (red lesions). Histologically, this may represent hyperkeratosis, parakeratosis, and dysplasia as a result of keratin and/or cytoplasmic changes. The risk for the development of invasive carcinoma in leukoplakia is 4 to 6% whereas the risk is as high as 30% in erythroplasia. Progression of the severity of dysplasia leads to carcinoma in situ, then frank invasion and subsequent metastasis to local and regional cervical lymph nodes. In some patients, progressive cytologic changes that are not apparent may develop into invasive squamous cell carcinoma. Eventually, distant metastasis to lung,

Fig. 23.2 Leukoplakia of the floor of mouth.

Fig. 23.3 Squamous cell carcinoma of the hard palate arising from squamous papilloma.

liver, and bone occurs. If left untreated, the disease is fatal. Treatment at earlier stages of disease is associated with improved survival and cure rates.

23.4.4 Potential Disease Complications

Complications of untreated oral tongue cancer include severe pain with impaired speech and swallowing, which can lead to aspiration pneumonia and significant morbidity. As a result of poor oral intake due to pain or dysphagia, malnutrition is a common problem. Invasion of the surrounding tissues, such as the nasal cavity, by cancers arising from the hard palate (□ Fig. 23.3) or upper alveolus may cause nasal obstruction and bleeding. Involvement of the pterygoid muscles will cause severe pain and problems with mastication as well as trismus. Tumors of the buccal mucosa can perforate the skin, and lesions of the gingiva will erode the mandible (□ Fig. 23.4).

23.4.5 Disease Staging: American Joint Committee Cancer Staging

Although invasion to a depth of more than 2 mm and higher histologic grade are associated with an increased risk for lymph node metastasis, the current tumor (T) grading system is based on the size of the primary lesion. T1 lesions are smaller than 2 cm, T2 lesions are 2 to 4 cm, and T3 lesions are larger than 4 cm. T4 lesions are more extensive; T4a disease includes invasion of underlying soft tissues, bone, or overlying skin, whereas T4b lesions are very advanced, with invasion of the masticator space, pterygoid plates, and skull base with or without internal carotid artery encasement.

Involved lymph nodes are classified by size and laterality. N1 nodal disease is involvement of a single ipsilateral lymph node 3 cm or less in size. N2 disease is more extensive; N2a disease is involvement of a single ipsilateral lymph node larger than 3 cm but smaller than 6 cm; N2b disease is involvement of multiple ipsilateral nodes (none larger than 6 cm), and N2c disease is involvement of bilateral or contralateral lymph nodes, none larger

Fig. 23.4 Floor of mouth carcinoma with erosion of the mandible.

Fig. 23.5 Oral tongue cancer on the lateral surface with ulceration.

than 6 cm. Finally, any nodal metastasis larger than 6 cm is classified as N3 disease.

For the classification of oral cavity cancers, stage 0 is an in situ primary lesion with no nodal or distant metastases. Stage I disease is a T1 lesion and stage II is a T2 lesion, each with no nodal or distant metastases. Stage III disease is a T3 lesion with no nodal or distant metastases, as well as any T1–T3 lesion with N1 nodal disease and no distant metastases. Stage IV disease is divided in IVA, IVB, and IVC disease. A T1–T3 lesion with N2 nodal disease or a T4a primary lesion with N0–N2 nodal disease is stage IVA disease. Stage IVB disease includes any primary tumor or with N3 nodal disease or a T4b lesion with any nodal state. Any distant metastasis establishes stage IVC disease.

23.4.6 Presenting Complaints and Clinical Findings

Presenting symptoms include persistent ulcers for more than 3 weeks, pain at the site of the lesion, pain on swallowing, referred otalgia, altered speech, and a lump in the neck. The clinical presentation of oral cavity malignancies may be ulcerative and endophytic with underlying firm and indurated soft-tissue components. Pain is usually severe with ulcerated lesions and with lesions located in the lateral border of the tongue (□ Fig. 23.5) and adjacent floor of mouth. Carcinomas arising

Fig. 23.6 (a) Lateral tongue and (b) lateral floor of mouth squamous cell carcinoma arising from leukoplakia.

from squamous papillomas may have papillary projections, and exophytic lesions may exhibit keratotic, verrucous, and cauliflower appearances. Occasionally, a superficial leukoplakic lesion presenting for a prolonged period of time with benign pathology may change and progress to carcinoma (□ Fig. 23.6). Bleeding from the surface of these lesions is highly suggestive of friability and malignancy.

23.4.7 Medical Evaluation and Physical Examination

A comprehensive history, including the patient's social history and etiologic risk factors such as tobacco and alcohol use and a family history of cancer, should be obtained. A complete head and neck examination including fiber-optic nasopharyngolaryngoscopy is performed. Palpation of tumors to delineate the extent of the lesion and inspection of tumors in proximity to adjacent mandible and maxilla are essential. Occasionally, examination under general anesthesia with biopsy is indicated for severely painful tumors that cannot be thoroughly evaluated in the office. A wedge or punch biopsy of tissue including the periphery of the lesion and sufficient depth is needed to establish the diagnosis and detect invasion.

23.4.8 Testing

In addition to obtaining a diagnosis with a tissue biopsy, the examiner routinely has specimens assessed for the presence of HPV because this is associated with improved survival and favorable response to treatments. Although the guidelines for the treatment of HPV-positive tumors have not yet changed compared with those for tobacco-related squamous cell carcinomas, studies are under way to determine whether adjustments in the current standard of care with decreased side effects can be achieved.

Once the diagnosis is established by biopsy, imaging studies, including computed tomography (CT) with intravenous contrast or magnetic resonance (MR) imaging of the neck and positron emission tomography (PET)-CT, is recommended to complete the staging of cancer. CT is essential in determining bone invasion by tumor, and MR imaging is superior for soft-tissue details. PET-CT will provide advanced information regarding the patient's pulmonary status and occasionally second synchronous primary cancers or distant metastases.

23.4.9 Differential Diagnosis

The differential diagnosis of lesions of the oral cavity representing squamous cell carcinoma includes, in order of frequency, minor salivary gland malignancies and adenocarcinomas such as mucoepidermoid carcinoma, adenoid cystic carcinoma, and low-grade polymorphous adenocarcinoma. Mucosal melanomas (□ Fig. 23.7) and other rare tumors such as lymphomas and sarcomas (including rhabdomyosarcoma, liposarcoma, and malignant fibrous histiocytoma) should also be included in the differential. Although rare, granular cell tumors and metastatic disease from another primary site are also possibilities.

23.4.10 Medical and Surgical Treatments and Complications

The three main modalities of treatment of oral cavity cancer are surgery, radiation therapy, and chemotherapy. Early-stage cancers (stages I and II) can be treated effectively with one modality (either surgery or radiation alone). For advanced-stage cancers (stages III and IV), a minimum of two combined treatment options is required, and for very advanced cases, all three modalities are required. Even early-stage cancers with pathologic features suggestive of aggressive behavior, such as extracapsu-

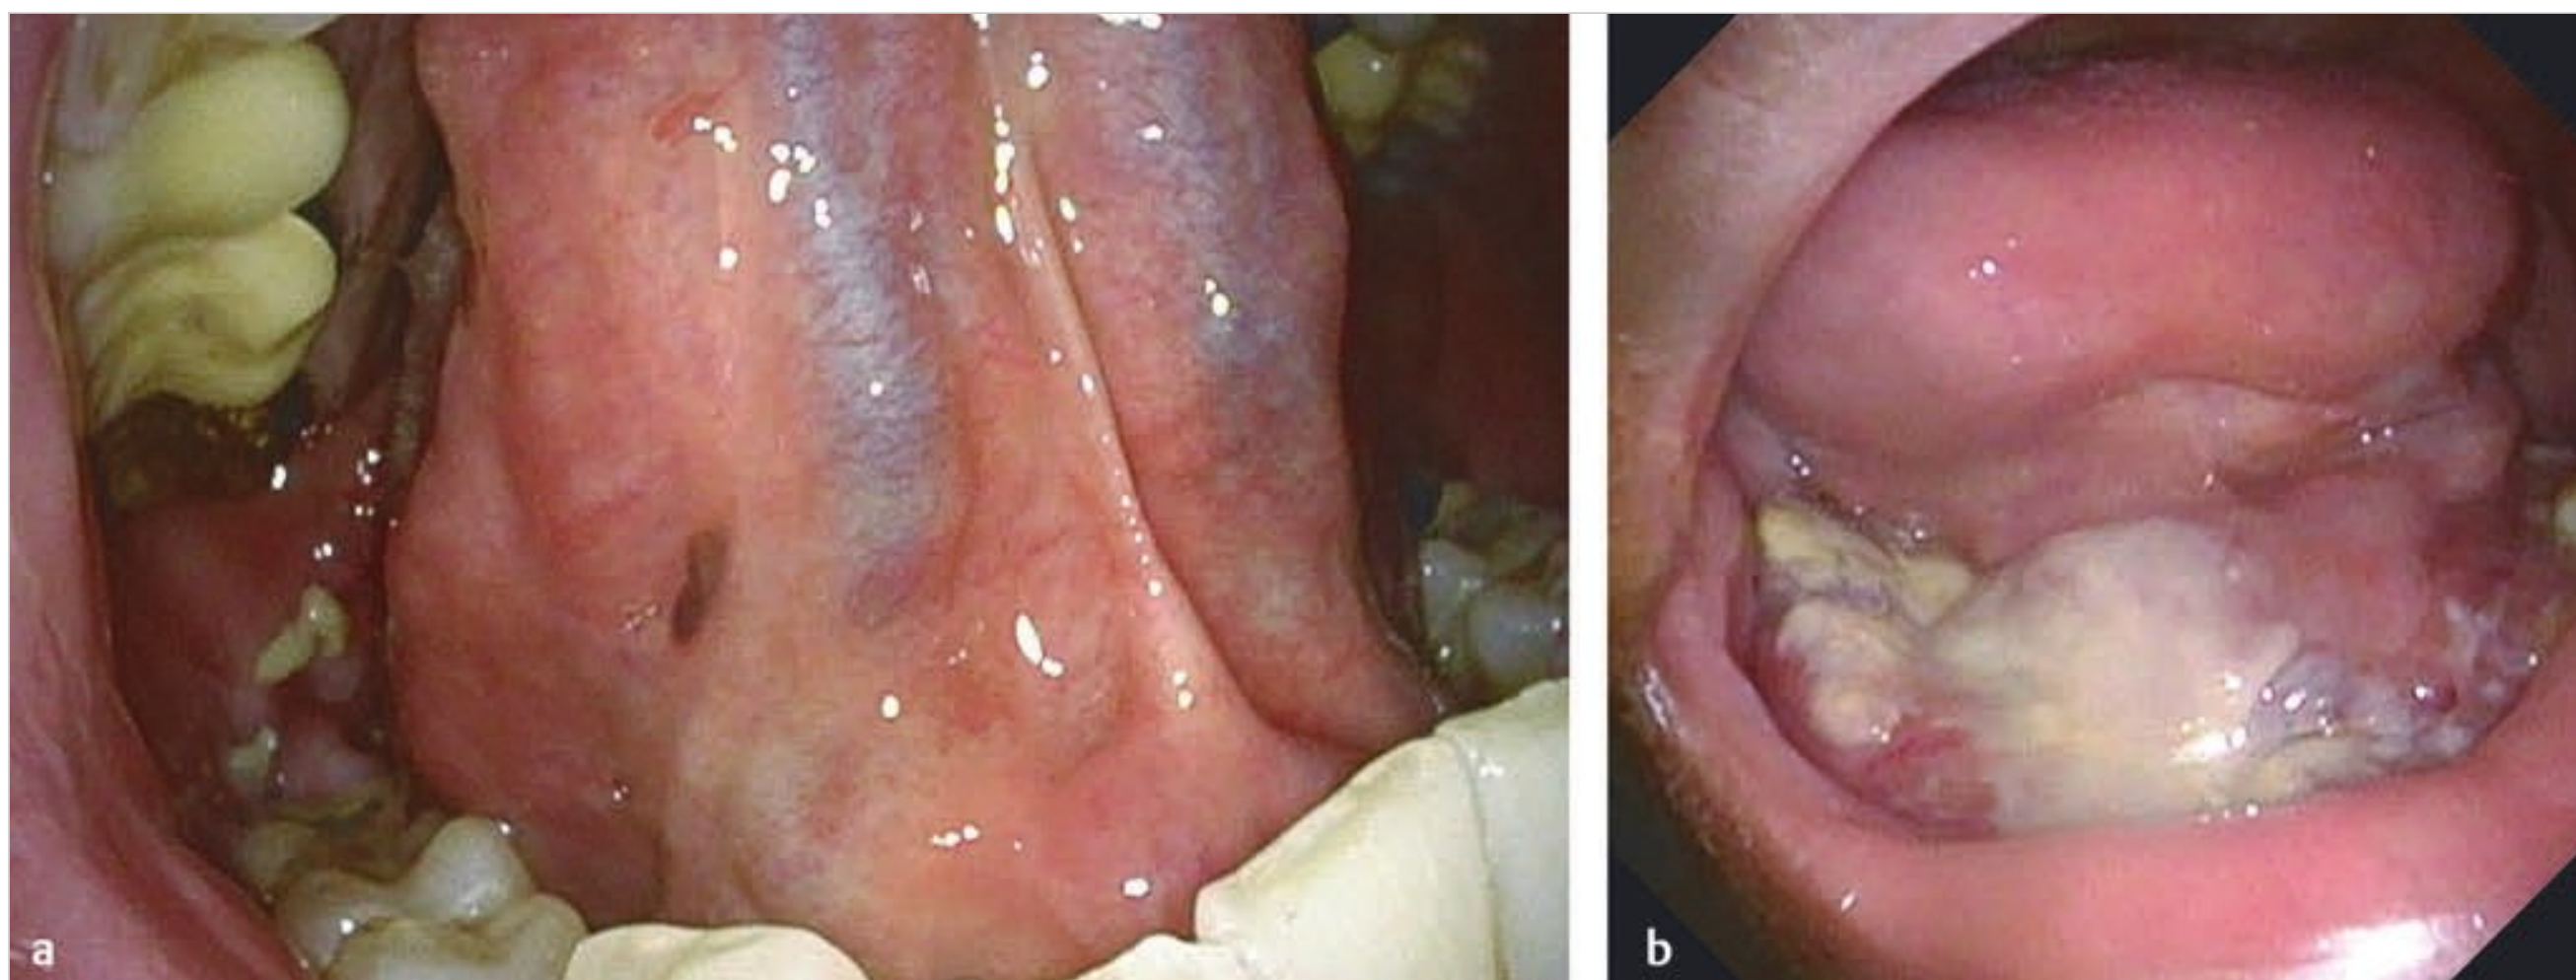

Fig. 23.7 (a) Invasive (early) mucosal melanoma of the ventral tongue. (b) Advanced mucosal melanoma of the floor of mouth.

Fig. 23.8 Reconstruction of the oral tongue with lateral thigh free flap after nearly total glossectomy. This patient is able to eat and speak intelligibly.

lar extension and perineural and vascular invasion, warrant treatment with additional modalities.

Appropriate goals of treatment are (1) to cure the cancer, (2) to preserve or restore form and function, and (3) to minimize the side effects of treatment. Other factors to consider in formulating a treatment plan are anterior or posterior location of tumors, proximity to bone, depth of invasion, and histologic type. Small tumors in the anterior part of the oral cavity can be surgically excised intraorally with minimal functional deficit. Surgery rather than radiation is the treatment of choice for early oral cavity cancer because of the long-term sequelae of xerostomia and the risk for dental caries and osteoradionecrosis of the mandible. If surgery is chosen for the treatment of early lesions, elective neck dissection should be performed for tumors of the oral tongue and floor of mouth and for tumors with significant depth of invasion, which have a higher rate of lymph node metastasis in clinically N0 necks. In patients with clinically palpable neck disease, a minimum of comprehensive neck dissection including levels I through V is advised.

For most patients with large primary tumors, surgery with reconstruction followed by radiation or chemoradiation therapy

is the treatment of choice. The location of the primary tumor will dictate the various surgical approaches described. Mandibulotomy, lower cheek flap, visor flap, and upper cheek flap approaches are some of the surgical techniques used to gain access to the primary tumor. Vertical or horizontal mandibulectomy or segmental mandibulectomy may be incorporated into the surgical plan, depending on the proximity and level of bone invasion by the tumor. Appropriate reconstruction with fibula, radial forearm, or anterolateral thigh free flaps is most commonly employed for the restoration of function and form in the oral cavity (□ Fig. 23.8). Although not optimal, pedicled flaps, such as a pectoralis major myocutaneous flap, or rotation flaps with local tissue, such as tongue or cheek mucosa, may be required for reconstruction of the oral cavity defects in certain circumstances. Patients with significant concurrent medical disease may not be candidates for lengthy microvascular free flap procedures, and alternative reconstructions with a shorter operating time may be the option. Defects that require sufficient donor tissue to prevent functional compromise (such as tethering of the tongue) but are not large enough to require a microvascular free flap may benefit from local tissue transfer techniques and/or skin grafts.

Complications of surgery include bleeding, aspiration pneumonia, and fistula formation. Late complications are poor speech clarity, as well as mastication and swallowing dysfunction. Early complications of radiation therapy consist of mucositis and loss of taste. Late complications involve permanent xerostomia, dental caries, and osteoradionecrosis. Chemotherapy-associated complications include myelosuppression; nausea/emesis; alopecia; mucositis; pulmonary, renal, and hepatic dysfunction; and neuropathy, including ototoxicity manifested by nerve hearing loss and peripheral vestibular symptoms.

23.4.11 Prognosis

The most important factor determining prognosis and survival is the stage of disease at presentation. The overall 5-year survival rates for stages I and II are 80% and 70% respectively. For patients with stages III and IV disease, the survival rates are 55% and 30% respectively.

23.5 Benign Neoplasms and Cysts of the Oral Cavity

Benign tumors of the oral cavity originate from the various tissues (epithelium, salivary glands, muscles, fibrous tissues, nerve, and bone) of the oral cavity. Epithelial tumors such as squamous papillomas are caused by HPV-6 and HPV-11. They may occur on the oral tongue, lips, and buccal mucosa, usually closer to the lip. The surface of these lesions appears warty with papillary projections. Malignant changes in papillomas associated with HPV-6 and HPV-11 are rare. These lesions can be treated with surgical excision or carbon dioxide laser ablation with excellent control.

Fibromas of the oral tongue and buccal mucosa may develop as a result of local trauma and irritation. They are found in 1.2% of the adult population. They appear as smooth, well-delineated, submucosal masses that can be sessile or pedunculated. They are usually solitary and measure less than 1.5 cm. If symptomatic, these lesions can be locally excised. Otherwise, they can be clinically observed.

Fewer than 10% of salivary gland tumors arise from minor salivary glands, and 20 to 40% of minor salivary gland tumors are benign. The most common adenoma arising from minor salivary glands of the oral cavity is pleomorphic adenoma, most commonly found on the hard palate. Other benign salivary gland tumors include canalicular adenoma, papillary cystadenoma, oncocytoma, and myoepithelioma. These tumors generally present as smooth, painless, slowly growing masses. Complete surgical excision can usually be achieved transorally.

Mucoceles of the lips are cystic lesions that form as a result of the extravasation of glandular contents into the surrounding tissue, usually after local trauma. A retention cyst or ranula is caused by obstruction of the ducts with subsequent dilatation of the sublingual gland and formation of a cyst. A plunging ranula is a cyst that plunges under the mylohyoid muscle into the neck. Surgical excision or marsupialization is the treatment of choice for retention cysts.

Dermoid cysts, enteric duplication cysts, and nasoalveolar cysts are rare congenital conditions of the oral cavity. Dermoid cysts occur along embryonic fusion lines and form from trapped epithelial cells. They are lined by keratinizing squamous epithelium and may contain epidermal appendages such as hair follicles and sweat glands. Enteric duplication cysts contain gastrointestinal mucosa and are lined with columnar or stratified squamous epithelium. Both types can be found in the floor of mouth and tongue. These congenital cysts may enlarge to cause functional problems of the oral cavity. Complete surgical excision is curative. Nasoalveolar cysts may arise from trapped epithelial cells between the lateral and medial maxillary nasal processes. They become symptomatic later in life as the cysts increase in size and present as smooth, nontender, soft swellings in the nasolabial area. On examination, the cysts may cause submucosal elevation over the gingivolabial sulcus or floor of the nose, or displacement of the nasal alae. Excision can usually be achieved via the sublabial approach.

Granular cell tumors are of neural origin, as are neurilemmomas (schwannomas) and neurofibromas. Fifty percent of granular cell tumors occur in the oral cavity, and the tongue is most commonly involved. Up to 15% of patients have synchronous

lesions. They present as firm, painless, pink, nodular, sessile masses. Granular cell tumors are malignant in about 1% of cases. Treatment requires surgical excision, with an overall recurrence rate of 10%. Neurofibromas are the most common peripheral nerve tumors found in the oral cavity and are derived from a combination of Schwann cells and perineural fibroblasts. Multiple neurofibromas may be associated with von Recklinghausen neurofibromatosis. In patients with this disorder, 70% of neurofibromas occur in the oral cavity and usually involve the tongue. They present as painless, slowly growing masses but are tender to palpation. Surgical excision is the treatment of choice, with a low risk for recurrence. Malignant transformation of a solitary neurofibroma is rare, but sarcoma may arise in 15% of patients with von Recklinghausen neurofibromatosis.

Pyogenic granulomas, or epulides (□ Fig. 23.9), may occur in any part of the oral cavity but most commonly involve the gingiva or, in certain conditions, tissue that is prone to the development of an exuberant inflammatory reaction. Etiologic factors include repeated trauma and irritation, infections, dental eruption, and pregnancy. Histologically, pyogenic granulomas consist of proliferative vascular channels and fibrous tissues. They may appear as raised, red to purple lesions. Epulides gravidarum are self-limiting, but others require surgical excision.

Vascular tumors (□ Fig. 23.10) of the oral cavity include hemangiomas and arteriovenous vascular malformations. Hemangiomas of the head and neck are common, with 14% occurring in the oral cavity, most frequently in the lip. They are

Fig. 23.9 Pyogenic granuloma.

Fig. 23.10 (a) Hemangioma of the tongue. (b) Venous vascular malformation of the tongue.

usually present at birth and grow during a rapid proliferative phase, followed by spontaneous regression over years. Thus, intervention is recommended only for symptomatic lesions. Vascular malformations, on the other hand, become clinically apparent later in life and may progress over years. When they are symptomatic, surgical excision and/or sclerosing agents can be used for treatment, with variable results depending on the size and location of these malformations.

Torus palatinus (□ Fig. 23.11) and torus mandibularis are benign, bony growths on the midline of the hard palate or on the lingual surface of the mandible. Tori of the oral cavity occur in 3 to 56% of the adult population and are more common in women. They can be pedunculated or broad-based, and they range from small to large (occupying almost the entire palate). They are usually asymptomatic, but when they cause problems with eating or pain from repeated trauma, a bur or osteotomes can be used to remove the bony masses. Tori are composed mostly of lamellar bone, with small marrow spaces that do not involve the deeper cancellous bone of the mandible or palate.

The following section on odontogenic tumors and cysts is a brief summary of the more commonly encountered lesions. For detailed information regarding odontogenic tumors and cysts, the reader is referred to the list of recommended reading at the end of this chapter.

Odontogenic cyst is a “pathologic cavity lined by epithelium of odontogenic derivation,” usually nonkeratinized. Cyst expansion occurs as a result of the accumulation of inflammatory cells, fibrin, serum, and desquamated cells and/or mitotic activity of the cystic wall. Common odontogenic cysts include dentigerous cyst (follicular cyst), eruption cyst, keratinizing odontogenic cyst, and odontogenic keratocyst. Eruption cyst is a subtype of dentigerous cyst that is confined by overlying alveolar mucosa. These cysts are associated with the crowns of unerupted teeth, developing teeth, and odontomas. Fluid accumulates between reduced enamel epithelium and tooth crown. Treatment is enucleation at the time of tooth extraction. Dentigerous cysts potentially have the ability to transform into true neoplasms.

Fig. 23.11 Torus palatinus.

Associated ameloblastomas are noted in 17% and rarely squamous cell carcinomas and mucoepidermoid carcinomas.

Keratinizing odontogenic cysts have an epithelial lining with thin keratinization. Keratinizing odontogenic cysts are usually

asymptomatic and are not associated with basal cell nevus syndrome (Gorlin-Goltz syndrome). These cysts have a recurrence rate of 2% after removal with curettage. Odontogenic keratocyst is also defined as a keratocystic odontogenic tumor, a term that stresses the neoplastic nature of this lesion. Soft-tissue extension, extension into adjacent bones with bony destruction, and increased mitotic activity histologically have been reported. These lesions are more common in the mandible than in the maxilla. Patients are often symptomatic, with swelling, pain, and trismus, especially when the cysts are infected, although odontogenic keratocysts are frequently identified as incidental findings on radiographs. Because the recurrence rate is as high as 62% with enucleation alone, additional curettage is recommended, which decreases the recurrence to 10%.

Malignant transformation of odontogenic cysts is rare but is considered to arise from residual cysts in an edentulous area. Malignant lesions are likely to present with pain, swelling, and dysesthesia. The age at occurrence is the sixth or seventh decade, with a 2:1 male predominance. Treatment is based on size, histologic type, and histologic grade.

Ameloblastoma is the most common odontogenic neoplasm. Ameloblastomas arise from rests of primitive dental lamina related to the enamel organ in alveolar bone. These tumors generally present in the third decade of life as a painless, expansile mass in the mandible (85%) or maxilla. Radiography reveals unilocular or multilocular radiolucency with cortical bone expansion. Histologically, they are solid infiltrating tumors with a follicular or plexiform pattern. Standard ameloblastoma is the most aggressive of the benign odontogenic tumors. Ameloblastomas can readily infiltrate medullary bone, but compact bone such as the inferior border of the mandible or ramus provides some barrier protection. Resection with adequate margins (1 cm) beyond the radiographic evidence of tumor is the treatment of choice to prevent recurrence. The recurrence rate can be high as 22% with one-half of recurrences occurring within 5 years. Rarely, malignant transformation can occur.

Unicystic ameloblastomas account for 15% of all ameloblastomas. Most are located in the posterior mandible. They occur in the second and third decades and are usually asymptomatic unless inflamed. Unicystic ameloblastomas are unilocular and unicystic, display no connective tissue invasion, and are considered prognostically distinct from the standard ameloblastomas. Histologic features involve only the luminal and intraluminal walls. The size of the lesion should be less than 2 cm. These lesions require only enucleation for treatment.

Malignant ameloblastomas are ameloblastomas with distant metastasis, which may occur many years following a delay in treatment or years after treatment. The lung is the most

common site, with reported cases in the cervical lymph nodes as well. Ameloblastic carcinoma is rare but has histologic features associated with malignancy, such as increased mitoses, nuclear pleomorphism, and hyperchromatism.

23.6 Roundsmanship

- For malignant neoplasms, the stage at presentation predicts survival, with improved outcome for early stages.
- Early-stage cancers (stages I and II) may be cured with a single modality of treatment, whereas advanced cancers (stages III and IV) require a combined modality of treatments.
- Smoking and alcohol consumption are important risk factors associated with squamous cell carcinoma.
- Human papillomavirus-associated squamous cell carcinomas in nonsmokers have an improved clinical response to treatment.
- Benign oral cavity neoplasms and cysts are curable with local excision when symptomatic.
- Biopsy of uncertain characteristic lesions of the oral cavity should be performed to determine pathology.
- The difference between the biological behavior of unilocular ameloblastoma and that of standard ameloblastoma, which dictates appropriate surgery, must be recognized.

24 Diseases and Neoplasms of the Pharynx and Esophagus

Pat Colley and Stimson P. Schantz

24.1 Anatomy

24.1.1 Pharynx

The pharynx is the shared chamber of the respiratory and digestive tracts. It can be divided into three separate parts: the nasopharynx, the oropharynx, and the hypopharynx. The most superior of these structures is the nasopharynx, extending inferiorly from just posterior to the nasal choanae to the soft palate. Below the nasopharynx is the oropharynx, through which food and air pass into the hypopharynx, where food enters the esophagus and air enters the larynx. These three areas of the pharynx are discussed separately below.

Nasopharynx

The nasopharynx is the portion of the pharynx continuous with the nasal cavity. It begins at the nasal choanae. The lateral walls of the nasopharynx contain the eustachian tube orifices, each bounded posteriorly by the torus tubarius. Immediately behind the torus is the pharyngeal recess (fossa of Rosenmüller). The cribriform plate and sphenoid sinus form the superior portion of the nasopharynx, with the clivus making up the posterior border. Because the nasopharynx is contiguous with the nasal cavity, the mucosa of this region is made up mostly of pseudostratified columnar ciliated epithelium. The lymphoid tissue in the nasopharynx, the pharyngeal tonsil, is a midline structure that occasionally extends laterally to the eustachian tubes as Gerlach tonsils.

Oropharynx

The oropharynx is the largest of the areas within the pharynx. It extends from the border of the soft and hard palate inferiorly to the level of the hyoid and the vallecula. The mucosa of this region is mainly stratified squamous epithelium and is innervated by cranial nerves IX and X in the pharyngeal plexus. Notable subsites within the oropharynx are the tonsillar fossae (including the tonsils), soft palate (including the uvula), the base of tongue, and the pharyngeal wall.

The base of tongue is defined as the continuation of the lingual tongue from the circumvallate papilla to the vallecula. It contains muscles as well as the lingual tonsils. Blood supply to this area comes from the lingual arteries. This area is considered a midline structure, so that malignant involvement carries a high risk for metastatic spread to bilateral lymphatics.

The tonsillar fossa is an area formed by the palatoglossus (anterior tonsillar pillar) and palatopharyngeus (posterior tonsillar pillar) muscles; it houses the palatine tonsil itself. It receives its blood supply from the dorsal lingual branch of the lingual artery, tonsillar and ascending palatine branch of the facial artery, ascending pharyngeal artery, and descending palatine branch of the maxillary artery. The palatine tonsils are the most visible part of the Waldeyer ring, which includes the adenoids, palatine tonsils, and lingual tonsils.

The soft palate and uvula are directly posterior to the hard palate and are made up of stratified squamous mucosa overlying muscle. These muscles act in coordination to seal the nasopharynx and propel food down the oropharynx during swallowing. The pharyngeal wall has similar layers of mucosa with underlying muscle.

Hypopharynx

This area extends from the hyoid bone to the inferior border of the cricoid cartilage. The hypopharynx serves as a transit point for all substances entering the esophagus. It receives innervation from the superior laryngeal nerve.

Muscles of the Pharynx

The major muscles of the oropharynx are the superior, middle, and inferior constrictor muscles. These three overlapping muscles encircle the oropharynx, each inserting into the pharyngeal raphe posteriorly. The superior constrictor originates from multiple points, including the medial pterygoid plate, pterygoid mandibular raphe, alveolar process of the mandible, and lateral tongue. The muscle courses superiorly and posteriorly toward the skull base and inserts into the pharyngeal raphe just inferior to the base of the skull. The superior border of this muscle lies just inferior and posterior to the pharyngeal recess in the nasopharynx and forms the Passavant ridge during swallowing. The middle constrictor originates only from the cornua of the hyoid bone and fans out as it courses posteriorly to insert into the raphe. Lastly, the inferior constrictor muscle originates from the lateral side and inferior cornu of the thyroid cartilage as well as the cricoid cartilage. It courses posteriorly to insert into the raphe, with the most inferior fibers forming the cricopharyngeus muscle. All three of the pharyngeal constrictors are innervated by pharyngeal branches of the vagus nerve, with a small contribution from the recurrent laryngeal branch inferiorly.

In addition to the constrictor muscles, five smaller muscles in the pharynx play an important role in its function. The palatoglossus originates from the soft palate and inserts into the side of the tongue. It is innervated by the vagus nerve via the pharyngeal plexus and is the only muscle of the tongue that is not innervated by the hypoglossal nerve. The palatopharyngeus also originates from the soft palate but travels farther inferiorly to join the stylopharyngeus and insert onto the posterior border of the thyroid cartilage. It too is innervated by the vagus nerve via the pharyngeal plexus. Both the palatopharyngeus and palatoglossus are continuous with their counterparts on the opposite side of the pharynx via the soft palate. Fibers from the musculus uvulae intertwine with those of the palatopharyngeus and palatoglossus as this muscle courses from its origin on the posterior nasal spine inferiorly to form the uvula. The levator veli palatini and tensor veli palatini are the final two muscles of the pharynx. The levator veli palatini acts as an elevator of the soft palate and travels from its origin at the under-surface of the petrous portion of the temporal bone inferiorly

and anteriorly to insert into the soft palate. The tensor veli palatini is just anterior and lateral to the levator and originates from the base of the medial pterygoid plate, the spina angularis of the sphenoid bone, and the lateral wall of the cartilage of the auditory tube. It passes inferiorly to insert near the midline of the soft palate. The tensor veli palatini plays an important role in proper functioning of the eustachian tube; contraction of this muscle opens the tube and allows middle ear pressure equalization. The tensor veli palatini is innervated by the medial pterygoid nerve, a branch of the third division of the trigeminal nerve. The levator veli palatini shares innervation with the other muscles of the soft palate and is innervated by the vagus nerve.

24.1.2 Esophagus

The esophagus begins at the inferior end of the hypopharynx and continues inferiorly for 38 to 40 cm before ending at the cardia of the stomach. The cricopharyngeus, or upper esophageal sphincter, forms the entrance to the esophagus. As stated above, the cricopharyngeus is made up of a portion of the inferior constrictor muscle and is therefore skeletal muscle. However, it is not under voluntary control. Relaxation of the upper esophageal sphincter is triggered by the swallow reflex and is therefore under control of the vagus nerve. The cricopharyngeus is the narrowest portion of the entire gastrointestinal tract and therefore the area at which a foreign body is most likely to become lodged. Inferior to the upper esophageal sphincter is the body of the esophagus, consisting of cervical, thoracic, and intra-abdominal portions. The esophagus ends at the cardia of the stomach, just below the lower esophageal sphincter. The lower esophageal sphincter is a 2- to 4-cm-long area of increased pressure just above the cardia of the stomach; it relaxes as a food bolus travels down the esophagus to allow entry into the stomach.

There are three distinct layers within the esophagus: the mucosal, submucosal, and muscular layers. The esophagus lacks a serosal layer, making perforation more likely, allowing the spread of malignancy, and making surgical repair significantly more challenging. The mucosal layer is composed almost entirely of stratified squamous epithelium except for the most distal 1 to 3 cm, which is lined by columnar epithelium similar to that of the stomach. The muscular layer of the esophagus is composed of outer longitudinal fibers and inner circular fibers. The upper third of these muscle fibers is striated muscle, whereas the inferior two-thirds is smooth muscle. These muscles receive innervation from the vagus nerve and the sympathetic chain. The blood supply to the esophagus comes from the inferior thyroid artery, thoracic aorta, and left gastric and inferior phrenic arteries.

24.2 Function

The basic functions of the pharynx are respiration and deglutition. During respiration, the pharynx must simply remain patent and allow air to pass from the oral and nasal cavities to the larynx and lungs. However, the act of swallowing is a complex sequence of events that requires precise timing and the proper functioning of multiple muscle groups as well as cranial nerves

V, VII, IX, X, and XII. The swallow is typically divided into three phases: oral, pharyngeal, and esophageal. The oral phase consists of mastication, addition of saliva to the oral contents, and assessment of the safety of the food. This entire phase is under voluntary control. When the decision is made to proceed with swallowing, the bolus is pressed against the anterior tonsillar pillar. This activates pressure receptors innervated by cranial nerves IX and X and initiates the involuntary pharyngeal phase.

The pharyngeal phase begins with contraction of the levator and tensor veli palatini in order to elevate the soft palate and create a seal against the posterior pharyngeal wall. This prevents regurgitation of the bolus into the nasopharynx. At the same time, the superior constrictor begins to contract, creating the Passavant ridge, just above its most superior border in the nasopharynx. Respiration pauses at this time, typically during expiration. Next, the true vocal folds close, followed by the false vocal folds. The arytenoids are pulled against the epiglottis, and the bolus is moved farther into the oropharynx by base of tongue elevation and contraction of the constrictor muscles. The larynx is elevated with the base of tongue causing rotation of the epiglottis posteriorly over the laryngeal vestibule. Elevation of the larynx causes dilation of the cricopharyngeus; this, when combined with active relaxation of the same muscle, allows passage of the bolus into the cervical esophagus, where the esophageal phase of swallowing begins. Primary peristalsis of the esophagus is initiated by bolus entry into the esophagus; the bolus is then propelled down the esophagus at a rate of 5 to 10 cm per second. Next, the lower esophageal sphincter relaxes and allows the bolus to pass into the stomach. Secondary peristalsis then clears the esophagus of any remaining food particles. In total, it takes 4 to 7 second for all three phases of swallowing to propel a bolus from the oropharynx through the esophagus into the stomach.

24.3 Infectious, Inflammatory Lesions of the Pharynx

Pharyngitis is one of the most common reasons why a patient visits his or her primary care physician and accounts for 15 to 20% of all office visits. It is defined as an inflammation of the mucosa and submucosa of the pharynx and can affect the nasopharynx, oropharynx, and hypopharynx. The introduction of bacteria or viruses into this area causes a significant reactive inflammatory response because of the high concentration of lymphatic tissue in the Waldeyer ring. In certain instances, infections in this area can lead to systemic disease, causing substantial morbidity and mortality.

24.3.1 Bacterial Pharyngitis

The normal bacterial flora of the pharynx is made up mostly of gram-positive aerobic organisms that live commensally until their environment is altered by outside forces or new organisms are introduced. These changes typically manifest clinically as pharyngitis. The most common cause of bacterial pharyngitis is infection by group A β -hemolytic streptococci. Patients with pharyngitis due to infection by group A β -hemolytic streptococci typically describe a sore throat, difficulty swallowing, and

headache. Cough and rhinorrhea are not usually associated with group A β -hemolytic streptococcal pharyngitis. The onset of group A β -hemolytic streptococcal pharyngitis tends to be more sudden than that of viral pharyngitis. On examination, these patients can have a high-grade fever, soft palate petechiae, and exudative tonsils. Tender anterior cervical adenopathy is seen 60% of the time with group A β -hemolytic streptococcal pharyngitis. However, the history and physical examination often can be misleading in patients with acute pharyngitis. Centor et al created an algorithm for the management of group A β -hemolytic streptococcal pharyngitis based on clinical factors that incorporates the absence of cough, swollen anterior cervical lymphadenopathy, presence of fever and tonsillar exudate, and patient age. However, this algorithm still requires that the majority of patients undergo laboratory testing in order to confirm the diagnosis of group A β -hemolytic streptococcal pharyngitis. Laboratory testing typically consists of either rapid antigen detection testing (RADT) or traditional throat culture. The gold standard for the confirmation of group A β -hemolytic streptococcal pharyngitis remains throat culture because of its high sensitivity (90 to 95%) and ability to identify antibiotic sensitivities. However, throat cultures take a minimum of 24 hours to provide clinicians with accurate results. The RADT was developed as a more rapid means of providing similar data to the treating physician. With sensitivities ranging from 79 to 88% and specificities above 95% RADT provides an excellent alternative to throat culture, and results are available immediately. Throat cultures are typically collected in addition to performing RADT because of the potential development of rheumatic fever as a result of not treating group A β -hemolytic streptococcal pharyngitis.

The treatment of group A β -hemolytic streptococcal pharyngitis typically consists of oral or intravenous antibiotic administration. Although group A β -hemolytic streptococcal pharyngitis is a self-limited disease, antibiotics are given to provide acute symptom relief, reduce suppurative complications, and reduce communicability. Penicillin is still the recommended first-line therapy in most areas of the country. However, if β -lactamase-producing organisms are present, treatment with clavulanate or another β -lactamase-inhibiting agent in addition to penicillin is required. Patients who are allergic to penicillin can be treated with erythromycin or a first-generation cephalosporin. Antibiotic treatment of group A β -hemolytic streptococcal pharyngitis reduces symptom duration by an average of 16 hours and significantly reduces rates of peritonsillar and retropharyngeal abscesses. The treatment of group A β -hemolytic streptococcal pharyngitis with antibiotics prevents rheumatic fever regardless of whether the group A β -hemolytic streptococcal pharyngitis has been fully eradicated or not. Antibiotic use does not have an effect on the development of acute post-streptococcal glomerulonephritis.

Rheumatic fever is a rare complication of untreated group A β -hemolytic streptococcal pharyngeal infection that develops after local invasion of bacteria causes the release of extracellular toxins and proteases. Group A β -hemolytic streptococci also release M proteins systemically that are similar in structure to myocardial sarcolemmal antigens. These proteins stimulate an inflammatory response against the patient's own cardiac muscle, joints, blood vessels, and subcutaneous tissues. The diagnosis is made with the American Heart Association modified

Table 24.1 American Heart Association's modified Jones criteria

Major criteria	Minor criteria
Carditis	Fever (101° to 102°)
Polyarthrits	Arthralgia without edema
Sydenham chorea (St. Vitus dance)	Prolonged PR Interval on electrocardiogram
Subcutaneous nodules	Acute phase reactants: increased erythrocyte sedimentation rate, presence of C-reactive protein or leukocytosis
Erythema marginatum	History of rheumatic fever or the presence of inactive rheumatic heart disease
	Evidence of preceding β -hemolytic streptococcal infection ^a

Note: The diagnosis requires two major criteria or one major and two minor criteria, along with evidence of a prior streptococcal infection.

^aEvidence of preceding streptococcal infection: increased antistreptolysin O or other streptococcal antibodies, positive throat culture for group A β -hemolytic streptococci, positive result of rapid antigen detection testing (RADT), or recent scarlet fever.

Fig. 24.1 "Strawberry tongue" of scarlet fever.

Jones criteria (□ Table 24.1). The disease typically resolves after 6 weeks but can have lasting neurologic and cardiac effects. The patient must have a preceding streptococcal infection and two major criteria or one major and two minor criteria in order for the diagnosis to be made. Treatment involves antibiotics for the group A β -hemolytic streptococcal pharyngeal infection, non-steroidal anti-inflammatory drugs, and corticosteroids, with possible treatment of cardiac complications.

Another complication of acute group A β -hemolytic streptococcal pharyngitis is scarlet fever. This condition manifests as a red, punctate, blanching rash that initially appears on the trunk but then quickly spreads to the entire body, sparing the face, palms, and soles. Patients will also have a swollen, red, and mottled "strawberry" tongue (□ Fig. 24.1), along with perioral skin erythema and desquamation. The production of erythrogenic toxin and lysis of the bacteria by a bacteriophage is

believed to be the mechanism behind this complication of group A β -hemolytic streptococcal pharyngitis. Before the advent of antibiotics, this condition carried a small but significant mortality risk that has all but disappeared since the discovery of penicillin.

Besides group A β -hemolytic streptococci, other bacteria can cause acute pharyngitis. The second most common cause of bacterial pharyngitis is *Staphylococcus* (*S. aureus* or *S. salivarius*). Infection by these bacteria tends to take place in patients who are dehydrated or are being treated with antibiotics. Patients may present with mucopurulent drainage, pharyngeal erythema, and edema as well as tonsillar pustules. Antistaphylococcal antibiotics, erythromycin, or first-generation cephalosporins are the antibiotics of choice for staphylococcal pharyngitis.

Another bacterial species known to cause pharyngitis is *Corynebacterium diphtheriae*. This gram-positive rod is found mostly in children younger than the age of 10 years in developing countries. After the bacteria gain access to the pharynx, bacterial exotoxin production causes local inflammation and tissue necrosis, resulting in the gray membrane classically associated with diphtheria. The local inflammation can affect the entire pharynx as well as the larynx, putting the patient at risk for airway obstruction. In addition, toxins released systemically can cause cardiomyopathy and dysrhythmias. The proper treatment of diphtheria includes management of the airway as well as antitoxin and antibiotic therapy. Widespread immunization programs have nearly eradicated diphtheria in developed nations.

Bordetella pertussis had been nearly eradicated in developed countries but is now having a strong resurgence because of waning immunity in adults vaccinated in childhood (as an increasing number of parents are choosing not to vaccinate their children). Infection by this gram-negative coccobacillus is characterized by a low-grade fever and upper respiratory symptoms. This marks the catarrhal phase of the disease. The paroxysmal phase follows, defined by the development of paroxysms of coughing followed by a loud inspiratory gasp that gives this disease its name, whooping cough. During this phase, *B. pertussis* produces an exotoxin that attacks ciliated epithelium and causes necrosis and mucopurulent exudate. The paroxysmal phase typically lasts 2 to 4 weeks and is followed by the convalescent stage, during which the coughing attacks slowly dissipate. The treatment of whooping cough is with a macrolide antibiotic in conjunction with supportive care. It is important to note that antibiotic therapy will not alter the course of the illness but will decrease infectiousness and spread of the disease.

Sexually transmitted diseases cause inflammation of the mucosal surfaces and can therefore affect the pharynx along with the genitals. *Neisseria gonorrhoeae* is a gram-negative diplococcus transmitted through sexual contact that can cause sore throat, tonsillar hypertrophy, and lymphadenopathy. Culture on chocolate or Thayer-Martin agar is required for identification of the organism. The treatment of gonococcal pharyngitis may be difficult because of a high incidence of antibiotic resistance, but ceftriaxone and doxycycline are recommended first-line agents. Infection by the spirochete *Treponema pallidum* may present as painless, dark red papules on the tonsils or pharyngeal wall, typically seen in secondary syphilis 2 to 3 months after primary

infection. These lesions are highly contagious, and treatment with penicillin, tetracycline, or erythromycin is required.

24.3.2 Viral Pharyngitis

Viral pharyngitis is the most common cause of a sore throat. Patients tend to have a low-grade fever and other associated symptoms of an upper respiratory tract infection, such as coughing, sneezing, and rhinorrhea, as well as generalized adenopathy. The clinical course of viral pharyngitis is more indolent than that of bacterial pharyngitis and is not responsive to antibiotic treatment. Many viruses are associated with pharyngitis, including coronavirus, adenovirus, and rhinovirus. Clinically, it is difficult to distinguish which virus is responsible for a particular infection. However, certain viruses cause distinct physical findings and require special mention below.

Infection of the pharynx by herpes simplex virus (human herpesvirus, or HHV) presents with inflammation of the oral and pharyngeal mucosa as well as small vesicular lesions throughout the same area. It is caused by one of the two serologically distinct subtypes of HHV. Type 1 HHV is typically associated with oral or pharyngeal infection, whereas type 2 is seen more commonly in genital infections. However, both viruses can affect either area without restriction. The original infection by HHV can manifest symptoms for 7 to 10 days followed by quick resolution. Neonates or patients with compromised immune systems are at risk for disseminated infection by this virus and should be monitored for central nervous system involvement. The diagnosis of HHV infection is made through tissue culture, Tzanck preparation, or antigen detection. Tissue culture is the gold standard but can take up to 4 to 5 days to provide a result. Tzanck preparation and antigen detection tests are quicker but have a sensitivity rate between 50% and 70%. The treatment of HHV pharyngitis is with an antiviral, such as acyclovir or valacyclovir. However, this has not been shown to decrease the duration of illness or reduce symptomatology and may best be reserved for the immunocompromised patient.

Epstein-Barr virus (EBV) infection leads to infectious mononucleosis, an illness associated with exudative tonsillitis, fever, posterior triangle cervical lymphadenopathy, and malaise. Classically, patients also have splenomegaly on examination, although this has been shown to be present only in roughly 50% of patients with this disease. EBV infects B lymphocytes and has been linked to nasopharyngeal carcinoma and Burkitt lymphoma, although other factors are believed to be involved in the development of these malignancies. The diagnosis of this disease is based on clinical history and serum testing for heterophile antibodies with the monospot test. Complications associated with infectious mononucleosis include splenic rupture and acute airway obstruction due to pharyngotonsillar inflammation. However, in the large majority of patients, the symptoms resolve after 2 to 6 weeks of supportive care. Antibiotics should be avoided in these patients because they are ineffective in treating the disease, and patients given ampicillin or another penicillin develop a severe rash.

Pharyngitis caused by coxsackievirus A most often occurs in children younger than 5 years of age. It is characterized by vesicular or ulcerative lesions along the tonsillar pillars and buccal mucosa known as herpangina. This illness has a rapid course that includes high fevers and possible vesicular lesions on the

extremities, including the palms of the hands and soles of the feet. The lesions on the extremities appear several days after the fever and pharyngitis begin. The diagnosis is made by clinical history and physical examination. The treatment of herpangina is supportive.

24.3.3 Fungal Pharyngitis

Although not a group of organisms commonly associated with pharyngitis, fungi can invade and damage the pharyngeal mucosa in individuals with compromised immune systems. *Candida* species are most commonly responsible for this condition. Patients with fungal pharyngitis will have a white, cheesy plaque along their oral or pharyngeal mucosa that is typically easily removed to reveal erythema below. The diagnosis is made by Gram stain or periodic acid–Schiff stain of a culture. Treatment is with topical nystatin or an oral azole. Individuals with no known history of immunosuppression should be sent for further immune testing once this diagnosis is confirmed.

24.3.4 Complications of Pharyngitis

Although infections of the pharynx are common, severe complications are rare. Most of these illnesses resolve spontaneously with few, if any, long-term sequelae. Occasionally, patients with pharyngitis will develop a condition that requires intervention beyond antibiotic treatment (e.g., peritonsillar abscess). The spread of infection beyond the tonsillar capsule allows purulent material to collect between the tonsillar capsule medially and the superior constrictor laterally. Patients have odynophagia, trismus, and soft palate swelling; uvular deviation away from the affected side and fullness in the superior soft palate are seen on physical examination. Symptoms of pharyngitis typically exist for at least 5 days before an abscess develops. The treatment of a peritonsillar abscess is incision and drainage with culture-directed antibiotic treatment for 7 to 10 days. Untreated, a peritonsillar abscess can spread to the parapharyngeal and retroesophageal spaces, causing airway obstruction, venous thrombosis, bacteremia; it may also spread to the mediastinum or even the central nervous system. However, these severe complications are rare now because of the effectiveness of antibiotic treatment. Patients with recurrent episodes of peritonsillar abscess are advised to undergo an elective tonsillectomy after resolution of their symptoms, with the goal of reducing or eliminating the risk for future infections.

24.4 Malignant Lesions of the Pharynx and Esophagus

24.4.1 Nasopharyngeal Cancer

Incidence and Background

Nasopharyngeal carcinoma (NPC) is a squamous cell carcinoma that develops from the epithelium of the nasopharynx. It is a rare cancer with an incidence of less than 1 per 100,000 in most countries. However, NPC occurs at a significantly higher rate in certain groups, such as ethnic Chinese in the southern part of China, Aleut Native Americans in Alaska, and Southeast Asians. The incidence in southern China has been documented to be as

high as 30 per 100,000. The increased incidence is believed to be related to nitrosamines found in heavily salted fish in this area.

EBV is thought to play some oncogenic role in this tumor because of the high rates of EBV genome detection in NPC specimens. Nearly all patients with NPC also have EBV infection, and EBV RNA is found in almost all NPC cells. However, no substantial causative evidence has ever been found supporting the role of EBV in NPC development. The use of EBV serology has been proposed as a possible means of screening patients for NPC in regions where its incidence is high.

It is likely that genetic factors also play a role in NPC, based on the fact that first-degree relatives of patients with NPC are six times more likely to develop this cancer than are controls. Additionally, the incidence of NPC remains high among Chinese who have immigrated to the United States, although it decreases somewhat among Chinese born in North America. These North America–born Chinese should have NPC incidence rates similar to those of the general population, but their rates remain elevated despite removal of the causative environmental agents. To date, the only genetic associations made with NPC are HLA-BW46 and HLA-B17.

Classification

The World Health Organization (WHO) created a classification of NPC based on histopathology (□ Table 24.2). Type I is the second most common type of NPC in North America and is referred to as sporadic NPC. Histopathologically, squamous differentiation is seen and is similar to that in other epidermoid carcinomas of the head and neck. Type I NPC is not associated with EBV but is related to tobacco and alcohol exposure. It carries a poor prognosis because of its lack of radiosensitivity. Type II NPC is the least common type. Together with type III NPC, it makes up the nonkeratinizing, or endemic, types of NPC. Type III NPC is the most common form. It includes a group of histopathologically similar forms of NPC, such as lymphoepithelioma and anaplastic and clear cell variants. Both type II NPC and type III NPC are associated with EBV and are radiosensitive.

Presentation

Nearly all patients with NPC are symptomatic at the time of diagnosis. One percent of NPCs are incidentally discovered on examination or imaging. The most common symptom of NPC at the time of diagnosis is a neck mass, followed by aural fullness and nasal obstruction. Neck masses typically present in level II or V and occur bilaterally in 20% of patients. Cranial neuropathies suggest infiltration of the skull base. Cranial nerves III through VI are the most commonly involved because of their location in relation to the skull base and cavernous sinus.

Table 24.2 World Health Organization classification of nasopharyngeal carcinomas

Type I	Keratinizing squamous cell carcinoma
Type II	Nonkeratinizing squamous cell carcinoma
Type III	Undifferentiated carcinoma

Evaluation

Computed tomography (CT) of the head and neck should be obtained, as well as magnetic resonance (MR) imaging, for all patients with NPC. CT provides information regarding cranial bone involvement and possible lymph node metastases. MR imaging allows better visualization of the soft tissues, including neural structures closely associated with the nasopharynx.

Differential Diagnosis

The differential diagnosis for NPC is limited but includes inflammation, infection, lymphoma, and Tornwaldt cyst. Individuals with Tornwaldt cysts have midline nasopharyngeal cysts that can mimic NPC lesions.

Staging

The staging of NPC is based on the 2010 American Joint Committee on Cancer (AJCC) staging guidelines. Both tumor and nodal staging are unique compared with that for the rest of the pharynx. The parapharyngeal space is a potential space shaped like an inverted pyramid, with its base at the skull base and extending inferiorly to the cornu of the hyoid bone. It is bordered medially by the constrictor muscle and laterally by the ramus of the mandible and deep lobe of the parotid. Involvement of this space portends a more locally advanced tumor.

A T1 lesion is confined to the nasopharynx or can extend to the oropharynx or nasal cavity without involvement of the parapharyngeal space, whereas a T2 lesion extends into this space. If the bony structures of the anterior skull base or sinuses are involved, the lesion is T3. T4 lesions have intracranial invasion and/or involvement of cranial nerves, hypopharynx, or orbit, or they extend into the infratemporal fossa or masticator space.

Unilateral cervical nodal metastasis above the supraclavicular fossa and/or uni- or bilateral retropharyngeal nodal involvement not larger than 6 cm represent N1 disease. N2 status is bilateral supraclavicular cervical nodal metastasis not larger than 6 cm. Nodal metastasis larger than 6 cm is classified as N3a, and nodal disease in the supraclavicular fossa is N3b. In situ disease is classified as stage 0, and T1 lesions with no nodal or distant metastasis are stage I. T1 disease with N1 nodal status or T2 primary lesions with N0 or N1 status are stage II disease. The combination of a T1 or a T2 primary lesion with N2 nodal status is stage III. T4 lesions with N0–N2 nodal disease are classified as stage IVA; any lesion with N3 nodal disease is stage IVB; any lesion with distant metastasis is stage IVC.

Treatment

Early-stage NPC is treated with radiation therapy; more advanced NPC is typically treated with combined chemoradiation therapy. Doses of 60 to 70 Gy are administered via external beam radiation to the nasopharynx and both sides of the neck. Accurate staging with precise pretreatment imaging by CT or MR imaging has allowed better dosimetry and a reduction in damage to adjacent tissue, reducing morbidity in such sensitive areas as the pituitary, eyes, ears, and surrounding neural structures.

Surgical resection of NPC is typically reserved for patients with tumor recurrence or radiation failure. Operating in the

nasopharynx is technically challenging because of the lack of accessibility of this area. Contraindications for surgical intervention include carotid involvement, skull base erosion, and intracranial involvement. NPC can be approached from either an open or an endoscopic approach. Endoscopic treatment is rare and is used primarily for small recurrences in the central portion of the posterior nasopharyngeal wall.

There are multiple options for an open approach. A lateral rhinotomy with a medial maxillectomy can be used for recurrences limited to the nasopharynx or involving the pterygopalatine fossa. This procedure carries few side effects but provides limited access compared with other approaches, including the maxillary swing. In this approach, a Weber-Ferguson incision is made, and the outer maxillary wall is rotated laterally with the skin and soft tissue attached. Access to the pterygopalatine fossa is improved with the maxillary swing but at the cost of a larger incision than is used for the lateral rhinotomy.

The other indication for surgery in patients with NPC is residual neck disease. The surgery of choice for this situation is radical neck dissection, based on the fact that recurrent nodal disease is often along the chain of lymph nodes of the upper internal jugular vein as well as the accessory nerve. Also, metastatic lymph nodes have a higher propensity for extracapsular spread in NPC than in other squamous cell carcinomas of the head and neck. Because the areas involved in this surgery have been previously radiated, the risk for carotid blowout is higher; therefore, incisions should be planned carefully, and a pedicled flap (e.g., a pectoralis major flap) should be used for carotid coverage if there is a risk for this complication.

Outcomes

Local and regional control of NPC depends on the stage but in general ranges between 70% and 80% with combined therapy. Five-year survival is also between 70% and 80% depending on the stage. However, the risk for recurrence of NPC continues after 5 years, and 10-year survival ranges from 10 to 40%. This decrease in long-term survival is due partly to the high rate of distant metastases in NPC. Between 25% and 30% of patients with NPC will develop distant metastases, the highest rate of any head and neck cancer. This should be considered when a patient previously treated for NPC is being followed.

Complications of Treatment

Side effects of radiation for NPC include mucositis, xerostomia, sinusitis, otitis media with effusion, sensorineural hearing loss, trismus, pituitary dysfunction, and cranial nerve palsies.

24.4.2 Oropharyngeal Cancer

Incidence and Background

Cancers of the oropharynx make up 12% of all malignancies of the head and neck. More than 90% of all oropharyngeal cancers are squamous cell carcinoma (SCC). The overall incidence of oropharyngeal SCC had been declining because of decreased rates of smoking and alcohol intake. However, between 1973 and 2004, the incidence rate increased, especially in white males younger than 60 years old. In this same time period, the rate of oropharyngeal SCC that tested positive for human papillomavi-

rus (HPV) nearly tripled, from a rate of 16.3% between 1984 and 1989 to a rate of 72.7% between 2000 and 2004. Oropharyngeal SCC had always been related to two main environmental factors, tobacco and alcohol intake; however, clinicians are now confronted with oropharyngeal SCC that lack the usual risk factors but are positive for HPV.

The oropharynx is composed mainly of mucosa, so it is clear why SCC accounts for the majority of malignant lesions in this region. However, the presence of the Waldeyer ring of lymphoid tissue in this area is the reason why the next most common malignancy seen in the oropharynx is lymphoma, typically involving the palatine tonsils or base of tongue. Lymphoepitheliomas also can develop from this ring of lymphoid tissue but are rare. Besides mucosa and lymphoid tissue, the oropharynx contains minor salivary glands that can undergo malignant transformation and lead to salivary gland carcinoma. Oropharyngeal malignancies can become very large before the onset of symptoms. For this reason, oropharyngeal SCC typically presents at an advanced tumor stage and with a rate of cervical lymph node involvement higher than 50% for all subsites. Lymph node metastases tend to occur in a stepwise progression, beginning at the superior lymph nodes in level II and proceeding inferiorly through levels III and IV. In addition, many oropharyngeal structures are midline, so both sides of the neck must be considered in treatment planning.

Evaluation

CT should be performed in all patients with oropharyngeal and hypopharyngeal SCC to assess for lymph node metastases and evaluate for invasion into surrounding structures. Patients with lesions in the inferior oropharynx and hypopharynx should undergo direct laryngoscopy and esophagoscopy in order to fully assess tumor involvement.

Differential Diagnosis

The differential diagnosis for an oropharyngeal lesion additionally includes infection, leukoplakia or erythroplakia, eosinophilic granuloma, pyogenic granuloma, giant cell tumor, papilloma, and verruciform xanthoma.

Staging

The staging of oropharyngeal cancer follows the TNM (tumor node metastasis) staging system and is based on the 2010 AJCC staging guidelines.

A T1 lesion is no larger than 2 cm. A T2 lesion is larger than 2 cm but smaller than 4 cm. Tumors that are larger than 4 cm or extend to the lingual surface of the tongue are classified as T3. T4a lesions invade the larynx, extrinsic tongue muscles, hard palate, pterygoid, or mandible. T4b lesions are very advanced locally, with invasion of the lateral pterygoid muscle, pterygoid plates, lateral nasopharynx, or skull base, or they encase the carotid artery.

N1 nodal disease is a single ipsilateral lymph node 3 cm or smaller. N2 disease is more extensive: N2a disease is a single ipsilateral lymph node larger than 3 cm but smaller than 6 cm; N2b disease is multiple ipsilateral nodes (none larger than 6 cm), and N2c disease includes bilateral or contralateral lymph

nodes, none larger than 6 cm. Finally, any nodal metastasis larger than 6 cm is classified as N3.

In situ disease is classified as stage 0, and T1 lesions with no nodal or distant metastasis are stage I. T2 primary lesions with N0 status are stage II disease. T3 primary lesions with no nodal involvement or T1–T3 lesions with N1 nodal status are stage III. T4a lesions with N0–N2 nodal disease or T1–T3 lesions with N2 nodal disease are classified as stage IVA; T4b primary lesions with any N status or any lesions with N3 nodal status are stage IVB; any lesion with distant metastasis is stage IVC.

Treatment

Tonsils and Lateral Pharyngeal Wall

The tonsils and surrounding pillars are the most common site of carcinoma in the oropharynx. Malignancies in this location can grow very large before detection. They most often present with dysphagia, odynophagia, otalgia, trismus, or a neck mass. Extension to adjacent structures is common, including the base of tongue, soft palate, retromolar trigone, and pterygoid muscles. At the time of diagnosis, clinically positive cervical lymphadenopathy accompanies 76% of tonsil carcinomas and 45% of tonsillar pillar carcinomas. Contralateral lymph node involvement is found between 5% and 11% of the time.

Early tonsillar cancer can be treated by either surgery or radiation therapy. Locoregional control rates and complications have been shown to be equivalent for both treatment modalities. Because it offers similar control rates, radiation therapy has become the treatment of choice for early tonsillar cancers.

Advanced tonsillar cancers can be treated with a variety of options, and a multidisciplinary approach is appropriate. Surgery is often a viable option but should be combined with postoperative radiation therapy or chemoradiation therapy. Advanced tonsillar cancer can also be treated with functional organ preservation therapy that combines chemotherapy and radiation. Several studies have shown that chemoradiation therapy achieves good locoregional control and has survival rates similar to those of surgery with postoperative radiation for advanced oropharyngeal SCC. However, no large randomized control trials that compare surgery plus radiation versus organ preservation therapy have been conducted at this time. Because of this, organ preservation therapy is often chosen as the initial therapy for tonsillar cancer, and surgery is used as salvage treatment after failure of the chemoradiation therapy.

In addition to treatment of the primary lesion, nearly all patients with tonsillar cancer require treatment of clinically present cervical metastases. Tonsillar SCC has a rate of nodal metastases higher than 20% for all T stages, and prophylactic treatment of a clinically negative neck is required. Lymph node metastases can be treated with neck dissection or radiation therapy, with both offering similar control rates; because of this, the method of neck treatment is typically the same method as is chosen to treat the primary lesion.

Tonsillar SCC can be approached transorally, but this is limited to the excision of very small lesions confined to the tonsillar pillar. Transoral robotic surgery may expand the number of lesions that can be approached through the mouth, but given the success of radiation therapy in treating small tonsillar lesions, the role of transoral robotic surgery may be limited. Another approach to tonsillar SCC is to use an anterior mandi-

bulotomy with mandibular swing. This approach provides good access to tonsillar cancers without bony involvement. If bony involvement is present, a segmental mandibulectomy with en bloc resection encompassing the tumor and involved bone is used. Removing such a large piece of tissue carries significant morbidity and typically requires osteomyocutaneous flap reconstruction.

Patients with early tonsillar SCC have high 5-year survival and locoregional control rates—80% and 90% respectively. However, both of these rates drop significantly with advanced tonsillar SCC. The 5-year survival and locoregional control rates range from 20 to 50% for stages III and IV disease.

Soft Palate

SCC of the soft palate is uncommon and accounts for fewer than 2% of all head and neck cancers. Because these lesions typically appear on the oral surface of the soft palate, they are easily detectable and frequently noted earlier than those at other oropharyngeal sites. Second primary lesions are found 13% of the time, and metachronous lesions are noted 26% of the time in patients with soft palate SCC. Rates of regional metastasis are higher than 20% for all T stages, with rates of bilateral spread as high as 15% for SCC of the soft palate. Tumor thickness of more than 3 mm in this area has been associated with regional metastasis.

The treatment of soft palate SCC is by radiation therapy or combined chemoradiation. Small lesions on the soft palate can be surgically excised transorally, but the resection of larger tumors has a high rate of velopharyngeal insufficiency and is best avoided. In addition to treatment of the primary lesion, patients with soft palate SCC should receive bilateral irradiation of the neck or bilateral neck dissection depending on the initial stage.

The rate of locoregional control of soft palate SCC is higher than 75% for early through stage III lesions. The 5-year survival is higher than 65% for this same group of patients. However, locoregional control and survival both drop to below 40% for stage IV lesions.

Base of Tongue

This region stretches from the circumvallate papillae of the posterior tongue to the vallecula. SCC of the base of tongue is less common, but more aggressive, than that of the oral tongue. In addition to SCC of the base of tongue, this area can give rise to lymphomas because of the presence of the lingual tonsil. Patients with base of tongue SCC present most commonly with otalgia and odynophagia. The diagnosis is difficult because of challenges in examining this area. SCC of the base of tongue can invade other oropharyngeal subsites as well as the larynx. Cervical lymph node metastases are present in more than 60% of patients at the time of presentation. SCC of the base of tongue, which is a midline structure, involves bilateral cervical nodes in 20% of cases.

Radiation therapy or chemoradiation therapy is typically used for base of tongue cancer, with surgery reserved for superficial lesions and salvage after radiation failure. Both surgery and radiation therapy have similar survival outcomes, but operating in this area is classically associated with significant

morbidity and functional disturbances. The cervical lymph node basins on both sides of the neck should receive treatment in patients with lesions of the base of tongue. If radiation therapy is used for the primary site, then it is typically used for the neck as well.

The surgery for base of tongue cancers is a hemiglossectomy and can be approached through methods similar to those used for tonsillar cancer. A mandibulotomy with a mandibular swing can be used to gain access to the base of tongue. Base of tongue lesions can also be treated surgically through the neck via a suprahyoid pharyngotomy approach. However, both of these approaches carry a moderate risk for postoperative functional morbidity. If a total or nearly total glossectomy is required for larger lesions, laryngectomy may be necessary to prevent chronic aspiration. Recently, the transoral approach has been advocated for appropriately selected patients with early base of tongue lesions. This operation can be performed with a handheld endoscope and a laser or robotically. Both endoscopic transoral surgery and transoral robotic surgery have been shown to have excellent locoregional control rates (higher than 85% for early base of tongue lesions).

Early base of tongue cancer is associated with a 5-year survival rate higher than 85% and a comparable locoregional control rate. However, advanced base of tongue carcinoma has a survival rate of less than 50% and is a particularly aggressive lesion.

Pharyngeal Wall

Lesions involving this subsite are rare but aggressive, with early invasion into surrounding structures such as the prevertebral fascia and hypopharynx. The metastatic potential is low for early pharyngeal wall cancers. Therefore, treatment of the lymphatic basins is often not required. Because most pharyngeal wall lesions cross the midline, lymph node metastases, when present, are often bilateral, and treatment of both sides of the neck is required. Lymphatic drainage is primarily to retropharyngeal and parapharyngeal lymph nodes but also may involve levels II through IV.

Pharyngeal wall cancers can be treated with surgery or radiation therapy. If surgery is performed, postoperative radiation therapy or chemoradiation therapy is typically incorporated. Because of its proximity to the spinal cord, administering radiation therapy to the posterior pharyngeal wall is challenging and requires precise planning. The treatment of lymph node metastases involves treating the retropharyngeal lymph nodes and therefore incorporates radiation therapy either as the primary treatment or as adjuvant therapy after neck dissection.

Pharyngeal wall lesions typically present at an advanced stage and carry a poor survival rate. One study noted a 5-year survival rate of less than 40% based on tumor staging.

Complications of Treatment

Side effects of radiation for oropharyngeal SCC include mucositis, xerostomia, sinusitis, osteoradionecrosis, dysphagia, laryngeal edema, and carotid artery rupture. Surgical complications depend on the approach used but include infection, malocclusion, and difficulty with speech and swallowing.

24.4.3 Hypopharyngeal Cancer

Hypopharyngeal cancer accounts for 6% of all head and neck cancers and has a worldwide incidence of from 0.8 to 5 cases per 100,000 persons. It is more common in well-developed countries. Of all hypopharyngeal cancers, 95% are SCC. These lesions are typically discovered late and are confined to the hypopharynx only 15% of the time. Regional lymph node metastases are noted at presentation in 65% of patients.

The main risk factors for hypopharyngeal SCC are tobacco and alcohol use, as for other head and neck cancers. In addition, hypopharyngeal cancer has also been associated with vitamin C deficiencies, exposure to asbestos and steel or coal dusts, and iron deficiency. Gastric reflux has been implicated in hypopharyngeal cancer, but no strong association has been discovered. Plummer-Vinson syndrome, however, has been associated with hypopharyngeal SCC, particularly in the postcricoid region. This syndrome affects mainly women and manifests with the triad of dysphagia, glossitis, and iron deficiency anemia. Improved nutrition and dietary fortification have reduced the incidence of Plummer-Vinson syndrome along with its role in hypopharyngeal SCC.

The hypopharynx is divided into three separate anatomical subsites: the piriform sinus, posterior hypopharyngeal wall, and postcricoid space. The piriform sinus is by far the most common subsite of hypopharyngeal cancer, accounting for approximately 75% of all lesions. The posterior pharyngeal wall accounts for 20% and the postcricoid region accounts for the remaining 5%. The hypopharynx is a physically small space, so cancers tend to invade surrounding structures quickly. Lesions of the piriform sinus can spread to the subglottis, paraglottic space, and thyroid cartilage. Posterior hypopharyngeal wall lesions tend to spread superiorly into the lower oropharynx, whereas cancers of the postcricoid space often spread to the cervical esophagus. Submucosal spread underneath intact epithelium is frequently seen with hypopharyngeal cancers.

Presentation

The most common symptoms at presentation are odynophagia, referred otalgia, dysphagia, hoarseness, and neck mass.

Evaluation

See the earlier section on evaluation of the oropharynx.

Staging

The staging of hypopharyngeal cancer follows the TNM staging system and is based on the AJCC guidelines from 2010.

A T1 lesion is no larger than 2 cm and is limited to one subsite of the hypopharynx. A T2 lesion is larger than 2 cm but smaller than 4 cm without fixation of the hemilarynx, or it invades more than one hypopharyngeal subsite or an adjacent site. T3 tumors are larger than 4 cm or associated with fixation of the hemilarynx. T4a lesions invade the thyroid or cricoid cartilage, hyoid bone, thyroid gland, or prelaryngeal strap muscles or subcutaneous fat. T4b lesions invade the prevertebral fascia, encase the carotid artery, or involve mediastinal structures.

N1 nodal disease is a single ipsilateral lymph node 3 cm or smaller in size. N2 disease is more extensive: N2a disease is a

single ipsilateral lymph node larger than 3 cm but smaller than 6 cm, N2b disease is multiple ipsilateral nodes (none larger than 6 cm), and N2c disease is bilateral or contralateral lymph nodes, none larger than 6 cm. Finally, any nodal metastasis larger than 6 cm is classified as N3.

In situ disease is classified as stage 0, and T1 lesions with no nodal or distant metastasis are stage I. T2 primary lesions with N0 status are stage II disease. T3 primary lesions with no nodal involvement or T1–T3 lesions with N1 nodal status are stage III. T4a lesions with N0–N2 nodal disease or T1–T3 lesions with N2 nodal disease are classified as stage IVA; T4b primary lesions with any N status or any lesion with N3 nodal status is stage IVB; any lesion with distant metastasis is stage IVC.

Differential Diagnosis

See the differential diagnosis for oropharyngeal cancer above. In addition, carcinoma of the larynx and esophagus should be included in the differential diagnosis for hypopharyngeal lesions.

Treatment

Early hypopharyngeal cancer is generally treated with radiation therapy because the disease-free survival rates are comparable and laryngeal and pharyngeal function is significantly better in patients treated with radiation than in those treated with surgery. Surgery is reserved for salvage after radiation failure or for lesions that are located in technically resectable areas, such as the upper piriform sinus and posterior pharyngeal wall. Transoral endoscopic resection with a laser is typically used for the surgical treatment of early hypopharyngeal cancers. Additional approaches for early lesions include partial laryngopharyngectomy and combined suprahyoid with lateral pharyngectomy. The partial laryngopharyngectomy can be used for cancers of the medial wall of the piriform sinus that are at least 1.5 cm from the apex. The combined suprahyoid resection with lateral pharyngectomy can be considered for early posterior hypopharyngeal wall cancers.

Advanced hypopharyngeal cancers involve surrounding structures, including the larynx and cervical esophagus, and therefore the treatment is similar to that for laryngeal or esophageal cancer. Organ preservation chemoradiation is commonly used as first-line therapy for advanced hypopharyngeal cancer. Surgery is reserved for poor responders and typically involves laryngectomy or laryngopharyngectomy. Esophageal involvement may require esophagectomy with gastric pull-up.

Hypopharyngeal cancer has a high rate of cervical lymph node metastasis, and the primary lesions often cross the midline. Because of this, both sides of the neck require treatment at all T stages. The decision whether to use radiation or surgery is typically based on the treatment of choice for the primary lesion.

Outcomes

Outcomes of the treatment of hypopharyngeal SCC depend on the subsite of the lesion. Pharyngeal wall SCC carries the worst prognosis, with a 5-year survival rate of 21%. Patients with piriform sinus lesions have the highest survival rate (approximately 50%). Postcricoid carcinoma has a survival rate of

35% In addition, the rate of distant metastases is high for hypopharyngeal cancer, approaching 20% depending on the T stage.

24.4.4 Esophageal Cancer

Incidence and Background

In 2012, there were an estimated 17,460 new cases of esophageal cancer in the United States. More than 95% of these cases will be SCC or adenocarcinoma of the esophagus. Until recently, SCC accounted for the large majority of esophageal malignancies. However, in the past two decades, the incidence of adenocarcinoma has continued to rise while the incidence of SCC has fallen. Now, these two types of malignancy occur with roughly equal frequency in the esophagus; adenocarcinomas occur mostly in the distal esophagus, whereas SCC is more evenly distributed throughout all the levels of the esophagus.

Risk factors for esophageal cancer vary depending on the histologic type. The risk factors for esophageal SCC are smoking, alcohol, Plummer-Vinson syndrome, a history of radiation treatment to the mediastinum, and nonepidermolytic palmoplantar keratoderma. Risk factors for adenocarcinoma of the esophagus include Barrett esophagus, obesity, acid reflux, tobacco use, and a history of radiation treatment. Barrett esophagus is metaplasia of the squamous mucosa in the distal esophagus to columnar epithelium similar to that of the stomach. Metaplasia progresses to dysplasia, followed by malignant transformation at a rate of 0.5% per year.

Presentation

At the time of diagnosis, between 50% and 60% of patients with esophageal carcinoma have an unresectable primary tumor, making prompt diagnosis of this disease extremely important. The propensity for advanced disease is believed to be largely due to the lack of serosa around the esophagus and to the fact that esophageal cancer is usually asymptomatic in its early stages. Symptoms of esophageal cancer include dysphagia, odynophagia, and weight loss. Hoarseness may also occur and carries a poor prognosis because it is a sign of invasion of the larynx. Carcinoma of the cervical esophagus is rare and most often comes from the spread of hypopharyngeal cancer to the esophagus rather than an esophageal primary.

Evaluation

Patients with esophageal carcinoma require CT of the neck, thorax, and/or abdomen depending on the location of the primary lesion. Endoscopic ultrasound and barium esophagram also provide valuable information about esophageal carcinoma and are typically obtained. In addition to imaging studies, flexible or rigid esophagoscopy should be performed to visualize the mass and obtain a histopathologic diagnosis.

Staging

The staging of esophageal cancer follows the TNM staging system and is based on the 2010 AJCC guidelines. It includes tumor type, depth, and spread; nodal metastasis; distant metastasis; histologic grade; and tumor location.

A T1 lesion invades the lamina propria, muscularis mucosae (T1a), or submucosa (T1b). T2 lesions invade the muscularis propria, and T3 lesions invade the adventitia. T4 status implies invasion of adjacent structures: resectable tumors invading the pleura, pericardium, or diaphragm (T4a) or unresectable tumors invading other structures, including the aorta, vertebral body, and trachea (T4b).

N1 nodal disease implies the involvement of one to two regional lymph nodes, N2 three to six nodes, and N3 seven or more regional nodes.

Staging of Squamous Cell Carcinoma of the Esophagus

In situ disease (high-grade dysplasia) is classified as stage 0. T1 low-grade lesions with no nodal or distant metastases are stage IA; if the tumor is of intermediate or high grade, it is stage 1B, as are low-grade T2–T3 lesions of the lower esophagus (below the lower border of the inferior pulmonary vein). T2 primary lesions with N0 status (intermediate or high grade if in the lower esophagus, or low grade if in the middle or upper esophagus) are stage IIA disease. T2–T3 primary lesions with N0 status (intermediate or high grade in the upper or middle esophagus) or any T1–T2 lesions with N1 disease are classified as stage IIB. Any T1–T2 lesion with N2 disease, T3 lesion with N1 disease, or T4a lesion with N0 disease is stage IIIA; T3 lesions with N2 disease are stage IIIB. A T4a primary lesion with N1–N2 nodal disease, any T4b lesion, and any lesion with N3 nodal status is considered to be stage IIIC. Any lesion with a distant metastasis is stage IV.

Staging of Adenocarcinoma of the Esophagus

In situ disease (high-grade dysplasia) is classified as stage 0. T1 low- or intermediate-grade lesions with no nodal or distant metastases are stage IA; if the tumor is high-grade, it is stage 1B, as are low- or intermediate-grade T2 lesions. High-grade T2 primary lesions with N0 status are stage IIA disease. T3 primary lesions with N0 status or any T1–N2 lesions with N1 disease are classified as stage IIB. Any T1–T2 lesion with N2 disease, T3 lesion with N1 disease, or T4a lesion with N0 disease is stage IIIA; T3 lesions with N2 disease are stage IIIB. A T4a primary lesion with N1–N2 nodal disease, any T4b lesion, and any lesion with N3 nodal status is considered to be stage IIIC. Any lesion with a distant metastasis is stage IV.

Differential Diagnosis

The differential diagnosis for esophageal carcinoma includes achalasia, eosinophilic esophagitis, leiomyosarcoma, and peptic strictures due to reflux.

Treatment

The treatment options for esophageal cancer include surgery, radiation, and chemotherapy. The optimal treatment depends on the location and stage of the disease. Surgery is an option for a minority of patients with early-stage disease and typically consists of a partial or total esophagectomy. This can be accomplished through a transthoracic or transhiatal approach if the

tumor involves the thoracic or distal esophagus. Gastric transposition or pull-up is required for reconstruction of this defect. A transcervical approach can be used for access to cervical esophageal cancer lesions. However, most tumors have invaded the esophageal wall by the time they are diagnosed or have metastasized to regional lymph nodes, making complete surgical resection nearly impossible. For these patients, chemoradiotherapy is often chosen as first-line treatment. Chemoradiotherapy may also be used preoperatively to reduce tumor size and allow complete resection. However, no survival benefit has been demonstrated from preoperative radiation therapy, chemotherapy, or combined chemoradiotherapy.

Outcomes

The overall prognosis for esophageal cancer is poor. The 5-year survival rate for patients with stage II disease or worse is less than 15%. Stage I disease has a survival rate of more than 50% but diagnosis at this stage is rare.

24.5 Roundsmanship

- NPC occurs at a significantly higher rate in certain groups, such as ethnic Chinese in the southern part of China, Aleut Native Americans in Alaska, and Southeast Asians.
- The proper evaluation of NPC includes CT and MR imaging.
- Between 25% and 30% of patients with NPC will develop distant metastases, the highest rate for cancer at any head and neck site.
- Plummer-Vinson syndrome (associated with hypopharyngeal SCC) affects mainly women and manifests with the triad of dysphagia, glossitis, and iron deficiency anemia.

- Hypopharyngeal cancers often cross the midline and have a high rate of cervical lymph node metastasis, so that treatment of both sides of the neck is required at all T stages.

25 Diseases and Neoplasms of the Larynx

Edward M. Stafford

25.1 Introduction

In the field of head and neck oncology, the evolution of the treatment of laryngeal cancer has followed the adage “everything old is new again.” Although laryngeal cancer was once treated primarily as a surgical disease, advances in “organ preservation” protocols and intensity-modulated radiation therapy (IMRT) ushered in a new paradigm in its treatment. Now, partly because of treatment failures and sometimes poor functional outcomes in patients treated with primary radiotherapy or chemoradiotherapy, the pendulum has shifted again over the course of the last decade, with a reemergence of primary surgical therapy in the treatment of both early and advanced laryngeal cancer. With advances in transoral endoscopic techniques as well as a new-found appreciation for time-tested open conservation approaches to laryngeal surgery, the treatment algorithm for laryngeal cancer demonstrates the need for today’s head and neck surgeons to have all the available tools, surgical and nonsurgical, at their disposal in treating this challenging malignancy. If there is one subsite in the head and neck where the surgeon’s judgment is of paramount importance in choosing among a variety of treatment options, it is the larynx.

25.2 Incidence of Disease

Cancer of the larynx, compared with other malignancies, such as cancers of the breast or lung, is relatively uncommon. It accounts for fewer than 1% of all human malignancies. Within the head and neck, however, laryngeal cancer is much more common, representing roughly 25% of all head and neck cancers. According to the American Cancer Society, there will be an estimated 12,360 new cases of laryngeal cancer in the United States in 2012. There will also be an estimated 3,650 deaths attributable to laryngeal cancer. According to the Surveillance Epidemiology and End Results (SEER) database, the 5-year survival of patients with laryngeal cancer depends predominantly on the presence of regional and distant disease. From 1996 to 2004, overall survival for all T stages was 62.5% the rates were 80.9% for patients with local disease, 50.2% for patients with metastatic disease in the neck, and 23.4% for those with distant disease.

25.3 Terminology

In order to understand the diagnostic and treatment algorithms in the treatment of laryngeal carcinoma, one must understand the associated terminology. First, when discussing the larynx as a functional unit, the surgeon will refer to the primary disease, or the site at which the carcinoma originates. The primary lesion is then described as occurring in the supraglottic larynx, glottic larynx, or subglottic larynx. As with other head and neck malignancies, when the carcinoma spreads outside the area of the primary lesion, the staging of the malignancy is affected. With regard to lymph node metastases, these are described as regional when they occur in the central and lateral neck compartments. When metastases occur outside the head and

neck, they are described as distant. Finally, particularly pertinent with cancer of the larynx, any extension of disease outside the boundaries of the larynx is categorized as extralaryngeal spread (□ Fig. 25.1).

With regard to treatment, surgical therapies are divided into several categories. Surgery that employs endoscopic laser techniques to remove laryngeal carcinoma is categorized as transoral laser surgery. Techniques that employ robotic technology are categorized as transoral robotic surgery (TORS). Open surgical techniques that remove part but not all of the larynx are categorized as conservation laryngeal surgery. With regard to the use of radiation therapy, techniques that treat laryngeal cancer without surgical excision but with radiation and possibly the addition of chemotherapy are called organ preservation techniques. Finally, radiation therapy or chemotherapy given after surgical excision is described as adjuvant treatment, whereas neoadjuvant chemotherapy precedes surgical excision.

25.4 Applied Anatomy

As with all surgical disease, a thorough understanding of the underlying anatomy is indispensable for an understanding of the pathogenesis of laryngeal cancer. The larynx can be divided into three subsites: supraglottic, glottic, and subglottic. Each subsite of the larynx has a unique embryonic development and subsequently distinct lymphatic drainage patterns. The glottic larynx, or glottis, includes the paired true vocal folds, anterior commissure, and posterior commissure. The supraglottic larynx is that portion of the larynx superior to the glottis, including the false vocal folds, arytenoids, aryepiglottic folds, and epiglottis. The subglottic larynx begins 10 mm below the free margin of the true vocal folds and extends to the inferior border of the cricoid cartilage. With regard to the substance of the larynx, it consists of a bony and cartilaginous framework, fibroelastic ligaments, muscles, and mucosal and submucosal surfaces. The

Fig. 25.1 Extralaryngeal spread as visualized in a patient with T4 glottic squamous cell carcinoma on computed tomography. Note the erosion of the outer table of the thyroid cartilage.

bony and cartilaginous framework includes the thyroid cartilage, cricoid cartilage, epiglottis, hyoid bone, and arytenoids.

Created by the various cartilages, ligaments, and membranes of the larynx are several distinct spaces that are of critical importance in evaluating the stage of laryngeal cancer, including the pre-epiglottic space, paraglottic space, and subglottic space. Of particular importance is a structure called the conus elasticus, which originates from the cricoid cartilage, attaches posteriorly to the arytenoid cartilages, and condenses medially to form the vocal ligament. Anteriorly, the conus elasticus attaches to the thyroid cartilage at the Broyle ligament, also known as the anterior commissure tendon. Because this area is devoid of an inner perichondrium (the thyroid cartilage normally has both an inner and an outer perichondrium), it is a frequent source of spread for lesions involving the anterior commissure. The anterior commissure is the area where the paired true vocal folds meet and is a frequent site of involvement in early larynx cancers. Other laryngeal ligaments and membranes of importance in delineating the potential spaces of the larynx include the thyrohyoid membrane, quadrangular membrane, and hyoepiglottic ligament.

The intrinsic muscles of the larynx control the movement of the true vocal folds. All intrinsic muscles of the larynx are innervated by the recurrent laryngeal nerve except the cricothyroid muscle. The cricothyroid muscle produces tension and elongation of the vocal folds and is innervated by the external branch of the superior laryngeal nerve. Other intrinsic muscles of note include the posterior cricoarytenoid, the only abductor of the vocal fold. The remainder of the intrinsic muscles of the larynx serve as vocal fold adductors to some extent.

25.5 The Disease Process

25.5.1 Etiology

The etiology of squamous cell carcinoma (SCC) of the larynx is typically multifactorial. As with other types of head and neck

cancer, alcohol and tobacco intake have a synergistic effect in the pathogenesis of SCC, the most common pathologic type of squamous cell cancer. Other factors promoting carcinogenesis include asbestos, ionizing radiation, wood dust, gastroesophageal reflux disease, and nitrogen mustard. The role of the human papillomavirus (HPV) in the pathogenesis of SCC in many locations of the head and neck has been elucidated over the course of the last decade. Like disease in other subsites of the head and neck, HPV-associated disease may behave in a biologically distinct manner. Organ preservation approaches in the treatment of HPV-associated disease require less aggressive and toxic regimens, particularly in the choice of chemotherapy agents. Studies elucidating the role of “deintensification” in the treatment of HPV-related disease have yet to reach a consensus in this regard. Interestingly, laryngeal papillomatosis, which is a benign HPV-related condition of the larynx, is thought to undergo malignant transformation in up to 10% of adult patients with chronic disease.

25.5.2 Pathogenesis and Pathology

Laryngeal malignancies

Despite the variety of malignancies described in the larynx, SCC predominates. A few notes on the more common varieties of SCC. Carcinoma in situ is characterized as dysplasia that involves the entire thickness of the mucosa but does not involve the basement membrane. Microinvasive carcinoma is defined by malignant cells that do not penetrate the basement membrane into the superficial lamina propria of the respiratory epithelium. Invasive SCC, the most common variety, accounts for 1% of all cancers and 95% of all laryngeal cancers. Invasive SCC, like microinvasive carcinoma, penetrates the basement membrane and extends through the lamina propria, but it also invades into the underlying tissues—in the case of the larynx, the underlying vocalis muscles (□ Fig. 25.2 and □ Fig. 25.3a).

Fig. 25.2 (a) Layers of the glottic larynx, from superficial to deep. (b) Depth of in situ, microinvasive, and invasive carcinoma of the larynx.

25.5.3 Natural History and Progression of Disease by Site

Supraglottic SCCs account for roughly 25 to 40% of all laryngeal cancers and include carcinomas of the epiglottis, false vocal folds, aryepiglottic folds, ventricles, and arytenoids, in order of descending frequency. In fact, 50% of supraglottic carcinomas involve the epiglottis, with a majority of supraglottic lesions in other locations partially involving the epiglottis. The natural history of supraglottic tumors is to spread upward toward the free edge of the epiglottis and aryepiglottic folds, into the pre-epiglottic space, or outside the larynx into the piriform sinus mucosa or tongue base. In contrast to patients with carcinoma

of the glottic larynx, those with early-stage supraglottic carcinomas may not have dysphonia. They often present with a globus sensation, cough, and exertional dyspnea, depending on the size of the lesion. Occasionally, a neck mass alone may be the presenting symptom. This is explained by a characteristic that distinguishes supraglottic carcinomas from glottic carcinomas: the rich lymphatic drainage of the supraglottic larynx. Up to 50% of patients with supraglottic carcinoma have a clinically positive lymph node metastasis. Additionally, as the T stage increases, the likelihood that regional lymph node metastases will be present at the time of diagnosis increases as well; similarly, as the size of clinically positive lymph node metastases increases, so does the likelihood that contralateral lymph node

Fig. 25.3 (a) Squamous cell carcinoma with invasion through the basement membrane, indicating invasive disease. (b) Thyroid cartilage invasion at the microscopic level. Notice invasion of squamous cell carcinoma into the islands of cartilage.

metastases will be present. In particular, carcinomas of the epiglottis are prone to bilateral lymph node metastases. Even among patients with early-stage epiglottic lesions, up to 20% have occult bilateral lymph node metastases at the time of diagnosis. Clinically, supraglottic carcinomas range from exophytic to ulcerative. Patients with exophytic tumors present with more airway symptoms, often with a “ball valve” effect if the lesions are very bulky, as the lesions may intermittently cause obstruction during quiet respiration. Interestingly, those tumors that are very bulky and less ulcerative often tend to be less hypoxic and, accordingly, respond better to radiation therapy.

Accounting for 60 to 65% of all laryngeal SCCs, glottic carcinomas are the most common type of laryngeal carcinoma in the United States. These lesions commonly present with dysphonia in the early stages and with progressive airway complaints in the later stages. Glottic carcinomas most commonly involve the anterior two-thirds of the vocal folds; involvement of the posterior one-third of the glottis is uncommon. The natural history of spread follows predictable patterns, including contralateral spread across the anterior commissure, anterior spread through the Broyle ligament with subsequent spread into the thyroid cartilage and soft tissues of the neck, extension to involve the posterior commissure and postcricoid mucosa, and supraglottic

extension (□ Fig. 25.3b). As lesions that start in the supraglottis less commonly spread to involve the glottis, lesions that involve the glottis and epiglottis or other areas of the supraglottic larynx are typically staged as glottic primary lesions. Of note, involvement of the anterior commissure is an important prognostic consideration, particularly when a choice is made between organ preservation and primary surgical approaches. Multiple reports in the literature suggest that early-stage lesions that involve the anterior commissure are relatively less curable with radiation than with transoral laser, TORS, or open partial laryngeal surgery techniques. As mentioned previously, in contrast to the supraglottis, the glottic larynx has a relative paucity of lymphatic drainage. Routine treatment of the neck is not necessary for early-stage lesions (T1 or T2), whereas regional lymph node metastases are more common in T3 and T4 disease.

Cancers of the subglottic larynx are the least common type of laryngeal cancer. They account for between 1 and 8% of laryngeal cancers. Subglottic SCCs are defined as those lesions that begin 1 cm below the apex of the ventricle and extend to the superior margin of the cricoid cartilage. These are typically poorly differentiated and often have a prolonged asymptomatic period; patients will present late in the course of disease with airway obstruction. The natural history of spread is typically circumferential and anterior, with involvement of the cricothyroid membrane and thyroid. They can also spread posteriorly to involve the esophagus, inferiorly into the trachea, or into the framework of the larynx, including the thyroarytenoid muscle and cricoarytenoid joint. Regional lymph node metastases are less common than in supraglottic carcinomas but more common than in glottic carcinomas. When regional metastatic disease occurs, subglottic carcinomas tend to spread to prelaryngeal and pretracheal nodal basins. Because patients tend to present with advanced disease, the overall 5-year survival rate is a dismal 40%; many patients treated with total laryngectomy have early an recurrence with peristomal disease.

25.5.4 Potential Disease Complications

Disease complications of untreated carcinoma are typically respiratory, phonation-related, or digestive. Progressive airway obstruction is inevitable in untreated SCC of the larynx. This may begin as intermittent dyspnea with a ball valve lesion and progress to constant dyspnea with minimal exertion. Typically, the patient will develop stridor, which may be inspiratory or biphasic depending on the site of the primary lesion. Occasionally, the lesion may bleed, and the patient may notice mild hemoptysis. In addition, although supraglottic lesions do not necessarily cause vocal changes, lesions involving the glottic larynx invariably cause some measure of hoarseness and occasionally a breathy voice depending on the extent of disease. Finally, swallowing problems may develop because of simple tumor bulk, coexisting vocal fold paralysis, or extralaryngeal spread of disease in the piriform sinus or postcricoid mucosa. Complications of metastatic disease depend on the location of the metastases, which can occur in areas as varied as the lungs, liver, brain, and spine. Terminal events from untreated disease are often caused by catastrophic airway obstruction or hemorrhage from vascular sites adjacent to areas of primary disease (□ Fig. 25.4).

Fig. 25.4 Coronal positron emission tomography demonstrating primary disease at the level of the supraglottic and glottic larynx, as well as mediastinal pretracheal metastatic adenopathy. Terminal events can result from the direct extension of both primary and metastatic disease into vascular structures.

25.6 Disease Grading: American Joint Committee on Cancer Staging

The American Joint Committee on Cancer (AJCC) guidelines are based on the TNM (tumor node metastasis) system of staging. The T stage depends not on size but on extent of disease within the anatomical divisions of the larynx. The N and M staging criteria are similar to those used in other regions of the head and neck. Of note, disease in each division of the larynx (supraglottic, glottic, and subglottic) is staged separately because carcinoma in each region exhibits distinct biological behavior.

25.6.1 Supraglottis

Tumors that are confined to one subsite of the supraglottis and do not affect vocal fold mobility are classified as T1 lesions. T2 lesions involve the mucosa of more than one adjacent glottic or supraglottic subsite or region outside the glottis, such as the mucosa of the vallecula, medial wall of the piriform sinus, or base of tongue, without laryngeal fixation. A tumor limited to the larynx with vocal fold fixation and/or invasion of the post-cricoid region, pre-epiglottic space, paraglottic space, or inner cortex of the thyroid cartilage are considered T3 lesions. T4 status indicates moderately advanced (T4a) or very advanced (T4b) primary disease. T4a lesions invade the thyroid cartilage and/or invade tissues beyond the larynx, whereas T4b lesions invade the prevertebral space or mediastinum or encase the carotid artery.

25.6.2 Glottis

T1 lesions involve one (T1a) or both (T1b) vocal folds, which retain normal mobility. T2 lesions extend into the supraglottis and/or subglottis or impair vocal fold mobility. T3 lesions are limited to the larynx, with vocal fold fixation and/or paraglottic space and/or thyroid cartilage invasion. T4a lesions penetrate the outer thyroid cartilage cortex and/or invade tissues beyond the larynx. As with supraglottic lesions, T4b primary lesions invade the prevertebral space or mediastinum or encase the carotid artery.

25.6.3 Subglottis

T1 subglottic lesions are limited to the subglottis. T2 lesions extend to the vocal folds; mobility is either normal or impaired. T3 lesions are limited to the larynx and cause vocal fold fixation. T4a lesions invade the thyroid or cricoid cartilage and/or invade tissues beyond the larynx. As with supraglottic and glottic lesions, T4b primary lesions invade the prevertebral space or mediastinum or encase the carotid artery.

Regardless of the subsite within the larynx of the primary tumor, N1 status implies involvement of a single lymph node that is ipsilateral and smaller than 3 cm. N2a indicates involvement of a single ipsilateral lymph node larger than 3 cm but smaller than 6 cm. N2b disease describes the involvement of multiple ipsilateral nodes, none larger than 6 cm, and N2c describes the involvement of contralateral or bilateral nodes, none larger than 6 cm. N3 status is reserved for nodal disease larger than 6 cm.

Stage 0 indicates in situ disease. T1 lesions with no regional or distant metastases are classified as stage I; likewise, T2 disease without nodal or distant metastases is stage II. T3 disease with no nodal or distant disease, or T1–T3 disease with N1 disease, is considered stage III. T4a primary disease with N0 or N1 nodal status, and T1–T3 disease with N2 nodes, are considered stage IVA; T4b disease with any N disease, or any T disease with N3 disease, is considered stage IVB. Any distant metastasis implies stage IVC disease.

25.7 Pretreatment Medical Evaluation

As for other malignancies of the head and neck, a thorough history and physical examination are of paramount importance in the diagnosis and ultimate preoperative work-up of the patient with laryngeal cancer. Of particular importance are the presence of any progressive airway complaints and the presence of ear pain or dysphagia, which may indicate the possibility of extralaryngeal spread. Although indirect mirror laryngoscopy is entirely appropriate on a screening head and neck examination, fiber-optic laryngoscopy provides a panoramic view of the subsites of the larynx, as well as the oropharynx and hypopharynx. Fiber-optic laryngoscopy allows the examiner to determine the subsite(s) of involvement and assess the mobility of the true vocal folds and arytenoids, and it can provide evidence of extralaryngeal extension. For subtle lesions of the glottic larynx, video stroboscopy may provide additional detail, as well as determine the depth of invasion of glottic carcinomas. Palpation of both the central and lateral neck is critical to screen for regional lymph node metastasis. In addition, palpation of the thyroid cartilage should reveal normal laryngeal crepitus when the larynx is moved back and forth. The loss of normal laryngeal crepitus may indicate extension of a laryngeal primary into the prevertebral fascia. Occasionally, tumor extending through the thyroid lamina can be palpated.

25.7.1 Radiographic Imaging

Preoperative imaging modalities include computed tomography (CT), magnetic resonance (MR) imaging, ultrasound, and positron emission tomography (PET)-CT. The relative merits of each are discussed as follows. CT is particularly helpful in determining the presence of thyroid cartilage erosion. In a review of the bony windows of a noncontrast CT scan, a deossified appearance of the inner table of the thyroid cartilage can predict at least T3 and sometimes T4 disease. Furthermore, the addition of intravenous contrast is helpful in screening for regional lymph node metastasis. MR imaging, because it tends to provide better detail of soft-tissue planes, is often superior to CT in determining the extent of pre-epiglottic or paraglottic space involvement. Ultrasound of the central and lateral nodal basins, in the hands of a skilled ultrasonographer, can serve as an adjunct to the clinical examination in screening for regional lymph node metastasis. Finally, in the setting of laryngeal cancer, PET-CT probably has the largest role in the work-up of distant disease, although in the setting of biopsy-proven disease, it often does not add any information beyond that obtained from the clinical examination and traditional staging modalities, including chest radiography, liver function studies, and the previously discussed modalities of CT, MR imaging, and ultrasound.

25.7.2 Direct Laryngoscopy and Biopsy

There is no substitute for direct laryngoscopy in the staging of laryngeal cancer, although dynamic evaluation of the larynx with flexible laryngoscopy is critically important in determining vocal fold and arytenoid mobility. If no gross airway obstruction is present, an orotracheal intubation with anesthesia

is entirely appropriate. The GlideScope GVL video laryngoscope (Verathon, Bothell, WA) can provide excellent visualization of the airway, which can assist in the placement of the endotracheal tube around an obstructing laryngeal lesion. Often, however, there is some degree of supraglottic or glottic airway obstruction beyond the comfort of the anesthesia team, and the otolaryngologist must take a leadership role in establishing the airway. In this circumstance, the table should be turned 90 degrees, with the otolaryngologist at the head of the table. For patients who have an airway that can safely accommodate a small-caliber (5.5 to 6 mm) endotracheal tube, the anesthesia team may provide sedation with propofol or a volatile anesthetic. If, with an oral airway in place, the patient can be safely ventilated with a bag mask, a short-acting paralytic will be administered. The otolaryngologist will then intubate through a Dedo laryngoscope. If the airway is marginally patent, an Eshmann stylet can be placed through the glottic airway, with the endotracheal tube then placed into the trachea over the stylet via Seldinger technique. In the event that the patient cannot tolerate a supine position or is not able to be safely ventilated with a bag mask, fiber-optic nasal intubation is an excellent option. Many anesthesiologists are trained in oral fiber-optic intubation or will attempt fiber-optic nasal intubation with the patient supine. This is inadvisable in the patient with laryngeal cancer and an obstructing lesion. Before the fiber-optic laryngoscope is placed into the glottic inlet, the topical application of 4% lidocaine can prevent laryngospasm during the intubation. After establishment of the airway via nasal fiber-optic intubation, a suspension microlaryngoscopy can commence. The orotracheal tube can then be placed through the vocal folds under direct visualization as the nasotracheal tube is withdrawn. Finally, for those patients with stridor, in whom a safe airway cannot be established by another method, an awake tracheotomy can be performed very quickly and safely immediately before staging direct laryngoscopy.

After establishment of the airway, direct laryngoscopy is performed. The Dedo and Hollinger laryngoscopes are used most commonly. The Hollinger, or anterior commissure, laryngoscope is particularly helpful in staging laryngeal carcinoma because it affords an excellent view of the anterior commissure. The Dedo laryngoscope is wider and easier to suspend for microlaryngoscopy, and the surgeon can pass instruments more easily through the lumen of this laryngoscope. Other laryngoscopes commonly used include the Lindholm laryngoscope, or supraglottiscope, which provides a more panoramic view of the supraglottic and glottic larynx. Finally, the Zeitels Universal Modular Glottiscope, like the Hollinger, has a tapered tip that affords an excellent view of the glottic airway and anterior commissure. In addition, like the traditional sliding Jackson laryngoscope, the Zeitels laryngoscope has a base that the surgeon can remove after suspension. This is helpful in situations in which the surgeon must intubate through a laryngoscope because one can withdraw the scope over the endotracheal tube more easily (□ Fig. 25.5 and □ Fig. 25.6).

The anterior extent of tumor, involvement of the anterior commissure, and involvement of the false vocal folds, ventricles, postericoid area, hypopharyngeal mucosa, and mucosa of the arytenoids are all factors of particular importance in staging a supraglottic or glottic carcinoma. Rigid angled endoscopes can be helpful in determining the inferior extent of a glottic lesion,

Fig. 25.5 Hollinger laryngoscope. This laryngoscope is ideal for difficult airways and the anterior larynx.

Fig. 25.6 Zeitel's Universal Modular Glottiscope. It is beveled anteriorly and good for the anterior larynx, and like the sliding Jackson laryngoscope, it can be retracted around an endotracheal tube after intubation.

Fig. 25.7 Left glottic lesion, pedunculated. The ultimate diagnosis was papillary squamous cell carcinoma. The patient tested positive for human papillomavirus and was treated with transoral laser excision with negative margins.

as well as in determining subglottic extension in circumstances in which a transglottic carcinoma is present. When partial laryngeal surgery approaches are being considered, a thorough assessment of the arytenoids preoperatively and intraoperatively is of paramount importance. All partial laryngeal surgical excisions require at least one fully mobile and sensate cricoarytenoid complex with no involvement of the inter-arytenoid mucosa. Traditionally, palpation of the arytenoids at laryngoscopy was emphasized; however, with advancements in fiberoptic technology and “distal chip” fiber-optic laryngoscopes in common use, much of this information can be determined before staging laryngoscopy. Arytenoid fixation, when present, indicates involvement of the cricoarytenoid joint with tumor. This may preclude conservation approaches to laryngeal surgery. Of note, true vocal fold fixation is not the same as arytenoid fixation; vocal folds may be fixed because of tumor bulk or because of paraglottic space involvement.

The biopsy of a laryngeal lesion can be complicated by previous radiation therapy, and superficial biopsies may not yield enough evidence for a pathologist to render a diagnosis. Unfortunately, deep biopsies in the postradiation setting can

precipitate laryngeal edema and sometimes chondronecrosis if cartilaginous structures are exposed. Diagnosing persistent disease early after treatment is particularly challenging in this regard because severe osteonecrosis of the larynx can mimic laryngeal cancer. Finally, for those obstructing supraglottic or glottic tumors diagnosed by intraoperative frozen section analysis, the use of a laryngeal microdebrider to reduce tumor bulk can improve the airway in those patients who may ultimately be candidates for organ preservation therapy.

25.7.3 Differential Diagnosis

As mentioned previously, the vast majority of laryngeal carcinomas are SCCs, and although a great variety of pathologic lesions can develop in this area, a biopsy often only confirms what the surgeon has first strongly suspected. Nonetheless, there are several conditions to mention that can mimic laryngeal cancer. For example, collagen vascular diseases, such as sarcoidosis, amyloidosis, and Wegener granulomatosis, can all cause mass lesions of the larynx. Internal laryngoceles can give the appearance of significant glottic edema that may look suspicious for carcinoma. Of note, the head and neck surgeon should be wary of the internal laryngocele in a longtime smoker because an internal laryngocele can develop in the presence of a coexisting SCC. Certainly (HPV-related) laryngeal papillomatosis in an adult can mimic the appearance of SCC (□ Fig. 25.7). Although rare, other benign epithelial lesions, such as minor salivary gland tumors, may be present in the larynx. A variety of benign mesenchymal and neuroectodermal lesions can present in the larynx, including granular cell tumors, rhabdomyomas, paragangliomas, lipomas, and hemangiomas, as well as numerous less common entities. These have variable appearances and less commonly mimic SCC. Finally, in the patient with suspected persistent or recurrent disease after definitive radiotherapy or chemoradiotherapy, one must consider the possibility of osteoradionecrosis of the larynx because profound post-treatment edema, although suspicious for malignancy, may be negative on serial biopsy despite the development of airway obstruction (□ Fig. 25.8).

Fig. 25.8 Right glottic and false fold squamous cell carcinoma in an elderly woman who was treated with definitive radiotherapy. Persistent postoperative edema prompted repeat biopsy, which confirmed persistent disease.

25.8 Medical Treatment of Laryngeal Cancer

Part of the multidisciplinary evaluation of the patient with glottic carcinoma includes an assessment by a radiation oncologist. Early glottic malignancies are notable for a low incidence of occult nodal metastasis, and therefore single-modality treatment with curative radiotherapy alone is often an acceptable modality for many patients. Radiation therapy has many advantages, including its noninvasive nature, acceptable vocal outcomes, and excellent local control rates. For patients with early-stage lesions, functional outcomes are generally very good, with most experiencing only self-limited symptoms of mucositis, xerostomia, dysphagia, and local soft-tissue reactions. Advances in radiation therapy techniques, predominantly the use of IMRT, have allowed the radiation oncologist to provide treatment to the larynx alone while sparing other sites in the neck in settings where there is no clinical presence or little risk for regional lymph node metastasis. Although vocal quality does change after radiation therapy, most patients experience a return to nearly normal phonation 1 year after the treatment of early glottic cancer. With regard to outcomes, primary radiation therapy of early T1 glottic carcinoma results in excellent local control rates, typically around 90%. Local control rates for T2 glottic carcinomas are less impressive but are as high as 80% in reported series. Of note, in many published series, patients with involvement of the anterior commissure at diagnosis who were treated with primary radiotherapy generally fared worse in terms of local control.

The treatment of supraglottic malignancies with primary radiotherapy generally results in excellent control rates exceeding 90% for early-stage lesions. The supraglottic larynx has more

substantial lymphatic drainage than the glottic larynx, so treatment volumes are generally higher because the radiation field must include the primary lesion as well as the regional lymph node basin. The specifics of radiation techniques vary with the institution and range from single-fraction once-daily treatments to twice-daily hyperfractionation and accelerated hyperfractionation schedules.

Although advanced (stage III or IV) laryngeal cancer had traditionally been managed with primary surgical therapy and possibly postoperative radiotherapy, a landmark study from the Department of Veterans Affairs Laryngeal Cancer Study Group in 1991 demonstrated that induction chemotherapy with definitive radiotherapy provides high larynx preservation rates without compromising overall survival. The past 20 years have seen a dramatic increase in the use of chemoradiation protocols in treating advanced laryngeal cancer. This paradigm shift has been controversial because chemoradiation protocols are associated with not-insignificant toxicity, including long-term dysphagia and xerostomia. Higher radiation treatment volumes can result in the devastating complication of osteoradionecrosis of the larynx, which can necessitate a tracheotomy or total laryngectomy, even in the setting of disease control. Coinciding with this paradigm shift, an overall survival decrease among patients with head and neck cancer was noted by Hoffman and others in a review of the National Cancer Data Base between the years of 1985 and 2001. The reasons for this change in survival are controversial. Current practice guidelines from the American Society of Clinical Oncology recommend a larynx preservation strategy, with surgery or radiation, for all patients who have T1 or T2 disease. For patients who have T3 or T4 disease without tumor invasion through cartilage into soft tissues, a larynx preservation strategy including chemoradiation therapy is an acceptable treatment option. These regimens may include neoadjuvant chemotherapy with concurrent chemoradiation, or alternatively concurrent chemoradiation. Choices among chemotherapeutic agents are diverse, ranging from traditional platinum-based agents such as cisplatin to newer agents such as cetuximab, a monoclonal antibody and epidermal growth factor receptor (EGFR) inhibitor.

With regard to postoperative radiotherapy or postoperative chemotherapy, many factors are considered. First, the extent of the disease is important to consider, including whether there is a close or positive margin, angiolymphatic invasion, or any extralaryngeal spread. With regard to the status of the neck, the presence of multiple positive lymph node metastases and extracapsular spread is considered when the need for adjuvant chemotherapy or radiation is determined. Adjuvant treatments are determined in conjunction with colleagues from medical and radiation oncology.

25.9 Roundsmanship

- The clinical examination is critically important in the preoperative evaluation of the patient with laryngeal cancer. Understaging a patient can result in treatment failures and intraoperative misadventures. Of particular importance in the staging of laryngeal carcinoma is anterior commissure involvement and subglottic extension (□ Fig. 25.9).

Fig. 25.9 Squamous cell carcinoma of the larynx. Transglottic lesion with extension into the subglottis.

- The supraglottic larynx lymphatic supply must be respected; elective treatment of the neck for patients with even early-stage supraglottic lesions should be considered.
- Many treatment modalities exist for the treatment of laryngeal cancer. Any treatment must be tailored to the individual patient, taking into account the biological behavior of the tumor as well as the ability of the patient to participate actively in recovery and rehabilitation. One size does not fit all.
- Although squamous cell carcinoma is far and away the most common type of laryngeal cancer, in the nonsmoking patient with few risk factors, conditions such as collagen vascular dis-

ease and other benign processes of the larynx can mimic laryngeal carcinoma. One should use caution in relying on an intraoperative frozen section results alone before undertaking definitive surgical extirpation.

26 Surgery of the Laryngopharynx

Edward M. Stafford

26.1 General Types of Intervention, Rationale, and Goals

The goal of surgical therapy for laryngeal cancer, as for other malignancies in the head and neck, is the extirpation of all disease with negative margins. Although postoperative radiotherapy may be indicated in certain situations, regardless of the surgical modality chosen, negative margins should take priority. Certainly, with advances in organ preservation techniques and the morbidity added by postoperative radiotherapy, this principle should guide the surgeon's decision-making process, both in choosing among surgical modalities and in determining the appropriate extent of resection. Although the goal of negative margins is unambiguous, there are a variety of other considerations that inform the decision-making process. Of paramount importance, regardless of the surgical modality chosen, is the preservation of function. Therefore, included among the goals of therapy should be a plan to ensure voice rehabilitation, the adequacy and safety of the airway, and short- and long-term nutritional strategies.

26.2 Pertinent Anatomy

As was discussed in Chapter 25, the larynx is divided into subsites: the supraglottic, glottic, and subglottic larynx, each with its own unique embryonic development and lymphatic drainage. The supraglottic larynx is the portion of the larynx superior to the glottis, including the false vocal folds, arytenoids, aryepi-

glottic folds, and epiglottis. The subglottic larynx begins 10 mm below the free margin of the true vocal folds and extends to the inferior border of the cricoid cartilage. Finally, the glottis includes the paired true vocal folds, as well as the anterior and posterior commissures. Of particular importance to the surgeon is an understanding of the anatomical spaces created by various cartilages, ligaments, and membranes of the larynx, including the pre-epiglottic, paraglottic, and subglottic spaces. Understanding these spaces is critically important in staging patients appropriately.

The pre-epiglottic space is an anatomical space with the following boundaries: anteriorly, the thyrohyoid membrane and the inner table of the thyroid cartilage; posteriorly, the epiglottis; superiorly, the hyoepiglottic ligament and mucosa of the vallecula; and inferiorly, the thyroepiglottic ligament. By definition, involvement of the pre-epiglottic space upstages a laryngeal carcinoma to at least a T3 lesion (□ Fig. 26.1).

The paraglottic space borders the glottis laterally. This space extends both above and below the true vocal folds and is created by the following boundaries: medially, the quadrangular membrane, ventricle, and conus elasticus; laterally, the perichondrium of the thyroid lamina and cricothyroid membrane; anterosuperiorly, the pre-epiglottic space; and posteriorly, the mucosa of the piriform sinus. Extension into the paraglottic space often portends the transglottic and extralaryngeal spread of disease (□ Fig. 26.2).

The subglottic space is a discrete anatomical space defined by the cricoid cartilage inferiorly and a distance of 5 to 10 mm inferior to the true vocal fold margin. When the extent of disease is not clear by physical examination alone, imaging modalities including computed tomography and in particular magnetic

Fig. 26.1 Laryngeal carcinoma with involvement of the pre-epiglottic space.

Fig. 26.2 Glottic carcinoma with extension into the paraglottic space.

resonance imaging can help elucidate it in the pre-epiglottic and paraglottic spaces, which often results in the upstaging of disease. This information is invaluable preoperatively or before the initiation of treatment if organ preservation techniques are employed.

A detailed description of the subsites of the larynx is included in the previous chapter, but a more detailed discussion of the glottic larynx is appropriate to review. The boundaries of the true vocal folds are the vocal processes of the arytenoids posteriorly and the anterior commissure anteriorly. The layers of the vocal folds, from superficial to deep, include the epithelium, followed by the lamina propria, followed by the vocalis muscle. The cartilaginous framework of the larynx at the glottic larynx is of particular importance in terms of how disease spreads locally. A structure called the conus elasticus, which originates from the cricoid cartilage, attaches posteriorly to the arytenoid cartilages and condenses medially to form the vocal ligament. Anteriorly, the conus elasticus attaches to the thyroid cartilage at the Broyle ligament, also known as the anterior commissure tendon. This area is devoid of an inner perichondrium and consequently is a frequent source of spread for lesions involving the anterior commissure. Understanding this anatomical relationship informs decision making when disease involves the anterior commissure because the extent of disease may be underestimated by flexible laryngoscopy alone.

26.3 Specific Techniques

26.3.1 Endoscopic Techniques (Including Specific Indications for Each Technique)

Transoral laser microsurgical approaches for treating squamous cell carcinoma of the larynx have improved significantly over the last 20 years, with advances in endoscopic instrumentation and laser technology. Advantages over primary radiation therapy or conservation laryngeal surgery include an abbreviated treatment time, potentially requiring only an outpatient surgical procedure. In addition, with transoral laser approaches, primary control is often attainable without adjuvant radiation therapy. Transoral laser techniques provide oncologic control rates roughly equivalent to those of organ preservation techniques, again typically exceeding 90% for early-stage lesions. Overall survival rates are also comparable. In addition, cost-benefit analyses argue in favor of transoral laser microsurgical approaches. Myers and colleagues from Pittsburgh demonstrated transoral laser surgery for T1 glottic lesions to be a cost-effective option compared with open conservation laryngeal surgery and radiation. A later report from the same group demonstrated equivalent quality-of-life outcomes and functional results when patients treated with endoscopic excision were compared with those treated with radiation, and the patients treated with radiation had an increased number of work hours missed and increased costs related to travel. Finally, although it has traditionally been accepted that vocal quality is better after radiation therapy than after transoral laser microsurgery for glottic carcinomas, many reports have questioned this assumption. Although the postsurgical patient tends to have a breathier voice and the postradiation therapy patient a harsher, raspy

voice, vocal quality after laser cordectomy is overall comparable with voice quality after radiation therapy.

The carbon dioxide laser is indispensable in transoral endoscopic approaches. The wavelength of the carbon dioxide laser is 10,600 nm. The helium–neon (He-Ne) aiming beam allows excellent finesse and control of this laser. Typically, the laser is applied through an operating binocular microscope (400-mm lens) and controlled with a micromanipulator. Carbon dioxide laser fibers can be threaded through the distal aspect of rigid instruments and provide the surgeon with other options when exposure is challenging. The surgeon will select the spot size, power of the laser, and mode of the laser (i.e., continuous or pulse). The system is always tested on a tongue blade before use on the patient. Nd:YAG (neodymium:yttrium aluminum garnet) and KTP (potassium titanyl phosphate) lasers, in contrast to carbon dioxide lasers, are absorbed by red pigment and may be preferable with very vascular lesions. These lasers are helpful, for example, in the treatment of subglottic or vascular tracheal lesions, such as hemangiomas.

The lesion is always photographically documented before resection is begun. After a secure airway has been established with a laser-safe endotracheal tube, a rigid 0-degree endoscope is used to assess and document the extent of disease. An angled endoscope may be helpful in assessing the anterior commissure. Even when a small-caliber (5.0 or smaller) endotracheal tube is used, the posterior commissure is often obscured by the endotracheal tube. This can be displaced anteriorly to allow better visualization, but removing the endotracheal tube is necessary to fully assess the extent of the lesion.

Endoscopic approaches can address the vast majority of early-stage and some late-stage laryngeal carcinomas. These approaches, with or without robotic assistance, allow the successful treatment of lesions ranging from T1 to limited T3 disease. For a variety of glottic T1 lesions, including T in situ, T1a, and T1b lesions, endoscopic cordectomy is an effective (and cost-effective) approach associated with minimal morbidity, and it provides superior functional and oncologic outcomes. Mid-fold T1a lesions are among the most readily accessible for this approach. T1 lesions extending into the anterior commissure can be addressed with this technique as long as the exposure obtained permits an adequate anterior exposure. Of note, one of the long-held principles of oncologic resection is Halstead's principle of en bloc resection. For the surgeon using transoral laser techniques, it is often not possible, or advisable, to attempt en bloc resection.

Endoscopic management is often the best option for patients with early-stage supraglottic squamous cell carcinoma, particularly lesions of the suprahoid epiglottis and aryepiglottic folds. As with glottic lesions, the traditional principles of en bloc resection are less relevant with these approaches because early epiglottic malignancies are often best addressed with the initial line of resection through the tumor, which facilitates lateral resection and adequate margins. As with patients who are candidates for open conservation laryngeal surgery, a preoperative pulmonary and speech–language pathology evaluation may be helpful, although patients treated with endoscopic approaches often recover more quickly than their counterparts undergoing open approaches (□ Fig. 26.3, □ Fig. 26.4, □ Fig. 26.5, □ Fig. 26.6).

Finally, for patients with more extensive disease, including those with T3 disease, endoscopic approaches can be an appro-

appropriate primary strategy as long as the extent of pre-epiglottic space involvement has been evaluated by imaging and judged to be resectable. Robotic techniques are particularly appropriate for disease that is at a more advanced stage. Although these approaches are still in their infancy, early data are promising in terms of both feasibility and oncologic efficacy. Robotic techniques offer increased degrees of freedom, allowing more three-dimensional access to the larynx. A cautionary note in reviewing the literature for patients treated with transoral endoscopic techniques is that in some of the reports touting the superior oncologic effectiveness of these approaches, a significant percentage of the patients also have received postoperative radiotherapy.

26.3.2 Surgical Management

Open Management of Laryngeal Cancer: Techniques and Indications

The open management of glottic and supraglottic malignancies is time-tested and oncologically sound. In increasing level of complexity, these procedures range from laryngofissure with cordectomy and reconstruction, vertical partial laryngectomy,

open supraglottic laryngectomy, and supra-cricoid laryngectomy to total laryngectomy. All approaches that do not result in complete extirpation of the larynx are referred to as organ preservation techniques.

Cordectomy with reconstruction is ideal for T1 glottic lesions that would otherwise be amenable to transoral laser microsurgical excision. However, some patients (including patients with trismus or retrognathia, and possibly patients with prior radiotherapy) do not have sufficient anterior exposure for these lesions to be addressed endoscopically. This approach is not recommended for patients with disease involving the contralateral vocal fold. A tracheotomy is generally necessary with this technique. For a simple cordectomy, healing by secondary intention is an acceptable reconstructive strategy, followed by alloplastic medialization procedures if necessary. Intraoperative reconstruction based on use of the ipsilateral strap muscles to augment the neocord has also been described. Most commonly, patients who undergo open cordectomy with laryngofissure typically compensate well from a speech and swallowing standpoint, although they may have a breathy voice postoperatively.

Vertical partial laryngectomy is most commonly used to treat T1 and selected T2 lesions of the vocal folds. A tracheotomy is likewise required for this approach. Contraindications to this approach include T3 disease without cricoarytenoid joint involvement; this is better addressed with a supracricoid laryngectomy. A laryngofissure is performed; the thyrotomy location is determined by the location of the tumor as assessed endoscopically. In the standard vertical partial laryngectomy, the resection extends from the anterior commissure to include the full extent of one membranous vocal fold and the intrinsic musculature of the larynx posteriorly to the vocal processes of the arytenoids. Many “extensions” of this procedure have been described, including the frontolateral vertical hemilaryngectomy, posterolateral vertical laryngectomy, and extended vertical laryngectomy (□ Fig. 26.7). In addition, as with simple cordectomy, a variety of local reconstructive techniques have been described to facilitate voice restoration.

Open supraglottic laryngectomy is appropriate for T1 and T2 lesions of the supraglottic larynx, with local control rates for T1 disease exceeding 90%. Contraindications include glottic level involvement, invasion of the cricoid or thyroid cartilage,

involvement of the tongue base to within 1 cm of the circumvallate papillae, and involvement of the deep muscles of the tongue base or pre-epiglottic space. The typical supraglottic laryngectomy preserves both true vocal folds, both arytenoids, the tongue base, and the hyoid bone (□ Fig. 26.8). Pre-epiglottic space involvement necessitates resection of the hyoid, which can otherwise be left intact. Of particular importance when the hyoid is resected is preservation of the superior laryngeal neurovascular pedicle. This is likewise critically important in the supracricoid laryngectomy. Reconstruction is similar to that of the supracricoid laryngectomy.

The supracricoid laryngectomy has perhaps the most diverse utility because it can be used in T1b, T2, T3, and selected T4 supraglottic and glottic carcinomas. It can also be used in patients with decreased vocal fold motion or fixation, pre-epiglottic space invasion, glottic involvement at the anterior commissure or ventricle, or limited thyroid cartilage erosion without extralaryngeal spread. Excellent local control rates and 5-year survival data are typical in most large series. Contraindications to supraglottic laryngectomy include fixation of the arytenoids secondary to cricoarytenoid joint fixation, extrinsic laryngeal

Fig. 26.7 Extent of vertical partial laryngectomies.

Fig. 26.8 Tissue resected in supraglottic laryngectomy.

muscle involvement, recurrent laryngeal nerve involvement, subglottic extension beyond 1 cm or direct invasion of the cricoid, posterior commissure involvement, extralaryngeal spread, or disease extension to the outer perichondrium of the thyroid cartilage. The surgical excision is en bloc and includes both true vocal folds, both false vocal folds, both paraglottic spaces, sometimes the epiglottis, and the entire thyroid cartilage, and it may include one partial or full arytenoid (□ Fig. 26.9). Of particular importance in the surgical resection is preservation of the recurrent laryngeal nerve when the cricothyroid joint is disarticu-

lated. As mentioned previously, preservation of the superior laryngeal neurovascular bundle is of critical importance in ensuring postoperative rehabilitation of swallowing. The reconstruction is predicated upon impacting the hyoid bone and tongue base with or without the epiglottis to the cricoid cartilage with three symmetric 1–0 Vicryl submucosal sutures (□ Fig. 26.10).

The complications of all conservational approaches to laryngeal surgery are very similar. Aspiration and postoperative dysphagia are common in the early postoperative setting but may

Fig. 26.9 En bloc resection in supracricoid laryngectomy.

be prolonged in some patients, resulting in the need for a percutaneous gastrostomy. Pharyngocutaneous fistula can occur, although the risk is much less than with total laryngectomy. Of note, it is critically important in open techniques such as supracricoid laryngectomy to separate the tracheostomy from the reconstructed neolarynx and remainder of the neck contents. Finally, an inability to decannulate the patient may result from an inadequate glottic airway secondary to reconstruction technique or recurrent laryngeal nerve injury.

Finally, total laryngectomy involves extirpation of the entire larynx as well as the hyoid and several tracheal rings, depending on the level of subglottic extension. Total laryngectomy creates a complete separation between the upper respiratory tract and pharyngoesophageal tract. It is a time-tested and oncologically sound procedure. The procedure typically begins with an awake tracheostomy if the patient has airway obstruction. Typically, a “high trach” is advisable to provide additional trachea that will be removed with the specimen. For lesions involving the supraglottic larynx, or in circumstances in which nodal metastases are present at diagnosis, bilateral neck dissections are performed first. In the N0 neck, a bilateral selective neck

dissection may be appropriate. Next, the suprahyoid and infrahyoid muscles are divided, and the inferior constrictors are divided at the lateral lamina of the thyroid cartilage. A freer elevator is used to mobilize the piriform sinus mucosa superiorly to preserve as much mucosa as possible for closure of the pharynx. The superior and inferior parathyroid glands should then be identified and lateralized on the side of the primary lesion while the inferior thyroid artery is preserved. On the side of the primary lesion, the thyroid lobe is typically included with the specimen. The contralateral thyroid lobe is mobilized off the trachea with Bovie cautery, leaving both the superior pole vascular pedicle and the inferior thyroid artery blood supply intact. Once the suprahyoid musculature has been divided, the hyoid bone is mobilized, typically with an Allis clamp, and the greater cornu of the hyoid is freed from the surrounding soft-tissue attachments. The hypoglossal nerve is identified and carefully preserved while the greater cornu is mobilized laterally (□ Fig. 26.11). At this time, if a tracheostomy was previously performed, the trachea should be transected at the level of the tracheostomy. A 2–0 polypropylene suture should be placed in the distal trachea to prevent retraction of the trachea into the

Fig. 26.10 (a,b) Reconstruction after supracricoid laryngectomy is facilitated by a cricohyoido(epiglott)pexy, impacting the residual neoglottis superiorly near the base of the tongue. This allows food boluses to pass posteriorly behind the airway, preventing aspiration. The epiglottis can be sacrificed, if necessary, for oncologic reasons.

Fig. 26.11 During total laryngectomy, the hyoid is freed from the superior muscles and mobilized. The hypoglossal nerve is at risk during this dissection and should be preserved.

mediastinum. The back wall of the trachea may be divided with a No. 15 blade or Bovie cautery down to the “party wall” between the esophagus and trachea.

Deciding where to enter the pharynx is predicated upon the preoperative laryngoscopy or direct laryngoscopy at the beginning of the case. Generally, the surgeon should endeavor to enter the pharynx in an area uninvolved with tumor, which will allow extirpation of the larynx under direct visualization. This may be in the vallecula, piriform sinus, or postcricoid mucosa. The vallecula is generally the most expeditious route. Place-

ment of a Yankauer suction or small Deaver retractor into the vallecula of the patient’s oropharynx will indicate an approximate location to enter. Once the pharyngeal mucosa has been incised, the epiglottis may be grasped with an Allis clamp. The surgeon, positioned at the head of the table, then uses curved Mayo scissors to incise the pharyngoepiglottic ligament, carefully leaving a healthy margin of tissue around the tumor. This continues inferiorly. One should endeavor to leave as much piriform sinus mucosa as is oncologically feasible. Inferiorly, the postcricoid mucosa will be incised, allowing removal of the larynx. When the margins of resection are unclear, intraoperative frozen section consultation is appropriate. Additional tracheal margins should be sent as well. A prophylactic stomoplasty is helpful in ensuring a patent tracheostoma, particularly if postoperative radiotherapy is contemplated. One option is a modified W-plasty. The midline trachea is incised through roughly two tracheal rings. A W-shaped wedge of skin is then excised from the peristomal skin. A 2–0 polypropylene suture is used, in a half-mattress technique, to bring each apex of the trachea to the bases of the W. Then, 2–0 polypropylene sutures with alternating 2–0 Polyglactin 910 sutures are used to create the lower half of the stoma (□ Fig. 26.12). A cricopharyngeal myotomy should be performed before closure of the pharynx. If a tracheoesophageal puncture (TEP) is to be placed, a right-angle clamp should enter the posterior wall of the trachea 1 cm inferior to the proposed stoma. A 14F red rubber catheter is then placed through the puncture site into the esophagus. Some centers will place a nasogastric feeding tube as well for enteric nutrition during the early postoperative period; however, with appropriate care, the red rubber catheter will allow enteric

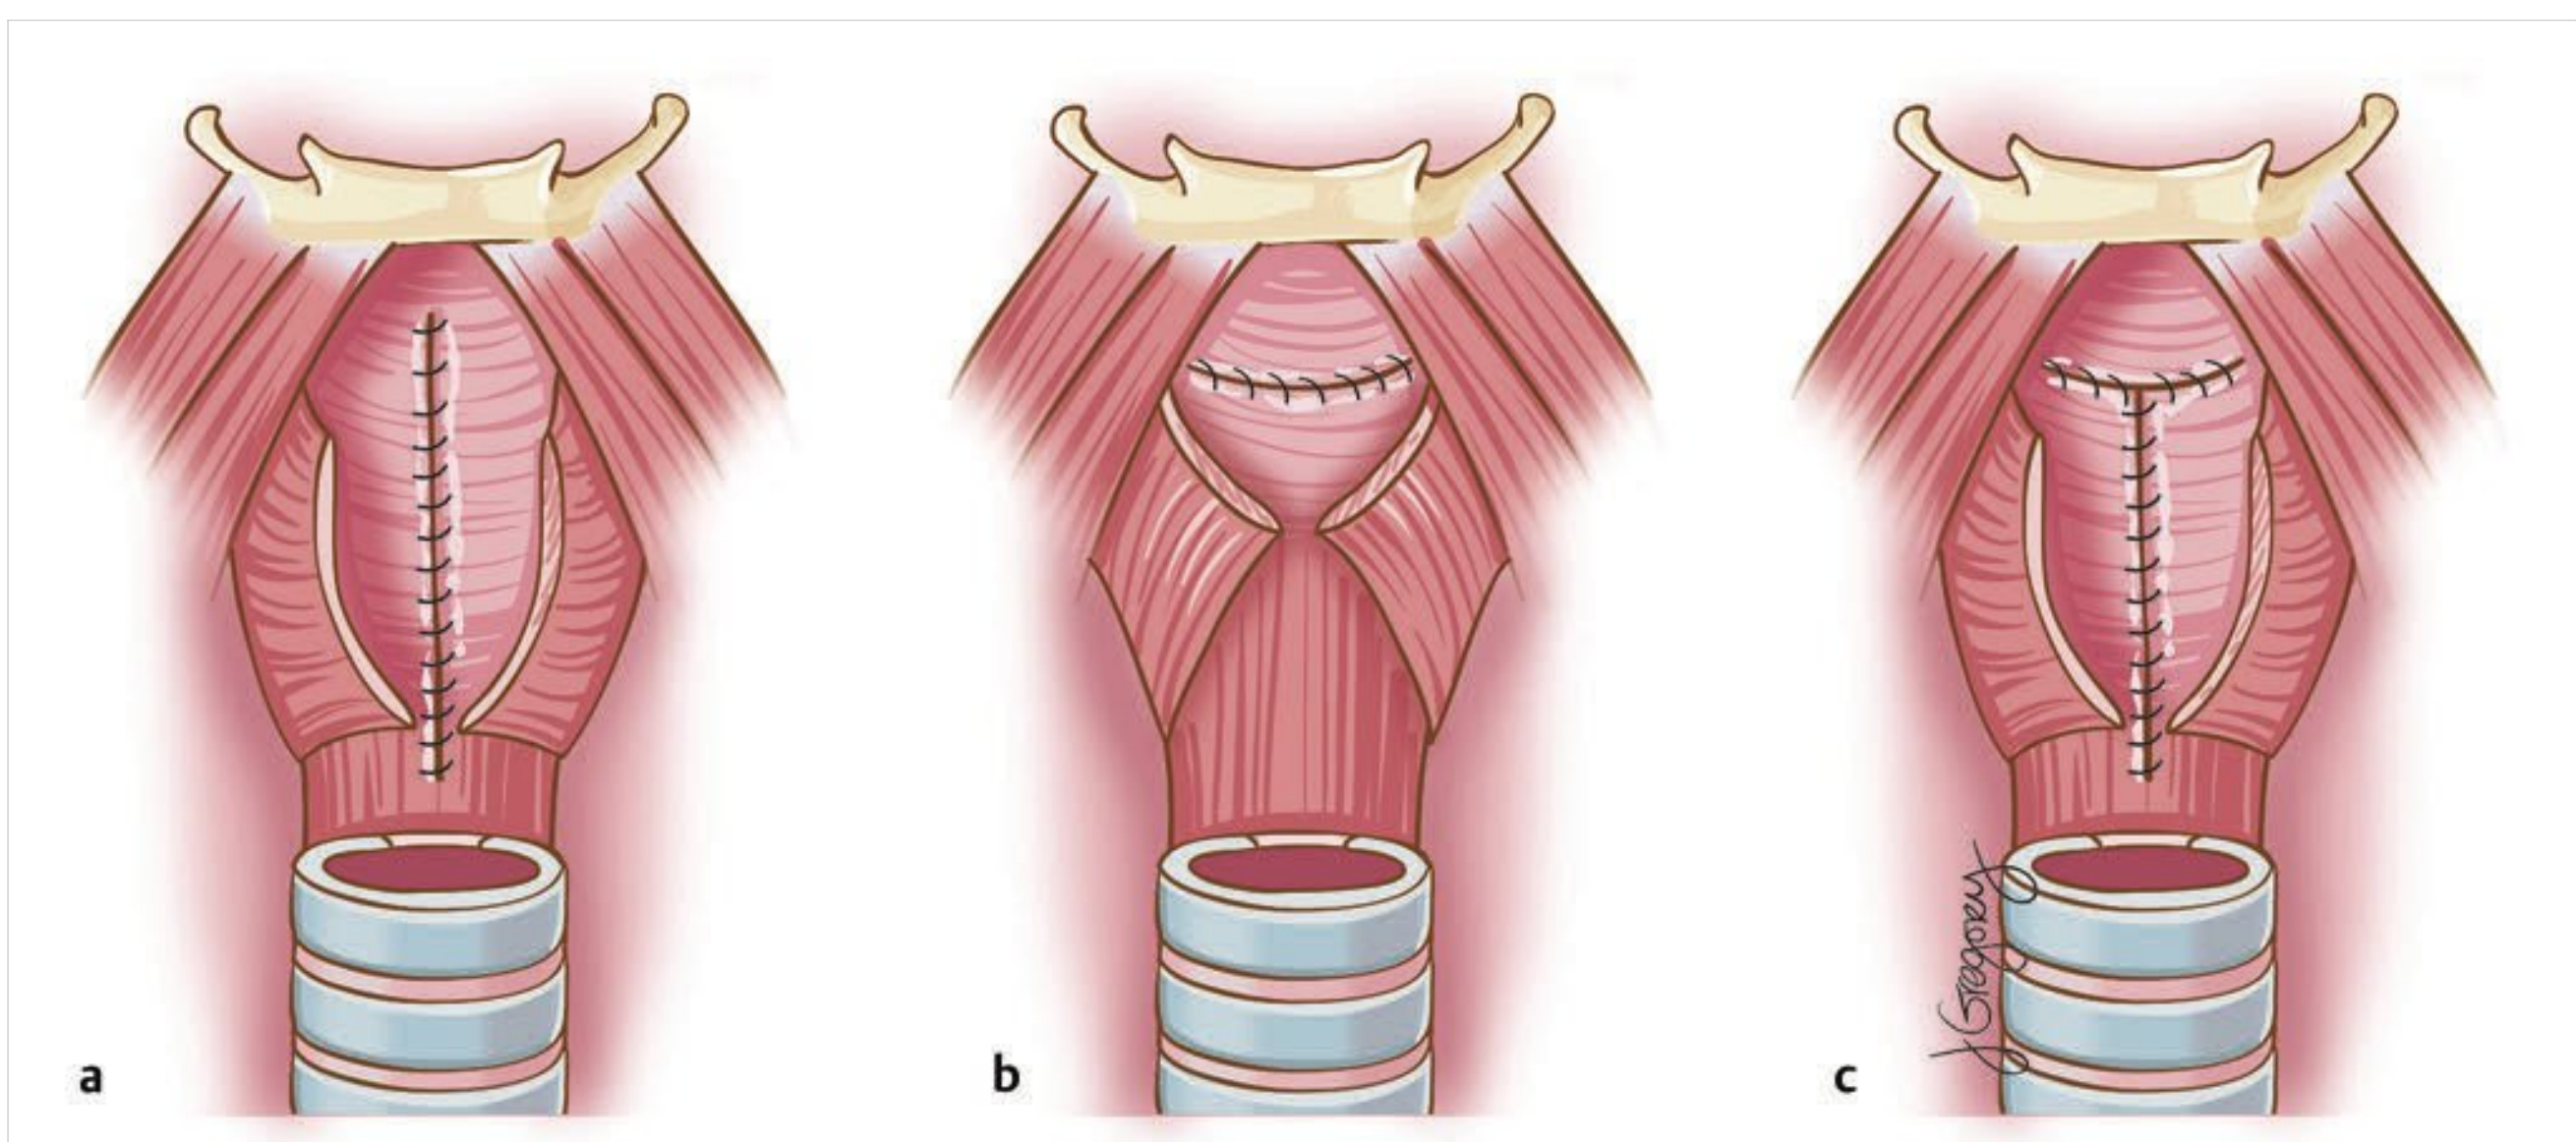

Fig. 26.13 (a,b,c) Pharyngeal closure can be in the shape of a T, vertical or horizontal.

nutrition and is less uncomfortable for the patient than a nasogastric feeding tube.

Closure of the pharynx depends on a variety of factors, including the amount of available piriform sinus mucosa, whether the patient has previously been treated with radiation, and surgeon preference. If adequate piriform sinus mucosa is available, a vertical closure with an inverted Connell suture is a reliable closure. This typically begins with an anchoring suture in the tongue base and extends inferiorly in the vertical plane. A reliable assistant should invert the edges of the piriform mucosa as the surgeon proceeds inferiorly with the closure. A horizontal closure is more challenging, particularly toward the center of the closure, because it is often under more tension at this point. Finally, a T closure has the disadvantage of a trifurcation at its

center, which is a natural point of weakness of the closure. When performed properly, however, all of these methods are acceptable choices (□ Fig. 26.13). Imbricating sutures reinforcing the pharyngeal closure are appropriate, although closure of the constrictor muscles may result in postoperative dysphagia. Saline dyed with methylene blue is then placed into the neopharynx with a bulb syringe to rule out extravasation of saline. Focal areas of leakage may be addressed with imbricating sutures. To minimize the risk for pharyngocutaneous fistula, meticulous care is used when the pharynx is closed, regardless of the method employed. Fibrin glue along the closure may help minimize fistula rates.

Reconstruction in the postradiation setting may proceed as described. Other options, even in the setting of adequate

piriform sinus mucosa, may include closure with a pectoralis major myocutaneous flap reconstruction, radial forearm free flap reconstruction, or anterolateral thigh free flap reconstruction. Advantages of these closures may include decreased risk for pharyngoesophageal stricture and decreased rates of pharyngocutaneous fistula. Several groups have described the use of prophylactic “muscle-only” pectoralis muscle flaps to augment the pharyngeal closure in the setting of salvage laryngectomy, with successful decreases in the incidence of postoperative pharyngocutaneous fistula formation.

Voice restoration techniques after total laryngectomy are diverse. TEP provides intelligible esophageal speech in appropriately chosen patients. Patients who are candidates for a TEP should have good or correctable eyesight and good hand–eye coordination, and they should be reliable in terms of follow-up because a TEP needs to be cleaned and changed on a regular basis. A variety of hands-free systems allow the patient to phonate without having to occlude the TEP opening digitally. An electro-larynx is another option, which provides robotic-sounding speech when the patient places the machine on the skin of the neck or in the mouth with an oral cavity adapter.

Finally, for selected patients who were formerly treated with primary radiotherapy or chemotherapy and who present with persistent or recurrent disease, although total laryngectomy traditionally has been the standard of care, transoral laser microsurgical and open conservational laryngeal surgery approaches are gaining acceptance. Steiner and colleagues have advocated transoral laser microsurgery as a surgical modality in the salvage setting. Holsinger and others have advocated conservation laryngeal surgical approaches, including supracricoid laryngectomy, in the salvage setting, although with an increased risk for postoperative aspiration, dysphagia, and airway obstruction secondary to neolaryngeal edema. Nonetheless, these strategies are useful tools in the armamentarium of the head and neck surgeon treating recurrent disease after radiotherapy.

Surgical Management of the Neck in Laryngeal Cancer

Factors influencing management of the neck in laryngeal cancer include the TNM (tumor node metastasis) stage of the primary lesion, the subsite of the larynx involved, and the modality chosen to treat the primary lesion. Patients with early-stage lesions of the glottic larynx have low rates of regional lymph node metastasis because of the paucity of lymphatic drainage from this area. For patients with early-stage lesions of the glottic larynx in an N0 neck, close observation is an acceptable management strategy. The supraglottic larynx, on the other hand, has an extensive bilateral network of lymphatics along the jugulodigastric nodal basin. Although conservative management of the neck in patients with selected T1 lesions treated with

transoral laser microsurgery may be appropriate, the majority of patients with higher-stage lesions will require elective treatment of the neck, regardless of the clinical stage of the neck on physical examination, through either routine bilateral selective neck dissection (levels II, III, and IV) or radiotherapy that includes at-risk nodal basins in the treatment field. In those patients whose primary lesions are treated with radiation, the central and lateral neck nodal basins will be included in the radiation field. Finally, those patients with N+ disease at presentation should be treated with an appropriate neck dissection.

26.4 Roundsmanship

- Postirradiation and postchemoradiation settings present challenges in terms of wound healing and functional outcomes. Organ preservation techniques in these patients, however, are not contraindicated.
- Early-stage disease involving the anterior commissure may be better managed with transoral laser microsurgical techniques or with open partial laryngeal surgical techniques than with radiotherapy alone.
- In the surgical management of glottic malignancies involving the supraglottic larynx and of supraglottic malignancies, the surgeon must address the bilateral regional nodal basins at risk with either surgery or radiotherapy.
- Although these reports are in their infancy, a careful review of the literature concerning newer techniques, including transoral laser microsurgical endoscopic techniques, should provide an understanding of which patients require postoperative radiotherapy or a tracheotomy, and of long-term oncologic efficacy.

27 Transoral Robotic Surgery

Sumeet M. Anand and Adam S. Jacobson

27.1 Introduction

Minimally invasive techniques in surgery are being readily evaluated and endorsed among both surgeons and patients. In otolaryngology, two evolving areas of great interest include transoral laser microsurgery (TLM) and, most recently, transoral robotic surgery (TORS). In the treatment of head and neck cancer, the evolution of these advances has been influenced by a paradigm shift toward organ preservation and toward offering, when possible, a management option with less morbidity than conventional chemoradiation.

The first report of robotic surgery in the head and neck came in 2005, when a supraglottic laryngectomy was performed in a canine model by Weinstein et al. This was a significant moment for the application of robotics as a surgical treatment option in the upper aerodigestive tract. In that same year, McLeod and Melder were the first to describe the use of robotic surgery in a patient, to excise a vallecular cyst. Over the next year, the group led by Weinstein and O'Malley pioneered the introduction and application of the da Vinci robot (Intuitive Surgical, Sunnyvale, CA) to head and neck surgery, publishing a series of reports on the feasibility, safety, and use of the technique in human patients. In 2009, the FDA approved the use of the da Vinci surgical system in TORS for benign processes and early-stage T1 and T2 mucosal malignancies of the oropharynx, hypopharynx, and larynx. Since 2009, there has been a rapid expansion in the number of cancer centers that are now incorporating TORS into the management of head and neck cancer, with the goal to potentially deintensify adjuvant treatment and improve quality-of-life and functional outcomes, while maintaining survival.

TORS presents a novel change from conventional surgical management in many facets, in particular for oropharyngeal squamous cell carcinoma (SCC). The oropharynx is an area that has traditionally required a challenging and extensive surgical approach. Surgical access requires a lip-splitting incision and mandibular osteotomy in order to swing the mandible out of the surgical field. This radical approach requires a tracheotomy for airway protection. In comparison, in treating oropharyngeal SCC, TORS does not require a lip incision, mandibulotomy, mandibular swing, or tracheotomy for airway protection. Eliminating such invasive surgical maneuvers provides a patient with a far less morbid procedure and increases operative efficiency.

A second paradigm shift that TORS represents is that the surgical defect created during extirpation is usually not reconstructed and instead is allowed to heal by secondary intention. This is a significant change from the conventional surgical philosophy that when a mucosal barrier is violated, the surgical defect is reconstructed immediately with a local, regional, or free tissue transfer. Traditionally, the oropharyngeal or hypopharyngeal conduit is reconstituted with a hermetic reconstruction to prevent a communication between the upper aerodigestive tract and the neck and avoid a potential salivary fistula. If a fistula occurs, the patient is at risk for a carotid blowout. Additionally, a salivary leak can delay postoperative oral intake

and the commencement of adjuvant treatment. In early-stage disease, the ability to avoid a reconstruction with TORS significantly reduces surgical time and the morbidity associated with the treatment of a cancer of the oropharynx. As the experience with TORS in head and neck surgery increases and the application expands to larger and more advanced lesions, the need for robotically assisted reconstructions will unquestionably become more significant. Recent reports have started to describe the role of robotically assisted local and free flap reconstruction for oropharyngeal TORS defects.

The da Vinci surgical robot provides several technical advantages in comparison with TLM and more traditional transoral suspension techniques. The visualization console of the robot is outfitted with two different three-chip cameras mounted within one integrated 12-mm stereoscopic endoscope. This optical system generates a wide-angle, high-definition illusion of a three-dimensional surgical field. The movable endoscope also offers a benefit of in-field optics, which can change viewing angles and position and so optimize visualization from unique perspectives. This technology overcomes the line-of-sight issue associated with TLM and traditional suspension approaches. Additional degrees of freedom, reduced natural hand tremor, and three-dimensional imagery allow a meticulous translation of larger hand movements at the operating console to small, highly dexterous movements of the robotic instruments at the surgical site. Collectively, these characteristics make possible a precise dissection of surgical tissue planes in the pharynx that was not attainable before application of the da Vinci robot to head and neck surgery.

The introduction of novel technology and operative equipment, plus a change in surgical philosophy, comes with an inherent learning curve. To date, establishing a TORS program has been shown to be a safe and efficient undertaking in a number of cancer centers. In most hospitals, head and neck robotic units are being initiated concurrently with da Vinci programs in urology, gynecology, general surgery, and cardiac and thoracic surgery. Moore et al reported that the learning curve for operative efficiency in TORS can be reached after approximately the first 10 patients. After preliminary experience of the operative team, the mean setup time for TORS is less than 30 minutes. In a review of seven studies reporting on feasibility, it was shown that the average operating time had decreased to less than 75 minutes for oropharyngeal SCC resections, a significant reduction in time from that required for traditional open oropharyngeal approaches.

There are differing opinions with respect to the management of neck disease in patients undergoing TORS. To permit healing of the surgical defect in advanced oropharyngeal SCC before the neck is entered, Weinstein et al advocate a separate staged neck dissection within 3 weeks of the initial TORS procedure. In adopting this algorithm, they theorize that the risk for creating a communication, with a resultant salivary fistula between the oropharynx and the neck, is reduced. Other studies advocating a concomitant neck dissection and TORS resection show that

operating on the neck simultaneously does not increase the risk for a salivary fistula. Moore et al recently reported their retrospective data on 148 patients undergoing TORS with a concomitant neck dissection. A communication between the oropharynx and neck was noted in 42 patients (29%), which were managed conservatively in all cases. Of the 42 patients, 6 (14%) developed a cervical fluid collection that required a formal incision and drainage. In no instances was there a delay in starting adjuvant radiation therapy. These investigators concluded that performing an oropharyngeal TORS resection with a concomitant neck dissection offers patients a single operation with acceptable risks and no delay regarding potential adjuvant treatment. For patients with advanced oropharyngeal SCC, all surgeons appear to agree on the need for a neck dissection; however, there is as of yet no consensus on the timing of the procedure. An assessment of regional nodal disease in oropharyngeal SCC is essential to determine the need for adjuvant external beam radiation therapy or chemoradiation.

Data regarding long-term oncologic results and functional outcomes with TORS are now being reported. In 2010, Weinstein et al published their results with 47 patients who had advanced stage III or IV oropharyngeal SCC. The rates of local, regional, and distant disease control were 97.9%, 95.7%, and 91.5% respectively, at a mean follow-up of 26.6 months. Overall survival rates at 1 and 2 years were 95.7% and 81.8% respectively. Their data showed rates with TORS management similar to those with standard treatment protocols. They also looked at gastrostomy tube dependence as a marker of swallowing function and found a significantly lower rate of gastrostomy tube dependence in patients undergoing TORS than in those undergoing traditional nonsurgical management. In 2012, Moore et al published their results with 66 patients undergoing TORS after more than 2 years of follow-up. Nearly all patients (64 of 66; 97%) were consuming an oral diet within 3 weeks of surgery and before starting adjuvant therapy. Long-term gastrostomy tube use was required in 3 (4.5%) of the 66 and long-term tracheotomy in 1 (1.5%). The 3-year estimated local control and regional control rates were 97.0% and 94.0% respectively. The 2-year disease-specific survival and recurrence-free survival rates were 95.1% and 92.4% respectively.

One of the primary premises for undertaking a TORS procedure is that if negative margins are achieved and no other adverse prognostic factors are noted in the specimen—namely, lymphovascular invasion, perineural invasion, multiple positive lymph nodes, and extracapsular extension—then adjuvant chemotherapy and external beam radiation therapy can potentially be deintensified or withheld. In 2011, Hurtuk et al published their results with 64 patients who had T1–T3 oropharyngeal SCC. Among 64 patients, 50% of those with stage I or stage II disease were spared adjuvant radiation therapy or combined chemoradiation, and 34% of those with stage III or stage IV disease were spared chemotherapy. In 2009, Moore et al published a prospective study on 45 patients with T1–T4 oropharyngeal SCC treated with TORS. In all instances, the resection margins were negative, and as such, the adjuvant radiation therapy dose was reduced.

Despite of all its advantages, there are also practical and technical limitations to the use of TORS. At times, it may be difficult to gain adequate exposure of the lesion within the pharynx and

larynx because of anatomical constraints. In our experience, it is imperative to individually select the correct retractor for each case to provide optimal exposure of the pharyngolaryngeal segment of interest. Reports have successfully described the Feyh-Kastenbauer (FK) retractor (Gyrus ACMI, Southborough, MA), the Crowe-Davis or Dingman mouth gag, and the LARS (Larynx Advanced Retractor System) retractor (Fentex, Tuttlingen, Germany) for different pharyngeal and laryngeal tumor sites. Adequate tumor visualization when there are anatomical constraints is a challenge in all transoral surgical approaches. Additional limitations of TORS include the thermal effects of monocautery, leading to a challenge in histopathologic margin analysis, and the lack of proprioception and tactile feedback. In selected reports, a flexible carbon dioxide laser and robotic bipolar forceps have been described. In future models, these may become more commonplace because they allow precise mucosal and muscular dissection with less peripheral tissue damage. It has been noted that the excellent three-dimensional imagery of the da Vinci robot can assist in partially offsetting the undeniable advantages of haptic feedback during an open operation.

In summary, TORS offers a novel surgical approach with less morbidity than conventional open surgery. This technology is feasible and safe, with an attainable learning curve for surgeons already familiar with transoral approaches. There are a growing number of reports suggesting that the short- and long-term functional outcomes of TORS are acceptable. Furthermore, the short- and long-term oncologic outcomes reported appear to be comparable with those of traditional nonsurgical management. As we move forward, patient outcomes with TORS must be critically evaluated and compared with those of current nonsurgical chemoradiation protocols. As this technology continues to evolve, there is emerging evidence for primary TORS resection and reconstruction in the upper aerodigestive tract, with a prospective opportunity for the deintensification of adjuvant treatment.

27.2 Roundsmanship

- TORS involves fewer invasive surgical maneuvers and provides the patient with a far less morbid procedure and increased operative efficiency.
- The surgical defect created during TORS extirpation is usually not reconstructed and instead is allowed to heal by secondary intention.
- Patients must be carefully selected for TORS because it may be difficult to gain adequate exposure of the lesion within the pharynx and larynx as a consequence of anatomical constraints.
- A growing number of reports suggest that the short- and long-term functional outcomes of TORS are acceptable.

28 Nonneoplastic Salivary Gland Diseases

Neha A. Patel and Stimson P. Schantz

28.1 Introduction

The salivary glands consist of the paired parotid, submandibular, and sublingual glands, as well as 600 to 1,000 minor salivary glands. Disease processes of the salivary glands are divided into nonneoplastic and neoplastic diseases. Nonneoplastic diseases of the salivary gland can be further divided based on etiology into inflammatory infectious, inflammatory noninfectious, and noninflammatory diseases (see Box Nonneoplastic Diseases of the Salivary Glands (p.236)).

Nonneoplastic Diseases of the Salivary Glands

Inflammatory, infectious

- Acute bacterial sialadenitis
- Acute viral sialadenitis
- Granulomatous infection

Inflammatory, noninfectious

- Sialolithiasis
- Radiation sialadenitis
- Sjögren syndrome
- Sarcoidosis

Noninflammatory

- Sialorrhea (ptyalism)
- Xerostomia
- Sialadenosis (sialosis)
- Cysts
- Mucoceles
- Trauma

28.2 Applied Anatomy

The salivary glands play an important role in oral hygiene because saliva has antimicrobial properties and acts as a barrier to protect the oral mucosa from local irritants. In addition, as a lubricant, saliva aids in the functions of speech and swallowing. Therefore, manifestations of salivary gland diseases can range from simple aesthetic changes to debilitating functional morbidities. Understanding salivary gland anatomy (□ Fig. 28.1) is critical in understanding the pathology of the salivary glands. During a physical examination of the salivary glands, it is important to palpate externally as well as intraorally.

28.2.1 Parotid Gland

The parotid gland is the largest salivary gland. It excretes predominantly serous secretions via the Stensen duct to the buccal mucosa at the level of the second maxillary molar. It lies lateral to the masseter and anterior to the ear from the zygomatic arch

superiorly to the angle of the mandible inferiorly, with its posterior tail overlying the sternocleidomastoid muscle. The facial nerve divides the gland into superficial and deep lobes. Parasympathetic innervation to the parotid is from the glossopharyngeal nerve via the otic ganglion (by way of the auriculotemporal nerve). Sympathetic innervation of all the salivary glands is from the superior cervical ganglion.

28.2.2 Submandibular Gland

The submandibular gland is the second largest salivary gland and excretes seromucous secretions via the Wharton duct to the anterior floor of mouth. It sits on the mylohyoid muscle in the submandibular triangle between the anterior and posterior bellies of the digastric muscle. Parasympathetic innervation of the submandibular gland and sublingual glands is from the superior salivatory nucleus through the chorda tympani (by way of the lingual nerve) before it synapses in the submandibular ganglion.

28.2.3 Sublingual Gland and Minor Salivary Glands

The sublingual gland and minor salivary glands excrete more viscous mucinous secretions that tend to contain higher levels of lysozymes and have more antimicrobial properties. The sublingual gland is superficial to the mylohyoid and drains in the floor of the mouth via the ducts of Rivinus (some of which fuse to form the Bartholin duct, which drains into the Wharton duct). On the other hand, minor salivary glands are located throughout the upper aerodigestive tract and drain individually.

28.3 Inflammatory, Infectious Diseases

28.3.1 Acute Bacterial Sialadenitis Pathogenesis

Acute bacterial sialadenitis is caused by decreased production/dehydration related to salivary stasis (as in obstruction caused by stones). Infection is most commonly caused by coagulase-positive *Staphylococcus aureus*, followed by *Streptococcus* species and other oral pathogens such as *Enterococcus coli*, *Haemophilus influenzae*, and anaerobes such as *Bacteroides*.

Evaluation

Acute bacterial sialadenitis usually presents with unilateral, tender glandular swelling and purulent drainage at the ductal orifice of the involved gland. The overlying skin may be warm, erythematous, and indurated. The disease may be seen in postoperative patients as well as in elderly patients, who often take medications that can cause dehydration. Patients may have

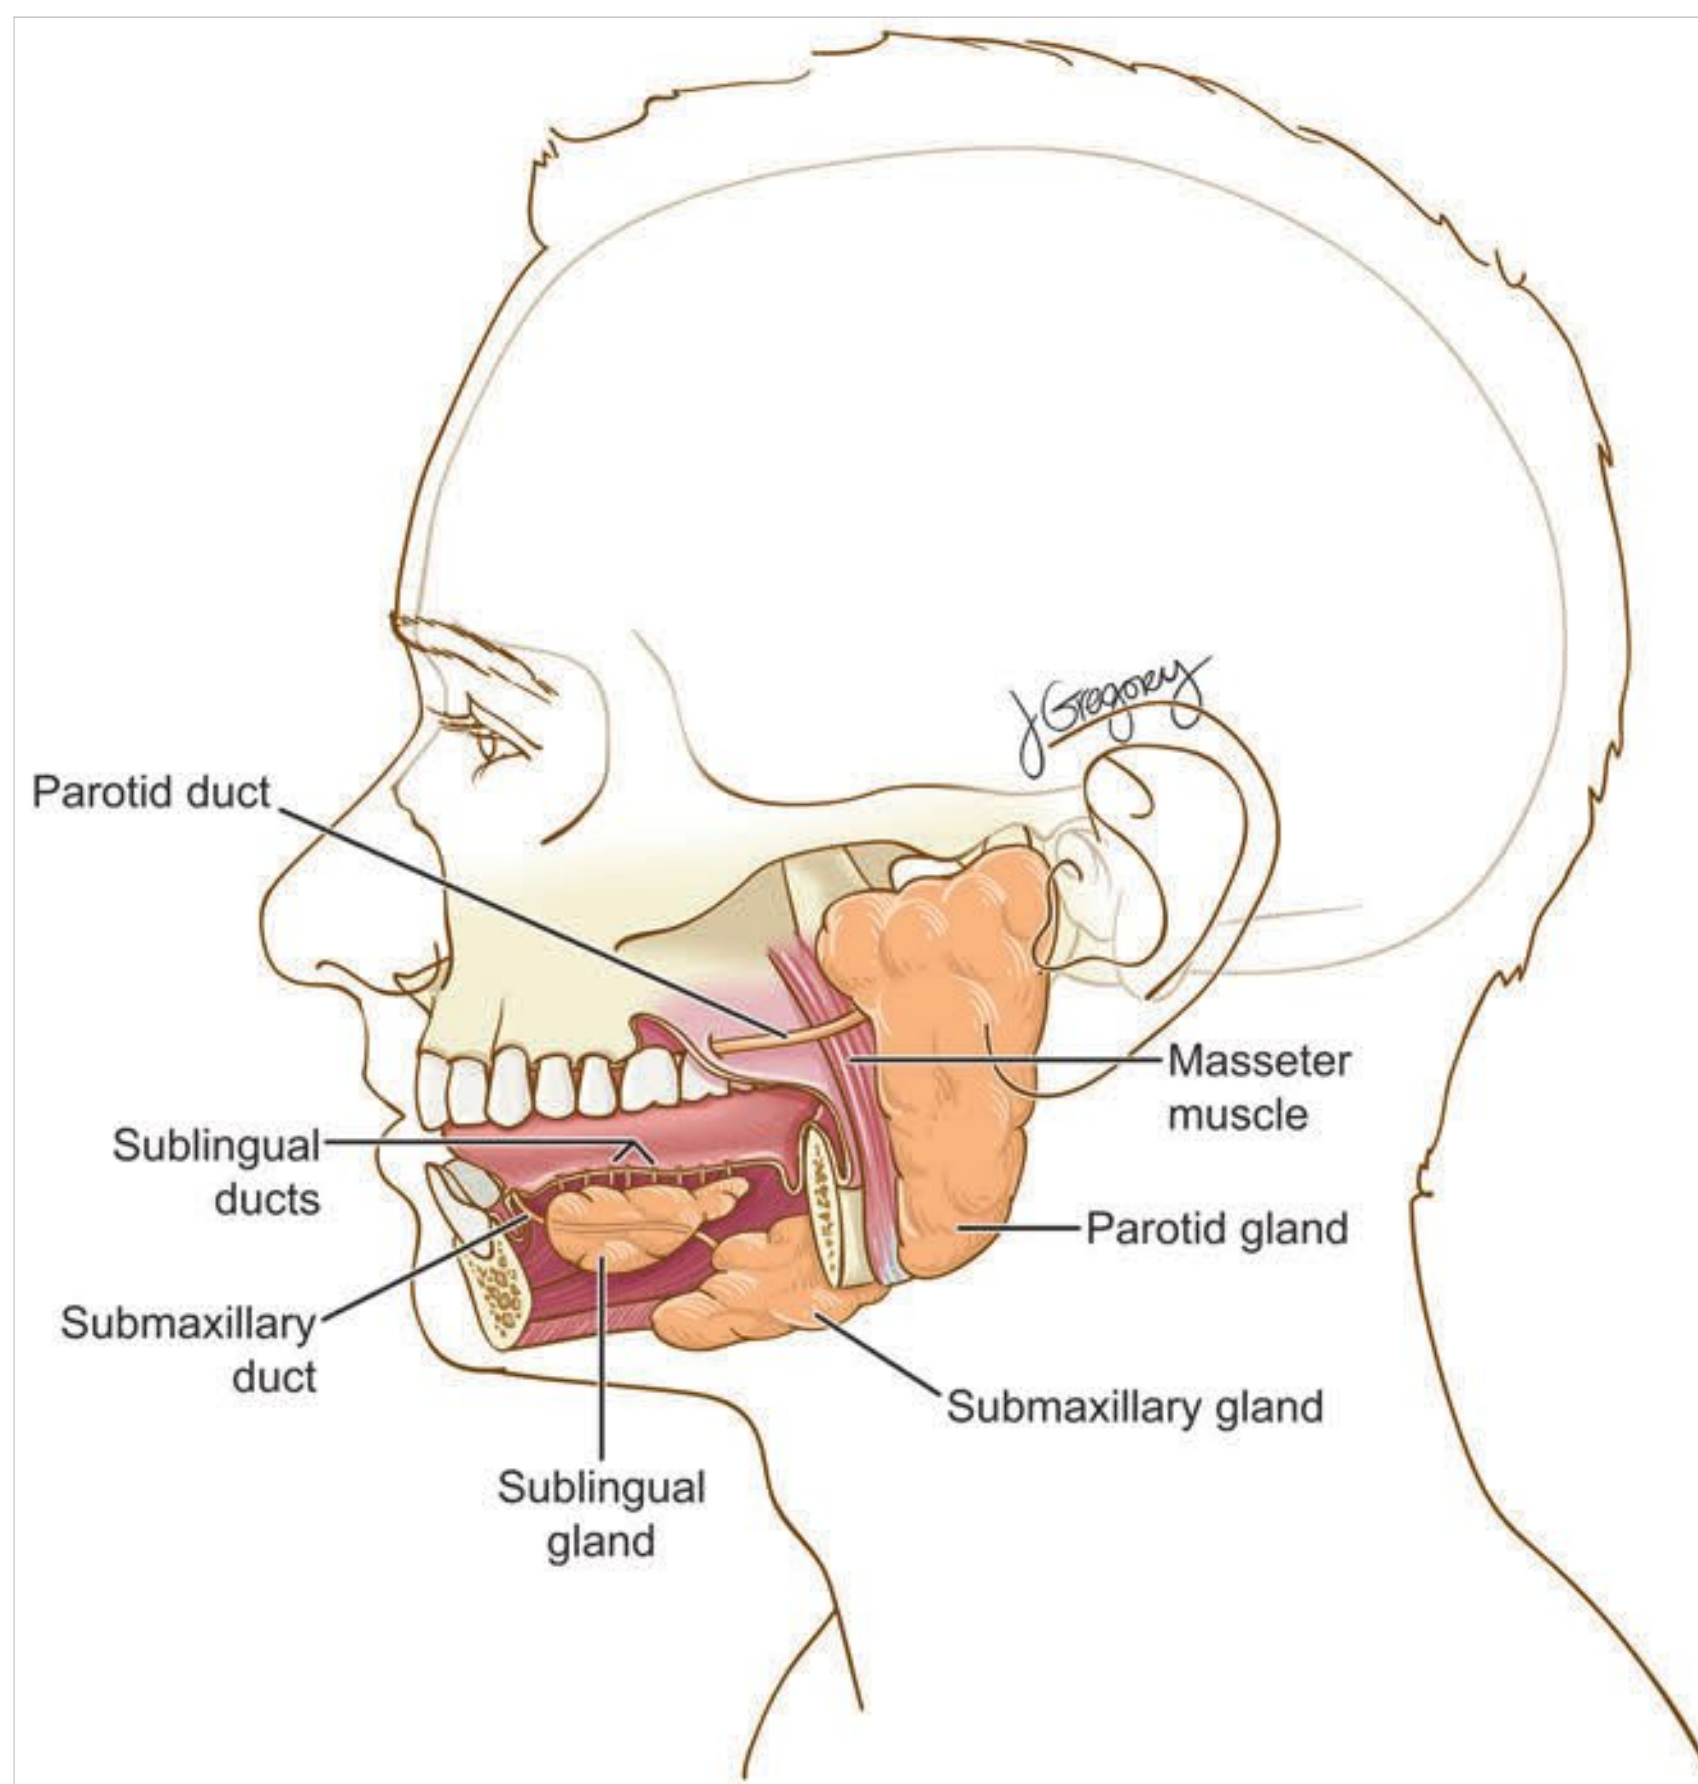

Fig. 28.1 The major salivary glands.

fevers, and blood work may show neutrophilia. The parotid gland may be more prone to infection because its predominantly serous secretions have less antimicrobial activity than submandibular gland saliva, which contains more mucin. The diagnosis is based on the clinical examination findings, although ultrasound and computed tomography (CT) can confirm the presence of stones and collections.

Treatment

Antibiotic treatment should cover for β -lactamase activity and, depending on severity, include oral amoxicillin/clavulanate, clindamycin, oral or intravenous ampicillin/sulbactam, or intravenous vancomycin/metronidazole. Culture can guide treatment. A “sialadenitis regimen” should be offered to all patients; this includes hydration, sialogogues (lemon drops, orange juice, or sugar-free gum), warm compresses, bimanual massage, oral hygiene, and smoking cessation.

Potential Complications

Untreated acute bacterial sialadenitis may lead to abscess formation, which may require incision and drainage and placement of a drainage catheter. In the case of a parotid abscess, instruments are spread in the direction of the facial nerve branches to preserve nerve function in the setting of an inflamed gland. Untreated infection can also lead to sepsis. Repeated episodes can lead to chronic sialadenitis.

28.3.2 Acute Viral Sialadenitis

Pathogenesis

Acute viral sialadenitis can be caused by infection with viruses such as the mumps paramyxovirus, coxsackievirus, cytomegalovirus, echovirus, and influenza virus. Mumps virus is the virus most commonly involved in parotitis. Salivary gland disease in association with HIV infection in the pediatric population is AIDS-defining.

Evaluation

Viral sialadenitis tends to be bilateral and is usually accompanied by symptoms such as low-grade fever, pain with chewing, fatigue, headache, and, myalgia. The mumps virus is a paramyxovirus that affects children 4 to 6 years old. The incubation period for mumps is 2 to 3 weeks, and the systemic symptoms often resolve before parotitis. On history, it is important to ask about the patient’s immunization history. On physical examination, the parotid glands will be swollen and firm but nonsuppurative. Imaging often shows diffuse bilateral enlargement of the glands. The diagnosis can be confirmed with a serum viral titer. The mumps virus is transmitted through contact with respiratory secretions and can be detected in a patient’s saliva. Cytomegalovirus can specifically cause a rare salivary gland inclusion disease in newborns. This is diagnosed by its association with other physical findings, such as cerebral atrophy, hepatosplenomegaly, thrombocytopenia purpura (“blueberry muffin”

baby), and jaundice. In HIV-associated salivary gland disease, patients may manifest glandular swelling, localized facial disfigurement, and xerostomia. Histology reveals periductal lymphatic infiltrates within the gland consisting of CD8+ T cells. In diffuse infiltrative lymphocytic syndrome, patients infected with HIV may have salivary and lacrimal gland swelling with diffuse hyperplastic, cystic lymphoid infiltrations throughout the body.

Treatment

The treatment of viral sialadenitis is symptomatic care, including hydration. The incidence of mumps has decreased since the introduction of the measles–mumps–rubella vaccine.

Potential Complications

Mumps can lead to meningitis and encephalitis, pancreatitis, and orchitis. Otolaryngologic complications of cytomegalovirus infection include mild or moderate sensorineural hearing loss, which may not manifest until months after the congenital infection. Finally, HIV infection is associated with benign lymphoepithelial lesions that rarely may undergo malignant transformation.

28.3.3 Granulomatous Infection

Pathogenesis

Infectious granulomatous diseases of the salivary gland include tuberculosis, infection with atypical mycobacteria, cat-scratch disease, toxoplasmosis (*Toxoplasma gondii*), and actinomycosis. Tuberculosis infection is thought to be spread from person to person when the glands are seeded from oral sites via the ductal system. Cat-scratch disease is caused by the gram-negative bacillus *Bartonella henselae* after a cat bite or scratch. Toxoplasmosis is spread by the ingestion of cysts in undercooked meats or cat feces. Actinomyces is a gram-positive branching anaerobe found in the oral cavity that can cause retrograde ductal seeding of the glands.

Evaluation: Mycobacterium

Tuberculosis infection is rare but presents primarily with acute unilateral parotid swelling. Secondary hematogenous or lymphatic spread of tuberculosis generally involves the submandibular and sublingual glands. In high-risk persons such as immigrants and patients with HIV infection, a purified protein derivative (PPD) test should be placed. The PPD test result can be negative in cases caused by atypical mycobacteria, more commonly seen in children 1 1/2 to 3 years old. Acid-fast staining may be sent with salivary cultures. Tuberculosis infection can also present chronically with a slowly growing tumor-like lesion that on fine-needle aspiration contains Langhans giant cells and acid-fast bacilli. On the other hand, lymphoid tissue involved in cat-scratch disease is positive for Warthin-Starry silver stain. Cat-scratch disease can present with cervical, submandibular, or periparotid erythematous and fluctuant lymphadenopathy near the site of the original papule formed at a

scratch site. On pathology, ultrasound, and CT, the lymph nodes are vascular with central necrosis. Serology can also help confirm cat-scratch disease. Actinomycosis can present with painless enlargement of the affected salivary gland and purulence that can cause cutaneous fistulas to form. The diagnosis is confirmed by the presence of sulfur granules in smears.

Treatment

The treatment of acute sialadenitis caused by tuberculosis is with a multidrug antituberculosis regimen and the excision of involved tumors. Lymphadenopathy caused by cat-scratch disease usually resolves in a few months; treatment is symptomatic with analgesics and warm compresses. Toxoplasmosis in immunocompromised patients, such as those with HIV infection, is treated with pyrimethamine and trisulfapyrimidines. Penicillin (doxycycline for penicillin-allergic patients) is the accepted treatment for actinomycosis.

Potential Complications

In patients with cat-scratch disease who are highly symptomatic, such as those with suppuration and severe fevers, ciprofloxacin and azithromycin have been used. Surgical excision may be necessary when actinomycosis is complicated by sinus tracts.

28.4 Inflammatory, Noninfectious Diseases

28.4.1 Sialolithiasis

Pathogenesis

Salivary calculi form in the context of stasis and consist predominantly of hydroxyapatite; 80% of calculi are in the submandibular gland. The submandibular duct is long, and flow through the duct is against gravity. Submandibular saliva is more alkaline, with a high concentration of calcium, phosphate, and viscous mucus. Gout-related calculi consist of uric acid.

Evaluation

Sialolithiasis presents with periprandial pain and swelling of the affected gland. Ultrasound, CT, and more recently magnetic resonance (MR) sialography (without contrast) has been used to detect calculi that are not palpable. On CT, about 90% of submandibular calculi are radiopaque, whereas 90% of parotid calculi are radiolucent.

Treatment

Superficial calculi can be removed intraorally, but acute obstructive sialadenitis can recur. For calculi in the hilum or for recurrent infections, surgical excision of the affected gland can be performed. With new, minimally invasive technology, conservative treatment, such as sialoendoscopy and laser intracorporeal lithotripsy, is an option. Surgery is avoided during episodes of acute inflammation to minimize ductal perforation.

Potential Complications

Sialolithiasis is often associated with chronic sialadenitis. It can also lead to ductal stricture and very rarely to sialocutaneous and sialo-oral fistulas.

28.4.2 Radiation Sialadenitis

Pathogenesis

During the treatment of head and neck cancer, exposure to more than 50 Gy of radiation can cause irreversible salivary gland damage and the loss of acinar cells. The parotid glands are most sensitive to damage. Salivary function can decrease by 60% with just 1 week of radiation therapy at 10 Gy. The treatment of thyroid cancer with radioactive iodine can also lead to radiation sialadenitis and xerostomia.

Evaluation

Radiation sialadenitis causes pain and swelling of the affected gland and is associated with xerostomia, oral infections, stomatitis, and increased dental caries.

Treatment

Hydration, sialagogues, and warm compresses can help with symptomatic management. Pilocarpine, a cholinergic secretagogue, may be used for postradiation xerostomia.

Potential Complications

Radiation sialadenitis can lead to xerostomia, taste alterations, and dental infections.

28.4.3 Sjögren Syndrome

Pathogenesis

Sjögren syndrome is an autoimmune disease that causes a lymphocytic infiltration and dysfunction of the salivary and lacrimal ducts. Patients may have primary Sjögren syndrome with xerophthalmia (keratoconjunctivitis sicca) and xerostomia alone, or they may have secondary Sjögren syndrome, in which another autoimmune disorder is also involved. There is a 9:1 female-to-male ratio of those affected, and most patients present in their fifties. The presence of HLA-B8 and HLA-Dw3 has been linked to an increased predisposition to primary Sjögren syndrome, whereas HLA-DRw4 is linked to the secondary form. It is hypothesized that environmental triggers, such as a viral infection (e.g., with HTLV-1 [human T-cell leukemia/lymphoma/lymphotropic virus] or Epstein-Barr virus), may induce cell lysis, leading to the formation of autoantigens that cause a lymphocytic infiltration of gland tissue and thus a decrease in glandular secretion.

Evaluation

Patients with Sjögren syndrome may present with dry eyes, inflamed and red conjunctivae, and a foreign body or sandy sensation in their eyes. Oral manifestations include dry mouth; changes in taste, speech, and swallow function; dry lips; fissured tongue; and poor oral hygiene. Ductal obstruction by lympho-

cytic infiltrates can cause recurrent salivary gland enlargement, particularly of the parotid gland, that can be bilateral and aggravated by eating. Extraglandular manifestations include low-grade fevers, arthritis, dry skin, myalgia, and purpura. Lower lip minor salivary gland biopsies show lymphocytic infiltrates. Histologically, benign lymphoepithelial lesions as described by Godwin can be associated with Sjögren syndrome, although patients with benign lymphoepithelial lesions do not always have symptoms of Sjögren syndrome. Objective tests include sialometry and the Schirmer test (less than 5 mm eye moisture in 5 minutes). Serology should be performed to test for anti-SS-A/Ro and anti-SS-B/La. In addition, Sjögren syndrome is associated with other autoimmune disorders, so testing for rheumatoid factor, antinuclear antibodies, and anticentromere antibodies can be positive.

Treatment

Symptomatic treatment includes hydration, sialagogues, oral hygiene, salivary substitutes, and artificial tears. Pilocarpine, the muscarinic agonist, has been used as a sialagogue but has systemic side effects of perspiration, flushing, and micturition, and it is contraindicated in patients with asthma. Steroids and immunomodulators are used for severe systemic manifestations of Sjögren syndrome.

Potential Complications

MR imaging may be helpful because there is a 44-fold increase in the risk for non-Hodgkin lymphoma in those with Sjögren syndrome. Care must be taken to follow patients with recurrent gland swelling, lymphadenopathy, vasculitis, lung infiltrates and hepatosplenomegaly, pancytopenia, hypergammaglobulinemia, and an increased erythrocyte sedimentation rate.

28.4.4 Sarcoidosis

Pathogenesis

Sarcoidosis is a noninfectious, inflammatory granulomatous disease of unknown etiology.

Evaluation

Sarcoidosis is more common in African-American women and often presents with cervical lymphadenopathy, pulmonary manifestations, and cutaneous nodules. Heerfordt syndrome (uveoparotid fever) is a form of sarcoidosis that begins with a prodrome of fever, fatigue, and night sweats and later manifests with acute parotitis and uveitis. Diffuse bilateral involvement of the glands of the face is possible, so a labial biopsy may reveal noncaseating granulomas involving lymphoid tissue.

Treatment

Glandular swelling may be chronic and usually resolves spontaneously, although steroids have been used in the acute setting.

Potential Complications

Facial paralysis not infrequently accompanies uveoparotid fever, but it tends to resolve with or without steroid treatment.

Symptomatic care includes artificial tears, lubricating ointment, and securing the eyes closed at night. An ophthalmologic evaluation is important because uveitis can lead to glaucoma. Rare cases of sudden hearing loss from neurosarcoidosis and supraglottic sarcoidosis have been reported.

28.5 Noninflammatory Diseases

28.5.1 Sialorrhea (Ptyalism)

Pathogenesis

Ptyalism, or sialorrhea, is the oversecretion of saliva. Medications like pilocarpine or the antipsychotic clozapine can cause hypersecretion of saliva. Stroke, Parkinson disease, and motor neuron diseases such as amyotrophic lateral sclerosis can cause sialorrhea in adults. In children, rather than being due to overproduction of saliva, drooling can be caused by the involuntary escape of saliva through the mouth, as seen in cerebral palsy. Ptyalism can accompany dysphagia in inflammatory conditions, such as a peritonsillar abscess. Ptyalism gravidarum is of unknown origin and often associated with hyperemesis during pregnancy.

Evaluation

Patients with sialorrhea often report difficulty swallowing. The patient should be assessed for deficits in sensation or oral motor function that would compromise swallowing or lip competence. Concurrent neurologic deficits may suggest a cerebrovascular accident.

Treatment

Speech therapy targeting oral movements is recommended for those with motor dysfunction. Anticholinergics such as scopolamine patches and oral atropine can help decrease secretions, but they may also lead to constipation, bradycardia, blurred vision, and urinary retention. Intraglandular botulinum toxin can temporarily treat sialorrhea. Surgical treatments include gland excision, ductal ligation, submandibular duct relocation, and the chorda tympani neurectomy.

Potential Complications

Sialorrhea has negative hygienic and social effects. It can also lead to skin maceration, infection, and aspiration.

28.5.2 Xerostomia

Pathogenesis

Inflammatory causes of dry mouth, or xerostomia, include radiation and autoimmune disorders like Sjögren syndrome, as described above. Other noninflammatory causes include dehydration, autonomic effects of stress, and medication side effects. Medications that can cause xerostomia due to anticholinergic side effects include antihypertensives, tricyclic antidepressants, antipsychotics, antihistamines, antiparkinsonian drugs, and anti-asthma bronchodilators. Diabetes has also been linked to xerostomia, presumably as a consequence of neuropathy, microvascular abnormalities, or metabolic dysfunction from inadequate control of diabetes.

Evaluation

Xerostomia is the subjective sensation of dry mouth, and this clinical finding does not correlate with objective measurements of salivary secretions. Patients who have xerostomia can present with a burning sensation in the mouth, dysphagia, speech and swallowing dysfunction, halitosis, and overall poor dental hygiene, including caries. On physical examination, patients may have cracked lips, pale oral mucosa, and dental decay.

Treatment

Hydration, sialagogues, stress management, and good oral hygiene should be encouraged. Changes in medication regimens can also help alleviate symptoms, especially in elderly patients taking numerous medications with anticholinergic side effects.

Potential Complications

Xerostomia can lead to oral infections such as candidiasis and to changes in taste, speech function, and swallow function.

28.5.3 Sialadenosis (Sialosis)

Pathogenesis

Sialadenosis, or sialosis, is a disease of the salivary glands characterized histologically by noninflammatory acinar enlargement. It has been linked to malnutrition and to metabolic and hormonal disturbances that may cause peripheral autonomic neuropathy. It is hypothesized that acinar enlargement is caused by neuropathy leading to impaired exocytosis of secretory granules and loss of myoepithelial mechanical support.

Evaluation

Sialadenosis typically presents with bilateral diffuse swelling of the salivary glands (typically the parotid glands). It is usually seen in association with a systemic condition such as diabetes, hypothyroidism, pregnancy, obesity, hypoproteinemia, alcoholic cirrhosis, or malnutrition. Imaging and biopsy are performed to establish a diagnosis.

Treatment

Partial or total gland excision has been performed in cases of pain and poor cosmesis despite conservative treatment and the management of systemic disturbances.

Potential Complications

Because sialosis may be related to systemic disturbances that lead to autonomic neuropathy, the remaining glands may become affected despite the surgical removal of one.

28.5.4 Cysts

Pathogenesis

Branchial cysts are true cysts with an epithelial lining and lymphoid tissue. Type I ectodermal first branchial cleft cysts arise from duplication of the membranous external auditory canal.

They run parallel to the external auditory canal toward the oropharynx and are lateral to the facial nerve. Type II first branchial cleft cysts are of ectodermal and mesodermal origin and have cartilaginous components. They can run medial or lateral to the facial nerve. Dermoid cysts can be congenital or acquired and are lined with epidermis. They contain trapped skin appendages such as sebaceous glands, hair follicles, and connective tissue. Acquired cysts may occur after trauma and inflammatory injury as described throughout this chapter.

Evaluation

Parotid branchial cysts usually present as slowly growing, painless, firm masses around the anterior and upper third of the sternocleidomastoid muscle. They tend to present in persons 10 to 30 years olds and can have sinus tracts. Type I sinus tracts can be in the region of the pinna. Type II sinus tracts tend to run from the external auditory canal and drain near the angle of the mandible. Dermoid cysts tend to present in orbital, oral, and nasal regions but rarely can present as a firm, rounded parotid mass.

Treatment

The treatment of branchial cysts is complete excision with cranial nerve preservation. Parotid dermoid cysts should be removed with a partial parotidectomy to prevent recurrence.

Potential Complications

Failure to completely excise a salivary gland cyst can lead to recurrent infections and abscesses.

28.5.5 Mucoceles

Pathogenesis

Mucoceleles are collections of mucus that can be true cystic lesions lined with epithelium (retention cysts) or pseudocysts that are simply covered with granulation tissue (extravasation cysts). Mucus retention cysts form from ductal dilation secondary to obstruction and the accumulation of mucus. A simple ranula is a retention cyst of the sublingual gland at the floor of the mouth. Trauma to a salivary duct can lead to the extravasation of mucus. If an excretory duct of a minor salivary gland is damaged, the salivary collection can cause an inflammatory reaction in the neighboring connective tissue, causing a granulation tissue-lined extravasation cyst to form. A plunging ranula is an extravasation cyst of the floor of the mouth.

Evaluation

Mucoceleles are commonly found in minor salivary glands of the lips, buccal mucosa, ventral surface of the tongue, and floor of the mouth. They present as a smooth swelling that tends to be painless but can be irritated by chewing or swallowing movements. Mucoceleles can be pink or blue from vascular congestion and the cyanosis of tissue stretched by saliva accumulation. A plunging ranula presents as a mass in the submandibular space. Imaging can help visualize the extent of a ranula, and fine-needle aspiration biopsy can rule out other cystic lesions.

Treatment

The treatment of mucoceles is complete excision. A ranula can also be completely excised, or treatment may involve excision of the entire gland to prevent recurrence. If critical nerves are involved, marsupialization of the cyst may be performed, with the risk for recurrence. A combined intraoral and cervical approach may be necessary for excision of a plunging ranula.

Potential Complications

Mucoceleles may rupture, reaccumulate, or become infected.

28.5.6 Trauma

Pathogenesis

Traumatic injury to the salivary glands is rare. The parotid glands are the most exposed and therefore more likely to be injured. Penetrating trauma is more likely to cause complications than is blunt trauma. Common causes of facial injury include knives, motor vehicle accidents, gunshots, and iatrogenic maneuvers.

Evaluation

Understanding the gland anatomy is key to recognizing the complications of trauma. The Stenson duct travels superior to the masseter in close proximity to the transverse facial artery and buccal branch of the facial nerve before piercing the buccinator muscle to enter the oral mucosa. Lacerations involving these structures should be repaired at the time of cheek laceration repair.

Treatment

Glandular trauma can be repaired by suturing the capsule, closing the laceration, and applying pressure dressings to prevent the formation of a sialocele. Hemostasis must be achieved, and facial nerve damage should be immediately addressed surgically. In the repair of ductal lacerations, intraoral probing of the ductal orifice or the retrograde injection of methylene blue can help identify the distal duct while the gland is milked, and an evaluation of salivary flow can help identify the proximal duct (this can be done more easily if atropine and glycopyrrolate, used to reduce secretions, have not been used during anesthesia). Three basic treatment options exist for ductal repair. Penetrating trauma is repaired with a microsurgical primary anastomosis, in which the duct is dissected off the neighboring tissue for a tension-free repair done over a stent. If primary repair is not possible, an autogenous vein graft can be interposed. Alternatively, saliva can be diverted by suturing the proximal duct to an opening in the oral mucosa. If damage to the gland is too extensive for diversion, salivary atrophy can be promoted by ligating the proximal duct, avoiding oral feeding, and administering antisialagogues and pressure dressings.

Potential Complications

Failure to identify and treat salivary gland injuries can lead to sialocele formation and cutaneous fistulas when ductal damage

is not addressed appropriately. Amylase levels in sialoceles can be higher than 10,000 U/L. Sialoceles can be conservatively managed with botulinum toxin A injections, pressure dressings, antisialagogues, and aspiration. Similar conservative and surgical options are available for fistula treatment, but it is best to explore a suspicious wound initially before ductal injuries are missed and fibrosis occurs.

28.6 Roundsmanship

- During a physical examination of the salivary glands, it is important to palpate externally as well as intraorally.
- For acute sialadenitis, a “sialadenitis regimen” includes hydration, sialagogues (lemon drops, orange juice, or sugar-free gum), warm compresses, bimanual massage, oral hygiene, and smoking cessation.
- Salivary function can decrease by 60% after just 1 week of radiation therapy at 10 Gy. Radioactive iodine treatment of thyroid cancer can also lead to radiation sialadenitis and xerostomia.
- In cases suspicious for Sjögren syndrome, serology should be sent for anti-SS-A/Ro and anti-SS-B/La in addition to rheumatoid factor, antinuclear antibodies, and anticentromere antibodies.
- In repairing ductal lacerations, intraoral probing of the ductal orifice or the retrograde injection of methylene blue can help

identify the distal duct while the gland is milked, and the evaluation of salivary flow can help identify the proximal duct.

- Sialoceles resulting from trauma can be conservatively managed with botulinum toxin A injections, pressure dressings, antisialagogues, and aspiration.
- Mucoceles are collections of mucus that can be true cystic lesions lined with epithelium (retention cysts) or pseudocysts simply covered with granulation tissue (extravasation cysts).

29 Benign Neoplasms of the Salivary Glands

Vikas Mehta and Stimson P. Schantz

29.1 Introduction

Benign neoplasms of the salivary glands usually present as slowly enlarging, painless masses arising in the face, oral cavity, or neck. However, despite their benign nature, differentiating these neoplasms from malignant tumors is difficult based on the history, physical examination, imaging, and fine-needle aspiration biopsy. Besides pleomorphic adenomas, which constitute the majority of all salivary gland tumors, many of the other benign neoplasms of the salivary gland are rarely encountered. Additionally, pleomorphic adenomas carry the potential for malignant transformation. All of these factors lead to the need for the surgical excision of these nonmalignant growths. Future research with molecular genetics and imaging may help head and neck surgeons tailor their treatment of these rare entities.

29.2 Incidence

Overall, salivary gland neoplasms are relatively rare, accounting for only 3 to 4% of all head and neck tumors. The incidence of salivary gland neoplasms as a whole is approximately 1.5 cases per 100,000 individuals in the United States. These tumors can be segregated into two major groups based on location: tumors of major salivary glands and tumors of minor salivary glands. The major salivary glands are the paired parotid glands, submandibular glands, and the sublingual glands. The minor salivary glands consist of approximately 600 to 1,000 small glands scattered throughout the upper aerodigestive tract.

Of all salivary gland tumors, 70 to 80% are located in the parotid gland, and 75% of these parotid neoplasms are benign. Submandibular neoplasms constitute 10 to 15% of all salivary gland neoplasms, and approximately half of these are malignant. The remaining tumors are situated in the sublingual and minor salivary glands, and 75% of these are malignant. In summary, as the size of the gland decreases, the overall incidence of tumors decreases and the incidence of malignancy rises by 25%. This is known as the 25/50/75 rule, referring to the percentages of malignant tumors in the parotid, submandibular, and sublingual/minor salivary glands, respectively.

In adults, approximately 60% of all tumors are pleomorphic adenomas, with Warthin tumors the second-most common benign neoplasm (12%). In general, 54% of salivary gland neoplasms in adults are benign, and 65% of all salivary gland neoplasms in children are benign. Hemangiomas are the most common salivary gland neoplasms in children, followed by pleomorphic adenomas.

29.3 Terminology

A list of benign tumors and their relative frequencies is provided in □ Table 29.1. In general, benign tumors are slowly growing, painless, firm masses that are well circumscribed and can be treated with surgical excision including a cuff of normal tissue. The most common of these rare neoplasms are listed in the table.

29.3.1 Pleomorphic Adenoma

Also referred to as benign mixed tumor, pleomorphic adenoma is the most common tumor of the salivary glands. Commonly presenting in the fifth decade of life, they affect men and women equally and present as an asymptomatic, solitary mass. Rare cases of multifocal primary disease have been described. These tumors are referred to as pleomorphic or benign mixed tumors because of their composition of epithelial and connective tissue components in varying proportions. As noted above, pleomorphic adenomas account for 75% of all benign salivary gland neoplasms.

In the parotid gland, pleomorphic adenomas arise lateral to the facial nerve 90% of the time. Rarely, these tumors will extend between the stylomandibular ligament and the mandibular ramus into the parapharyngeal space and create the characteristic “dumbbell-shaped” appearance seen on imaging. Only 10% of parotid gland pleomorphic adenomas originate from the deep lobe of the parotid. Pleomorphic adenomas are the most common tumors of the prestyloid parapharyngeal space. Of all submandibular gland tumors, 36% are benign mixed tumors. The most common locations of a minor salivary gland pleomorphic adenoma are the palate and upper lip.

Pathologically, pleomorphic adenomas are firm and round, and the color varies from whitish gray to yellow. They are usually well encapsulated in the parotid gland and nonencapsulated in the minor salivary glands. Histopathologic analysis can show areas of focally thin capsule with pseudopodia, which are microextensions of the tumor into surrounding tissue. It is therefore imperative to take a cuff of normal tissue when excising the tumor. Abiding by this principle can lead to a recurrence rate of less than 5%. A benign mixed tumor never invades the facial nerve, so the facial nerve should never be sacrificed during excision.

Recurrence of these tumors poses a particular challenge for the head and neck surgeon. They often recur in a multifocal fashion, and the cure rate after salvage resection can be 25% or less. Surgical excision remains the mainstay of treatment for recurrent tumors, but the risk for facial nerve paralysis is significantly higher. Radiation therapy is controversial but can be employed in cases of inadequate margins or multifocal disease. Malignant transformation of pleomorphic adenoma is rare but can occur in patients with long-standing tumors. The risk for malignant transformation to carcinoma ex-pleomorphic adeno-

Table 29.1 The most common benign salivary gland neoplasms and their relative frequencies among all salivary gland neoplasms

Benign salivary neoplasm	Relative frequency
Pleomorphic adenoma	45%
Warthin tumor	10%
Monomorphic adenoma	2%
Oncocytoma	<1%
Hemangioma and vascular malformations	<1%

ma is 1.5% within the first year of diagnosis, but this risk increases to 10% after observation for more than 15 years.

29.3.2 Warthin Tumor (Papillary Cystadenoma Lymphomatosum)

Warthin tumors are the second most common benign tumors of the salivary glands, accounting for approximately 10% of lesions. The more appropriate name for these tumors is papillary cystadenoma lymphomatosum because of their histopathologic characteristics. Warthin tumors occur almost exclusively in the parotid gland and affect men more often than women (male-to-female ratio, 5:1). This has been hypothesized to occur because of the role smoking plays in the pathogenesis of Warthin tumors. Warthin tumors are bilateral in 10% of cases and occasionally may be painful as a result of inflammation secondary to an immunologic response to the lymphoid component.

Pathologically, these tumors are spherical or ovoid, smooth or lobulated, and encapsulated. Upon sectioning, the tumors exhibit solid gray tissue encapsulating white lymphoid tissue and multiple papillary cysts containing a mucoid brown fluid, explaining the name papillary cystadenoma lymphomatosum. The recommended treatment is surgical excision with facial nerve preservation. Recurrence may occur because of the multifocal, bilateral nature of these lesions.

29.3.3 Monomorphic Adenoma

The most common monomorphic adenomas are basal cell adenomas and clear cell adenomas. These lesions account for 2% of all salivary neoplasms. They occur most commonly in the upper lip and parotid gland. They are the least aggressive of all salivary gland tumors, presenting as firm, well-encapsulated, slowly growing masses. They have an intact basement membrane without extracapsular extension. These tumors may be difficult to distinguish from the solid variant of adenoid cystic carcinoma, but certain characteristics help with the distinction; lack of invasion into surrounding tissues, peripheral palisading of the outer basaloid cells, lack of perineural invasion, and a vascular stroma are unique characteristics of basal cell adenomas.

29.3.4 Oncocytoma

Oncocytes are large epithelial cells with a granular eosinophilic cytoplasm. The granular appearance is due to the large number of mitochondria in these cells, which can be identified on electron microscopy. These unusual tumors account for 1% of all salivary gland neoplasms and occur later in life with an equal predilection for men and women. They present as painless, solitary masses. Oncocytomas are most commonly found in the superficial lobe of the parotid gland but can occur in all of the salivary glands, as well as the pancreas, respiratory tract, thyroid, parathyroids, pituitary, adrenal glands, and kidneys.

Oncocytomas are usually well-circumscribed and encapsulated neoplasms that are pink or rust-colored. However, in minor salivary glands, the capsule is not present, which allows the tumors to be locally destructive. They can erode cartilage or bone but rarely metastasize. Benign oncocytomas must be

differentiated from malignant salivary tumors with oncocytic components (i.e., adenoid cystic carcinoma, mucoepidermoid carcinoma, adenocarcinoma, and malignant oncocytoma), as well as metastatic renal cell and thyroid carcinoma. The treatment for benign oncocytoma is surgical excision.

29.3.5 Hemangioma and Vascular Malformations

As stated above, the most common benign salivary gland lesions in children are hemangiomas. A more detailed description of hemangiomas is described elsewhere in this text, but in general, hemangiomas present in infancy and undergo a growth phase from 1 to 6 months of age followed by an involution phase that can last up to 12 years. Hemangiomas are more common in girls and are usually asymptomatic, unilateral, compressible masses. They occur most commonly in the parotid gland and can cause changes of the overlying skin.

On pathologic examination, they are dark red, lobulated tumors without a capsule. Histopathologically, they are composed of capillaries lined with proliferative endothelial cells. A full discussion of the treatment of these complicated tumors is beyond the scope of this chapter, but surgery is traditionally reserved for tumors that continue to proliferate despite medical therapy (steroids and more recently propranolol) and cause significant compressive, vascular, and/or cardiac symptoms.

Vascular malformations are different from hemangiomas in that they are not true neoplasms. They may be one of three types: venous malformations, arteriovenous malformations, or lymphatic malformations. Generally, these lesions are congenital and present at birth, and they continue to enlarge throughout life. Surgery of these lesions can be tedious and treacherous because they often invade locally and can bleed excessively. However, surgery currently remains the mainstay of treatment for vascular malformations of the salivary glands.

29.4 Applied Anatomy

As mentioned previously, these tumors are preferentially located in the superficial lobe of the parotid, followed by the submandibular glands and finally the sublingual and minor salivary glands. Surgical excision of primary benign salivary gland tumors remains the treatment of choice, and a detailed understanding of the usually consistent anatomy can result in largely complication-free surgical procedures.

Embryologically, the salivary glands start to form at 6 to 9 weeks of gestational age. The major salivary glands arise from ectodermal tissue, while the minor salivary glands arise from either ectodermal or endodermal tissue. The submandibular gland becomes encapsulated earlier than the parotid gland, which allows lymph nodes to be trapped in the parotid gland. This embryologic difference explains why lymphatic metastases may manifest within the substance of the parotid gland but not the submandibular gland.

The excretory unit of the salivary gland consists of acini and ducts. The acini secrete saliva that is either mucinous or serous, or both. The acini cells drain into the intercalated ducts, then the striated duct, and finally the excretory duct. Myoepithelial cells surround the acini and intercalated duct and serve to expel

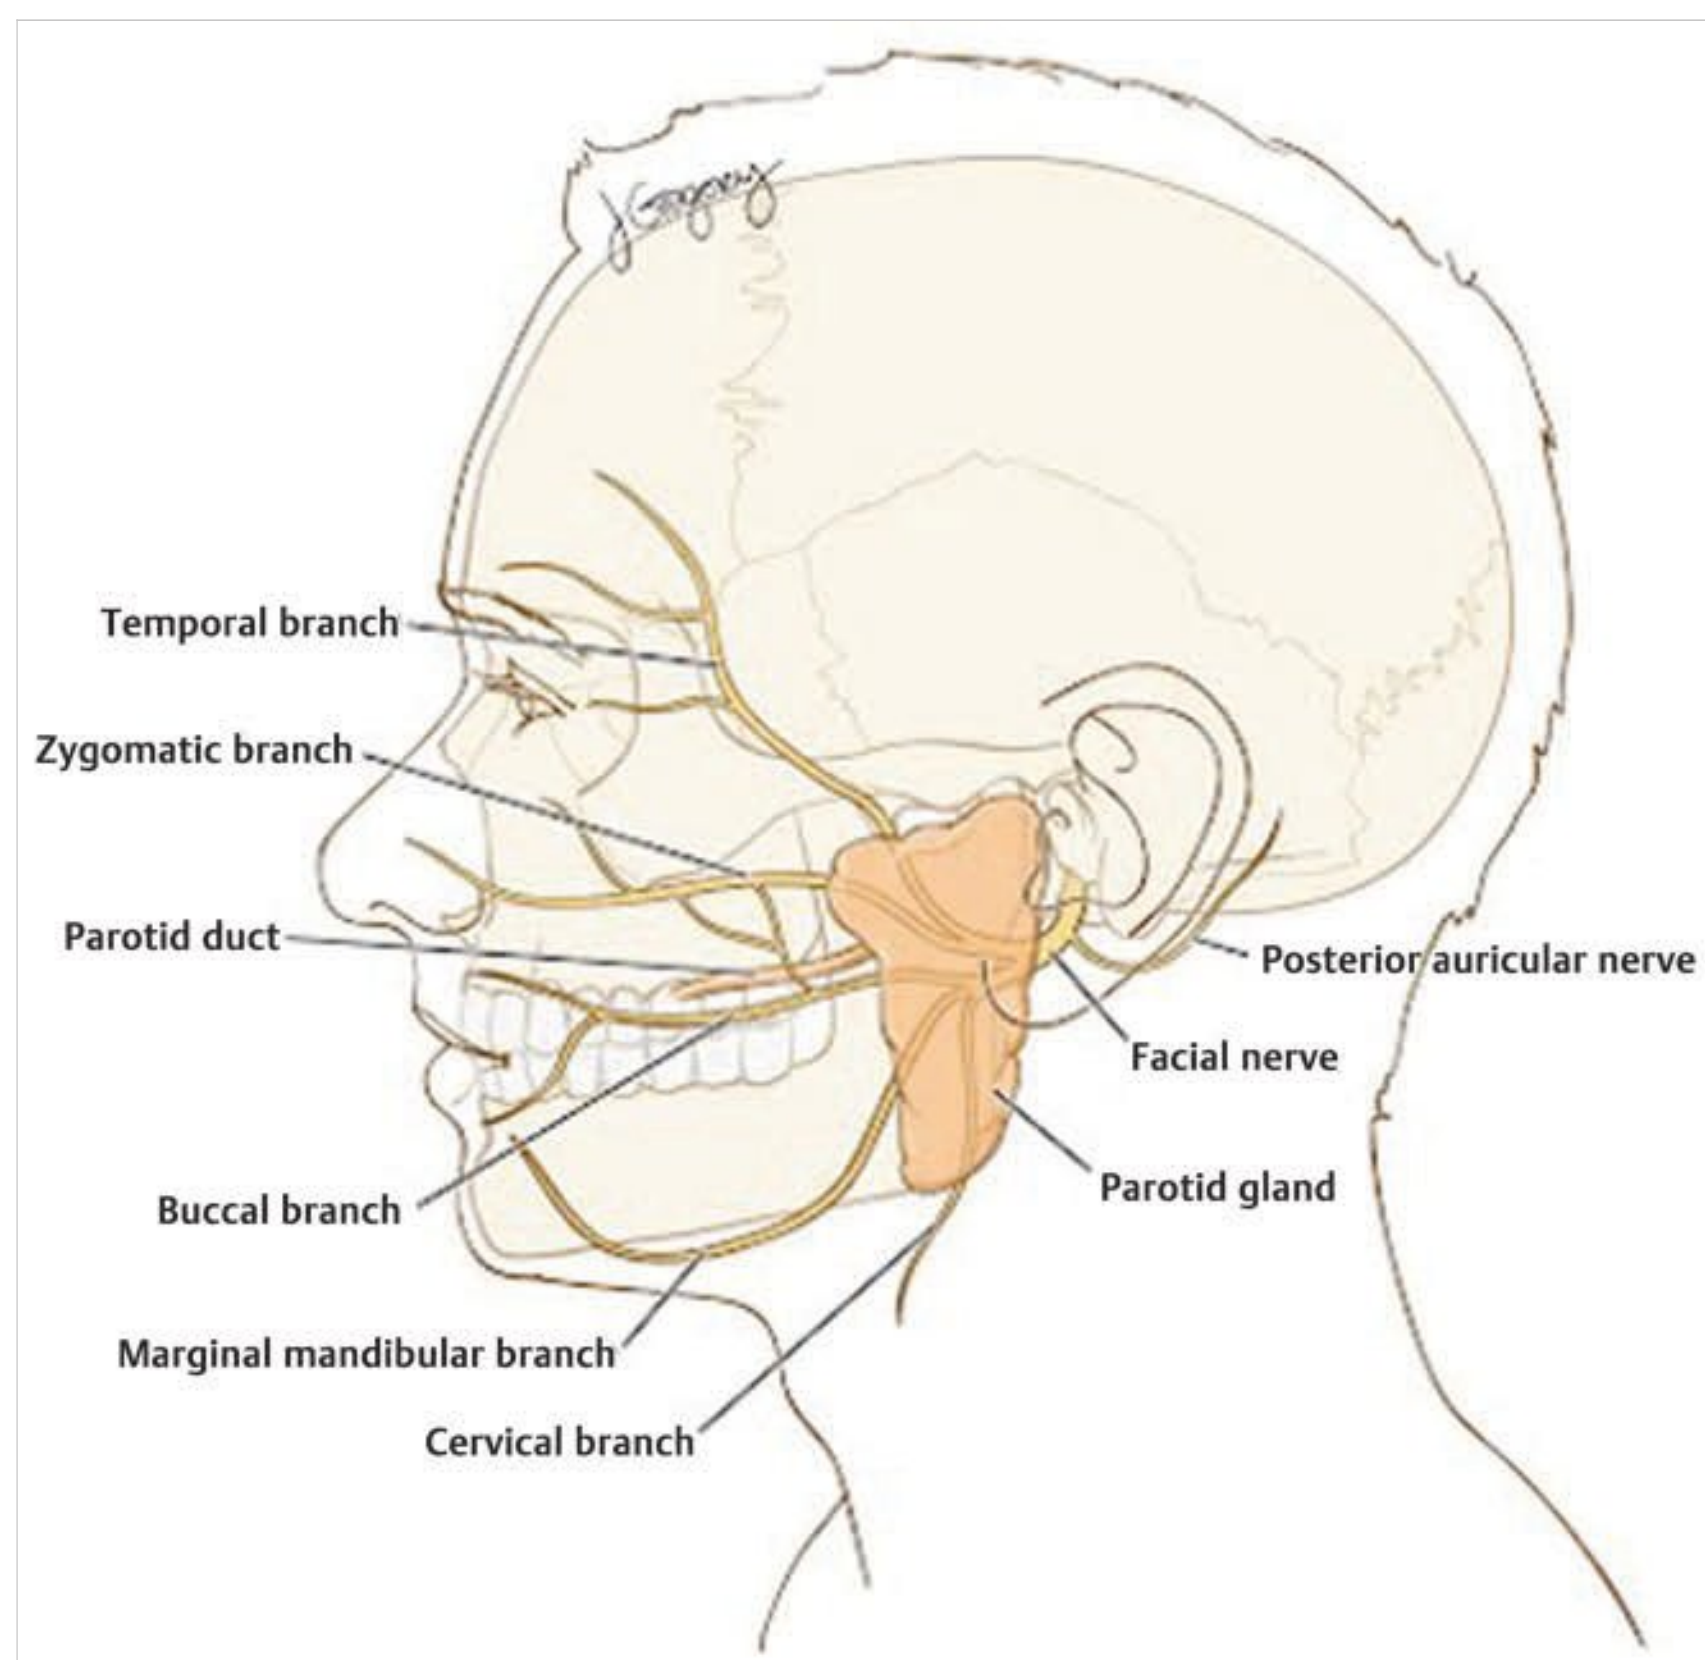

Fig. 29.1 Anatomy of the facial nerve as it exits the stylomastoid foramen and enters the parotid gland. The nerve is shown dividing into its various branches within the parotid parenchyma. Note that the Stensen duct travels with the buccal branch of the facial nerve.

secretory products into the ductal system. The saliva from the parotid is predominately serous, the sublingual and minor salivary glands secrete mucinous saliva, and the submandibular gland has a mixed product.

29.4.1 Parotid Gland

The parotid gland is actually a single-lobe gland that is described as having a superficial and a deep lobe based on the surgical resection of glandular tissue lateral and medial to the facial nerve, respectively. The gland receives parasympathetic innervation from preganglionic fibers arising in the inferior salivatory nucleus, which travel with the glossopharyngeal nerve (cranial nerve [CN] IX) via the jugular foramen. Upon exiting the skull base, the preganglionic fibers leave CN IX to form the Jacobson nerve and reenter the skull via the inferior tympanic canaliculus. The fibers traverse the middle ear space over the cochlear promontory and exit the temporal bone superiorly as the lesser petrosal nerve. The lesser petrosal nerve exits the middle cranial fossa through the foramen ovale, where the preganglionic fibers synapse in the otic ganglion. The postganglionic fibers travel with the auriculotemporal nerve to supply the parotid gland.

The Stensen duct drains the parotid gland. It runs approximately 1 cm below the zygoma in a horizontal direction, often in close proximity to the buccal branch of the facial nerve (□ Fig. 29.1). The duct penetrates anterior to the masseter muscle through the buccinator muscle, where it opens intraorally just opposite the second maxillary molar. The arterial

supply to the parotid gland is via the external carotid system, and it is drained by the posterior facial vein. As mentioned above, the parotid gland contains lymphatics within that drain to the jugular lymphatic chain.

The parotid gland is contained in what is termed the parotid compartment. The wedge-shaped parotid compartment is bounded superiorly by the zygomatic arch; anteriorly by the masseter muscle, lateral pterygoid muscle, and mandibular ramus; and inferiorly by the sternocleidomastoid muscle and posterior belly of the digastric muscle. The deep portion lies lateral to the parapharyngeal space, styloid process, stylomandibular ligament, and carotid sheath. The parotid fascia envelops the gland and suspends it from the zygoma. The parotid compartment contains the facial, auriculotemporal, and greater auricular nerves; the superficial temporal and posterior facial veins; and the external carotid, superficial temporal, and internal maxillary arteries.

The facial nerve (CN VII) exits the stylomastoid foramen and travels anterolaterally to enter the parotid gland. The nerve gives off motor branches to the posterior auricular muscle, posterior belly of the digastric muscle, and stylohyoid muscle before entering the gland (see □ Fig. 29.1). Immediately upon entering the gland, the facial nerve divides into two major branches (upper and lower) at the pes anserinus. Generally, the upper branch divides into the temporal and zygomatic branches, while the lower branch is subsequently responsible for the buccal, marginal mandibular, and cervical divisions. Knowledge of this anatomy is imperative for facial nerve preservation during parotid gland surgery.

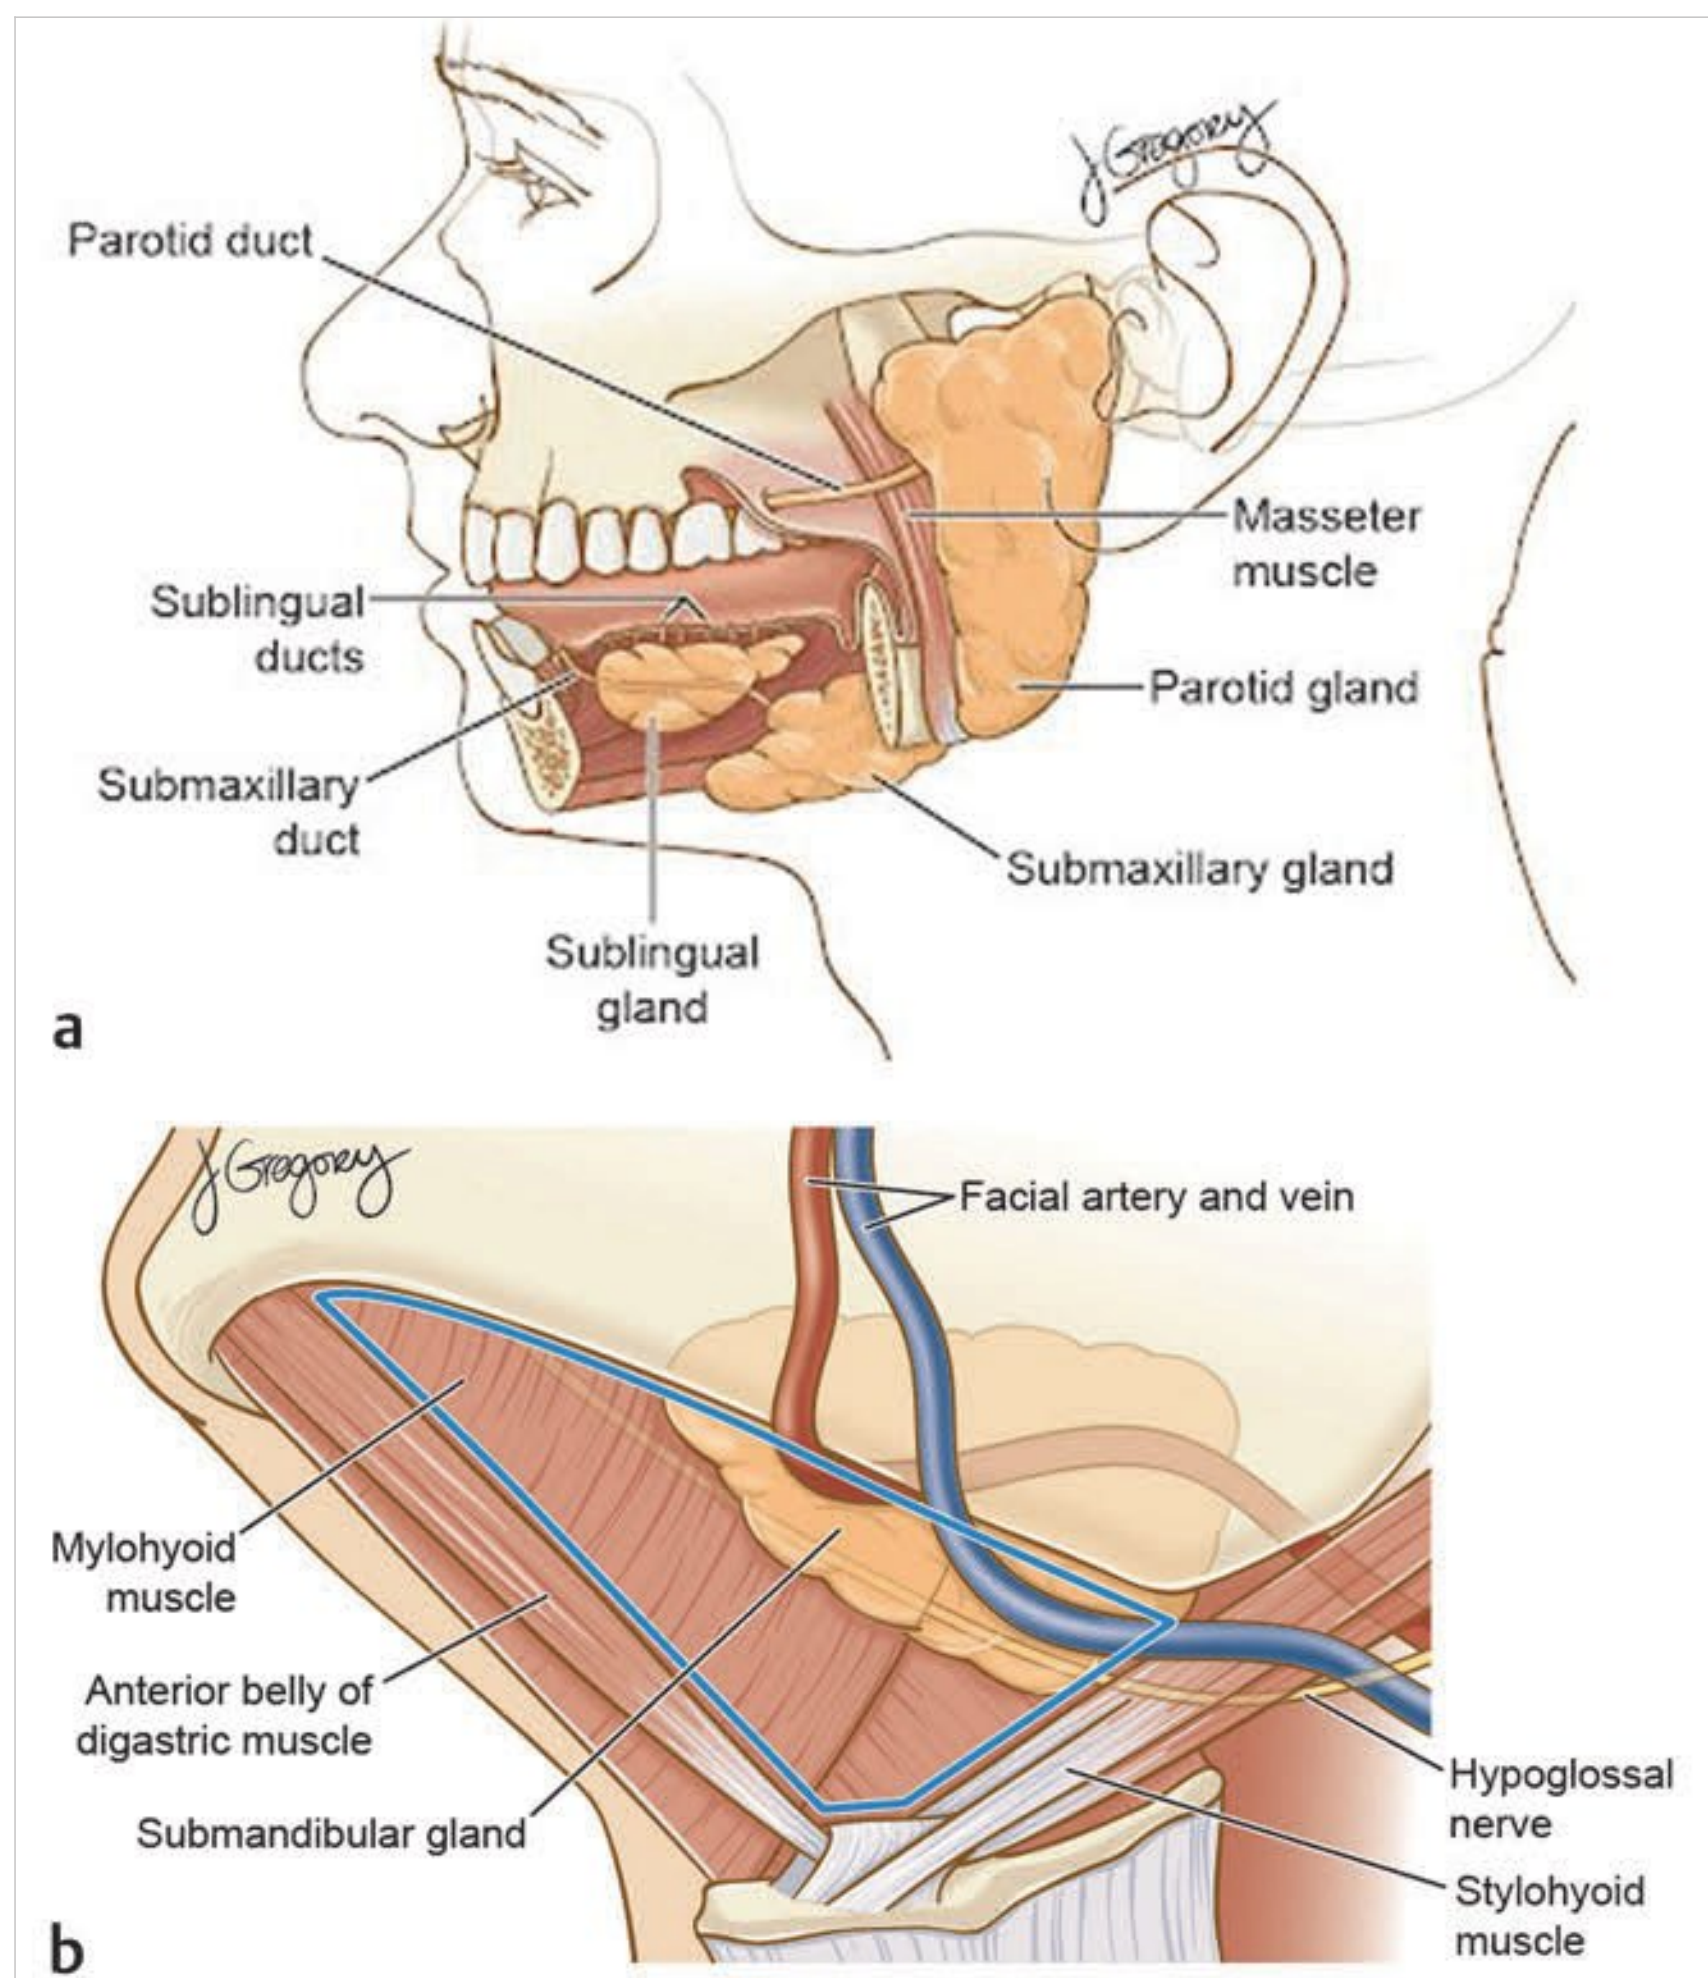

Fig. 29.2 (a) Major salivary glands. (b) Anatomy of the submandibular triangle and the important neurovascular structures in relation to the submandibular gland. The hypoglossal nerve is shown passing deep and inferior to the gland, while the facial artery and vein are deep and superior.

29.4.2 Submandibular Gland

The submandibular gland is located in the submandibular triangle, which is bound by the anterior and posterior bellies of the digastric muscle and the mandible. The gland receives preganglionic parasympathetic innervation from the superior salivatory nucleus. These fibers leave the brainstem and travel via the nervus intermedius to the facial nerve and then with the chorda tympani. The chorda tympani synapses in the submandibular ganglion and provides postsympathetic innervation. The submandibular ganglion is located just deep to the gland near the lingual nerve. The arterial supply is from the lingual and facial arteries, venous drainage is to the anterior facial veins, and lymphatic drainage is to the submandibular nodes. The Wharton duct, which drains the gland, passes between the mylohyoid and hyoglossus muscles along the genioglossus and enters the oral cavity just lateral to the frenulum of the tongue.

There are several important neurovascular structures surrounding the gland that must be preserved during removal (see □ Fig. 29.1 and □ Fig. 29.2). The marginal mandibular nerve lies superficial to the gland. The hypoglossal nerve is deep to the gland, inferior to the Wharton duct. The lingual nerve is superior to the gland and deep to the mylohyoid muscles. Finally, the facial artery sits deep to the gland, and only its branch to the gland should be ligated during excision.

29.4.3 Sublingual and Minor Salivary Glands

The sublingual gland is an unencapsulated gland that is situated medial to the mandible just above the mylohyoid muscle and deep to the floor of the mouth. The gland has 8 to 20 small ducts that penetrate the oral mucosa posterolateral to the Wharton duct. Innervation is via the same pathway as the submandibular gland, arterial supply is from the lingual artery, and lymphatic drainage is to the submental and submandibular nodes.

The minor salivary glands are scattered throughout the upper aerodigestive tract and number approximately 600 to 1,000. Each gland has a discrete opening into the oral cavity and functions as a separate unit.

29.5 The Disease Process

29.5.1 Etiology

The exact etiology of salivary gland neoplasms is not known. However, certain factors, such as radiation, smoking, and specific occupational exposures, have been shown to increase the risk for developing salivary gland tumors. A recent study found a 4.5-fold increase in the incidence of salivary gland cancer and a 2.6-fold increase in the incidence of benign tumors (especially

Warthin tumors) among persons exposed to head and neck irradiation. Warthin tumor is also strongly associated with cigarette smoking. Occupational exposure to silica dust and nitrosamines among rubber workers has been linked to an increased risk for cancer of the salivary glands.

29.5.2 Pathogenesis

There are two competing theories for the origin of salivary gland neoplasms: the bicellular stem cell theory and the multicellular theory. The multicellular theory implies simply that each tumor type arises from a specific, previously differentiated cell (e.g., pleomorphic adenomas arise from intercalated duct cells, oncocytomas from striated duct cells, and acinic cell carcinomas from acinar cells). The bicellular theory posits that tumors arise from either of two undifferentiated stem cells: the excretory duct reserve cell or the intercalated duct reserve cell. Intercalated stem cells give rise to pleomorphic adenomas, oncocytomas, adenoid cystic carcinomas, adenocarcinomas, and acinic cell carcinomas, whereas excretory stem cells give rise to squamous cell and mucoepidermoid carcinomas. The bicellular theory is supported by the presence of multiple cell types in pleomorphic adenomas and Warthin tumors.

29.5.3 Natural History and Progression

Overall, benign neoplasms of the salivary glands tend to enlarge slowly over a period of years. Despite their slow growth, patients may still report a “recent” growth. The vast majority are painless, with the notable exception of Warthin tumors, which will occasionally have an inflammatory component.

29.5.4 Potential Disease Complications

These neoplasms may cause cosmetic disfigurement, but functional obstruction generally develops only once they become very large. Deep lobe tumors may enlarge intraorally or into the parapharyngeal space and create dysphagia and/or trismus. Minor salivary gland tumors can also cause dysphagia and odynophagia in the oral cavity or oropharynx. If located in the nasal cavity or nasopharynx, they can cause obstructive sinusitis. Finally, laryngeal minor salivary glands can cause hoarseness and airway obstruction. If either the Stensen duct or Wharton duct is obstructed by a neoplasm, salivary backup and sialadenitis can develop in the parotid and submandibular glands, respectively. Oncocytomas may cause local destruction of cartilage or bone, and pleomorphic adenomas can undergo malignant transformation over time.

29.6 Disease Grading

There is no standard grading system for benign salivary gland tumors. See the earlier sections for discussion of the individual tumor types.

29.7 Presenting Complaints

Many diseases can affect the salivary glands, but most nonneoplastic causes can be excluded based on a thorough history. Autoimmune, inflammatory, and infectious diseases can all

mimic neoplastic processes. Acute, diffuse painful swelling is usually associated with an infectious or inflammatory process. Bilateral disease is often associated with viral infection (i.e., HIV infection or mumps) or Sjögren syndrome. Infection is more common in those who are elderly, malnourished, immunocompromised, or dehydrated. Care should be taken not to assume, however, that a patient with these problems does not have a neoplasm because a salivary gland tumor, whether benign or malignant, can cause all of these symptoms.

Initial questioning should focus on the presentation of the mass, growth rate, changes in size or symptoms with meals, facial weakness or asymmetry, and associated pain. A firm, unilateral, slowly growing painless mass in the parotid is more often than not a benign neoplasm, whereas such a presentation in the submandibular gland is often due to chronic obstruction and inflammation. Questions about a history of smoking and toxin exposure should be asked, as well. Further description of possible patient complaints is discussed above.

29.8 Clinical Findings, Physical Examination

Patients with a salivary gland mass should undergo a thorough head and neck examination. Those with parotid neoplasms should undergo thorough palpation, including bimanual, intraoral palpation to ascertain involvement of the parapharyngeal space. A facial nerve examination should be performed and documented (even if normal) as part of the preoperative documentation. Submandibular gland neoplasms may sometimes be difficult to discern from diffuse gland enlargement but can be distinguished if freely mobile. Both submandibular and sublingual gland masses should also be assessed via bimanual palpation. The patient with a submandibular gland mass should also be assessed for any weakness or numbness of the tongue and weakness of the facial nerve, indicating perineural spread via the hypoglossal, lingual, and marginal mandibular nerves, respectively.

A benign neoplasm of the salivary gland will appear as a firm, well-circumscribed, freely mobile tumor on examination. Fixation to the surrounding structures or skin, nerve paresis or paralysis, regional lymphadenopathy, and local destruction are often associated with malignancies. Recall that minor salivary gland tumors are rarely benign, so these should be treated more aggressively.

29.9 Testing

Currently, the work-up for a salivary gland neoplasm can involve a combination of fine-needle aspiration biopsy and/or imaging. The use of these techniques is not disputed when the tumor occurs in an unusual location (i.e., parapharyngeal space) or where there is a high chance of malignancy. However, when a single, mobile, firm nodule presents in the superficial lobe of the parotid, the utility of these diagnostic procedures can be questioned.

29.9.1 Fine-Needle Aspiration Biopsy

Fine-needle aspiration biopsy is an extremely sensitive (86 to 99%) and specific (96 to 100%) tool when performed at an

institution familiar with salivary gland neoplasms. The test is easily performed, safe, and relatively inexpensive. If the lesion is deep, the accuracy of the biopsy can be improved with the use of ultrasound. In general, fine-needle aspiration biopsy is a better test for benign lesions than for malignant ones because there are many lesions that can mimic malignancies on cytologic analysis.

Proponents of fine-needle aspiration biopsy state that the test can prevent surgery in patients with certain benign lesions (e.g., chronic inflammation, benign lymphoepithelial lesions), high-risk or elderly patients with benign lesions, and those with lymphoma. Also, the ability to plan preoperatively for an extensive cancer resection and counsel a patient regarding the potential morbidities and outcomes is a valuable asset that fine-needle aspiration biopsy provides. Opponents argue that if the patient's work-up is done properly, the test is not necessary on all lesions. Also, despite the general safety of the procedure when performed with a 25-gauge needle, Warthin tumors can become inflamed after the procedure, further complicating resection. Few would argue for the use of fine-needle aspiration biopsy in the submandibular gland or minor salivary gland areas because tumors in these glands are likely to be malignant or metastatic disease.

29.9.2 Imaging

When contemplating the use of imaging, a surgeon must consider how the use of this modality will alter the treatment plan. Although an argument can be made for fine-needle aspiration biopsy, a patient with a solitary, firm, mobile nodule of the parotid gland usually does not require any type of imaging study because this will rarely change the proposed surgery. If there is suspicion for a malignancy or the tumor involves any location other than the superficial lobe of the parotid, an imaging modality is clearly warranted.

The two most commonly used modalities for imaging salivary gland neoplasms are computed tomography (CT) and magnetic resonance (MR) imaging. CT should be performed with contrast, and the salivary glands are readily visualized with this modality. Encapsulated lesions can be identified easily with CT (□ Fig. 29.3), but the various tumors cannot be distinguished from one another. Bilateral disease and cervical metastases are also readily appreciated on both MR imaging and CT, which can help with treatment planning. If readily available and not contraindicated, MR imaging is the study of choice for salivary gland neoplasms in any location. Dynamic contrast-enhanced MR imaging can be used to differentiate pleomorphic adenomas and Warthin tumors with a sensitivity of 100% and a specificity of 80%. Pleomorphic adenomas have a very high T2-signal intensity, whereas Warthin tumors display a highly characteristic necrotic, cystic component. MR imaging is also superior to CT in showing extraglandular extension, perineural invasion, parapharyngeal space involvement, and demarcation from the glandular tissue itself. Despite the accuracy of MR imaging, the only salivary gland neoplasm that can be definitively diagnosed via imaging is a lipoma. All others require a pathologic diagnosis.

Ultrasound is usually used for directing fine-needle aspiration biopsy in children and pregnant women. It can provide a quick, inexpensive evaluation of the tumor by helping to clarify

whether the process is diffuse or isolated, cystic or solid, or vascular; identify margins; and potentially diagnose the tumor.

29.10 Differential Diagnosis

The differential includes all the lesions described above (see □ Table 29.1), the salivary gland malignancies discussed in the next chapter, and the various inflammatory processes discussed in the previous chapter.

29.11 Treatment: Surgical Excision

Currently, the only acceptable treatment for benign neoplasms of the salivary gland is surgical excision. Radiotherapy can be used for recurrent, multifocal disease. Observation is usually reserved for those patients who are high-risk surgical candidates. As a general principle, regardless of pathology, all benign tumors of the salivary glands require excision with a cuff of normal tissue to prevent recurrence.

29.11.1 Parotidectomy

A clear drape should be placed over the ipsilateral portion of the patient's face to allow adequate visualization to identify any intraoperative stimulation of the facial nerve muscles. The standard Blair parotidectomy incision is made in the preauricular crease, starting at the level of the root of the helix. The incision extends inferiorly around the lobule of the ear over the mastoid tip. It gently curves down along the sternocleidomastoid muscle and then slightly forward in a natural skin crease in the upper neck 1 to 2 finger breadths below the mandible. Skin flaps are elevated in the plane superficial to the parotid fascia in the preauricular region and in the subplatysmal plane in the cervical portion of the incision. The great auricular nerve and the external jugular vein are identified over the sternocleidomastoid muscle and may be divided to free the tail of the parotid gland.

Next, the posterior belly of the digastric muscle is exposed proximal to its attachment to the mastoid bone. The facial nerve will lie in the same plane superior to this muscle. The parotid gland is then dissected free of the auricular cartilage and retracted anteriorly. This exposes the tragal pointer; unless displaced by tumor, the facial nerve is usually located approximately 1 to 1.5 cm deep and inferior to the tragal pointer. A more constant landmark also used to identify the facial nerve is the tympanomastoid suture line, which runs approximately 6 to 8 mm superficial to the stylomastoid foramen. Finally, the facial nerve can also be identified by finding one of its peripheral branches and following it to the main trunk (see Box Methods of Facial Nerve Identification (p.248)).

Methods of Facial Nerve Identification

- Superior to the posterior belly of the digastric muscle
- 1 to 1.5 cm deep and inferior to the tragal pointer
- Deep to the tympanomastoid suture line
- Retrograde dissection along peripheral branch of facial nerve

Fig. 29.3 (a) Axial and (b) coronal computed tomographic scans of the neck with intravenous contrast in a patient with a right-sided parotid pleomorphic adenoma. (c) Axial and (d) coronal slices in a patient with a right-sided submandibular pleomorphic adenoma. Note that the tumors are well encapsulated with clearly delineated borders and do not invade the surrounding structures.

Once the facial nerve is identified, the branches are traced peripherally, and the parotid tissue overlying it can be dissected free and resected. If the tumor abuts the facial nerve, the neoplasm should be meticulously dissected from the nerve with a scalpel. The facial nerve should never be sacrificed for benign disease. If the tumor extends to the deep lobe, a total parotidectomy may be indicated, requiring deep dissection between the peripheral branches of the nerve.

Complications

Facial nerve injury can range from neurapraxia to complete transection. Temporary dysfunction is fairly common (46%), but

permanent paralysis is rare (4%) after parotid surgery. The transient weakness is usually due to traction on the nerve and will often resolve within days. However, it can take up to a few months, and proper eye care measures should be taken if complete weakness is noted. If a portion of the nerve or the entire nerve is transected and this is noted intraoperatively, a primary neurotomy or nerve cable graft should be performed to optimize the outcome.

Frey syndrome occurs when the disrupted postganglionic, parasympathetic fibers to the parotid gland cross-innervate the sympathetic fibers to the sweat glands. This results in gustatory sweating, which is flushing and sweating of the ipsilateral facial skin during mastication. The exact percentage of patients in

whom this actually occurs is unknown, but rarely are the symptoms severe enough to require treatment. A glycopyrrolate roll-on antiperspirant, botulinum toxin A injections, and tympanic neurectomy have all been described to treat Frey syndrome. Placing an autologous or cadaveric acellular dermal graft or expanded polytetrafluoroethylene (e-PTFE) sheet under the skin after removal of the parotid gland has also been described to prevent postoperative gustatory sweating.

Other common complications are sensory deficits due to great auricular nerve sacrifice, hematoma, and sialoceles. Great auricular nerve sacrifice is overall well tolerated. Hematomas should be addressed immediately to prevent skin flap necrosis. Sialoceles can be managed conservatively with aspiration and pressure dressings.

29.11.2 Submandibular Gland Excision

A 3- to 4-cm incision is marked, preferably in a neck skin crease approximately 2 to 3 cm below the inferior border of the mandible overlying the gland. The incision is carried down through the platysma layer, and small subplatysmal flaps are created inferiorly and superiorly, with care taken to avoid injuring the marginal mandibular branch of the facial nerve. The nerve lies immediately beneath the deep cervical fascia and can be identified crossing the anterior facial vein. The vein is ligated well below the nerve, and upward retraction of the transected vein displaces the nerve superiorly, protecting it from injury. In managing bulky tumors or malignancy, positive identification and dissection of the marginal mandibular branch provide wider exposure and allow complete excision of the level I lymph nodes.

The facial artery is then divided as it approaches the mandible, freeing the superior portion of the gland. The submandibular gland is dissected free of its anterior attachment to the mylohyoid muscles. The mylohyoid muscle is retracted medially while the gland is pulled laterally and outward. This maneuver exposes the undersurface of the submandibular gland and reveals the hypoglossal nerve inferiorly, the lingual nerve superiorly, and the Wharton duct. These structures lie superficial to the hyoglossus muscle. The contributions of the lingual nerve to the submandibular gland and the Wharton duct are both ligated. The facial artery is ligated again near the external carotid, and the submandibular gland is removed.

Complications

The major complications of submandibular gland excision arise when either the lingual or hypoglossal nerve is injured or transected. Although rare, injury results in unilateral tongue paresthesia (lingual) and paresis/paralysis (hypoglossal). Hematoma and sialocele are also common complications and are dealt with as they are in the parotid gland.

29.11.3 Parapharyngeal Space Tumor Excision

The approach to the surgical excision of salivary gland tumors within the parapharyngeal space is based on the location and

size of the tumor. For a smaller tumor in the deep lobe of the parotid or inferior part of the parapharyngeal space, a parotid incision with further cervical extension is made. First, a superficial parotidectomy is performed if the tumor involves the deep lobe of the parotid. If not, only the inferior portion of the facial nerve is identified and preserved. Further dissection involves identification and preservation of the internal and external carotid arteries, internal jugular vein, and CNs IX, X, XI, and XII. The stylomandibular ligament is divided, and the styloid process can be resected to deliver larger tumors. In patients with very large tumors or those located at the skull base, the addition of a mandibulotomy may be needed.

29.12 Prognosis

After surgical excision with a cuff of normal tissue, the patient with a benign salivary gland neoplasm can usually be considered cured. The recurrence rate for pleomorphic adenoma is less than 5% with the other tumor types demonstrating similar responses to therapy. Recurrence of pleomorphic adenoma remains particularly troublesome, as mentioned previously. Overall, the prognosis of these patients is excellent.

29.13 Roundsmanship

- Of all salivary tumors, 75% are located in the parotid gland, and 75% of those are benign.
- The 25/50/75 rule: as the size of the gland decreases (parotid, submandibular, sublingual/minor salivary glands), the likelihood that a salivary neoplasm is malignant increases.
- Pleomorphic adenomas make up 75% of all benign lesions. They can become malignant over time, and postsurgical recurrence is difficult to treat.
- Warthin tumors can be bilateral and are the only benign tumors that can present with pain.
- Surgical resection is the mainstay of treatment for benign salivary gland neoplasms. Cranial nerves should never be sacrificed during excisions.
- Preoperative fine-needle aspiration biopsy is generally accepted as the standard of care. However, imaging is not necessary in a tumor that is isolated, superficial, mobile, and small. MR imaging is the imaging modality of choice.

30 Malignant Neoplasms of the Salivary Glands

Vikas Mehta and Stimson P. Schantz

30.1 Introduction

Malignant neoplasms of the salivary glands account for only 6% of all head and neck malignancies, with an incidence of 11.65 per 1 million people per year in the United States. There are more than 20 different histologic subtypes of malignant salivary gland tumors, not including the various cancers that can metastasize to the salivary glands. In the majority of patients, the presenting symptoms are exactly the same as in those with benign salivary gland disease. All of these factors contribute to the difficulty and confusion that exists in the treatment of these rare entities. This chapter will focus on the more common salivary gland malignancies and the currently accepted standards of care.

30.2 Incidence

Approximately 1 per 100,000 people per year will develop a salivary gland malignancy. The epidemiology of malignant salivary gland tumors varies based on age, sex, and tumor location. The majority of salivary gland carcinomas occur in the parotid gland (accounting for 25% of parotid gland neoplasms). Mucoepidermoid carcinoma is the most common malignant neoplasm of the salivary glands (29 to 43% of all salivary malignancies). Of mucoepidermoid carcinomas, 70% occur in the parotid gland, so that it is the most common malignancy in this location. Adenoid cystic carcinoma and adenocarcinoma are the second and third most common types, accounting for 20% and 14% of all salivary gland malignancies, respectively. However, adenoid cystic carcinoma is the most common malignancy of the minor salivary glands and submandibular gland.

Salivary gland malignancies occur much more often (3- to 5-fold higher frequency) in patients older than 50 years of age, but they are distributed equally in males and females. Of the more common tumor types, squamous cell carcinoma occurs more often in older patients and in males. Acinic cell carcinoma and adenoid cystic carcinoma are more common in female patients and younger patients. Risk factors for salivary gland malignancies include smoking, alcohol intake, irradiation, and certain occupational and environmental exposures, with the exact etiology to be discussed elsewhere.

30.3 Terminology

Salivary gland malignancies are classified according to histologic subtype. A list of the more common malignancies is provided in □ Table 30.1 with their relative frequencies. A full discussion of all tumor subtypes is beyond a scope of this chapter. As discussed in the previous chapter, if one subscribes to the bicellular theory of tumor origin, the tumors that arise from the intercalated duct (adenocarcinoma, adenoid cystic carcinoma) tend to be less aggressive than those arising from the excretory duct (squamous cell carcinoma and mucoepidermoid carcinoma).

30.3.1 Mucoepidermoid Carcinoma

Mucoepidermoid carcinoma occurs most commonly in the parotid gland, accounting for 8% of all parotid tumors. When it occurs in the minor salivary glands, the buccal mucosa and palate are the two most common sites. Mucoepidermoid carcinomas contain two different cell types: mucous cells and epidermoid cells. Based on the relative cellular composition of the tumors, they are classified into low-, intermediate-, and high-grade tumors. Low-grade tumors have a larger percentage of mucous cells, whereas epidermoid cells are much more prevalent in high-grade malignancies, which can be difficult to distinguish from squamous cell carcinoma. Only special staining for the few mucoid cells present will distinguish these two neoplasms.

On gross examination, low-grade tumors tend to be small and mostly encapsulated, with cystic components. High-grade tumors are large and infiltrative, lack a definitive capsule, and frequently have lymphatic metastases. On histologic examination, the presence of four or more mitotic figures per 10 high-power fields, perineural invasion, necrosis, a small cystic component, and cellular anaplasia indicate high-grade behavior.

The prognostic significance of tumor grade has been demonstrated in several studies. The 5-year survival rates for the three grades in one study were 95%, 72%, and 0% respectively. At 10 years, the majority of patients with low-grade neoplasms remain free of disease (80 to 90%), whereas a much larger percentage of patients with high-grade disease either have died or have recurrence locally or in regional nodes. Likewise, the histologic grade determines the adjuvant treatment required for each patient. Despite the improved outcome, patients with low-grade tumors may have recurrence more than 15 years after initial treatment, so that significant long-term follow-up is required regardless of tumor grade.

30.3.2 Adenoid Cystic Carcinoma

Adenoid cystic carcinoma is the second most common malignancy of the salivary glands and the most common in the submandibular and minor salivary glands. Adenoid cystic carcinoma occurs most frequently in the oral cavity, with the palate

Table 30.1 Malignant salivary gland neoplasms and their relative frequencies

Malignant salivary gland neoplasms	Relative frequency
Mucoepidermoid carcinoma	34.4%
Adenoid cystic carcinoma	22.0%
Adenocarcinoma	17.6%
Carcinoma ex-pleomorphic adenoma	12.6%
Acinic cell carcinoma	6.6%
Squamous cell carcinoma	4.1%
Other	2.7%

the predominant subsite. Grossly, the tumors are nonencapsulated and infiltrate the surrounding tissues. There are three different histologic subtypes of adenoid cystic carcinoma: solid, cribriform, and tubular. Solid tumors demonstrate sheets of neoplastic epithelial cells with few cystic spaces. The tubular pattern is characterized by cells arranged in small ducts and tubules. The cribriform subtype has a many cystic spaces with basophilic mucus filling the spaces. Adenoid cystic neoplasms may contain all three subtypes, but usually one predominates. The solid pattern carries the worst prognosis, and the cribriform type usually has the best outcome.

Adenoid cystic carcinoma is known for its slow growth, perineural invasion, and distant metastasis. This tumor is notoriously difficult to eradicate and can recur locally or distantly (most often in the lungs) one to two decades after treatment. The 5-year survival rate is 65% because of the slow growth of the tumor, and patients can live for many years, even after recurrences are detected. However, adenoid cystic carcinoma does carry a 15-year survival rate of 12%. Regional node metastases are rare (12%), so there is often no need to address the cervical nodes. Treatment involves surgical resection, with postoperative radiation showing moderate benefit.

30.3.3 Acinic Cell Carcinoma

Acinic cell carcinoma is a rare form of malignancy comprising only 6 to 8% of all salivary gland malignancies. The tumor originates from serous cells, accounting for its high prevalence in the parotid gland. Acinic cell tumors are encapsulated, hard, gray–white tumors made up of lobules of round, uniform-appearing cells with abundant cytoplasm arranged in nests. Occasionally, they will have a clear cytoplasm, resulting in their alternative name—clear cell carcinoma.

Overall, acinic cell carcinomas tend to carry the best prognosis. Recently, evidence has demonstrated that there may be different grades of these tumors with varying prognoses. Facial pain or paralysis, deep lobe invasion, and/or multiple cervical metastases are all associated with a significantly worse outcome. The 5-, 10-, and 15-year survival rates are 83%, 76%, and 65% respectively. These tumors are treated with surgical resection and neck dissection if clinical nodes are evident.

30.3.4 Malignant Mixed Tumor

The term malignant mixed tumor refers to three distinct entities: carcinoma ex-pleomorphic adenoma, carcinosarcoma, and metastasizing mixed tumor. These tumors collectively account for 5 to 12% of all salivary gland malignancies and are distinct entities with unique behaviors. As mentioned in the previous chapter, pleomorphic adenoma carries a 1 to 1.5% per year chance of degeneration into carcinoma ex-pleomorphic adenoma. On gross examination, the tumor is firm, unencapsulated, and necrotic, with areas of hemorrhage. Patients report a long-standing, stable mass that has started to enlarge rapidly. The lesions are most often located in the parotid and microscopically show a malignant process within a pleomorphic adenoma. The 5-, 10-, and 15-year survival rates are 40%, 29%, and 19% respectively, with a significant number of patients developing cervical and distant (especially bone and lung) metastases. Patients with submandibular or minor salivary gland disease often fare worse.

Carcinosarcomas, or true mixed tumors, are very rare and carry an even worse prognosis. One series showed a 5-year survival rate of 50% which dropped to 30% over 10 years. Finally, metastasizing mixed tumors (metastasizing benign pleomorphic adenomas) are most common in the parotid gland and are unusual in that both the primary tumor tissue and metastatic (typically seen in bones and the lungs) tumor tissue appear benign on histopathologic examination. Patients can even develop distant metastasis, but few die of their disease. For all of these tumors, surgical resection remains the treatment of choice, and postoperative radiation is indicated for carcinosarcoma and carcinoma ex-pleomorphic adenoma.

30.3.5 Adenocarcinoma

Adenocarcinoma was traditionally described as any carcinoma arising from the salivary duct unit and accounted for almost 20% of all salivary gland malignancies. However, as the understanding of salivary gland tumors evolved, three distinct tumors within this larger group were identified and noted to behave differently clinically. What is now referred to as an adenocarcinoma (or adenocarcinoma “not otherwise specified”) accounts for 1 to 9% of all salivary gland malignancies. This rare tumor (68% occur in the minor salivary glands) is quite aggressive, with a 50% recurrence rate; cervical metastases occur 17% of the time, and 5-year survival rates are less than 40%. Tumors have been subclassified into adenocarcinoma, mucinous adenocarcinoma, papillary adenocarcinoma, trabecular adenocarcinoma, and sebaceous adenocarcinoma.

Polymorphous low-grade adenocarcinoma (also known as terminal duct carcinoma) is the general exception to salivary gland malignancies in terms of clinical course. As the name suggests, patients with this indolent variant of adenocarcinoma demonstrate a 10-year survival rate of more than 90%. The tumors occur primarily in the oral cavity, with the palate and lip the most common locations. The rate of cervical metastasis is less than 5% and the tumors rarely recur after wide local excision. Adjuvant therapy and neck dissection are rarely indicated and have not been shown to improve outcomes.

Salivary duct carcinoma is at the opposite end of the spectrum from terminal duct carcinoma. This highly aggressive malignancy predominantly affects males in their seventies and presents in the parotid with cervical metastases (50%). On histologic analysis, islands of tumor cells with comedonecrosis appear similar to mammary duct carcinoma. Salivary duct carcinoma tends to recur both locally and distally, so that patients require total parotidectomy, neck dissection, and adjuvant chemoradiation.

30.3.6 Squamous Cell Carcinoma

Squamous cell carcinoma of the salivary glands is almost always metastatic from the skin, external auditory canal, or upper aerodigestive tract. Additionally, high-grade mucoepidermoid carcinoma is difficult to distinguish from squamous cell carcinoma. These factors make true primary salivary gland squamous cell carcinoma a rare entity. It occurs most often in the parotid gland. Cervical metastasis is present in 46% of patients, and 30% have occult cervical disease. Patients often develop local and regional recurrences, and the 5-year survival is only

24%. Treatment should involve radical resection, neck dissection, and postoperative radiation.

30.3.7 Lymphoma and Metastatic Carcinoma

Neoplastic disease in the salivary gland does not always originate from the salivary gland itself. Lymphoma can arise primarily in the lymphatics surrounding the tissue or can represent systemic disease. This most often occurs in the parotid, and patients with Sjögren disease have a 40-fold increased risk for developing primary lymphomas in the parotid. Chemotherapy and/or radiation remain the mainstay of treatment except for MALT (mucosa-associated lymphoid tissue) lymphoma, which can also be treated with surgical excision.

Metastatic spread (lymphatic or hematogenous) to the parotid and submandibular glands may occur. The parotid is most at risk for lymphatic spread from cutaneous malignancies of the scalp and face, while metastases to the submandibular gland are likely to come from the oral cavity and oropharynx. The most likely culprits for distant metastasis to the salivary glands are kidney, lung, and prostate malignancies.

30.4 Applied Anatomy

See the previous chapter for anatomical descriptions of the salivary glands.

30.5 The Disease Process

30.5.1 Etiology

Little is understood about the exact etiology of salivary gland malignancies. However, several risk factors have been identified, with exposure to ionizing radiation the most common and often described. An increased risk has been demonstrated in atomic fallout survivors in Japan, patients treated with radiation for Hodgkin lymphoma, those imaged with full-mouth dental X-rays (while those imaged with Panorex X-rays did not), and those who received radiation in childhood for both benign and malignant conditions. The exact dose required to increase the risk is unknown, but the correlation is evident.

Other risk factors include working in the rubber industry, cooking with kerosene fuel, exposure to nickel alloy, exposure to silica dust, and use of hair dye. Tobacco and alcohol have not been shown to be specific risk factors for salivary gland malignancy but do increase the risk for salivary gland lesions. Finally, Sjögren disease drastically predisposes a person to developing primary lymphoma of the parotid gland. The most common location and type of induced malignancy among patients exposed to irradiation is a parotid mucoepidermoid carcinoma.

30.5.2 Pathogenesis

The competing theories for the origin of salivary gland tumors are the bicellular stem theory and the multicellular theory. Of these two, recent evidence has suggested that the bicellular theory is more likely to be correct. For a further in-depth

discussion of these theories, the reader is referred to the preceding chapter.

30.5.3 Natural History and Progression

The most common initial presentation of a salivary gland malignancy is a firm, solitary, painless mass. Clinically, it is often difficult to distinguish a malignant from a benign lesion. Usually, the lesion has been enlarging slowly over time. In the parotid or submandibular gland, the lesion will be an asymptomatic mass. Minor salivary gland tumors can cause obstructive symptoms, depending on their location. If located in the oral cavity or oropharynx, they can cause dysphagia or dysphonia. In the nasal cavity, enlargement can lead to sinusitis or nasal obstruction. Laryngeal masses can cause airway obstruction, dysphonia, and dysphagia.

Malignant lesions of the salivary glands will cause specific symptoms in 25% of patients, and the presence of symptoms often indicates an advanced lesion. The most common symptoms are pain and nerve palsies. A parotid neoplasm can cause a facial nerve palsy, which dramatically decreases the chance of survival; the 10-year survival rate of patients with facial nerve palsies is 12%. The proximity of the submandibular gland to the lingual and hypoglossal nerves may result in specific neurologic tongue deficits. Constant pain is usually associated with a malignancy, whereas intermittent pain can be due to obstruction of drainage pathways with associated inflammation. Other common symptoms include bleeding, trismus, fixation, loosening of dentition, and paresthesias.

Malignant lesions will progress to regional and distant metastases, depending on their histology. In general, high-grade mucoepidermoid carcinoma, salivary duct carcinoma, carcinoma ex-pleomorphic adenoma, and adenocarcinoma all carry a significant risk for cervical metastases, and therefore treatment of the regional nodes is warranted. Distant metastasis is likely to occur in lung and bone. Spread to these tissues is possible with all types of salivary gland malignancy (especially in the long term) but most notoriously occurs in adenoid cystic tumors. More specific descriptions of the natural progression of each tumor type can be found in the respective sections on histology.

30.5.4 Potential Disease Complications

As previously mentioned, the possible complications of salivary gland malignancies depend on the location of the tumor and on the tumor type and grade. Despite aggressive treatment, many tumors recur, and patients die of their disease. Often, the sequelae occur years after treatment, and therefore these patients require life-long follow-up.

30.6 Disease Staging

The most recent American Joint Commission on Cancer (AJCC) staging system was released in 2010, and salivary gland malignancies are staged based on the TNM (tumor node metastasis) system.

T1 primaries are smaller than 2 cm and T2 lesions are between 2 and 4 cm, both without extraparenchymal extension. T3 lesions are larger than 4 cm and/or have extended beyond

the gland. T4a lesions invade skin, mandible, external auditory canal, and/or the facial nerve, while T4b lesions invade the skull base or pterygoid plates and/or encase the carotid artery.

N1 status implies involvement of a single lymph node that is ipsilateral and smaller than 3 cm. N2a indicates involvement of a single ipsilateral lymph node that is larger than 3 cm but smaller than 6 cm. N2b disease is the involvement of multiple ipsilateral nodes, none larger than 6 cm, and N2c disease is involvement of contralateral or bilateral nodes, none larger than 6 cm. N3 status is reserved for nodal disease larger than 6 cm.

Stage I disease indicates T1 lesions, and stage II disease indicates T2 lesions, both without nodal or distant metastasis. A T3 lesion without metastasis and T1–T3 lesions with N1 disease are classified as stage III disease. T4a primary lesions with N0–N1 nodal status or T1–T3 or T4a lesions with N2 nodes are stage IVA. T4b primary lesions with any N status or any T status with N3 disease is stage IVB. Any distant metastasis is classified as stage IVC.

The 5-year survival rates are 85% for stage I tumors, 66% for stage II, 53% for stage III, and 32% for stage IV. These figures suggest the poor outcome associated with large nodal disease, nerve involvement, extraparenchymal or extracapsular spread, and distant metastasis. The major flaw of the AJCC staging system is that it does not include the histopathologic subtype, which, as discussed above, can vastly change the survival rate of patients with the malignancy. As more information is gathered about these rare malignant neoplasms, the survival data for each neoplastic subtype will be extrapolated and further clarified. It is hoped that, as was done with thyroid cancer, tumor subtype will be included in the next classification scheme.

30.7 Presenting Complaints

As discussed in the chapter on benign salivary gland tumors, many diseases can mimic a salivary gland tumor. Eliciting a thorough history can tease out many of these nonneoplastic forms of salivary gland pathology. However, every unilateral salivary gland mass should be treated as a possible malignancy unless proven otherwise, especially if it occurs in the sublingual or minor salivary glands. Seventy-five percent of patients with a malignant salivary gland neoplasm will present with a painless, firm, solitary mass, making it difficult to distinguish a malignant lesion from a benign one. Pain, fixation, cervical adenopathy, trismus, paresthesias, paralysis, bleeding, and loose dentition are all signs of advanced malignancy and warrant a more aggressive work-up and early intervention.

30.8 Clinical Findings, Physical Examination

A patient with a salivary gland mass should undergo a thorough head and neck examination. Those with parotid neoplasms should undergo thorough palpation, including bimanual, intra-oral palpation. A facial nerve examination should be performed and documented because it is important not only for ruling out malignant disease but also for preoperative documentation. Submandibular gland neoplasms are difficult to discern from diffuse gland enlargement but can be distinguished if freely mobile.

Both submandibular and sublingual gland masses should also be assessed via bimanual palpation. In addition, the patient with a submandibular gland mass should be assessed for any weakness or numbness of the tongue and facial nerve weakness, indicating perineural spread via the hypoglossal, lingual, and marginal mandibular nerves, respectively. If the tumor occurs in the nasal cavity, an assessment of ocular function and visualization of the skull base are important. Any tumor of the pharynx or larynx mandates a fiber-optic examination and documentation of vocal cord function.

30.9 Testing

Fine-needle aspiration biopsy and imaging are the two modalities used to evaluate salivary gland tumors. Their use in patients with solitary, mobile, well-circumscribed, superficial parotid tumors is controversial. However, any other salivary gland lesion, especially those that are suspected malignancies, warrants preoperative testing to guide treatment properly.

30.9.1 Biopsy

Fine-needle aspiration biopsy is a highly sensitive and specific test that many argue is an essential preoperative tool. Tissue sampling is the only way to confirm a malignancy, and fine-needle aspiration is simple to perform and requires no anesthesia. Proponents of fine-needle aspiration biopsy state that its use helps in counseling patients before surgery if a malignancy is identified. However, most physicians would agree that major treatment decisions (i.e., deep lobe dissection, facial nerve sacrifice, chemoradiation vs surgical resection) should be made only after an open biopsy. Frozen section, although highly sensitive and specific, is not 100% accurate. It is therefore prudent to await the results of the permanent histologic diagnosis and appropriately discuss the expected surgical outcome with the patient. Tumors that are readily accessible (oral and nasal) can be biopsied with standard techniques.

30.9.2 Imaging

The two most commonly used modalities for imaging salivary gland neoplasms are computed tomography (CT) and magnetic resonance (MR) imaging. CT should be performed with contrast, and the salivary glands are readily visualized with this modality. Also, the interface between soft tissue and bone can be interpreted on CT. Encapsulated lesions can be identified easily with CT, but the various tumors cannot be distinguished from one another. Bilateral disease and cervical metastases are also readily appreciated on both MR imaging and CT, which can help with treatment planning. If readily available and not contraindicated, MR imaging is the study of choice for salivary gland neoplasms in any location. MR imaging is superior to CT in showing extraglandular extension, perineural invasion, parapharyngeal space involvement, and demarcation from the glandular tissue itself. MR imaging does not identify bony involvement as readily as CT but can show bone marrow extension. Despite the accuracy of MR imaging, the only salivary gland neoplasm that can be definitively diagnosed via imaging is a lipoma. All others require pathologic diagnosis.

In positron emission tomography (PET)–CT, the pattern of radionuclide uptake by cancerous tissue is superimposed on anatomical CT images, and PET-CT has become widely used in many different cancers. A recent article found PET-CT to be both highly specific and sensitive for salivary gland malignancy. However, CT alone was comparable in its ability to diagnose malignancy and distant metastasis. PET-CT was most useful in determining the resectability of high-grade malignancy and whether adjuvant or palliative treatment would be indicated.

30.10 Differential Diagnosis

The differential diagnosis for a salivary gland mass includes all of the malignant subtypes discussed above, the benign neoplasms mentioned in the previous chapter, and various nonneoplastic causes that are addressed elsewhere in this book. It is important to rule out a benign or nonneoplastic cause before any major resection of these rare entities is considered.

30.11 Treatment

Besides lymphoma, the current primary treatment modality for malignant tumors of the salivary glands is surgical excision. Adjuvant therapy and cervical node dissection may be implemented based on tumor stage and histology.

30.11.1 Surgical Excision

Based on the location of the tumor, the appropriate surgical excision with clear margins is indicated. For more detailed descriptions of salivary gland surgery, the reader is referred to the surgical descriptions in the chapter on benign neoplasms of the salivary glands. If facial nerve sacrifice is required, an attempt at primary anastomosis should be made. If the segment removed is too long to achieve a tension-free closure, a nerve graft should be attempted while the nerve is exposed. An in-depth description of all facial nerve rehabilitation techniques is beyond the scope of this chapter.

Cervical lymphadenectomy is reserved for those cases in which there is obvious disease, either palpable or seen on imaging, or in which the risk for regional metastasis of the tumor subtype is high. If an elective node dissection is to be performed, the surgeon can perform a selective node dissection and reserve more comprehensive cervical lymphadenectomy for those patients with nodal disease. In general, ipsilateral level I through III dissection is sufficient for tumors larger than 4 cm, squamous cell carcinoma, adenocarcinoma, undifferentiated carcinoma, and high-grade mucoepidermoid carcinoma of the parotid. Selective neck dissections for minor salivary gland tumors will differ depending on the location.

30.11.2 Adjuvant Therapy

Radiation and chemotherapy are reserved for those patients with stage III or IV tumors or those with aggressive histology or features. Radiation therapy has been shown to have a greater positive impact on locoregional control than on overall survival. However, better locoregional control has been shown to improve overall quality of life, making it an important factor to consider. Adenoid cystic carcinoma remains highly resistant to radiation treatment, although some promise has been shown with neutron-based irradiation. Chemoradiation has been shown to improve survival for advanced-stage salivary gland malignancies but increases the morbidity and mortality associated with treatment.

30.12 Prognosis

The long-term prognosis remains fairly dismal for patients with most salivary gland malignancies, depending on the tumor stage and histology.

30.13 Roundsmanship

- The most common salivary gland malignancy is mucoepidermoid carcinoma, and the most common location is the parotid gland.
- Adenoid cystic carcinoma is the second most common malignant neoplasm and the most common submandibular and minor salivary gland malignancy.
- High-grade mucoepidermoid carcinoma, squamous cell carcinoma, adenocarcinoma, and carcinoma ex-pleomorphic adenoma require elective neck dissection because of the high rates of cervical metastasis.
- Adenoid cystic carcinoma is notorious for lung metastasis and perineural spread, which can occur more than 15 years after treatment.

31 Diseases and Neoplasms of the Thyroid

Nisha Jayani and Monica Dorin Schwarcz

31.1 Thyroid Physiology

The thyroid gland regulates metabolism and thermogenesis within the body via thyroid hormones. Numerous spherical follicles (□ Fig. 31.1) make up the thyroid gland, with parafollicular (or C cells) interspersed throughout the gland. The follicles are composed of a single layer of secretory epithelial cells called follicular cells, which secrete into their center proteinaceous colloid. Colloid contains thyroglobulin, which is the substrate involved in thyroid hormone synthesis. When the thyroid is actively synthesizing and secreting thyroid hormone, the follicles swell and increase in size.

31.1.1 Thyroid Hormone Production

At the follicular lumen, iodine is oxidized through an organification reaction with thyroid peroxidase and hydrogen peroxide. The reactive iodine atoms rapidly attach to tyrosyl residues in thyroglobulin to form iodotyrosines (mono- or diiodotyrosine). Thyroid peroxidase also joins iodotyrosine residues via an ether linkage, which produces T_3 or T_4 , depending on the number of iodine atoms present in a reaction called coupling. Thyroid hormones may be released into the bloodstream, and thyroglobulin is taken back into the follicular cell. Thyroid hormone synthesis is summarized in □ Fig. 31.2.

31.1.2 Thyroid-Stimulating Hormone Action

Thyroid-stimulating hormone (TSH) regulates thyroid function via the TSH receptor, which is a 7-transmembrane G protein-coupled receptor on the basolateral surface of follicular cells. The TSH receptor is coupled to the α subunit of the G protein, which activates adenyl cyclase, thereby increasing cyclic ad-

enosine monophosphate (cAMP) production. This action leads to thyroglobulin resorption from the lumen of the follicle and proteolysis within the cells, allowing the release of produced thyroid hormones into the bloodstream. TSH also stimulates phospholipase C, causing increased phosphatidylinositol turnover. Thyrotropin-releasing hormone (TRH), from the hypothalamus, stimulates TSH release from the pituitary gland. Excess circulating thyroid hormone inhibits the release of TSH via T_3 receptors in the pituitary gland. Other molecules, such as insulin-like growth factor-1, epidermal growth factor, transforming growth factor- β , endothelins, and various cytokines, also regulate thyroid hormone synthesis.

31.1.3 Thyroid Hormone Transport and Metabolism

The thyroid secretes approximately 20 times as much T_4 as T_3 . T_3 has a shorter half-life than T_4 . Both are bound to plasma proteins, which increase the pool of circulating hormone, delay hormone clearance, and modulate hormone delivery to selected tissues. These plasma proteins include thyroxine-binding globulin, transthyretin, and albumin. Thyroxine-binding globulin has the highest affinity for the thyroid hormones, and although it is present at a low concentration in the plasma, it carries approximately 80% of the bound hormone. In contrast, albumin has a low affinity for thyroid hormones but has a higher concentration in the plasma. Transthyretin carries the smallest amount of the bound thyroid hormones.

There are several deiodinases that convert T_4 to T_3 . Type I deiodinase has a lower affinity for T_4 and is found predominantly in the thyroid, liver, and kidneys. Type II deiodinase has a higher affinity for T_4 and it is found predominantly in the pituitary, brain, brown fat, and also in the thyroid. Type III deiodinase converts T_3 and T_4 to reverse T_3 . Conversion of T_4 to T_3 can be impaired by a variety of conditions, including fasting, systemic illness, acute trauma, oral contrast, and medications.

31.1.4 Thyroid Hormone Action

Thyroid hormones may enter cells via specific transporters or by passive diffusion. They act primarily on nuclear receptors, although they may also stimulate plasma membrane and mitochondrial enzymatic responses. In the nucleus, thyroid hormones bind to α and β nuclear thyroid hormone receptors with high affinity, each having unique isoforms that are expressed at different levels in various organs. The nuclear thyroid hormone receptors bind to specific DNA sequences called thyroid response elements, which are found in promoter regions of target genes. The activated receptors can either stimulate or inhibit gene transcription. T_3 binds with greater affinity than T_4 to the thyroid receptors.

Thyroid disease is diagnosed with assessment of the hypothalamic-pituitary-thyroid axis and an understanding of its feedback mechanism (□ Fig. 31.3). TSH secretion is very sensitive to the plasma concentration of free thyroid hormone, and

Fig. 31.1 Thyroid follicular structure.

Fig. 31.2 Thyroid hormone production. ATPase, adenosine triphosphatase; cAMP, cyclic adenosine monophosphate; TSH, thyroid-stimulating hormone; TSH-R, thyroid-stimulating hormone-releasing hormone.

small changes in thyroid hormone production will produce large changes in TSH. Invariably, patients with hyperthyroidism and thyroid hormone overproduction will have suppressed TSH, whereas patients with primary hypothyroidism will have increased TSH and decreased T₃ and T₄ values. A suppressed TSH level with normal T₃ and T₄ levels is labeled subclinical hyperthyroidism; it is often asymptomatic but associated with an increased risk for atrial fibrillation in older patients. Subclinical hypothyroidism is characterized by slightly elevated TSH with normal T₃ and T₄ values. Hypothyroidism may also be secondary to decreased pituitary secretion of TSH resulting from a pituitary mass effect or damage.

The only direct measurement of thyroid function is with radioactive iodine uptake (RAIU), in which a radioactive isotope of iodine (¹²³I) is used. The rate of hormone synthesis and release can be inferred from the percentage uptake calculated within 24 hours as the plasma level of the tracer iodide decreases exponentially. A normal uptake is usually between 5% and 20% in an iodine-sufficient area. RAIU can be helpful in distinguishing hyperthyroidism caused by Graves hyperthyroidism from that caused by thyroiditis and toxic nodules.

31.2 Thyrotoxicosis

The term thyrotoxicosis refers to the physiologic manifestations of excessive thyroid hormone levels resulting from any source of thyroid hormone. The term hyperthyroidism also refers to overproduction of thyroid hormone by the thyroid gland but may present with few or no symptoms, only laboratory evidence of disease. Most patients with thyrotoxicosis have hyperthyroidism, but not all conditions are directly caused by increased thyroid hormone synthesis. Examples include silent subacute thyroiditis, exogenous thyrotoxicosis from excessive thyroid hormone replacement, and destructive thyroiditis from drugs such as amiodarone (see Box Rare Causes of Thyrotoxicosis (p.257)).

Rare Causes of Thyrotoxicosis

- Thyroid-stimulating hormone-producing pituitary adenoma
- Struma ovarii
- Choriocarcinoma
- Thyrotoxicosis factitia
- Functional metastatic thyroid cancer

Fig. 31.3 Hypothalamic–pituitary–thyroid axis. TRH, thyrotropin-releasing hormone; TSH, thyroid-stimulating hormone.

Conditions producing hyperthyroidism commonly include Graves disease, toxic adenoma, and toxic multinodular goiter. Hyperthyroidism can also be induced by the ingestion of iodine or iodine-containing drugs. Iodine-induced hyperthyroidism (Jod-Basedow phenomenon) occurs in previously euthyroid patients with multinodular or endemic goiters after they have been given large doses of iodine, such as in imaging contrast medium. Subclinical hyperthyroidism is characterized by suppressed TSH concentration and normal serum T_3 and T_4 levels, which can occur in the setting of mild Graves disease, toxic multinodular goiter, or thyroiditis. The patient is usually asymptomatic or has mild symptoms of thyrotoxicosis.

Although toxic nodular goiter is less common than Graves disease, its prevalence increases with age and in the presence of iodine deficiency. Toxic multinodular goiter occurs when

hyperthyroidism arises from autonomous thyroid hormone production in a long-standing multinodular goiter. Painless and subacute thyroiditis results in the inflammation of thyroid tissue with the release of preformed hormone into circulation. About 10% of hyperthyroid patients present with painless thyroiditis and can occur post partum, with certain medications such as lithium or cytokine therapy, and in 5 to 10% of amiodarone-treated patients. Subacute or de Quervain thyroiditis is characterized by pronounced thyroid tenderness and fever.

The typical signs and symptoms of thyrotoxicosis are easily evident in the young; but in the elderly, a masked or apathetic thyrotoxicosis may be present, with cardiac arrhythmias and weight loss as the only obvious markers of disease. Excess thyroid hormone affects almost every organ system, and manifestations can range from minimal to life-threatening cardiac

arrhythmias. An increased metabolic rate causes many of the cardiovascular symptoms in thyrotoxicosis. The increase in sympathetic tone and decrease in vagal tone account for many of the manifestations. Peripheral vascular resistance is decreased, cardiac output increased, and stroke volume increased. There is a direct inotropic effect on cardiac contractions, causing tachycardia and widening of the pulse pressure. The “palpitations” often described are a result of this increased force of contraction. Atrial fibrillation may be present, and patients older than 60 years have an increased risk for developing this arrhythmia. Atrial fibrillation is one of the most serious consequences of hyperthyroidism and can lead to increased embolic events. The treatment of hyperthyroidism can often lead to a restoration of cardiac rhythms.

The elevated metabolic rate that accompanies thyrotoxicosis produce increased appetite, heat intolerance, and increased lipid metabolism. The increase in sympathetic nervous system activity is not due to an increase in plasma concentrations of epinephrine and norepinephrine; rather, the excess thyroid hormone exerts an additive effect and increases receptor sensitivity to catecholamines. Manifestations of hyperthyroidism include hyperkinesia, nervousness, hyperreflexia, and emotional lability. There is an association between Graves disease and myasthenia gravis, and they are coexistent in approximately 3 to 5% of patients. Eye changes seen in thyrotoxicosis are due to increased adrenergic sensitivity; patients often have a “stare” from retraction of the upper and lower eyelids. Additionally, some patients with Graves disease would benefit from receiving iodine for about 1 week and may have infiltrative and edematous changes in the eyes, leading to Graves orbitopathy. Patients also note increased sweating, with moist soft skin and fine hair. Frequent bowel movements and increased appetite may occur. Thyrotoxicosis affects the skeletal system by increasing the excretion of calcium and phosphorus, leading to bone loss and an elevated alkaline phosphatase level. Clinical symptoms of thyrotoxicosis involve most organ systems, as summarized in □ Table 31.1.

31.2.1 Graves Disease

Graves disease, the most common cause of hyperthyroidism, is caused by circulating autoantibodies specific to the TSH receptor, resulting in increased thyroid hormone production. It is most common in the third and fourth decades, often presents with a goiter and thyrotoxicosis, and can be accompanied by infiltrative orbitopathy and dermatopathy. The gland is characterized by a lymphocytic infiltration without follicular destruction. The natural course of the disease is unpredictable, with some patients having cyclic recurrences or persistent disease for many years. Approximately one-third of patients become hypothyroid after 20 years. Orbitopathy, characterized by inflammation of the orbit, proptosis, and exophthalmos, may occur before, during, or even after the diagnosis of hyperthyroidism.

The laboratory diagnosis of hyperthyroidism is initially made with a low (usually undetectable) TSH level, along with elevated T_4 and T_3 levels. Radioactive iodine scans (□ Table 31.2) may be helpful in differentiating the hyperthyroidism caused by Graves disease and toxic goiter, which have elevated iodine uptake values (□ Fig. 31.4), from the subacute, painless, and iodine-

induced hyperthyroidism characterized by low iodine uptake (□ Fig. 31.5).

Treatment

There are three main treatment types for Graves disease: antithyroid medications, radioactive iodine therapy, and surgical resection. Definitive treatment is tailored to the individual patient after an assessment of the likelihood of remission, pregnancy considerations, patient comorbidities, and patient preference.

Medical therapy includes β -blockade and thionamides. β -Blockers help relieve symptoms of tremulousness, palpitations, excessive sweating, eyelid retraction, and increased heart rate secondary to increased adrenergic sensitivity. Propranolol also weakly blocks the conversion of T_4 to T_3 . Treatment with β -blockade can be continued until euthyroidism is restored by antithyroid drugs, unless it is contraindicated in patients with heart failure or asthma.

Thionamides, including propylthiouracil (PTU) and methimazole, inhibit oxidation and the organic binding of thyroid iodide and produce an intrathyroidal iodine deficiency, resulting in decreased thyroid hormone production. PTU also inhibits the conversion of T_4 to T_3 . Because of possible increased adverse hepatic effects of PTU, the American Thyroid Association states that methimazole is currently the drug of choice, except during the first trimester of pregnancy. Antithyroid drugs can be used short term to prepare patients for radioactive iodine therapy or surgery and may even induce remission in a minority of patients. Frequent follow-up is required every 4 to 6 weeks until the levels of free T_4 have normalized. Adverse reactions include skin rashes, arthralgias, gastrointestinal upset, and abdominal pain. More severe side effects include hepatitis, cholestasis, and agranulocytosis; these adverse events are idiosyncratic. Agranulocytosis (0.2 to 0.5%) is often accompanied by fever and sore throat. Methimazole is contraindicated in the first trimester of pregnancy because of teratogenic effects. Other medications that have been used in hyperthyroidism include lithium and dexamethasone. Lithium inhibits thyroid hormone secretion; this effect is temporary because the blocking effect is lost over time. In patients who are allergic to thionamides, these agents may be used as temporizing measures.

Definitive therapy is required in most patients with hyperthyroidism, leading to treatment with radioactive iodine or surgical resection. Radioactive iodine for thyroid ablation is safe and effective and can be used as first-line treatment in Graves hyperthyroidism or toxic goiter. Contraindications include desired pregnancy within 6 months of dose, pregnancy, diagnosis of thyroid cancer, and failure to comply with safety precautions. Treatment usually involves a fixed or calculated dose of ^{131}I , with higher doses given for toxic adenoma and toxic multinodular goiter than for Graves disease. Thionamides interfere with radioactive iodine therapy and should be discontinued 3 to 7 days before treatment. The effects of treatment are seen within 8 weeks, with most patients becoming hypothyroid in 6 months. Standard precautions to minimize radioactivity exposure to others are taken after treatment. Active Graves ophthalmopathy is a relative contraindication to radioactive iodine because radioactive iodine has been associated with exacerbation

Organ system	Hypothyroidism	Hyperthyroidism
Hair	Coarse, thin hair	Hair loss
	Loss of outer third of eyebrows	
Brain	Mental slowing	Emotional lability
	Apathy	Fatigue
	Tiredness	Anxiety
	Psychosis	Restlessness
Face, ears, eyes	Myxedema features (i.e., puffy face, coarse features)	Exophthalmos
	Deafness	Lid retraction
		Lid lag
		Predisposition to keratitis
Neck	Goiter	Goiter
	Hoarse voice	
Heart	Bradycardia	Palpitations
		Tachycardia
		Atrial fibrillation
Bowel	Constipation	Diarrhea
		Increased appetite
Sexual organs	Amenorrhea	Menorrhagia
		Infertility
		Reduced libido
Muscles	Slowing of activity	Proximal myopathy
	Proximal myopathy	
Hands	Cold hands	Tremor
	Carpal tunnel syndrome	Warmth
		Sweating
Reflexes	Slow relaxation phase	Increased
Skin, bones, adipose tissue	Weight gain	Osteoporosis
	Cold intolerance	Heat intolerance
	Decreased sweating	Increased sweating
	Chronic edema (caused by increased capillary escape of albumin)	Weight loss
	Cold, dry skin	Pretibial myxedema

Etiology	Radioactive iodine uptake
Graves disease	Elevated
Toxic multinodular goiter	Elevated in nodules
Toxic adenoma	Elevated in nodules
Subacute thyroiditis	Low
Iodine-induced hyperthyroidism	Low

tion of disease, and pretreatment with glucocorticoids may be required.

Surgery is used less frequently for treating Graves disease in the United States and usually involves subtotal thyroidectomy leaving approximately 2 g of tissue. Indications include very large goiters, thyroid cancer, and uncontrolled disease despite treatment with thionamides. Surgery is also indicated for patients desiring pregnancy in the very near future, those who are pregnant and whose disease is not controlled with thionamides, and those with significant thyrotoxicosis who cannot be

Fig. 31.4 Hot nodule in the inferior left lobe of the thyroid gland on ^{123}I scan.

Fig. 31.5 Absence of radioactivity in the left lower lobe indicates a cold nodule.

treated with radioactive iodine and have had adverse reactions to thionamide therapy. To prevent thyroid storm, patients should be euthyroid if possible before surgery, preferably through pretreatment with thionamides. If thionamides are contraindicated, the patient can be prepared with β -blockers and high doses of iodine, such as Lugol solution, to block new thyroid hormone production. Iodine is used only in the short term because there is an iodine escape called the Wolff Chaikoff effect; after iodine loses efficacy, it can exacerbate hyperthyroidism. Additionally, all patients with Graves disease should receive iodine for about 1 week preoperatively to decrease thyroid vascularity. After surgery, patients are hypothyroid and will require thyroid hormone replacement.

31.2.2 Thyroid Storm

Thyroid storm is an extreme form of thyrotoxicosis that can be fatal if not promptly treated. It usually occurs abruptly in the setting of preexisting thyrotoxicosis that has been incompletely treated or undiagnosed. Precipitating factors such as infection and intercurrent illness are commonly involved. Before it became possible to control disease preoperatively, thyroid storm frequently occurred after thyroidectomy. The clinical picture is one of severe hypermetabolism, with fever, tachycardia, and possibly pulmonary edema or heart failure. Nausea, vomiting, abdominal pain, and extreme restlessness may also be present.

The diagnosis of thyroid storm is based on symptoms, and guidelines have been published. Treatment involves large doses of antithyroid drugs, iodine in form of Lugol solution or SSKI (saturated solution of potassium iodide), and glucocorticoids. Although it is preferable to start antithyroid drugs before iodine, in the setting of thyroid storm iodine treatment should not be withheld to rapidly decrease thyroid hormone release. Large doses of dexamethasone to support the stress response

and inhibit hormone release are also given. In the absence of cardiovascular insufficiency or asthma, β -blockade can be administered. Supportive measures to bring down fever should be instituted in febrile patients. Salicylates should be avoided because they compete with T_3 and T_4 for binding to thyroxine-binding globulin and transthyretin, increasing free hormone levels. If treatment is successful, improvement occurs within days and recovery within a week, at which point iodide and dexamethasone can be discontinued and plans for long-term treatment instituted.

Treatments for other forms of hyperthyroidism depend on the etiology. Subacute thyroiditis is treated symptomatically with β -blockers and nonsteroidal anti-inflammatory drugs, and with glucocorticoids for severe cases. Silent thyroiditis and postpartum thyroiditis may present with an initial hyperthyroid phase that resolves spontaneously, often leading to hypothyroidism. Amiodarone-associated thyrotoxicosis requires either medical management or rarely thyroidectomy, if feasible, if medical management is not successful in controlling a significant thyrotoxic state. Radioactive iodine treatment cannot be used in the short term, given the high iodine content of amiodarone and its prolonged half-life.

31.3 Hypothyroidism

Thyroid hormone deficiency causing hypothyroidism is common, with a prevalence of 2% of the population. In primary hypothyroidism, TSH is elevated and thyroid hormones are reduced. Hypothyroidism can be transient or permanent. Worldwide, iodine deficiency is the most common cause of hypothyroidism, but Hashimoto thyroiditis or chronic autoimmune thyroiditis is the most common cause in North America. Patients with autoimmune hypothyroidism will usually have elevated titers of antibodies to thyroid peroxidase and

sometimes to thyroglobulin. Hashimoto thyroiditis is more common in women and increases in incidence with age. Elevated titers of antithyroid antibodies may also be present in patients with subacute thyroiditis. In these patients, the hypothyroidism is usually transient and follows a brief phase of thyrotoxicosis. In secondary hypothyroidism, TSH deficiency can occur in the setting of a pituitary or hypothalamic disorder, especially after surgery in the area of the pituitary. The presenting symptoms of hypothyroidism range from nonspecific and mild to severe and life-threatening. Common symptoms include cold intolerance, fatigue, weight gain, and constipation. Signs may include delayed tendon reflexes, bradycardia, hypothermia, and periorbital edema, summarized in the Box Rare Causes of Thyrotoxicosis (p.257). An elevated TSH level is the best initial screening test for primary hypothyroidism. Treatment involves levothyroxine, usually dosed at 1.6 $\mu\text{g}/\text{kg}$ daily. Replacement thyroid hormone is taken without food because foods, as well as calcium and iron supplements, interfere with thyroid hormone absorption. Drugs such as estrogen and anticonvulsants may increase dose requirements; estrogens increase thyroxine-binding globulin levels, and some anticonvulsants increase the metabolic clearance of thyroxine. Elderly patients who may have cardiac disease should initially be given lower doses of levothyroxine (25 to 50 μg) and monitored closely.

The goals of therapy are to bring the TSH levels into the normal range and lessen the symptoms associated with hypothyroidism. TSH should be measured about 6 weeks after treatment initiation. The T_4 level will usually exhibit change within 7 days and may also be used to monitor therapy. Liothyronine or T_3 has been used in conjunction with T_4 in some patients who have hypothyroidism. There are no convincing data that combination therapy is superior to treating with levothyroxine alone. Patients who require urgent surgery and have untreated hypothyroidism are usually not at increased risk for perioperative mortality, but elective surgery should be delayed until patients are euthyroid. In those patients undergoing surgery in whom thyroid hormone is adequately replaced, levothyroxine can be held for several days after surgery until the patients can eat. This does not result in hypothyroidism, given the 7-day half-life of levothyroxine.

Patients who are hospitalized may develop sick euthyroid syndrome, initially characterized by decreased total T_3 , then decreased total T_4 and sometimes low free T_4 with TSH that may be normal, decreased, or sometimes elevated in the recovery phase. The syndrome is probably due to decreased conversion of T_4 to T_3 , inhibition of T_4 binding to plasma proteins, and central hypothyroidism, which can be seen in severe illness. Treatment is not indicated in these patients.

31.4 Thyroid Neoplasia and Carcinoma

Nontoxic goiter can be defined as thyroid enlargement. Goiter may be endemic in a region with iodine deficiency or sporadic. In an autopsy series, thyroid nodules were found in almost 50% of cadavers. The etiology of goiter appears to be multifactorial—both genetic and environmental. The TSH concentration is usually normal in patients with goiter, so the process may be TSH-independent. Nontoxic goiter is more common in females and

often clusters within families. Very large goiters can cause physical discomfort, but most are asymptomatic. The goiter may displace the trachea, esophagus, and neck vessels and can be associated with stridor and dysphagia.

The increase use of medical imaging, including computed tomography (CT) and magnetic resonance (MR) imaging of the neck and chest and carotid duplex scanning, has augmented the diagnosis of asymptomatic thyroid nodules and subsequently increased the diagnosis of thyroid carcinoma. Thyroid nodules are quite common, with epidemiologic studies showing the prevalence of palpable nodules to be 5% in women and 1% in men in iodine-sufficient areas. Thyroid “incidentalomas” that are nonpalpable and found on high-resolution ultrasound are detected in 19 to 67% of individuals. A minority, approximately 5 to 15% are diagnosed as carcinomas, whereas the majority are benign thyroid nodules. Although the incidence of thyroid cancer has increased, the mortality has not, likely because of the small size and early stage of these incidentally discovered thyroid carcinomas. Differentiated thyroid cancer, including papillary and follicular cancer, accounts for almost 90% of all cases of thyroid cancer. The yearly incidence increased 2.4-fold from 1973 to 2002, primarily because of the increase in small papillary thyroid cancer.

The history and physical examination can often favor a benign versus a malignant nodule. Features that would make a physician concerned include a family history of thyroid cancer, male sex, and older age. A history of exposure to external ionizing radiation in childhood, such as acne therapy, treatment for Hodgkin lymphoma, or thymus irradiation, and of exposure to nuclear accidents such as the one at Chernobyl increases the risk for thyroid carcinoma. A rapidly growing mass, abnormal lymphadenopathy, and vocal cord paralysis are also concerning features. Given the high prevalence of thyroid nodules and the excellent prognosis of papillary microcarcinomas, nodules smaller than 1 cm are usually not investigated unless concerning features are present. In general, patients with thyroid carcinoma are euthyroid, but there may be a slightly increased risk for thyroid cancer in patients with Graves disease. □ Fig. 31.6 outlines the decision-making process in evaluating thyroid nodules.

31.4.1 Imaging

Ultrasonography (□ Fig. 31.7) often detects even minute thyroid nodules, with one study showing 65% of patients having nodularity. Ultrasound can characterize the heterogeneous echotexture of the pseudonodules of Hashimoto thyroiditis (□ Fig. 31.8) and demonstrate increased blood flow on Doppler in Graves hyperthyroidism. It is most useful in characterizing thyroid nodules and neck lymphadenopathy. Ultrasound is the imaging modality of choice in patients with nodules, and certain ultrasonographic features increase the suspicion of thyroid cancer. Benign indicators include a completely cystic nodule and hyperechogenicity. Criteria predictive of malignancy include solid hypoechoic nodules, especially with microcalcifications; irregular margins; absence of halo; and nodules taller than they are wide (□ Fig. 31.9). If a ^{123}I scan is done to evaluate thyroid function and a nodule not concentrating radioactive iodine is found, further investigation, including ultrasound-guided fine-needle aspiration, is usually indicated.

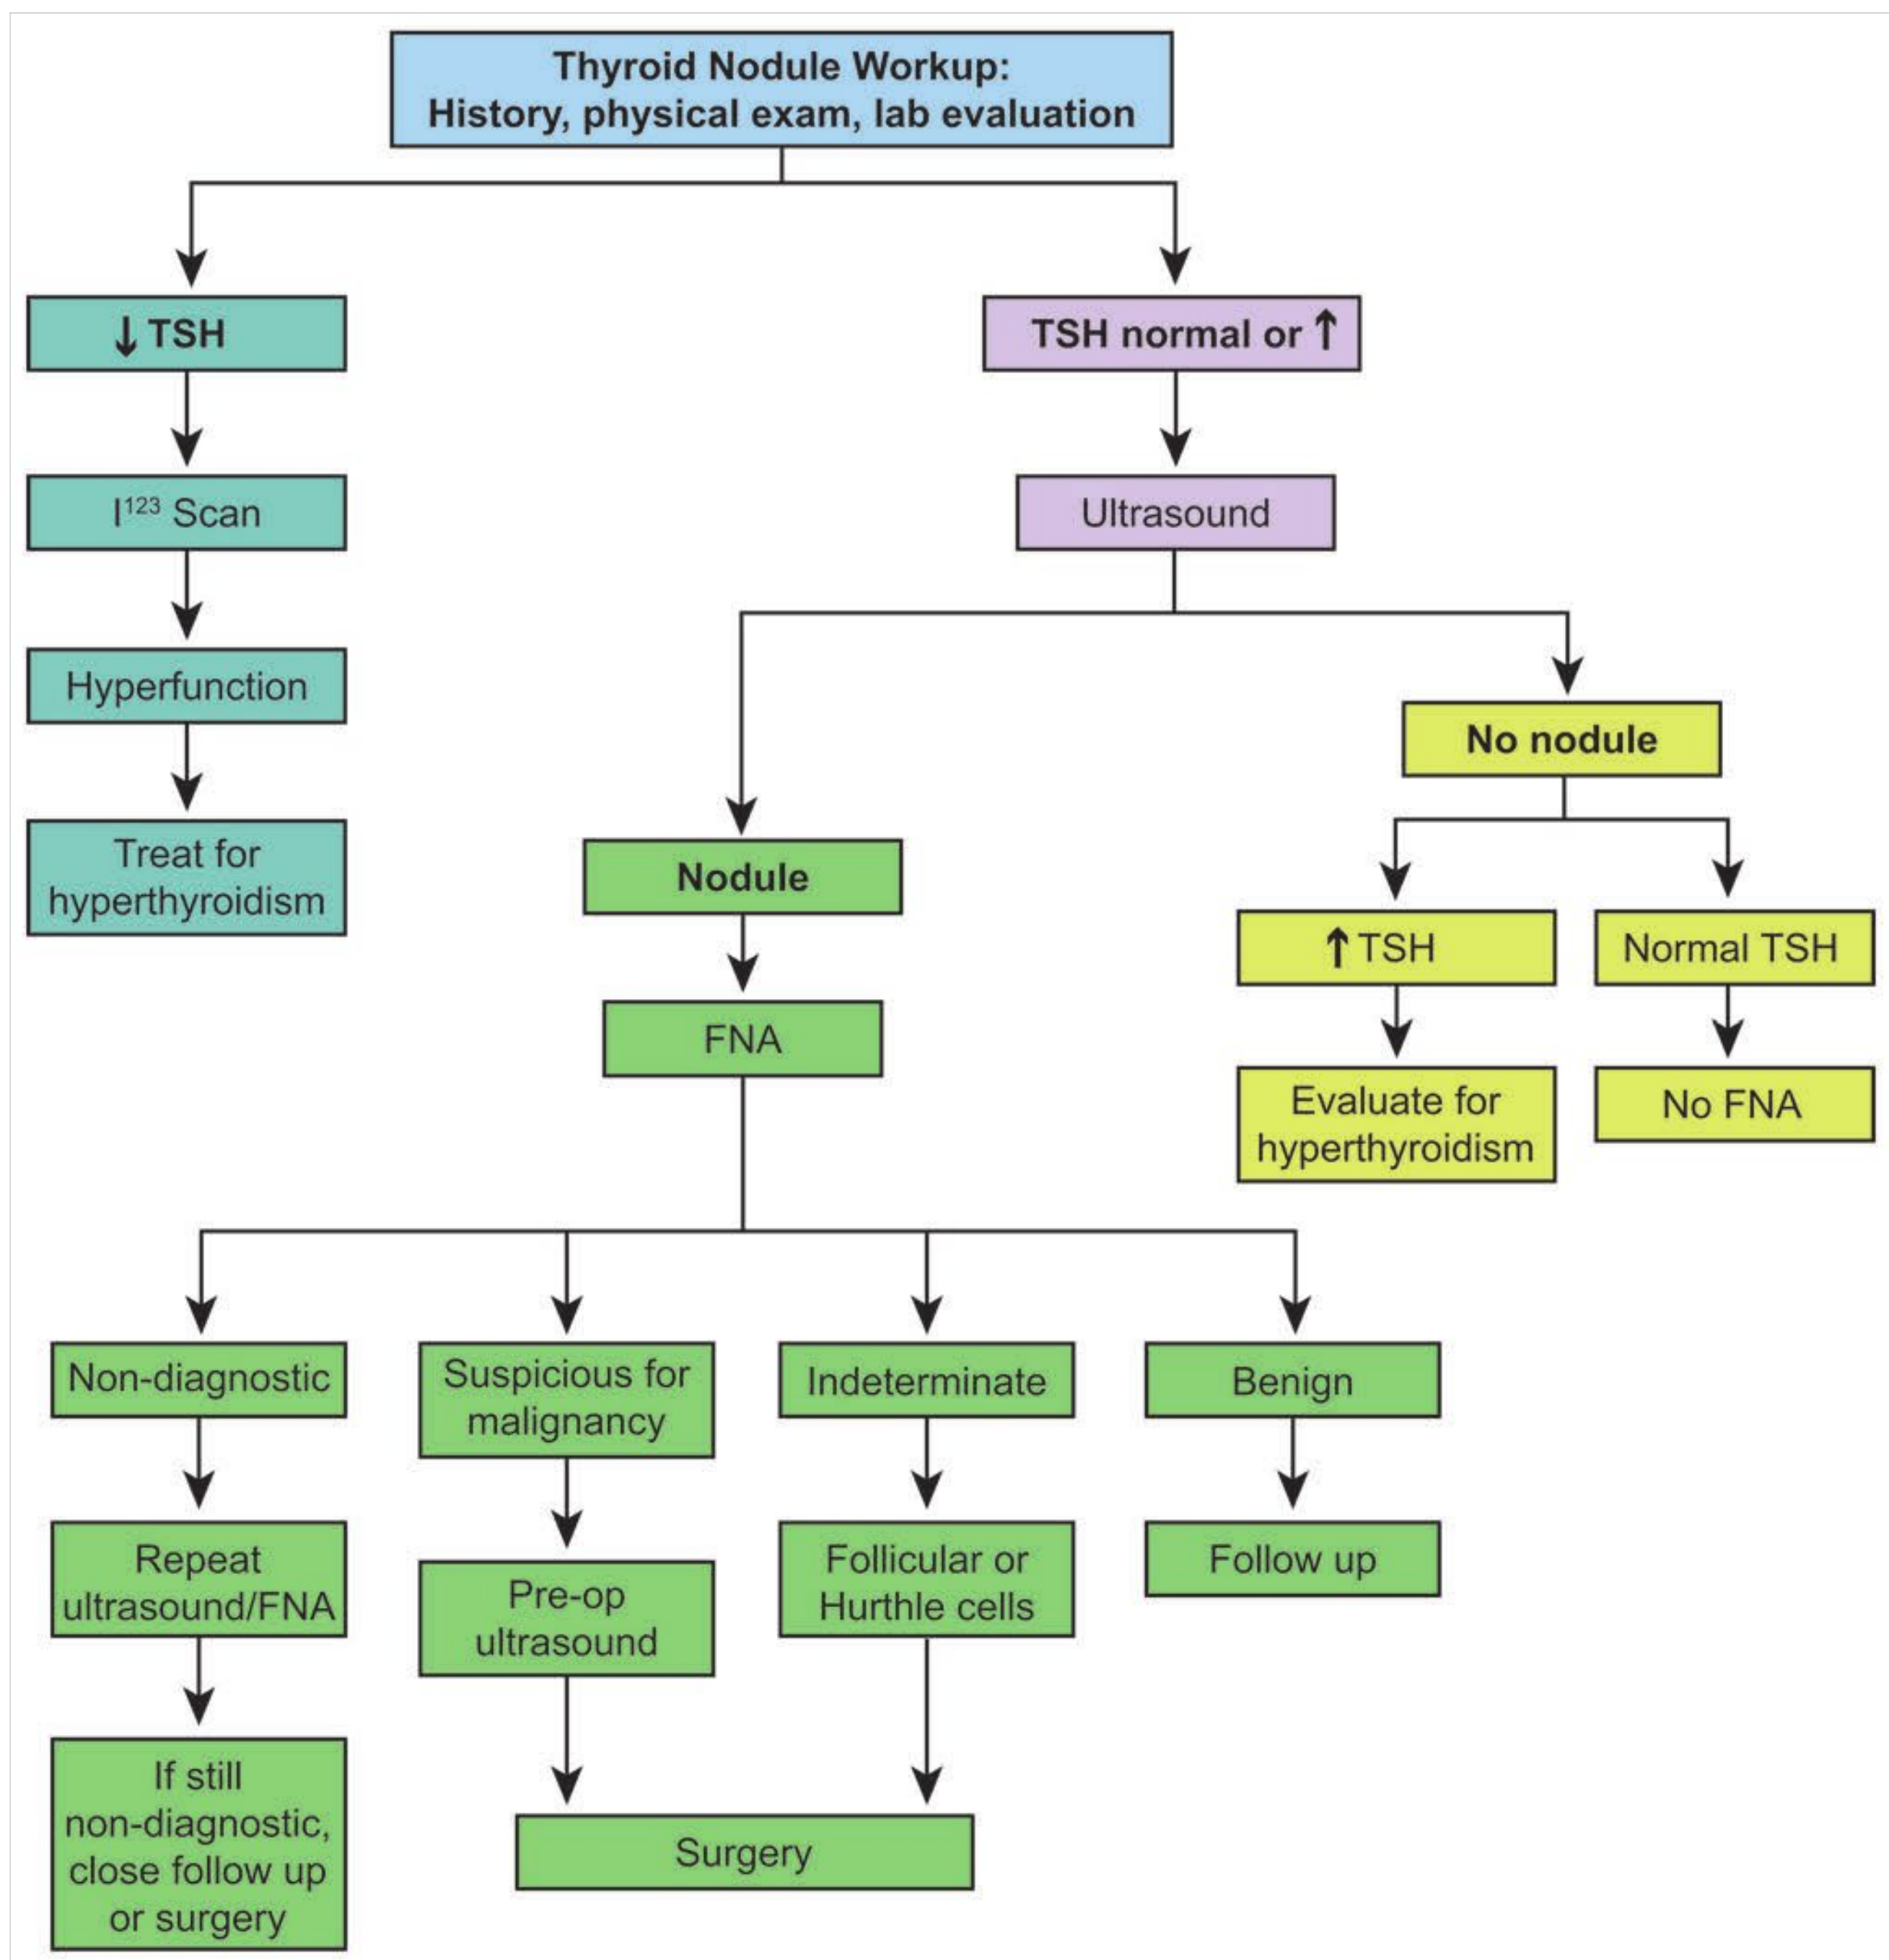

Fig. 31.6 Evaluation of a thyroid nodule. FNA, fine-needle aspiration; TSH, thyroid-stimulating hormone.

Nodules that are suspicious for malignancy should undergo fine-needle aspiration biopsy. This technique has excellent sensitivity and specificity of more than 90% especially when performed under ultrasound guidance. It is easy to perform and safe, and it causes little discomfort. A satisfactory specimen needs to include at least six groups of 10 to 15 well-preserved cells obtained from three to six passes in the nodule. Generally, a 25- or 27-gauge needle is used for the aspiration. Fine-needle aspiration biopsy is extremely useful in diagnosing papillary thyroid cancer through the nuclear changes observed in cytology. The sensitivity and specificity approach 100% Follicular

neoplasms, by contrast, are more difficult to differentiate. Often, these aspirations are characterized as indeterminate, and surgical resection and lobectomy of the affected side are required for accurate diagnosis. At surgery, follicular neoplasms are commonly benign; the rate of finding carcinoma in suspicious nodules is approximately 20%. Recently, BRAF analysis has become commercially available. BRAF is a mutation commonly found in papillary and follicular cancers and may aid in the management of indeterminate nodules.

Patients with a multinodular thyroid gland have the same risk for malignancy as those with a solitary nodule. The Ameri-

Fig. 31.7 Ultrasound of a normal thyroid gland. The gland lies over and around the trachea and abuts both carotid arteries. T, trachea; C, carotid artery.

can Thyroid Association recommends aspirating those nodules that are larger than 1 cm and have a suspicious sonographic appearance. If a nodule is found to have benign cytologic findings, follow-up with serial ultrasound is recommended, with repeat fine-needle aspiration if there is a 50% increase in volume or an increase in size of 2 mm or more within two nodule dimensions.

31.5 Prevalence of Thyroid Carcinoma

Differentiated thyroid cancers are the most common malignant thyroid tumors, with papillary thyroid carcinoma accounting for more than 80% of cancers and follicular carcinoma comprising about 15% of cases. Medullary carcinoma, a neuroendocrine tumor of the calcitonin-producing thyroid cells, occurs 3% of the time and may be associated with multiple endocrine neoplasia type II. Anaplastic carcinoma, with an aggressive course, occurs in 1 to 2% of cases. Lymphoma of the thyroid can also rarely occur in a background of Hashimoto thyroiditis and may be diagnosed in a rapidly growing thyroid mass.

31.5.1 Staging of Thyroid Carcinoma

Thyroid carcinoma staging is based on tumor type and size, extension beyond the thyroid gland, lymph node status, and patient age. T1a lesions are 1 cm or smaller; T1b lesions are between 1 and 2 cm. T2 lesions are 2 to 4 cm in size without extrathyroid extension. T3 lesions are those larger than 4 cm and limited to the thyroid or any tumors with limited extrathyroid extension (sternothyroid muscle or perithyroid soft tissues).

T4a lesions are of any size but extend beyond the thyroid to invade the larynx, trachea, esophagus, recurrent laryngeal nerve, or subcutaneous tissues; T4b tumors invade the prevertebral fascia or encase the carotid artery. The above categories apply to all thyroid tumors except anaplastic tumors, which are all considered T4 lesions; T4a lesions are intrathyroid, and T4b tumors extend beyond the thyroid.

Level VI (pretracheal, paratracheal, and prelaryngeal) lymph node involvement is considered N1a disease; unilateral, bilateral, or contralateral involvement of cervical, retropharyngeal, or superior mediastinal nodes is classified as N1b.

Papillary and Follicular Carcinoma

For patients younger than 45 years of age, disease is considered stage I unless there is a distant metastasis, in which case is classified as stage II. In patients older than 45 years, T1 tumors are stage I and T2 lesions are stage II in the absence of nodal disease. T3 lesions without nodal disease or T1–T3 tumors with N1a nodes are graded as stage III. T1–T3 lesions with N1b nodes or any T4a lesion without metastasis is considered stage IVA. T4b lesions without distant metastases are considered stage IVB, and any distant metastasis is defined as stage IVC disease.

Medullary Carcinoma

T1 medullary carcinoma is considered stage I, and T2 and T3 lesions are considered stage II if there is no nodal involvement. T1–T3 lesions with N1a disease are considered stage III. T1–T3 tumors with N1b nodal status and any T4a lesion are classified as stage IVA. All T4b lesions are considered stage IVB, and any distant metastasis is classified as stage IVC disease.

Anaplastic Carcinoma

All anaplastic carcinomas are considered stage IV. T4a lesions are considered stage IVA, T4b tumors are stage IVB, and the presence of a distant metastasis implies stage IVC.

31.5.2 Management of Thyroid Carcinoma

Surgical resection is the mainstay of treatment in thyroid carcinoma, with total thyroidectomy and lymph node dissection if indicated. Subcentimeter tumors may also be treated with lobectomy provided no high-risk features are present. Total thyroidectomy is also indicated in patients with indeterminate nodules, marked atypical or suspicious cytology, or a family history of thyroid carcinoma or radiation exposure. Preoperative ultrasound of the neck for contralateral lobe findings and lymph node involvement is recommended. Ultrasound-guided fine-needle aspiration of sonographically suspicious lymph nodes should be performed to confirm malignancy. After surgical resection, the TNM (tumor node metastasis) classification system is used for prognostication and follow-up.

31.5.3 Postsurgical Treatment

If a patient undergoes total thyroidectomy, postoperative radioiodine may be required depending on pathology results. Patients at decreased risk for recurrence do not usually require radioactive iodine therapy, whereas patients with larger tumors and those with extrathyroidal spread usually benefit. Ablation of the small amount of residual normal thyroid remaining after total thyroidectomy may facilitate the early detection of recurrence based on serum thyroglobulin measurement. In addition, new data have indicated that lower doses of radioactive iodine may be as effective as higher doses in preventing recurrence in low-risk cancers. Higher doses may be appropriate in those patients with aggressive tumor histology (tall cell, insular columnar cell carcinoma). Patients undergoing radioactive iodine therapy require levothyroxine withdrawal to raise the TSH level above 30 mU/L and a diet low in iodine. Recombinant TSH can be used in some patients in lieu of withdrawal, and studies have shown short-term recurrence rates to be similar. One week after radioactive iodine remnant ablation, a scan is performed to evaluate for metastases.

Differentiated thyroid cancer expresses TSH receptor on the cell membrane and responds to TSH stimulation with increased expression of several thyroid-specific proteins and increased rates of cell growth. Suppression of TSH with levothyroxine therapy is used to decrease the risk for thyroid cancer recurrence. Suppression of TSH to below 0.1 mU/L is recommended for patients with high- and intermediate-risk thyroid cancer, while maintenance of the TSH level at the lower limit of normal or slightly below is appropriate for patients with low-risk disease (0.1 to 0.5 mU/L).

The long-term management of differentiated thyroid cancer includes surveillance for possible recurrence. In patients who have not undergone total thyroidectomy and those who have

not undergone ^{131}I ablation, measurement of thyroglobulin and thyroglobulin antibodies and ultrasonography of the neck are the mainstays of follow-up. Anti-thyroglobulin antibodies, which are present in approximately 25% of patients with thyroid cancer, may falsely lower the thyroglobulin determination in immunometric assay. Approximately 20% of patients who are clinically free of disease, with serum thyroglobulin levels below 1 ng/mL during thyroid hormone suppression of TSH, will have a detectable serum thyroglobulin level after TSH stimulation at 1 year after initial therapy. One-third of these will have persistent or recurrent disease; the others will have stable or decreasing stimulated serum thyroglobulin levels over time. Patients who develop locoregional disease or tumors in the cervical lymph nodes or soft tissues of the neck will require surgical resection.

31.6 Roundsmanship

- TRH stimulates the pituitary secretion of TSH. Circulating thyroid hormone provides negative feedback, inhibiting TSH release via pituitary T_3 receptors.
- The thyroid secretes 20 times more T_4 than T_3 , and T_3 has a shorter half-life than T_4 . T_4 is also deiodinated peripherally to produce T_3 .
- Graves disease is the most common cause of hyperthyroidism.
- Methimazole is the drug of choice in treating hyperthyroidism except in the first trimester of pregnancy.
- The treatment of thyroid storm includes antithyroid medication, iodine (Lugol solution or SSKI), glucocorticoids, and β -blockers if not otherwise contraindicated.
- Iodine deficiency is the most common cause of hypothyroidism worldwide, but Hashimoto thyroiditis is the most common cause in North America.
- Treatment of hypothyroidism includes 1.6 μg of levothyroxine per kilogram per day; patients with cardiac disease and elderly patients should be started at 25 to 50 $\mu\text{g}/\text{d}$. TSH measurement should be repeated 6 weeks after the initiation of treatment.
- Fine-needle aspiration biopsy is highly sensitive and specific for papillary thyroid carcinoma; only 20% of thyroid glands with follicular neoplasms diagnosed by fine-needle aspiration are found to have follicular carcinoma at surgery.

32 Parathyroid Hormone, Vitamin D, and Bone Mineral Metabolism

Guy Valiquette

32.1 Introduction

The physiology of parathyroid hormone is so intricately intertwined with vitamin D and bone mineral metabolism that these topics must be approached together if the discussion is to be cogent and comprehensive. These interactions are summarized graphically in □ Fig. 32.1. PTH primarily regulates the concentration of extracellular ionized calcium, whereas vitamin D regulates the absorption of calcium from the diet and, indirectly, bone mineralization, which accounts for 99% of the calcium reserves in the body.

“Bone is an organ?” Yes! Bone is very active metabolically and, as the primary repository of the body’s calcium stores, is intimately involved in the regulation of the body’s extracellular calcium and ionized calcium concentrations. The extracellular ionized calcium concentration is critical to multiple cellular functions, including intracellular signaling, hormone secretion, and muscle and neural functions, and it must be maintained within very tightly controlled limits. Hypocalcemia leads to neuromuscular hyperexcitability; milder degrees are manifested as hyperesthesia with positive Chvostek and Trousseau signs, whereas more severe hypocalcemia may lead to tetany, seizures, and death. Hypercalcemia leads to lethargy, weakness, and eventually coma and death. Approximately 50% of extracellular calcium is present as ionized calcium, but this is somewhat pH-dependent. Intracellular calcium concentrations are several orders of magnitude below the extracellular concentration, although some organelles, such as the mitochondria, have higher concentrations. Extracellular ionized calcium normally is regulated within a margin of less than $\pm 10\%$

32.2 Physiology

32.2.1 Parathyroid Hormone

Human parathyroid hormone (PTH, hPTH) is an 84–amino acid polypeptide hormone; the amine-terminal 34–amino acid fragment of hPTH, hPTH 1–34, expresses the full classic biological activity of hPTH and is used clinically, particularly to treat osteoporosis. The classic PTH receptor has been sequenced; it is a G protein–linked, 7-transmembrane-spanning segments receptor that binds PTH and the PTH-related peptide (PTHrp) with equal affinity, although PTHrp does not stimulate 1-hydroxylase activity in the kidney to the same extent that PTH itself does. The PTH receptor is heavily expressed in bone and in the kidneys, although other organs also express the receptor at lower levels. More recently, a novel PTH receptor that binds the carboxyl-terminal fragments of PTH, present in the circulation and previously thought to be inactive, has been identified. This novel receptor does not bind PTHrp, and it is not yet clear what role, if any, it plays in bone mineral metabolism, or in any other function.

Parathyroid gland cells express a calcium-sensing receptor, another G protein–linked, 7-transmembrane-spanning segments

receptor, that binds and responds to multiple cations, of which only the divalent cations calcium and magnesium are physiologically relevant. Lower levels of ionized calcium will stimulate PTH secretion, whereas higher levels of ionized calcium will suppress PTH secretion, thereby controlling PTH secretion and maintaining ionized calcium levels within narrow limits. Multiple mutations in this receptor, with both loss and gain in function, have been reported and are key to understanding familial hypocalciuric hypercalcemia (FHH; see below) and certain hypocalcemic syndromes, such as familial hypoparathyroidism.

PTH increases the resorption of calcium from the kidneys, increases bone resorption, and increases vitamin D 1-hydroxylase activity in the kidneys. All these actions contribute to restoring a normal ionized calcium level in the circulation.

32.2.2 Vitamin D

Pro-vitamin D (cholecalciferol) is synthesized in the skin from 7-dehydrocholesterol by photocatalysis in the presence of ultraviolet light in the 290- to 315-nm range (see □ Fig. 32.1). This wavelength is at the very limit of the atmosphere’s transparency to ultraviolet light, and the synthesis of pro-vitamin D in the skin is seasonal at higher latitudes. Pro-vitamin D precursors are also photolabile, and prolonged exposure to sunlight does not lead to vitamin D intoxication. Therefore, the rate of pro-vitamin D production, with long-term irradiation, is not related to skin pigmentation, although it is reduced in darker-skinned individuals with short-term irradiation. Pro-vitamin D is bound to transcalciferin (vitamin D–binding protein) and is carried to the liver, where it undergoes 25-hydroxylation to become calcidiol.

The availability of vitamin D in our diet is limited, and very few foodstuffs provide us with vitamin D. Milk and dairy products in the United States and Europe are fortified with vitamin D, and they provide approximately 100 international units (IU) of vitamin D per portion. Unfortified dairy products and human milk are very poor sources of vitamin D. Eggs provide approximately 20 IU of vitamin D per yolk; egg whites do not contain any vitamin D. Fish are a major source of dietary vitamin D, which ranges from about 250 IU per portion of canned tuna up to 1,000 IU per portion of fresh wild salmon. No vegetable product contains vitamin D, but mushrooms may contain up to 1,500 IU/100 g if grown in the presence of sunlight.

Vitamin D is actually a pro-hormone; the active hormone is 1–25-(OH)₂ vitamin D (calcitriol). Normally, calcitriol is produced in the kidneys from vitamin D, calcidiol, by 1-hydroxylation of this pro-hormone. The renal 1-hydroxylase activity is under the control of PTH, and therefore 1–25-(OH)₂ vitamin D levels correlate with PTH levels. High PTH levels, generally in response to hypocalcemia, will therefore stimulate 1–25-(OH)₂ vitamin D production and increase the intestinal absorption of calcium to normalize serum levels of ionized calcium. Some other tissues can express 1-hydroxylase activity, independently of PTH control, in some pathologic conditions (see below).

Fig. 32.1 Integration of vitamin D, parathyroid hormone, and bone mineral metabolism. Vitamin D precursors are produced in the skin from 7-deoxycholesterol by photocatalysis in the presence of ultraviolet radiation. The synthesis of 25-OH vitamin D, the storage form of the pro-hormone, to 1,25-(OH)₂ vitamin D, the active hormone, is under the control of parathyroid hormone. 1,25-(OH)₂ Vitamin D increases calcium absorption from the gastrointestinal tract. Serum calcium and phosphate levels allow the mineralization of new bone matrix and feedback on parathyroid hormone secretion. Higher levels of parathyroid hormone increase bone resorption when necessary to maintain normal serum calcium levels and stimulate the synthesis of 1,25-(OH)₂ vitamin D by the kidneys.

32.2.3 Bone Mineral Metabolism

Bone is generally thought of as a major structural component of the body. However, bone also has a significant metabolic function as a reservoir for calcium, phosphate, and carbonate, and it

plays a significant role as a buffer in the body's acid-base balance. Bone is made of a matrix of connective tissue, which is mostly but not completely mineralized, and specialized bone cells. The skeleton is generally conceptually divided into the axial skeleton, which includes the skull, vertebrae, sternum, ribs,

and pelvis, and the appendicular skeleton, which includes the long bones of the limbs down to the digits. Bone can also be divided into trabecular, or cancellous, bone, which is highly active metabolically, and cortical bone, which is denser and less active metabolically but can be recruited in severe or prolonged bone disease. The axial skeleton has a higher proportion of trabecular bone, whereas the appendicular skeleton has more cortical bone.

Specialized bone cells include the osteoblasts, osteocytes, and osteoclasts. Osteoblasts are derived from mesenchymal stem cells and produce the connective tissue matrix; this secondarily becomes mineralized, thereby producing new bone. Most osteoblasts undergo apoptosis, but a minority are integrated in the bone matrix to become osteocytes or remain on the surface of the bone to form the periosteum. In becoming osteocytes, these cells develop multiple long processes radiating from the cell bodies that form gap junctions with neighboring osteocytes and the periosteum. Osteocytes act as sensors of the mechanical stresses to which bones are subjected and play an important role in the modulation of bone remodeling. Osteoclasts are large multinuclear cells derived from the fusion of mononuclear cells of the macrophage lineage, stimulated mainly by nuclear factor- κ B (RANKL), produced during the apoptosis of osteoblasts, and by macrophage colony-stimulating factor. Osteoclasts destroy both the mineral component of bone by dissolution and the collagenous matrix by proteolysis, thereby mediating bone resorption.

Normal bone is constantly being broken down through resorption by osteoclasts, and new bone is laid down by osteoblasts in what is described as the bone-remodeling cycle. Normally, bone resorption and bone formation are in balance. The bone-remodeling cycle is important in repairing microfractures resulting from the everyday stresses imposed on the skeleton and thereby maintaining its structural integrity.

32.2.4 Calcium-Sensing Receptor

As mentioned above, parathyroid cells express the calcium-sensing receptor. The calcium-sensing receptor was first identified in bovine parathyroid glands and later confirmed in human tissues. The calcium-sensing receptor is expressed in parathyroid glands, where it was first isolated, and also in kidneys, bone, intestine, lungs, brain, and other tissues.

Both mutations and acquired disorders of the calcium-sensing receptor can lead to clinically relevant disease, causing hypocalcemia as well as hypercalcemia. The clinical relevance of these disorders is discussed in detail further below.

32.3 Hypercalcemic Disorders

32.3.1 Pseudohypercalcemia

Pseudohypercalcemia is an elevation in the total serum calcium with a normal level of ionized calcium. It is generally due to an increase in serum proteins (mainly albumin) associated with severe dehydration or to the presence of abnormal proteins, such as the paraproteins of multiple myeloma. Note, however,

that multiple myeloma can also cause true hypercalcemia through bone resorption (see below).

32.3.2 Primary Hyperparathyroidism

Primary hyperparathyroidism is by far the most common cause of hypercalcemia. The prevalence of hyperparathyroidism, as estimated in recent studies, is about 2% in women ages 55 to 75 years, with an annual incidence rate of 22 per 100,000. The etiology of the disorder is not clear but does not involve a mutation in the calcium-sensing receptor. Primary hyperparathyroidism is most commonly caused by a solitary parathyroid adenoma, and less frequently by parathyroid hyperplasia involving all four glands; most of these cases are sporadic, but a minority are secondary to hereditary syndromes. Cases of parathyroid carcinoma are rare, accounting for fewer than 1% of all cases.

Since the introduction of automated chemistry analyzers in the late 1970s, most cases of primary hyperparathyroidism have been asymptomatic at the time of diagnosis. The classic clinical presentation of symptomatic hypercalcemia, with nephrolithiasis and bone lesions or bone pain, is rarely seen today in the developed world, although a certain number of cases still present as nephrolithiasis. Most cases are diagnosed after a diagnostic work-up for incidental hypercalcemia.

Normocalcemic forms of primary hyperparathyroidism have been proposed but remain controversial. What is agreed upon is that causes of secondary hyperparathyroidism must be carefully excluded before a diagnosis of normocalcemic hyperparathyroidism is made. There are no guidelines for the management of normocalcemic hyperparathyroidism.

Clinical manifestations of primary hyperparathyroidism, when present, may include nephrolithiasis, fatigue, anxiety, and muscle weakness. Hypertension and cardiovascular disease are more common in patients with hyperparathyroidism than in the general population. Low bone mineral density in the appendicular bones, such as the distal third of the radius, is common, whereas bone mineral density in the axial skeleton, such as the spine, is more commonly normal.

Laboratory characteristics of primary hyperparathyroidism include hypercalcemia (generally mild), hypophosphatemia, and elevated or inappropriately normal PTH levels. Total serum calcium must be corrected for the albumin: $\text{corrected total serum calcium (mg/dL)} = \text{actual total serum calcium (mg/dL)} + \{[4.0 - \text{serum albumin (g/dL)}] \times 0.8\}$. Occasionally, it must also be corrected for other serum protein levels, and serum ionized calcium may be measured directly for confirmation or clarification. Urinary calcium levels, measured in a 24-hour urine collection, are usually normal or high despite the increased fractional resorption of calcium. It is also important to rule out hypercalcemia due to FHH before making a diagnosis of primary hyperparathyroidism because surgery is contraindicated in this syndrome (see below).

Relevant imaging studies include distal radius bone mineral density, renal ultrasound, and abdominal computed tomography (CT), to rule out nephrolithiasis or nephrocalcinosis, and a sestamibi nuclear scan (□ Fig. 32.2). The sestamibi scan should

Fig. 32.2 For a sestamibi parathyroid scan, the neck is imaged with a gamma camera twice after an injection of technetium Tc 99 m sestamibi: first in an early-phase scan at 10 to 20 minutes after injection and then in a late-phase scan at approximately 2 hours. The early phase images the thyroid gland as well as the parathyroid glands; in the late-phase image, the thyroid gland “washes out” while the radioactivity in the parathyroid gland(s) persists better and so images the adenomatous parathyroid tissue. (a) Early and (b) delayed images show a strikingly obvious, but far from typical, parathyroid adenoma. (c) Early and (d) delayed images show a more typical (lower left) parathyroid adenoma.

not be used for diagnostic purposes, only for localizing purposes to assist the surgeon in preparing for the surgery. Ultrasound exploration of the neck (□ Fig. 32.3) may also be useful in identifying a parathyroid adenoma, again to assist the surgeon, not for diagnostic purposes.

The natural history of primary hyperparathyroidism has been better defined by the study of one cohort of patients over 10 and 15 years. In this study, 37% of the patients who either did not meet criteria for surgery or initially declined surgery

developed symptomatic disease and eventually met these criteria. Although asymptomatic mild primary hyperparathyroidism can safely be observed for several years, the advisability of this approach is now being questioned.

The most recent guidelines developed by the Third International Workshop on the Management of Asymptomatic Primary Hyperthyroidism recommend surgery for asymptomatic patients that meet any of the following criteria: (1) total serum calcium more than 1 mg/dL above the upper limit of normal,

Fig. 32.3 Ultrasonographic view of a large parathyroid adenoma inferior and lateral to the thyroid gland.

(2) estimated creatinine clearance below 60 mL/min, (3) bone mineral density T score at any site of less than -2.5 or any fragility fracture, and (4) age younger than 50 years. The previous criterion of a urinary calcium excretion rate of more than 400 mg/d has been dropped, although many physicians still use it in their decision-making process.

Immediate postoperative care should include close monitoring for hypocalcemia, which is frequent but generally mild and transient. More severe hypocalcemia may require intravenous and oral calcium supplementation. Postoperative hypocalcemia is more common and more severe in patients with concomitant vitamin D deficiency, and vitamin D deficiency generally should be corrected preoperatively.

32.3.3 Tertiary Hyperparathyroidism

Tertiary hyperparathyroidism is parathyroid hypertrophy and hyperplasia in patients with end-stage renal failure on hemodialysis or patients who were previously on hemodialysis after renal transplant. Parathyroid hyperplasia and parathyroid adenomas develop as a result of prolonged stimulation of the parathyroid glands from uncontrolled hypocalcemia, calcitriol deficiency, or hyperphosphatemia. This parathyroid hyperplasia obviously persists after renal transplant, when the physiologic environment is dramatically changed. There are no clear guidelines for parathyroid surgery in tertiary hyperparathyroidism; however, most experts agree that surgery is indicated in cases of uncontrolled hypercalcemia or of hyperparathyroid metabolic bone disease or extraskeletal calcifications refractory to oral phosphate binders, and in the presence of a high PTH level, generally above 600 to 800 pg/mL. There is no consensus on the surgical approach; both subtotal parathyroidectomy and total parathyroidectomy with auto-transplant have their proponents.

32.3.4 Familial Hypocalciuric Hypercalcemia

FHH is a relatively rare cause of hypercalcemia, with a prevalence rate estimated to be between 1 per 10,000 and 1 per 100,000. This may actually be an underestimate because FHH is generally totally asymptomatic. The main reason for surgeons to be well aware of this syndrome is that FHH had been identified as the cause of failed parathyroid surgery in patients misdiagnosed as having primary hyperparathyroidism; this misdiagnosis may account for nearly 25% of failed parathyroid surgeries. FHH is an autosomal-dominant disorder resulting from a loss-of-function mutation in the calcium-sensing receptor gene, which leads to a resetting of the PTH–calcium set point and a mild to moderate hypercalcemia; because the calcium-sensing receptor is present along most of the nephron, hypocalciuria is typical of this syndrome, in contrast to the hypercalciuria generally seen in primary hyperparathyroidism. The diagnosis is usually suggested by a calcium-to-creatinine urinary clearance ratio of less than 0.01 and is confirmed by a positive family history or genetic testing. Note, however, that there is significant overlap in the calcium-to-creatinine clearance ratios of FHH and primary hyperparathyroidism, in which the ratio is typically, but not always, above 0.01. Acquired cases of an FHH-like syndrome due to autoantibodies to the calcium-sensing receptor have also been described.

32.3.5 Other Causes of Hypercalcemia

There are many other causes of hypercalcemia, generally of interest more to the endocrinologist than to the surgeon. Nevertheless, these will be reviewed briefly here (see Box Causes of Hypercalcemia (p.273)). Generally, it is most useful to start the evaluation of a patient with hypercalcemia by measuring the serum PTH, PTHrp, and 1,25-(OH)₂ vitamin D levels.

Causes of Hypercalcemia

- Pseudohypercalcemia
- Primary hyperparathyroidism
- Secondary hyperparathyroidism
- Tertiary hyperparathyroidism
- Familial hypocalciuric hypercalcemia
- Paraneoplastic syndrome
 - Parathyroid hormone-related peptide (PTHrp)-mediated hypercalcemia
 - Parathyroid hormone (PTH)-mediated hypercalcemia
 - Tumor necrosis factor-, interleukin-1-, or RANKL-mediated hypercalcemia
- Vitamin D intoxication

Causes of hypercalcemia mediated by the PTH receptor include primary hyperparathyroidism, either sporadic or associated with a multiple endocrine neoplasia syndrome; tertiary hyperparathyroidism, typically in a patient with renal failure after renal transplant; and PTHrp-mediated hypercalcemia, a paraneoplastic syndrome. Rarely, some tumors may secrete PTH itself, rather than PTHrp. FHH-associated hypercalcemia, as discussed above, results from a reduced sensitivity of the calcium-sensing receptor to circulating ionized calcium levels. Finally, hPTH 1–34 (teriparatide) is approved for the treatment of osteoporosis; its use normally results in a transient hypercalcemia lasting only a few hours, but it may cause persistent hypercalcemia in some individuals.

Vitamin D intoxication can cause hypercalcemia, but hypercalcemia is generally seen only in patients with a 25-(OH) vitamin D level above 100 ng/mL. This cause of hypercalcemia was seen much more frequently before the development of histamine type 2 (H₂) receptor antagonists and proton pump inhibitors (PPIs), when calcium carbonate and milk were recommended in the treatment of peptic ulcers (“milk alkali syndrome”). Extrarenal sources of vitamin D 1-hydroxylase, not under the control of PTH, can also lead to hypercalcemia. This is generally seen in disorders, benign or malignant, involving cells of the macrophage lineage, such as lymphomas or chronic granulomatous diseases.

Tumors can cause hypercalcemia, as mentioned above, by secreting PTHrp or rarely PTH itself, but other tumors, including solid tumors with bony metastases and multiple myelomas, cause hypercalcemia by secreting various cytokines. These cytokines include tumor necrosis factor, interleukin-1, RANKL, and others.

32.4 Hypocalcemic Disorders

32.4.1 Pseudohypocalcemia

As noted above under the heading of hypercalcemia, pseudohypocalcemia is also possible if calcium-binding proteins in serum are decreased. This most commonly is the result of hypoalbuminemia due to hepatic or renal disease. Acidosis will also reduce total serum calcium by increasing albumin binding of calcium.

32.4.2 Hypocalcemia with Low Parathyroid Hormone Levels

The major cause of hypoparathyroidism is surgery. Surgical hypoparathyroidism can occur after thyroid, parathyroid, or other head and neck surgery. Transient hypoparathyroidism occurs in up to 50% of patients undergoing a total thyroidectomy for thyroid cancer, and permanent hypoparathyroidism in up to 20% of patients with neck dissections. Rates of permanent hypoparathyroidism can be as high as 1 to 3% in patients undergoing a total thyroidectomy for benign disease. Other causes include autoimmune hypoparathyroidism and other, more unusual disorders (see Box Causes of Hypocalcemia (p.273)). Autosomal-dominant hypocalcemia is the counterpart of FHH, in which a gain-of-function mutation in the calcium-sensing receptor gene results in a lower set point for serum calcium regulation.

Causes of Hypocalcemia

- Low parathyroid hormone Levels
 - Postoperative hypoparathyroidism
 - Autoimmune hypoparathyroidism
 - Autosomal-dominant hypocalcemia
- High parathyroid hormone levels
 - Acute pancreatitis
 - Severe vitamin D deficiency
 - Pseudohypoparathyroidism

The treatment of hypocalcemia in low-PTH conditions, except autosomal-dominant hypocalcemia, is based on increasing calcium absorption with calcium supplementation and supra-physiologic doses of vitamin D. Typically, these patients may require up to 6 g of calcium and 2 µg of calcitriol, or 1,25-(OH)₂ vitamin D, daily. Because these patients lack the calcium-retaining effect of PTH in the kidneys, urinary calcium must be monitored closely to avoid hypercalciuria, urolithiasis, and nephrocalcinosis. It may be necessary to add a thiazide diuretic to reduce the urinary excretion of calcium. Also, serum calcium does not need to be corrected completely into the normal range; a low normal or slightly low serum level of calcium is acceptable if the patient is asymptomatic. Although trials have shown that treatment with PTH itself is effective in treating hypoparathyroidism, this treatment is not approved by the FDA.

Autosomal-dominant hypocalcemia should not be treated with calcium supplements and vitamin D; fortunately, this syndrome is very rare and generally asymptomatic.

32.4.3 Hypocalcemia with High Parathyroid Hormone Levels

The treatment of high-PTH hypocalcemic states is more diverse. Secondary hyperparathyroidism is the normal response of the parathyroid glands to hypocalcemia, whatever the etiology. Therefore, acute pancreatitis, in which hypocalcemia is due to the sequestration of serum calcium in calcium soaps by released free fatty acids, and severe vitamin D deficiency, in which hypocalcemia is due to the decreased absorption of

dietary calcium, both induce secondary hyperparathyroidism to maintain serum free calcium levels. Note, however, that most patients with vitamin D deficiency [levels of 25-(OH) vitamin D below 20 ng/mL] present with a high PTH level and a normal serum calcium level.

Pseudohypoparathyroidism, which is the result of loss of function of the PTH receptor, is treated with calcium supplements and vitamin D, just like hypoparathyroidism. Vitamin D deficiency is obviously treated by replenishing vitamin D, generally with 50,000 IU weekly for 6 to 8 weeks. The hypocalcemia associated with hypomagnesemia is completely reversible by correcting the hypomagnesemia. Generally, other conditions causing hypocalcemia respond to treatment of the underlying cause.

32.5 Osteoporosis

As we noted above, bone is constantly turning over, allowing the repair of damages from everyday stresses. Normally, bone resorption and bone deposition are tightly coupled, and bone mass remains constant. If bone deposition lags behind bone resorption, bone mass decreases, and the result is osteoporosis. This overview addresses the most common form of osteoporosis, postmenopausal osteoporosis. The management of osteoporosis in premenopausal women and in men does differ from that in postmenopausal women to a significant extent, and the reader is referred to recent relevant reviews.

Osteoporosis can be diagnosed only by a determination of bone mineral density. The “gold standard” technology for determining bone density is dual-energy X-ray absorptiometry (DEXA). Although other technologies, such as calibrated CT and quantitative ultrasound measurements of the calcaneus, have been proposed, either they have not gained universal acceptance (calibrated CT) or they measure parameters other than bone density that may predict fracture risk (ultrasound) but are not comparable with bone mineral density. Osteoporosis is defined as a bone mineral density that is more than 2.5 standard deviations below the mean of young adults (T score). The bone mineral density can also be compared with that of persons of the same age and sex (Z score), but this metric is used only for epidemiologic studies, not for fracture prediction or therapeutic decision making. Osteopenia is defined as a bone mineral density T score between -1.0 and -2.49 .

The treatment of osteoporosis involves both nonpharmacologic and pharmacologic interventions. Nonpharmacologic interventions include diet, exercise, smoking cessation, and avoidance of drugs that may increase bone mineral loss, primarily glucocorticoids. The diet should include an adequate intake of calories and protein, in addition to calcium and vitamin D supplementation. Consuming a diet rich in calcium (mostly dairy products) is preferable to supplementation, but this may be difficult or may interfere with other dietary goals (e.g., reducing cholesterol intake). If necessary, calcium supplementation should consist of about 500 to 1,000 mg/d, taken in divided doses and with food. Recently, there has been some controversy over what daily intake of vitamin D should be recommended for the general population. However, there is no doubt that vitamin D deficiency is extremely prevalent in older adults and

carries an increased risk for mortality. Most osteoporosis experts recommend supplementing the diet with up to 2,000 IU of vitamin D. Exercise has been shown to reduce the risk for fracture and to slightly increase bone mineral density; generally, a minimum 30 minutes of weight-bearing exercise three times weekly is recommended for skeletal health.

Pharmacotherapy should be considered for postmenopausal women who have fragility fractures or osteoporosis or who are at high risk for osteoporosis. The World Health Organization has developed a fracture prediction tool, FRAX, to estimate the 10-year osteoporotic fracture risk and assist in treatment decision making. Pharmacotherapy regimens used for the treatment of osteoporosis can be classified as either antiresorptive or anabolic. Antiresorptive agents include bisphosphonates, selective estrogen receptor modulators (SERMs), postmenopausal estrogen replacement therapy, and denosumab. The only anabolic agents approved are teriparatide (PTH 1–34) and intact PTH (PTH 1–84).

Strontium ranelate is approved in Europe for the treatment of osteoporosis and appears to have both antiresorptive and anabolic properties, although its exact mechanism of action in humans is not clear.

Other therapeutic modalities have either been shown to be ineffective (calcitriol) or have mostly been abandoned because of the emergence of more effective modalities (calcitonin).

The treatment of osteoporosis is obviously quite complex, requiring careful decision making and balancing the risks and potential benefits of treatments designed to prevent serious complications of an asymptomatic condition over years, if not decades. This overview is therefore not designed to be a treatment guide, but rather a summary of the problem and various treatment options.

32.6 Roundsmanship

- Parathyroid hormone primarily regulates extracellular ionized calcium concentration, whereas vitamin D regulates the absorption of calcium from the diet and, indirectly, bone mineralization, which accounts for 99% of the body's calcium reserves.
- Approximately 50% of extracellular calcium is present as ionized calcium.
- Pro-vitamin D (cholecalciferol) is synthesized in the skin from 7-dehydrocholesterol during photocatalysis by ultraviolet light in the 290- to 315-nm range. This is further modified in the liver and kidneys to produce the active hormone.
- Pseudohypercalcemia is an elevation in the total serum calcium with a normal level of ionized calcium. It is usually due to an increase in serum protein concentrations seen in severe dehydration, or to the presence of abnormal proteins, such as the paraproteins of multiple myeloma.
- Primary hyperparathyroidism is most commonly caused by a solitary parathyroid adenoma, and less frequently by parathyroid hyperplasia involving all four glands.
- Tertiary hyperparathyroidism consists of parathyroid hypertrophy and hyperplasia in patients with end-stage renal failure on hemodialysis or in patients who were previously on hemodialysis after renal transplant.

33 Surgical Techniques for the Management of Thyroid and Parathyroid Diseases

Augustine L. Moscatello and Mike Yao

33.1 Thyroid

The four most common types of thyroid cancer are papillary, follicular, medullary, and anaplastic. Although the techniques described in this portion of this chapter are applicable to any of these pathologies, the indications for surgery and lymph node dissection pertain only to well-differentiated thyroid cancers (papillary and follicular). The management of anaplastic and medullary thyroid cancer is beyond the scope of this chapter.

33.1.1 History of Thyroid Surgery

Modern thyroidectomy is credited to Theodor Billroth and his pupil, Theodor Kocher. From 1860 to 1867, as professor in surgery at the University of Zurich, Billroth performed 20 thyroidectomies for compressive symptoms. Eight of 20 patients died perioperatively, causing him to suspend these operations. When he relocated to the University of Vienna in 1867, he applied new techniques of anesthesia, hemostasis, and antisepsis and decreased his mortality rate to less than 10%. Theodor Kocher was a student of Dr. Billroth and is often lauded as the “father of thyroid surgery” because of his contributions to making thyroid surgery safer. He improved techniques of hemostasis and asepsis to decrease the mortality rate to less than 0.2% by 1898. Kocher was a meticulous surgeon and was able to remove the thyroid with minimal disruption of the surrounding tissues. In this manner, he was able to preserve parathyroid function before a defined understanding of the presence and function of these glands had been acquired. Based on his work to understand the function of the thyroid gland and improve the safety of surgery, he was the first surgeon awarded the Nobel Prize in Medicine and Physiology, in 1909. Largely through his discoveries, the complications of hypothyroidism, hypoparathyroidism, and vocal cord paralysis were understood and avoided, making thyroid surgery a safe operation.

33.1.2 Indications for Thyroid Surgery

The three main indications for thyroid surgery are concern for cancer, goiter causing symptoms, and hyperthyroidism. Based on the American Thyroid Association (ATA) guidelines from 2009, most thyroid nodules 1 cm or larger should be biopsied by fine-needle aspiration. The results of fine-needle aspiration are divided into six categories based on The Bethesda System for Reporting Thyroid Cytopathology: nondiagnostic, malignant, benign, neoplasm (either follicular or Hürthle cell), suspicious for malignancy, and follicular lesion of undetermined significance. Thyroid surgery should be performed for a diagnosis of malignant, suspicious for malignancy, or neoplasm suspicious for Hürthle cell. Patients with biopsy categories of nondiagnostic, neoplasm suspicious for follicular lesion, and follicular lesion of undetermined significance may or may not undergo surgery depending on other factors, such as a family history of thyroid cancer, history of radiation exposure, and

patient preference. Some of these patients may undergo biopsy again or followed with ultrasound. Nodules that grow rapidly, are symptomatic, or cause vocal cord paralysis require surgical intervention.

33.1.3 Indications for Neck Surgery

Therapeutic lymph node dissection is the removal of lymph nodes harboring cancer. Typically, an entire lymph node level is dissected if diseased lymph nodes are found in that level. Neck levels II, III, and IV are at the highest risk. There is controversy about the risk for disease in levels IIb and V. Elective lymph node dissection is the removal of lymph nodes with high risk for disease but without evidence of disease on imaging or physical examination. Elective lateral neck dissection is probably not indicated, and elective central neck dissection is controversial. The ATA guidelines recommend consideration of an elective central neck dissection for advanced primary tumors (T3 or T4), although we tend to perform only therapeutic lymph node dissections.

The ATA guidelines for central neck dissection have standardized the boundaries:

1. Superior: hyoid bone
2. Lateral: carotid artery
3. Anterior: superficial layer of the deep cervical fascia
4. Posterior: deep layer of the deep cervical fascia
5. Inferior: innominate artery on the right and the corresponding axial plane on the left

Careful dissection of the parathyroid glands and the recurrent laryngeal nerves is necessary during a central neck dissection. The recurrent laryngeal nerves need to be traced inferiorly with atraumatic techniques. For the parathyroid glands, the ATA consensus statement on central neck dissections reports that the “superior parathyroid gland is preserved in situ along with its primary blood supply from the superior branch of the inferior thyroid artery. The inferior parathyroid gland is usually reflected laterally along with its blood supply from the inferior thyroid artery.” Glands that are devascularized can be autotransplanted after frozen section confirmation of parathyroid tissue.

33.1.4 Indications for Radioactive Iodine Treatment after Surgery

The ATA guidelines recommend postoperative radioactive iodine ablation in patients with known distant metastases, incomplete tumor resection, gross extra-thyroidal extension, and primary tumor larger than 4 cm. Radioactive iodine ablation is recommended for selected patients with tumors between 1 and 4 cm confined to the thyroid who have lymph node metastases, microscopic tumor invasion of tissues, aggressive tumor histology, or thyroglobulin levels out of proportion to the radioactive

iodine uptake scan. Aggressive histologies include tall cell, columnar cell, diffuse sclerosing, trabecular, insular, and solid. Radioactive iodine ablation is not recommended for patients with tumors smaller than 1 cm without other high-risk features.

33.1.5 Procedure

Intubation

Laryngeal nerve EMG endotracheal tubes are widely available in many operating rooms. The standard EMG endotracheal tubes have contact electrodes that sense electrical activity in the laryngeal musculature. These contact electrodes are not as sensitive as the intramuscular electrodes typically used in facial nerve monitoring, and thus they do not give as much feedback during the dissection. We typically use the EMG endotracheal tube with a stimulator probe to confirm the identity of the recurrent laryngeal nerve and do not use it as a warning for excessive manipulation of the nerve; however, to use it to monitor excessive nerve damage, some practitioners increase the sensitivity of the nerve monitoring in an attempt to approximate the sensitivity of the intramuscular electrodes.

Skin Incision

The incision is typically made in a horizontal neck crease. From a visualization perspective, an incision at level of the thyroid isthmus or cricoid cartilage affords the easiest access to both the superior and inferior poles of the thyroid; however, this results in a scar that is in the middle of the neck. With this in mind, some surgeons displace the incision inferiorly to approximately 1 finger breadth above the sternal notch. In this low position, the scar is more easily hidden by clothing or jewelry. The disadvantage of a low incision is that dissection around the superior poles of the thyroid is more difficult. This visualization can be improved by using endoscopic video techniques. A scar placed inferiorly over the clavicles or sternum will tend to widen and become less cosmetically acceptable.

Dividing the Strap Muscles

In most cases, subplatysmal dissection is not necessary, and dissection beneath the strap muscles is adequate for visualization. Dissection is carried through the subcutaneous fat to the level of the anterior jugular veins and the strap musculature. The anterior jugular veins are ligated as necessary but can often be left intact unless there are communicating vessels that cross the midline. The sternohyoid and sternothyroid muscles are elevated off the thyroid gland carefully to avoid damage to the prominent blood vessels in the capsule of the thyroid gland. Electrocautery or the harmonic scalpel is used to ligate any small blood vessels that are encountered to keep the surgical field as dry as possible. Once elevated, the strap muscles are retracted laterally, and the thyroid gland is retracted medially. Sometimes, it is necessary to transect the medial aspect of the superior attachment of sternothyroid muscle to the thyroid cartilage to allow better exposure (□ Fig. 33.1). The lateral aspect of the thyroid gland needs to be dissected carefully to avoid damage to the middle thyroid vein, which can bleed profusely if damaged or avulsed (□ Fig. 33.2).

Identification of the middle thyroid veins requires enough medial and lateral retraction to stretch the veins slightly without enough traction to avulse them. Novice thyroid surgeons often will not retract the thyroid gland and trachea enough to develop the surgical space to identify these veins. Once identified, the middle thyroid vein(s) need to be ligated close to the thyroid capsule in order to medialize the gland. At this level, the common carotid artery can be seen and should be dissected laterally away from the thyroid gland.

Most surgeons approach the thyroid dissection from lateral to medial and either medialize the gland to identify the recurrent laryngeal nerve and parathyroid glands or dissect the superior pole and ligate the superior pole blood vessels. We tend to do whichever maneuver is easiest first. However, in this manuscript, we describe medialization first. In addition, sometimes dividing the thyroid isthmus initially can help to mobilize the gland when routine mobilization methods are not successful.

Medializing the Thyroid Lobe

The gland is retracted anteriorly and medially, and dissection is performed on the capsule of the thyroid gland to free it from the surrounding soft tissues, including the carotid artery, spine, and esophagus (□ Fig. 33.3). The ease of this step depends on the size of the gland, the extent to which the gland wraps posterior to the esophagus, and the degree of inflammation. In most cases, this can be achieved by using careful and patient blunt dissection with a Kelly clamp or Kittner (peanut) sponges. Once the esophagus is freed from the gland, the tracheoesophageal groove is exposed.

The recurrent laryngeal nerve ascends in the tracheoesophageal groove. On the left side, it wraps around the aortic arch, and on the right, it wraps around the subclavian artery before ascending in the tracheoesophageal groove. Because of this anatomical difference from side to side, the right recurrent laryngeal nerve is typically more lateral and superficial in position than the left. Non-recurrent laryngeal nerves occur mostly on the right side and are associated with arteria lusoria (in which the right subclavian artery originates from the aortic arch and passes posterior to the esophagus). Left sided non-recurrent laryngeal nerves are associated with dextrocardia.

Some surgeons find the recurrent laryngeal nerve at the level of the inferior thyroid artery and trace it superiorly to the Berry ligament (posterior suspensory ligament; □ Fig. 33.5). In this region, the nerve is found in the recurrent nerve triangle bound by the carotid artery laterally, trachea medially, and thyroid gland superiorly. The branches of the inferior thyroid artery are not ligated until the recurrent laryngeal nerve and all of its branches are identified and protected. The location of the recurrent laryngeal nerve is more variable in this low position, and a longer segment of the nerve needs to be dissected when this technique is used.

Alternatively, careful blunt dissection in the tracheoesophageal groove can be performed to further medialize the thyroid lobe until the area of the Berry ligament is reached without finding the nerve in the low position. In the high region, the superior parathyroid gland is often overlying the recurrent laryngeal nerve (see □ Fig. 33.4). If this technique is used, great

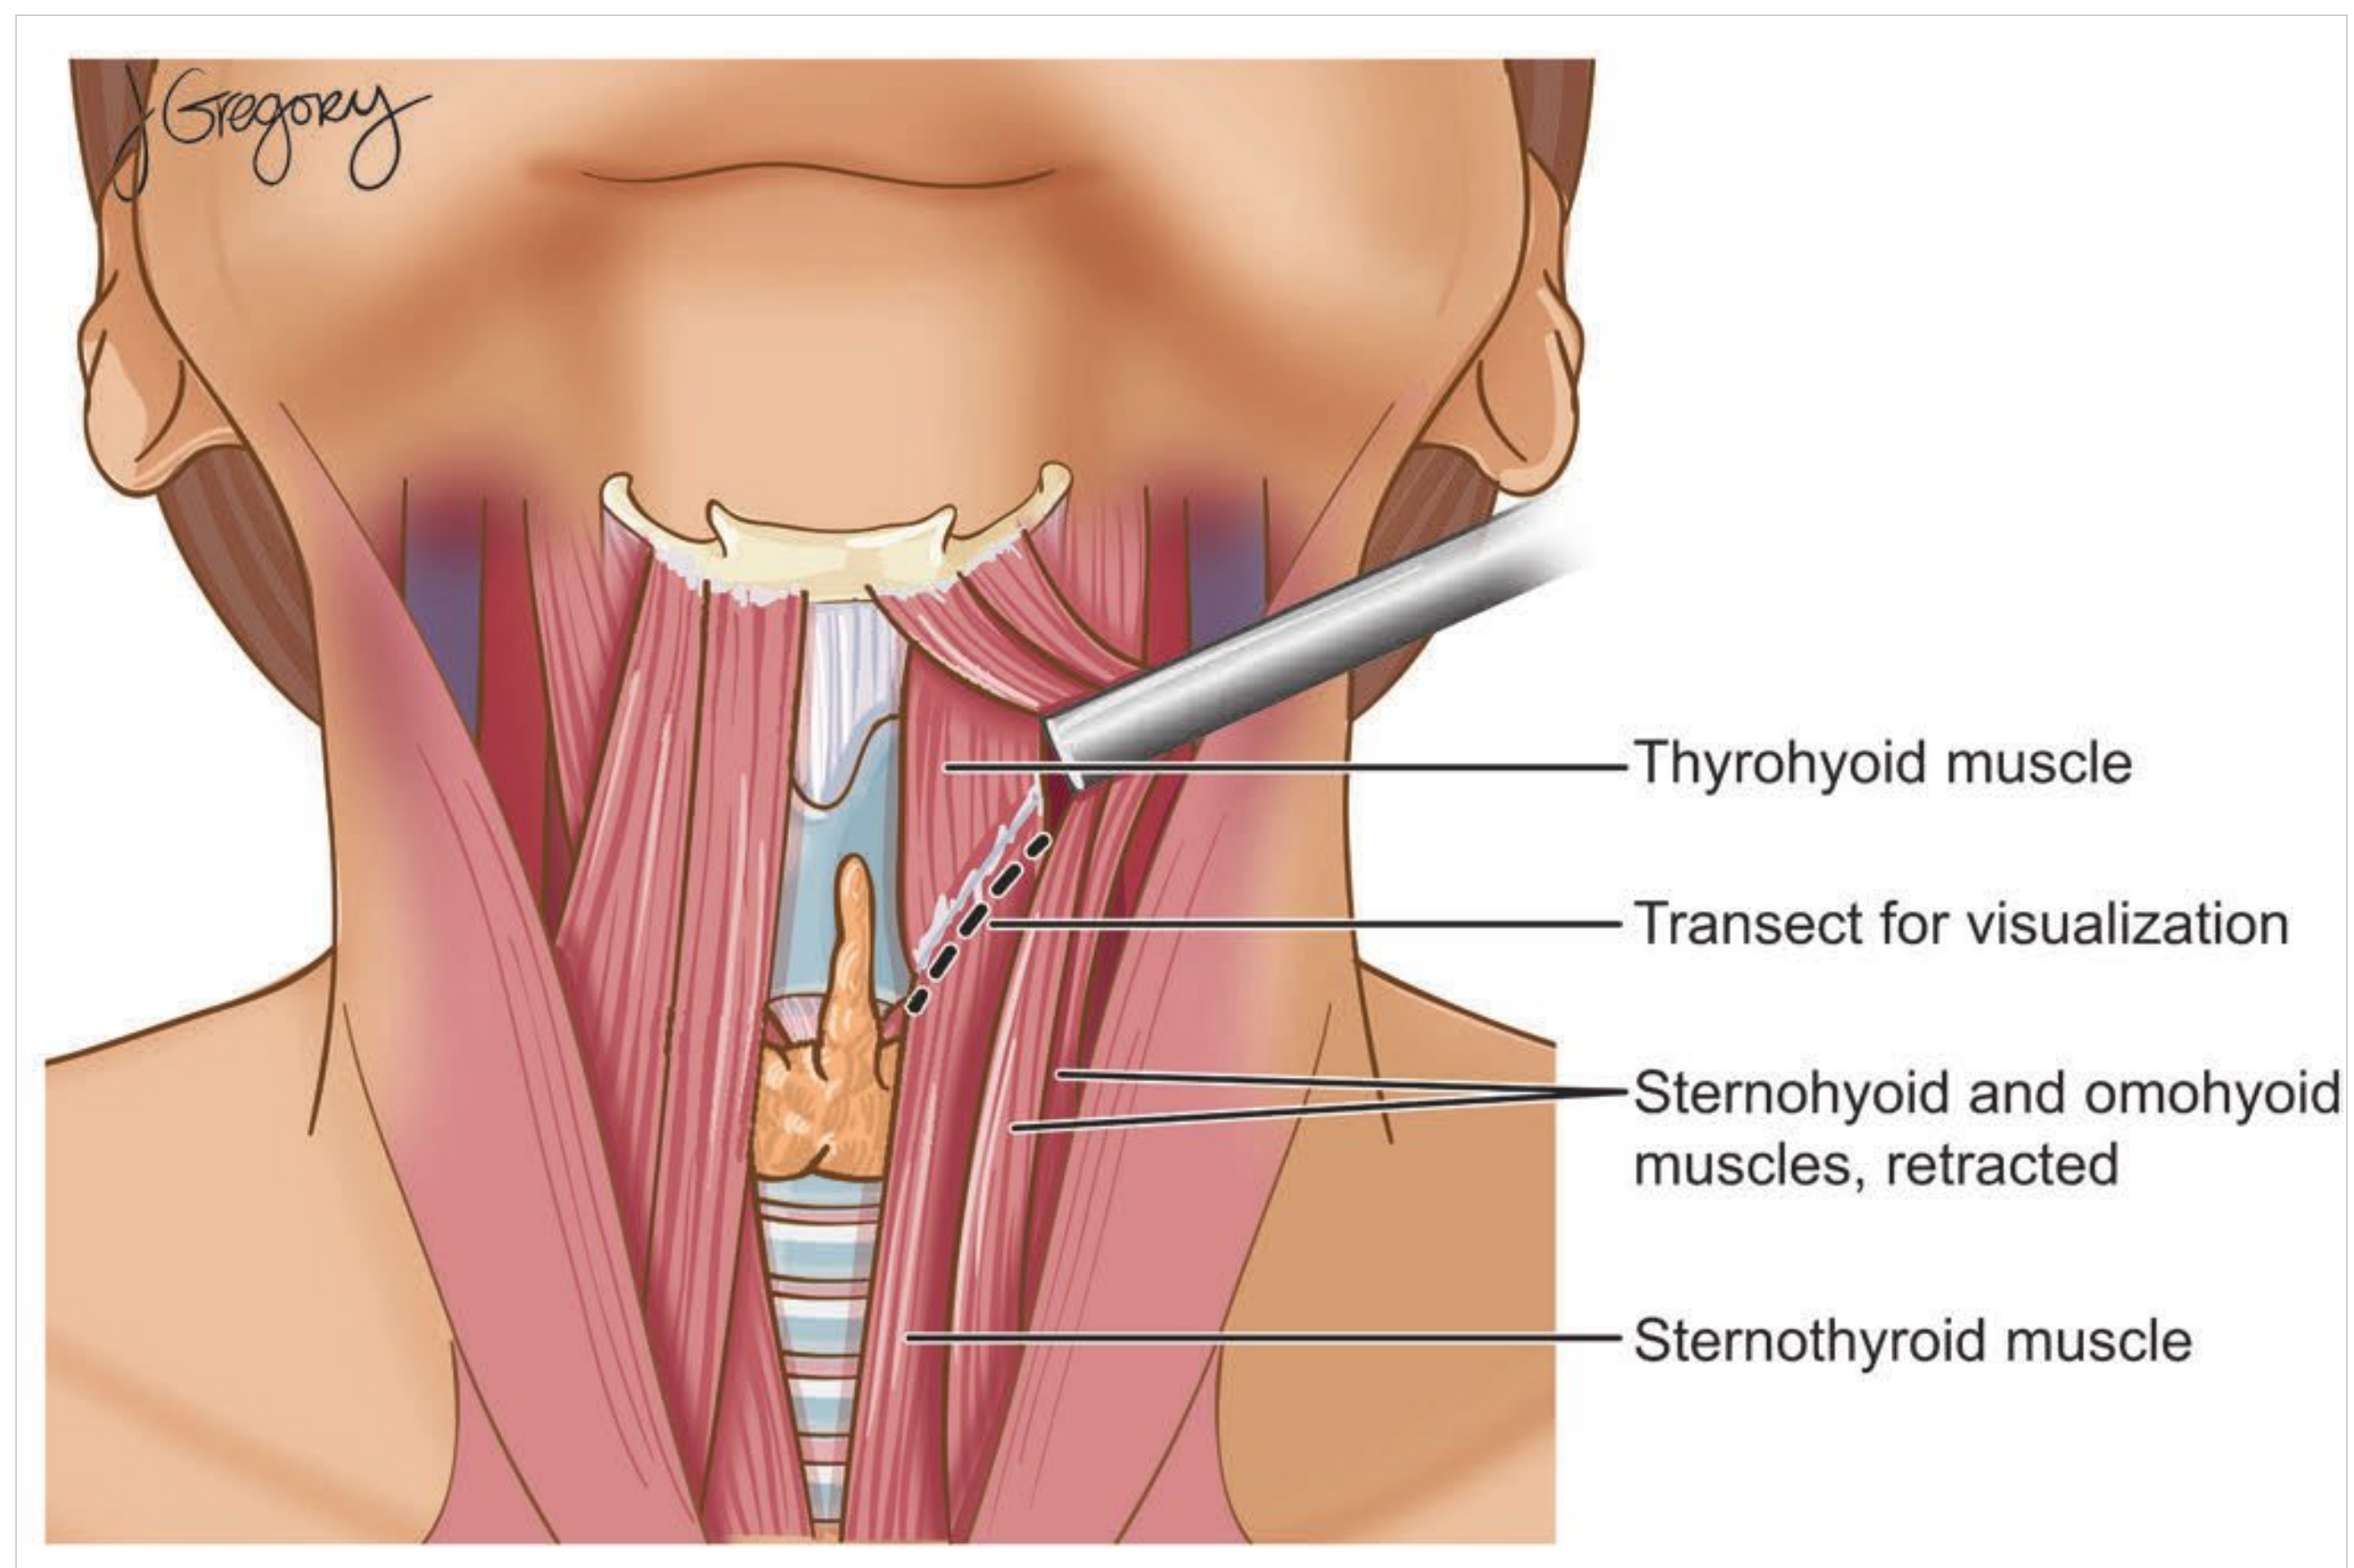

Fig. 33.1 Initial dissection of the strap muscles. The strap muscles are divided in the midline and dissected away from the thyroid gland. Sometimes, it is necessary to transect the medial aspect of the superior attachment of sternothyroid muscle to the thyroid cartilage to allow better exposure.

care must be taken to dissect the superior parathyroid gland away from the thyroid gland without devascularizing it and without damaging the recurrent laryngeal nerve. Even bipolar cautery must be used with great caution in this area because of the proximity of the parathyroid blood supply and the recurrent laryngeal nerve. Care must be taken to peel the parathyroid gland off the thyroid gland along its medial aspect to avoid damage to blood supply (□ Fig. 33.5). The parathyroid gland is often identified and dissected free from the recurrent laryngeal nerve before the recurrent laryngeal nerve is identified. On occasion, the superior parathyroid gland is within the capsule of the thyroid gland, and dissection beneath the capsule is needed to free it. In all cases, the inferior thyroid artery is not ligated until the recurrent laryngeal nerve is identified and protected.

With either approach, once the recurrent laryngeal nerve is identified, it is traced superiorly and the Berry ligament is divided. The recurrent laryngeal nerve enters the larynx posterior to the cricothyroid joint, which can be identified on palpation as the region just below the inferior cornu of the thyroid cartilage. The nerve is dissected and protected all the way to its entrance into the larynx. The recurrent laryngeal nerve frequently branches before entering the larynx, and all of the branches need to be carefully protected. The fibers of the Berry ligament can be very adherent in the region of the cricothyroid joint, so great care is needed to divide these fibers without damage to the nerve. Often, there are small terminal branches of the

inferior thyroid artery that run superficial and parallel to the recurrent laryngeal nerve. These vessels can lead to troublesome bleeding and increased risk for recurrent laryngeal nerve injury if they are not ligated appropriately. Cautery cannot be used in this region, and some surgeons advocate the use of cotton pledgets soaked in epinephrine.

The recurrent laryngeal nerve is traced inferiorly, and the branches of the inferior thyroid artery are divided close to the inferior portion of the thyroid gland. Hugging the inferior pole of the thyroid gland minimizes the risk for damage to the blood supply to the inferior parathyroid glands.

Dissecting the Superior Pole

The superior pole of the thyroid and the trachea can be separated by using blunt dissection. Few blood vessels cross this area, and in most patients this is a bloodless plane (□ Fig. 33.6). In this space, the external branch of the superior laryngeal nerve can be encountered (□ Fig. 33.7). Most surgeons prevent injury to the external branch of the superior laryngeal nerve by avoiding it without identifying it. Some surgeons report identification of the external branch of the superior laryngeal nerve in 80% of cases and believe it is safer to attempt to identify it in every case. The external branch of the superior laryngeal nerve can run superficial to, through, or deep to the inferior constrictor muscle. When it is deep to the muscle, it cannot be identi-

Fig. 33.2 Identification of the middle thyroid veins and dissection of the lateral aspect of the thyroid lobe. Once the strap muscles are elevated, the middle thyroid vein(s) need to be identified and carefully ligated close to the thyroid capsule. Identification of the middle thyroid veins requires enough medial and lateral retraction to stretch the veins slightly without enough traction to avulse them. Novice thyroid surgeons often will not retract the thyroid gland and trachea enough to develop the surgical space to identify these veins.

fied. When it is superficial or pierces the inferior constrictor muscle, it can be identified. Stimulation of the external branch of the superior laryngeal nerve provokes a brisk response in the cricothyroid muscle. We dissect the superior pole by hugging it closely and ligating only structures that are clearly entering the superior pole of the thyroid and appear vascular. Any structures that we think may be the external branch of the superior laryngeal nerve are stimulated and dissected away from the thyroid if possible, particularly any structures that cross toward

the larynx as they run inferiorly. Once the superior pole blood vessels are isolated and ligated, the remainder of the superior pole is freed with blunt dissection.

Removing the Thyroid Lobe

The medial portion of the thyroid lobe is dissected off the trachea, cricoid cartilage, thyroid cartilage, and cricothyroid muscle without damage to these structures. The pyramidal lobe

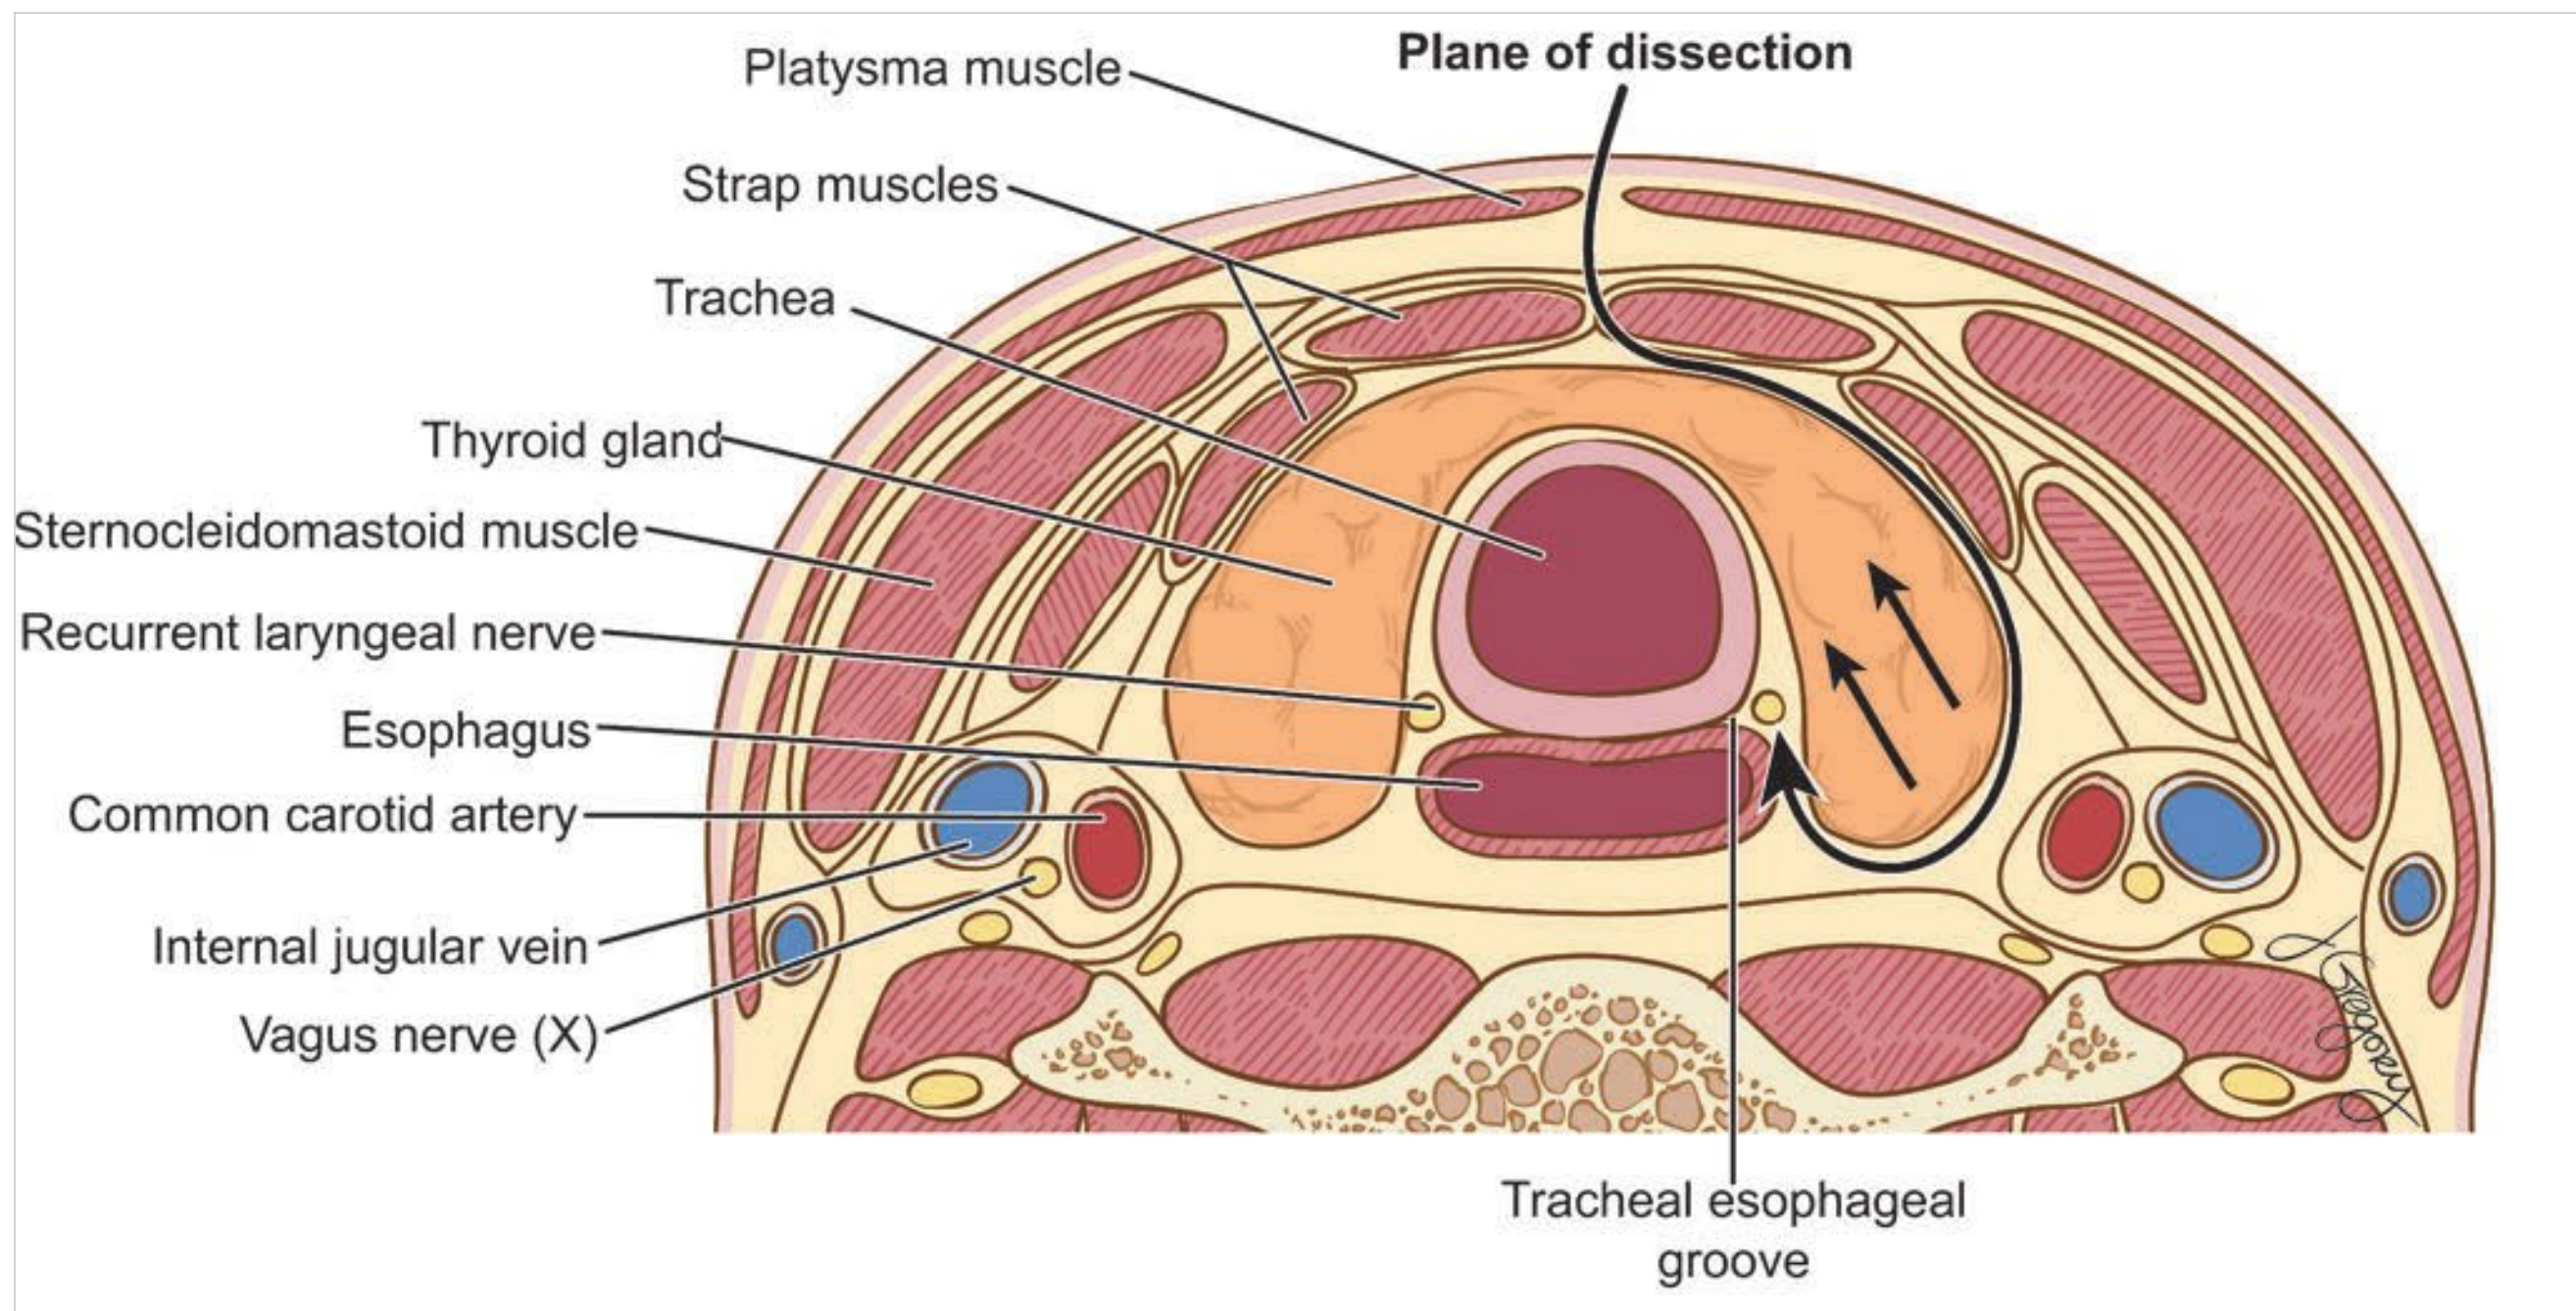

Fig. 33.3 Medialization of the thyroid lobe. The gland is retracted anteriorly and medially, and dissection is performed on the capsule of the thyroid gland to free it from the surrounding soft tissues, including the carotid artery, spine, and esophagus. The ease of this step depends on the size of the gland, the extent to which the gland wraps posterior to the esophagus, and the degree of inflammation. In most cases, this can be achieved by using careful and patient blunt dissection with a Kelly clamp or Kittner sponges (peanut). Once the esophagus is freed from the gland, the tracheal esophageal groove is exposed.

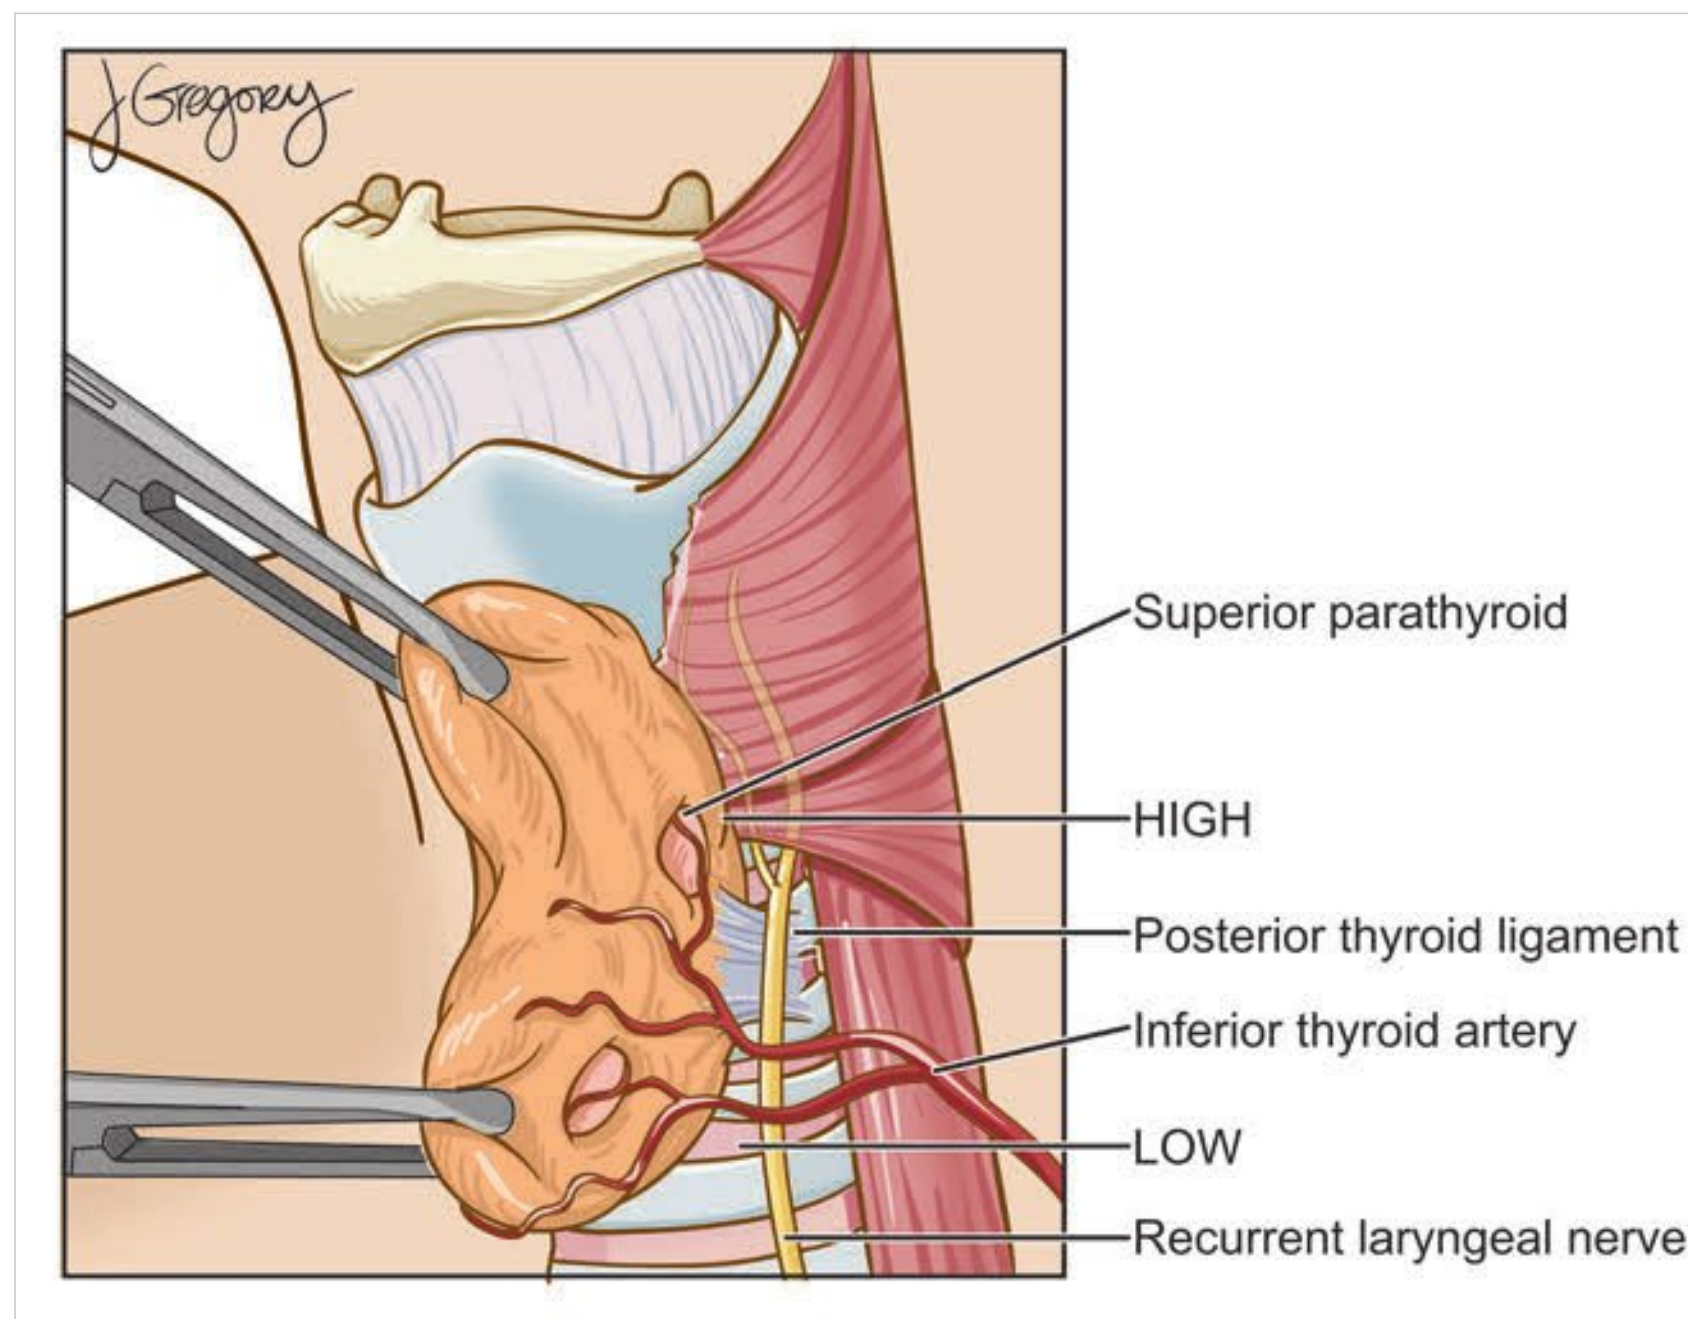

Fig. 33.4 Identification of the recurrent laryngeal nerve. The recurrent laryngeal nerve can be found at the level of the inferior thyroid artery (LOW) or in the region of the superior parathyroid gland and Berry ligament (HIGH). In the LOW region, the recurrent laryngeal nerve is found in the recurrent nerve triangle bound by the carotid artery laterally, trachea medially, and thyroid gland superiorly. To get to the HIGH region, careful blunt dissection in the tracheal esophageal groove is performed to further medialize the thyroid lobe until the area of the Berry ligament is reached without finding the nerve in the LOW position. In the HIGH region, the superior parathyroid gland is often overlying the recurrent laryngeal nerve. If this technique is used, great care must be taken to dissect the superior parathyroid gland away from the thyroid gland without devascularizing it and without damaging the recurrent laryngeal nerve.

of the thyroid extends superiorly in the midline, and its extent varies from patient to patient.

For a total thyroidectomy, we typically place the dissected thyroid lobe back into the surgical bed and then proceed to the contralateral lobe and repeat the same dissection.

For a thyroid lobectomy, the isthmus is divided closer to the opposite side. When a lobectomy is planned, we do not elevate the strap muscles on the opposite side because if a completion thyroidectomy is ever needed in the future, that dissection increases scarring and the difficulty of a second surgery.

Fig. 33.5 Anatomical relationship of the superior parathyroid gland to the recurrent laryngeal nerve. Dissection of the superior parathyroid gland must be done along its medial aspect to avoid damage to the lateral blood supply. The parathyroid gland is often identified and dissected free from the recurrent laryngeal nerve before the recurrent laryngeal nerve is identified. On occasion, the superior parathyroid gland is within the capsule of the thyroid gland, and dissection beneath the capsule is needed to free it.

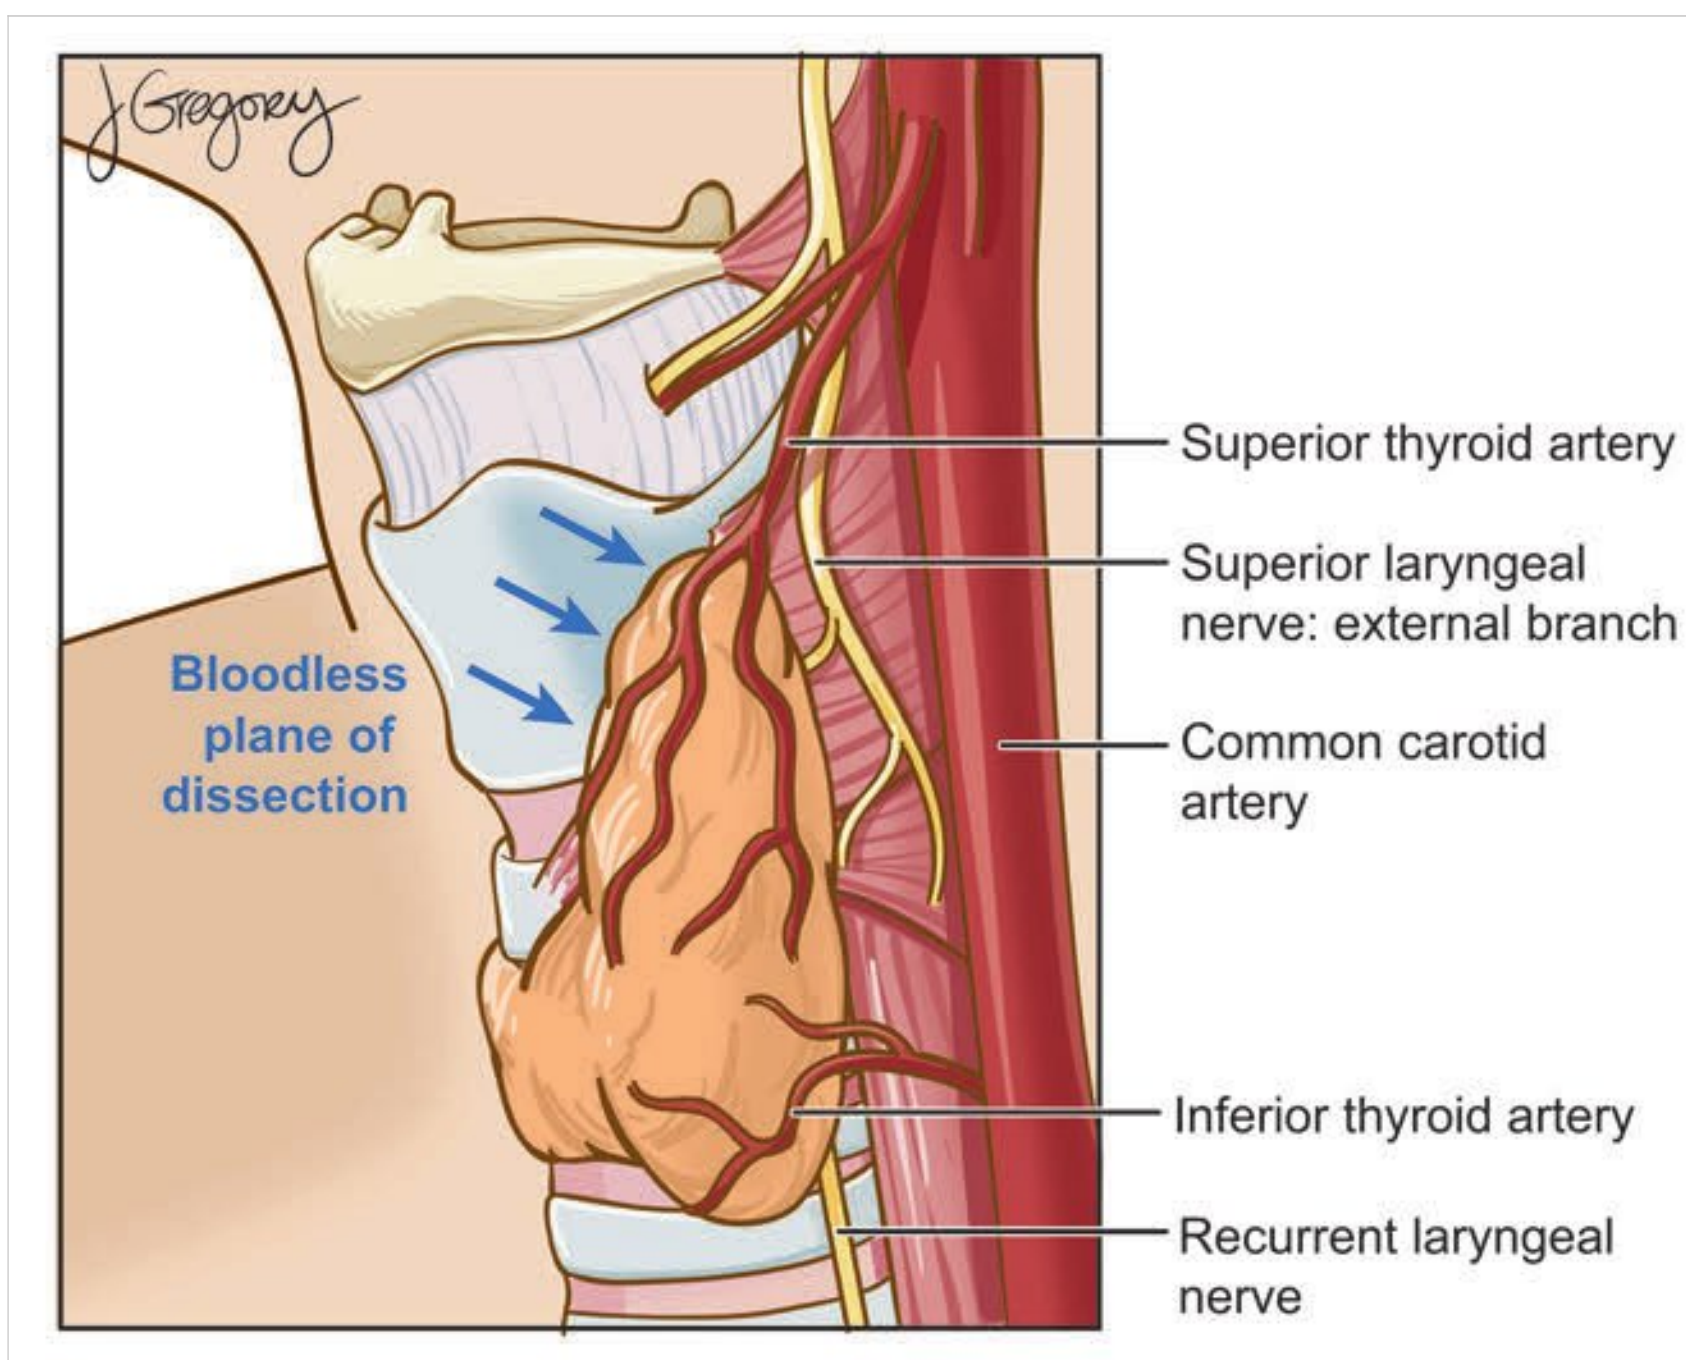

Fig. 33.6 Freeing the superior pole of the thyroid from the trachea. The superior pole of the thyroid and the trachea can be separated by using blunt dissection. Few blood vessels cross this area, and in most patients this is a bloodless plane. In this space, the external branch of the superior laryngeal nerve can be encountered.

33.2 Parathyroid Surgery

33.2.1 History

The parathyroid glands were first identified in 1850 by Richard Owen in an Indian rhinoceros at the London Zoo, and then in humans in 1887 by Ivar Sandstrom. Based on Sandstrom's work, Gley in 1890 noted that resection of the parathyroid glands in animals resulted in tetany, and MacCallum in 1909 explained the relationship of the parathyroid glands and calcium metabolism. Erdheim in 1907 reported the relationship of osteomalacia and parathyroid enlargement but explained this as being compensatory. Schlagenhauser suggested in 1915 that

parathyroid enlargement was the cause of bone disease, not a compensatory phenomenon, and recommended removal of the enlarged glands as treatment for bone disease. It was not until 1925 that Mandl reported the first resection of an enlarged parathyroid gland in a patient with severe bone disease, with dramatic results. Soon after, multiple centers reported success with the procedure.

33.2.2 Embryology

There are few surgeries in which an understanding of the embryology of the target tissue is more important than parathyroid surgery. Knowledge of the pattern of embryologic tissue

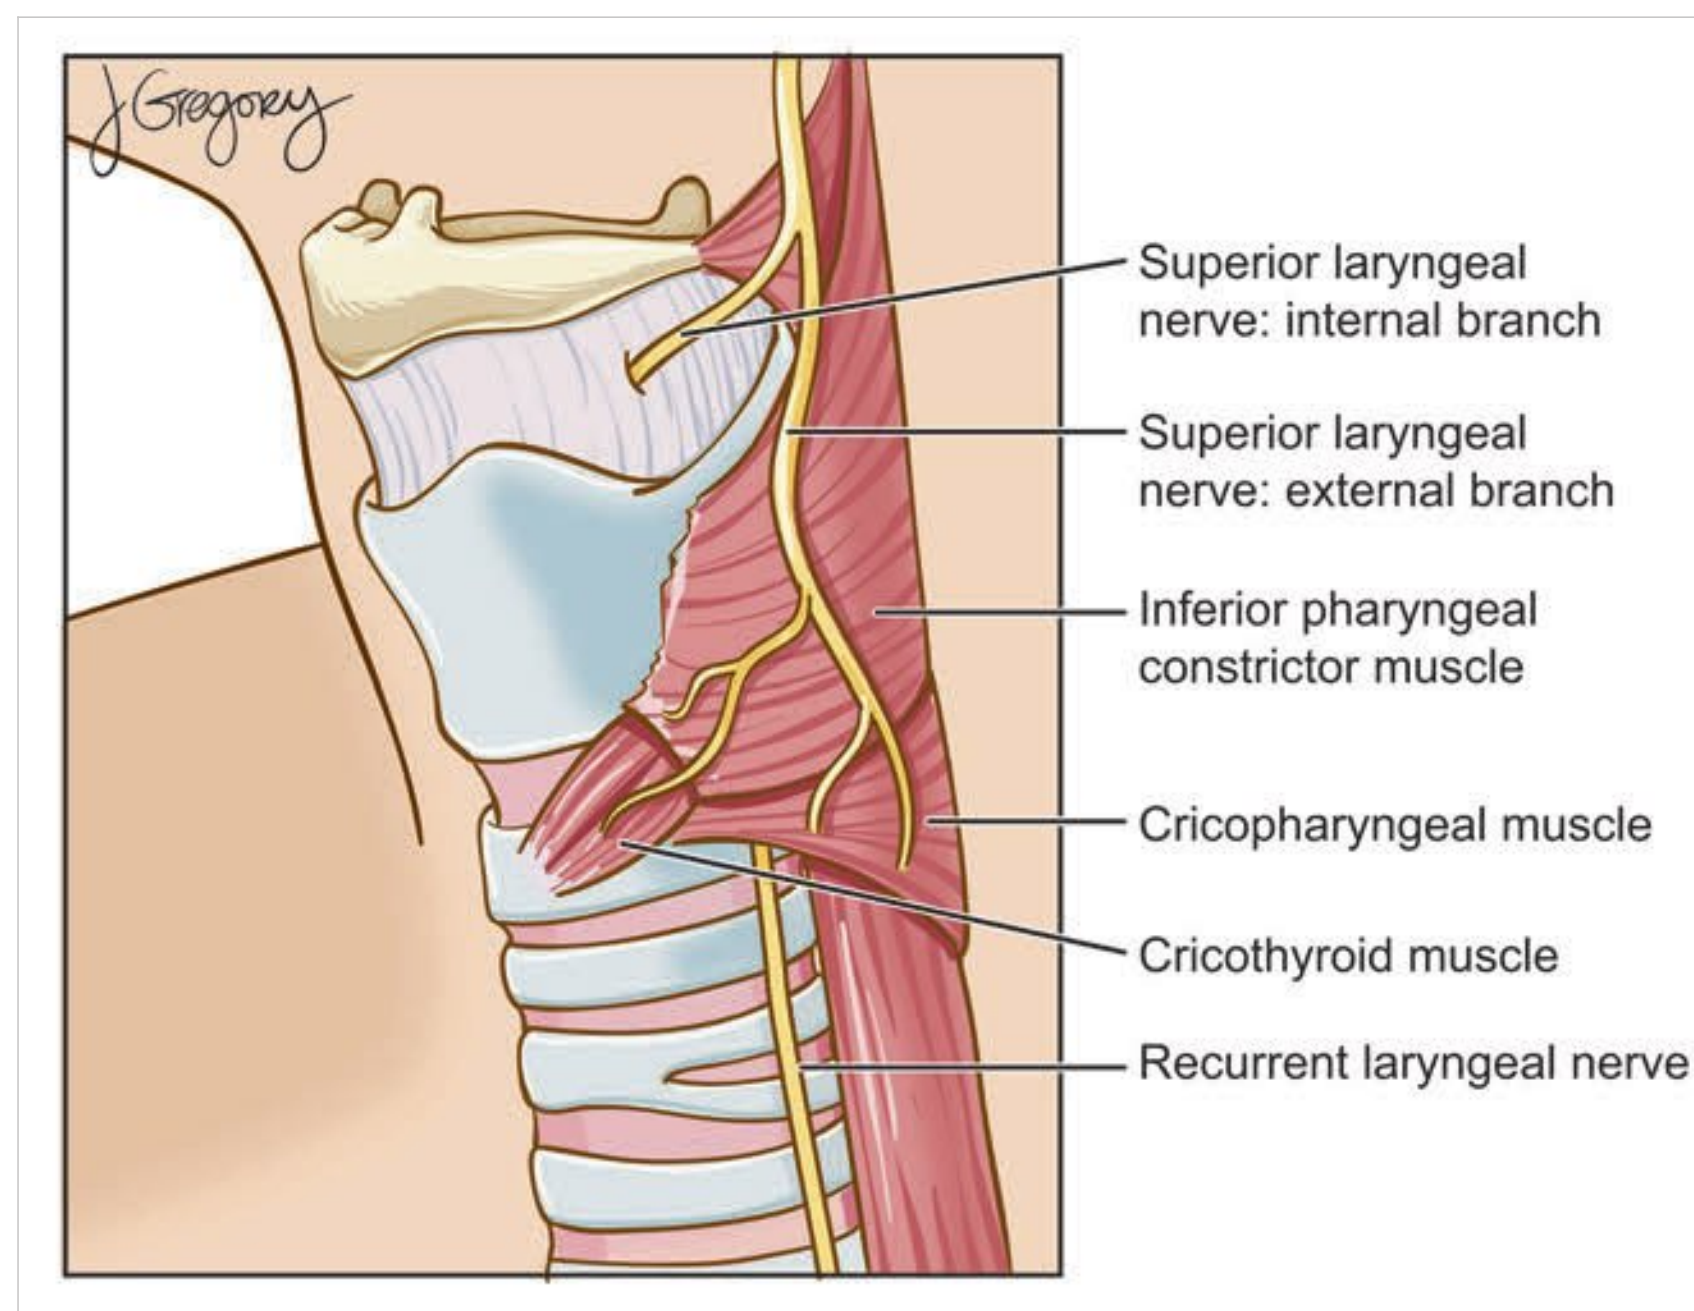

Fig. 33.7 Avoiding the superior laryngeal nerve. The external branch of the superior laryngeal nerve can run superficial to, through, or deep to the inferior constrictor muscle. When it is deep to the muscle, it cannot be identified. When it is superficial or pierces the inferior constrictor muscle, it can be identified. When the blood vessels of the superior pole of the thyroid are ligated, the external branch of the superior laryngeal nerve must be avoided. Stimulation of the external branch of the superior laryngeal nerve provokes a brisk response in the cricothyroid muscle, and this can be used to determine the location of the nerve before vessel ligation.

migration is essential in predicting the possible location of normal and ectopic parathyroid glands. The glands arise from the endoderm of the third and fourth branchial pouches. Differentiation occurs at the 8- to 10-mm stage. The inferior parathyroid glands arise from the third branchial pouch, as does the thymic tissue. The superior glands arise from the fourth branchial pouch. The fourth and fifth pouches combine, forming the caudal pharyngeal complex from which the ultimobranchial bodies of the lateral thyroid gland arise. These structures then migrate inferiorly.

The inferior parathyroid glands separate from the thymus to rest at the inferior pole of the thyroid gland, and the superior parathyroid glands come to rest at the posterior-lateral aspect of the middle one-third of the thyroid gland. The longer migratory course of the inferior parathyroid glands compared with the superior glands explains the greater variability in the final location of the inferior glands. The inferior parathyroid glands can be found anywhere from the angle of the mandible to the pericardium (□ Fig. 33.8). The inferior parathyroid glands are adjacent to the inferior pole of the thyroid gland 61% of the time, in the thyrothymic ligament or superior thymus 26% of the time, and bordering the middle one-third of the thyroid lobe 7% of the time; less frequently, they can be located more superiorly. The superior parathyroid glands are adjacent to or just above the superior one-third of the thyroid gland 85% of the time. If they are not in the typical location, they tend to descend in the retroesophageal space and can be as low as the posterior-superior mediastinum (□ Fig. 33.9). Intrathyroidal parathyroid glands are seen in 0.7% of cases.

33.2.3 Hyperparathyroidism

Primary hyperparathyroidism is diagnosed based on elevated serum calcium and parathyroid hormone levels (PTH). It is caused by a single adenoma in 80% of cases and a double adenoma in 2 to 5% of cases. Parathyroid hyperplasia is the second most common cause of primary hyperparathyroidism. In second-

Fig. 33.8 Inferior parathyroid glands. The inferior parathyroid glands lie within 1 cm of the inferior pole of the thyroid gland in 61% of cases and in the thyrothymic ligament or superior thymus in 26% of cases.

dary hyperparathyroidism, an elevated serum parathyroid level is present in response to low serum calcium levels. This is most commonly due to chronic renal disease and often can be treated medically. Tertiary hyperparathyroidism results from

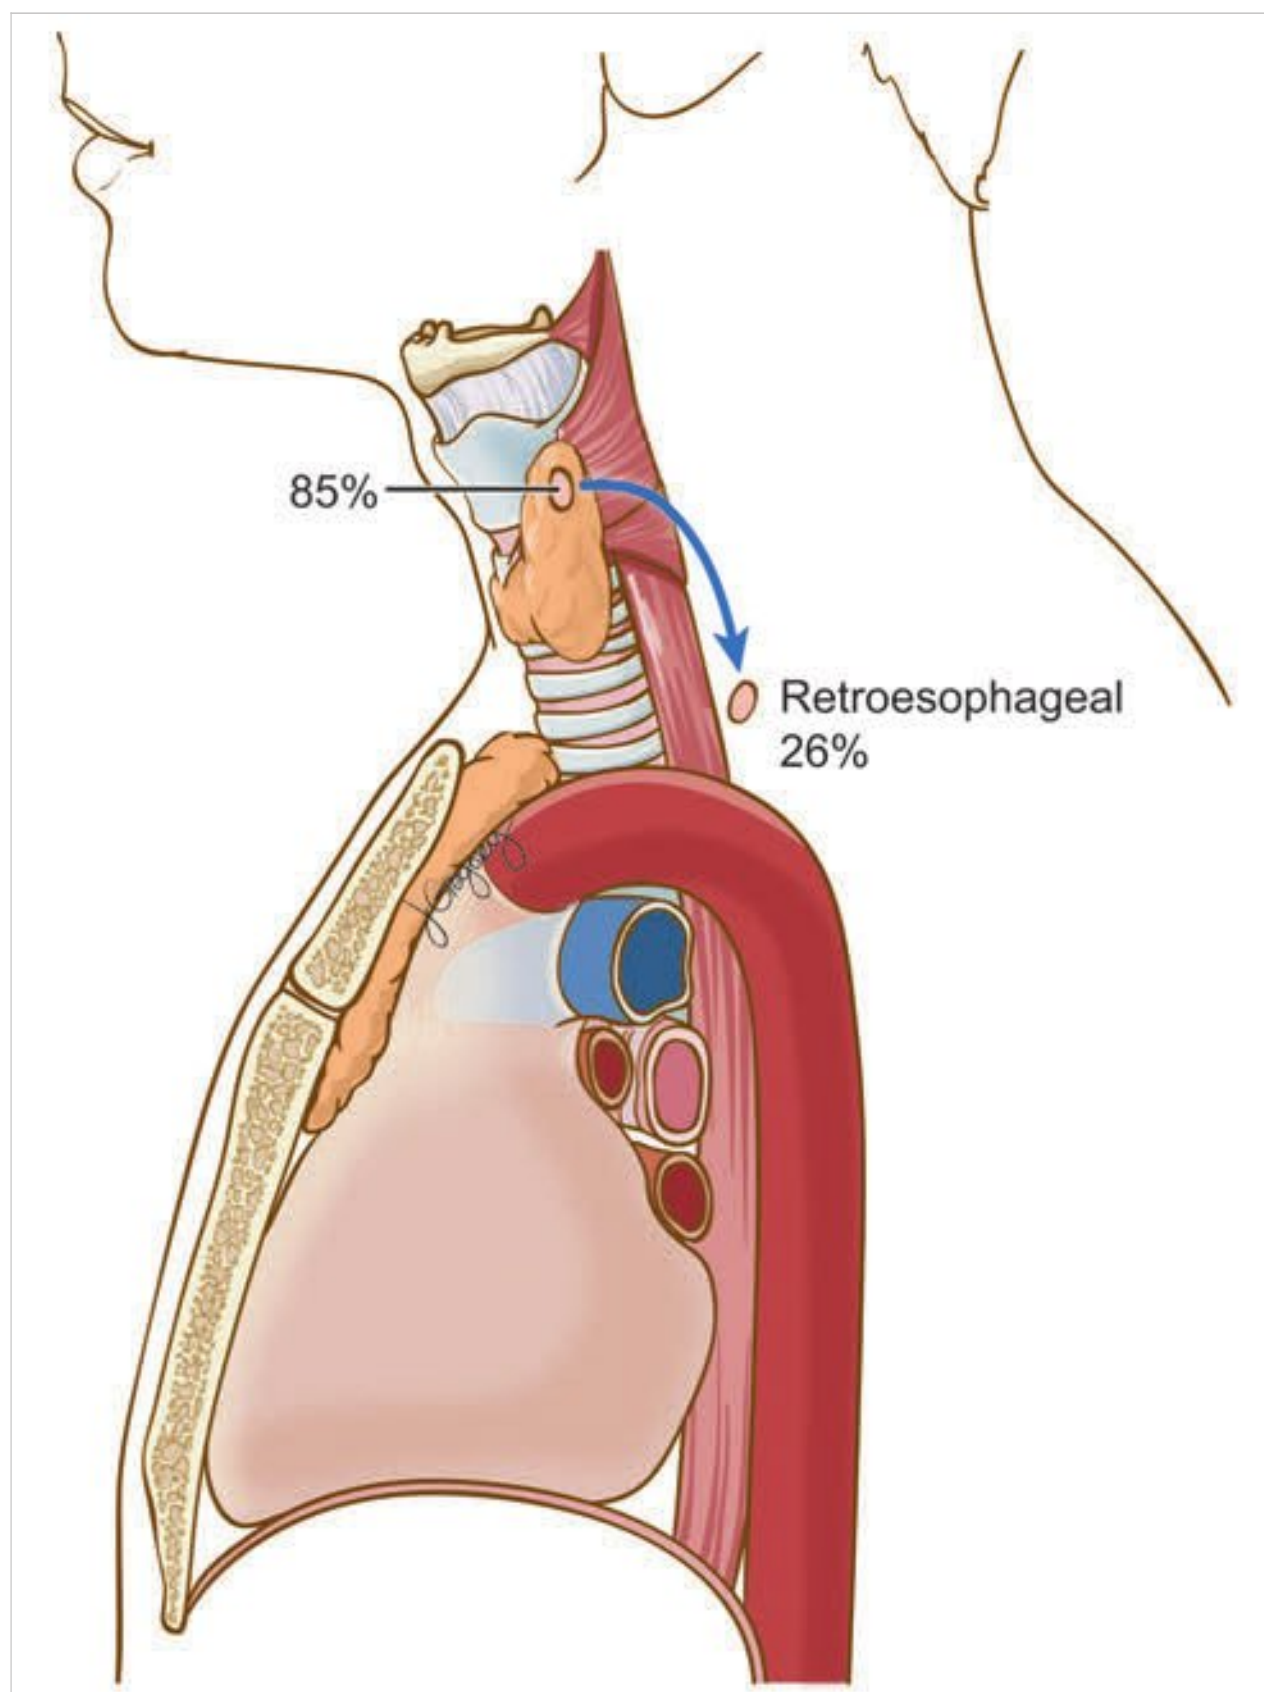

Fig. 33.9 Superior parathyroid glands. The superior parathyroid glands are adjacent to or just above the superior one-third of the thyroid gland 85% of the time. If they are not in the typical location, they tend to descend in the retroesophageal space and can be as low as the posterior–superior mediastinum.

the autonomous secretion of PTH related to long-term overstimulation in secondary hyperparathyroidism.

Traditionally, the complaints of patients with hyperparathyroidism included “stones, bones, and groans” secondary to nephrocalcinosis, osteitis fibrosa cystica, bone resorption, muscle weakness, and psychiatric disorders. Although neuropsychiatric abnormalities such as depression, anxiety, and cognitive disorders have been attributed to hyperparathyroidism, it has not been clearly shown that these conditions are relieved following surgical correction of the endocrinopathy. Although most patients today are asymptomatic at presentation, kidney stones are the most common clinical manifestation of the disease. The peak incidence is between 50 and 60 years of age, and women are three times more likely to be affected than men.

33.2.4 Indications for Parathyroid Surgery

Primary Hyperparathyroidism

The indications for parathyroid surgery are fairly well established based on workshop consensus statements, most recently from 2008:

1. Elevated serum calcium level to 1.0 mg/dL above the upper limit of normal

2. Creatinine clearance rate below 60 mL/min
3. Tscore below -2.5 for bone mineral density at any site and/or previous fragility fracture
4. Age younger than 50 years
5. Pregnancy (hyperparathyroidism can cause agenesis of the fetal parathyroid glands)
6. History of kidney stones
7. Symptoms: bone pain, neurocognitive disorder

Secondary Hyperparathyroidism

Surgery for secondary hyperparathyroidism is estimated to be needed in only 0.5 to 1.5% of patients based on improvements in medical management with calcimimetic medications like cinacalcet. For the few patients who fail calcimimetic therapy, the surgical guidelines are not well established. General indications for surgery are as follows:

1. Elevated PTH levels (500 to 800 pg/mL)
2. Severe osteoporosis
3. High bone turnover as demonstrated by bone metabolic markers, bone scintigraphy, or biopsy
4. Hypercalcemia
5. Enlarged parathyroid glands on ultrasound
6. Uncontrolled hyperphosphatemia
7. Ectopic calcification
8. Anemia resistant to erythropoietin

Tertiary Hyperparathyroidism

Renal transplant cures most patients of secondary hyperparathyroidism by correcting the metabolic abnormalities responsible for the disease. However, about 25% of patients have tertiary hyperparathyroidism with persistently elevated PTH levels at 1 year after transplant.

33.2.5 Localization Studies

The rate of failure to cure hyperparathyroidism after surgery has been stated to be as high as 5 to 10% in many series. Causes of failure include ectopic glands, multiple adenomas, and multiglandular hyperplasia. Preoperative localization studies to identify hypersecreting glands are performed in an attempt to decrease the incidence of surgical failure. The validity of the often-repeated aphorism that “the only localization study needed by a patient undergoing initial parathyroid surgery is to locate an experienced parathyroid surgeon” has been challenged by advances in parathyroid imaging and intraoperative rapid PTH monitoring. These advances have promoted the widespread acceptance of minimal access parathyroid surgery.

Technetium Sestamibi

Scanning with technetium Tc 99m sestamibi is the most commonly used localization study. The radioactively labeled sestamibi is absorbed by both parathyroid and thyroid tissue. Parathyroid tissue is distinguished from thyroid tissue based on the higher rate of washout in the thyroid gland relative to the parathyroid glands. Persistent uptake 2 to 3 hours after injection of the sestamibi corresponds to parathyroid tissue.

Both normally located and ectopic adenomas can be localized. The reported sensitivity for single adenomas is between

85% and 100% which drops to 37% for multiple adenomas. The sensitivity for hyperplastic glands is 62%. The sestamibi localizes in mitochondria, and the lower concentration of mitochondria-rich oxyphil cells in hyperplastic glands than in adenomas explains the decreased sensitivity in hyperplastic tissue. Multinodular thyroid disease also can confound the findings. The surgeon should always personally review the sestamibi scans, particularly negative scans, because the findings can be too subtle for the radiologist to make a definitive reading.

In addition to preoperative localization, ^{99m}Tc -sestamibi is used to determine the completeness of surgical resection without the need to wait for intraoperative PTH levels. Dr. James Norman and his associates inject patients with sestamibi just before surgery and use a gamma probe to quantify the amount of PTH each gland is producing. According to the “Norman rule,” when the radioactivity in the resected gland is at least 20% of the excision site/background radioactivity, a solitary parathyroid adenoma is confirmed, with no further identification of other parathyroid glands necessary. Their data show that all solitary parathyroid adenomas contain radioactivity that is at least 18% of the excision site/background radioactivity, with the levels in most much higher. Hyperplastic glands always contain less than 16%. In 87% of patients, excised glands have radioactivity levels that are more than 20% of the excision site/background radioactivity, allowing the immediate confirmation of surgical cure.

Negative ^{99m}Tc -sestamibi scans occur with regularity and can deter endocrinologists and surgeons from pursuing surgical cure for parathyroid disease. Dr. Norman argues that negative scans are as useful as positive scans, if done well, and indicate that the abnormal gland is not outside the normal location for parathyroid glands. In his experience, the negative parathyroid scan almost always guarantees that the abnormal parathyroid gland is in a favorable location behind or around the thyroid.

Ultrasound

The accuracy of ultrasound is operator-dependent. In recent years, surgeon-performed ultrasound of the neck has gained widespread acceptance. The parathyroid glands are seen as a homogeneous, well-demarcated mass with lower echogenicity than that of thyroid tissue. Ultrasound has a reported sensitivity of 85% and a specificity of 94% for adenomas, and a sensitivity of 69% for hyperplasia. The identification of ectopic glands is limited because these often occur in areas that are not well visualized with ultrasound, such as the mediastinum and retroesophageal areas.

Ultrasound can be used to perform guided fine-needle aspiration biopsies to confirm the presence of parathyroid tissue. Aspirated samples can be sent for cytology, but a much more sensitive test for parathyroid tissue is PTH washout. The aspirated needle is washed with 2 mL of saline, and this is sent to the laboratory for a determination of PTH levels. Generally, a PTH level higher than the serum PTH level indicates parathyroid tissue.

Computed Tomography

This modality is particularly useful in the localization of ectopic glands. When used, the studies should be done with contrast

and thin cuts (3 to 5 mm). For adenomas, the sensitivity is 50% and the specificity is 98%. The sensitivity for hyperplasia is 40%

Magnetic Resonance Imaging

This modality is also useful in the identification of ectopic glands. Adenomas have increased T2 signal and are isointense on T1 sequences. Sensitivities of 78% for adenomas and 90% for ectopic mediastinal adenomas have been reported. The sensitivity is 71% for hyperplastic glands.

Single photon emission computed tomography (SPECT) and positron emission tomography (PET) have also been proposed as helpful localizing techniques but are not as widely used as the techniques discussed above.

Methylene Blue Injection

An intravenous injection of saline-diluted methylene blue given intraoperatively can help identify abnormal parathyroid glands as a result of absorption of the dye, which stains the glands blue. The recommended dose is 5 to 7.5 mg/kg. The mechanism of this action is not understood, but it can be a useful adjunct in the arsenal of a parathyroid surgeon. The administration of methylene blue should be avoided in patients taking selective serotonin reuptake inhibitors because neurologic side effects have been reported.

33.2.6 Surgical Considerations

The basic steps of a parathyroid exploration are the same as those for a thyroid lobectomy, as described earlier in this chapter. We generally use electrophysiologic monitoring of the recurrent laryngeal nerve and intraoperative PTH assays during all of our surgeries. Although some surgeons use a lateral approach to the parathyroid glands, dissecting between the anterior border of the sternocleidomastoid muscle and the lateral border of the strap muscles, we generally use a medial approach for an initial exploration. Meticulous hemostasis and strict adherence to the principle of dissection along natural tissue planes cannot be overstressed. Blood staining of tissue will complicate identification of the parathyroid glands, as well as other structures, such as the recurrent laryngeal nerves and the fine blood vessels that supply the glands. The parathyroid glands are often described as tan to reddish in color, with an oval shape. A normal gland weighs between 20 and 50 mg.

Once the thyroid lobe is dissected laterally, it is delivered into the wound. Occasionally, the superior pole vessels require suture ligation, and the superior medial aspect of the sternohyoid muscle may need to be incised to aid in lateralization of the strap muscles and delivery of the thyroid lobe. If preoperative localization studies have identified an enlarged gland, the exploration begins at that site. If not, the exploration begins with a search for the glands in their most common anatomical locations as part of the primary survey. Each surgeon should develop an algorithm for exploration that is methodical and complete, approaching each procedure with the goal of finding all four of the parathyroid glands, whether in normal locations or ectopic. Once an obviously enlarged gland is identified and removed, we do not continue exploring and base the need for further exploration on the results of the intraoperative PTH assay.

If the PTH levels drop 50% and into the normal range, the surgery is concluded. If not, the exploration for a second adenoma or additional hyperplastic glands continues.

In a patient with a nonlocalizing preoperative work-up, we generally begin the exploration at the superior thyroid pole. Although not essential, dissection of the recurrent laryngeal nerve is often helpful in locating the superior parathyroid gland. The superior gland will be within 1 cm of the point of entry of the nerve into the larynx 85% of the time, lateral and deep to the nerve (see □ Fig. 33.9). The inferior gland is within 1 cm of the inferior thyroid pole 61% of the time, commonly inferior and deep to the thyroid gland and medial to the recurrent laryngeal nerve (see □ Fig. 33.8). If two normal glands are identified or if an enlarged gland is excised and the PTH level does not normalize, the exploration proceeds to the opposite side. Double adenomas are present in 2 to 5% of patients, with the second lesion contralateral 80% of the time.

If only one normal gland and no enlarged gland is identified, a secondary survey is undertaken. The secondary survey involves a sequential exploration of the common locations of ectopic glands. An upper parathyroid gland is likely to be, in decreasing frequency, in the area posterior and lateral to the upper lobe of the thyroid, in the retrolaryngeal/retroesophageal space, or above the upper pole of the thyroid (see □ Fig. 33.9). On rare occasions, it may be found in the carotid sheath or scalene fat pad.

For the inferior gland, secondary areas to be explored are the thyrothymic ligament and upper thymus gland, the lateral neck at the level of the inferior thyroid pole, the area medial to the inferior pole along the trachea, the lower thymic tissue in the anterior mediastinum, and finally, although much less commonly, the upper neck from the mandible to the hyoid and carotid bifurcation (see □ Fig. 33.8). If at this point the involved gland has not been identified, termination of the procedure should be considered. A thyroid lobectomy on the side of the missing gland is not recommended unless preoperative imaging studies show the presence of a nodular lesion within the thyroid. If the exploration is unsuccessful, further localization studies including selective venous sampling should be done postoperatively to determine the likely location of the missed adenoma.

In the presence of hyperplasia in multiple glands, the surgical treatment can be total parathyroidectomy with auto-transplantation of parathyroid tissue in the forearm or subtotal parathyroidectomy with preservation of a 20- to 50-mg parathyroid remnant. In choosing one technique over the other, the risk for autograft failure should be weighed against the risk for recurrent hyperparathyroidism and need for reexploration in a previously dissected neck. If a parathyroid remnant is preserved, it should be marked with a surgical clip at the time of the original surgery to aid its identification if the need for reexploration should arise.

33.3 Roundsmanship

- The four most common types of thyroid cancer are papillary, follicular, medullary, and anaplastic.
- Theodor Kocher, the “father of thyroid surgery,” won a Nobel Prize in Medicine and Physiology in 1909 for his work on thyroid and parathyroid physiology.

- The main indications for thyroid surgery are cancer, concern for cancer, symptomatic goiter, and hyperthyroidism.
- The Bethesda System for Reporting Thyroid Cytopathology divides the results of fine-needle aspiration biopsy of the thyroid into six categories: benign, malignant, nondiagnostic, neoplasm (either follicular or Hürthle cell), suspicious for malignancy, and follicular lesion of undetermined significance.
- The right recurrent laryngeal nerve is in a more lateral position than the left.
- Non-recurrent laryngeal nerves occur mostly on the right side and are associated with arteria lusoria (in which the right subclavian artery originates from the aortic arch and passes posterior to the esophagus).
- A left-sided non-recurrent laryngeal nerve is associated with dextrocardia.
- To preserve the blood supply to the superior parathyroid glands, the medial aspect of the parathyroid gland must be carefully peeled off the thyroid while the lateral blood supply is protected. Occasionally, the superior parathyroid gland is in the capsule or underneath the capsule of the thyroid.
- The external branch of the superior laryngeal nerve innervates the cricothyroid muscle, and it can lie in close proximity to the blood vessels of the superior pole of the thyroid.
- The superior parathyroid glands arise from the fourth branchial pouch and are typically adjacent to the upper one-third of the thyroid gland. They lie lateral and dorsal to the recurrent laryngeal nerve.
- The inferior parathyroid glands arise from the third branchial pouch and are typically adjacent to the inferior pole of the thyroid. They lie ventral and medial to the recurrent laryngeal nerve.
- For primary hyperparathyroidism, a drop in the PTH level of 50% into the normal range is indicative of surgical cure. Alternatively, with radioactivity-guided parathyroidectomy, radioactivity in the removed adenoma that is more than 20% of the excision site/background radioactivity indicates surgical cure.

34 Soft-Tissue Tumors of the Head and Neck

Mark S. Persky and Theresa N. Tran

34.1 Introduction

Head and neck soft-tissue tumors comprise a diverse group of benign and malignant lesions, ranging from vascular tumors with indolent behavior to locoregionally destructive soft-tissue sarcomas with a high potential for distant metastases. This chapter highlights the wide spectrum of these tumors, with an emphasis on their natural history, evaluation, and treatment.

34.2 Paraganglioma

34.2.1 The Disease Process

Paragangliomas are vascular tumors that arise from the extra-adrenal paraganglia derived from the neural crest. They most commonly occur in the head and neck region. These tumors are closely associated with either blood vessels (carotid artery, jugular bulb) or nerves (vagus, tympanic plexus). Paragangliomas are usually slowly growing tumors in which the growth pattern may be described as biphasic because the growth rate of very small and very large paragangliomas is slower than that of intermediate-size tumors.

Paragangliomas may occur in patients with familial multiple endocrine neoplasia (MEN), both type IIA (pheochromocytoma, medullary thyroid carcinoma, and parathyroid hyperplasia) and type IIB (also includes mucosal neuromas). A familial history of paragangliomas may be present, and there is a significant incidence of multicentric tumors in both familial and sporadic cases. Familial or hereditary paragangliomas have been reported to account for 5 to 10% of all cases of head and neck paragangliomas, although some report that they may account for up to 25 to 50% of cases. Most (90%) cases of hereditary paragangliomas involve the carotid body. If a familial history is present, there is a 78 to 87% possibility of multiple paragangliomas. The most common multicentric combination is that of two carotid body tumors (□ Fig. 34.1), which occurs in approximately 20% of patients with carotid body tumors.

Malignant paragangliomas are uncommon, and their diagnosis can be confirmed only by metastatic disease because histologic examination of the primary tumor is unreliable for establishing a diagnosis of malignancy. The prevalence of malignancy depends upon the site of the primary tumor, and there has been considerable variability in the reported frequency. The most common sites of distant carotid body tumor metastases are the bones, lungs, and liver. Malignancy is generally less common in familial paragangliomas than in sporadic cases. The most common sites of metastases for jugulotympanic paragangliomas are, in decreasing frequency, the lungs, lymph nodes, liver, vertebrae, ribs, and spleen. Although the reported rate of malignancy of vagal paragangliomas is as high as 19% a 10% frequency is most frequently accepted. Vagal paragangliomas probably have the highest rate of malignancy (16 to 19%) among the more common types of head and neck paragangliomas. Primary orbital and laryngeal tumors demonstrate the highest rate of malignancy (20 to 25%) of all head and neck paragangliomas.

Carotid Body Tumor

As the carotid body tumor grows, it tends to splay the carotid bifurcation and progressively involves the carotid adventitia. Classically, the internal carotid artery is displaced posteriorly and laterally (□ Fig. 34.2). With continued growth, the tumor extends superiorly along the internal carotid to the skull base and may cause bony erosion and/or affect adjacent cranial nerves, most commonly the vagus and hypoglossal nerves. Occasionally, the sympathetic chain is involved. Medial extension into the parapharyngeal space is reported in 20% of cases.

Jugular and Tympanic Paragangliomas

Tympanic paragangliomas arise from the paraganglia associated with the Jacobson and Arnold nerves. They may fill the middle ear cavity and extend posteriorly into the mastoid air cells or inferiorly to the jugular bulb. Jugular paragangliomas tend to spread along the paths of least resistance in multiple directions and gain access to various portions of the temporal bone and base of the skull neurovascular foramina. Progressive temporal involvement leads to posterior cranial fossa involvement. Intracranial extension can occur as posterior extension directly through the petrous bone, extension into and through the internal auditory canal, or infralabyrinthine extension. There is early intraluminal jugular extension into the sigmoid sinus and

Fig. 34.1 Axial computed tomographic scan with contrast revealing bilateral, markedly enhancing carotid body tumors.

Fig. 34.2 Axial computed tomographic scan with contrast showing posterolateral displacement of the internal carotid artery by carotid body tumor. CBT, carotid body tumor; ICA, internal carotid artery; IJV, internal jugular vein.

internal jugular vein, with possible growth into the inferior petrosal sinus. Tumor can invade the middle ear cleft, petrous apex, or mastoid and retrofacial air cells. Inferiorly, jugular paragangliomas may extend through the infratemporal fossa and post-styloid parapharyngeal space into the neck.

Vagal Paragangliomas

Vagal paragangliomas most commonly arise from the nodose (inferior) ganglion, although they may also originate from the middle and superior ganglia, and less frequently anywhere along the course of the vagus nerve. Compared with the discrete carotid body, the vagal paraganglia are distributed more diffusely within the nerve or perineurium. Vagus nerve fibers “splay over” the surface of the vagal paraganglioma or, early in their development, enter the substance of the tumor; therefore, preservation of the vagus nerve is usually not possible with complete tumor resection.

Vagal paragangliomas have three basic patterns of spread. Because most vagal paragangliomas originate at the nodose ganglion, they tend to spread inferiorly into the post-styloid parapharyngeal area. Extension superiorly toward the skull base in the area of the jugular foramen results in early involvement of the internal jugular vein and adjacent cranial nerves (IX, XI, XII). The tumor causes early anterior displacement of the internal carotid artery. Vagal paragangliomas

originating from the superior ganglion have a greater chance of assuming a “dumbbell” form with posterior cranial fossa tumor, in addition to extending into the parapharyngeal space inferiorly.

34.2.2 Evaluation

Carotid Body Tumor

The median age of patients at presentation for carotid body tumors is 45 to 54 years, with a range from 12 to 78 years. Most series report a female predominance of approximately 2:1. The most common presenting symptom of a carotid body tumor is a neck mass located at or superior to the carotid bifurcation and deep to the sternocleidomastoid muscle. On palpation, it is vertically fixed and laterally mobile because of its fixation to the carotid artery, and it may be pulsatile. Bruits have been reported in 10 to 16% of cases. Pain is present in approximately 25% of cases. Medial extension into the parapharyngeal space has been reported and may cause submucosal bulging of the lateral oropharynx and medial displacement of the tonsils. Cranial neuropathies are present in approximately 10 to 30% of cases at presentation.

Jugular and Tympanic Paragangliomas

Tympanic paragangliomas occur most commonly during the sixth decade of life, have a marked female preponderance, and usually present with a conductive hearing loss, pulsatile tinnitus, and a mass behind the tympanic membrane. On otoscopic examination, a red–blue middle ear mass that blanches on positive pneumatoscopic pressure (Brown sign) may be present. Perforation of the tumor through the tympanic membrane may occur, producing a vascular “polyp” that may bleed spontaneously. Within the middle ear, continued growth results in ossicular involvement and a subsequent conductive hearing loss. Continued growth with vestibular involvement produces a sensorineural hearing loss, vertigo, and occasionally pain from the associated inflammatory response.

Jugular paragangliomas most commonly occur in the fifth and sixth decades of life and demonstrate a female-to-male ratio of 4:1 to 6:1. Extension into the middle ear results in symptoms similar to those of tympanic paragangliomas and may result in a conductive or sensorineural hearing loss, depending on the extent of vestibular involvement. Hearing loss (55 to 77%) and tinnitus (56 to 72%) are the most common presenting symptoms. Symptoms related to lower cranial nerve (VII through XII) deficits are also common. Tumors of the skull base without extensive middle ear extension may present with isolated tongue weakness, hoarseness, dysphagia, or shoulder drop or with symptoms of multiple cranial nerve dysfunction. The jugular foramen syndrome (cranial nerve IX, X, and XI palsy, or Vernet syndrome) is occasionally encountered, and cranial nerve IX through XII palsy (Collet-Sicard syndrome) occurs in approximately 10% of patients with jugular paragangliomas.

Vagal Paragangliomas

Vagal paragangliomas most commonly present as an asymptomatic mass of the upper neck, typically more cephalad than carotid body tumors. Vagal paragangliomas are slow-growing,

with a female-to-male preponderance of 2:1 to 3:1. As the tumor enlarges, it encroaches upon the lower cranial nerves and the adjacent sympathetic chain. Signs and symptoms include unilateral vocal cord paralysis, hoarseness, dysphagia, nasal regurgitation, atrophy of the hemitongue, shoulder weakness, and Horner syndrome. Hearing loss and pulsatile tinnitus are usually indicative of temporal bone extension.

Computed tomography (CT) and magnetic resonance (MR) imaging usually establish the diagnosis of paraganglioma. Imaging with indium In 111 pentetate (OctreoScan; Mallinckrodt Medical, Petten, The Netherlands) or fluorine F 18 dihydroxyphenylalanine (DOPA) positron emission tomography (PET) can also be used to evaluate paragangliomas, define multiple tumors, and detect the possible presence of metastatic disease. Angiography defines the vascular supply, may visualize vessel involvement (invasion), and paves the way for preoperative embolization, which is important if surgery is contemplated.

34.2.3 Treatment

Surgery

Traditionally, surgery has been the preferred method of treatment, especially with the evolution of more sophisticated approaches to the skull base, safer embolization protocols, and advanced vascular bypass procedures. However, postoperative cranial nerve dysfunction is anticipated in patients with those paragangliomas characterized by early neural involvement and skull base involvement, in whom surgery would require extensive rehabilitation efforts. The role of surgery should therefore be reevaluated as the primary treatment of choice for these slow-growing tumors. Some paragangliomas, especially very small ones, have been shown not to be progressive, and “wait and scan” management may be advisable. Relative contraindications to surgery include extensive skull base or intracranial involvement, advanced age of the patient, medical comorbidities, and bilateral or multiple paragangliomas for which surgery may result in the unacceptable postoperative morbidity of bilateral lower cranial nerve palsies.

If surgery is the chosen treatment course, preoperative embolization is often performed. There are major advantages in the use of combined endovascular embolization and subsequent surgery, assuming that certain criteria are fulfilled before embolization. Surgery is performed within 2 days of angiography and embolization in order to avoid recruitment of collateral tumor blood supply and before the onset of a significant postinflammatory effect. Short-term steroids are administered if there is concern about tumor edema that may compromise tumor dissection.

Radiation Therapy

Radiotherapy has traditionally been the treatment of choice for unresectable paragangliomas or those tumors in the medically infirm and elderly. However, radiotherapy has more recently been proved to be an effective therapeutic option and therefore should be considered as a form of primary treatment, especially in the setting of the significant potential morbidity that accompanies surgery for some tumors. Radiotherapy has been used

primarily to treat jugular paragangliomas of the temporal bone and less frequently for the treatment of carotid body or vagal paragangliomas. Radiotherapy is the preferred treatment option for advanced tumors. Stereotactic radiosurgery offers the possibility of a single, highly focused, small-field treatment with a steep dose gradient to maximally spare the surrounding normal tissue.

34.3 Juvenile Nasopharyngeal Angiofibroma

34.3.1 The Disease Process

Juvenile nasopharyngeal angiofibroma (JNA) is a highly vascular, histologically benign, but locally aggressive and destructive tumor that exclusively affects boys of adolescent age. It accounts for approximately 0.5% of all head and neck neoplasms. The etiology and pathogenesis of the disease remain to be elucidated. The tumor appears to originate in the posterior nasal cavity rather than the nasopharynx. Specifically, it develops in the posterolateral wall of the superior aspect of the nasal cavity, at the junction of the sphenoid process of the palatine bone, the horizontal ala of the vomer, and the root of the pterygoid process of the sphenoid bone, near the superior margin of the sphenopalatine foramen. These tumors are unencapsulated and consist of proliferating, irregular vascular spaces lined by a single endothelial layer. The channels lack a complete muscular layer between the endothelial cells and stromal cells and are therefore subject to severe bleeding.

At diagnosis, most angiofibromas have extended beyond the nasal cavity and nasopharynx, with anterolateral erosion of the posterior wall of the maxillary sinus and lateral growth into the pterygomaxillary fossa. Extension into the pterygomaxillary fossa can erode the pterygoid process of the sphenoid bone. Further lateral extension via the pterygomaxillary fissure can fill the infratemporal fossa and produce the classic bulging cheek. Tumor can extend under the zygomatic arch and cause swelling above the arch. From the pterygomaxillary fossa, the angiofibroma can erode the greater wing of the sphenoid bone and the middle cranial fossa and invade both the inferior and superior orbital fissures. Posterior extension into the sphenoid sinus through the floor or ostium fills the sinus, and extension farther superiorly fills the sella turcica. Tumor in the sella or orbit can cause loss of vision. These tumors typically grow by centrifugal expansion, not by invasion; therefore, they may be intracranial but are usually extradural. The cavernous sinus may be compressed but not invaded. Cranial nerve palsies are rare, even with large tumors. However, particularly aggressive angiofibromas may invade the cavernous sinus and threaten multiple cranial nerves, the internal carotid artery, hypophysis, and optic chiasm.

Despite its tendency to be invasive, the rate of growth of JNA is thought to be slow. Because the tumor is rarely seen in young adults, it is believed to regress spontaneously. However, because regression cannot be assumed, these tumors should be treated. The prognosis for patients with JNA is good with early diagnosis; unfortunately, the diagnosis most often is made during later stages of the disease because of the nonspecific and innocuous presenting symptoms of JNA. JNA is characterized by

Fig. 34.3 (a,b) Sagittal computed tomographic scan displaying anterior bowing of the posterior wall of the maxillary sinus, known as the Holman-Miller sign, which is diagnostic for juvenile nasopharyngeal angiofibroma. (b) Lateral subtracted angiogram of internal maxillary artery (arrow) revealing tumor hypervascularity of the angiofibroma.

high recurrence rates, reportedly as high as 30 to 50%. It is a benign disease that is not multifocal; therefore, recurrence usually reflects persistent disease.

34.3.2 Evaluation

JNA is typically found in adolescent males; patients range in age from 7 to 29 years, with a median age of 15 years at diagnosis. They classically present with the triad of unilateral nasal obstruction, recurrent severe epistaxis, and nasopharyngeal mass; other common but nonspecific symptoms are purulent nasal discharge due to infection secondary to obstruction, hyponasal speech, and anosmia. Nasal obstruction and epistaxis occur in more than 80% of patients. Symptoms may be present for months to years before the diagnosis is made. Delay in presentation and/or diagnosis can be attributed to the tendency to associate the indolent symptoms of JNA with more common entities, such as rhinitis, sinusitis, and nasal polyposis.

Examination often shows a red-gray, smooth, lobulated mass in the nasopharynx and/or posterior aspect of the nose. The overlying mucosa is rarely ulcerated unless the patient has previously undergone biopsy or therapy. Other signs include facial deformity, proptosis, palate extension, serous otitis media, and visual or auditory impairment. Neurologic deficits may be seen in patients who have angiofibromas with significant intracranial extension.

The radiographic findings of angiofibroma are characteristic. On CT scan, there is anterior bowing of the posterior wall of the maxillary sinus, known as the Holman-Miller sign, and enlargement of the superior orbital fissure, which are considered diagnostic for JNA (□ Fig. 34.3). CT is also ideal for localizing the tumor and useful in delineating the extent of the tumor. Magnetic resonance (MR) imaging is indicated in patients with intracranial extension. Angiography is not necessary in most patients but is useful in those whose diagnosis remains in question, usually those in whom previous treatment has failed. It

also is necessary for embolization, especially when surgery is anticipated.

34.3.3 Treatment

Surgery

The mainstay of treatment for JNA is surgery. The various surgical approaches are transpalatal, transnasal (including endoscopic), transantral, transmandibular, transzygomatic, combined craniotomy and rhinotomy, lateral rhinotomy, and mid-face degloving. Recurrence does not necessarily indicate the need for further treatment unless there are associated symptoms of bleeding, nasal obstruction, eye findings, or progressive growth as defined by radiographic studies.

The main blood supply of a JNA is from the internal maxillary artery; however, the thyrocervical trunk and the dural, sphenoidal, and ophthalmic branches from the internal carotid system can also contribute. Because of this extensive arterial supply, ligation of the external carotid artery before surgical excision does not help to decrease bleeding but instead may have the opposite effect by encouraging arterial collateralization from vessels that are less accessible or inaccessible. Techniques that have been used to decrease bleeding include preoperative embolization, ligation of the internal maxillary artery, electrocoagulation, and irradiation.

Radiation Therapy

Although surgery is considered to be the treatment of choice for JNA, the potential morbidity associated with the surgical resection of some extensive tumors makes radiation treatment a possible alternative. Radiotherapy is often considered an appropriate option for the treatment of recurrent angiofibromas. Lee et al reported 27 patients with extensive tumors who received radiation as the primary mode of treatment, with minimal

Fig. 34.4 Coronal computed tomographic scan demonstrating the usual location of olfactory neuroblastoma. Caret, intact skull base; asterisk, intact lamina papyracea.

complications and perhaps less risk for significant morbidity and mortality than that associated with surgical intervention. Long-term complications consist of growth retardation, panhypopituitarism, temporal lobe necrosis, cataracts, and radiation keratopathy.

34.4 Olfactory Neuroblastoma

34.4.1 The Disease Process

Olfactory neuroblastoma (also known as esthesioneuroblastoma) is an uncommon malignancy of neural crest origin arising in the olfactory epithelium of the nasal cavity. The cells of origin are presumed to be basal cells of the olfactory epithelium. Its histologic resemblance to undifferentiated small cell carcinoma can lead to a misdiagnosis. Neuroblastomas account for approximately 2 to 3% of all malignant nasal neoplasms and 0.3% of upper aerodigestive tract malignancies. No clear etiology for the development of olfactory neuroblastoma has been established.

Olfactory neuroblastomas are locally aggressive tumors that frequently invade the paranasal sinuses, skull base, and orbit. These tumors can be multicentric, with separate tumors above and below the cribriform plate and no gross or microscopic connection between the tumors. The location of this tumor, at the interface between the superior nasal cavity and anterior cranial fossa, leads to early involvement of the cribriform plate and allows rapid penetration into the anterior cranial fossa (□ Fig. 34.4).

Metastasis to cervical lymph nodes can be found, either at diagnosis or at regional recurrence many years after treatment. Reports of the overall incidence of cervical metastasis range from 10 to 33% and the incidence of distant metastasis ranges from 10 to 40% of patients, with the lungs, brain, and bones the most common sites. The overall 5- and 10-year survival rates for olfactory neuroblastomas are better than those for most

superior nasal vault malignancies and are estimated to be approximately 80% and 50%, respectively. Long-term endoscopic and MR imaging surveillance is mandatory because local, regional, and distant metastasis may be expected to occur for as long as 10 years or more after treatment.

34.4.2 Evaluation

Olfactory neuroblastomas can be found in patients ages 3 to 90 years. There is a bimodal distribution in age groups, with peaks at 11 to 20 years and at 51 to 60 years. Others have found a unimodal distribution concentrating in the fifth decade of life. There is no predilection for either gender. Early lesions are usually asymptomatic. Grossly, these tumors appear as soft, red-gray, polypoid masses located high in the nasal cavity. They present with symptoms of epistaxis and unilateral nasal congestion, which may be present for months to years. Additional symptoms include rhinorrhea, hyposmia or anosmia, headache, and serous otitis media. Other findings are related to sites of invasion and metastasis. Orbital symptoms, including proptosis, visual field defects, orbital pain, epiphora, and blindness, suggest orbital or intracranial extension and indicate a poor prognosis. The diagnosis is usually made late in the course of disease, and tumor extension may be extensive at presentation. A high index of suspicion is needed to diagnose olfactory neuroblastoma in patients presenting with unilateral nasal symptoms and epistaxis.

Radiographic findings are nonspecific, consisting of unilateral opacification of the ethmoid sinuses, with or without accompanying bone destruction, and a soft-tissue mass within the nasal cavity, with possible extension into the sphenoid and maxillary sinuses, orbit, and cranial vault. Bone expansion seen on radiographic imaging is consistent with slow progression of the tumor. MR imaging can aid in the initial diagnosis by differentiating neoplasm from obstructive disease and by identifying intracranial extension. MR imaging is also most useful for postoperative surveillance. CT is helpful in defining possible intracranial involvement in tumors with skull base erosion. Angiographic findings vary from definitive hypervascularity with early-draining veins to a faint but discrete tumor blush.

34.4.3 Treatment

Surgery

Surgical resection is the recommended treatment for olfactory neuroblastomas. The various surgical approaches used in the management of olfactory neuroblastomas include lateral rhinotomy or transnasal endoscopic resection, craniofacial resection, and combined endoscopic nasal and anterior craniotomy resection, depending on the size and extent of the tumor and the surgeon's expertise.

Adjuvant Therapy

Combined treatment with radiation, given before or after surgery, is often advocated to decrease the chance of local recurrence of olfactory neuroblastomas. Several investigators recommend surgery alone in low-grade or early-stage disease, whereas others advocate the addition of either preoperative or postoperative radiation, which has been demonstrated to

significantly improve local control, even in early-stage disease. Furthermore, Koka et al showed improved outcomes with the addition of chemotherapy, but not radiotherapy.

No true consensus exists as to the best treatment approach; however, multimodality treatment regimens are currently the most frequently advocated interventions, with craniofacial resection the most commonly recommended surgical approach. Various sequences of surgery, radiation, and chemotherapy are used, depending on the extent of disease. Olfactory neuroblastomas are believed to be chemosensitive. Chemotherapy is usually given as neoadjuvant treatment for advanced disease. Several authors advocate preoperative chemotherapeutic treatment to reduce tumor size before surgical resection is attempted. Chao et al also advocate elective treatment, by either irradiation or radical neck dissection or both, of the upper neck in patients with more extensive disease, especially when the tumor has spread beyond the nasal cavity or paranasal sinuses.

34.5 Hemangiopericytoma

34.5.1 The Disease Process

Hemangiopericytoma of the head and neck is a rare neoplasm that originates from the pericytes, or cells of Zimmerman, surrounding normal vascular channels. It is considered by some to be a lesion with a low risk for malignant potential and by others to be a malignant lesion with high metastatic potential. Thus, it is known as a tumor that varies greatly in appearance and biological behavior. Hemangiopericytomas account for 3 to 5% of all soft-tissue sarcomas and 1% of all vascular tumors.

In the head and neck, the clinical behavior of a hemangiopericytoma may vary from a slowly enlarging rubbery mass to an infiltrating aggressive neoplasm. Distant metastasis to lung, liver, and bone may occur, but regional spread to lymph nodes has not been observed. The rate of metastasis varies significantly from 10 to 60% and is consistent with the observation that this tumor varies greatly in biological behavior. Gengler et al emphasize the difficulty of predicting the clinical behavior of hemangiopericytomas and patient outcomes; thus, close long-term follow-up is crucial for patients with hemangiopericytomas because of the high incidence of local recurrence and the potentially metastasizing course.

34.5.2 Evaluation

Hemangiopericytomas occur most commonly in the sixth and seventh decades of life and have no sex predilection. Many of these tumors may have been present for a long time before they are diagnosed, and patients typically present with a slowly growing mass that occasionally reaches a considerable size. Symptoms include facial pain, occasionally facial swelling, epistaxis, sinusitis, visual changes, and nasal obstruction, depending on the anatomical site of involvement. The facial skin overlying the tumor may be warm to the touch because of the rich vascularity of the hemangiopericytoma. In the oral cavity, its clinical appearance is that of a firm, usually well-circumscribed swelling of the mucosa. In the nose, it is usually described as soft, rubbery, pale gray or tan polypoid mass. Despite the pale, avascular appearance, these tumors bleed vigorously

when biopsied. Because of their benign clinical appearance, they can be misdiagnosed as benign tumors or nasal polyps.

The diagnosis of hemangiopericytoma depends on an accurate pathologic assessment of the biopsied specimen. Radiographic imaging assists in the diagnosis. Hemangiopericytomas appear as rounded, sharply outlined or well-circumscribed, homogeneous masses that often displace neighboring structures on CT scan. CT can clearly demonstrate bone destruction within the nasal cavity, paranasal sinuses, and adjacent intracranial structures. Angiography shows a richly vascularized mass, dilated arteries, and diffuse capillary blush. Occasionally, early visualization of the veins suggests arteriovenous shunting. MR imaging reveals several characteristic features suggesting the diagnosis of a solitary fibrous tumor: isointensity on T1-weighted imaging and iso- to hypointensity on T2-weighted imaging.

The follow-up of patients with hemangiopericytoma should include regular clinical as well as radiologic examinations, especially patients with deep-seated tumors or those with suspicion of tumor recurrence and/or metastasis. Long-term follow-up of patients with these tumors should be maintained because some hemangiopericytomas, including histologically low-grade tumors, display late recurrence and metastasis, even beyond 5 years.

34.5.3 Treatment

The preferred treatment for hemangiopericytomas is wide surgical excision, usually performed via lateral rhinotomy, midface degloving, craniofacial resection, or endoscopic resection. Many advocate a craniofacial approach for patients with cribriform plate or base of skull involvement. Schlosser et al have demonstrated that endoscopic approaches can provide excellent visualization and tumor resection, even for tumors with skull base erosion, while avoiding the external facial incisions and complications associated with open techniques.

Preoperative Embolization

Perioperative embolization has been suggested as an adjuvant for decreasing tumor vascularity and size preoperatively, although most head and neck hemangiopericytomas are relatively small and amenable to en bloc resection without embolization. Several investigators encourage the use of routine angiography and preoperative embolization to delineate the extent of these tumors and their feeding vessels and to reduce intraoperative hemorrhage.

Adjuvant Therapy

Radiation therapy may decrease the size of the tumor, but cure is rare with radiation alone. Radiation therapy has been advocated as adjuvant treatment for hemangiopericytoma to reduce the rate of local recurrence. Some recommend adjuvant radiotherapy for patients when a hemangiopericytoma is larger than 5 cm or when the resection margins are inadequate. However, it is not clear whether the addition of radiotherapy improves survival. The role of adjuvant or palliative chemotherapy is not well defined for patients with hemangiopericytoma, even for those with advanced or unresectable disease.

Fig. 34.5 Multiple facial neurofibromas in a woman with neurofibromatosis.

34.6 Nerve Sheath Tumors

34.6.1 The Disease Process

Nerve sheath tumors, most commonly referred to as schwannomas, neurilemmomas, or neurofibromas, are benign tumors that arise from Schwann cells in the nerve sheath.

Schwannoma

Head and neck schwannomas are most often solitary, slow-growing, well-encapsulated tumors associated with the nerve of origin (cranial nerves, cervical sympathetic chain, cervical sensory plexus, and brachial plexus). Rarely, schwannomas may be multiple. Approximately 25 to 45% of extracranial schwannomas occur in the head and neck. Schwannomas are the most common solitary neurogenic tumors in the neck and are usually seen in patients between 20 and 50 years of age.

Neurofibroma

Neurofibromas are unlike schwannomas in that they are not encapsulated; nerve fibers traverse and are frequently incorporated into the tumors. They are often multiple and are usually part of von Recklinghausen disease (neurofibromatosis; □ Fig. 34.5). The incidence of the latter is 1 in 3,000 births. The distinction between schwannoma and neurofibroma is important clinically and prognostically. Schwannomas are not known to have malignant potential, but neurofibromas can give rise to malignant peripheral nerve sheath tumors.

34.6.2 Evaluation

Most patients with nerve sheath tumors are asymptomatic and present with a painless neck mass, although some may present with nasal obstruction, hearing loss, dysphagia, and hoarseness, depending on the location of the tumor. Schwannomas associated with cranial nerves or the sympathetic chain may present as a mass displacing the lateral pharyngeal wall.

CT and MR imaging are helpful in establishing the diagnosis of schwannoma, and MR imaging is superior to CT in its ability

to differentiate schwannomas from other types of tumors with similar presentations. Histologic examination assists in the diagnosis of schwannoma by demonstrating the typical spindle cell features of elongated nuclei and alternating areas of organized, compact cells (Antoni type A) and loosely arranged, relatively acellular tissue (Antoni type B). In addition, immunohistochemical staining for the S-100 protein, a neural crest antigen present in the supporting cells of the nervous system, is helpful when classic morphological features are not obvious.

34.6.3 Treatment

Conservative local excision of the tumor with preservation of the nerve of origin is the treatment of choice. The relatively avascular nature of the tumor allows dissection of the tumor within the capsule and separation from the nerve of origin. However, if the nerve cannot be preserved during surgery, immediate reconstruction with postoperative rehabilitation should be undertaken.

34.7 Malignant Peripheral Nerve Sheath Tumors

34.7.1 The Disease Process

Malignant peripheral nerve sheath tumors are rare tumors that may arise sporadically or within a preexisting benign peripheral nerve sheath tumor, the latter usually in a patient with neurofibromatosis. They may be referred to as malignant schwannomas, neurofibrosarcomas, neurogenic sarcomas, neurilemmosarcomas, malignant fibrosarcomas, or malignant neurilemmomas. Malignant peripheral nerve sheath tumors comprise 2 to 6% of head and neck sarcomas. They arise in 13 to 29% of patients with neurofibromatosis; 20% of patients with malignant peripheral nerve sheath tumors have neurofibromatosis. Exposure to radiation is believed to play a role in the formation of malignant peripheral nerve sheath tumors, with a latency period of 10 to 20 years; therefore, some recommend that patients with neurofibromatosis who receive radiation treatment should be carefully monitored for the development of sarcoma. In a study by Loree et al, overall survival at 5 years approximated 52%, with improved survival in female patients and patients with low-grade tumors. The development of distant metastases correlated with tumor grade. Age, tumor site, and size had no impact on survival. Patients with neurofibromatosis had worse survival than those with sporadic forms of disease.

34.7.2 Evaluation

Patients with malignant peripheral nerve sheath tumors may present with mass lesions, and although some may be asymptomatic, others may present with pain, airway obstruction, or dysphagia, depending on the location of the tumor. In a study by Loree et al, the median age of these patients was 43 years, and 41% of them had a history of neurofibromatosis. CT and MR imaging assist in the diagnosis of malignant peripheral nerve sheath tumors, and immunohistochemical staining for p53, Ki-67, and MDM2 markers improves the accuracy of this diagnosis, although immunoperoxidase staining for S-100 has been the only reliable marker for a neurogenic tumor.

Fig. 34.6 Recurrent angiosarcoma seen as violaceous macules on the scalp of a patient who previously underwent wide local excisions.

34.7.3 Treatment

The mainstay of treatment of a malignant peripheral nerve sheath tumor is wide excision of the tumor. Clear margins are essential for achieving local control. Adjuvant radiotherapy is advocated to improve local control, including in patients with negative margins at the time of resection. Regional metastasis is rare; thus, elective neck dissection is not indicated.

34.8 Sarcoma

34.8.1 The Disease Process

Sarcomas of the head and neck comprise a heterogeneous group of tumors that range widely in biological behavior, from slowly growing tumors to aggressive lesions with metastatic potential. They affect numerous subsites within the head and neck and are classified by their tissue of origin. Malignant fibrous histiocytoma, also known as pleomorphic sarcoma, is the most common histologic subtype of soft-tissue sarcoma and includes tumors within a broad range of cellular origins. Angiosarcoma is an extremely rare type of vascular sarcoma (1 to 2% of all soft-tissue sarcomas), of which at least half occur in the head and neck region. It arises from cells of endothelial origin, and unlike most sarcomas, which tend to occur in deep locations, it commonly occurs in the skin or superficial soft tissues. Rhabdomyosarcoma is the most common form of sarcoma in children and arises in the head and neck in approximately 40% of cases. These tumors have a significant potential for metastasis to cervical lymph nodes as well as systemic metastases.

34.8.2 Evaluation

The clinical presentation is determined by the subsite of origin. Sarcomas arising in the neck usually present as a painless mass. However, deep tumors may impinge on vital structures, pro-

ducing symptoms of pain, paresthesias, dysphagia, or hoarseness. Malignant fibrous histiocytomas often present as subcutaneous or submucosal lesions in the parotid gland or neck and in the sinonasal tract. Angiosarcomas classically present as violaceous macules and plaques on the scalp or face (□ Fig. 34.6) that can progress to nodular and ulcerated lesions. The diagnosis is often delayed because the lesion commonly mimics other dermatologic entities and is generally asymptomatic.

CT and MR imaging assist in establishing the diagnosis by accurately assessing the size and location of the sarcoma, as well as delineating bony involvement, intracranial extension, and regional metastasis. MR imaging offers much better soft-tissue resolution and is therefore better at evaluating the primary lesion, perineural extension, dural involvement, bone marrow replacement, and orbital invasion. Unfortunately, however, none of the imaging characteristics can be considered diagnostic, and thus a biopsy, which should be performed after the imaging, is necessary to definitively establish the diagnosis. Immunohistochemical stains and cytogenetic studies assist in confirming the diagnosis. Because sarcomas spread most commonly to the lungs, CT of the chest is also necessary to rule out pulmonary metastasis.

34.8.3 Treatment

In the absence of metastatic disease, surgical resection with wide margins provides the best chance of cure for sarcomas of the head and neck. The optimal treatment of angiosarcoma is not clearly defined because of the rarity of angiosarcomas and their poor prognosis, although several investigators have reported that the combination of surgery with postoperative radiation offers the best prognosis. The major challenges in the treatment of angiosarcomas include characteristics such as ill-defined borders, the frequency of multifocal disease, and a propensity to metastasize. The ability of these neoplasms to spread subcutaneously over large areas makes local recurrence

a defining quality of these malignancies. Therefore, truly negative surgical margins are unlikely to be achieved, and frozen section analysis at the time of excision to ensure complete resection has little impact on outcome. Chemotherapy may have an emerging role in the management of sarcomas. However, its use is currently limited to unresectable tumors or nonsurgical candidates. The intralesional injection of cytokines has also been used for angiosarcomas in conjunction with surface irradiation, resulting in extended partial response. Recent literature supports the use of neoadjuvant chemotherapy, especially in patients in whom surgical treatment with or without radiation therapy can result in severe disfigurement.

34.9 Lymphoma

34.9.1 The Disease Process

Extranodal lymphomas of the head and neck constitute approximately 10% of all non-Hodgkin lymphomas and occur in the Waldeyer ring, most frequently the tonsils, paranasal sinuses, nasal cavity, larynx, oral cavity, salivary glands, thyroid, and orbit. Most are B-cell malignancies. Marginal zone lymphoma of the mucosa-associated lymphoid tissue (MALT) type is particularly associated with inflammatory conditions in the thyroid and salivary glands.

34.9.2 Evaluation

Patients with head and neck lymphomas may present with a variety of symptoms, depending on the subsite involved; these may include tonsillar swelling, nasal obstruction, sore throat, hoarseness, dyspnea, and neck mass. The diagnosis is most reliably made by open biopsy, although fine-needle aspiration biopsy is increasingly used. Radiographic imaging is used to assist in staging the disease. Chest X-rays are sufficient to evaluate for mediastinal or hilar adenopathy, and CT and MR imaging are useful in evaluating the extent of the primary lesion. More recently, PET-CT has become a major tool in the evaluation of lymphomas. Other tests performed in staging disease include complete blood cell count, liver function tests, lumbar puncture, and bone marrow biopsy.

34.9.3 Treatment

Surgery has a role only in the staging of head and neck lymphomas; the management of most extranodal lymphomas in the head and neck consists of radiation therapy and/or chemotherapy. For low-grade stage I or II lymphomas, the standard treatment has been involved field or extended field radiation therapy. For low-grade stage III or IV lymphomas, the standard treatment is chemotherapy. Interferon- α has been given after chemotherapy in selected patients and has been shown to prolong remissions, but not overall survival. For intermediate-grade stage I or II lymphomas, both radiation and chemotherapy are advocated, and for intermediate stage III or IV lymphomas, chemotherapy is the primary treatment. High-grade lymphomas, such as T-cell lymphoma, require combination chemotherapy including central nervous system prophylaxis. An exception is natural killer/T-cell lymphoma of the nasal type, which has a poor response to anthracycline-

based chemotherapy regimens; therefore, high-dose radiation is required. Intensity-modulated radiotherapy (IMRT) has been recommended for these cases to minimize risks to surrounding normal tissues. Thyroid and orbital lymphomas are commonly treated with radiation alone, although chemotherapy is often added for diseases with poor prognostic factors or high-grade histology. Stages III and IV disease is treated primarily with combination chemotherapy.

34.10 Malignant Melanoma

34.10.1 The Disease Process

Melanoma is a malignant neoplasm that arises in the melanocytic cells found in the basal layer of the epidermis. These cells are of neural crest origin and located predominantly in the skin but also in the eyes, ears, gastrointestinal tract, leptomeninges, and oral and genital mucous membranes. Melanoma frequently develops in a preexisting nevus. This chapter focuses on nonmucosal forms that occur within the head and neck. The behavior of head and neck melanoma is aggressive, and melanoma in this region has an overall poorer prognosis than that of melanoma in other skin sites. The prognosis of individuals affected with melanoma has been demonstrated to correlate with depth of invasion, which was initially reported as the Clark level, corresponding to varying regions of the epidermis and dermis. However, a more accurate measurement of tumor thickness, defined by the Breslow level, has become the standard to assess prognosis and is now used for tumor staging. The most important adverse prognostic factors are a high Clark level of invasion, increased tumor thickness, more than one mitosis per high-power field, clinical ulceration, a high degree of pleomorphism, the presence of microscopic satellites, a lack of tumor-infiltrating lymphocytes, primary site in the scalp, and regional lymph node metastasis. The incidence of distant metastasis is reported to be 50 to 85% in patients with involvement of the cervical lymph nodes. The incidence of occult nodal disease is approximately 4 to 23%.

34.10.2 Evaluation

Head and neck melanomas most often occur on the face, with the cheeks the most common site. Other common sites include the neck, scalp, and auricles. The most common physical finding is a new or changing nevus. Variation in color and/or an increase in the diameter, height, or asymmetry of the borders of a pigmented lesion are noted by more than 80% of patients with melanoma at the time of diagnosis. Other symptoms, such as bleeding, itching, ulceration, and pain in a pigmented lesion, are less common.

A full-thickness biopsy is crucial for an adequate diagnosis of the lesion and determination of the depth of invasion. Excisional biopsy is recommended for small lesions and for large lesions in a cosmetically favorable location. The biopsy should extend down to the subcutaneous fat, with a small (2 to 3 mm) peripheral margin. For large lesions and those in cosmetically unfavorable locations, and for those with a low suspicion of melanoma, an incisional or punch biopsy can be performed. Shave and curet biopsies are not recommended.

34.10.3 Treatment

The management of melanoma consists of wide local excision. Recommended margins of resection were determined based on the results of prospective randomized clinical trials organized by the World Health Organization Melanoma Group to evaluate the margins required to produce adequate local control. In general, for in situ lesions, the margin should be 0.5 cm; for lesions less than 1 mm in thickness, the margin of resection should be 1 cm; for lesions between 1.0 and 2.0 mm in thickness, the margins are generally accepted to be 1 to 2 cm. For melanomas thicker than 2 mm, 2-cm margins are required.

The risk for regional lymph node spread and distant metastatic disease is closely correlated with the depth of invasion, and the risk persists despite adequate excision of the disease at the primary site. It is believed that as the thickness of the primary melanoma increases to more than 1 mm, the likelihood of nodal metastases increases to more than 10 to 15%. Sentinel lymph node biopsy has been used to assess for presence of tumor cells in the lymphatics. However, the widespread use of sentinel lymph node biopsy in melanoma has been limited by several concerns, including potential damage to the facial nerve because 25 to 30% of the sentinel nodes are found within the parotid gland.

The role of elective neck dissection in the management of melanoma remains controversial because of the morbidity of the dissection without clear evidence of survival benefit. When elective neck dissection is contemplated, the site of the primary lesion must be considered. For primary lesions involving the parietal and frontal scalp, temple, lateral forehead, lateral cheek, or ear, superficial parotidectomy is performed in conjunction with neck dissection.

For patients with palpable cervical nodes, the likelihood of nodal metastases increases up to 80% and a functional neck dissection is advocated. However, therapeutic neck dissection also has not been shown to have a survival benefit, although many favor the procedure for locoregional control. Survival drops to approximately 10% in the presence of a single positive lymph node. Thus, many feel that removal of the affected nodes would have a minimal effect on the already-poor survival. Nevertheless, there is a consensus among head and neck surgeons that surgical control of regional disease may improve patients' quality of life.

Numerous adjuvant therapies have been investigated for the treatment of melanoma. High-dose interferon alfa-2b has been approved by the FDA as an adjuvant treatment for high-risk melanomas. More recently, immunotherapy with a monoclonal antibody called ipilimumab has been approved by the FDA for patients with advanced or metastatic melanoma. No survival benefit has been demonstrated for adjuvant chemotherapy, nonspecific or passive immunotherapy, radiation therapy, retinoid therapy, vitamin therapy, or biologic therapy.

34.11 Roundsmanship

- Paragangliomas may occur in patients with type IIA familial multiple endocrine neoplasia (MEN) (pheochromocytoma, medullary thyroid carcinoma, and parathyroid hyperplasia) or type IIB MEN (also includes mucosal neuromas).
- Juvenile nasopharyngeal angiofibroma (JNA) typically presents in males 7 to 29 years of age (median age, 15 years) with the triad of unilateral nasal obstruction, recurrent severe epistaxis, and nasopharyngeal mass. Nasal obstruction and epistaxis occur in more than 80% of the patients.
- Radiographic anterior bowing of the posterior wall of the maxillary sinus (Holman-Miller sign) and enlargement of the superior orbital fissure are considered diagnostic for JNA.
- For malignant melanomas, in situ lesions are resected with a margin of 0.5 cm; for lesions less than 1 mm in thickness, the margin of resection should be 1 cm; for lesions between 1.0 and 2.0 mm in thickness, margins are generally accepted to be 1 to 2 cm; for melanomas thicker than 2 mm, 2-cm margins are required.

35 Principles and Techniques of Neck Dissection

Moustafa Mourad and Stimson P. Schantz

35.1 Introduction

The earliest documentation of head and neck cancer dates back to 3500 BC, in the Egyptian texts of the Ebers Papyrus. The papyrus describes the treatment of an “eating ulcer on the gums” with cinnamon, honey, gum, and oil. The importance of the presence of nodal disease in the prognostication of the disease was not fully appreciated or documented in the medical literature until 1790, and before the nineteenth century, no attempt at controlling metastatic nodal disease by surgery was made.

In 1837, John Collins Warren attempted to control metastatic spread to the cervical nodes with isolated, single-node excisions. With advances in antisepsis and antimicrobials, anesthesia, surgical technique, and perioperative management, the late nineteenth century saw an increase in the attempted management of nodal disease. En bloc resections of nodal disease were conducted in cases of advanced disease, pioneered by Europeans: Bernhard Rudolf Konrad von Langenbeck, Christian Albert Theodor Billroth, Richard von Volkman, and Theodor Kocher. Sir Henry Trentham Butlin introduced the concept of elective neck dissections in 1885, which brought about a dramatic improvement in local disease control and the survival rates of patients.

The early twentieth century saw a refinement in the surgical technique of nodal excisions, as well as the introduction by George Washington Crile of the radical neck dissection. Today, there are three major classifications of neck dissections, with a number of subtypes, all of which are a fundamental part of head and neck surgery and have drastically improved the outcomes of patients with head and neck cancer. A thorough understanding and appreciation of head and neck anatomy is essential in performing neck dissection.

35.2 Details of the Lymph Node Levels of the Neck

The lymph nodes within the neck maybe divided into seven anatomical subsites (□ Fig. 35.1).

Level I: The nodes in this level can be subdivided into submental (IA) and submandibular (IB) nodes.

The submental (IA) nodes are contained within a triangular region bounded by the anterior belly of the digastric muscle and the hyoid bone. The submandibular (IB) nodes are found in the region bounded by the anterior belly of the digastric muscle, the body of the mandible, and the stylohyoid muscle.

Level II: Contains the upper jugular lymph nodes. The nodes in this level can also be subdivided into level IIA and level IIB nodes.

Level II lymph nodes are found in the region bounded posteriorly and laterally by the posterior border of the sternocleidomastoid muscle, superiorly by the skull base, inferiorly by the inferior border of the hyoid bone, and anteromedially by the stylohyoid muscle. The nodes in levels IIA and IIB are subdivided based on their relationship to the vertical plane created

by the spinal accessory nerve in this region: level IIA nodes are anteromedial to this plane, whereas IIB nodes are posterolateral to the plane.

Level III: Contains the middle jugular lymph nodes. This region is defined as lying in an area bounded superiorly by the inferior border of the hyoid bone and inferiorly by the inferior border of the cricoid cartilage. Medially, these nodes are lateral to the lateral boundary of the sternohyoid muscle, and posteriorly and laterally they are bounded by the posterior border of the sternocleidomastoid muscle.

Level IV: Contains the lower jugular nodes. This level is defined as the area bounded superiorly by the inferior border of the cricoid cartilage, inferiorly by the clavicle, posteriorly by the posterior border of the sternocleidomastoid muscle, and anteriorly by the lateral border of the sternohyoid muscle.

Level V: Contains the posterior triangle lymph nodes and can be subdivided into levels VA and VB.

Level V nodes are found in the region bounded superiorly by the intersection point of the sternocleidomastoid muscle and the trapezius muscle, inferiorly by the clavicle, anteriorly by the posterior border of the sternocleidomastoid, and posteriorly by the anterior border of the trapezius muscle. Level V is divided into sublevels VA (above) and VB (below) by a horizontal plane created by the inferior border of the anterior cricoid arch.

Level VI: Contains the anterior compartment lymph nodes, including the prelaryngeal (delphian), pretracheal, and paratracheal nodes. This level is defined as an area with the superior boundary formed by the hyoid bone, the inferior boundary formed by the suprasternal notch, and the lateral boundaries formed by the common carotid arteries.

35.2.1 Details of Lymph Drainage

Understanding the patterns of lymphatic drainage in the various sites of the head and neck is critical to the performance of an appropriate neck dissection. □ Fig. 35.2 details the course of the lymphatics. Lymph nodes are commonly seen to course parallel to major venous pathways, as well as along selected neural pathways.

Afferent lymphatics from the submental and submandibular nodes drain the floor of the mouth, apex of the tongue, and lower lips. Subsequent efferent drainage courses to deep cervical nodes toward the internal jugular vein at the level of the hyoid bone (levels IIA and IIB), as well as to submaxillary nodes. The anterior cervical node afferents drain the subglottic and glottic larynx, apex of the piriform sinus, and cervical esophagus. Anterior cervical node efferent lymphatic drainage courses toward level II nodes, as well as upper mediastinal nodes. Level II nodes receive drainage from the oral cavity, nasopharynx, oropharynx, hypopharynx, and larynx, as well as the scalp, auricles, and back of the neck. Level II nodes also receive drainage from other nodal groups, particularly from the anterior cervical compartment, as well as the submental and submandibular group. Level II efferents subsequently drain into levels IV and V. Levels IV and V nodes receive drainage from the nasopharynx, oropharynx, and cutaneous structures of the posterior

Fig. 35.1 Nodal levels of the neck.

scalp and neck. Efferents from this region join with efferents from levels II and III to form the jugular trunk. On the right side, the jugular trunk terminates at the branching point of the internal jugular vein from of the right subclavian vein. The jugular trunk on the left joins the thoracic duct.

35.2.2 Details of the Thoracic Duct

The thoracic duct originates in the cisterna chyli, a saclike structure located inferior to the right crus of the diaphragm at the level of L1 and L2. The duct enters the thorax lateral to the descending aorta and medial to the azygous vein. It continues to ascend through the thorax, crossing the arch of the aorta in the superior mediastinum. The duct then courses laterally at the level of C7. The duct continues to run along the medial border of

the anterior scalene muscle, looping inferiorly and crossing the first segment of the subclavian artery anteriorly. The thoracic duct terminates at the junction of the left internal jugular vein and the subclavian vein, below the level of the clavicle. The thoracic duct drains the lower extremities (through the right and left lymphatic trunks) and abdomen.

35.3 Details of the Arteries of the Neck (□ Fig. 35.3)

35.3.1 Details of the Subclavian Arteries

The right subclavian artery originates from the innominate artery posterior to the sternoclavicular joint and arches above the

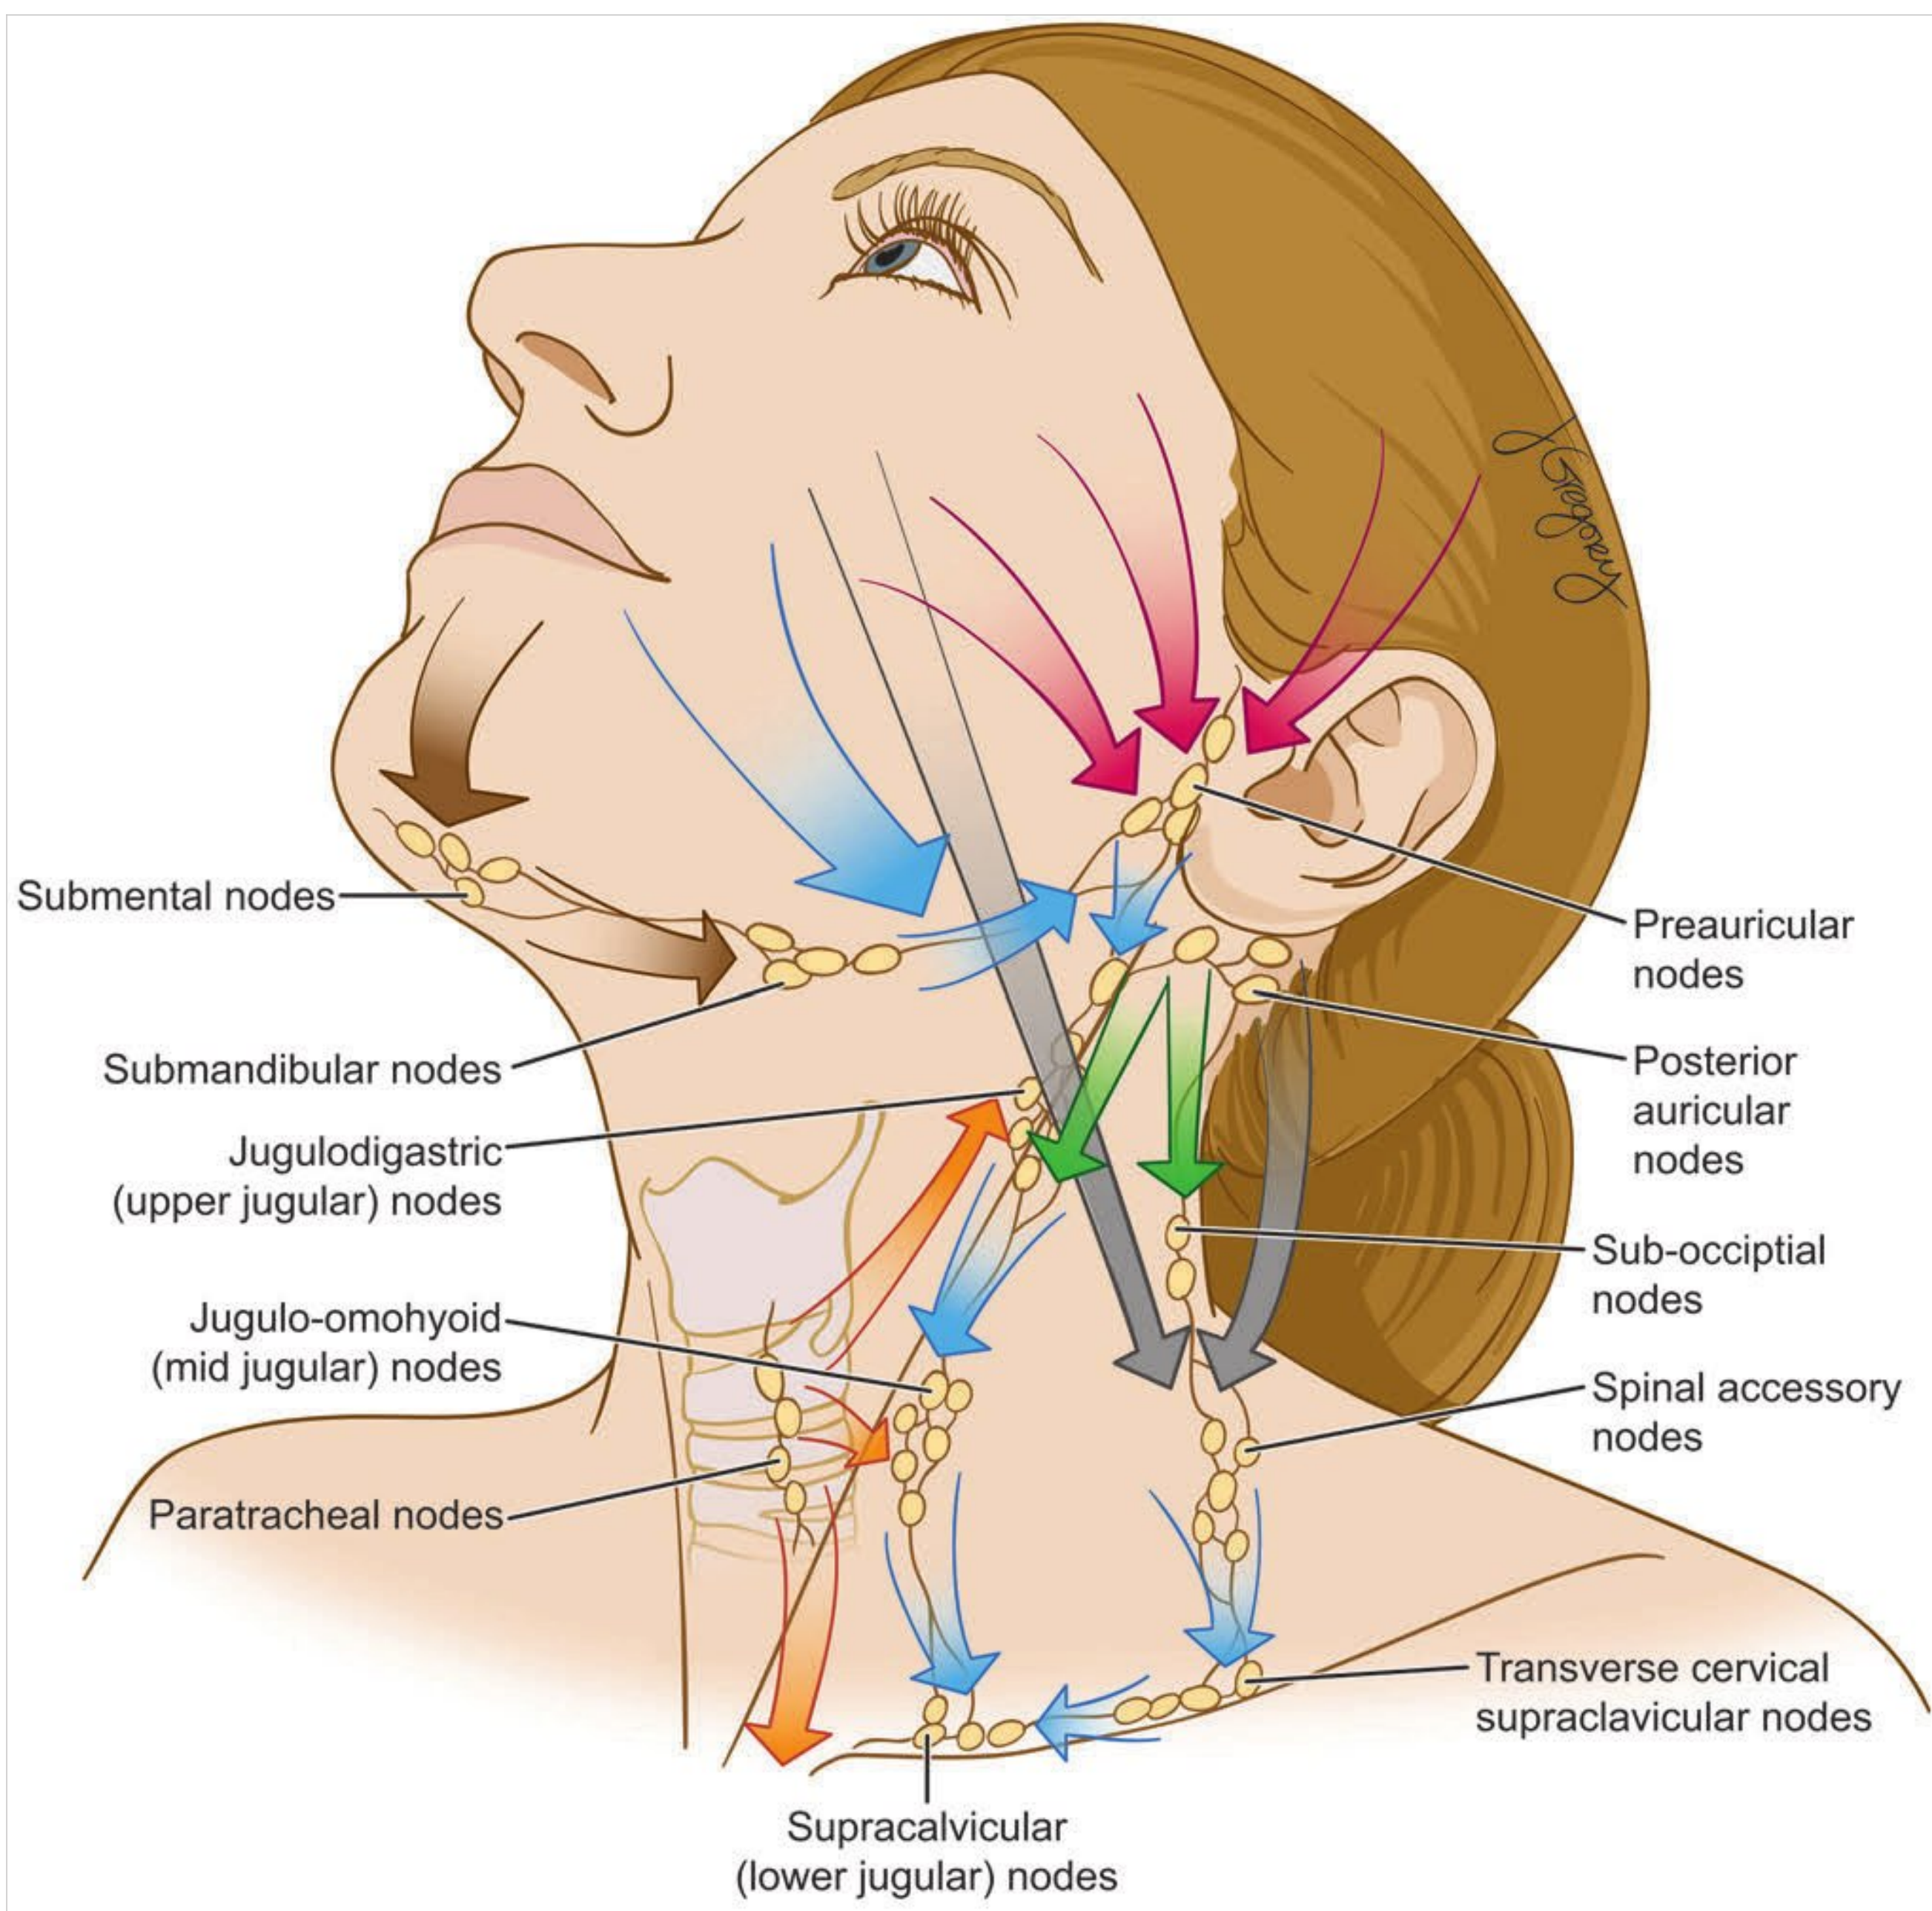

Fig. 35.2 Patterns of lymphatic drainage in the neck.

clavicle and subclavian vein. The right subclavian artery leaves the neck at the level of the first rib, becoming the right axillary artery. The left subclavian artery originates directly from the arch of the aorta and enters the base of the neck through the superior mediastinum. Similar to the right subclavian artery, the left subclavian leaves the neck at the level of the first rib to become the left axillary artery.

The subclavian artery can be subdivided into three segments based on its relationship to the anterior scalene muscle: the first segment lies medial, the second segment lies behind, and the third segment lies lateral to the muscle. The first segment on the right side is crossed by the internal jugular and vertebral veins and the vagus nerve. The first segment on the left side is crossed by the left common carotid artery, ansa

subclavia, vagus nerve, and internal jugular vein. Importantly on the left side, posterior to the first segment lie the esophagus, trachea, thoracic duct, and left recurrent laryngeal nerve. The third segment of the subclavian artery is crossed by the external jugular vein anteriorly and the middle scalene muscle posteriorly.

The branches of the subclavian artery arise predominantly from the first segment, although in some individuals the second and third segments may be the origin of the thyrocervical trunk. Branches of the subclavian artery include the vertebral artery, thyrocervical trunk, suprascapular artery, transverse cervical artery, inferior thyroid artery, internal thoracic artery, costocervical trunk, supreme intercostal artery, and deep cervical artery.

Fig. 35.3 Major vessels of the neck.

The transverse cervical artery originates from the thyrocervical trunk and is generally encountered in level V neck dissections. The artery crosses the anterior scalene muscle and brachial plexus and then penetrates the trapezius muscle, dividing into a superficial branch and a deep branch.

The inferior thyroid artery also originates from the thyrocervical trunk and ascends anterior to the vertebral artery, giving rise to the ascending cervical artery at C6. The artery passes behind the carotid sheath, arching downward, to reach the posterior pole of the thyroid gland.

35.3.2 Details of the Common Carotid Arteries

The right common carotid artery originates from the brachiocephalic artery at the level of the sternoclavicular joint, whereas the left common carotid artery is a direct branch of the aorta. Both common carotid arteries are protected by the sternocleidomastoid and the strap muscles of the neck. The carotid arteries bifurcate at the level of the thyroid cartilage, giving rise to the internal and external carotid arteries.

The internal carotid artery originates at the bifurcation of the carotid artery at the upper border of the thyroid cartilage. The internal carotid artery ascends superiorly under the sternocleidomastoid and posterior belly of the digastric before entering

the carotid canal within the temporal bone without giving off any branches within the neck. Identification of the internal carotid artery, along with the internal jugular vein, cranial nerves IX through XII, and the sympathetic plexus, is aided by identification of the C1 transverse process immediately posteriorly.

The external carotid artery is formed at the bifurcation of the common carotid artery at the level of the thyroid cartilage and runs anteromedial to the internal carotid artery. The external carotid artery ascends posterior to the sternocleidomastoid muscle and deep to the posterior belly of the digastric muscle, penetrating the parotid behind the angle of the mandible before dividing into the terminal branches of the superficial temporal and maxillary arteries. The branches of the carotid artery include the superior thyroid artery, ascending pharyngeal artery, lingual artery, facial artery, and occipital artery.

The superior thyroid artery most commonly originates as the first branch of the external carotid artery, but it may be seen to arise from the common carotid artery. The artery passes anteroinferiorly to supply the intrinsic muscles of the larynx and the superior pole and isthmus of the thyroid gland just before terminating.

The lingual artery ascends deep to the digastric muscle in the lateral wall of the pharynx, coursing anteriorly until it reaches the hyoglossus muscle.

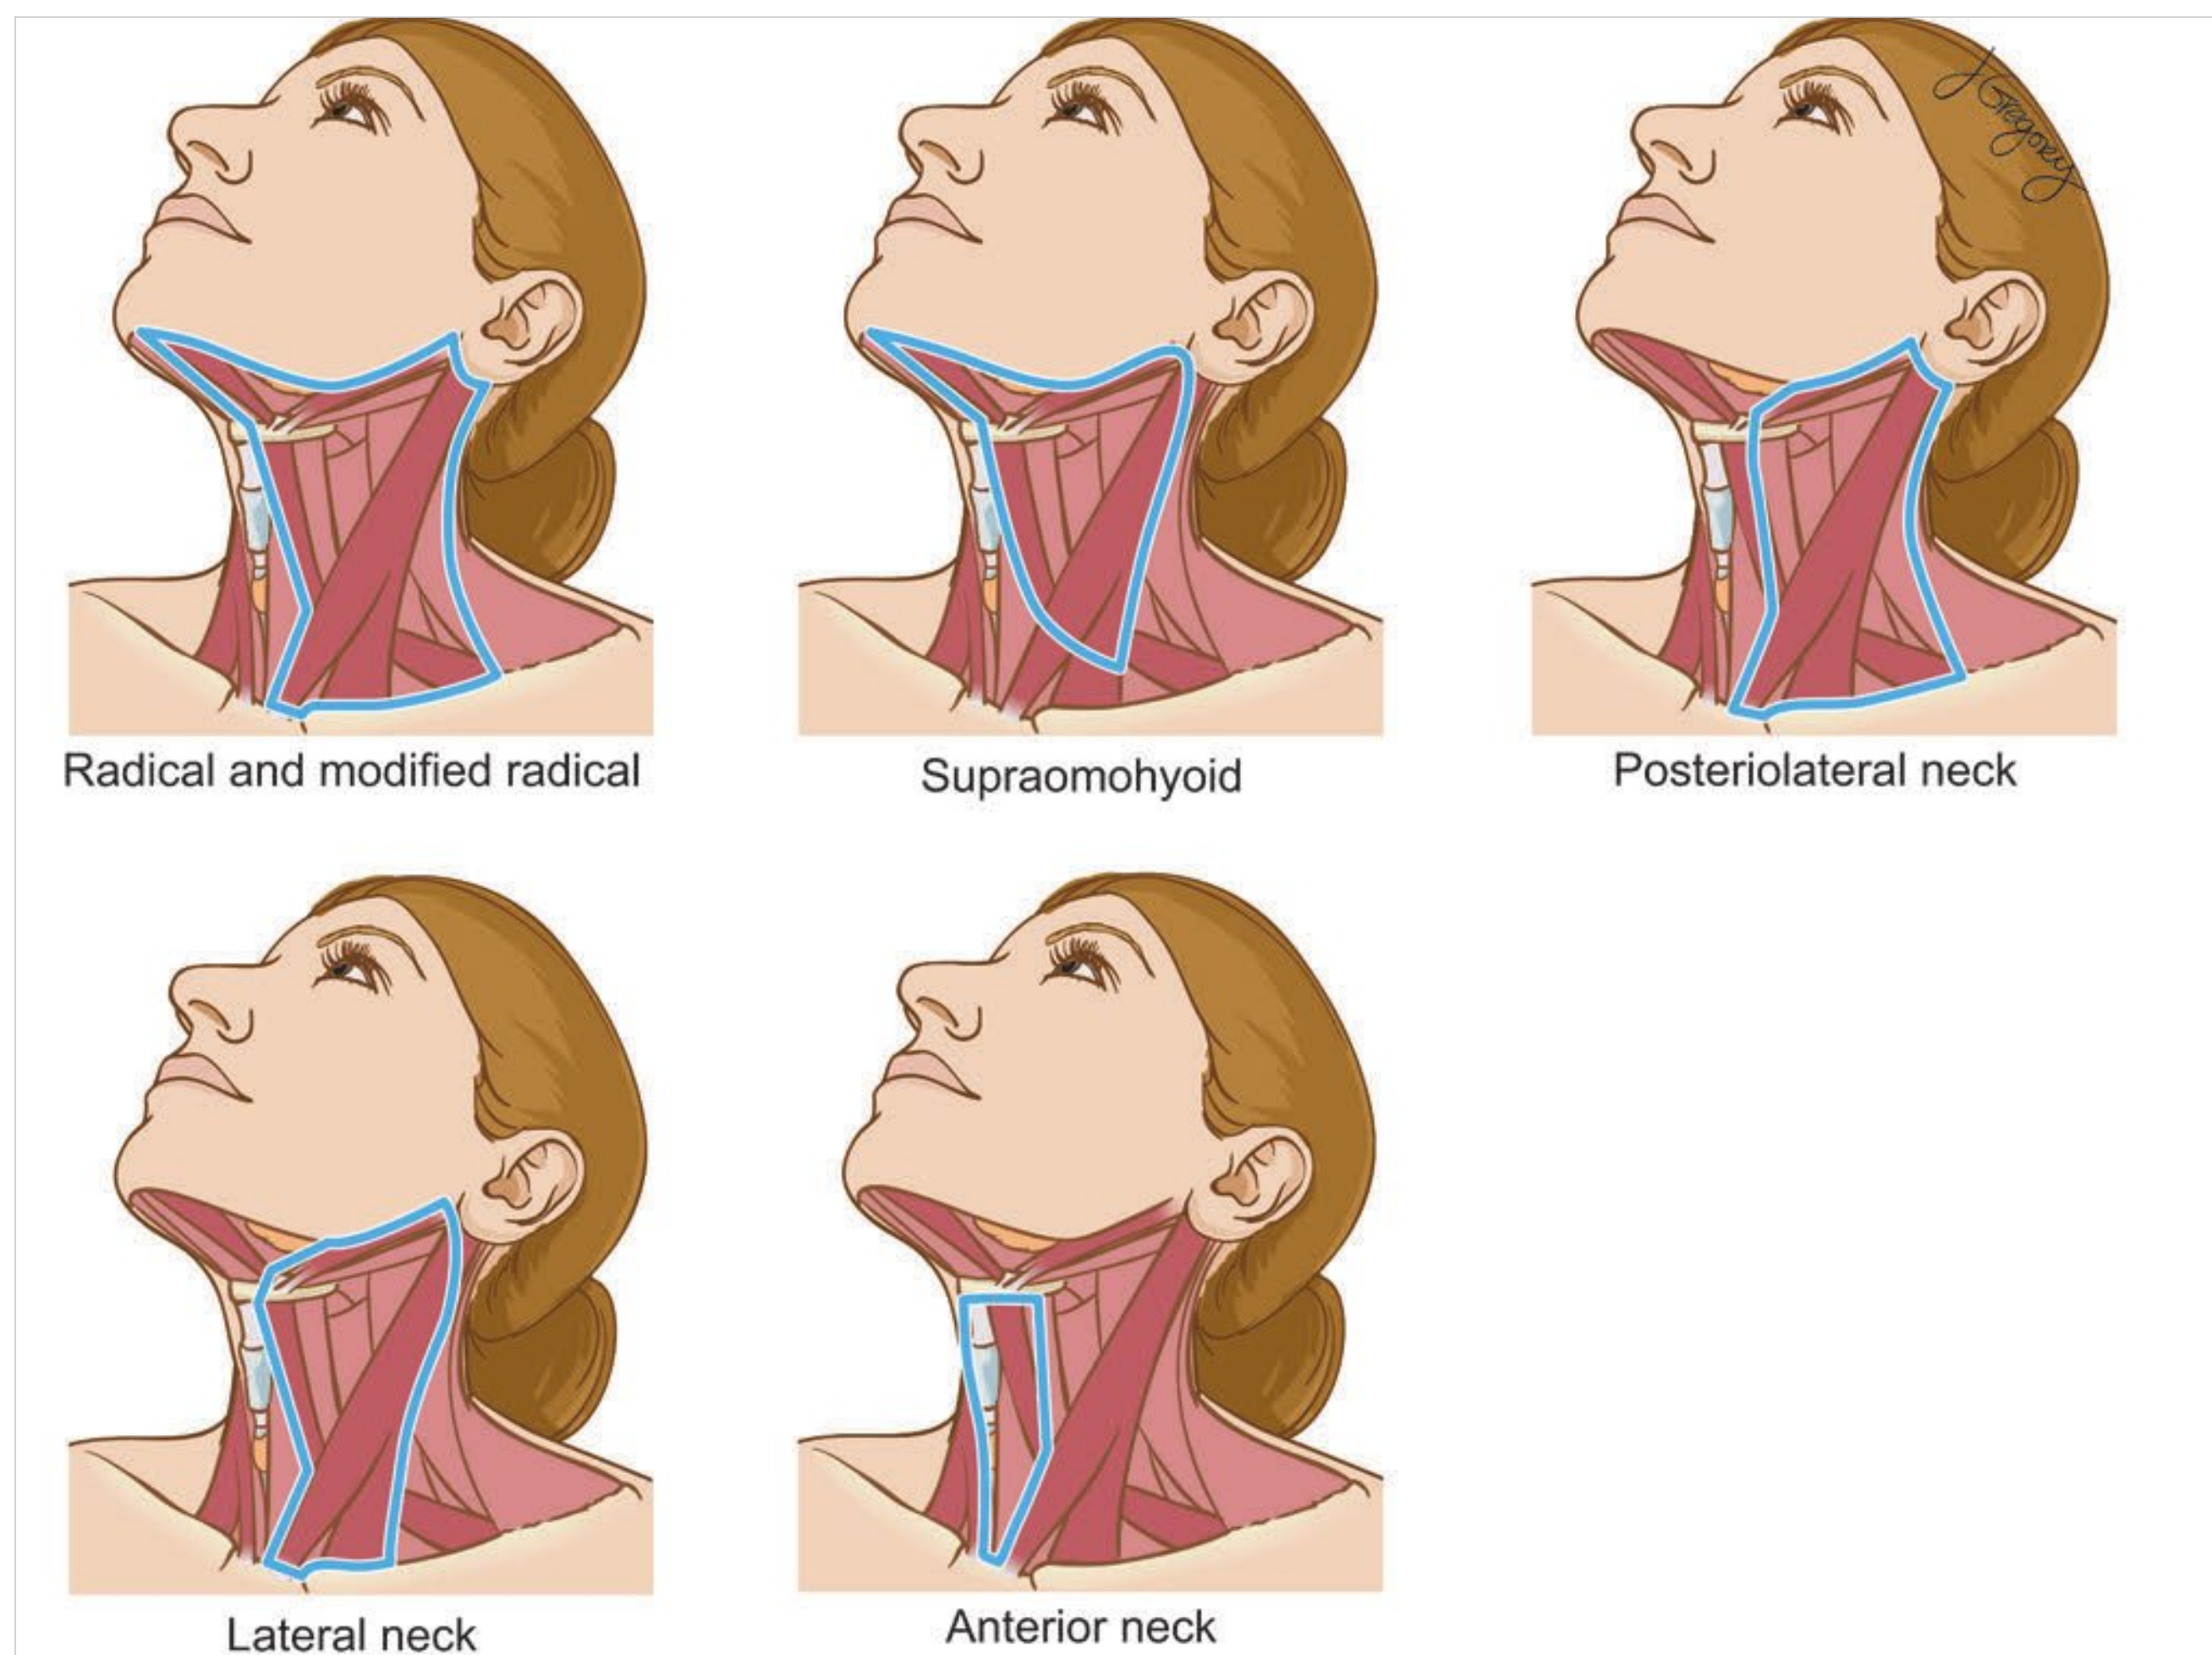

Fig. 35.4 Types of neck dissections.

The facial artery originates at digastric muscle near the level of the angle of the mandible. From its origin site, it ascends deep to the digastric and stylohyoid muscles to the submaxillary triangle.

35.4 Details of the Veins of the Neck

The veins of the neck can be subdivided into superficial and deep veins.

35.4.1 Superficial Veins

External Jugular Vein

The external jugular vein drains the external portion of the skull and deeper portions of the face. The retromandibular and postauricular veins unite to form the external jugular vein within the substance of the parotid gland at the level of the angle of the mandible. The external jugular vein courses along the sternocleidomastoid deep to the platysma. It continues its course into the posterior triangle, entering the deep fascia, where it terminates into the subclavian vein (two-thirds) or the

internal jugular vein (one-third). The external jugular vein receives tributaries from the anterior and posterior jugular, transverse cervical, suprascapular, and cephalic veins.

Anterior Jugular Vein

The anterior jugular vein originates at the hyoid or suprahyoid level, formed by a confluence of veins from the parotid or retro-mandibular veins. Bilateral veins travel inferiorly over the sternohyoid and sternocleidomastoid muscles in a paired fashion, just off the midline of the neck. The right and left lines join above the sternum, forming a venous arch that descends to terminate in the subclavian or external jugular vein. Variations include the presence of only one midline cervical vein, absent venous arch, or absent anterior jugular vein.

35.4.2 Deep Veins

Internal Jugular Vein

The internal jugular vein receives venous drainage from the brain, face, and neck. The right internal jugular vein is usually larger than the left, and in 10% of individuals it is the predominant drainage of the head and neck. The internal jugular vein is

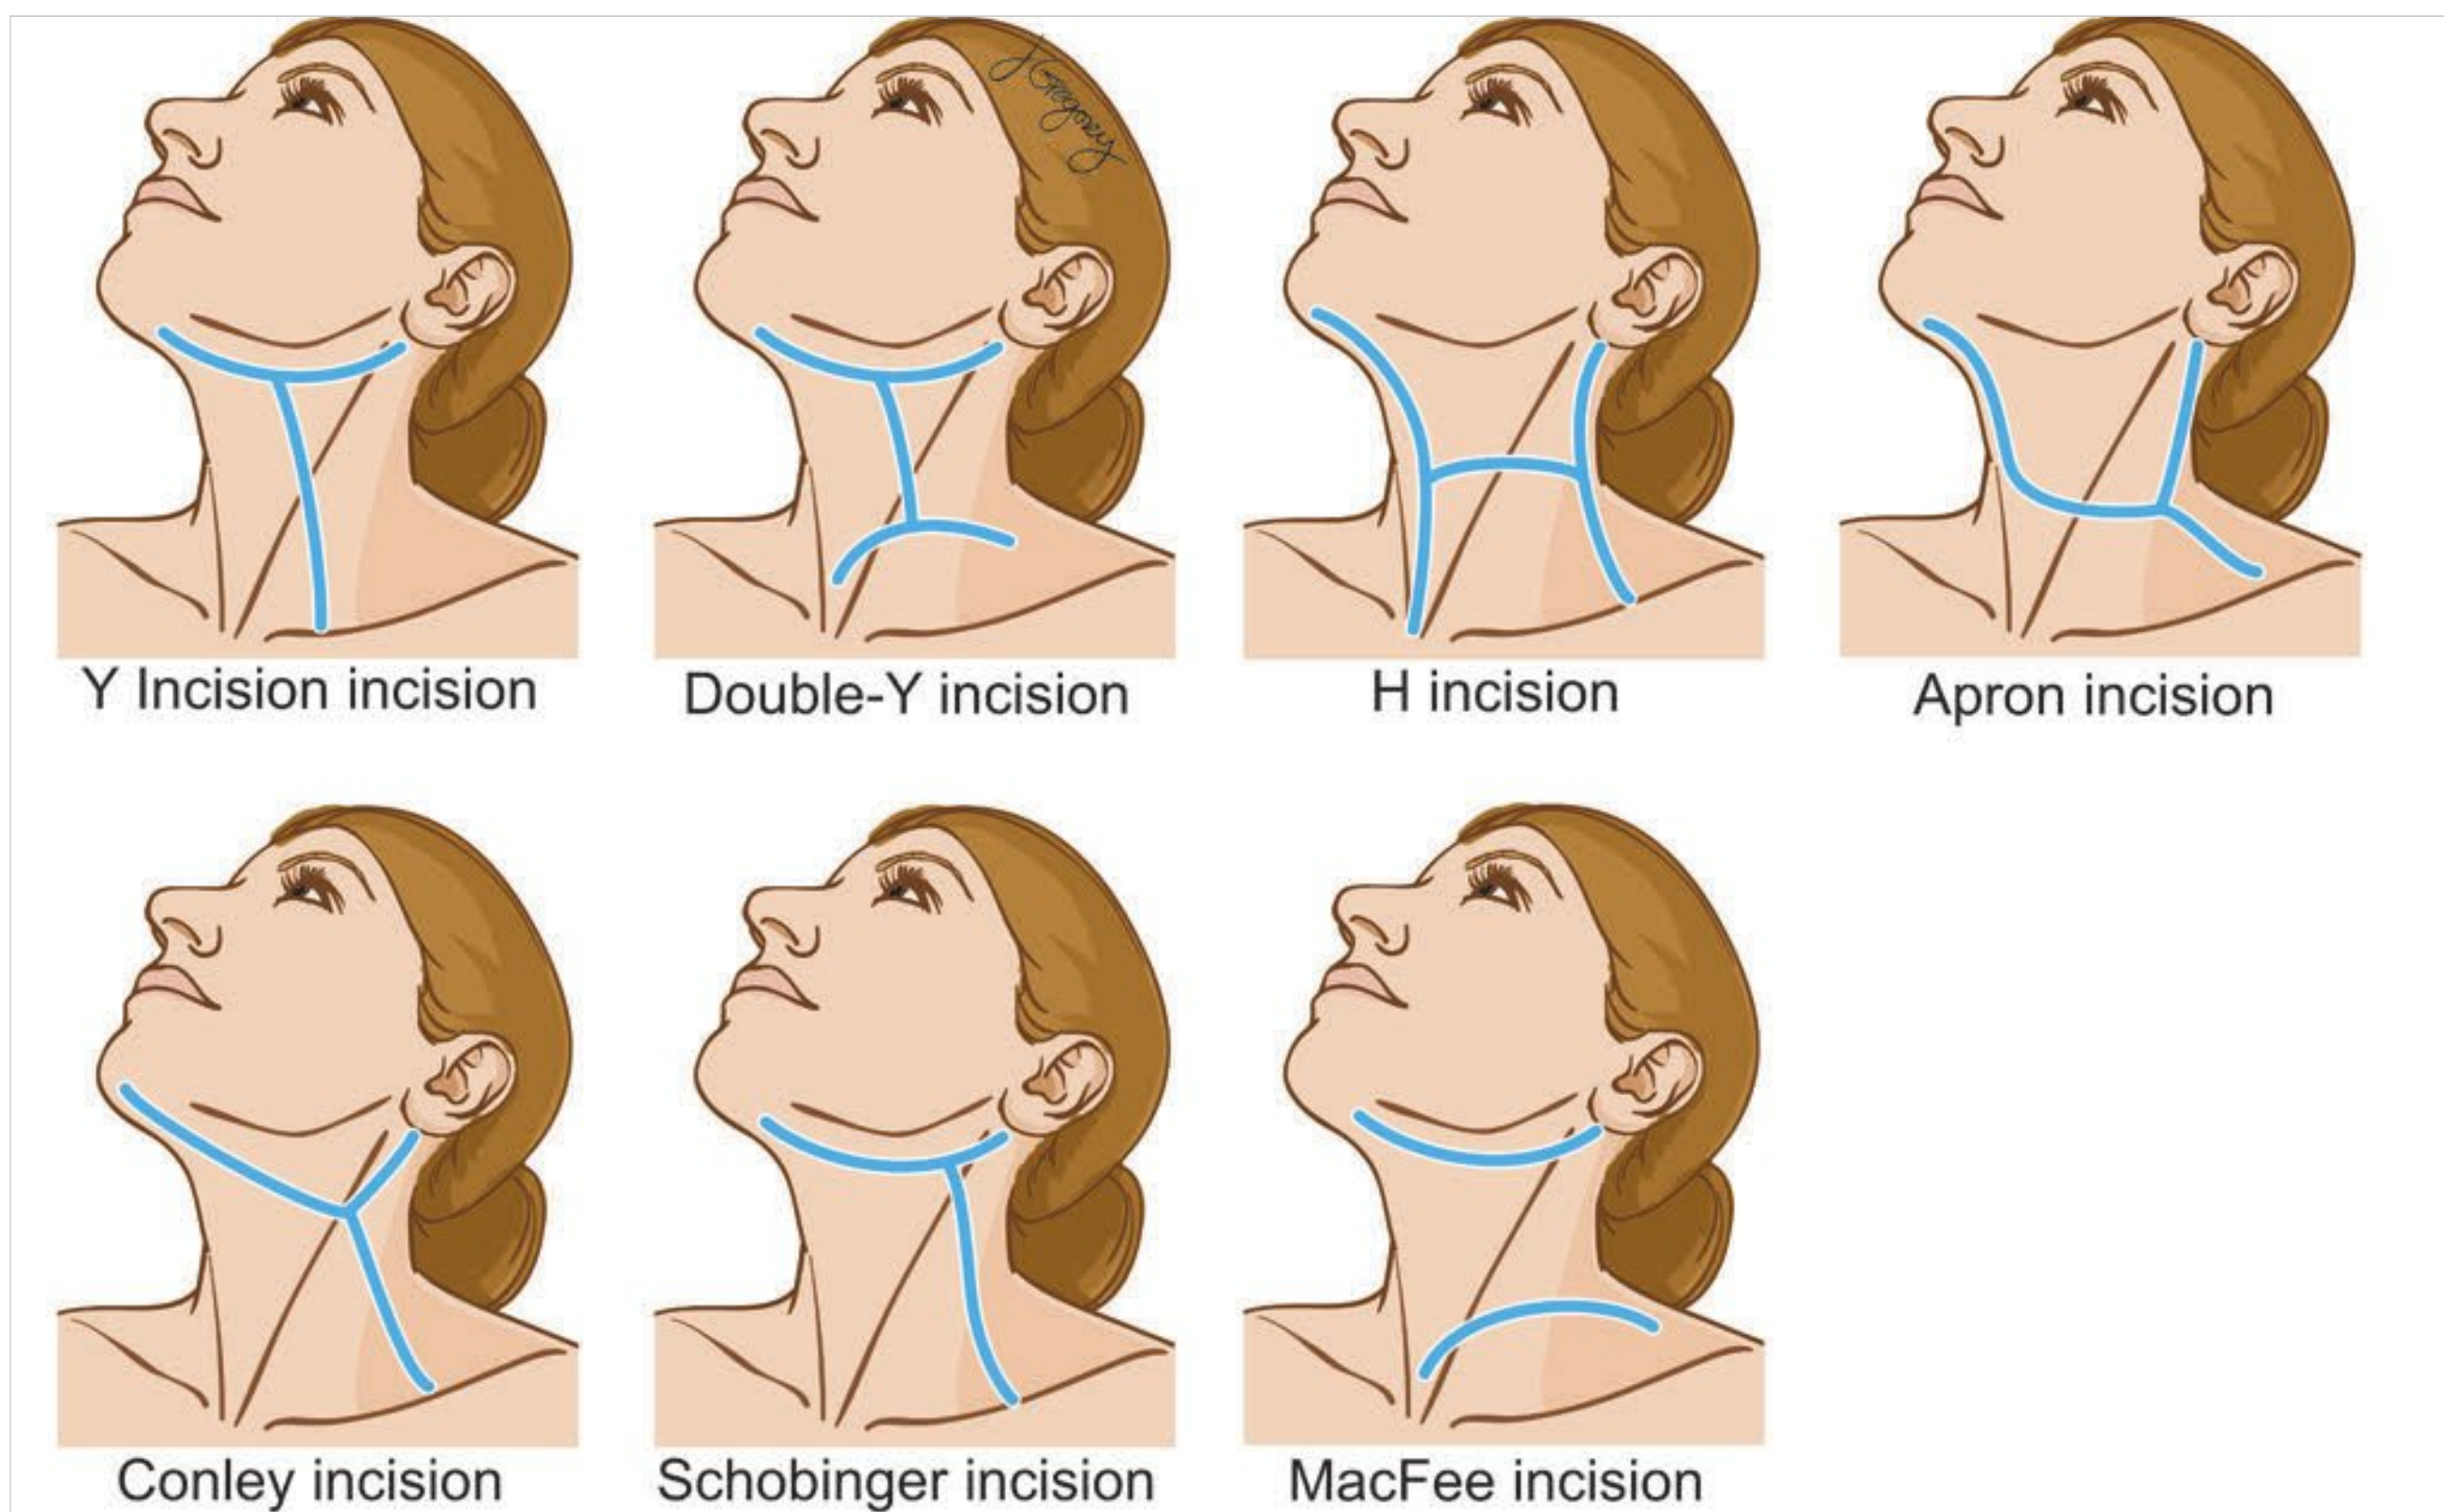

Fig. 35.5 Incisions for neck dissection.

formed by the union of the inferior petrosal sinus and the sigmoid sinus within the posterior compartment of the jugular foramen, exiting with cranial nerves IX, X, and XI. The vein also receives drainage from the lingual vein, facial vein, and retro-mandibular vein, forming a trunk below the level of the angle of the mandible.

The jugular bulb is the first portion of the vein as it descends into the floor of the middle ear space. The vein continues its course downward, crossing the transverse process of the atlas, with an anterolateral trajectory. The vein is encased within the carotid sheath, running lateral to the internal and common carotid arteries and anterior to cranial nerve X. At the level of the angle of the mandible, the vein is crossed by the posterior belly of the digastric muscle, stylohyoid muscle, occipital artery, and cranial nerve XI. In the right base of neck, the internal jugular vein crosses the first segment of the subclavian artery separated from the common carotid artery, while on the left side, the vein overlaps the artery. The subclavian vein joins the internal jugular vein, forming the brachiocephalic vein, inferior to the subclavian artery on the right and anterior to it on the left.

Subclavian Vein

The subclavian vein is a continuation of the axillary vein. It originates at the border of the first rib and continues to the medial border of the anterior scalene muscle. The subclavian veins course anterior to the subclavian artery and anterior scalene muscle.

35.5 Details of the Nerves of the Neck

35.5.1 Spinal Nerves

The dorsal (posterior) rami of the cervical nerves (except for the rami of C1) innervate the muscles and skin of the neck. The dorsal rami contain medial and lateral branches; the medial branches innervate muscle and skin, and the lateral branches supply only muscle.

35.5.2 Cervical Plexus

The cervical plexus is formed by the anterior ventral rami of the C1 to C4 nerve roots and is located anterior to the levator muscle of the scapula and the middle scalene muscle. Anteriorly, it is covered by prevertebral fascia, which forms a barrier separating the plexus from the internal jugular vein. The cervical plexus can be subdivided into deep and superficial branches.

The deep branches of the cervical plexus contain the superior and inferior root of the ansa cervicalis. The superior root contains fibers originating from C1 and C2 that join with cranial nerve XII, providing innervation to the thyrohyoid and geniohyoid muscles. The inferior root of the ansa cervicalis contains fibers that originate in the C2 and C3 nerve roots. The superior and inferior roots connect to form the ansa hypoglossi, which provides innervation to the infrahyoid muscles.

The superficial (cutaneous) branches of the cervical plexus are formed by nerve roots C2 to C4 and include the lesser occipital, great auricular, transverse cervical, suprascapular, anterior (medial) supraclavicular, middle (intermediate) supraclavicular, and posterior (lateral) supraclavicular nerves. The lesser occipital nerve originates from C2 to C4, coursing around the posterior border of the sternocleidomastoid muscle and providing sensory innervation inferior and posterior to the auricle. The great auricular nerve originates from C2 to C3 and also courses behind the posterior border of the sternocleidomastoid muscle before running superiorly toward the ear; it provides sensory innervation to the skin overlying the parotid gland, the auricle, and the skin of the mastoid process.

35.5.3 Phrenic Nerve

The phrenic nerve originates from the C3, C4, and C5 nerve roots. It courses on the anterior surface of the anterior scalene muscle and is covered by prevertebral fascia.

35.5.4 Brachial Plexus

The brachial plexus is formed by ventral rami of the C5 through T1 nerve roots. The plexus originates between the middle and anterior scalene muscles and continues to run posterior to the inferior belly of the omohyoid muscle. The plexus continues with the subclavian vein into the axilla, providing muscular and cutaneous innervation to the upper limb.

35.5.5 Cervical Sympathetic Trunk

The cervical sympathetic trunk consists mainly of ascending preganglionic nerve fibers that travel through ventral roots of the upper thoracic nerves. The cervical sympathetic trunk includes the superior, middle, vertebral, and stellate (inferior) sympathetic ganglia; the vertebral and middle sympathetic ganglia are inconsistently found.

Superior Cervical Ganglion

The superior cervical ganglion is located at the level of C2 and C3 above the carotid bifurcation, posterior and medial to the beginning portion of the internal carotid artery. The ganglion sits along the longus capitis muscle. The ganglion branches into the external carotid and internal carotid nerve plexuses. The internal carotid nerve plexus is the major continuation of nerves from the superior cervical ganglion, providing fibers that supply the upper part of the face and the orbit.

Middle Sympathetic Ganglion

The middle sympathetic ganglion is located at the carotid tubercle (transverse process of the C6 vertebra) in close proximity to the inferior thyroid artery. It is the smallest of the cervical ganglia and is present in only 62.3% of cervical trunks. Branches of this ganglion communicate with rami of the fifth and sixth cervical nerves and also form thyroid branches that travel with the inferior thyroid artery to the thyroid gland.

Inferior (Stellate) Sympathetic Ganglion

The inferior sympathetic ganglion is located between the transverse process of C7 and the first rib, medial to the vertebral ganglion. Often, this may be fused with the first thoracic ganglion and is known as the stellate ganglion. The inferior portion of the ganglion lies inferior and posterior to the subclavian artery.

35.5.6 Cranial Nerves of the Neck

Facial Nerve

Within the neck, the cervical and mandibular branches of the facial nerve are commonly encountered. The mandibular branch appears along the anterior border of the parotid gland. This branch runs inferiorly below the lower border of the mandible, crossing the anterior facial vein and the superficial layer of the deep cervical fascia at the level of the submandibular gland. This branch innervates the depressor anguli oris muscle. The cervical branch runs at the inferior border of the parotid gland, coursing behind the angle of the mandible, providing innervation to the platysma. Terminal branches supply the depressor muscles of the lower lip.

Glossopharyngeal Nerve

The glossopharyngeal nerve (cranial nerve IX) is a combined motor and sensory cranial nerve that exits the brainstem at the level of the upper medulla. The glossopharyngeal nerve exits the jugular foramen lateral to the vagus nerve and the accessory nerve, medial to the internal carotid artery, and anteromedial to the jugular bulb. At the jugular foramen, cranial nerve IX gives off two branches—the tympanic branch (Jacobson nerve), which provides innervation to the middle ear, and the vagal communicating (auricular) branch, which provides innervation to the external ear. After exiting the foramen, the glossopharyngeal nerve continues to run between the jugular vein and the internal carotid artery, deep to the styloid process, providing its only motor innervation to the stylopharyngeal muscle. The nerve passes along the lateral border of the stylopharyngeal muscle and along the middle constrictor muscle. The nerve then turns anteriorly toward the tongue. The glossopharyngeal nerve divides into its tonsillar and lingual branches deep to the hyoglossal muscle.

Vagus Nerve

The vagus nerve (cranial nerve X) exits the jugular foramen medial to cranial nerves IX and XI, passing into the carotid sheath. As the nerve courses rostrally within the neck, the nerve is located between and posterior to the carotid artery and internal jugular vein. Branches of cranial nerve X within the neck include the auricular branch (Arnold nerve), pharyngeal branch, superior laryngeal nerve, external laryngeal nerve, internal laryngeal nerve, cervical cardiac branches, and recurrent laryngeal nerve.

The auricular branch (Arnold nerve) originates in the jugular fossa and exits from the tympanomastoid fissure, supplying skin of the back of the external auditory canal, skin of the lower part of the meatus, and inferior portion of the tympanic

membrane. The pharyngeal branch runs along the lateral side of the internal carotid artery, providing motor innervation to the pharyngeal muscles. The superior laryngeal nerve is a branch of the vagus nerve that also has contributions from the superior sympathetic ganglion. The superior laryngeal nerve divides into the external and internal laryngeal nerves. The external laryngeal nerve provides innervation to the inferior constrictor muscles, terminating within the cricothyroid muscle. The internal laryngeal nerve courses anteriorly and pierces the thyrohyoid membrane along with the superior thyroid artery, innervating the laryngeal mucosa. The right recurrent laryngeal nerve branches off the vagus nerve anterior to the subclavian artery and courses upward posterior to the artery back toward the larynx. The nerve continues posterior to the trachea, crossing posterior or anterior to the inferior thyroid artery, and into the cricothyroid joint. The left recurrent laryngeal nerve branches off the vagus at the level of the aortic arch, looping posterior to the arch. The nerve then runs superiorly, within the tracheoesophageal groove, before terminating at the level of the cricothyroid joint.

Accessory (Spinal Accessory) Nerve

The spinal accessory nerve (cranial nerve XI) exits the jugular foramen along with the internal jugular vein, internal carotid artery, and cranial nerves IX and X. In two-thirds of individuals, the nerve crosses over the jugular vein, and behind the jugular vein in the remaining one-third. The jugular vein is crossed at approximately the level of the posterior belly of the digastric muscle. The nerve continues to run posteriorly and inferiorly toward the sternocleidomastoid. The nerve may run posterior to (18%) or through (82%) the sternocleidomastoid and then continues posteriorly, eventually terminating in the anterior muscular fibers of the trapezius muscle.

Hypoglossal Nerve

The hypoglossal nerve (cranial nerve XII) exits the skull base from the hypoglossal canal of the occipital bone. It travels toward the vagus nerve, running medial to the internal jugular vein and internal carotid artery. The nerve then runs deep to the posterior belly of the digastric muscle toward the submandibular fossa as it proceeds toward the tongue.

35.6 Types of Neck Dissections (□ Fig. 35.4)

1. Radical neck dissection involves the resection of levels I through V nodes, as well as the spinal accessory nerve, internal jugular vein, sternocleidomastoid muscle, tail of the parotid, and submaxillary gland.
2. Modified radical neck dissection, like radical neck dissection, includes the removal of levels I through V nodes, with sparing of one or more of the following structures: spinal accessory nerve, sternocleidomastoid muscle, and internal jugular vein.
3. Selective neck dissections include the supraomohyoid neck dissection, posterolateral neck dissection, lateral neck

dissection, anterior neck dissection, and extended neck dissection.

- (a) The supraomohyoid neck dissection removes nodes from levels I through III lymph nodes.
- (b) The posterolateral neck dissection removes lymph nodes from levels II through V, including suboccipital lymph and retroauricular lymph nodes.
- (c) The lateral neck dissection removes levels II through IV lymph nodes.
- (d) The anterior neck dissection removes nodes from the anterior compartment of the neck.
- (e) The extended neck dissection includes a dissection of all structures resected in a radical neck dissection, in addition to lymphatic nodes in the retropharynx, superior mediastinum, buccinator space, and paratracheal space. Nonlymphatic structures that may be resected in an extended neck dissection include deep muscles of the neck; one or more segments of the carotid artery system; the hypoglossal, vagus, and facial nerves; and the hyoid bone and clavicle.

35.7 Types of Incisions

Factors to consider in determining a flap incision (□ Fig. 35.5) include location of the primary lesion, exposure provided, flap viability, carotid artery protection, planned reconstructive procedures, history of prior radiotherapy, prior scars, and anticipated aesthetic results. Acute angles in flaps may produce narrow sections of skin that have an increased tendency to become necrotic because of compromised collateral circulation. Additionally, posterior cervical flaps have a higher tendency to flap failure than do superiorly and medially based flaps.

35.7.1 Y Incision

Advantages: Provides exposure of the mandible and upper neck; can provide oral cavity exposure if used in conjunction with a mandibulotomy.

Disadvantage: Produces an acute angle within the incision, with an increased likelihood for wound dehiscence and flap necrosis in the region covering the carotid artery.

35.7.2 Apron Incision

Advantage: Provides good exposure of the upper and lower neck.

Disadvantage: The large superior flap may become edematous in patients previously treated with radiation.

35.7.3 Schobinger Flap

Advantages: Provides excellent exposure as well as protection of the carotid arteries, with an improved cosmetic result due to decreased scarring in the middle neck.

Disadvantages: Produces a single acute angle below the angle of the mandible, at the posterosuperior tip of the flap. Exposure of the inferior sternocleidomastoid is limited, as well.

35.7.4 H Incision

Advantage: Provides excellent exposure of the anterior and posterior neck.

Disadvantages: There is strong potential for flap breakdown, particularly in the posterior flap. Flap breakdown over the superior flap may also result in carotid artery exposure.

35.7.5 MacFee Incision

Advantage: Provides an excellent cosmetic result.

Disadvantages: Compromised exposure, especially in shorter, fatter necks. There is also limited blood supply to the central segment and along the upper border of the flap. This may produce necrosis directly over the segment covering the carotid artery, especially in patients previously treated with radiation. There is also greater potential for seroma formation below the central flap.

35.8 Neck Dissection Technique (Authors' Preference: Right Modified Radical Neck Dissection)

The incision is marked extending from the mastoid tip on the right down in a Schobinger style fashion into the natural skin crease in the lower neck. The incision is then injected with 1% lidocaine and 1:100,000 epinephrine. The incision is made through the skin and subcutaneous tissue and down through the platysma muscle. Superior (up to the level of the horizontal ramus) and inferior (inferiorly to the level the clavicle) skin flaps are then raised in the subplatysmal plane. Flaps are raised anteriorly to the midline and posteriorly to the level of the posterior edge of the sternocleidomastoid. During the posterior dissection, care is taken not to injure the spinal accessory nerve as it emerges from the posterior border of the sternocleidomastoid. The anterior border of the sternocleidomastoid muscle is then dissected in an inferior to superior direction, taking care to gently apply pressure with a clamp to any tissue along the superior sternocleidomastoid muscle and checking for muscle twitching in order to prevent injury to the spinal accessory nerve. This dissection is carried posteriorly beneath the sternocleidomastoid to its most posterior edge.

As the anterior border of the sternocleidomastoid muscle is dissected superiorly, the spinal accessory nerve is identified running in an oblique fashion on the undersurface of the sternocleidomastoid muscle. It is generally found approximately 3 cm below the mastoid tip. It runs superiorly to the undersurface of the posterior belly of the digastric muscle, and at that point, it continues superiorly along the lateral border of the internal jugular vein. The carotid sheath structures are also identified at this point, and any fibrofatty tissue adjacent to the sternocleidomastoid muscle is elevated from the deep tissue, avoiding the rootlets of the cervical plexus. Once the spinal accessory nerve is identified, it is followed superiorly to identify the posterior belly of the digastric muscle, which is identified in its entirety. The submandibular fascia is then incised, and the fascia is raised off the submandibular gland in order to protect

the marginal mandibular nerve. The submandibular gland is then separated inferiorly from the surrounding tissue.

The common facial vein is identified, as is the facial artery, as they cross the facial notch on the inferior edge of the midportion of the horizontal ramus of the mandible. The mylohyoid muscle is then identified and retracted medially with a loop retractor. The lingual nerve is identified superiorly and the submandibular ganglion is ligated, separating the submandibular gland from the lingual nerve. The submandibular duct is also identified and ligated. The hypoglossal nerve is identified inferiorly and protected as the submandibular gland and surrounding tissue are elevated in an anterior to posterior direction.

Perifacial lymph nodes within the submandibular triangle are also identified. These nodes are then dissected free from the surrounding tissue, respecting the submandibular fascia in order to preserve the marginal mandibular nerve. The tissues are retracted in a posterior direction and left in direct continuity with level II lymph nodes.

The level IIB lymph nodes are then dissected. An incision is created in the fascia surrounding the fibrofatty tissue down in level IIB, posterior to the spinal accessory nerve. The fibrofatty tissue is dissected free from the floor of the neck, with care taken to preserve the internal jugular vein, which enters this compartment. The tissue is then dissected free from the surrounding tissue and the tail of parotid, as well as the sternocleidomastoid muscle, and passed below the spinal accessory nerve and left in continuity with level IIA nodes. Once the entirety of the anterior border of the sternocleidomastoid muscle is separated from the fibrofatty tissue, the floor of the deep cervical fascia is incised. The fibrofatty tissue is then dissected free from the floor of the neck, superficial to the cervical rootlets, and dissected in a lateral to medial direction toward the internal jugular vein.

The omohyoid muscle is then identified inferiorly and left in continuity. The fibrofatty tissue along the floor of the neck is elevated and then dissected in a posterior to anterior dissection toward the carotid sheath structures. With a No. 15 blade, the cervical fascia investing the carotid sheath is separated from the internal jugular vein and elevated in continuity with the fibrofatty tissue medially. The vagus nerve and carotid artery are also identified at this point, and any fascia overlying these structures is separated and left in continuity with the fibrofatty tissue.

Once the remaining portions of the neck contents are elevated on the internal jugular vein, a No. 15 blade is used to separate them from the internal jugular vein and toward the sternohyoid muscle. This fibrofatty tissue is then dissected free from the sternohyoid muscle in a sharp fashion.

A thorough examination of the neck should reveal continuity of the spinal accessory, hypoglossal, and lingual nerves. The cervical rootlets should also be identified and continuity ensured. Finally, the internal jugular vein as well as the carotid artery should be inspected and found to be intact.

The wound is then copiously irrigated with normal saline, and blood and clots are cleared with suction. Hemostasis is achieved with bipolar cautery. After placement of a suction drain, the wound is closed by approximating the platysma with a running 3-0 chromic suture and the skin with staples.

35.9 Roundsmanship

- An understanding the lymphatic drainage patterns of the head and neck aids in the choice of proper neck dissection technique.
- Neck dissection incisions are chosen to provide adequate access for nodal dissection; the development of healthy, vascularized skin flaps, especially for carotid artery protection; and maximal cosmesis.
- Pertinent veins and significant arteries and nerves are preserved, if possible, during neck dissection; however, involvement by tumor generally requires that these structures be sacrificed.

36 Evaluation and Management of the Solitary Neck Mass

Ameet R. Kamat and Stimson P. Schantz

36.1 Introduction

The management of a solitary neck mass is an often-encountered dilemma for the otolaryngologist. However, a thorough history and physical examination, along with a concise differential diagnosis, usually will lead to the proper diagnosis. The treatment of a solitary neck mass is dictated by the clinician's confidence in that diagnosis. As in any other field of medicine, a step-by-step plan for diagnosis and treatment is imperative to helping the patient.

36.2 Terminology and Applied Anatomy

A concrete understanding of neck anatomy is essential to a timely diagnosis and the effective treatment of solitary neck masses. For convenience of localization, the neck can be divided into several triangles. The neck is first divided into anterior and posterior triangles. The anterior triangle is bordered by the posterior border of the sternocleidomastoid muscle laterally, the inferior margin of the mandible superiorly, and the clavicle inferiorly. The posterior triangle is bordered by the posterior margin of the sternocleidomastoid muscle medially, the anterior margin of the trapezius muscle laterally, the skull base superiorly, and clavicle laterally (middle one-third). For details of the smaller triangles that make up the neck, the reader is referred to Chapter 8 (Head and Neck Anatomy) and Chapter 35 (Principles and Techniques of Neck Dissection).

For purposes of localization, especially in the management of regional metastasis from upper aerodigestive tract carcinoma, the neck is divided into a series of levels as detailed in □ Table 36.1.

36.3 Medical Evaluation

36.3.1 Presenting Complaints

The differential diagnosis of a solitary neck mass is quite broad in comparison with that for other presenting symptomatology. A thorough and well-directed history and physical examination will allow the clinician to develop a concise differential diagnosis and guide further testing.

Focusing first on the neck mass itself, a clinician should elicit information regarding the onset and growth progression. Next, starting at the top of the head and proceeding to the base of neck, the clinician should elicit a thorough head and neck review of systems. The initial investigation should include a determination of the presence of constitutional symptoms, such as fever, weight loss, night sweats, loss of appetite, and fatigue. Symptoms such as trismus, decreased tongue mobility, dental pain, rhinorrhea, postnasal drip, sore throat, shortness of breath, hoarseness, dysphagia, and odynophagia should be duly noted. A history of recent upper respiratory tract infection, including recent sinusitis (facial pressure, pain, nasal discharge),

otitis media/externa (otalgia, otorrhea, aural fullness), and pharyngitis (sore throat, odynophagia), must also be included. Additional contributory factors include recent travel; exposure to pets, wild animals, or individuals with tuberculosis; and a history of immunodeficiency, including HIV infection, chemotherapy/radiation, steroids, and uncontrolled diabetes.

The age of the patient should guide further questioning because most pediatric neck masses are either inflammatory or congenital, and those in adults carry a higher risk for malignancy. A full social history should be elicited in an adult with a neck mass, including tobacco, alcohol, and illicit drug use.

36.3.2 Physical Examination

The character of the mass should be recorded with respect to size (larger or smaller than 3 cm); location; mobility; consistency (firm, soft, fluctuant, compressible); tenderness to palpation; and the presence of other lesions. Of these characteristics, location can help narrow the differential diagnosis in pediatric patients because most congenital or developmental masses tend to occur either midline or lateral neck at specific levels of the sternocleidomastoid (SCM) muscle or adjacent to other structures. Even in adult patients, the location of metastatic lymphadenopathy can help identify the primary site of a carcinoma in the upper aerodigestive tract. The character of the overlying skin is also significant in regard to erythema, induration, rash, blanching, audible bruit, palpable thrill, or fistula.

A systematic examination of all external and internal aspects of the head and neck should also be conducted. Especially with adult patients, attention should be paid to the external ear, nasal cavity, nasopharynx, oral cavity, oropharynx, hypopharynx,

Table 36.1 Neck node levels

Levels	Borders
IA	Symphysis of mandible, hyoid bone, medial aspect of anterior belly of each digastric muscle
IB	Body of mandible, posterior belly of digastric muscle, anterior belly of ipsilateral digastric muscle, stylohyoid
IIA	Skull base, level of hyoid bone, stylohyoid, spinal accessory nerve
IIB	Skull base, level of hyoid bone, spinal accessory nerve, posterior border of sternocleidomastoid
III	Hyoid bone, inferior border of cricoid cartilage, sternohyoid, posterior border of sternocleidomastoid
IV	Inferior border of cricoid cartilage, clavicle, sternohyoid, posterior border of sternocleidomastoid
VA	Convergence of sternocleidomastoid and trapezius, level of cricoid cartilage, posterior border of sternocleidomastoid, anterior border of trapezius
VB	Level of cricoid cartilage, clavicle, posterior border of sternocleidomastoid, anterior border of trapezius
VI	Hyoid bone, suprasternal notch, bilateral common carotid arteries

and larynx. The patient should be evaluated for skin or scalp lesions, and the palpation of other lymphatic sites (including axillary, supraclavicular, and occipital nodes) should not be forgotten. The palpation of all salivary glands and the thyroid gland, liver, and spleen can also provide important information.

36.4 Testing

36.4.1 Laboratory Testing

Laboratory testing may include simply a complete blood cell count with differential to identify markers of infection, such as an increased white blood cell count with a neutrophil predominance. For neck masses that may be a manifestation of systemic disease, the erythrocyte sedimentation rate levels of rheumatoid factor, antinuclear antibody, and HIV antibody can be diagnostic. In the case of specific infectious causes, serologic testing can provide definitive information, as with tuberculosis (purified protein derivative), infectious mononucleosis (monospot test or viral capsid antigen immunofluorescence), cat-scratch disease (antibody titers), and toxoplasmosis (antibody titers).

36.4.2 Pathological Testing

Fine-needle aspiration biopsy has become an essential tool in the diagnosis of neck masses. The procedure is quick and safe, and it can yield an abundant amount of information. A 22- to 25-gauge needle attached to a 10-mL syringe is inserted through the skin into the neck mass, and while the plunger is pulled and held back to maintain suction, multiple passes through the lesion are made. The aspirate is typically placed on a microscope slide for pathologic analysis. Although tissue architecture is generally not apparent, fine-needle aspiration biopsy can differentiate cystic from solid, benign from malignant, and lymphoid from squamous masses. Some controversy still exists regarding the timing of fine-needle aspiration biopsy before or after imaging. Nonetheless, the utility and ease of fine-needle aspiration biopsy cannot be discounted. If indeterminate, or if tissue architecture is needed for diagnosis and treatment such as with lymphoma, an excisional biopsy is frequently conducted in the operating room.

36.4.3 Imaging

Computed tomography (CT) and magnetic resonance (MR) imaging of the neck can be extremely helpful in the characterization of a solitary neck mass. They can define the actual size of a lesion and its effect on surrounding vasculature. It can also differentiate cystic, solid, vascular, and invasive characteristics. A mass can be further characterized by its relation to important head and neck structures. For example, a thyroglossal duct cyst can be identified by its close relation to the hyoid bone. With regard to head and neck cancer, CT can help delineate specific areas of possible local and regional involvement, with special attention to bone. MR imaging can aid the clinician in the definition of soft-tissue planes. Positron emission tomography (PET) can aid the diagnosis in the difficult scenario of a neck metastasis with an unknown primary. Ultrasonography can identify cystic masses and is especially useful with thyroid

masses. It can also be used to aid accuracy during fine-needle aspiration of nonpalpable masses.

36.5 Differential Diagnosis

36.5.1 Inflammatory and Infectious Masses

Viral Lymphadenopathy

Reactive lymphadenopathy secondary to a viral infection is the most common type of cervical lymphadenitis to affect both children and adults. Typically, the reactive lymphadenopathy presents during or after a recent upper respiratory tract infection (URI). Common viruses include adenovirus, rhinovirus, coxsackie virus A and B, Epstein Barr virus (EBV), cytomegalovirus, herpes simplex virus, and human immunodeficiency virus (HIV). Importantly, reactive lymph nodes can become secondarily infected by a bacterial agent causing suppurative lymphadenopathy. However, in most cases the lymph nodes are bilateral, symmetric, and regress in the 1–2 weeks following resolution of the URI. Treatment is typically supportive unless suppurative lymphadenopathy is suspected in an acutely enlarging, fluctuant, asymmetric, or exquisitely painful lymph node. Biopsy may be necessary if a lymph node persists several weeks beyond a cleared URI or if other alarming features discussed earlier arise.

Bacterial Lymphadenopathy

Bacterial lymphadenopathy, or suppurative lymphadenopathy, presents similarly to viral lymphadenopathy after an upper respiratory tract infection. However, these masses are often larger, more fluctuant, and accompanied by a sore throat, skin lesions, or high fever. The most common causative organisms are *Staphylococcus aureus* and group A β -hemolytic streptococci, although anaerobic and gram-negative bacteria can also be present. Treatment begins with a trial of antibiotics covering gram-positive and anaerobic bacteria. If this fails, intravenous antibiotics alone or incision and drainage with culture-directed antibiotic therapy is usually necessary. Other more common bacterial causes of lymphadenopathy include:

Cat-Scratch Disease

Cat-scratch disease typically is seen in patients younger than 20 years of age. Symptoms include tender submandibular or periauricular lymphadenopathy associated with fever, malaise, and a history of contact with cats. Parinaud (oculoglandular) syndrome can occur from inoculation near the eye or from eye rubbing. It presents with unilateral conjunctivitis and regional lymphadenitis. The causative bacterium is *Bartonella henselae*, which can be identified by Warthin-Starry staining. The diagnosis can also be aided by indirect fluorescent antibody testing for *Bartonella* DNA, which has been found to be both sensitive and specific. Treatment is typically supportive because the course is usually self-limited. However, antibiotic therapy with azithromycin or ciprofloxacin can expedite resolution. Incision and drainage should be avoided because of the potential for sinus formation.

Mycobacterial Infections

Atypical mycobacterial infections are typically caused by multiple mycobacteria including *M. avium-intracellulare*, *M. scrofulaceum*, and *M. kansasii*. They typically present as unilateral, anterior-superior cervical lymphadenopathy with overlying skin involvement. They are more common in children, immunocompromised patients, or those with recent foreign travel. The treatment of atypical mycobacterial infections can include complete excision or incision and drainage followed by antitubercular antibiotics.

In contrast, lymphadenopathy caused by *M. tuberculosis* is bilateral and not localized to a particular cervical region. While not as common with atypical infections, tuberculosis are associated with constitutional symptoms such as fever and weight loss. They are more common in adults, immunocompromised patients, recent foreign travel or exposure to an endemic population. The diagnosis of cervical tuberculosis (scrofula) is usually confirmed by acid-fast stain and culture after a lymph node biopsy, but can be suggested by positive tuberculin skin testing. Treatment of scrofula is simply antitubercular antibiotics.

Tularemia

Tularemia presents as an acute tonsillitis with fever, chills, and painful cervical lymphadenopathy. It is caused by the bacterium *Francisella tularensis* and transmitted to humans via rabbits, ticks, and contaminated water. The diagnosis is by serology and culture. The treatment is antibiotic therapy with intramuscular streptomycin.

Brucellosis

Brucellosis presents as a generalized lymphadenopathy with associated fever and malaise. It is caused by the bacterium *Brucella* and typically afflicts children after the ingestion of unpasteurized milk. The diagnosis is by serology and culture. The treatment typically includes antibiotic therapy with either trimethoprim/sulfamethoxazole or tetracycline.

Fungal Infections

Fungal infections are much less common than bacterial or viral infections in immunocompetent patients. However, their incidence rises dramatically in the immunocompromised population. Typical offending pathogens include *Candida*, *Histoplasma*, and *Aspergillus*. The diagnosis is typically by fungal smear with culture or by serology. The treatment is aggressive with agents such as intravenous amphotericin B and in some cases correction of the underlying immunocompromised state.

Protozoal Infections

One of the most common causes of protozoal lymphadenitis is toxoplasmosis. *Toxoplasma gondii* infection typically presents as a nonspecific cervical adenitis with an associated influenza-like illness. Inoculation typically occurs after the ingestion of uncooked meat or of oocytes from cat feces. The diagnosis is typically by serum titers or lymph node biopsy. The treatment includes antiprotozoal agents such as pyrimethamine or sulfonamides.

HIV-Associated Cervical Lymphadenopathy

Cervical lymphadenopathy in the patient with HIV infection may be due to idiopathic follicular hyperplasia. However, in immunosuppressed patients, other infectious or neoplastic conditions such as tuberculosis and lymphoma cannot be excluded without work-up. Typically, excisional biopsy is done for suspicious lesions that are rapidly enlarging or have failed antibiotic therapy. Patients with HIV infection patients may also be diagnosed with persistent generalized lymphadenopathy when no other identifiable cause is found. Typically, these patients will have adenopathy in both the axillary and inguinal regions for longer than 3 months. The treatment is typically observation with standard treatment of the HIV infection.

36.5.2 Noninfectious Inflammatory Disorders

Sarcoidosis

Sarcoidosis is an idiopathic granulomatous disease of unknown etiology. It is marked by the accumulation of mononuclear cells in affected organs with subsequent noncaseating granulomatous reaction and fibrosis. It most commonly presents in females and in the second decade of life; in the United States, African-Americans are more commonly affected, although worldwide Caucasians are more likely to be affected. Head and neck symptoms most commonly include cervical adenopathy, but nasal, orbital, and supraglottic masses are also possible. Heerfordt syndrome (uveoparotid fever) is the constellation of fever, parotid swelling, facial nerve palsy, sensorineural hearing loss, and uveitis. Systemically, sarcoidosis can be asymptomatic or present with progressive cough, dyspnea, and bone and joint pain. Pulmonary involvement is most common, but subcutaneous nodules, hepatosplenomegaly, cardiac arrhythmias, and cutaneous rashes can also be seen. The diagnosis is by chest radiography showing hilar adenopathy, biopsy of affected tissue showing noncaseating granulomas, and blood work showing increased serum angiotensin-converting enzyme (ACE) levels. The treatment includes steroids for acute exacerbations.

Rosai-Dorfman Disease

Rosai-Dorfman disease typically presents in children with massive, non-tender, bilateral cervical lymphadenopathy associated with constitutional symptoms such as fever and weight loss. It can also affect other nodal systems in the mediastinum, inguinal area or retroperitoneum. Extranodal locations include the skin, soft tissue, and upper aerodigestive tract (nasal cavity). Intracranial manifestations can also occur. Although the exact etiology is unknown, the disease is thought to result from an abnormal histiocytic response to a viral infection. The diagnosis is established by biopsy showing dilated sinuses, plasma cells, and histiocytic proliferation. The treatment is generally conservative because this disease has a self-limited course.

Kawasaki Disease (Mucocutaneous Lymph Node Syndrome)

Kawasaki disease initially presents in children younger than 5 years of age with fever lasting for at least 5 days in association

with at least four of the following: acute, unilateral, nonpurulent cervical lymphadenopathy; rash; bilateral conjunctival injection; erythema of the lips and oral cavity; or erythema, induration, and desquamation of the hands and feet. The subacute and chronic phases are marked by thrombocytosis, the formation and enlargement of coronary aneurysms, and a risk for myocardial infarction. The diagnosis is by history and physical examination, with cardiac work-up more imperative in the later stages. The treatment is typically high-dose gamma globulin therapy in the acute phase. Aspirin and dipyridamole can be used for coronary aneurysms.

36.5.3 Congenital Neck Masses

These include branchial cleft cysts, thyroglossal duct cysts, dermoids and teratomas, laryngoceles, and sternocleidomastoid tumors. Lymphangiomas, hemangiomas, and vascular malformations are also within the differential diagnosis, but they will be discussed elsewhere.

Thyroglossal Duct Cysts

Thyroglossal duct cysts make up more than two thirds of all congenital neck masses and are the second most common pediatric neck masses. They are typically diagnosed before the age of 10, but can be seen as late as the third decade of life. They originate from a persistence of the tract followed by the thyroid diverticulum as it descends caudally from the foramen cecum of the tongue, just anterior to the hyoid bone, to its final paratracheal destination. Thyroglossal duct cysts present either as painless, cystic neck masses in the midline of the neck near the hyoid bone or as painful, cystic masses when acutely infected. However, they can be found anywhere between the tongue and thyroid gland, sometimes even within the tongue. A hallmark feature is the movement of these cysts when the patient protrudes the tongue or swallows. Treatment involves an excision not only of the dominant cyst but also of the medial portion of the hyoid bone and a cone-shaped cuff of tissue from the hyoid to the base of the tongue. This operation (Sistrunk procedure) is thought to reduce the risk for recurrence. Infected cysts often necessitate needle aspiration and antibiotic therapy; formal incision and drainage is not recommended.

Branchial Cleft Cysts

Branchial cleft anomalies account for roughly 30% of all congenital neck masses. While they present most commonly as cysts, they can also present as sinuses or fistulas to the aerodigestive tract. They typically present in childhood or early adulthood and do not have a sex predominance. The mechanism for their development is unclear, but some suspect they originate from the cervical sinus of His and become trapped, without an external (or internal) opening. Simply, they are thought to originate from a failure of obliteration of the branchial clefts and pouches. Others theorize that they develop from epithelial rests of tissue in the Waldeyer ring. A branchial cleft cyst typically presents as a fluctuant mass at the anterior border of the sternocleidomastoid muscle. The physical examination should include an evaluation of the upper airway, including the tonsillar fossae and piriform sinuses, for any evidence of connection. CT, MR

imaging, and ultrasound can be used to better characterize the mass. Fine-needle aspiration biopsy is contraindicated unless for drainage of an infected cyst because it makes surgical excision more difficult. However, in adults, FNA can be used to differentiate a branchial cleft cyst from cystic degeneration of a metastatic lymph node.

1. First branchial cleft cysts: These cysts make up fewer than 1% of all branchial cleft anomalies. They can involve the external auditory canal, parotid gland, or less frequently the middle ear. They are known to course close to the facial nerve, sometimes crossing between fibers. They are typically classified as type I or type II.
 - a) Type I: These masses form as duplications of the membranous external auditory canal, contain ectoderm only, typically course lateral to the facial nerve, and may present as cysts near the auricle.
 - b) Type II: These masses contain both ectoderm and mesoderm, can sometimes contain cartilage, and typically course medial the facial nerve. Their presentation is more variable than that of type I. They can present anywhere from the external auditory canal to the submandibular area. Most commonly, they present as cysts near the angle of the mandible, with tracts coursing superiorly through the parotid gland to end inferior to or in the external auditory canal.
2. Second branchial cleft cysts (□ Fig. 36.1): These cysts are the most common, accounting for approximately 95% of all branchial cleft anomalies. They most typically present as solitary neck masses just anterior to the sternocleidomastoid muscle, separate from the carotid sheath. However, they can lie anywhere along a potential tract that passes deep to the sternocleidomastoid between the internal and external carotid arteries and pierces the tonsillar fossa.
3. Third branchial cleft cysts: These cysts are quite rare. Third branchial cleft cysts present at the lower, anterior border of the sternocleidomastoid (near the superior pole of the thyroid gland). The tract passes deep to the internal carotid artery and glossopharyngeal nerve and superficial to the vagus nerve, then enters the thyrohyoid membrane to enter the pharynx at the piriform sinus above the internal branch of the superior laryngeal nerve.

Treatment

Excision of first branchial cleft anomalies, especially type II anomalies, may include a superficial parotidectomy with facial nerve dissection. Unfortunately, recurrence is quite common, even after excision. Second branchial cleft anomalies can be resected through a standard transcervical incision. However, if a tract is noted, techniques that include cannulation, methylene blue injection, and stepladder incisions may be used to trace the entire length of the tract. Third branchial cleft cysts are treated similarly to second branchial cleft cysts. However, a thorough endoscopic examination is important to identify a piriform sinus opening.

Dermoid Cysts

Neck dermoid cysts comprise only 20% of all head and neck dermoids. They are thought to originate from the entrapment of

Fig. 36.1 Left-sided second branchial cleft cyst. Note the close relationship to the anterior border of the sternocleidomastoid muscle.

Fig. 36.2 Left-sided laryngopyocele. Note the origin medial to the thyroid cartilage, with extension externally through the thyrohyoid membrane.

epithelium along embryologic lines of fusion but can also occur from traumatic implantation. Dermoids contain both ectodermal and endodermal elements. They are lined by epithelium but can contain other elements, such as hair follicles and sebaceous glands. Dermoids present similarly to thyroglossal duct cysts, as midline (usually in the submental region), painless, slow-growing, superficial neck masses that can move during tongue protrusion and swallowing. However, infection is rare, and they can gradually increase in size. Surgical excision is the treatment of choice.

Teratomas

Head and neck teratomas comprise approximately 2% of all teratomas; aside from the neck, the other most common site in the head and neck is the nasopharynx. These teratomas form

during the second trimester, are more common in females, and differ from dermoids in that they contain all three germ layers. Teratomas typically present at birth as firm, midline neck masses, with the CT/MR imaging finding of calcifications. They can sometimes be identified on prenatal ultrasound. If a teratoma is discovered prenatally, cesarean section may be necessary because of rapid growth and the potential for airway compromise and esophageal compression. Surgical excision is the treatment of choice.

Laryngoceles

A laryngocele is an air-filled dilatation or herniation of the laryngeal saccule that can also become infected (□ Fig. 36.2). Laryngoceles are rare in children but can present in a congenital form as a remnant sac. However, typically they present in adults

as an acquired form secondary to increased intraglottic pressure. There are three types of laryngoceles: internal, external, and combined. An internal laryngocele is a dilatation that does not extend beyond the thyroid cartilage. An external laryngocele extends beyond the thyroid cartilage through the thyrohyoid membrane and can present as a lateral neck mass. In addition to a lateral neck mass, all types of laryngoceles can present with hoarseness, dyspnea, and dysphagia. Endoscopic evaluation typically reveals a dilatation at the level of the ventricle or false vocal folds for an internal laryngocele. It is also important to rule out a laryngeal mass. CT is the diagnostic test of choice to differentiate laryngoceles from fluid-filled saccular cysts. Treatment is typically surgical: endoscopic excision for small internal laryngoceles or excision via an external approach for larger ones.

Thymic Cysts

Thymic cysts develop from the implantation of thymic tissue along the tract that the third branchial pouch takes as it descends into the mediastinum. They typically present as unilateral (more commonly left-sided), asymptomatic cystic neck masses. Like other congenital cysts, they can present after infection with pain and rapid enlargement. Surgical excision is the treatment of choice.

Sternocleidomastoid Tumors of Infancy

Sternocleidomastoid tumor of infancy typically presents 1 to 8 weeks after birth as a firm, painless, thickened mass confined to the muscle that slowly increases in size and then regresses. The infant usually holds its head and neck to the affected side and the chin to the opposite side. The tumors are thought to result from birth trauma, muscle ischemia, or intrauterine positioning. Their slow but typically complete regression allows conservative management with physical therapy and excision only for persistent cases.

36.5.4 Neoplastic Disorders

Metastatic squamous cell carcinoma from the upper aerodigestive tract, lymphoma, thyroid disease, paraganglioma, lipoma, and salivary gland neoplasms can all present as solitary neck masses. They are discussed in other chapters.

36.6 Treatment

The treatment of a solitary neck mass is dictated by the diagnosis. For congenital neck masses, the treatment is typically surgi-

cal excision. However, if the mass presents as an acute infection, then antibiotics, aspiration, and observation before excision are appropriate. Infectious and inflammatory neck masses are treated with either close observation or antibiotic therapy. However, the diagnosis of an infectious or inflammatory mass is often made with surgical excisional biopsy. Complications of treatment include bleeding, infection, and pain from surgical incisions. In addition, damage to surrounding structures such as nerves, arteries, and veins during surgical excision is a costly complication. There is also a high risk for recurrence, especially of surgically excised congenital neck masses. The prognosis for a patient with a solitary neck mass depends on the diagnosis and is improved by early evaluation and expeditious management.

36.7 Roundsmanship

- A thorough history and physical examination will lead to a concise differential diagnosis for the patient with an isolated neck mass.
- An understanding of the neck levels is important not only for localization but also for surgical management and an awareness of the potential complications associated with neck masses.
- Congenital neck masses can present during an acute infection. Incision and drainage is contraindicated in most instances.
- Virus-induced lymphadenopathy is the most common type of cervical lymphadenitis in both adults and children.
- Cervical lymphadenopathy in the patient with HIV infection is most commonly due to idiopathic follicular hyperplasia.

37 Blunt and Penetrating Neck Injuries

James Azzi, Jean-Paul Azzi, and Stimson P. Schantz

37.1 Penetrating Neck Injuries

Penetrating neck injuries are defined as any violation of the platysma. They comprise 5 to 10% of all traumas. Because the neck is a small, vulnerable area that houses a multitude of vital structures, trauma to this area can be emergent and life-threatening; hemorrhage is the most common cause of death in this group.

Air passages and vascular, gastrointestinal, and neurologic structures can all potentially be injured by penetrating neck trauma. Signs and symptoms can be divided among these groups of structures. Laryngotracheal injury may present with respiratory distress, stridor, hemoptysis, hoarseness, tracheal deviation, subcutaneous emphysema, or a sucking wound. Vascular injuries may present with a hematoma, persistent bleeding, neurologic deficit, absent pulse, hypovolemic shock, bruit, thrill, or change in sensorium. Neurologic injury may present with hemiplegia, quadriplegia, cranial nerve deficit, change in sensorium, or hoarseness. Pharyngoesophageal injury may be characterized by subcutaneous emphysema, dysphagia, odynophagia, hematemesis, hemoptysis, tachycardia, or fever. It is important to note that esophageal injuries are often subclinical.

To aid in decision making, the neck can be divided into three anatomical zones. Zone II lies between the cricoid and the angle of the mandible and is the zone most commonly injured. Zone I, the most caudal zone, lies between the cricoid and the sternal notch; injuries to this zone carry the highest mortality risk. Zone III lies between the mandibular angle and the skull base. Of great concern in the management of penetrating neck injuries is ease of surgical exposure. Zone II is the most easily accessed. Zones I and III are better protected by bone, so that surgical explorations are more difficult (□ Fig. 37.1).

Patients presenting with penetrating neck injuries can be divided into three groups: unstable, stable, or asymptomatic. When this information is combined with knowledge of the neck zones involved, an algorithm for management can be established.

37.1.1 Mechanism

The mechanism of injury and velocity of the projectile are key factors influencing the risk for major injury. Gunshot wounds generally can be divided into low-velocity and high-velocity wounds. Most civilian handguns have a low muzzle velocity.

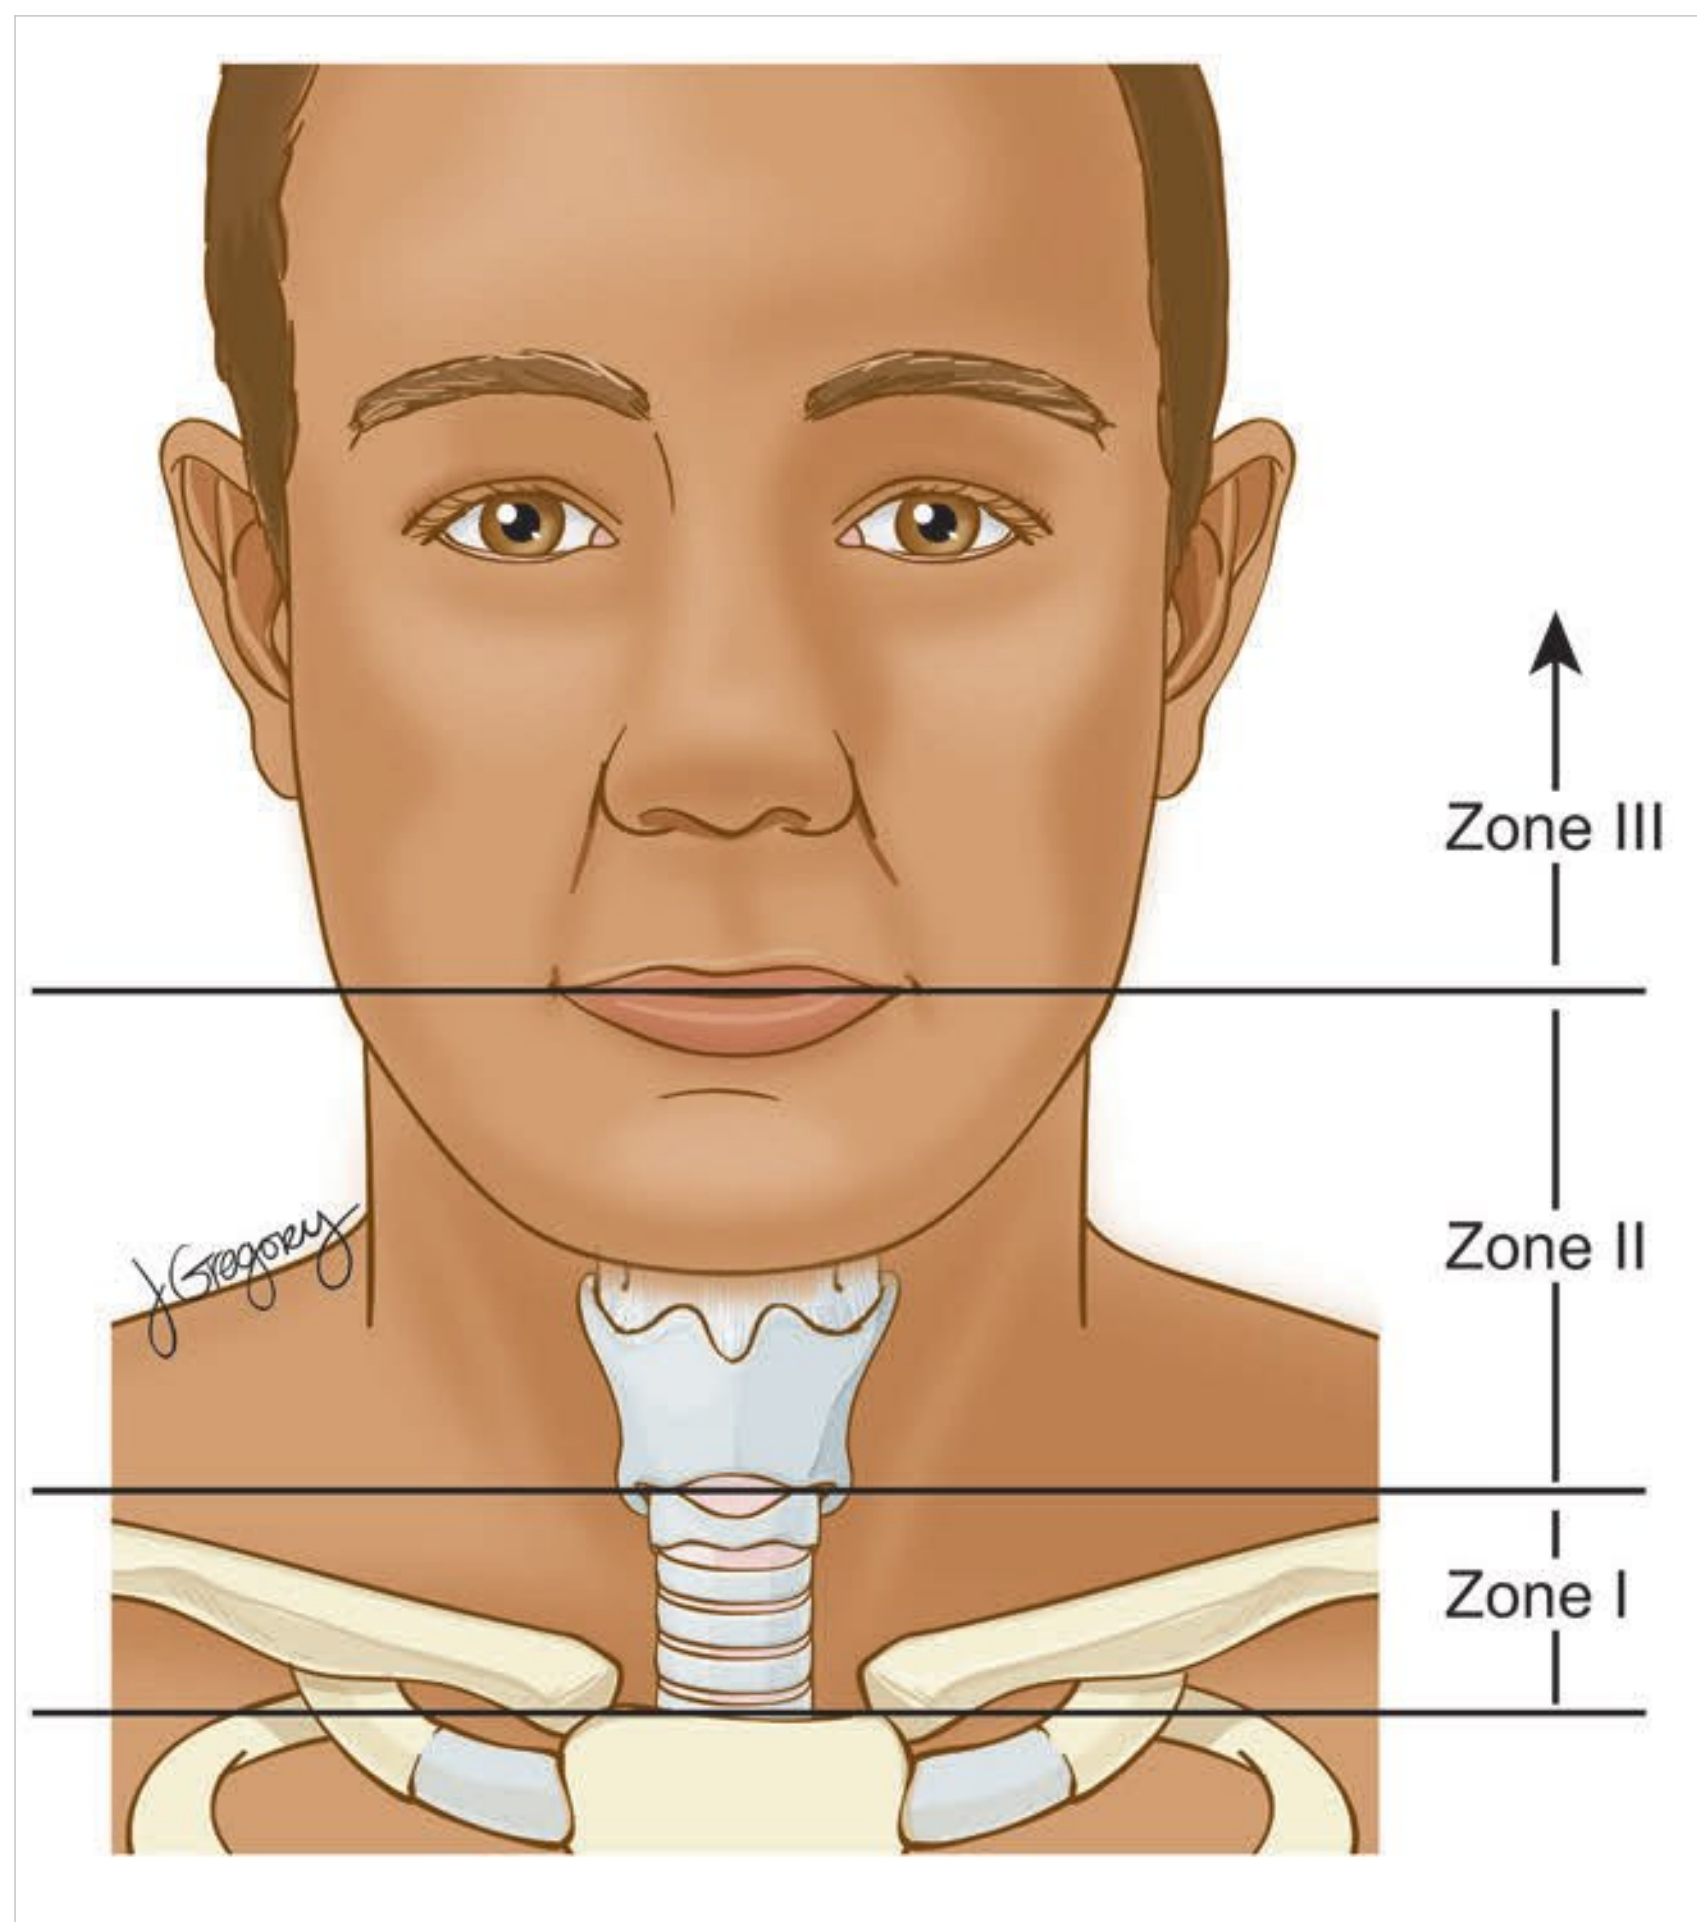

Fig. 37.1 Zones of the neck.

These projectiles often will follow tissue planes, pushing aside vital structures and causing relatively less damage. High-velocity projectiles, like those of military rifles, cause greater destruction by transmitting energy to surrounding tissue after penetration. The path of destruction is more direct and the damaged cavity is wider, often deceptively so compared with the dimensions of the entry and exit wounds. Structures as far as two inches away from the cavity of a wound may be injured. Victims of these injuries to the neck often do not survive, and emergent surgical exploration often means the difference between life and death. In the event of a stable patient, selective surgical management is often an option.

Stab injuries take a more predictable path than gunshot wounds. One key difference is the risk for subclavian vessel injury. Gunshot wounds commonly run perpendicular to the neck, and the clavicles provide some protection to the subclavian vessels. Because the trajectory of a knife is often in a downward direction, penetration over the clavicle makes subclavian vessel lacerations more common than they are with gunshots.

37.1.2 Mandatory versus Elective Exploration

Penetrating neck injuries are managed according to the presentation. The first determination is whether or not an injury is immediately life-threatening. Signs of hemorrhage are key indicators, including expanding hematoma, hemodynamic instability, hypovolemic shock, hemothorax, and hemomediastinum. In these cases, immediate surgical exploration is mandatory.

In stable patients, imaging is often useful to determine the extent of injury and aid in the decision of whether or not to explore. To further aid in decision making, the neck may be divided into three zones, each with unique considerations.

Zone I injuries are particularly dangerous because of the presence of the great vessels. Although the bone cage of the thorax protects this region from injury, it also makes surgical exploration much more difficult. Zone I injuries have a mortal-

ity rate as high as 12%. Because of these factors, angiography is recommended to locate any possible injuries before surgical exploration.

Zone III includes structures above the angle of the mandible. High carotid artery and cranial nerve injuries are of great concern in this region. As in zone I, surgical exploration is difficult because of the narrow confines of the skull base and mandible. Therefore, in a stable patient with an intact airway and no signs or symptoms of hemorrhage, evaluation with angiography is appropriate. Furthermore, regular intraoral examinations are necessary because edema or hematoma formation can potentially compromise a once-stable airway.

Zone II, lying between the cricoid and the angle of the mandible, is the most frequently injured zone because it is the most exposed; for the same reasons, it is also the least difficult to explore surgically. There has been much debate regarding whether to make exploration mandatory in all zone II injuries or to use a more conservative approach of selective exploration with repeated examinations, endoscopy, and angiography. In favor of open treatment is that isolated venous and pharyngoesophageal injuries have been shown to be potentially difficult to detect preoperatively. However, clinically stable patients with zone II injuries can be admitted and evaluated with frequent, repeated physical examinations. These patients can undergo additional endoscopic and radiologic evaluation (□ Fig. 37.2).

Patients with penetrating neck injuries, like all patients with trauma, first require management of the ABCs: airway, breathing, and circulation. Airway control is gained by intubation, cricothyroidotomy, or tracheostomy. In an airway with a direct injury, direct tracheal intubation is often the safest option. Care should be taken to avoid exacerbating an existing airway injury either by poor visualization during intubation or simply by extending the neck. Pneumothorax should be treated emergently with chest tube placement. Large-bore intravenous lines should be placed in all patients. Direct pressure should be placed to control hemorrhage or an expanding hematoma. Patients with major vessel hemorrhage should be surgically explored

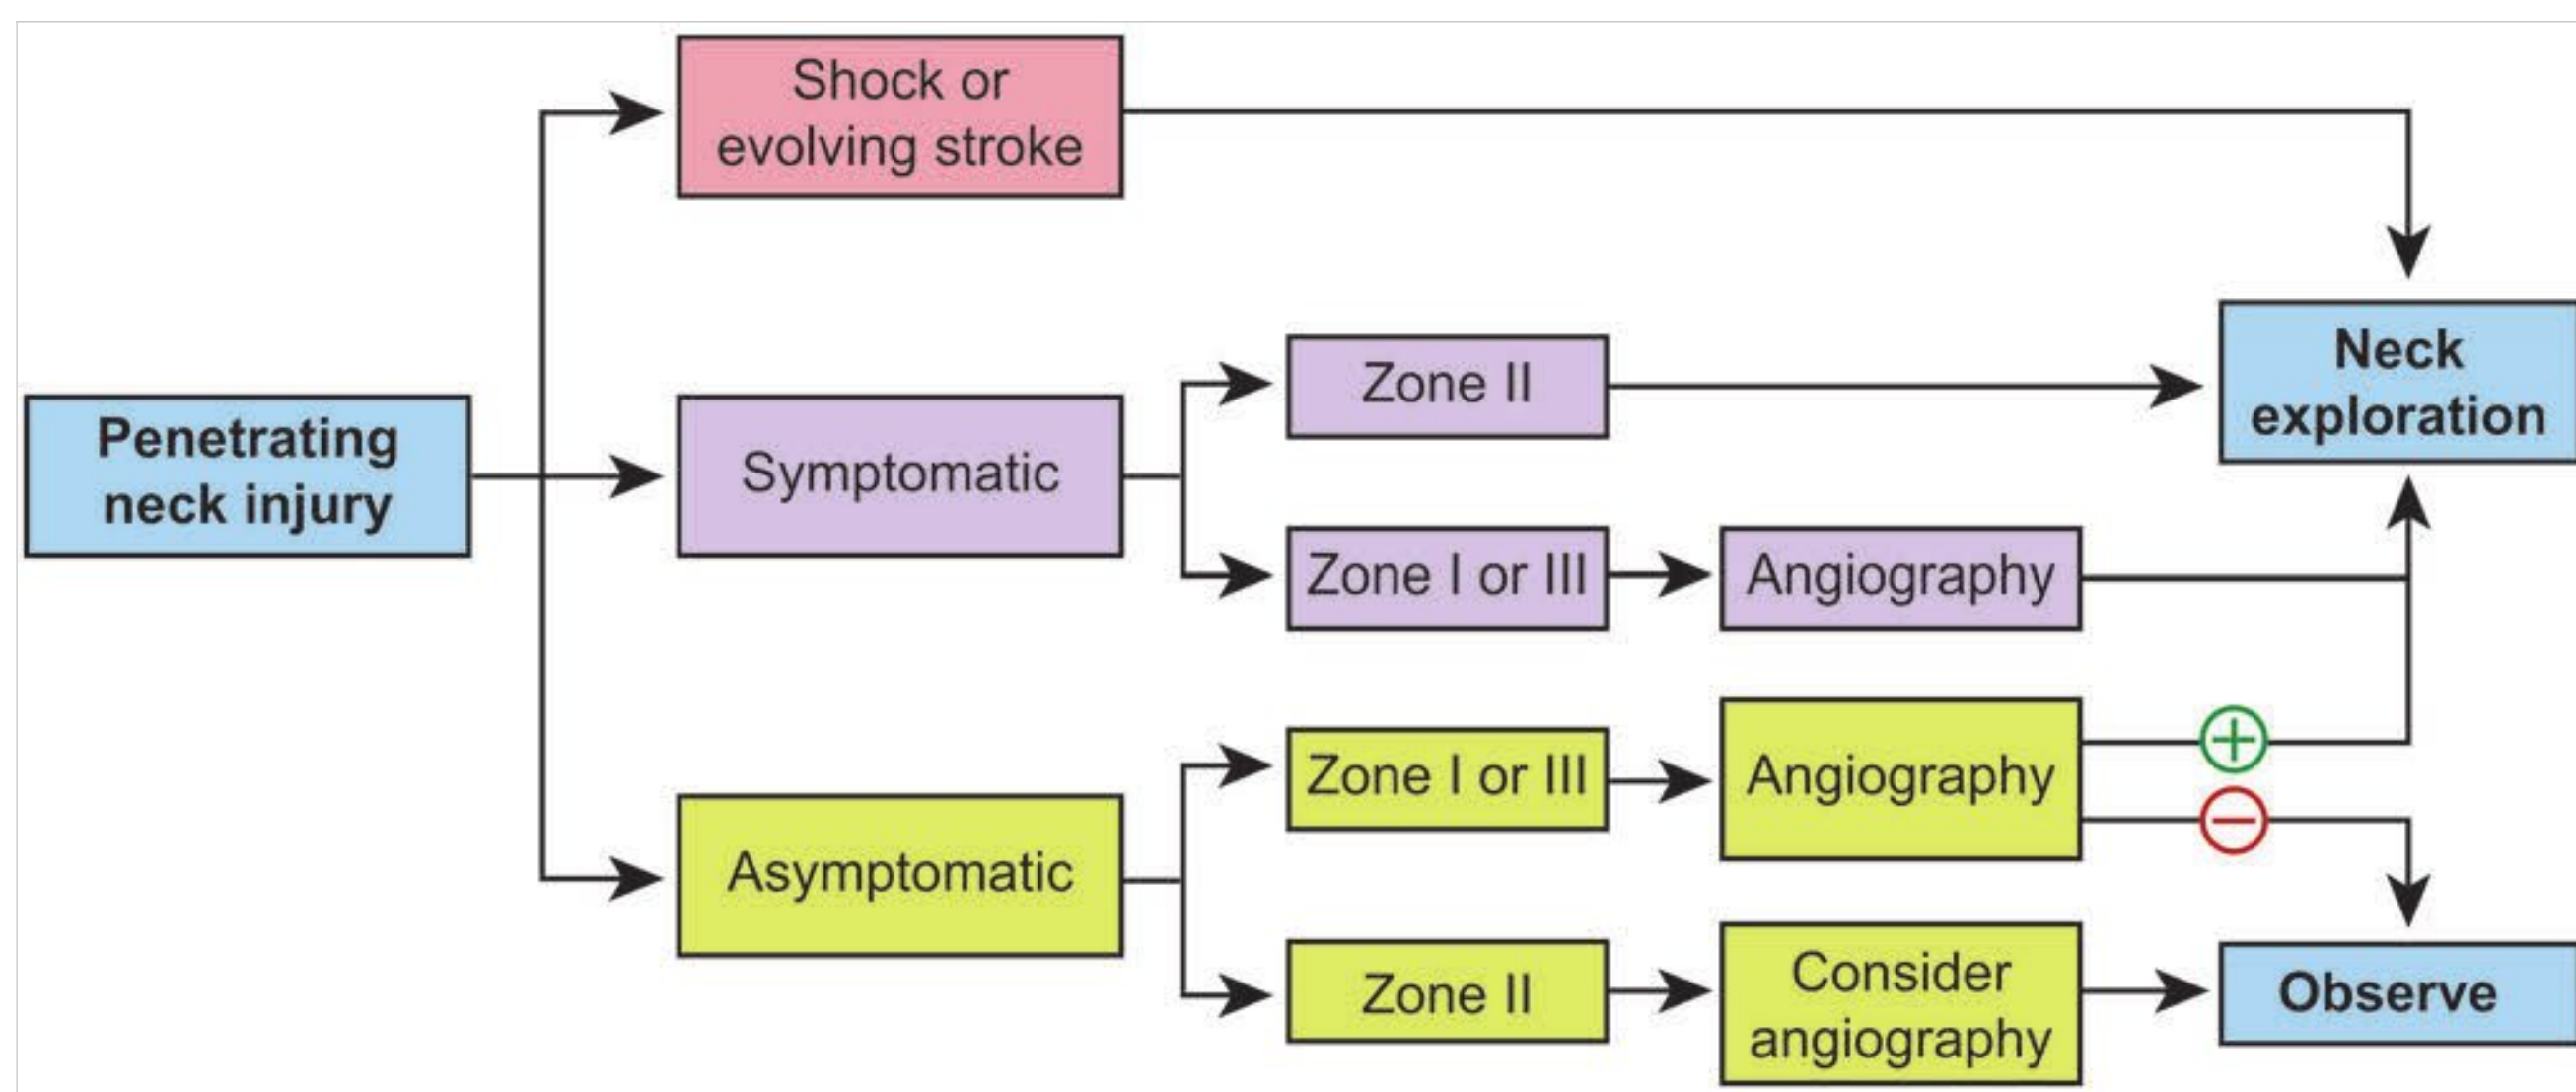

Fig. 37.2 Management of penetrating neck injuries.

emergently. Patients should be examined closely for vascular and neurologic signs because some findings can suggest the path of the projectile and additional injuries; for example, hypoglossal nerve deficit, hoarseness, or Horner syndrome would suggest possible concomitant carotid injury.

37.1.3 Diagnostic Evaluation

In a stable patient, a careful and thorough history and physical examination are performed. Particular attention should be paid to entrance and exit wounds and a comprehensive neurologic examination. Cervical spine radiographs should be obtained to rule out fractures, and chest X-rays will rule out hemothorax, pneumothorax, and pneumomediastinum; in some cases, subclavian injury can also be identified. Marking wounds with radiopaque objects can aid in the evaluation.

Some disagreement exists as to whether mandatory exploration is superior to selective management. Because prospective studies have not shown one approach to be better than the other, many centers employ selective management. This approach divides patients into three groups: unstable, which includes those with shock or evolving stroke; stable symptomatic; and stable asymptomatic. Unstable patients undergo emergent neck exploration. Stable patients with zone I or zone III injury are triaged to angiography, and subsequent exploration is performed as necessary.

Stable symptomatic patients with zone II injury undergo neck exploration. Asymptomatic patients with zone II injury can be considered for angiography or observed for 48 hours.

Penetrating zone II injury can be evaluated further to detect occult injury. The first consideration is whether the airway is compromised. If compromised, the patient is first stabilized, and then angiography, contrast gastrointestinal examination, and flexible and rigid endoscopy should be performed in order, with any positive finding warranting neck exploration. If the airway is adequate, attention is directed toward symptoms of the digestive, respiratory, vascular, and neurologic systems. Appropriate diagnostic evaluation is then done to determine whether exploration is necessary. Regardless of the results, all patients should be observed for 48 hours with frequent physical examinations.

37.1.4 Management of Vascular Injury to the Neck

Although a low cervical incision may suffice, zone I vascular injuries generally require thoracotomy, and early consultation with the thoracic surgery team is appropriate.

Zone II injuries can involve the common or internal carotid arteries. This zone is explored through an incision along the anterior border of the sternocleidomastoid muscle. A large hematoma or proximal interruption of the carotid artery can significantly decrease pulsation, making identification of the damaged artery more difficult. In these instances, it is often necessary to follow branches of the external carotid in a retrograde fashion. Injury to branches of the external carotid artery can generally be managed by suture ligation because of the abundant collateral circulation. Veins in the neck can also be safely ligated; however, if both internal jugular veins are damaged, an attempt to repair one is appropriate.

Zone III injuries may require a mandibulotomy. Injuries to this area often involve multiple vascular structures, including the internal carotid artery, internal maxillary artery, and external carotid artery. Consultation with an interventional radiologist should be considered when a challenging access at the skull base must be dealt with.

Several techniques for vascular repair have been described, including vessel wall repair, vessel ligation, vessel patch graft, autogenous vessel graft, and synthetic vessel graft. Autogenous grafting or end-to-end anastomoses are recommended when stenosis is evident on imaging studies. Ligation of the internal or common carotid arteries is not recommended and is considered only for irreparable injuries. Unrepaired vascular injuries may result in several delayed complications, including aneurysm formation, dissection, and arteriovenous fistulas.

37.1.5 Evaluation of the Digestive Tract

In the patient with a possible esophageal perforation, a thorough evaluation is paramount. Missed tears can progress to mediastinitis, which is associated with considerable morbidity and mortality. Studies have reported the use of flexible esophagoscopy to bypass the general anesthesia required for a rigid endoscopy; however, there have been reports of missed perforations in areas of mucosal redundancy.

Imaging can play a significant role in the diagnosis of esophageal perforations. Gastrografin swallow studies are performed initially because extravasated barium can cause a chemical mediastinitis; barium extravasation can also radiographically distort tissue planes. If this study is deemed to be normal and suspicion remains for a perforation, a barium swallow should be considered.

If suspicion of a perforation remains despite a normal examination, the patient can be observed while taking nothing by mouth. A widening mediastinum on serial chest radiographs, fever, or tachycardia will likely require repeated endoscopy or neck exploration.

Many surgeons perform direct laryngoscopy, bronchoscopy, and rigid esophagoscopy for penetrating injuries to the neck with air in the soft tissues, hemoptysis, or any other suspicious findings. When an esophageal perforation is found, management generally involves a primary, two-layer closure with débridement and adequate drainage. Some surgeons also advocate the placement of a muscle flap over the suture line for further protection. It is imperative, however, that definitive management of any airway compromise be a priority.

37.1.6 Tracheal and Laryngeal Injuries

Tracheal lacerations that do not encroach on the airway or detach a tracheal ring can usually be repaired without a tracheotomy. With more severe injuries, a tracheotomy, either through or below the injury, is prudent.

Mucosal lacerations of the larynx secondary to penetrating trauma should be repaired within 24 hours to decrease scarring and improve voice. Surgical approximation is necessary for significant glottic and supraglottic lacerations, as well as for displaced cartilage fractures. Computed tomography (CT) and endoscopy help differentiate between patients who require thyrotomy or open fracture reduction and those who require only

observation. The reader is referred to Chapter 92 (Laryngeal Trauma) for further discussion.

37.2 Blunt Neck Trauma

Blunt trauma to the neck may occur following assault, sports injury, or a motor vehicle accident. The force may result in injury to any combination of airway, vascular, or digestive structures. Because the effects may be delayed in onset and therefore missed, close observation is recommended.

Patients with multisystem trauma are at risk for having their laryngotracheal injuries overlooked. These patients can have a slow progression of edema that may compromise the airway hours after the initial insult. CT can be helpful in determining the degree of injury to both the larynx and nearby vessels. Blunt trauma to the cervical vessels can result in tears, thrombosis, dissection, and possibly pseudoaneurysm. These injuries can be treated by observation, anticoagulation, or surgery. The treatment depends principally on the mechanism, type, and location of injury. Consultation with a vascular surgeon should be considered.

37.3 Roundsmanship

- Surgical exploration is necessary in patients with any penetrating neck trauma and life-threatening signs or symptoms.

- Hemorrhage is the leading cause of death in patients with penetrating neck injuries, and patients should be monitored for at least 48 hours.
- Classifying the injury by zone and mechanism can be helpful in determining the likelihood of major injury.

38 Facial Analysis

Alexander Ovchinsky

38.1 Introduction

Comprehensive facial analysis is a crucial element in the process of achieving a successful surgical outcome. A facial plastic surgeon, like an artist, should be able to envision the final result of his or her work, which depends not only on the surgeon's expertise but also on the anatomical characteristics of a given patient. Patients' characteristics may vary widely with ethnicity, age, gender, medical or surgical history, and history of facial trauma or prior surgery. Therefore, a thorough understanding of what is generally accepted to be the facial norm is essential in building a foundation for a successful result. Patients' expectations may sometimes be unrealistic because of certain anatomical limitations; it is of a paramount importance to communicate to the patient these limitations and how they will affect the final outcome in order to avoid an unhappy patient postoperatively.

38.2 Incidence of Disease

All humans eventually will exhibit aging-related changes in facial anatomy because of a combination of multiple factors, such as facial bony resorption, loss of soft-tissue support, soft-tissue atrophy, and age-related skin changes. Some patients will exhibit these changes earlier than others as a consequence of various factors, such as genetic predisposition (e.g., in progeria or Ehlers-Danlos syndrome); excessive sun exposure with resultant skin changes (wrinkling, pigmentation, loss of elasticity); body habitus; and certain medical conditions (e.g., skin changes in patients on long-term steroid therapy, facial lipodystrophy in patients on HIV antiretroviral therapy). Multiple syndromic conditions affect facial anatomy and will cause noticeable deviation from the norm at birth (e.g., Treacher Collins syndrome, Crouzon syndrome, Waardenburg syndrome).

38.3 Terminology

There are several important anatomical landmarks that greatly assist in facial descriptive analysis. Beginning superiorly, the trichion marks the superior extent of the forehead and corresponds to the level of the hairline. The glabella is the most prominent point of the forehead on the profile. The nasion is the depression at the root of the nose and corresponds to the nasofrontal suture line. The radix, incorrectly used interchangeably with the nasion, is the root of the nose and marks the deepest point of the nasofrontal angle. The rhinion corresponds to the bony-cartilaginous junction on the nasal dorsum. The subnasale is the junction of the columella and the upper lip at the base of the nose. The vermilion border of the lips is the mucocutaneous junction. The menton is the lowermost position of the soft tissues of the chin, while the pogonion marks the most anterior projection of the chin. The tragion is located at the supratragal notch and is an important landmark for determining the appropriate horizontal position, or Frankfort horizontal plane, which passes from the tragion to the inferior orbital rim (□ Fig. 38.1).

38.4 Applied Anatomy

The face is commonly subdivided into horizontal "thirds" (□ Fig. 38.2) and vertical "fifths" (□ Fig. 38.3). The upper facial third is bounded by the hairline and the brows/glabella, the middle third spans the face from the glabella to the subnasale, and the lower third runs from the subnasale to the menton. This is a rough approximation, however, and the lower third of the face is generally slightly longer than the middle third (□ Fig. 38.4). In addition, the lower face can also be divided into thirds, with the length of the upper lip equaling one-third and the lower lip and chin equaling two-thirds. Vertical fifths assist with the assessment of facial symmetry on the frontal view, in which each fifth approximates one eye width: helical rim to lateral canthus (two), lateral canthus to medial canthus (two), and intercanthal distance (one).

There are a number of facial angles that are used to define the relationships of the various facial structures to one another. Some of these angles are nearly constant for males and females, whereas others are variable depending on the sex of the patient (□ Fig. 38.5 and □ Fig. 38.6). The nasofrontal angle measures the facial angle at the nasion or, in other words, the transition angle from the forehead onto the nasal dorsum. This angle ranges from 115 degrees (men) to 120 degrees (women). The nasolabial angle is the angle between the columella and the upper lip. It should be around 90 to 95 degrees in men and around 100 to 110 degrees in women. An increase in this angle results in an appearance of over-rotation of the nose, whereas a decrease leads to an appearance of under-rotation. The cervicomental angle measures the angle of transition of the neck into the inferior aspect of the chin; an increase in submental fat or a low-set hyoid bone leads to blunting of the cervicomental angle.

38.5 The Disease Process

38.5.1 Etiology

There are several theories of aging, all of which are concentrated around a common notion that facial aging is the result of progressive soft-tissue descent. Over time, the soft tissues of the face sag off bony structures, forming the distinctive wrinkles, folds, and skin and soft-tissue redundancy of the aging face. This descent is partially due to subcutaneous soft-tissue atrophy, leading to a proportional increase in the amount of skin and skin ptosis. Age-related loss of facial volume due to gradual bony resorption is also a contributing factor. This decrease in bony volume translates into a decrease in the amount of support for the soft tissues of the face, thus causing downward rotation of the soft tissues and ptosis. Sun-related skin damage, also known as actinic damage or solar elastosis, leads to a loss of skin elasticity, pigment changes, and a general appearance of aging.

38.5.2 Natural History and Progression

Superficial skin lines, or wrinkles, are discrete at first and over time become more numerous, deeper, and multidirectional.

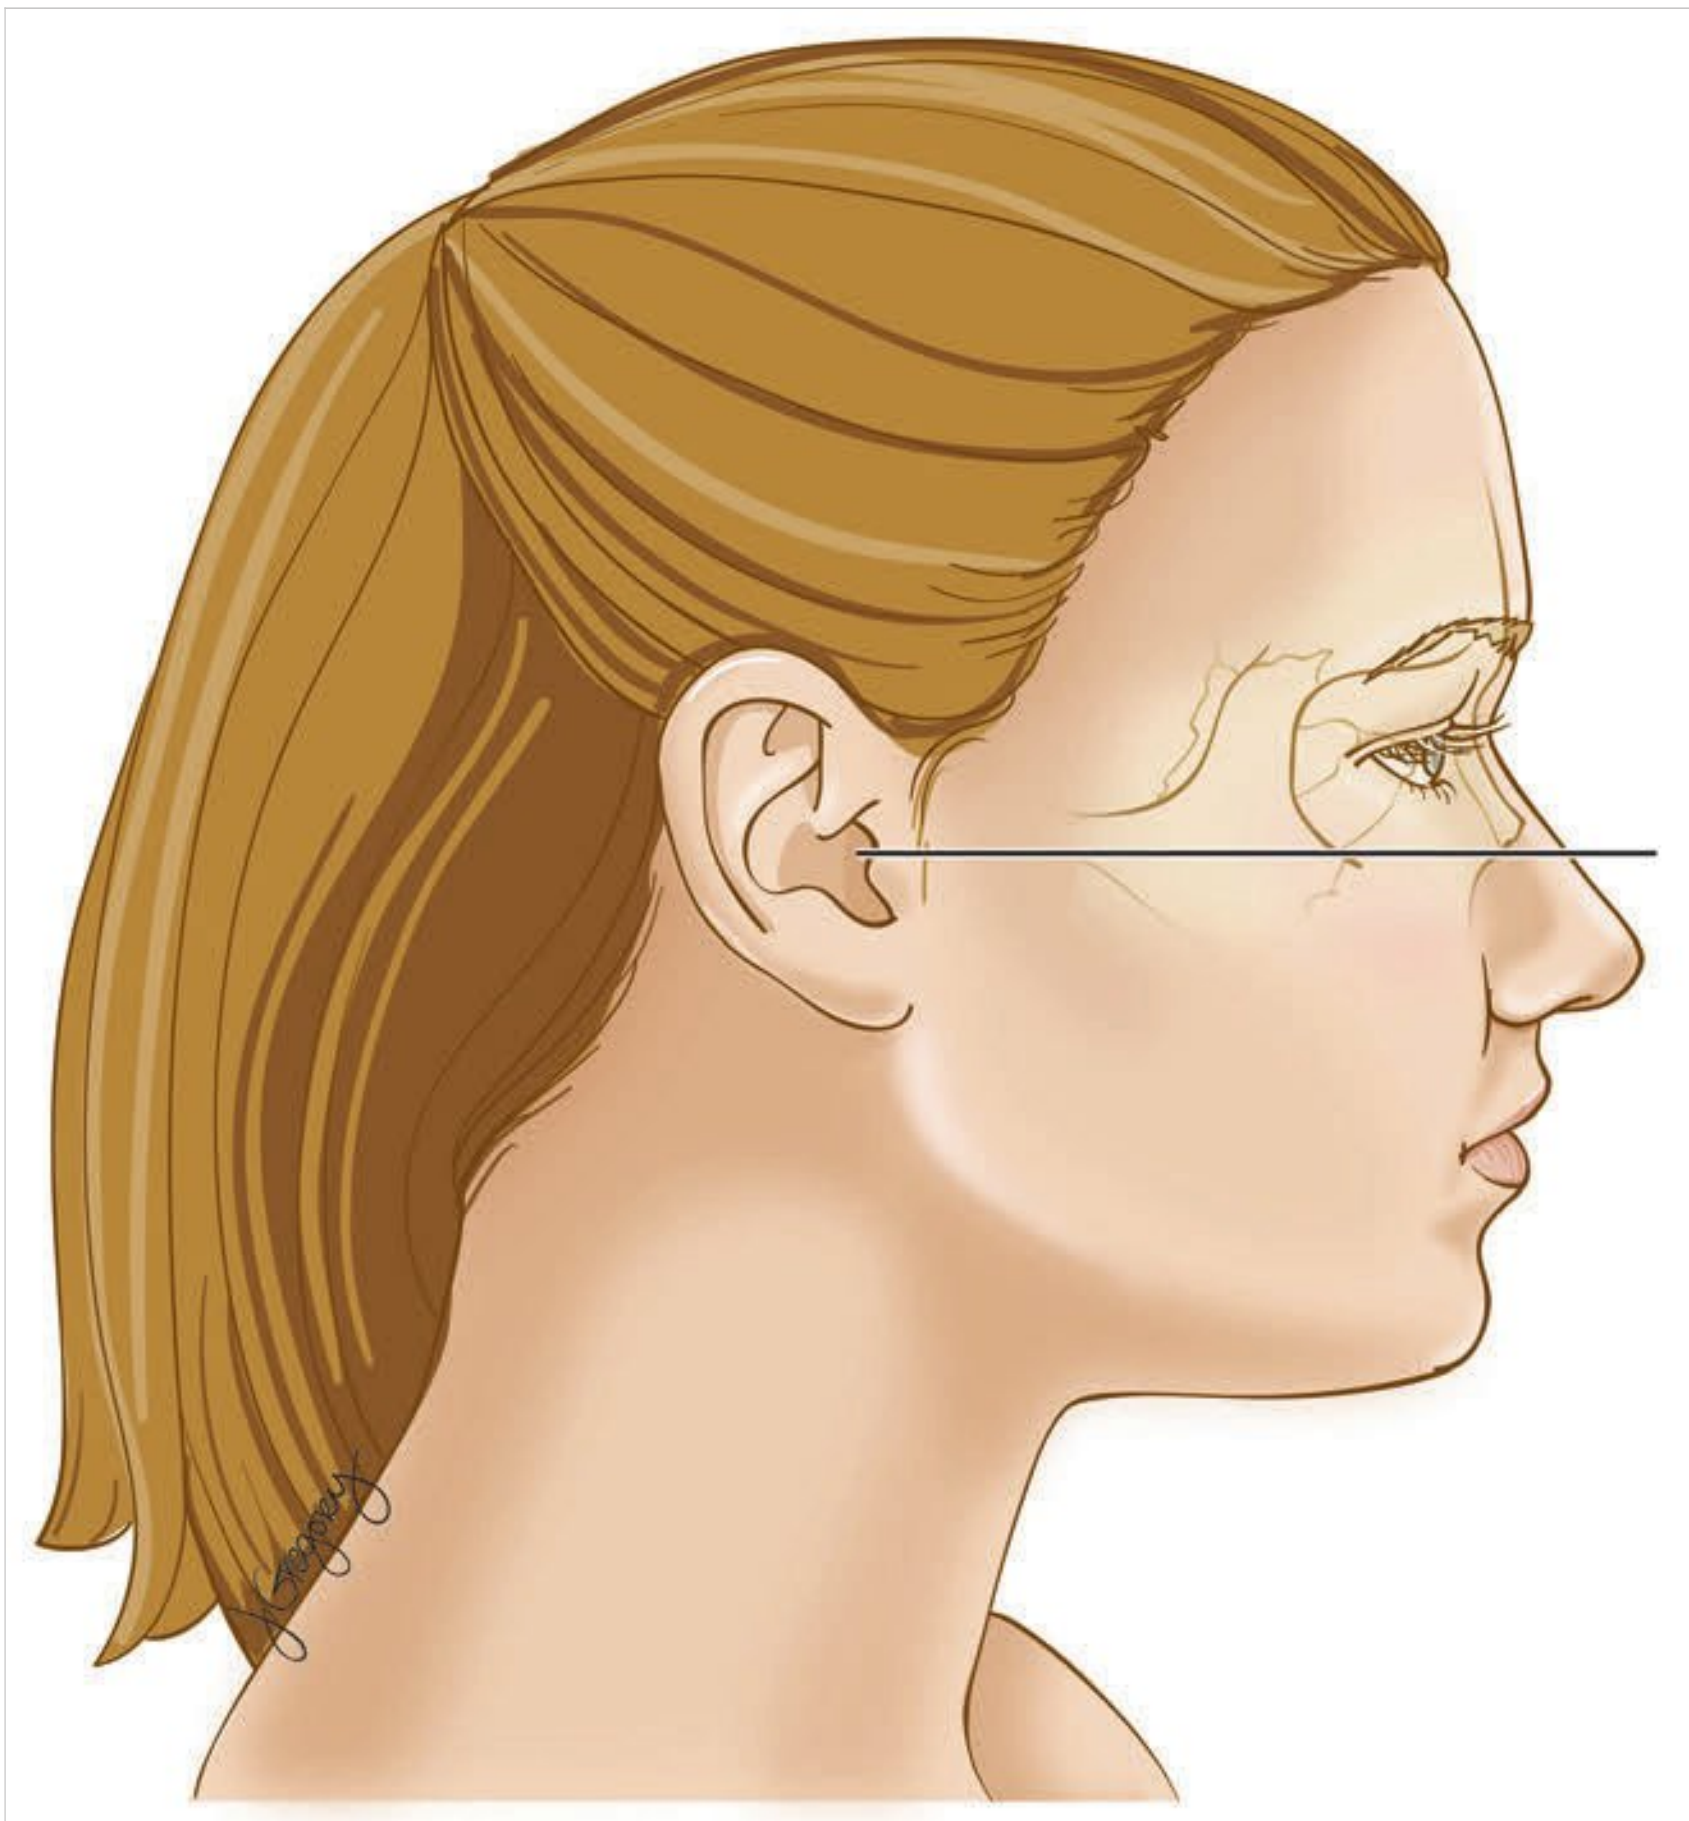

Fig. 38.1 The Frankfort horizontal plane is established by drawing a line from the trignon to the inferior orbital rim. Proper facial analysis is performed with the Frankfort horizontal plane parallel to the floor.

When wrinkles become associated with textural changes in the skin surface from photodamage and repeated muscular contraction, they become mimetic lines. The deepening of the mimetic lines into the dermis leads to the appearance of skin furrows. As skin redundancy worsens and skin ptosis continues, skin furrows slowly progress into skin folds.

38.6 Medical Evaluation

38.6.1 Clinical Findings, Physical Examination

It is important to consider the major aesthetic units of the face individually as well as in relationship to the rest of the face. These include the forehead, periorbital region, midface, nose, perioral region and chin, neck, and ears.

Forehead

Alopecia, or hair loss, may cause an elevation of the hairline, increasing the height of the upper face. Frontalis muscle hypertonicity and loss of skin elasticity can cause “worry lines” or horizontal forehead lines, which may range in severity from minor mimetic lines to deep, corrugated furrows. Procerus muscle action over time will cause the formation of horizontal nasal root wrinkles, while the action of the corrugator supercilii muscle forms the vertical glabellar lines.

Hypertonicity of these muscles also produces brow ptosis. Another factor contributing to brow descent is a decrease in the amount of supraorbital subcutaneous tissue, leading to “deflation” of the brow region. The brows should be examined for the degree of ptosis and for ptosis localization within the brow (i.e., medial, lateral, or generalized), as well as for any asymmetry accompanying bilateral brow ptosis. In the event of brow asymmetry, it is very important to bring this to the attention of the patient because it may not be corrected by browlifting procedures. When brow ptosis progresses, it may result in “lateral hooding” of the upper eyelid, causing a peripheral visual field deficit, a functional indication for brow ptosis correction.

Periorbital Region

The size, shape, position, and symmetry of the individual components should be assessed. The intercanthal distance, which should be equal to the width of one eye, may be increased in certain syndromes, as well as after facial trauma to the naso-orbital region, causing hypertelorism. Asymmetry of the palpebral apertures may be due to a unilateral upper lid ptosis, which should be documented and addressed during a corrective procedure. Other periorbital abnormalities, such as enophthalmos, exophthalmos, and lower lid laxity and ectropion, should be documented during the evaluation of the region. Signs of eyelid aging may be due to increased skin laxity (dermatochalasis),

Fig. 38.2 The face can be divided roughly into vertical thirds, from the trichion to the glabella, the glabella to the subnasale, and the subnasale to the menton.

pseudoherniation of orbital fat through the orbital septum causing the development of the “eye bags,” or a combination of the above. Hypertrophy of the orbicularis oculi muscle may lead to the formation of prominent wrinkles and muscular roll, seen mainly in the lower eyelids. Malar bags are thought to represent edema of the lateral infraorbital soft tissues.

Midface

The loss of midfacial ligamentous support results in anterior–inferior descent of the midfacial subcutaneous fat, causing a relative loss of the superior–lateral cheek fat and a relative increase in the inferior–medial cheek fat. The net effect of this fat redistribution is deepening of the nasolabial fold, the development of cheek skin folds lateral to the nasolabial fold, and skeletonization of the zygomatic region with the formation of submalar hollow and tear trough deformity.

Nose

If the cartilaginous nasal framework weakens with time or as the nasal skin thins and becomes less elastic, so will the support of the nasal tip, resulting in tip ptosis and a decreased nasolabial angle. The tip may also become broader because of weakening of the intercrural ligament and divergence of the domal regions of the lower lateral cartilages. A dorsal hump may become more prominent because of tip ptosis and thickening of the nasal skin.

Perioral Region and Chin

Atrophy of the soft tissues, or deflation of the perioral region, results in lengthening of the upper lip, thinning of the red lip portion, and the formation of perioral rhytids. “Marionette lines,” which extend from the oral commissure inferiorly

Fig. 38.3 The horizontal fifths of the face are bounded by the helical rims, lateral canthi, and medial canthi.

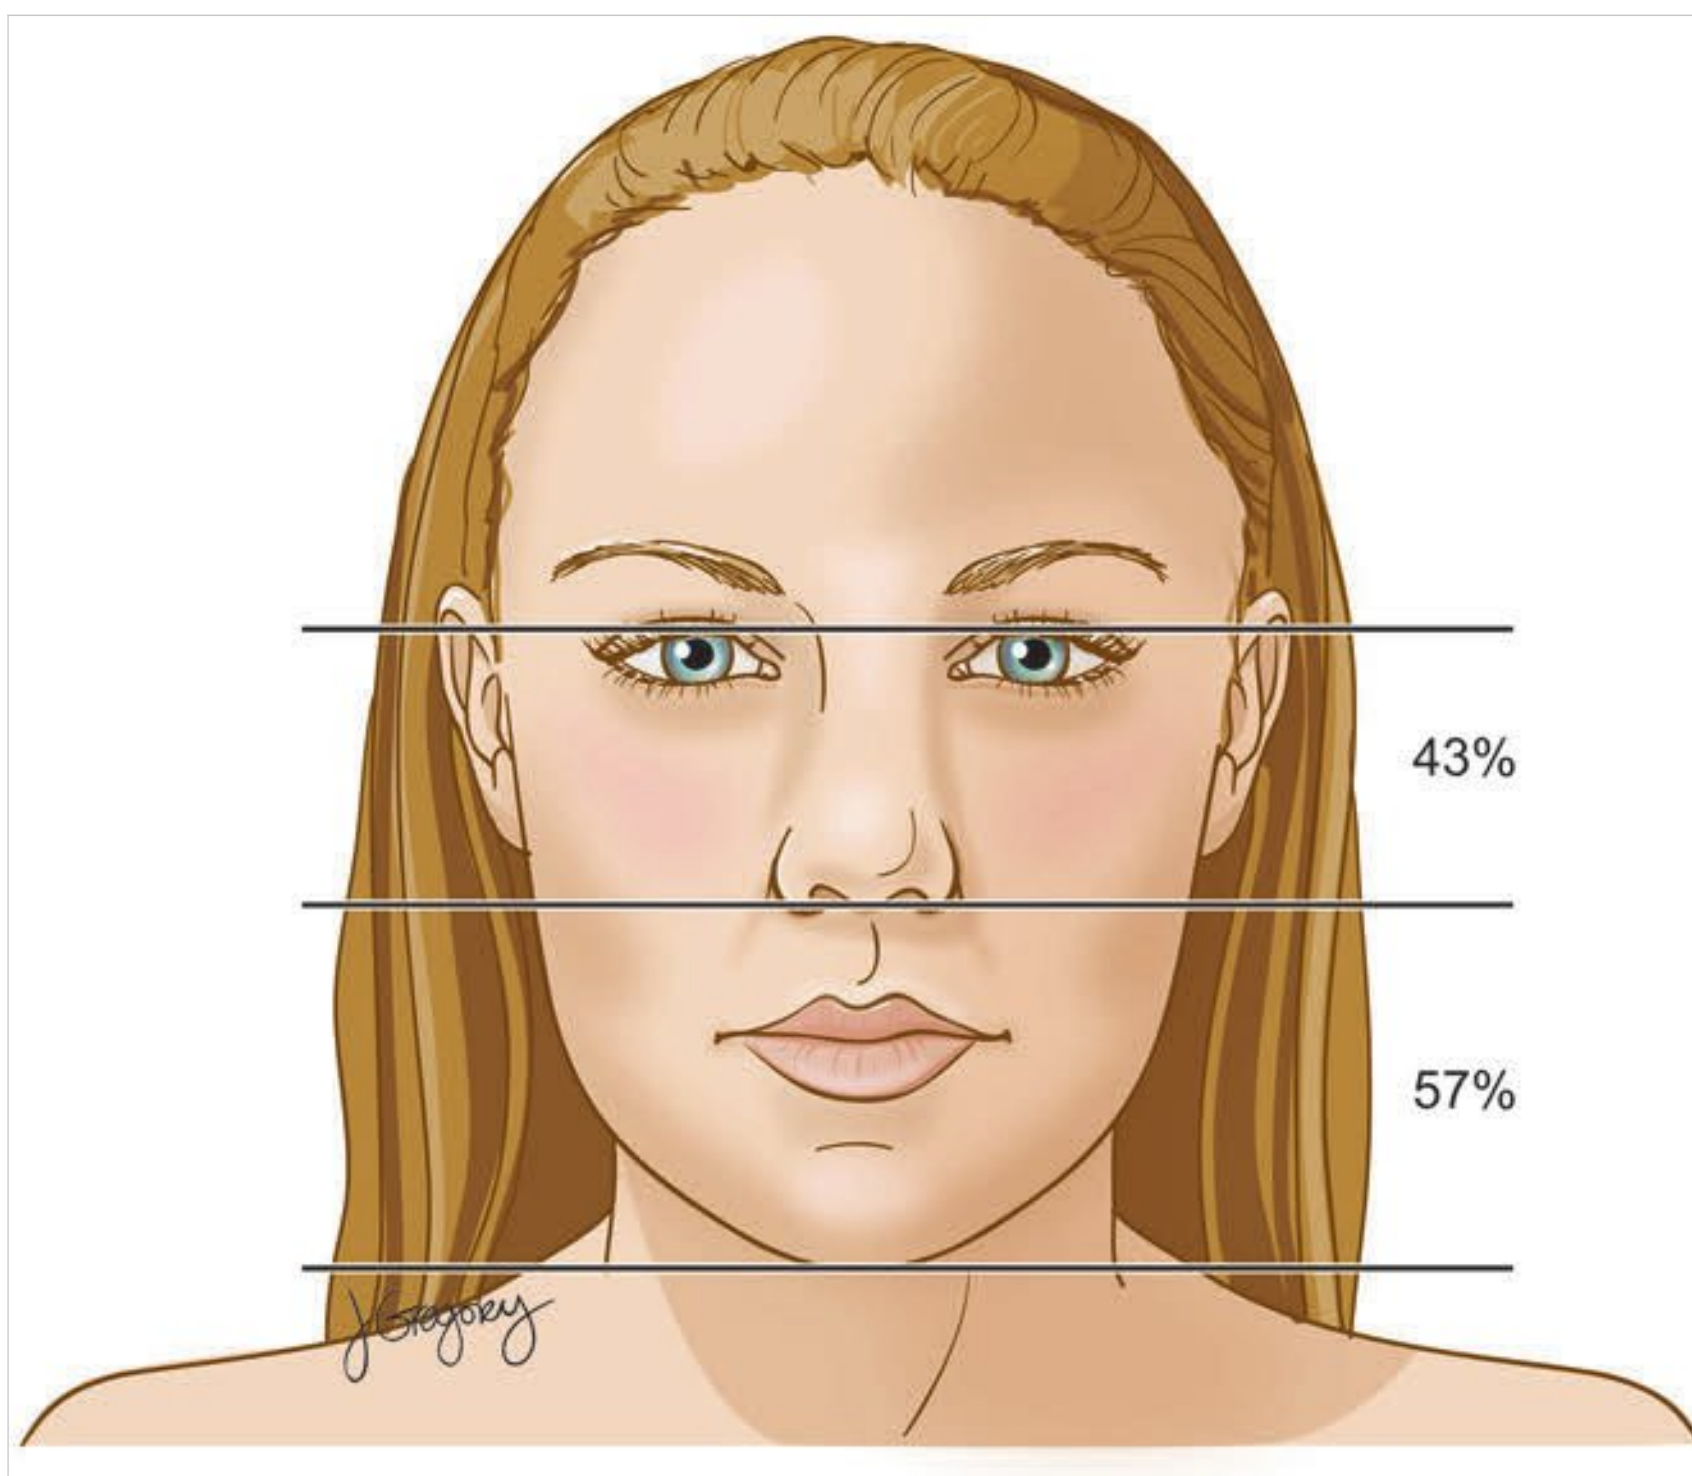

Fig. 38.4 The midface is generally shorter than the lower face.

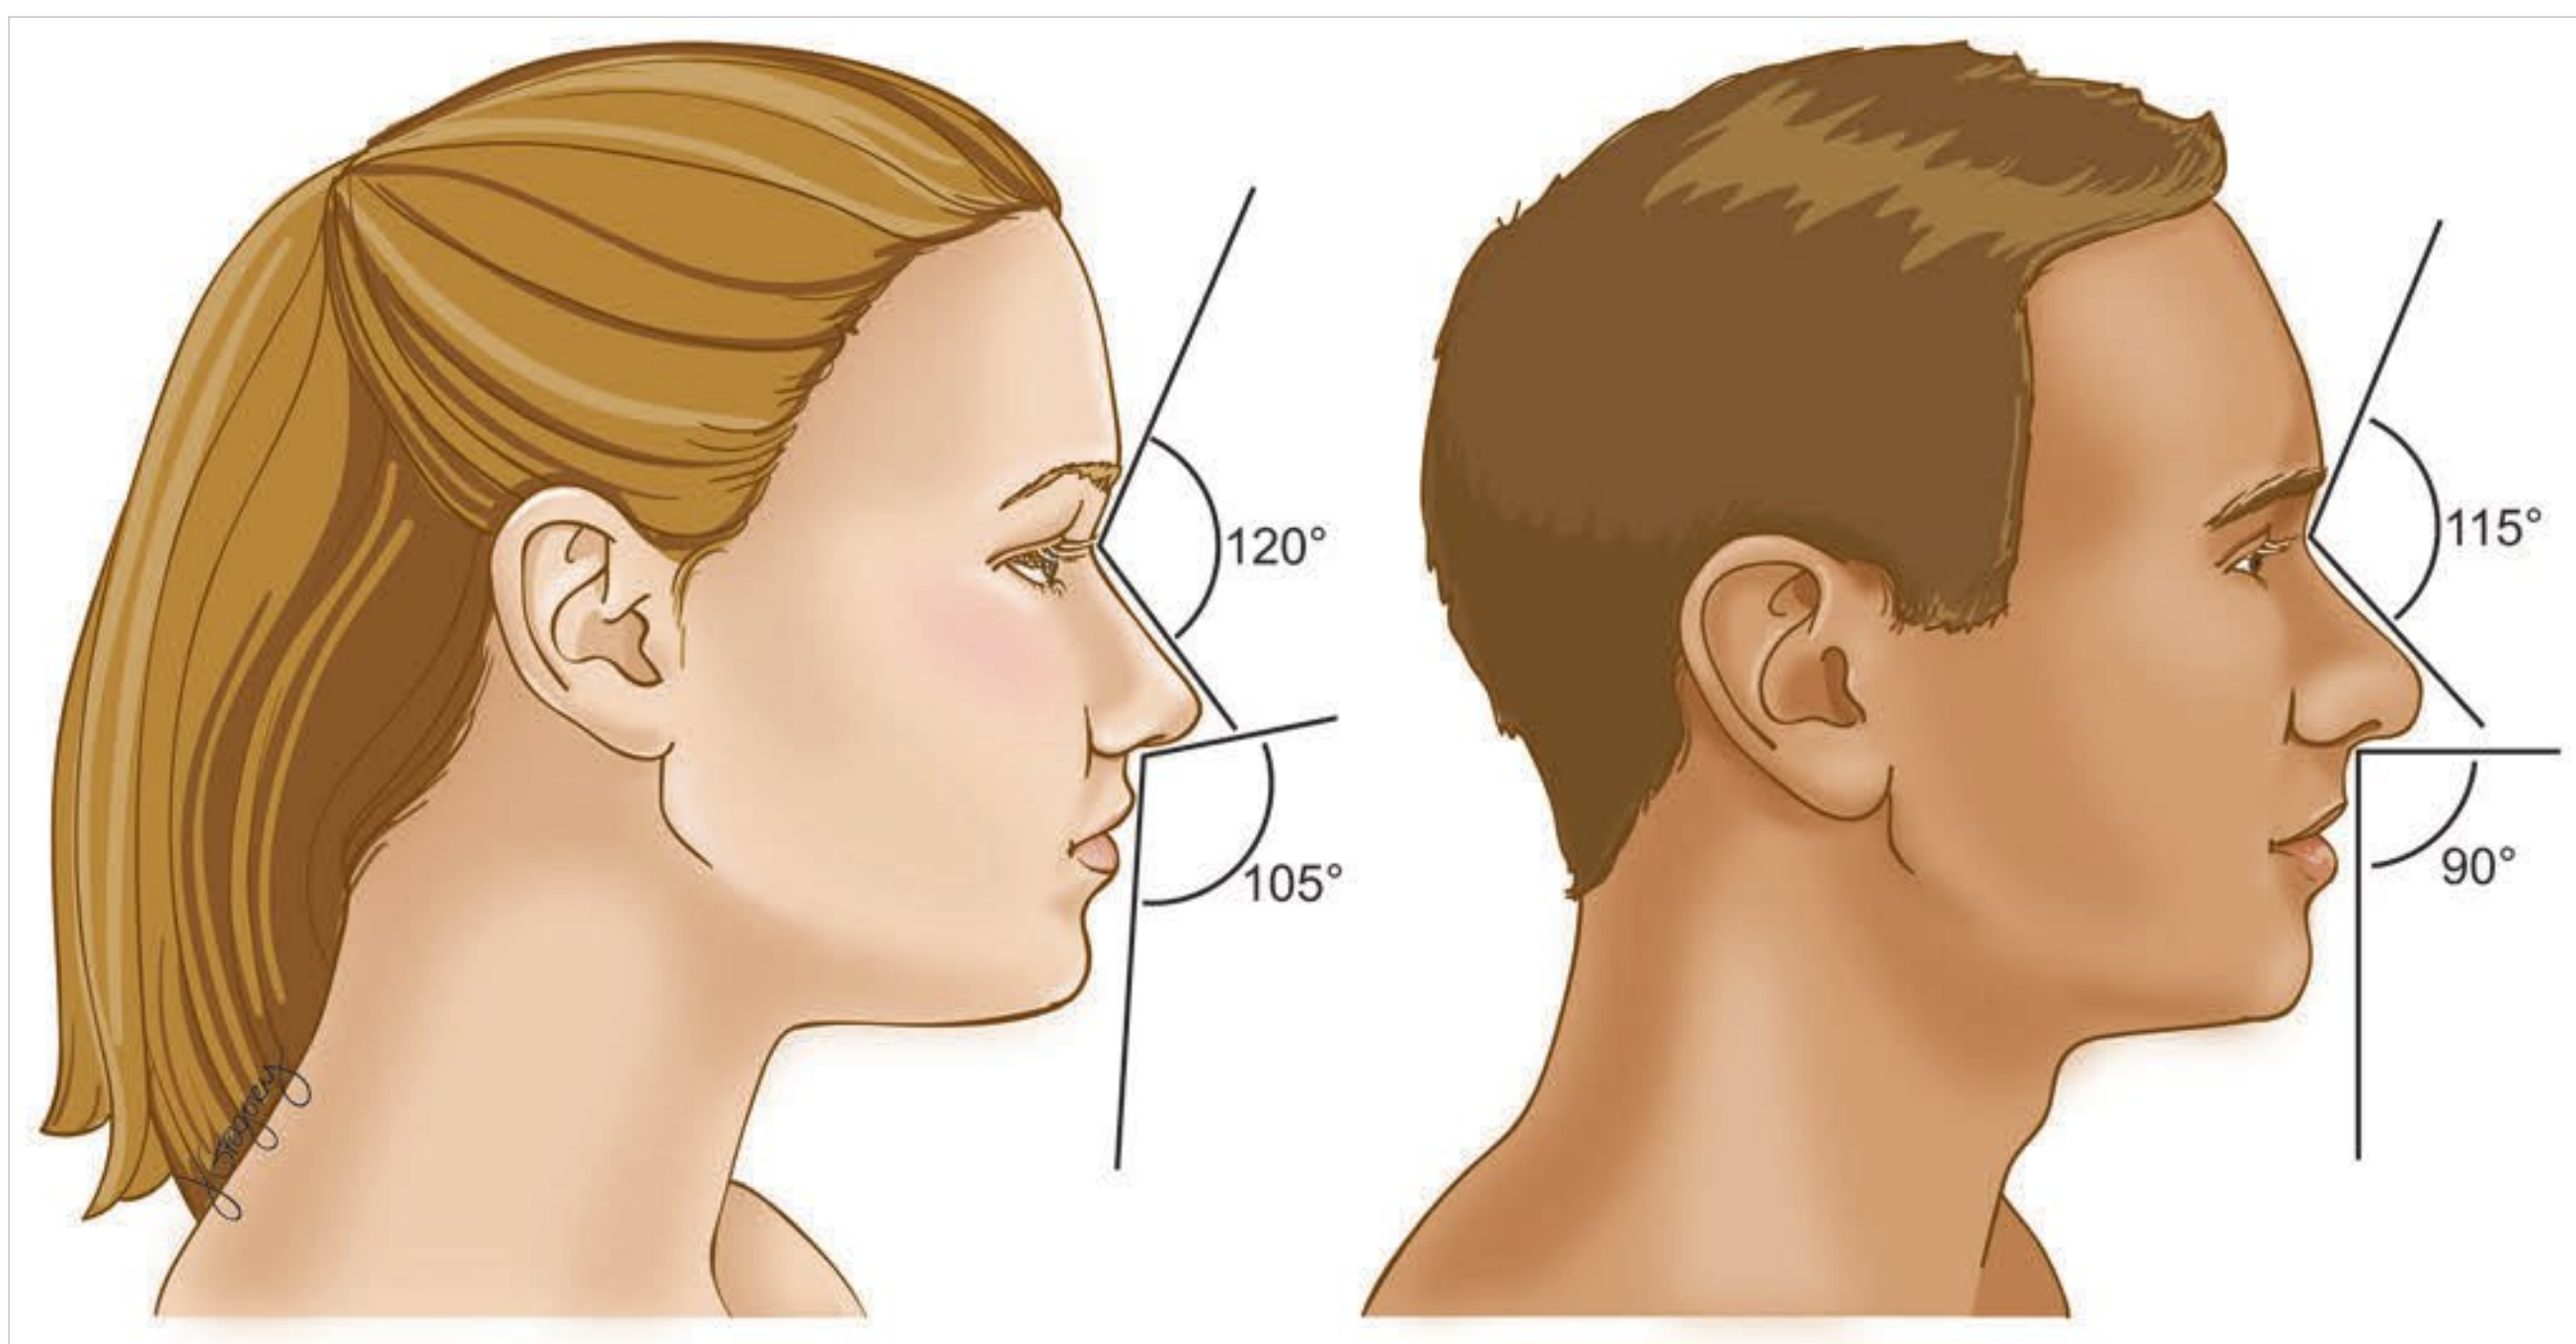

Fig. 38.5 Women tend to have wider nasofrontal and nasolabial angles than men.

Fig. 38.6 The nasofrontal angle is generally larger in women than in men.

into the lower face, also become more prominent. Resorption of the mandible results in a decrease in chin projection, or microgenia.

Neck

Ptosis of the midfacial and lower facial soft tissues along the jawline causes the development of “jowls.” Loss of elasticity of

the skin with hypertonicity of the platysma muscle results in the formation of platysmal bands and blunting of the cervicomental angle. A congenitally low-set hyoid bone also makes the cervicomental angle more obtuse, and this should be noted before surgical correction is undertaken because it will affect the final outcome.

Ears

Ear malformations are most commonly developmental abnormalities but may also be acquired as a result of an infection, trauma, or surgery. Prominent, or lop, ears usually result from either a large conchal cartilage or maldevelopment of the anti-helical fold. An increase in the size of the ear lobule is usually related to the aging process or heavy earring use.

38.6.2 Testing

The degree of a peripheral visual deficit due to brow ptosis and upper lid blepharochalasis can be assessed with visual field testing. The test compares the size of the peripheral visual field with and without correction of the upper eyelid hooding, which is done by taping the upper lids and brows in the elevated position.

Lower lid support is assessed with the use of a pinch or a snap test, in which the lower lid is manually pulled away from the globe or pulled downward, respectively, and then released; delayed return of the lid to the globe surface or return only after blinking is abnormal and generally indicates a need for lid tightening.

38.7 Prognosis

The final outcome of medical and surgical interventions depends not only on the expertise and knowledge of the physician

but also (probably to the greater extent) on the physical characteristics of the patient. Patients' medical comorbidities, the degree of the problem in question, and social factors that include smoking, alcohol or drug use, and a history of sun exposure will profoundly affect the final result. Proper patient evaluation and a detailed facial analysis are of paramount importance in the process of achieving the best outcome possible.

38.8 Roundsmanship

- One needs to be thoroughly familiar with normal facial anatomy in order to fully apprehend the deviation from the norm and come up with the best possible corrective approach.
- It is helpful to break the face down into separate aesthetic subunits and analyze those individually as well as in conjunction with the rest of the face in order to conduct a thorough and comprehensive facial assessment.
- The changes of aging result from loss of skin elasticity, solar skin damage, decrease in the amount of the subcutaneous tis-

sues, loss of fibrous soft-tissue support, attenuation of the muscles of facial expression, and resorption of the facial bony skeleton.

- Because the changes of facial aging involve multiple facial anatomical components, they commonly require multimodality therapy for an optimal result.

39 Wound Healing

Grigorly Mashkevich

39.1 Introduction

Wound healing is a complex process consisting of several overlapping phases: inflammatory, proliferative, and remodeling. Each phase serves a specific function and has defining characteristics at the molecular and tissue levels. Healing may occur by primary, secondary, or tertiary intention. Each type of wound healing has its own advantages and disadvantages, and selection depends on the presenting wound characteristics and various patient factors.

39.2 Incidence of Disease

Wounds can arise in multiple settings, most commonly trauma or surgery. Their incidence is not well enumerated because of the wide variety of presentations that lead to wound formation.

39.3 Terminology

The three phases of wound healing overlap one another (□ Fig. 39.1). The inflammatory phase is the initial stage of wound healing, which begins immediately following tissue injury. This phase is characterized by sealing of the wound and the attraction of inflammatory immune system components. In the proliferative phase, a stable wound matrix forms, and granulation tissue is introduced into the healing wound. In the remodeling phase, which lasts up to 2 years, the scar matures and the wound is strengthened. Granulation tissue is newly forming tissue composed of fibroblasts and developing blood vessels.

Primary intention healing occurs in wounds repaired by direct closure. This results in elimination of the dead space and rapid re-epithelialization of the wound surface. Healing by secondary intention is a process in which wounds are allowed to heal on their own, without surgical intervention. Delayed primary closure, or healing by “tertiary intention,” is typically used for infected wounds. Such wounds require daily care until the infection resolves, at which point the wound edges may be surgically approximated.

Wounds can affect all tissue layers. Soft tissues include the skin and subcutaneous tissues, such as fat, muscles, nerves, and blood vessels. More complex wounds involve trauma to the cartilage and bones comprising the facial skeleton.

39.4 The Disease Process

39.4.1 Etiology

The overwhelming majority of wounds arise from trauma or surgery.

39.4.2 Pathogenesis

Open wounds may fail to heal in a satisfactory fashion if appropriate wound care is lacking. Exposed wounds are at risk for becoming infected, leading to local tissue destruction and delayed healing. Dirty wounds and dry scabs interfere with healing by retarding epithelial migration across the surface of the wound. In addition to forming unfavorable scars, poorly healing

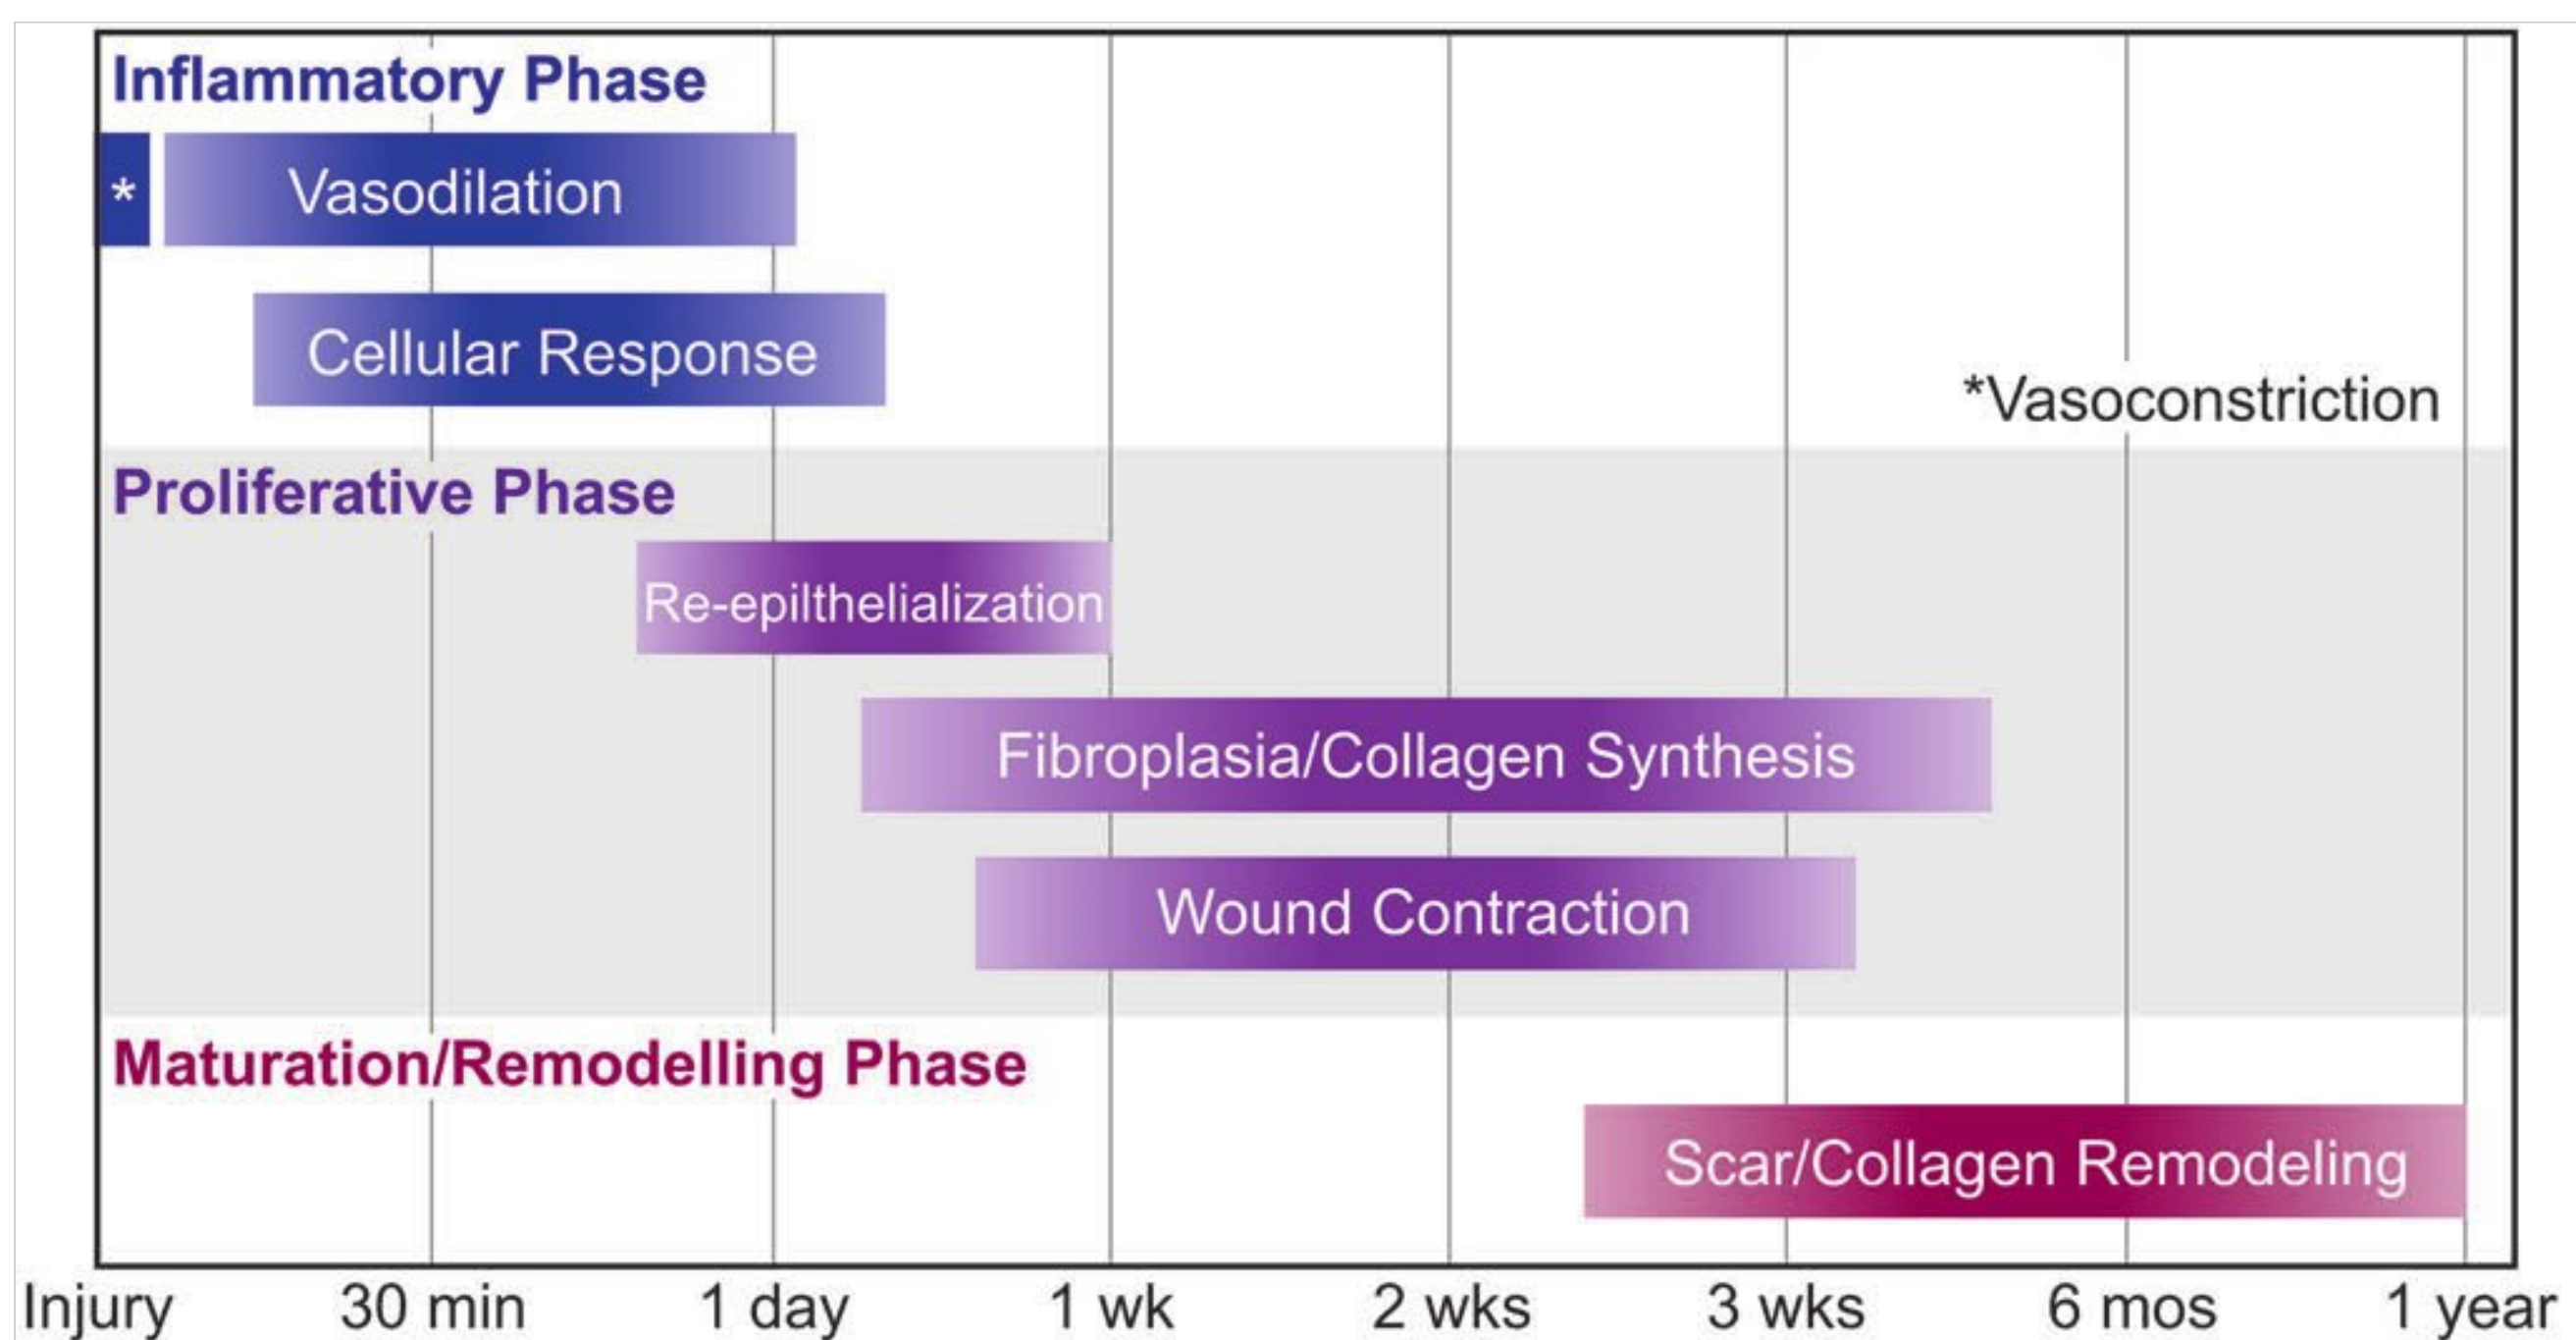

Fig. 39.1 The stages of healing.

wounds in the vicinity of the eye and nose may cause functional deficits, such as eyelid retraction and nasal obstruction.

39.4.3 Natural History and Progression

During the inflammatory phase, clot formed from bleeding tissues seals the wound. This process is accompanied by initial vasoconstriction followed by controlled vasodilation, which attracts platelets and fibrin into the wound. The clot also protects the wound from the environment and contamination. Inflammatory immune system components are attracted into the wound bed and release important cytokines and immune factors that regulate the remainder of the healing process. These include fibroblast growth factors (FGFs), platelet-derived growth factor (PDGF), and transforming growth factors (TGFs). A matrix consisting of fibronectin is eventually formed, creating the necessary mesh for cellular and protein deposition. Cellular immune components, such as neutrophils and monocytes, enter the wound bed and participate in phagocytosis. On the periphery of the wound, epithelial cells prepare to migrate as soon as 12 hours following injury. This process is marked by epithelial cell flattening and the formation of pseudopods. In sutured wounds, surface re-epithelialization can be completed within 48 hours. The inflammatory phase lasts from 5 to 15 days, depending on the size of the wound and degree of contamination. Clinically, edema and inflammation accompany the processes delineated above.

The proliferative phase guides regeneration of the cellular framework inside the wound. During this stage of wound healing, fibroblasts actively proliferate and deposit collagen, and granulation tissue, composed of inflammatory cells and regenerating blood vessels, is deposited. Clinically, a yellowish fibrinous exudate present during the inflammatory phase is gradually replaced by a cleaner, reddish granulation tissue.

The remodeling phase begins several weeks into the wound-healing process. This is the longest phase, lasting up to 2 years following tissue injury. Collagen fibers continue to be deposited and become thicker via cross-linking. Type III collagen is gradually degraded and replaced by type I collagen, which provides greater scar strength. The cellular components undergo changes that enhance long-term support of the healing wound. For example, fibroblasts differentiate into myofibroblasts, thereby promoting wound contracture. Blood vessels slowly regress, corresponding clinically to diminishing wound erythema and the white appearance typical of mature scars.

39.4.4 Potential Disease Complications

Untreated wounds may develop an infection and heal with cosmetically unacceptable scars. Significant bleeding may be encountered in open wounds with lacerations of the named vessels in the face and neck. Unrecognized facial nerve injury may lead to permanent paralysis. Lacerations of the parotid parenchyma or duct can cause a salivary cutaneous fistula or sialocele.

39.5 Medical Evaluation

The evaluation and management of wounds are covered in Chapter 41 .

39.5.1 Presenting Complaints

Patients' complaints related to healing wounds consist primarily of pain and discomfort. Deeper soft-tissue wounds in the head and neck may additionally involve nerve dysfunction or a salivary leak. These may not be obvious to the patient and require a thorough examination by the physician. Facial bony injuries may lead to additional complaints, such as diplopia in orbital blowout fractures or malocclusion in midfacial and mandibular fractures.

39.5.2 Clinical Findings, Physical Examination

Please see Chapter 41 .

39.5.3 Testing

In most patients with soft-tissue wounds, additional testing is unnecessary. Penetrating wounds of the head and neck should raise suspicion of deep vascular injury, requiring imaging with computed tomographic (CT) angiography. Any bony injuries require radiographic evaluation with facial bone CT. Basic blood testing (hemoglobin levels, electrolytes, and coagulation) is necessary in patients with wounds that require repair in the operating room.

39.5.4 Differential Diagnosis

The etiology of a wound is typically known at presentation. Just as pertinent in dealing with soft-tissue wounds is the physician's ability to formulate a "differential" for the treatment strategy. The reconstructive ladder is a conceptual paradigm for wound repair that starts with the simplest strategy and progresses to include more complex solutions. In order of increasing complexity, the reconstructive ladder includes the following steps:

1. Wound healing without surgical repair (secondary intention)
2. Wound healing with delayed surgical repair (tertiary intention)
3. Simple closure of the wound with sutures (primary intention)
4. Complex repair with local tissue rearrangement (primary intention)
5. Skin grafting
6. Complex repair with distant tissue (regional or free flaps)

39.6 Treatment

The medical and surgical management of wounds is covered in Chapter 41. Facial wounds best suited for healing by secondary intention are shown in □ Fig. 39.2.

39.7 Prognosis

Proper wound assessment and selection of the appropriate treatment strategy diminish the chance of unacceptable scarring and frequently lead to satisfactory outcomes. Certain wounds may require revision surgery for optimal results to

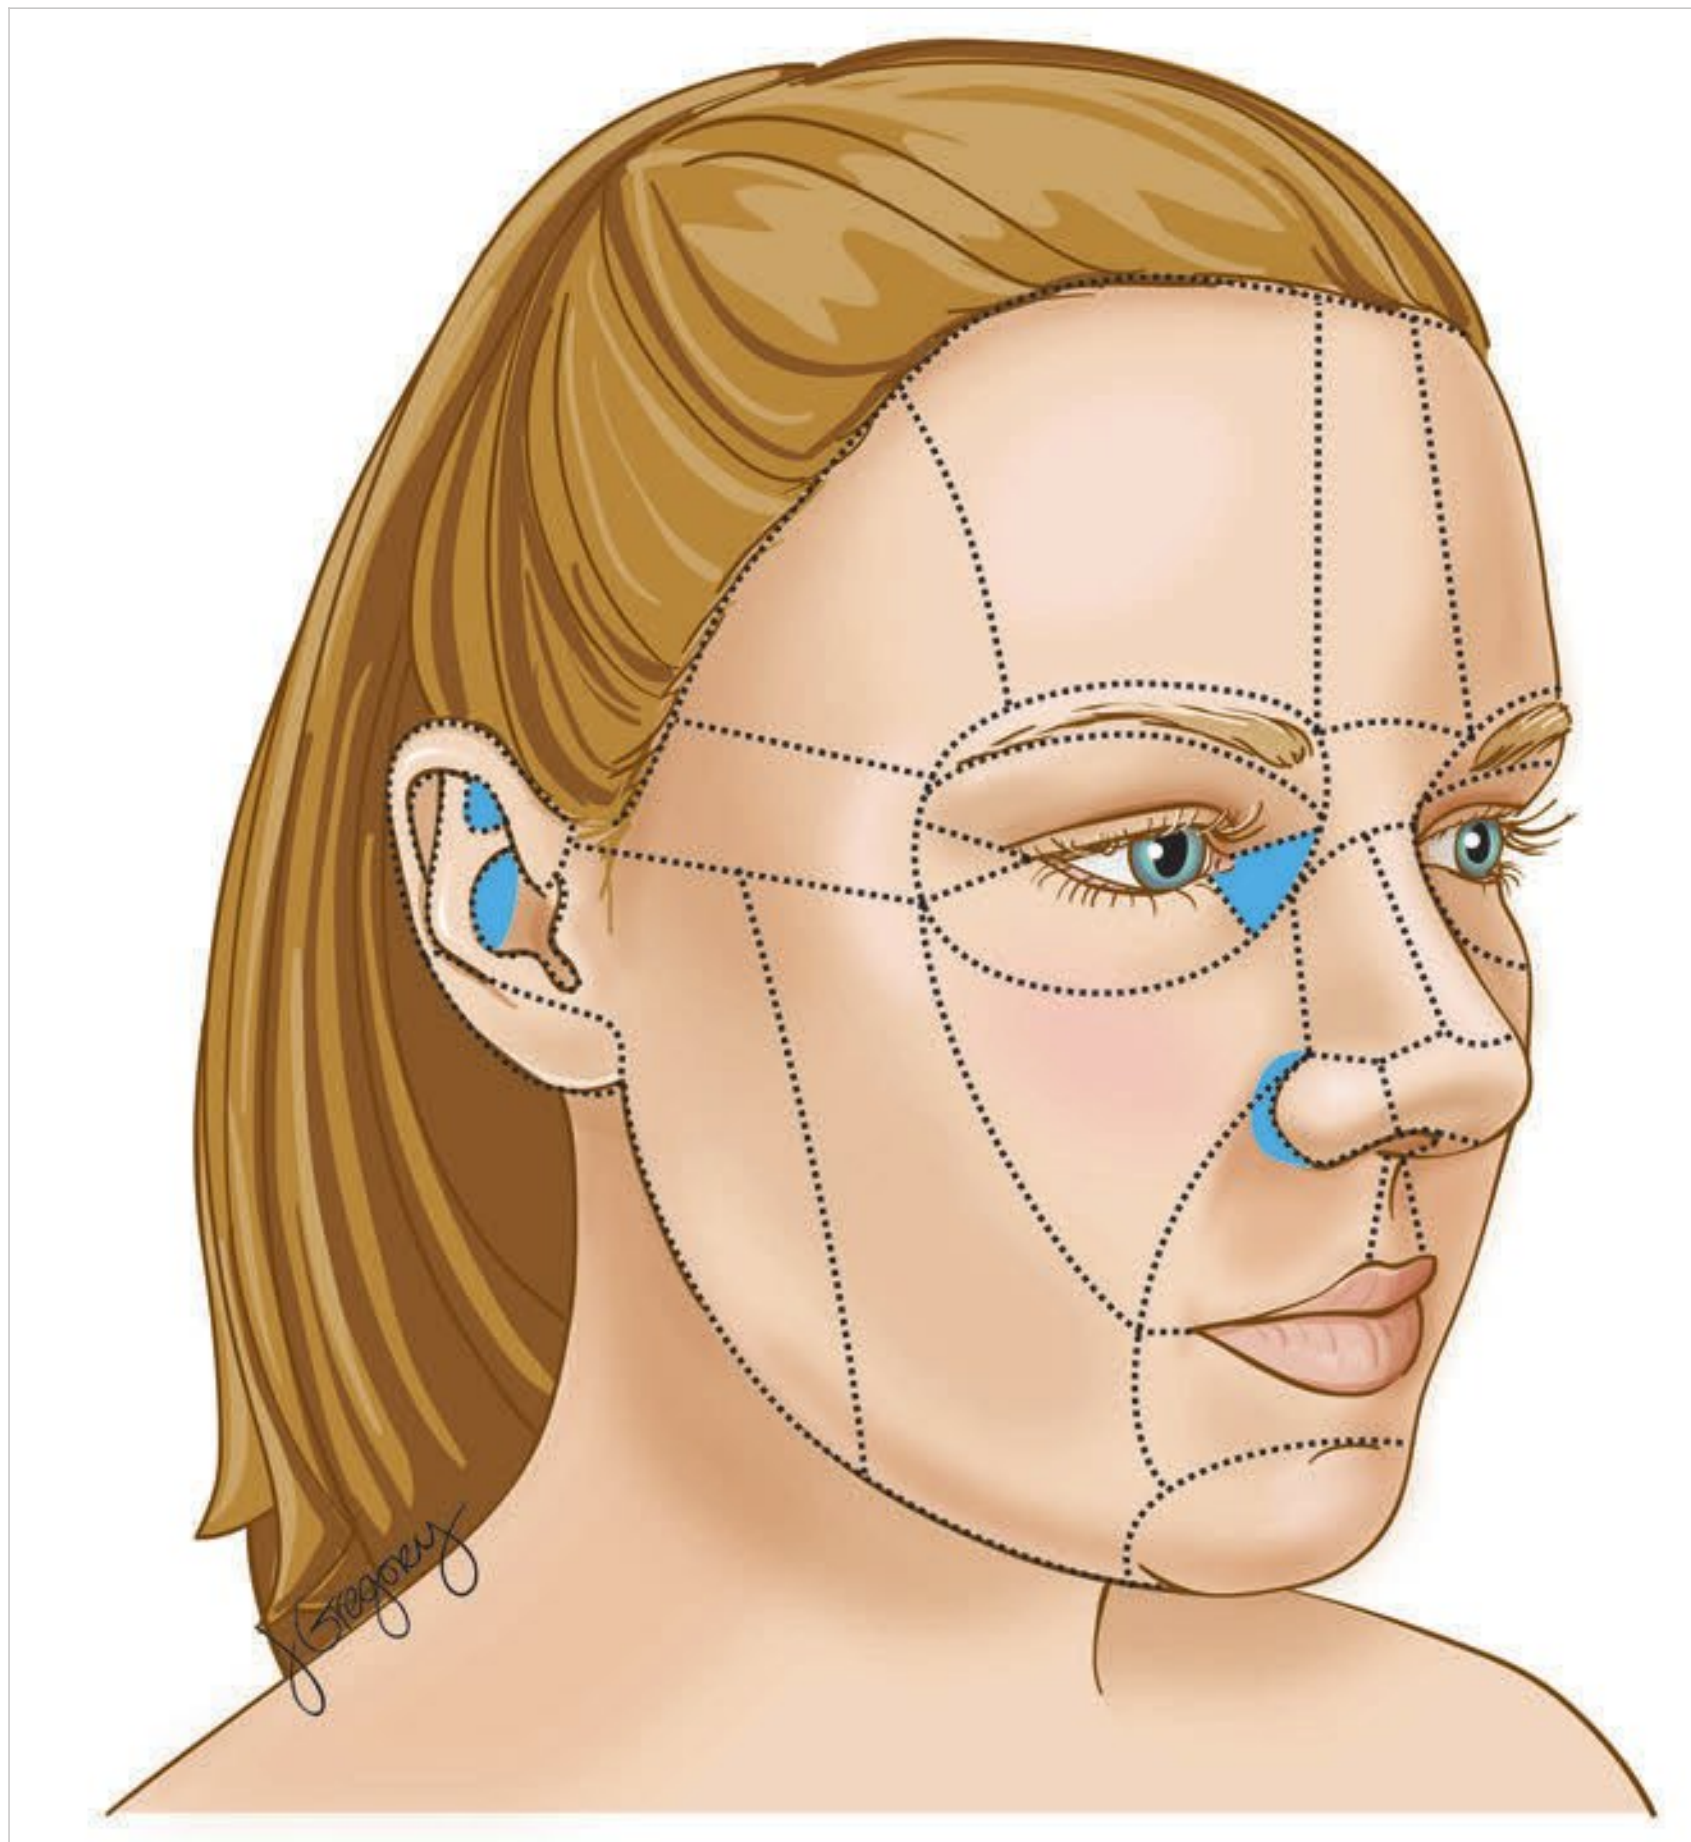

Fig. 39.2 The facial areas optimal for healing by secondary intention.

be achieved. Surgeon and patient commitment to the wound-healing process is a critical factor in influencing outcome and prognosis.

39.8 Roundsmanship

- The phases of wound healing phases consist of inflammatory, proliferative, and remodeling phases.
- The types of wound healing include primary, secondary, and tertiary.
- A reconstructive ladder helps formulate a treatment plan for healing wounds.

40 Local and Regional Anesthesia for Facial Plastic Surgery

Alexander Ovchinsky and Anthony P. Sclafani

40.1 Introduction

The popularity of cosmetic surgery has increased significantly over the last decade, with facial plastic surgery procedures such as blepharoplasty, rhinoplasty, and facelift the ones most commonly performed. Although there is a tendency of patients and the media to minimize the risk of cosmetic procedures, most cosmetic surgeries are considered major surgeries from the perspective of anesthesia.

40.2 Incidence

Patients undergoing cosmetic surgery have traditionally received local anesthesia with or without sedation. Regional anesthesia (via nerve blockades), alone or to supplement other forms of anesthesia, can be used, as well. However, owing to the increasing complexity of facial plastic procedures and the increased duration of surgery, general anesthesia has become more popular with the advent of anesthetic agents that have rapid action and safe recovery profiles.

40.3 Terminology

Local anesthesia is achieved with numerous injectable local anesthetic agents (□ Table 40.1) that have various onsets of action and durations of effect. The agents act locally and directly on peripheral sensory nerves.

40.4 Applied Anatomy

A detailed knowledge of facial anatomy in general, and of sensory innervation of the face in particular, assists greatly in the administration of good locoregional anesthesia.

Regional nerve blocks are commonly used for various facial plastic procedures. The supraorbital and supratrochlear nerves are the branches of the ophthalmic (V_1) division of the trigeminal nerve. The supraorbital and supratrochlear nerves emerge, respectively, from the supraorbital and supratrochlear foramina

and supply sensory innervation to the forehead region. Supraorbital and supratrochlear nerve blocks allow good anesthesia of the upper third of the face and are generally adequate to carry out various procedures in the forehead/brow region, such as browlift, locoregional flaps, and scar revision. The infraorbital nerve, a branch of the maxillary (V_2) division of the trigeminal nerve, emerges from the infraorbital foramen and provides sensory innervation to the cheek/midface region. Infraorbital nerve block is commonly used for midface anesthesia. The mental nerve, a terminal branch of the inferior alveolar nerve (mandibular [V_3] division of the trigeminal nerve), emerges from the mental foramen, located near the lower border of the mandible between the first and second premolars. Mental block achieves anesthesia of the chin and lower lip and is used alone or in combination with other anesthetic modalities for the various procedures in this region (local flaps, repair of lacerations, chin implant placement, dermal filler use, excision of lesions, others). The dorsal nasal nerve is a branch of the anterior ethmoidal nerve and runs on the undersurface of the nasal bones, emerging 5 to 8 mm from the midline just below the caudal edge of the nasal bones. The dorsal nasal nerve supplies sensation to the lower nasal dorsum and the nasal tip. The zygomaticotemporal nerve, which innervates the skin lateral to the orbital rim and the zygoma, is a branch of the maxillary (V_2) division of the trigeminal nerve. The zygomaticofacial nerve is also a branch of the maxillary (V_2) division of the trigeminal nerve and innervates a quarter-size area of skin over the malar eminence.

40.5 The Disease Process

40.5.1 Etiology

Local anesthetics produce anesthesia by inhibiting the excitation of nerve endings or by blocking conduction in peripheral nerves. This is achieved by reversibly binding to and inactivating sodium channels. Two basic classes of local anesthetics exist, the amides and the esters, which differ in several respects (□ Table 40.1). Esters are metabolized in the plasma by pseudo-

Table 40.1 Properties of local anesthetic agents

Drug	Onset	Maximum dose (with epinephrine)	Duration (with epinephrine)
Lidocaine	Rapid	4.5 mg/kg (7 mg/kg)	2 h (4 h)
Mepivacaine	Rapid	5 mg/kg (7 mg/kg)	3 h (6 h)
Bupivacaine	Slow	2.5 mg/kg (3 mg/kg)	4 h (8 h)
Ropivacaine	Medium	2–3 mg/kg	3 h (6 h)
Levobupivacaine	Medium	2.0 mg/kg or 400 mg/24 h	4–6 h (8–12 h)
Procaine	Slow	8 mg/kg (10 mg/kg)	45 min (90 min)
Chlorprocaine	Rapid	10 mg/kg (15 mg/kg)	30 min (90 min)
Prilocaine	Medium	5 mg/kg (7.5 mg/kg)	90 min (360 min)
Tetracaine	Slow	1.5 mg/kg (2.5 mg/kg)	3 h (10 h)

cholinesterase, whereas amides are metabolized in the liver. Esters are unstable in solution, but amides are very stable in solution. Esters are much more likely than amides to cause allergic hypersensitivity reactions. Commonly used amides include lidocaine, mepivacaine, prilocaine, bupivacaine, etidocaine, ropivacaine, and levobupivacaine. Commonly used amino esters include cocaine, procaine, tetracaine, chlorprocaine, and benzocaine. An easy way to remember which drug belongs in which category is that the names of all of the amides contain the letter *i* twice.

The physiologic activity of local anesthetics is a function of their lipid solubility, diffusibility, affinity for protein binding, percent ionization at physiologic pH, and vasodilating properties. All local anesthetics, with the exception of cocaine, are vasodilators. Vasodilation occurs via the direct relaxation of peripheral arteriolar smooth-muscle fibers. Greater vasodilator activity of a local anesthetic leads to faster absorption and thus a shorter duration of action. To counteract this vasodilation, epinephrine is often added to local anesthetic solutions. The maximum tolerable dose of lidocaine is 4.5 mg/kg; thus, for a 70-kg patient, the maximum dose is about 300 mg, or 30 mL of 1% lidocaine solution. The addition of epinephrine to the solution decreases the rate of local absorption of lidocaine, thus increasing the maximum tolerable dose, which then increases to 7 mg of lidocaine per kilogram. The maximal tolerable doses of other common local anesthetics are listed in □ Table 40.1.

40.5.2 Potential Complications

The two main manifestations of local anesthetic overdose are central nervous system (CNS) toxicity and cardiovascular toxicity. CNS toxicity usually precedes cardiovascular symptoms. The early signs of CNS toxicity are mild sedation, an abnormal metallic taste sensation, and (occasionally) tinnitus, which then may progress to seizures. Signs of cardiovascular toxicity included arrhythmias, heart block, and decline in cardiac contractility.

The treatment of early signs of CNS toxicity is aimed at the prevention of seizures by using medications to increase the seizure threshold, such as benzodiazepines (midazolam, diazepam) or barbiturates (thiopental, others). Significant cardiovascular toxicity may require a formal cardiovascular resuscitation; side effects related to epinephrine, such as anxiety and palpitations, are usually controlled with β -blockers.

40.6 Treatment

40.6.1 Supraorbital and Supratrochlear Nerve Blocks

Blockade of the supratrochlear nerve can easily be accomplished by injecting 1 to 2 mL of local anesthetic at the orbital rim above the medial canthus. The needle is then advanced along the supraorbital rim to inject an additional 1 to 2 mL

along the orbital rim above the midpupil to block the supraorbital nerve.

40.6.2 Dorsal Nasal Nerve Block

The dorsal nasal nerve can be blocked by injecting approximately 1 mL of local anesthetic at the caudal edge of the nasal bones about 5 to 8 mm lateral to the midline.

40.6.3 Infraorbital Nerve Block

The infraorbital nerve is blocked by injecting local anesthetic just below the infraorbital rim in line with the medial limbus. This can be done directly through the skin or through a sublabial needle stick. The index finger of the nondominant hand is placed at the infraorbital rim to ensure protection of the globe.

40.6.4 Mental Nerve Block

The mental nerve is blocked by injecting anesthetic approximately 1 cm below the first and second premolars.

40.6.5 Zygomaticotemporal Nerve Block

The zygomaticotemporal nerve is blocked by introducing a needle alongside the lateral orbital rim until it is deep to and at the level of the middle of the zygoma. At this point, 1 to 2 mL of local anesthetic is injected.

40.6.6 Zygomaticofacial Nerve

To block the zygomaticofacial nerve, 1 to 2 mL of local anesthetic is injected over the bone at the junction of a line drawn along the zygoma and another line extending down from the lateral orbital rim.

40.7 Roundsmanship

- Local anesthetics work by reversibly inactivating neuronal calcium channels, blocking nerve impulse conduction.
- Epinephrine is added to local anesthetics to cause local vasoconstriction, which limits the diffusion and clearance of the local anesthetic and extends its duration of action.

41 Facial Soft-Tissue Trauma

Grigorly Mashkevich

41.1 Introduction

Facial soft-tissue trauma may arise from motor vehicle accidents, physical altercations, work-related accidents, and other sources. Patients with facial trauma often present with concomitant injuries requiring a multidisciplinary evaluation. Most severe facial soft-tissue injuries resulting in open wounds may lead to significant scarring, facial nerve palsy, and parotid duct injury. In a setting of animal and human bites, facial penetration can be a source of communicable disease transmission. Although some wounds cannot be closed, the optimal management of most open wounds requires careful assessment and meticulous repair with the techniques discussed in this chapter.

41.2 Incidence of Disease

In 2006, emergency departments across the United States registered more than 5.4 million visits for all head and neck injuries. Although the specific breakdown is unknown, presumably many of these visits were for the treatment of facial soft-tissue trauma.

41.3 Terminology

Blunt trauma results in tissue injury without separation of the overlying skin. Penetrating injuries cause direct trauma to deep tissues via laceration of the skin. Animal and human bites are examples of penetrating trauma. Avulsion injury results in tissue loss. Primary closure is the approximation of wound edges, resulting in the elimination of dead space and rapid re-epithelialization of the wound surface. Healing by secondary intention is a process in which wounds are allowed to heal on their own. Delayed primary closure, or healing by “tertiary intention,” is frequently utilized in infected wounds; such wounds require daily care until the infection resolves, at which point the wound edges are surgically approximated.

41.4 Applied Anatomy

The facial nerve traverses the substance of the parotid gland and exits at its periphery via several identifiable branches. The temporal branch of the facial nerve exits the superior aspect of the parotid gland and crosses the zygomatic arch at the junction of its anterior one-third and posterior two-thirds. An additional surface landmark is a line that begins at the inferior aspect of the ear lobule and bisects a line connecting the tragus and the lateral canthus (□ Fig. 41.1). The buccal branch of the facial nerve closely follows the parotid duct, which runs along a line from the tragus to the midportion of the upper lip. The marginal branch of the facial nerve exits from the inferior aspect of the parotid gland, at the angle of the mandible, and descends up to 2 cm inferior to the body of the mandible before returning to innervate the mentalis and depressor anguli oris muscles (□ Fig. 41.2).

41.5 The Disease Process

41.5.1 Etiology

Facial soft-tissue injuries may arise in multiple settings, most notably during motor vehicle accidents, physical altercations, and sports. These injuries may be blunt or penetrating.

41.5.2 Pathogenesis

The degree of facial soft-tissue damage is directly related to the shape of the striking object, the force with which it strikes, and the location of the impact. A greater depth of penetration places neurovascular and glandular structures at a higher risk for injury.

41.5.3 Natural History and Progression

Most open facial soft tissue wounds are “clean-contaminated.” The head and neck region maintains a robust circulation, which helps prevent infection by maximizing wound oxygen tension and rapidly attracting immune system components. Untreated open wounds are at risk for delayed healing and significant scarring. Although no definitive rules exist on the timing of facial wound repair, most noninfected wounds can be closed primarily regardless of their duration. Conversely, any infected wounds, as judged by the presence of purulence and cellulitis, should be left open and treated with packing and antibiotics until all signs of infection are eliminated. Injuries to the facial nerve or parotid duct are not likely to heal without prompt surgical intervention with exploration and repair.

41.5.4 Potential Disease Complications

Untreated wounds may develop an infection and heal with cosmetically unacceptable scars. Significant bleeding may be encountered in open wounds with lacerations of named vessels in the face and neck. Unrecognized facial nerve injury may lead to permanent paralysis (□ Fig. 41.3). Lacerations of the parotid

Fig. 41.1 Facial surface landmarks for the frontotemporal division of the facial nerve. See text for details.

Fig. 41.2 Anatomy of the peripheral facial nerve.

parenchyma or duct can cause a salivary cutaneous fistula or sialocele.

41.6 Medical Evaluation

A complete medical history and account of the traumatic event should be obtained from the patient. Witness descriptions may be of value in the case of patients with altered states of consciousness. Any suspected domestic abuse should be reported and investigated.

41.6.1 Presenting Complaints

Complaints related to soft-tissue trauma consist primarily of pain and discomfort. Patients may report difficulty with facial movement (cranial nerve VII involvement) or sensory deficits (cranial nerve V), both of which can arise from swelling alone. Any additional complaints indicating injury to adjacent structures (e.g., vision changes, trismus, malocclusion, breathing or swallowing difficulties) should trigger appropriate investigations.

41.6.2 Clinical Findings, Physical Examination

Any patients with trauma requires an initial evaluation of airway patency, breathing, and circulation. During the primary survey, all sites of injury are assessed, including the cervical spine.

The ENT (ear, nose, throat) evaluation consists of a complete examination of the head and neck. This includes a fiber-optic

Fig. 41.3 Paralysis of the left marginal mandibular branch of the facial nerve.

assessment of the airway to rule out concomitant injuries to the upper aerodigestive tract. Palpation of the facial skeleton, with attention to trismus and bite abnormalities, should be performed to rule out fractures. Penetrating injuries of the head and neck require special protocols to exclude vascular or upper aerodigestive tract injury; these are discussed in Chapter 37.

The soft-tissue evaluation relies on meticulous visual inspection and documentation of all abrasions and lacerations. Wounds may require cleaning for an adequate assessment of the depth of

injury. Any suspected penetration of the neck should not be probed beyond the platysma muscle because doing so may disturb injured vessels and result in significant bleeding in an uncontrolled setting. Suspected penetrating injuries of the neck are best assessed with computed tomographic (CT) angiography. Facial injuries may be safely cleaned with half-strength peroxide diluted in saline or water. Cotton-tipped applicators are useful in separating wound edges and examining the extent of facial soft-tissue injury. Bleeding wounds may be temporarily packed with gauze to achieve hemostasis until a definitive treatment is undertaken. Head elevation, pressure dressings, and the placement of epinephrine-soaked gauze into the wound may further assist with hemostasis and visualization. Clamps in bleeding facial wounds should be used with caution because such action may inadvertently injure branches of the facial nerve.

Any patient with a laceration situated in the anatomical distribution of the facial nerve (see □ Fig. 41.2) requires a complete neurologic assessment of this structure. Deficiencies in brow elevation or eyelid closure, oral commissure excursion during smiling, and lip pucker indicate facial nerve injury. Any neurologic assessment of cranial nerve VII must occur before the use of local anesthetics. In sedated patients or those with altered mental status, a painful stimulus (such as chest rub) may induce a sufficient grimace to provide a baseline assessment of seventh cranial nerve integrity.

An assessment of the parotid duct may be difficult to perform at the bedside because of blood, debris, and poor lighting. Any presence of clear fluid, especially if expressed on manual compression of the gland, should raise suspicion of parotid duct injury. If available, lacrimal probes may be used intraorally to cannulate the orifice of the parotid duct to aid its identification in the wound.

41.6.3 Testing

Radiographic studies may include cervical spine X-rays and CT of the facial skeleton and cranium. Electrocardiography and basic blood tests for hemoglobin and electrolytes are important studies in patients presenting with suspected significant blood loss or any hemodynamic changes, or in those anticipated to undergo soft-tissue repair in the operating room. Photographic documentation of any open wounds before repair is critical from a medicolegal standpoint.

41.6.4 Differential Diagnosis

In addition to soft-tissue injury, the differential diagnosis includes concomitant skeletal injuries (orbital, maxillary, mandibular, and cranial fractures), vascular damage, and neurologic impairment. A specialist assessment may be necessary, especially in the areas of ophthalmology, neurosurgery, oral surgery, and vascular surgery.

41.7 Treatment

41.7.1 Medical Treatment

Soft-tissue bruising responds well to pain medications and the frequent application of ice in the first 48 to 72 hours. This diminishes inflammation, swelling, and discomfort. Beyond 72

hours, warm compresses and anti-bruising creams, such as *Arnica montana* (wolf's bane), can offer a quicker resolution of bruising and discoloration.

Superficial abrasions are best managed with daily cleaning (mild soap and water, with half-strength hydrogen peroxide for any crusts) and the application of antibiotic ointment (bacitracin) to hasten wound re-epithelialization in a moist environment. If an allergic reaction (itching, rash, or erythema) develops in response to bacitracin, a bland ointment such as petrolatum (Aquaphor, Vaseline) can be applied instead. Such treatment strategy results in healed abrasions in 5 to 14 days.

Bite injuries require antibiotic prophylaxis for potentially transmitted pathogens. Most common animal bites are from dogs, with a resultant multibacterial aerobic and anaerobic pathogen profile. The most common species include *Streptococcus*, *Staphylococcus*, *Pasteurella multocida*, and *Bacteroides*. Empiric antibiotics, such as amoxicillin/clavulanate, provide adequate coverage while culture identification is pending. Human bites are also multibacterial but may transmit viruses, as well. Any suspicion of possible HIV or hepatitis virus transmission should be brought to the immediate attention of the emergency department staff and infectious disease specialists. Hospital-specific protocols for testing, disclosure, and treatment should be closely followed.

Tetanus and rabies prophylaxis deserve consideration in appropriate cases. Wounds heavily contaminated with soil carry the highest risk for tetanus. Tetanus toxoid should be administered along with a booster injection, if one has not been given within 10 years. The need for rabies prophylaxis depends on the history (whether the offending animal is known to be ill), geographic rabies patterns, and examination of a captured rabid animal.

41.7.2 Surgical Treatment

Any manipulation of soft tissues requires informed patient consent. In a setting of soft-tissue trauma, this process may be complicated by patient's altered state of consciousness, resulting from either cranial involvement or sedative medications. Appropriate relatives and healthcare proxies, if designated, must be engaged in this process. In addition, photographic documentation must precede any attempted repair for medicolegal reasons.

Open wound repair requires a thorough assessment of tissue loss and preparation of the injured site by careful removal of debris and sharpening of the skin edges. This is made easier by introducing local anesthesia before any tissue manipulation, which diminishes oozing and improves patient comfort. The injection of 1% lidocaine with 1:100,000 epinephrine, buffered with 10% sodium bicarbonate (4:1 dilution), through a small (27- to 30-gauge) needle provides an effective means of achieving local anesthesia. Regional blocks of the supratrochlear, supraorbital, infraorbital, and mental nerves can be performed for larger wounds. Anesthetic agents with longer durations of action (such as bupivacaine) may be added if wound closure is expected to last several hours, or for prolonged postoperative pain control.

Local tissue rearrangement (advancement, rotation, and transposition skin flaps) may be necessary to achieve wound

closure, especially in avulsion injuries. As much as possible, scars should be placed in existing wrinkles or within relaxed-skin tension lines. Sharp skin undermining and wound edge eversion are critical in achieving a tension-free closure and aesthetically pleasing scars. Sites of higher tension require the placement of permanent or long-lasting absorbable sutures (3–0 or 4–0 PDS [polydioxanone] or Vicryl), in some cases passed through the periosteum to counter unfavorable soft-tissue vectors. More quickly absorbed subcutaneous sutures (4–0 or 5–0 Monocryl) should be placed in areas with less tension. Nonabsorbable (5–0 or 6–0 Prolene or nylon) fine sutures are used for cutaneous closure. These cause minimal tissue reaction and are removed in 5 to 7 days.

Auricular Lacerations and Avulsions

Auricular lacerations can be challenging because of complex surface topography, the presence of cartilage, and a relative lack of tissue mobility. Through-and-through defects require meticulous approximation of all involved tissue layers. Skin eversion is particularly important in preventing external notching and contour irregularities. Any exposed cartilage should be identified and approximated with either permanent or long-lasting absorbable sutures.

The repair of composite auricular tissue loss relies on the preservation of native cartilage. In segmental auricular avulsions, a retroauricular pocket can be formed to store cartilage from the avulsed ear segment. Steps include de-epithelialization of the avulsed segment, reattachment of the cartilage stump to the remaining auricular cartilage, and placement of the avulsed segment under temporal skin coapted to the edge of skin on the auricular cartilage. After 6 weeks, the avulsed segment of the auricle is elevated along with the overlying temporal skin, and a skin graft is placed on its posterior aspect. The direct reattachment of avulsed segments, without pocket storage, is unpredictable and becomes especially unsuccessful with segments larger than 1.5 cm.

Subtotal avulsions with any remaining cutaneous attachments heal remarkably well following primary closure. An abundant blood supply to the ear provides an excellent circulation through the remaining attachments, allowing adequate perfusion of the auricle. In cases of total auricular avulsion, replantation with microvascular repair can be considered. Supportive measures for survival of the reconstructed auricle, such as hyperbaric oxygen, anticoagulation, and medicinal leeches, may be necessary adjunctive steps in most of these cases.

Lip Lacerations

The repair of lip lacerations must separately address all involved tissue layers. In the lip, these include skin, muscle, and mucosa. The cutaneous lip can be further divided into subunits, which consist of the philtrum medially, lateral segments laterally, and vermilion inferiorly. The vermilion–cutaneous junction is an important visual landmark. Even the slightest irregularities of this border can be highly noticeable because of the transition in color.

If possible, lip lacerations should be rearranged to allow final scars to fall into the borders between lip subunits. This optimizes scar camouflage. Additional incisions may be necessary

to achieve adequate tissue advancement or rotation. If transected, the orbicularis oris muscle must be approximated with a 2–0 or 3–0 long-lasting absorbable suture. Superficial or small mucosal defects can heal inconsequentially by secondary intention. Larger or deeper mucosal wounds should be approximated with short-lasting absorbable suture material.

Eyelid Lacerations

All eyelid lacerations require work-up for concomitant ocular injuries. An ophthalmologist should be consulted to rule out damage to the cornea and retina. Physical examination of the periocular tissues must also exclude injuries to the levator muscle (ptosis), canthal tendons (displacement or rounding of the canthal angles), and canaliculi (epiphora).

Early eyelid repair is important in providing immediate corneal protection. Any particulate matter must be removed in order to avoid the development of a traumatic tattoo. Suspected injury to the canaliculi should be evaluated with lacrimal probes. The repair of duct walls requires loupe or microscopic magnification and is best accomplished with interrupted 9–0 permanent sutures placed over a Silastic stent.

Avulsion of the medial canthal tendon is addressed with a periosteal stitch to the lacrimal bone. Insufficient periosteum may require screw placement or transnasal wiring. Inadequate repair of this structure can lead to widening of the intercanthal distance, resulting in telecanthus.

Lacerations extending to the lid margin are best repaired with a 6–0 silk suture placed in a vertical mattress fashion to ensure eversion and prevent notching. Suture repair should begin at the gray line to properly align the lid edges. The tarsus and orbicularis oculi are approximated with 6–0 absorbable sutures. Lubricating ointment is applied liberally in the postoperative setting.

Facial Nerve Lacerations

Any suspected facial nerve injury requires immediate exploration and repair. The distal portion of the severed nerve continues to conduct and can be stimulated for up to 48 to 72 hours following transection. This greatly enhances identification of the nerve in the operating room with a nerve stimulator (0.5 to 1 mA). Nerve repair should be performed under loupe magnification (3.5x or higher) or microscopic magnification. Nerve ends must be exposed and mobilized for 1 to 2 cm for advancement and reduction of tension. Each nerve end must be cut clean, which removes about 1 mm of distance on each side. Adequate mobilization usually makes up for such a loss. In cases of missing nerve segments, grafting must be contemplated with one of several donor sources (great auricular, lateral antebrachial cutaneous, or sural nerve). This possibility needs to be discussed with the patient in advance of the operation. Nerve approximation requires the placement of three to seven interrupted 9–0 nylon sutures through the epineurium (□ Fig. 41.4).

Parotid (Stensen) duct repair is determined by the extent of duct injury. For simple lacerations or transections, direct repair is performed over a stent placed intraorally. Small-caliber pediatric feeding tubes serve as excellent parotid duct stents and can be sutured intraorally to maintain the egress of saliva for 2 to 4 weeks. Injuries resulting in a loss of the parotid duct are

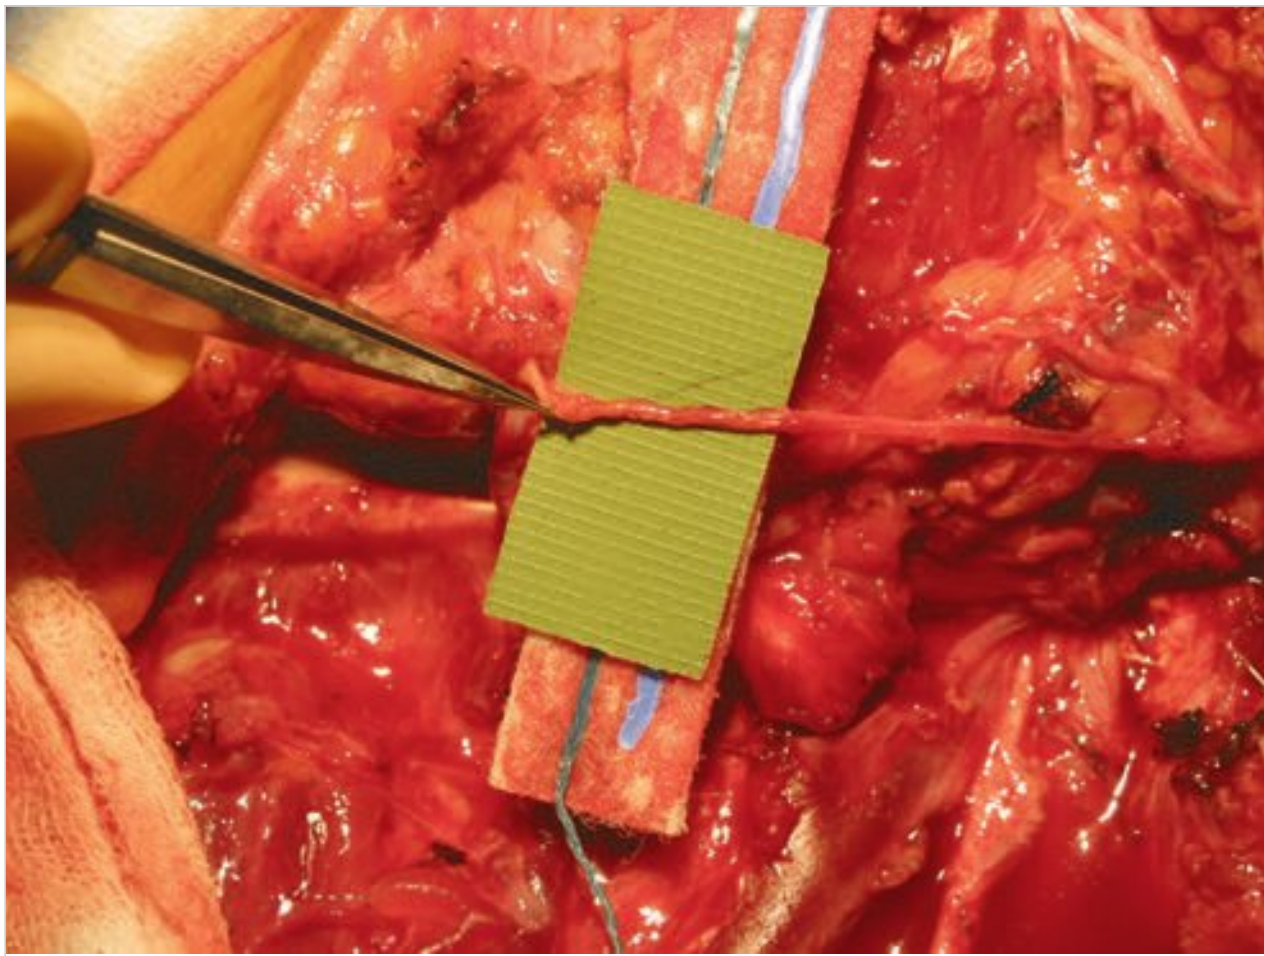

Fig. 41.4 Facial nerve repair under the microscope.

more difficult to repair. If both ends can be identified, an interposition vein graft (anterior or external jugular) is placed over a stent to replace the missing segment. In cases in which the distal parotid duct cannot be identified and the site of injury is anterior to the masseter, a diversion of the proximal duct introrally can be performed. If the site of injury is posterior to the masseter, or if the proximal parotid duct cannot be identified, watertight closure of the parotid fascia to tamponade salivary flow should be performed with a permanent or long-lasting absorbable suture placed in a running locking fashion. In addition, 50 to 100 units of botulinum toxin can be injected into the parenchyma of the parotid gland to extinguish salivary production. This strategy rarely results in gland inflammation and/or infection.

41.8 Prognosis

Facial soft-tissue bruising, hematomas, and superficial abrasions resolve fully without major sequelae. Hyperpigmentation of abraded areas can be managed with sun protection and bleaching creams (2% or 4% hydroquinone). Repaired wounds may take 6 to 12 months to fully mature. Hypertrophic scars, keloids, and pincushioning may complicate wound healing. These respond to periodic steroid injections (triamcinolone acetate, 10 or 40 mg/mL). Cosmetically poor scars may require revision to improve appearance.

41.9 Roundsmanship

- Patients with facial soft-tissue trauma require a complete assessment for concomitant skeletal, upper aerodigestive, neurologic, and vascular injuries.
- Noninfected open wounds are optimally managed with tissue preparation and meticulous primary closure.
- Parotid duct and facial nerve injury must be considered in open wounds overlying these structures.
- Transected facial nerve branches are best repaired within 72 hours, when the distal ends can still be stimulated.

42 Maxillofacial Trauma

Alexander Ovchinsky

42.1 Introduction

Maxillofacial injuries remain serious clinical problems because of the high density of neural, vascular, digestive, and respiratory tissues in this area. In addition to these life-threatening issues, maxillofacial trauma can have significant psychological effects on patients because of the aesthetic deformities that they can cause.

42.2 Incidence of Disease

In the United States, trauma constitutes the third major cause of death among all age groups and the leading cause of death among the persons younger than 44 years of age. The major causes of trauma-related death are central nervous system injury and hemorrhage. In addition to fatal injuries, roughly 40 million people are treated in emergency departments each year, and the total cost associated with injuries is estimated to be more than \$250 billion per year. Currently, more than 400 people in the United States die of injuries every day, and 50% of these deaths occur before arrival at the hospital. However, it is worth mentioning that the obligatory use of seat belts and the invention of air bag systems has resulted in approximately a 25% decrease in the frequency of injuries due to motor vehicle accidents.

The incidence of facial trauma as a whole peaks in the first decade of life and slowly declines over the remaining decades of life. The incidence of facial bone fractures, in contrast, peaks in the third decade of life. Counter to the increasing incidence of facial bone fractures in the first three decades of life, the actual relative risk for facial bone fractures per accident increases with increasing age (4.4% per year of life) because of the associated decrease in bone density.

Most injuries in the first decade of life are isolated soft-tissue lacerations or dentoalveolar trauma (tooth impaction, alveolar process fractures, crown fractures, others), as opposed to the facial bone fractures seen in the adult population.

42.3 Classification of the Disease Process

The classification of maxillofacial trauma is usually related to the type of the injury sustained. Bruises or contusions are the result of soft-tissue blunt trauma followed by subcutaneous bleeding. The extent of bruising depends on the severity of the impact, the laxity of the tissues, the individual's predisposition to bruising, and the individual's age. Abrasions are superficial wounds that do not penetrate the full thickness of the dermis. Deeper abrasions, extending to the level of papillary and reticular dermis, frequently bleed, sometimes profusely. Abrasions are frequently associated with foreign bodies, such as wood splinters and road dirt. Lacerations are full-thickness wounds penetrating through the dermis and frequently extending into subcutaneous tissues and muscles; they are usually caused by a

sharp object. If the length of the wound exceeds its depth, it is referred to as slash wound, and if the converse is true, a stab wound. Fractures are the loss of structural integrity of a bone resulting from mechanical overload and failure to resist deformation. Fractures may be further classified as closed fractures, in which there is no communication of the fractured bone with the outside environment, and open fractures, in which the fracture is exposed to the external environment via laceration or penetration of the fracture fragments through the overlying soft tissues and skin. Fractures are also categorized based on the region or bones involved.

42.4 Applied Anatomy

A thorough knowledge of normal facial anatomy is essential for the successful management of maxillofacial trauma. Although a detailed description of facial anatomy may be found in other textbooks, the surgical and anatomical considerations pertaining to patients with facial trauma are the basis of this discussion.

The frontal bone forms the anterior part of the skull and essentially the major portion of the upper face. It is connected to the zygoma laterally via the zygomaticofrontal process, and to the nasal bones medially via the nasofrontal suture line. These connections form three so-called vertical facial buttresses, two zygomaticofrontal and one nasofrontal, which serve as a major support mechanism for the facial skeleton. Inferiorly, the frontal bone articulates with the ethmoid, sphenoid, and lacrimal bones. Anterior pneumatization of the frontal bone forms the frontal sinus, with its anterior and posterior tables. Frontal sinus drainage is via the nasofrontal duct, which opens into the middle nasal meatus. The frontal bone is one of the strongest bones in the human body, and significant force is required to cause a fracture. Therefore, frontal sinus fractures are commonly associated with other significant injuries, such as cervical spine or brain injuries.

The nasal bones are paired rectangular bones that connect to each other in the midline to form the bony nasal dorsum. They articulate with the frontal bone superiorly, nasal processes of the maxilla laterally, and upper lateral cartilages inferiorly. On the undersurface, the nasal bones are connected with the bony and cartilaginous nasal septum. Because of their exposed location and relative fragility, the nasal bones are frequently injured.

The maxilla is formed by its alveolar, zygomatic, palatal, and nasal processes. The pyramid-shaped maxillary sinus occupies the midportion of the maxilla, draining into the middle nasal meatus. The anterior wall of the maxillary sinus is very thin and thus is easily fractured. The palatal processes merge in the middle, forming the larger portion of the hard palate; the alveolar process contains the dentition and forms the inferior portion of the maxilla. It joins the pterygoid plates of the sphenoid bones posteriorly; pterygoid plate fracture is the key component of all Le Fort-type fractures of the maxilla. The zygomatic and nasal processes are extensions of the maxilla that are important for facial form and function.

The zygoma forms the cheek eminence. It consists of a body and three processes—temporal, frontal, and maxillary—that connect the zygoma to the temporal and frontal bones and the maxilla, respectively. The zygoma also forms the part of the lateral orbital floor.

The mandible consists of the central symphysis and the bilateral mandibular bodies, rami, angles, and coronoid and condylar processes. The alveolar process of the mandible forms its superior portion and contains the lower dentition, which is innervated by the inferior alveolar nerve. The condylar process articulates with the glenoid fossa of the temporal bone, forming temporomandibular joint.

The orbit protects, supports, and maximizes the function of the eye. The orbit is shaped like a quadrilateral pyramid, with its base in a plane with the orbital rim. Seven bones join together to form the orbital structure. The orbital process of the frontal bone and the lesser wing of the sphenoid form the orbital roof. The orbital plate of the maxilla joins the orbital plate of the zygoma and the orbital plate of the palatine bones to form the floor. Medially, the orbital wall consists of the frontal process of the maxilla, the lacrimal bone, the sphenoid, and the thin lamina papyracea of the ethmoid. The lateral wall is formed by the lesser and greater wings of the sphenoid and the zygoma.

42.5 The Disease Process

42.5.1 Etiology

Maxillofacial injuries can be classified with respect to their etiology, including assaults, falls, sport-related injuries, animal or human bites, motor vehicle accidents, gunshot injuries, and burns. The etiology of facial fractures varies between urban and rural environments. Penetrating trauma and assault-related injuries are more common in cities, whereas injuries related to motor vehicle accidents, sports, and other recreational injuries are seen frequently in rural hospitals. In community emergency departments, fractures of the nose and mandible are the most common; in trauma centers, however, midface and zygomatic injuries are more frequent. Domestic violence and elder and child abuse are important causes of facial trauma. Facial injuries account for the majority of emergency department visits related to domestic violence. As many as one-fourth of women with facial trauma are victims of domestic violence.

42.5.2 Pathogenesis

The kinetic energy of a moving object is a function of its mass multiplied by the square of its velocity. The dispersion of this kinetic energy during impact produces the force that results in injury. High-impact and low-impact forces are respectively defined as those that are more or less than 50 times the force of gravity. These parameters determine the extent of the resultant injury because the amount of force required to cause damage to the facial bones differs regionally. A high-impact force is required to damage the supraorbital rim, mandible (symphysis and angle), and frontal bones, but a low-impact force is all that is required to damage the zygoma and nasal bone. Orbital blowout fractures are thought to occur when a sudden increase in the intraorbital pressure causes blowout of the thin medial wall and/or orbital floor.

42.5.3 Natural History and Progression

What the extent of the final deformity will be may not be very obvious immediately after the injury. However, with time, as the soft-tissue swelling subsides, the resultant facial asymmetry may become more pronounced. Later, the loss of structural support in uncorrected or poorly corrected facial fractures frequently translates into functional deficits. For example, telecanthus may gradually develop as the loose bony fragments of a naso-orbito-ethmoid (NOE) fracture lateralize because of the loss of medial canthal tendon stability. Enophthalmos may also be a late finding in orbital blowout fracture as the orbital contents slowly retract into the maxillary sinus. Diplopia may follow as the orbital contents herniate and become trapped within the fracture fragments.

42.5.4 Potential Disease Complications

The complications arising from maxillofacial trauma differ widely in severity, ranging from mild cosmetic deformity without any functional deficit, to significant functional disability related to orbital and neurovascular injury and malocclusion, to death in acute settings resulting from airway compromise, hemorrhage, and associated intracranial and spine injuries.

42.6 Disease Grading

Broadly speaking, maxillofacial injury can be classified as either blunt or penetrating trauma. Blunt trauma results from motor vehicle accidents, sports, falls, and occupation-related injuries. Penetrating trauma includes gunshot injuries, stab wounds, and injuries caused by impalement. The type and extent of injury and subsequent management depend on the region injured and the vital structures in proximity to the path of the penetrating object. With firearm injuries, the velocity, caliber, and presumed path of the bullet and the distance from the weapon provide important clues to the extent of the injury.

Maxillofacial fractures may be differentiated by their severity (displaced vs. nondisplaced, open vs. closed) and by the anatomical region involved. In nondisplaced fractures, the anatomical alignment of the fractured bone is maintained, whereas in displaced fractures, this alignment is lost, leading to specific findings on the physical examination such as loss of support and symmetry, palpable bony step-offs, and injury to vital structures by displaced bony fragments. Closed fractures do not have any communication with the outside environment, whereas open fractures communicate with the outside and so are more prone to infection or bleeding.

Based on the anatomical region involved, maxillofacial fractures are subdivided into the following categories:

- Frontal sinus fractures
- NOE fractures
- Zygomatico-orbital fractures
- Maxillary fractures
- Mandible fractures

Frontal sinus fractures may be further subdivided as follows:

1. Anterior table fractures
2. Posterior table fractures
3. Anterior and posterior table fractures

Fig. 42.1 Coronal computed tomographic scan of the facial bones depicting a mixed pattern of maxillary fractures, with Le Fort type I fractures on the right side and Le Fort type II fractures on the left side. The right-sided fractures involve the right piriform aperture and anterior–lateral wall of the maxillary sinus. The left-sided fractures involve the zygomaticofrontal process (white arrow) and inferior orbital wall/floor (hollow arrow).

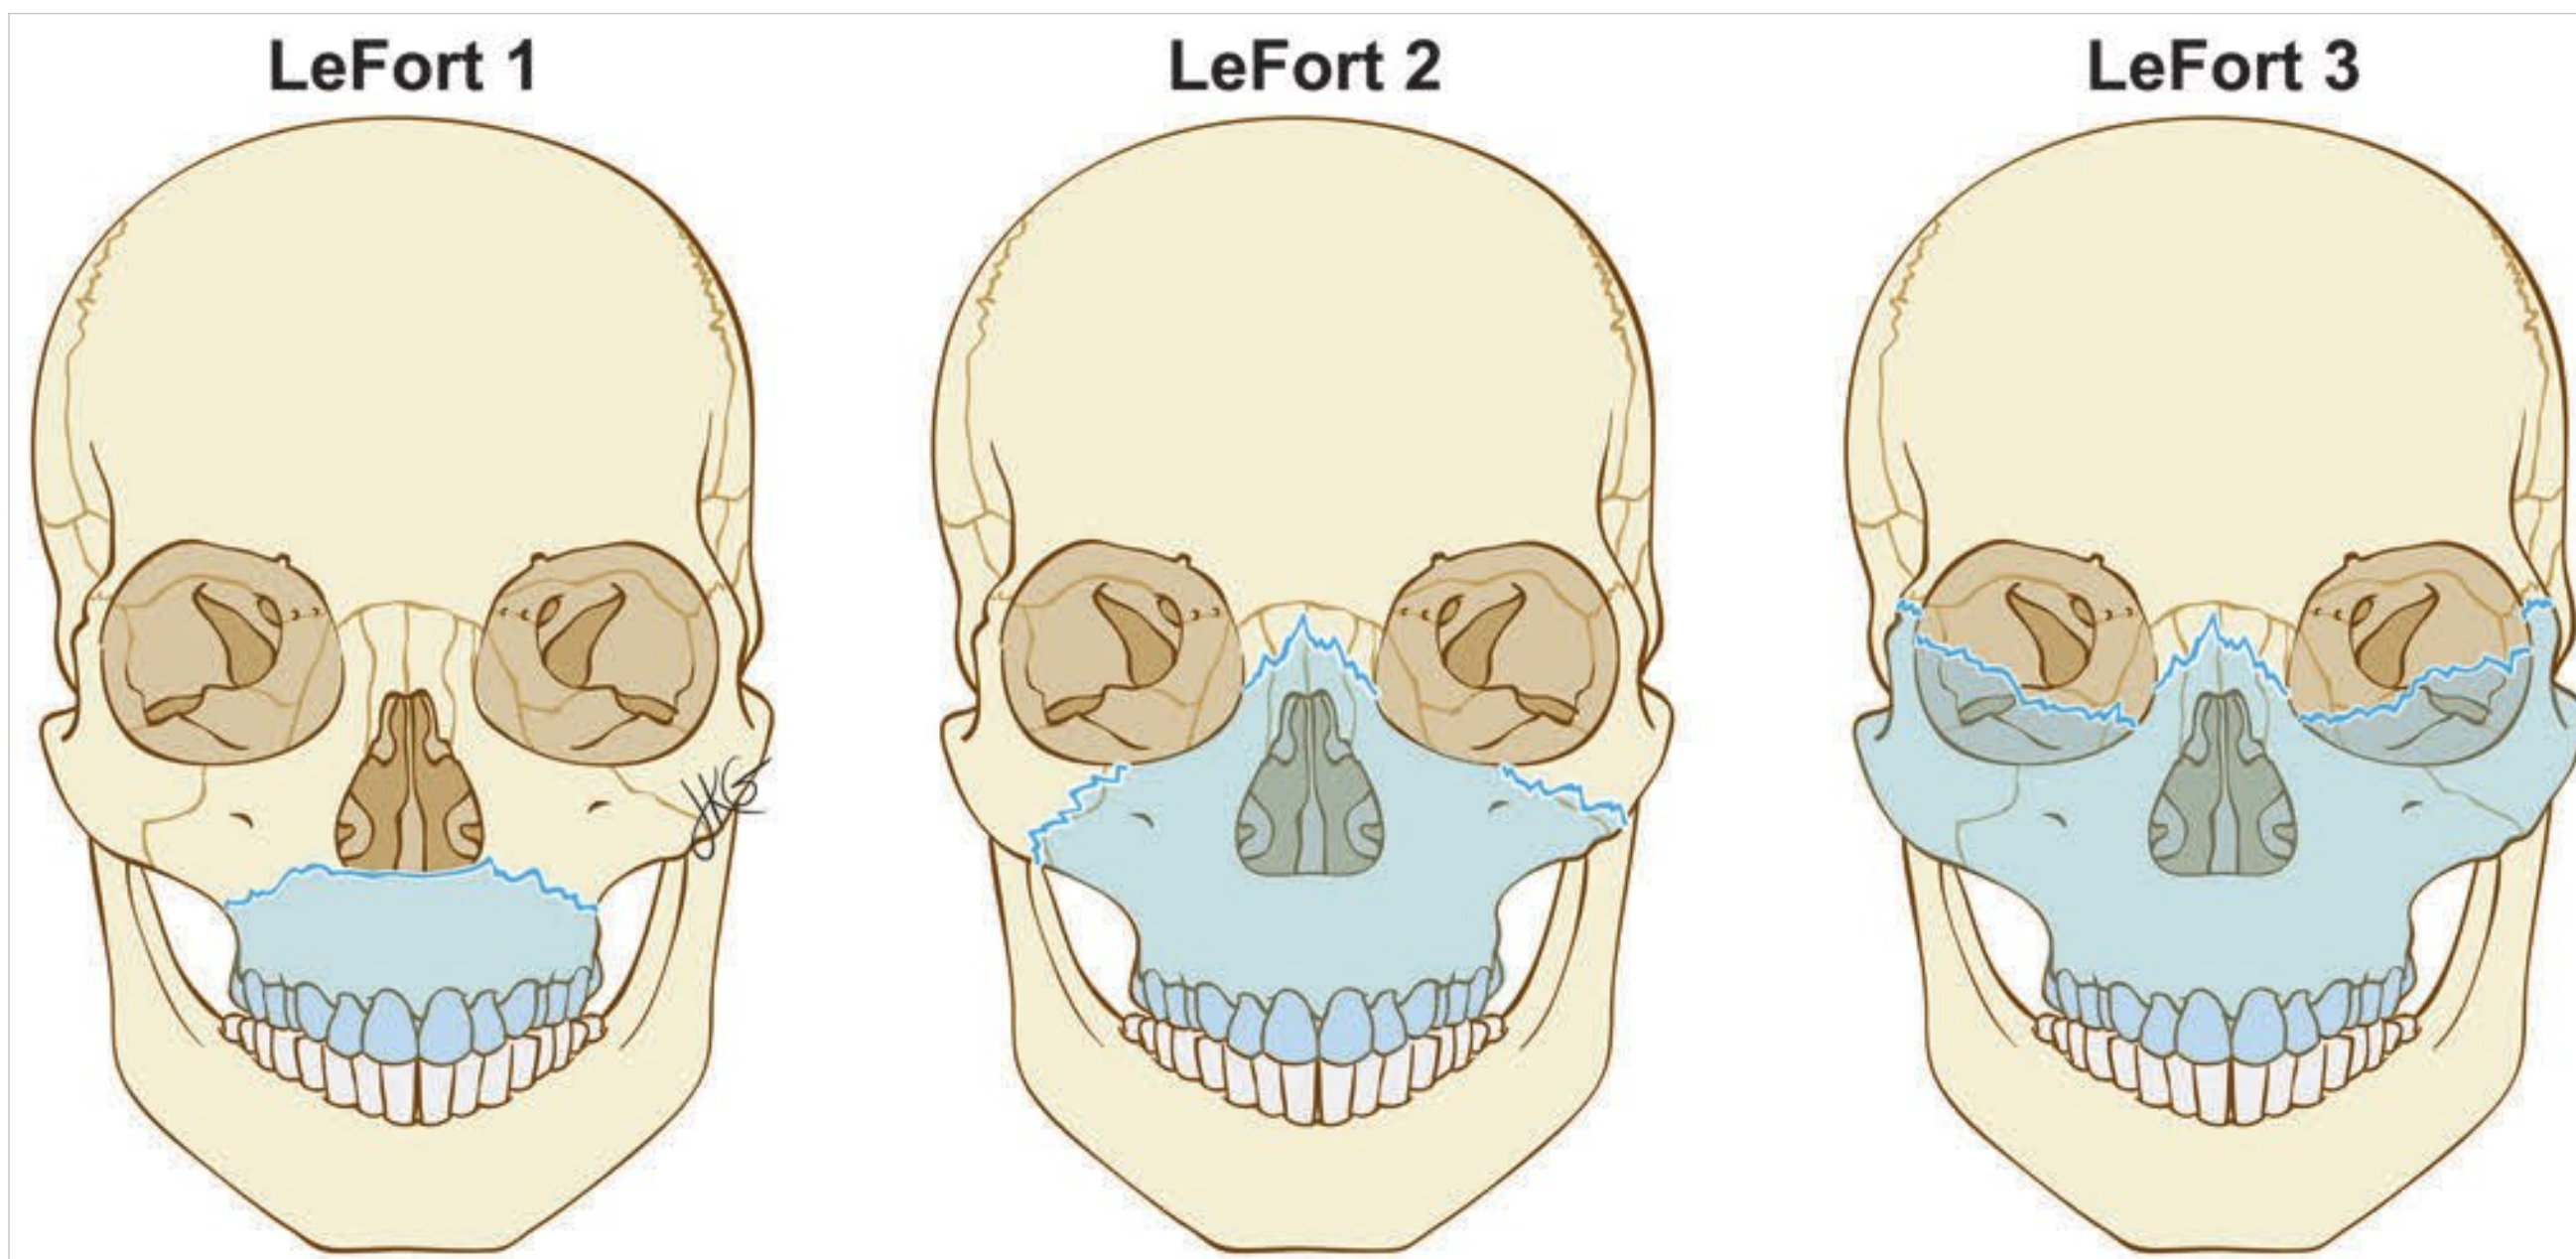

Fig. 42.2 Types of Le Fort fractures. The key distinguishing fractures are at the piriform aperture (Le Fort I), inferior orbital rim (Le Fort II), and zygomatic arch (Le Fort III).

NOE fractures may be type I, II, or III depending on the degree of disruption of the medial canthal region (see Box Naso-orbito-ethmoid (NOE) Fractures (p.334)).

Maxillary fractures (□ Fig. 42.1), with the exception of alveolar and palate fractures, are commonly described according to the classification of René Le Fort published in 1901 (□ Fig. 42.2; see also Box Maxillary Fractures (p.335)):

All three types of Le Fort fractures include fractures through the pterygoid plates.

Naso-orbito-ethmoid (NOE) Fractures

- Type I: minimal displacement of the whole NOE complex
- Type II: more comminution of the NOE complex with preservation of the medial canthal ligamentous attachment to a larger bony fragment, which can be plated
- Type III: severely comminuted fracture with disruption of the medial canthal tendon

Fig. 42.3 Panorex film of the mandible showing bilateral mandible fractures: right body fracture and left ramus fracture (arrows).

Maxillary Fractures

- Le Fort I: fractures through the inferior portions of the medial and lateral maxillary buttresses and nasal septum; key fracture (differentiating this type from other types)—piriform aperture
- Le Fort II: fractures through the zygomaticomaxillary and frontomaxillary sutures; key fracture—inferior orbital rim
- Le Fort III: also known as craniofacial dissociation, involves fractures through the nasofrontal and zygomaticofrontal sutures and zygomatic arch; key fracture—zygomatic arch

Maxillary fractures rarely follow the classic bilateral Le Fort pattern and commonly present as a combination of Le Fort types. For example, one may see a type I pattern on the right side and a type II on the left.

Mandible fractures (□ Fig. 42.3) are classified by the part of the mandible involved and include symphyseal, body, ramus, angle, and subcondylar fractures. Favorable fractures of the mandible are those in which the fracture edges tend to be drawn together by the forces of the masticator muscles; these edges are distracted in unfavorable fractures (□ Fig. 42.4).

42.7 Medical Evaluation

42.7.1 Presenting Complaints

Patients with maxillofacial trauma usually present with swelling, ecchymosis, and pain in the area of injury. Open fractures are usually associated with hemorrhage from the wound. Patients with displaced fractures have associated facial asymmetry and deformity on examination. Frontal sinus and NOE

fractures may present with cerebrospinal fluid (CSF) rhinorrhea, which should be differentiated from normal nasal secretions (see below). NOE fractures commonly present with flattening of the nasal bridge and telecanthus. Rounding of the medial canthus and excessive caruncular show are signs of medial canthal tendon disruption. Epiphora is frequently seen as a consequence of nasolacrimal duct obstruction. Patients with orbital fractures may have diplopia, pain on moving the eye, and/or decreased visual acuity. A swollen and tense globe may be the sign of intraorbital hematoma. Midface numbness is a common symptom and is secondary to infraorbital nerve injury. Displaced zygomatic fractures commonly present with trismus due to entrapment of the masseter and temporalis muscles by a fracture fragment. Flattening of the midface is seen as a result of displacement and rotation of the zygoma. Maxillary and mandibular fractures are usually associated with malocclusion, trismus, and pain on opening the mouth.

42.7.2 Clinical Findings, Physical Examination

Airway Management

Airway compromise in maxillofacial injuries can result from direct laryngeal injury, foreign bodies (including aspirated teeth and bone fragments), or active bleeding from an upper airway source. Treatment of the compromised airway is complicated by the likelihood that about 10% of patients with facial trauma have a cervical spine injury. Comminuted fractures of the mandible can lead to loss of support of the hyomandibular complex, with consequent ptosis and retroposition of the tongue. Manual anterior traction on the mandible symphysis often temporarily

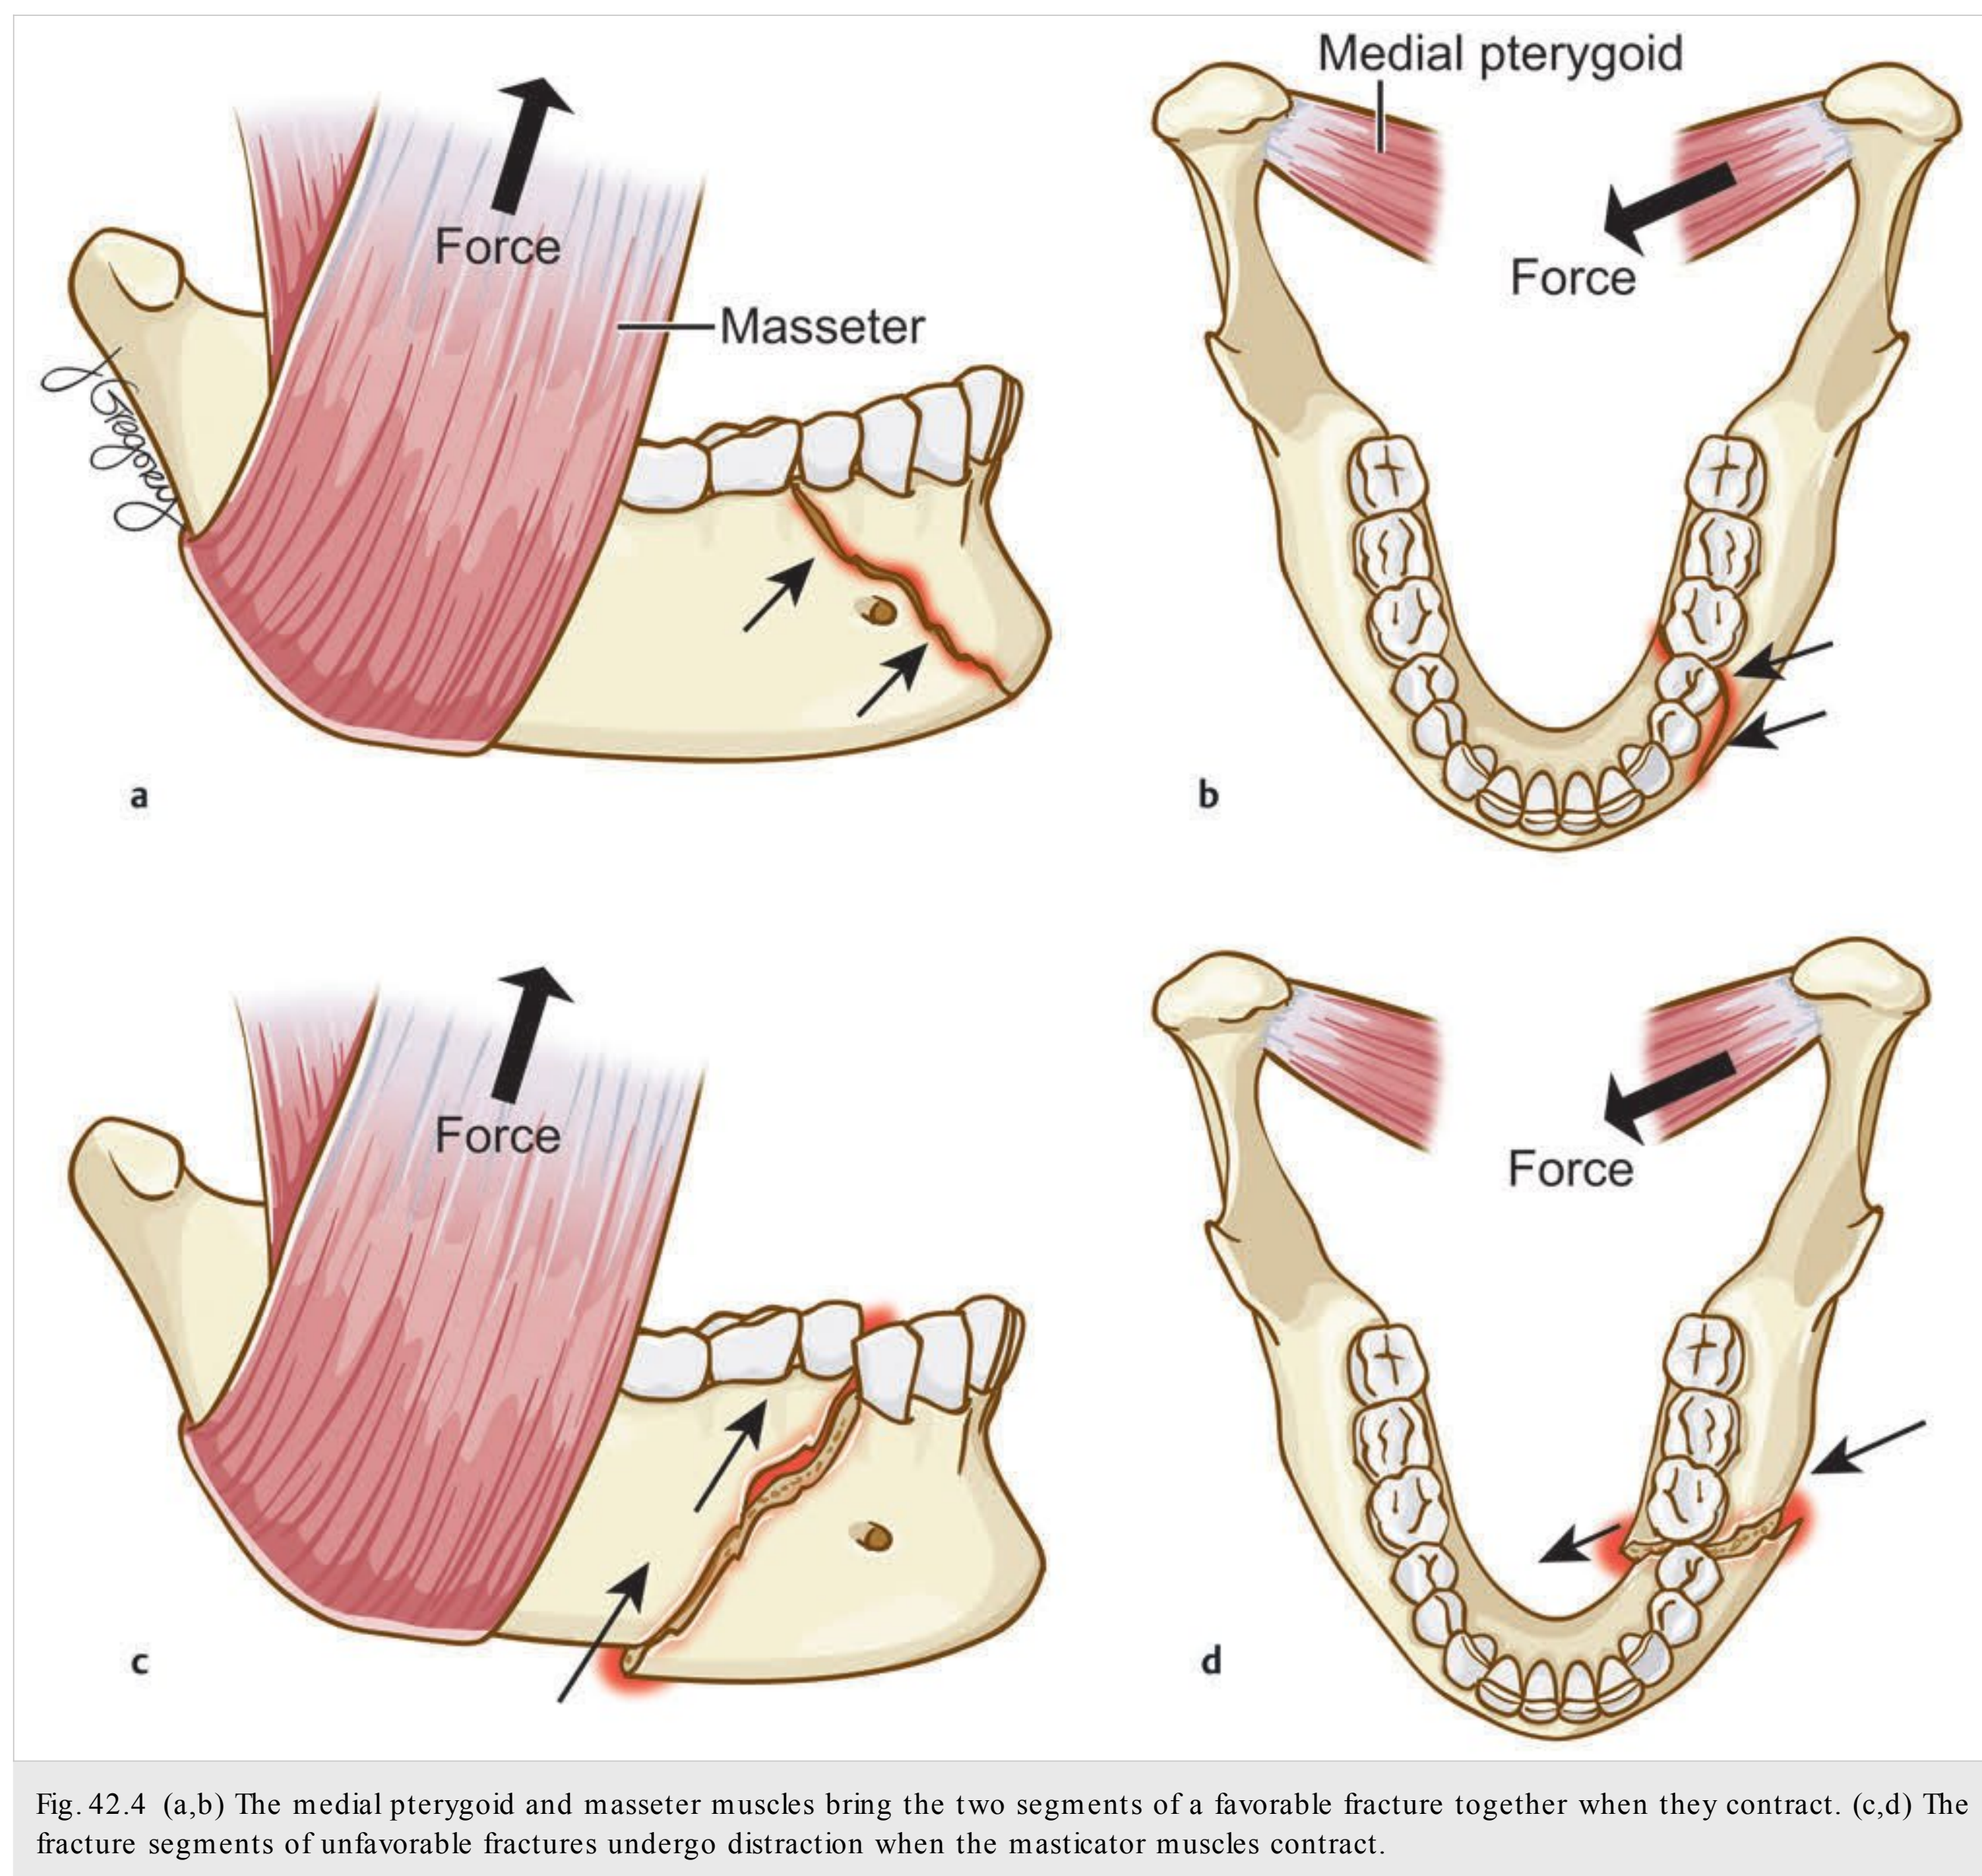

Fig. 42.4 (a,b) The medial pterygoid and masseter muscles bring the two segments of a favorable fracture together when they contract. (c,d) The fracture segments of unfavorable fractures undergo distraction when the masticator muscles contract.

resolves this obstruction until definitive control of the airway can be achieved.

Hemorrhage

The extensive vascularity of the head and neck can result in rapid, significant blood loss. The location of the injuries, however, allows sufficient access for direct pressure to control the hemorrhage. One must visualize the source of bleeding before suture ligation or cautery to avoid collateral damage to important adjacent structures.

Ocular Injury

Direct injury to the globe should be suspected in all patients with orbital fractures or lacerations to the periorbital region. Pain, decreased vision, and the appearance of spots before the

eyes are all highly suggestive of globe damage. During the neurologic phase of the trauma assessment, a brief clinical ophthalmologic examination should be performed, including an assessment of visual acuity, pupillary response to light and accommodation, extraocular range of motion, and globe position. If there are any abnormal findings on the examination, an immediate ophthalmologic consult should be obtained for examination of the retina and ocular pressures. Injuries that may require immediate ophthalmologic treatment or result in permanent sequelae include corneoscleral lacerations, lens dislocation, major hyphema, acute glaucoma, and retinal detachment. Blindness at the time of presentation is rare but is an extremely poor prognostic factor for future sight. Patients who have light perception at the time of presentation but who then demonstrate progressive loss of vision during the trauma assessment must be treated aggressively. The most common cause of this presentation is traumatic optic neuropathy secondary to optic

nerve compression from a retrobulbar hematoma, a bone fragment, or edema.

Disruption of the medial canthal ligament in type III NOE fractures leads to telecanthus (increase in interpalpebral distance). One may also see rounding of the medial canthus secondary to loss of support, or epiphora due to disruption of the nasolacrimal duct. A significant increase in the orbital volume due to a blowout orbital fracture may lead to the development of enophthalmos. Diplopia may be present as a consequence of the entrapment of extraocular muscles.

Cerebrospinal Fluid Leak

An active search for CSF leaks in patients with craniofacial or high maxillary fractures should be undertaken. Clear or serosanguineous nasal discharge, anosmia, or a salty taste in the mouth are highly suggestive of CSF rhinorrhea. A CSF leak into the nasal cavity implies abnormal communication between the subarachnoid space and the external environment. The thin bone in the anterior skull base and the close adherence of the dura to the anterior fossa and cribriform plate predispose to the penetration of fracture fragments into the subarachnoid space. Common associated fracture patterns include Le Fort II and III midface fractures, NOE fractures, orbital roof fractures, and displaced fractures of the posterior table of the frontal sinus. CSF is differentiated from normal nasal secretions on laboratory examination by its low protein concentration and by the presence of glucose (nearing plasma levels) but no mucin. The gold standard test for CSF is measurement of the β_2 -transferrin levels, but it is more time-consuming than measurement of the glucose levels. Most traumatic CSF fistulas close spontaneously with bed rest. Fistulas that do not close spontaneously can be visualized on CT with metrizamide contrast, followed by surgical exploration and obliteration of the fistula.

Occlusion

Occlusion is contact of the posterior masticating (chewing) and anterior incising (cutting) surfaces of the maxillary and mandibular teeth. Malocclusion is an indicator of orthognathic fracture or dental injury. Angle's classification of occlusion refers to

the relation of the first maxillary and first mandibular molars (□ Fig. 42.5). In normal (class I) occlusion, the mesiobuccal (front lateral) cusp of the maxillary molar interdigitates with the mesiobuccal groove of the mandibular molar. In class II occlusion, the mandibular molar is shifted distally (posteriorly), and in class III occlusion, the mandibular molar is shifted mesially (anteriorly). Typical malocclusion patterns seen following fractures include an anterior open bite (gap between the upper and lower front teeth), which indicates that the fractured maxilla is impacted upward or that both condyles of the mandible have collapsed; a posterior open bite (gap between the upper and lower back teeth), often associated with a unilateral condylar fracture; or a posterior cross bite (back teeth lateral or medial to the normal arch form), which indicates either a mandible fracture or a comminuted fracture of the maxilla and palate. These malocclusive patterns indicate that surgical intervention is required.

Facial nerve injuries may result from penetrating trauma in the area of the main trunk or distal branches of the nerve, or from fracture of the temporal bone involving the intraosseous facial nerve canal. Parotid duct injury may result from penetrating facial trauma in the region of the superior aspect of the masseter muscle. This usually manifests as the absence of salivary flow or the presence of sanguineous secretions from the parotid duct on the involved side.

42.8 Testing

Laboratory testing in maxillofacial trauma should include a complete blood cell count to evaluate for possible blood loss, SMA (sequential multiple analysis) 12 to monitor for possible electrolyte imbalance and acidosis, and type and crossmatch in cases associated with significant blood loss.

Cervical spinal injury should be ruled out before any manipulation of the neck. Axial and coronal computed tomography (CT) is the gold standard in evaluating the majority of facial fractures. Three-dimensional CT reconstruction comes in very handy when complex panfacial fractures are being evaluated. Simple X-rays are still used in screening for facial fractures, but CT provides more detail. Panoramic dental X-rays (panorex) are a very useful adjunct for evaluating the fracture pattern and

Fig. 42.5 In the Angle classification, normal occlusion (the mesiobuccal cusp of the first maxillary molar articulates with the mesiobuccal groove of the first mandibular molar) is class I. In class II occlusion, the cusp is positioned mesial to the groove by at least the width of a premolar. In class III occlusion, the cusp is shifted distally.

dentition status in patients with mandible fractures. Cervical spine series are required in patients with suspected cervical spine injuries or high-velocity trauma, or in unconscious patients. When vascular injury is suspected, CT angiography or standard angiography is indicated.

In all patients with maxillofacial fractures (other than isolated mandible fractures), an ophthalmologic examination is indicated to rule out orbital injury and retinal detachment, and to document visual acuity.

The traction test is used in patients with NOE fractures to evaluate for the integrity of the medial canthal tendon. The test involves grasping the edge of the lower eyelid and pulling it against its medial attachment. If an obvious “give” of the tendon occurs, a disruption of the medial canthus is likely.

The “tongue blade” test is used in patients with suspected mandible fracture. The patient is asked to bite down hard on a tongue blade. If the jaw is fractured, the patient cannot do this effectively and will experience pain.

42.9 Differential Diagnosis

Different fracture patterns may present with similar findings on physical examination. Therefore, it is very important to establish the correct diagnosis because the treatments may differ significantly. For example, both severe nasal bone fracture and NOE fracture may present with saddling of the nasal dorsum; however, in the case of NOE fracture, this finding may coexist with disruption of the medial canthus, which needs to be addressed to prevent telecanthus and/or a CSF leak. Open-bite deformity may result from both bilateral subcondylar fractures and palatine fracture, but the treatments obviously differ. Mandibular parasymphyseal fractures, routinely treated by rigid fixation alone, are frequently associated with contralateral subcondylar fracture, which requires additional closed or open reduction.

42.10 Treatment

42.10.1 Medical Treatment

The ABCDE (airway, breathing, circulation, disability, exposure) universal trauma protocol should be applied to all patients with maxillofacial trauma. For definitive control of the airway, an artificial oral or nasal airway is often possible, but blind nasal intubation should be carried out with caution. Nasal intubations can exacerbate bleeding from the nasal and nasopharyngeal regions, and the tube may be inadvertently placed into the cranial fossa in the obtunded patient with a comminuted skull base fracture. As for all patients with facial trauma, an airway should be secured early in the trauma assessment for those with significant maxillofacial injury. The secondary swelling that occurs over the first few hours following the trauma can impede, or in some cases prevent, oral intubation. Emergent tracheotomy is rarely indicated except in the unusual circumstance of laryngeal fracture or the inability to intubate orally because of massive bleeding or swelling. Semi-elective tracheostomy in the operating room is reserved for those patients requiring prolonged intubation because of massive soft-tissue and bony injuries or impaired consciousness.

Trauma patients are given intravenous fluids for volume replacement and packed red blood cells in cases of extensive blood loss. Intravenous antibiotics are given to prevent infection, especially in patients with significant soft-tissue trauma and open fractures. Tetanus prophylaxis is also indicated. Pain is usually controlled with intravenous or oral pain medications, depending on the patient’s status.

The management of progressive vision loss remains controversial because it is unclear which patients benefit from emergent orbital decompression. If the eyeball is tense, then immediate lateral canthotomy and cantholysis is indicated to release the confining force of the lids. If a clear source of compression is visualized on CT, immediate operative decompression is indicated. All other patients are treated immediately with high-dose steroids; surgery is reserved for those with progression of vision loss.

42.10.2 Surgical Treatment

The facial stigmata of unreduced or poorly reduced fractures are fortunately rarely seen, but when present, they may be severe. Minor cosmetic changes after facial injuries are common; however, in modern society, “good” results are often not enough, and perfection is demanded. The common causes of poor outcomes include bad choice of surgical access, inability to operate early or operating too early, and poor reduction of fracture fragments.

The majority of facial fractures in adults with any significant displacement will require open reduction and internal fixation. Some fractures, such as nasal bone fractures and some mandibular fractures, may be treated with closed reduction techniques.

Frontal Sinus Fractures

Nondisplaced fractures of the anterior and posterior tables of the frontal sinus may be managed by observation. Displaced anterior table fractures (by more than the width of the anterior table) lead to noticeable cosmetic forehead deformity if left untreated and therefore need to be reduced. Displaced posterior table fractures frequently lead to complications such as CSF leak and intracranial hemorrhage. These fractures are managed either by open reduction and frontal sinus obliteration with abdominal fat, or by removal of the posterior table (which allows the brain to expand into the frontal sinus in a process known as cranialization) in cases of severe comminution. Frontal sinus fractures involving the nasofrontal duct are highly likely to be associated with duct stenosis and mucocele formation, so that sinus obliteration is commonly required. Common surgical approaches include the use of existing lacerations for small, isolated anterior table fractures, but generally, bicoronal or hemicoronal incisions are used.

Zygomatico-Orbital Fractures

The standard treatment of displaced zygomatico-orbital fractures is open reduction and internal fixation (□ Fig. 42.6). Ideally, three-point fixation is required to guarantee stability and proper reduction. Common plating areas include the following: the zygomaticofrontal suture line (accessed via an upper or lower blepharoplasty incision or via a hemicoronal

Fig. 42.6 Axial computed tomographic scan showing right zygomaticomaxillary complex fractures involving the anterior maxillary wall (long arrow), posterior–lateral wall of the maxillary sinus (medium arrow), and zygomatic arch (short arrow).

incision, if one is needed for other purposes); the infraorbital rim (approached via a transconjunctival or lower blepharoplasty incision); and the zygomaticomaxillary buttress (accessible via a transoral approach and a gingivobuccal incision).

Single, isolated zygomatic arch fractures are reduced via a Gillies approach, dissecting down from a temporal fossa incision in the plane below the temporalis fascia to place the elevator deep to the arch fracture. This approach is, by definition, an open reduction of the zygomatic arch fracture without internal fixation. Comminuted fractures require open reduction and internal fixation; exposure of the zygomatic arch is gained via a hemiconal incision, and dissection is in a plane deep to the temporoparietal fascia.

Indications for the repair of isolated orbital floor fractures include large fractures (>50% of the floor), posttraumatic enophthalmos, and diplopia due to muscular entrapment. The orbital contents that have herniated into the maxillary sinus are reduced into the orbit and supported by either a bone graft, cartilage graft, or alloplastic material. A transconjunctival approach is used.

Naso-Orbito-Ethmoid Fractures

Displaced NOE fractures require open reduction and internal fixation. A disrupted medial canthal tendon, as in type III NOE fractures, is repaired by suturing the tendon to a miniplate or wiring to the opposite nasal bone. Saddle nasal deformity is corrected with the use of an onlay graft (bone, cartilage, or alloplastic graft). Existing lacerations and bicoronal incisions are the most common approaches used in obtaining the access to the region.

Maxillary (Le Fort) Fractures

Proper occlusion must first be established by placing the patient into maxillary–mandibular fixation (MMF). The fractures are then sequentially reduced and fixed with the plates either starting at the most inferior fractures and going superiorly, or

vice versa. Common approaches include gingivobuccal incisions and midfacial degloving, which allows simultaneous bilateral exposure.

Mandible Fractures

The appropriate treatment of a mandibular fracture requires establishing proper occlusion with MMF. Nondisplaced or favorable fractures may be treated with MMF alone for 4 weeks or with rigid fixation. Displaced or unfavorable fractures are treated with open reduction and rigid fixation. Either miniplates or mandibular or reconstruction plates are used. Alternatively, a lag screw can be used to reconstruct the bony segments. Lag screw fixation (□ Fig. 42.7) requires overdrilling the holes in the proximal bone, allowing the standard screw to glide through this segment of bone. When the threads of the screw engage the distal bone segment, this bone is drawn tightly against the proximal bone.

Ideally, a single plate is placed along the Champy line of ideal osteosynthesis (□ Fig. 42.8), where the compressive forces along the lower mandible equal the distractive (tension) forces (□ Fig. 42.9) along the dental border; however, in most locations along the mandible, this line lies along the course of the inferior alveolar nerve. An alternative treatment is to place a miniplate along the lower mandibular border and to use arch bars on the lower teeth to provide tension and maximally stabilize the bone segments.

Subcondylar fractures have commonly been treated with closed reduction (MMF); however, there has been a shift in paradigm in recent years toward the use of rigid fixation via an open or endoscopic approach. The surgical approach to the mandible fractures is generally intraoral via a gingivobuccal incision, but external (submental, submandibular, or preauricular) approaches are viable alternatives in certain cases. Generally, unstable or devitalized teeth along a fracture line are removed, but otherwise teeth, even if loose, are left in place to assist in alignment.

Fig. 42.7 In lag screw fixation, the distal end of the screw is used to engage and pull the distal bone segment into the proximal segment.

Fig. 42.8 (a,b) Ideal lines of osteosynthesis.

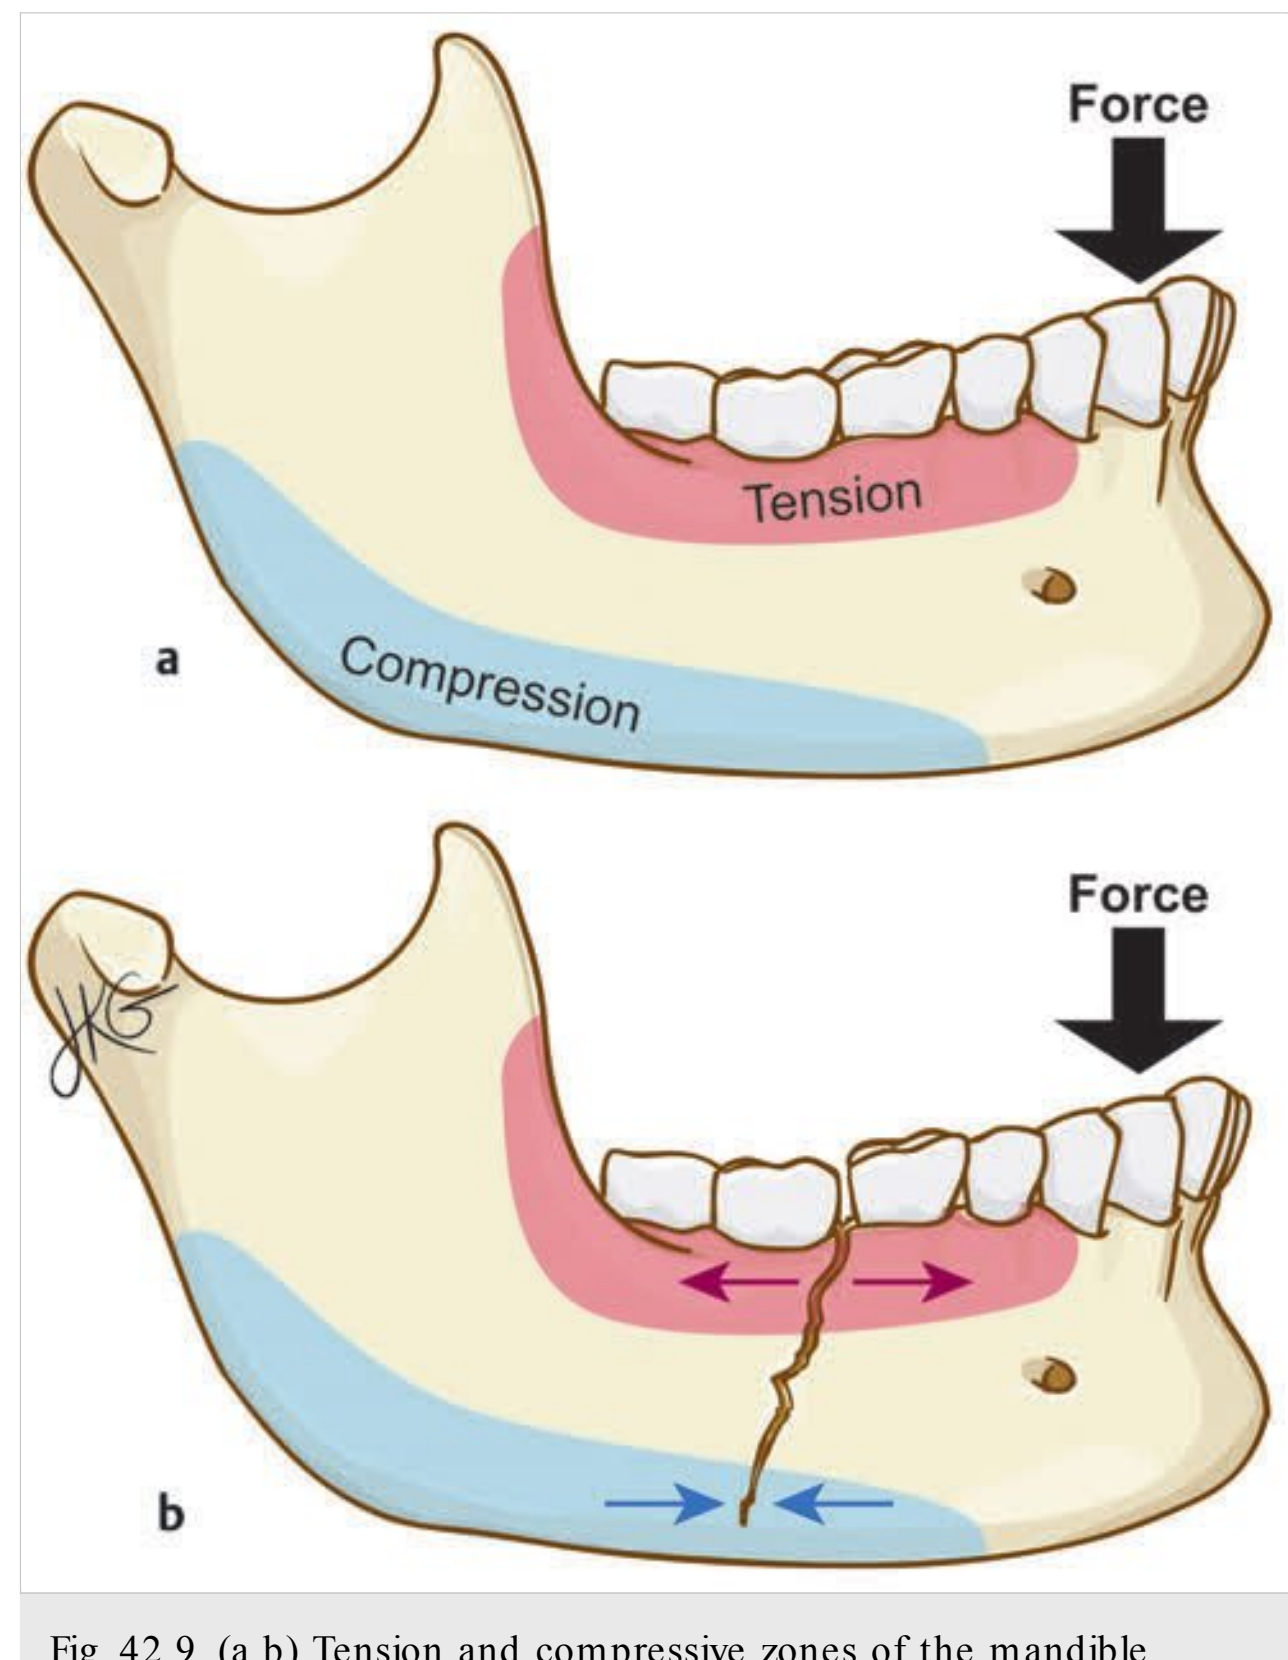

Fig. 42.9 (a,b) Tension and compressive zones of the mandible.

42.11 Complications

Potential complications of open reduction and rigid fixation of the facial fractures include poor reduction of the fracture segments leading to persistent deformity. Malunion or nonunion of the fracture due to improper alignment, infection, or insufficient immobilization commonly requires revision surgery. Iatrogenic injury to adjacent neural structures, such as facial

nerve and the branches of the trigeminal nerve (inferior alveolar, infraorbital, mental, others), may lead to temporary and occasionally permanent motor or sensory deficit. Improperly reduced or missed mandibular fractures can lead to malocclusion. Injuries to the teeth due to the improper application of plating hardware have been described. Because the hardware used for rigid fixation is a foreign body, there is always a risk for infection (especially around carious or devitalized teeth).

Injury to orbital structures during the manipulation of fracture fragments and during the surgical approach to the fracture may result in diplopia, vision loss, and blindness.

42.12 Roundsmanship

- Maxillofacial trauma is frequently associated with life-threatening injuries, and patients should be assessed for concomitant airway, central nervous system, and orthopedic injuries.
- Initial management of maxillofacial trauma follows ATLS principles and involves airway management, control of hemorrhage, and rapid identification of injuries with significant morbidity, ocular injury, CSF leakage, neurologic damage, and malocclusion.
- A structured history, physical examination, CT-guided diagnosis, and reconstruction of the major facial buttresses with open reduction and internal fixation performed in a timely fashion are crucial for optimal functional and aesthetic outcome.
- Potential complications of open reduction and internal fixation include malunion or nonunion, poor fracture alignment,

hardware infection, osteomyelitis, and injury to the surrounding vital structures.

43 Scar Revision

Joseph J. Rousso and Anthony P. Sclafani

43.1 Introduction

When multiple layers of skin have been affected by an injury and the reticular dermis violated, the resultant healing process includes the inevitable formation of scar tissue. This can be a difficult and emotionally traumatizing process for even the least self-conscious of patients, particularly if the scar involves the face. The scarring process may also result in functional deficits if contracture forms in areas that limit movement of the eyes, mouth, nose, or neck. Scar revision refers to the various methods, both medical and surgical, to alter the appearance and form of the affected tissue. Scar revision can serve both cosmetic and functional purposes, depending on the site of scar formation. The human eyes' perception of scarring is based on anatomical locations and the orientation of the visible tissue. Therefore, a keen understanding of the geometric concepts of relaxed skin tension lines (RSTLs), aesthetic units, tissue healing, and general wound care is necessary to provide the patient with the best possible options for scar revision.

43.2 Incidence of Disease

Although scar revision is not associated with any “disease,” several processes can lead to scar formation. Scar revision is performed in both the ambulatory and inpatient settings and accounts for a large percentage of procedures and treatments performed by various specialty practitioners, including facial plastic surgeons and dermatologists.

43.3 Terminology

A discussion of scar revision requires an understanding of the basic terminology used in describing wounds and an appreciation of the common nomenclature. Relaxed skin tension lines (RSTLs; □ Fig. 43.1) of the face refer to linear arrangements whose organization is based on the level of tension. These borderlines run in linear and curvilinear fashion perpendicular to the facial muscles underlying the subcutaneous tissue. Lines of maximal extensibility (LMEs) are oriented perpendicular to the RSTLs. Aesthetic units (□ Fig. 43.2) and subunits (□ Fig. 43.3) are units of the face contained within anatomical boundary lines. Aesthetic units contain tissue that is similar in color, texture, vascularity, density, and other qualities and may be bounded by skin transitions and folds. Furthermore, the human eye perceives the face in units based upon light reflections and shadows from these aesthetic boundaries.

43.4 Applied Anatomy

The aesthetic units of the face include the forehead, eyes, ears, nose, lips, chin, and neck. The subunits break the face down further into smaller, anatomically bounded areas. Specific areas of focus should be mentioned because of their unique characteristics and the challenges they present in scar revision. The cheek

is a facial subunit spanning an area extending from the malar eminence to the mandible, where a scar can draw much attention. RSTLs of the cheek are curvilinear—more horizontal medially and close to the lower eyelid, more oblique and vertical laterally and inferiorly. The forehead is vertically bounded by the trichion (hairline) cephalically and the glabella caudally. The RSTLs of the forehead are particularly prominent and run horizontally in most areas but obliquely in the region of the glabella and the temples. The eyebrows present a challenge because scars that affect hair-bearing areas can be very difficult to camouflage. The nose contains paired lateral nasal sidewall, lateral and medial alar, and soft-tissue facet subunits, and unilateral dorsal, tip, and columellar subunits. The ear's subunits correspond to identifiable anatomical landmarks.

43.5 The Disease Process

43.5.1 Etiology and Pathogenesis

Scar formation can result from any injury or trauma, including previous surgical incision. Inflammation and infection can lead to severe scarring. Acne can create crater-like and pitted marks; ice pick, rolling, and boxcar scars can result from the inflammatory process. Problematic scars are formed secondary to various factors, including configuration of the scar with respect to the location of RSTLs; extensive trauma; underlying medical conditions such as diabetes, smoking, nutritional deficiencies, and poor circulation; age; and sun-damaged skin.

Two specific forms of scarring that deserve particular attention are keloids and hypertrophic scars. The term keloid refers to a dense scarring process at an injured site, which results in a firm collagen mass that overgrows the boundaries of the wound. A hypertrophic scar, as its name would imply, is a form of overly thickened scar tissue, but it does not overgrow the boundaries of the injury site. Keloids are an exceptionally bothersome form of scarring because they do not regress spontaneously and are prone to recurrence after surgical excision. In contrast, a hypertrophic scar may undergo partial regression throughout its maturation course. Although hypertrophic scarring and keloids can occur in any patient population, white patients are less commonly affected than black and Hispanic patients.

43.5.2 Natural History and Progression

Tissue and wound healing is generally divided into three phases. The inflammatory phase occurs with the initial formation of a clot and subsequent inflammation mediated via chemotactic factors. The proliferative phase occurs within 24 to 72 hours and consists of the formation of granulation tissue, collagen production, and re-epithelialization. Finally, the maturation phase of wound healing produces collagen remodeling and wound contraction. Excisional wounds or injuries that create a large tissue defect are more likely to lead to substantial scarring on account of the more intense inflammatory reaction that

Fig. 43.1 Relaxed skin tension lines.

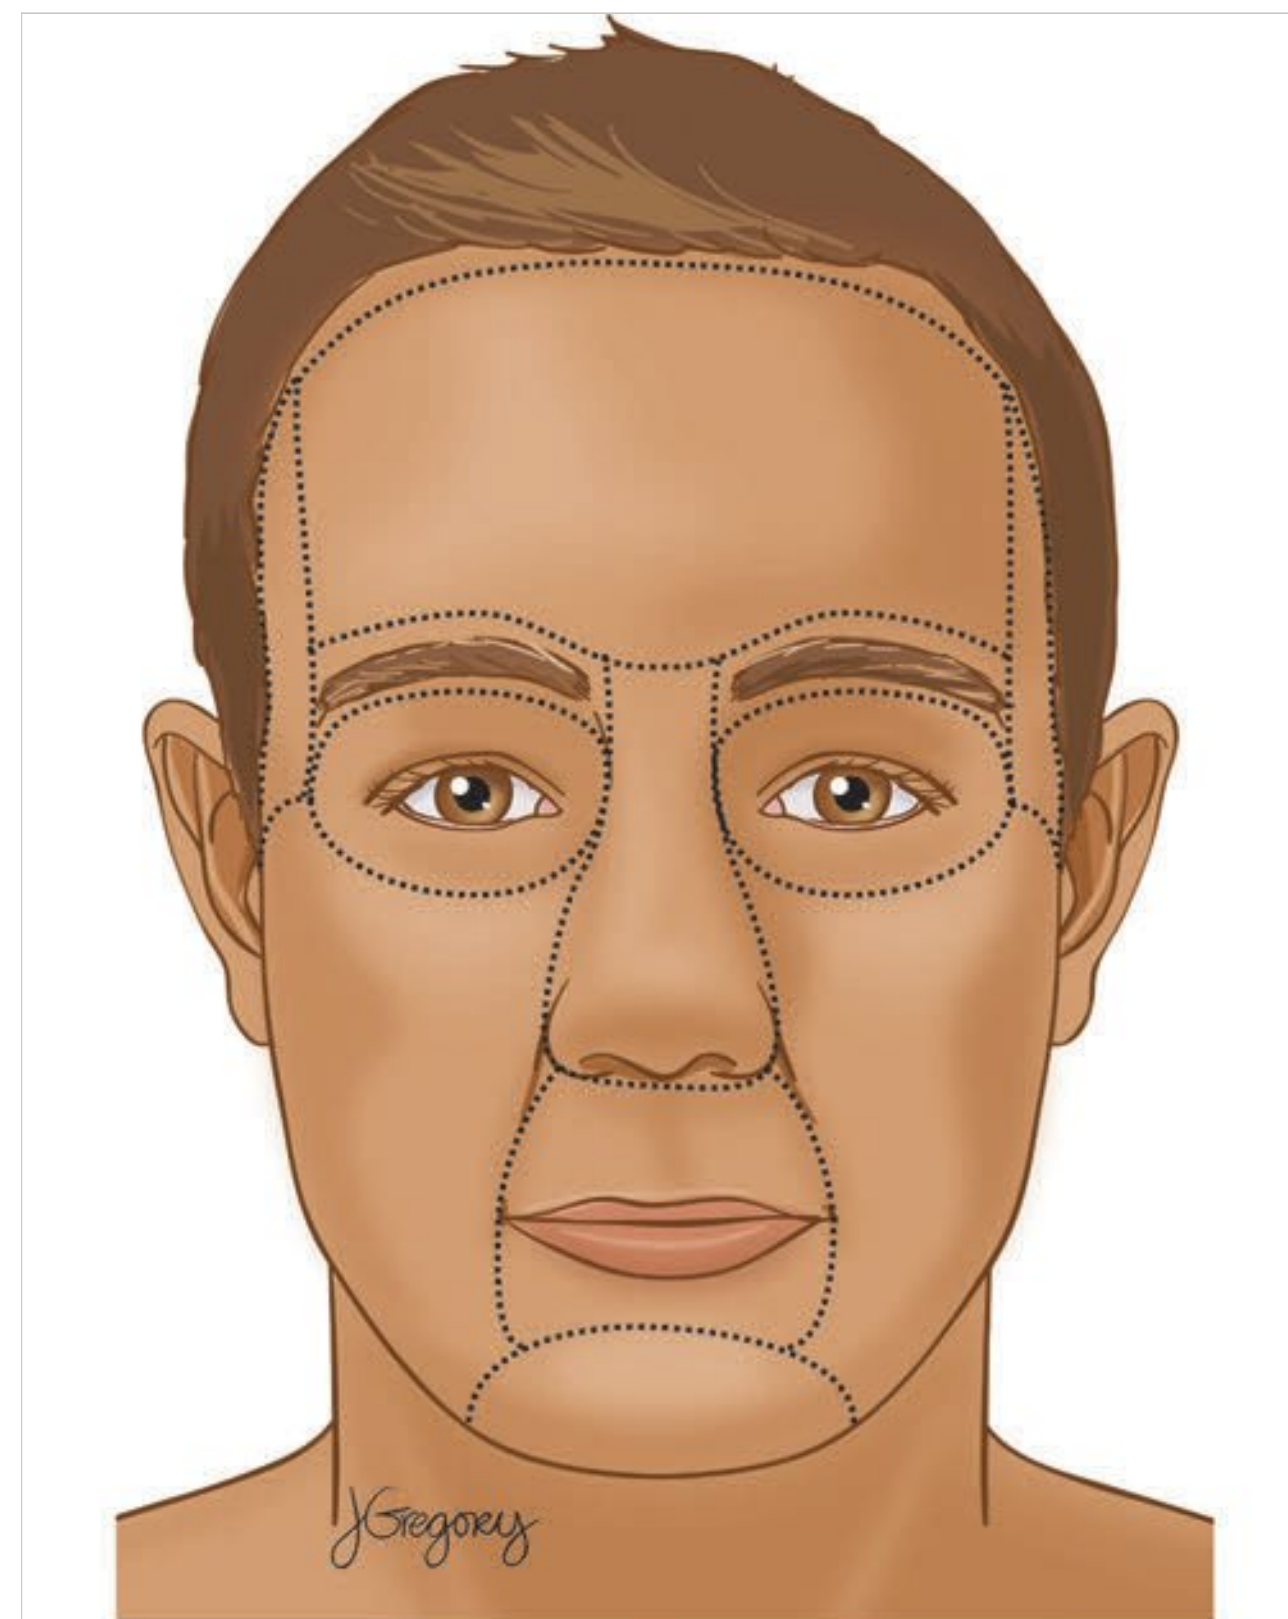

Fig. 43.2 Facial units.

eventually leads to extensive collagen deposition. The single most important factor to delay healing is local infection due to the persistence of inflammation. Narrow and well-positioned scars continue to change and mature over the course of 12 to 36 months, and appearances may improve during this period.

43.5.3 Potential Disease Complications

Wound healing and scar formation can potentially lead to undesirable outcomes such as hypertrophic scars and keloids. Scar contracture may distort local tissues if located close (and especially perpendicular) to mobile structures such as the eyelids or lips. Scar revision procedures themselves can lead to further inflammation and continued collagen deposition. Psychological complications are a well-known morbidity associated with facial scar formation. Depression, unrealistic expectations, posttraumatic stress disorder, and anxiety are all considerations in the patient with facial scars. Accordingly, concomitant consultation with a mental health professional is warranted in patients who show signs of unrealistic expectations or psychological distress.

43.6 Medical Evaluation

43.6.1 Presenting Complaints

The presentation of patients can vary from simple dislike of their appearance to pain, restricted mobility, and decreased range of motion. It is important to emphasize to patients that scar revision can, at best, partially improve a scar's appearance.

Patients must have realistic expectations and should be informed that the scar will not be invisible but will be modified and camouflaged to appear less noticeable and bothersome.

43.6.2 Physical Examination

The physical examination is the most critical tool in the physician's arsenal for scar revision. The physician should present a detailed description of the affected area to the patient in terms that the patient can comprehend. This allows the physician and patient to have a common understanding of the most bothersome characteristics of the scar. As part of a detailed physical examination, photographs of the affected area should be taken in an area with appropriate lighting and a nonreflective background. These photos can be compared with photos taken after treatment to quantify changes in appearance. Specific features that should be described in the physical examination include size, shape, elevation, color, hair-bearing areas, consistency, geometric configuration, orientation to the RSTLs, and aesthetic unit(s) through which the scar runs.

43.6.3 Laboratory Studies and Imaging

Laboratory studies and imaging studies are dictated by the underlying cause of scarring or comorbid conditions.

43.6.4 Differential Diagnosis

Scarring can be diagnosed by physical examination alone; however, other pathologic entities can present similarly to scar tissue and include dermatofibromas, dermatofibrosarcomas, desmoid tumors, infection, granulomas, and foreign body reactions.

43.7 Medical Treatment

43.7.1 Cosmetology

Scar camouflage can be largely achieved with alterations in makeup and hairstyling. The assistance of a licensed cosmetologist is invaluable because this person can play a pivotal role in masking the appearance of a scar and accentuating other appealing features that may redirect visual focus away from the scar. Cosmetics can be particularly helpful in camouflaging dyspigmented scars or persistent erythema.

43.7.2 Intralesional Steroid Injections

Intralesional injections of corticosteroids are commonly used for keloids and other unfavorable scars. The injection should be placed within the substance of the scar or keloid and should avoid the unaffected dermis. Although noninvasive, intralesional injections generally must be repeated several times at intervals of 3 to 6 weeks before any benefit is appreciable. Side effects may include localized skin hypopigmentation and dermal or fat atrophy at the injection site.

43.7.3 Silicone Gel Sheeting

The topical placement of silicone gel sheets over sites of keloid formation and hypertrophic scars has shown significant benefit.

Although the mechanism is unknown (possibly related to scar hydration or direct interaction with silicone), patients are instructed to wear the silicone sheets for at least 8 hours per day for 6 to 12 months. Silicone gel sheeting is often attempted before surgical scar revision because the associated morbidity is minimal.

43.8 Surgical Treatment

43.8.1 Scar Excision with Primary Wound Closure

A scar that is appropriately oriented (within 30 degrees of RSTLs) and has formed secondary to improper wound closure may be treated by surgically with excision of the scar tissue and appropriate primary wound closure. The excision should remove all scar tissue and create fresh wound edges. The scar is removed by elliptical excision; if the central portion of the scar is depressed, the deep scar tissue is left in place to form a base for wound closure above it. Closure should be performed in layers, with absorbable sutures placed at a dermal level and minimally reactive, monofilament sutures placed at the external epidermal level. Closure should follow the tenets of Halsted: avoidance of tension, obliteration of dead space in the wound, and the use of fine, nonirritating sutures. In addition, wide undermining of adjacent tissue will assist in creating everted wound edges with minimal tension.

43.8.2 Serial Partial Excision and Tissue Expansion

In the case of extremely wide scars, closure after excision of the entire scar may either be impossible or require unacceptable wound closure tension. In this case, serial partial excision can be used. In this method, a portion of the scar is resected, with the incision placed along the edge or within the substance of the scar. The surrounding tissue is undermined and the wound is closed, effectively narrowing the scar. After wound healing and skin stretch by the process of biologic creep have been allowed to take place over a period of a few months, the remaining scar can be fully excised and the wound closed primarily. Alternatively, tissue expanders (see Chapter 50 for a discussion of tissue expansion) can be placed adjacent to the scar and the skin actively expanded over several weeks. The expanders can then be removed and the expanded skin used to fill the defect caused by removal of the scar tissue.

43.8.3 Irregularization Techniques

Scar revision is rooted in the principle of camouflaging visible scars so that they are less apparent to the human eye. Those scars that are most noticeable are linear and run perpendicular to RSTLs. Irregularization techniques achieve a more desirable appearance by breaking linear scars into zigzag lines adjusted to fall within the RSTLs and aesthetic subunits. The three most commonly used irregularization techniques are Z-plasty, W-plasty, and geometric broken line closure (GBLC).

Fig. 43.4 (a) Z-plasty. (b) Solid lines, incision lines; (c) stippled lines, relaxed skin tension lines.

Z-plasty

Z-plasty creates a change in the direction and an increase in the length of the scar. The idea of the Z-plasty is to allow the new scar to fall closer to or exactly in the direction of the RSTL, as well as to break the forces of scar contracture. The scar is made longer, and the resultant tension is transposed and more widely distributed through the wound.

Z-plasty is performed by transposing triangles (□ Fig. 43.4), in which the scar tissue lies in the central limb. The amount of scar lengthening that will be produced by this irregularization technique can be predicted based on the angles of the transposed triangle. As a rule of thumb, 30-degree Z-plasty angles will increase the length of a scar by 25%, 45-degree angles will lengthen the scar by 50% and 60-degree angles will lengthen it by 75% (□ Table 43.1). Multiple Z-plasties can be performed if necessary. Z-plasty is most useful for dealing with scars that cross RSTLs or distinct anatomical landmarks, or that create bands across concavities. Lengthening of the scar can improve function by releasing contracture.

W-plasty

W-plasty is an irregularization technique that is most useful around convex areas, including the nasal dorsum, border of the mandible, and dorsum of the nose. Unlike the aforementioned Z-plasty, W-plasty does not lengthen the scar. This technique essentially consists of regular, W-shaped complementary skin excisions on both sides of the existing scar (□ Fig. 43.5). The scar tissue is excised and the surrounding tissue undermined. The triangular flaps are then interdigitated and the wound closed.

Geometric Broken Line Closure

GBLC is a powerful tool to reduce the visibility of long, unbroken facial scars, particularly those on convex areas. GBLC works well in areas that are large and flat, such as the forehead and cheek. Like W-plasty, GBLC does not increase the scar length; rather, it improves the scar appearance by creating an irregular scar pattern. GBLC is performed (□ Fig. 43.6) by creating a series of irregular, small shapes that have equivalent counterparts on the opposite side of the scar edge. As with W-plasty, each limb of the GBLC should measure between 4 and 6 mm. The scar is

Table 43.1 Amount of lengthening of the central scar when Z-plasty is use for scar revision

Angles formed by central limb (scar axis) and lateral arms of Z-plasty	Percentage of lengthening of central limb
30 degrees	25%
45 degrees	50%
60 degrees	75%

Fig. 43.5 (a,b) W-plasty.

excised, the surrounding tissue is undermined, and the geometric shapes are interdigitated. W-plasty and GBLC generally benefit from postoperative dermabrasion.

43.8.4 Dermabrasion/Laser Scar Resurfacing

Dermabrasion is not routinely used as a free-standing method for scar revision in the head and neck. However, it can be very

Fig. 43.6 (a,b) Geometric broken line closure.

useful as a complementary procedure to aid in wound healing after a scar revision procedure. Dermabrasion consists of removal of the superficial components of skin, allowing the stimulation of basal cells to achieve final wound closure. A rapidly rotating dermabrader (with a diamond-coated or wire brush wheel) is used to remove epidermal and superficial dermal layers, with injury to the underlying adnexal structures, which contribute to the regeneration of new epidermis, avoided. Passes are made at 45-degree angles to one another to avoid creating ridges, and the edges of the abraded areas should be feathered. Laser abrasion is performed similarly with carbon dioxide or Er:YAG (erbium-doped yttrium aluminum garnet) lasers (ablative or fractional); similar skin layers are removed, depending upon energy parameters and the number of laser passes. After skin abrasion, the wounds should be kept moist with hypoallergenic petroleum-based ointments (e.g., Vaseline; Unilever US, Englewood Cliffs, NJ; Aquaphor (Eucerin); Beiersdorf AG, Hamburg, Germany) until re-epithelialization is complete. Sun precaution is necessary until the erythema has faded, generally 6 to 12 weeks after treatment.

43.8.5 Laser Treatment of Telangiectasia/Scar Erythema

Telangiectasia around or on a scar will make the scar more noticeable as the observer's attention is drawn to the area of color difference. Even thin, flat, and well-healed scars will be visible if they are erythematous or surrounded by telangiectasia. Laser light at or near the wavelengths for peak hemoglobin absorption, such as 585 or 1,064 nm, can selectively cause blood vessels to constrict as the waves pass through the more superficial tissues without causing damage and are selectively absorbed by the hemoglobin in red blood cells. This absorbed energy is then converted to heat, lysing the red blood cells and initiating an in-

flammatory response in the vessel walls, eventually causing vessel constriction. This process, selective photothermolysis, reduces the red hues visible in the skin and helps fade the appearance of the scar.

43.9 Prognosis

Recovery after scar revision procedures is a multifactorial phenomenon. In addition to ensuring that patients have realistic expectations, it is imperative that the physician convey to them that the final appearance of the revised scar may not be appreciated until almost a year after the procedure is performed. Healing is a continuous process that is altered by factors such as smoking, diet, infection, and general overall health. In order to ensure the best outcomes after a scar revision procedure, meticulous wound care and frequent follow-up should be performed.

43.10 Roundsmanship

- When the reticular dermis has been fully violated, scar formation occurs.
- The ultimate perception of scarring depends upon the contours, anatomical location and orientation, width, and color of the scar.
- A keen understanding of the geometric concepts of relaxed skin tension lines (RSTLs), aesthetic units, tissue healing, and general wound care is necessary to provide the patient with the best-possible options for scar revision.
- It is important to ensure that patients have realistic expectations and are informed that the scar will not be invisible, but that it will be modified and camouflaged to appear less noticeable and bothersome.
- Wound healing and scar formation can potentially lead to complicated outcomes, such as hypertrophic scars and keloids.
- The three most commonly used irregularization techniques are Z-plasty, W-plasty, and geometric broken-line closure.
- Healing is a continuous process that is altered by factors such as smoking, diet, infection, and general overall health.

44 Rosacea

Robert Deeb and Thomas C. Spalla

44.1 Introduction

Rosacea is one of the most common dermatologic conditions affecting the head and neck. It is characterized by persistent central facial erythema involving the convex areas of the face. Additional primary features are papules and pustules, transient flushing, and telangiectasia. Secondary features of the disease include burning or stinging, plaques, dryness, edema, ocular manifestations, peripheral locations, and phymatous changes. Given the prominent location of the disease pattern, individuals affected with this condition often feel a great deal of anxiety in both social and professional settings.

Although rosacea has readily identifiable characteristics, it remains a diagnosis of exclusion. This is due to the fact that there is no reliable laboratory test. Biopsies are often required to rule out other conditions that may mimic the clinical findings. A broad differential diagnosis must always be considered. Some diseases that must be considered include lupus erythematosus, chronic actinic damage, polycythemia vera, dermatomyositis, mixed connective tissue disease, carcinoid, mastocytosis, and allergic contact dermatitis.

44.2 Pathogenesis

The cause of rosacea remains unknown, although a large variety of mechanisms have been proposed. There is a great deal of debate as to whether or not the subtypes of rosacea all have a common underlying etiology. An alternate theory proposes that each subtype is a distinct disease entity and thus has a unique pathophysiologic mechanism. Given the heterogeneous nature of the disease presentation and the varied responses to treatment, it is likely each subtype represents a varied response to a combination of these purported factors.

Proposed etiologic mechanisms may be categorized according to the central trigger that activates the clinical symptomatology. These categories include vasculature, climate exposures, matrix degeneration, chemicals and ingested agents, pilosebaceous unit abnormalities, and microbial organisms. Each of these pathogenic theories has some supporting evidence, although none offers a comprehensive answer.

44.3 Classification

In 2002, the National Rosacea Society Expert Committee on the Classification and Staging of Rosacea developed a standardized classification system that divided rosacea into four distinct subtypes. Although the different subtypes have some manifestations in common, the committee emphasized the importance of recognizing each subtype as a somewhat distinct entity. The importance of this stratification lies in the fact that treatment options vary widely depending on the constellation of findings within the subtype. Additionally, this system provides uniform diagnostic criteria, which subsequently allow meaningful translational research.

The expert panel also made treatment recommendations for each subtype; these will be outlined, as well. It is important to emphasize that a progression from one subtype to another generally does not take place.

44.3.1 Erythemato-telangiectatic Type

The hallmark finding of the erythemato-telangiectatic rosacea (ETR) subtype is flushing and persistent erythema of the central face. There is characteristic sparing of the periocular skin. The stimuli that bring on the flushing may be emotional stress, hot drinks, alcohol, spicy foods, exercise, cold or hot weather, and hot baths or showers. These patients may also have telangiectasia, although this is not a diagnostic requirement. Common secondary features include burning and stinging sensations, edema, and roughness or scaling. Generally, patients with ETR are more sensitive to topically applied substances. The skin usually has a fine texture and lacks the sebaceous quality that is found in other subtypes.

This subtype of rosacea is often difficult to treat. No drugs have been approved to reduce flushing. As such, the mainstay of treatment is the avoidance of environmental and lifestyle triggers. Additionally, the use of nonirritating cosmetics may conceal the appearance of erythema and telangiectasia.

The telangiectasia and background erythema can also be treated with laser therapy. Most lasers used to treat the vascular components of rosacea have wavelengths in the 500- to 600-nm range. These are nonablative ranges and are thus not intended to destroy tissue. Options include long-pulsed dye, potassium titanium phosphate, and diode lasers. Treatment with flashlamp pulsed dye laser has been shown to be effective, as well.

44.3.2 Papulopustular Type

Papulopustular rosacea (PPR) is considered to be the classic presentation of the disease (□ Fig. 44.1). This subtype is characterized by persistent central facial erythema and transient central facial papules or pustules, or both. Secondary features of burning and stinging are sometimes reported. Flushing may occur, although this symptom is less severe than in the ETR subtype. Telangiectasia is often subtly present; however, the telangiectasia may be obscured by the erythematous background. Irritation from external stimuli or topical applicants is not a constant feature.

Like that of all subtypes of rosacea, the treatment of PPR depends on the severity of the condition. Mild cases may be treated with a topical therapy such as metronidazole, azelaic acid, or sodium sulfacetamide. The addition of oral therapy is indicated for more severe disease. A first-line option, which is FDA-approved, is a controlled-release formulation of oral doxycycline. Of note, the dose of this drug achieves low plasma levels that do not exert antimicrobial effects while retaining anti-inflammatory activity.

Refractory cases may require off-label oral trimethoprim/sulfamethoxazole, metronidazole, erythromycin, ampicillin, clindamycin, or dapsone.

Fig. 44.1 Papulopustular type of rosacea.

44.3.3 Phymatous Type

Phymatous rosacea is characterized by many of the primary features of rosacea, including flushing, erythema, and papules or pustules. However, the presence of characteristic features of skin thickening, irregular surface nodules, and pustulous follicles defines this subtype. Affected areas include the chin, forehead, cheeks, and ears; however, the nose is most commonly affected (i.e., rhinophyma).

As previously mentioned, a progression from one subtype to another generally does not occur. However, a possible exception is the progression of severe papulopustular rosacea to the phymatous type.

Management options for early-stage phymatous changes include topical and systemic antibiotics if inflammatory lesions are present. Isotretinoin therapy has been demonstrated to decrease nasal volume in rhinophyma, especially in younger patients with less advanced disease, although the volume may increase again after therapy is stopped. More severe forms of phymatous rosacea may require surgical intervention; these are detailed in the section below on the treatment of rhinophyma.

44.3.4 Ocular Type

The cardinal symptoms of ocular rosacea are blepharitis and conjunctivitis. The eyes generally have a watery or bloodshot appearance, and patients experience foreign body sensation, burning or stinging, dryness, itching, light sensitivity, and blurred vision. Patients may also have a history of recurrent chalazion. Telangiectasia of the eyelid margins or lids and periocular erythema may also be present. Inflammation of the mei-

Fig. 44.2 Patient with rhinophyma after Mohs excision of two basal cell carcinomas. Note the extreme thickening of the skin.

bomian glands may be present. Ocular rosacea may precede the cutaneous signs by many years, and more than 60% of patients with cutaneous rosacea may also have ocular involvement.

Generally, patients with ocular rosacea should have regular interval evaluations by an ophthalmologist. Early-stage disease is treated with artificial tears, warm compresses, and regular cleansing of the eyelashes with baby shampoo. Antibiotic ointment may have benefit to decrease the presence of *Propionibacterium acnes*, *Staphylococcus epidermidis*, and *Staphylococcus aureus*. Severe disease may require treatment with a systemic tetracycline with or without a topical steroid. Cyclosporine ophthalmic emulsion may be used in severe cases, as well.

44.4 Rhinophyma

Phyma is a Greek word meaning “swelling,” “mass,” or “bulb.” These growths typically occur about the face and ears. The most common form affects the nose and is thus termed rhinophyma. Rhinophyma is a slowly progressive dermatologic condition of the nose characterized by sebaceous hypertrophy, which leads to the appearance of a bulbous, greasy, and sometimes erythematous nose. With progressively increasing growth, the condition can lead to impaired breathing and severe cosmetic disfigurement. It occurs almost exclusively in men.

Rhinophyma is sometimes considered the end stage of acne rosacea because in many male patients with rhinophyma, the disease has slowly progressed from rosacea. This is not always the case, however. There is some thought that the inflammatory process may be triggered by a mite, *Demodex folliculorum*. There are four variants of rhinophyma.

44.4.1 Glandular Form

In this form of rhinophyma, the nose is enlarged primarily by lobular sebaceous gland hyperplasia. Superficially, the nose is characterized by pits and deep indentations. The tumor-like growths occurring on the nose are often asymmetric and when compressed yield a cheesy white discharge (□ Fig. 44.2).

44.4.2 Fibrous Form

In this variant, the dominant characteristic is overgrowth of the connective tissue. Variable amounts of sebaceous gland hyperplasia are also present.

44.4.3 Fibroangiomatic Form

The fibroangiomatic form of rhinophyma causes the nose to become coppery red to dark red in appearance. Additionally, it is associated with pustules and a network of venous ectasia.

44.4.4 Actinic Form

In this variant, which is seen primarily in patients of Celtic origin (i.e., Fitzpatrick type I skin), the nose is distorted by nodular masses of elastic tissue.

44.4.5 Nasal Obstruction

With progressive disease, the tissue bulk can cause pressure on the upper lateral cartilages, restricting airflow through the internal nasal valve region. Additionally, the proliferation may result in excess bulk along the nasal ala and cause collapse of the external valve. In extreme cases, as reported by Lomeo et al, the sebaceous hypertrophy can become so significant as to block the nasal passages almost completely.

44.4.6 Treatment

Medical management of rhinophyma should be considered for patients who have mild disease or for those in whom surgery is best avoided or contraindicated. The modalities used to treat early-stage rhinophyma are similar to those employed in the management of rosacea. Additionally, topical forms of statins can be used in the treatment of acne, seborrhea, rosacea, and rhinophyma. When medical management of the disease is unsuccessful, and after appropriate counseling, surgical management of rhinophyma may be undertaken. As with all facial plastic surgery, photographic documentation is imperative. Several methods have been proposed to improve cases of rhinophyma.

Farrior has found that bulky disease can first be removed with a dermatome, and the edges may be blended with a wire brush dermabrader. Williams and Lam are in agreement; they also state that rhinophymatous tissue takes longer to heal and that a longer duration of the need for occlusive dressings and ointments is to be expected.

Electrocauterization and cryosurgery may also be used in the management of this disease. Seiverling found the Shaw scalpel helpful in relieving a patient of nasal obstruction secondary to rhinophyma. Additionally, coblation has been noted to yield acceptable outcomes, and Timms et al purport advantages due to the lower temperatures used with this technique. Radio frequency has been used successfully by Arikan et al, and the harmonic scalpel has also been employed.

Lasers offer another treatment modality to relieve rhinophyma. Ablative lasers allow tissue removal as well as new collagen formation, leading to tightening of the skin and an improved appearance. Carbon dioxide, Nd:YAG (neodymium:yttrium-aluminum garnet), and Er:YAG (erbium:yttrium-aluminum garnet)

lasers have been used successfully for these purposes. Also, a diode laser has been found to yield acceptable results according to Tahery et al, and the Smoothbeam laser has been used to treat moderate rhinophyma.

Some authors recommend low-dose isotretinoin before and after surgical intervention to reduce the bulk of disease and maintain results. However, there is some concern that oral isotretinoin taken close to the time of surgery may result in hypertrophic scarring. This is the reason why many facial plastic surgeons will not resurface a patient's skin until the patient has refrained from using isotretinoin for 6 to 12 months.

44.4.7 Other Considerations

The excised tissue should be sent for pathologic examination. There are approximately 46 reported cases of malignancy within excised rhinophymatous tissue in the literature. In a study by Lazzeri et al, two cases of basal cell carcinoma and one case of squamous cell carcinoma were identified in the pathologic specimens.

44.5 Roundsmanship

- Rosacea is characterized by persistent central facial erythema involving the convex areas of the face, often in association with papules and pustules, transient flushing, and telangiectasia.
- Rosacea is divided into four distinct subtypes: papulopustular, erythematotelangiectatic, phymatous, and ocular.
- Rhinophyma is a slowly progressive condition of the nose characterized by sebaceous hypertrophy that leads to the appearance of a bulbous, greasy, and sometimes erythematous nose.
- There are four variants of rhinophyma: glandular, fibrous, fibroangiomatic, and actinic.

45 Common Facial Skin Lesions

John A. Carucci and Joshua W. Trufant

45.1 Examining the Skin

The physical examination is an essential component of a thorough patient evaluation. Although dermatologists specialize in diseases of the skin, general internists and other medical specialists cannot help but examine the skin during a focused evaluation of their particular organ systems of interest. In addition to yielding important insights into internal disease states, the skin examination is an opportunity for physicians to screen patients for cutaneous malignancies. The early detection of skin cancers has been shown to decrease their associated morbidity and mortality. Otolaryngologists—head and neck surgeons are particularly well positioned to identify suspicious lesions for several reasons:

- Approximately 80% of nonmelanoma skin cancers—the most common malignancies worldwide—and 90% of cases of lentigo maligna—a form of malignant melanoma in situ—are located on the head, likely in part because of strong associations with exposure to ultraviolet (UV) light.
- Nonmelanoma skin cancers of the ears and central face have higher rates of local recurrence and metastasis in comparison with cutaneous cancers on the trunk or extremities.
- Invasive nonmelanoma skin cancers of the head and neck can result in cosmetic disfigurement that may be difficult if not impossible to conceal, causing patients significant psychological distress.
- Individuals receiving immunosuppressive therapies or ionizing radiation for internal malignancies, including head and neck cancers, are at increased risk for cutaneous malignancies.

It follows that in order to identify concerning lesions, the physician must also be able to identify common benign lesions of the head and neck. A working knowledge of benign facial lesions can also help the nondermatologist answer patients' questions and know when to refer them to a dermatologist for further evaluation. As in patient encounters across all specialties, the history can provide valuable diagnostic information. Lesion duration, the presence of symptoms such as pain, itching, bleeding, and discharge, and any changes in size, color, or appearance are particularly important. The ABCDE (asymmetry, border irregularities, color variegation, diameter larger than 6 mm, and evolving lesion that is changing in any way over time) acronym, initially devised to aid the lay public and primary care physicians in recognizing malignant melanoma, has been validated as a useful screening tool for evaluating pigmented lesions. Any of these characteristics may be cause for concern, although there are melanomas that do not have them (e.g., amelanotic melanoma) and benign lesions that do (e.g., seborrheic keratoses larger than 6 mm).

Proper lighting is critical to performing an adequate examination of the skin. Magnification can also aid in identifying smaller lesions or surface changes. Dermoscopy is an examination with a handheld device that combines magnification with polarized light or a fluid interface; it allows the visualization of structures in the epidermis or papillary dermis that are not visible to the naked eye.

45.2 Terminology

Familiarity with dermatologic terminology will also improve diagnostic accuracy and communication with physician colleagues. Although exact definitions vary, the following are useful working definitions of just a few of the most common primary lesions found on the head and neck. A macule is a circumscribed, flat lesion with color change that is up to 1 cm in size. A patch has similar characteristics but is larger than 1 cm. A papule is a circumscribed, elevated, superficial, solid lesion up to 1 cm in size. A plaque has similar characteristics but is larger than 1 cm. A nodule is also elevated and up to 1 cm in size, but it has more depth than a papule. A mass is a lesion with a depth of more than 1 cm.

When a confident diagnosis of benignity cannot be made by physical examination and history, or when a clinically malignant-appearing lesion is identified, a biopsy is required. Various techniques may be employed. Shave biopsy refers to shallow removal of a lesion to the depth of the dermis, typically performed with a scalpel or dermablade. Saucerization refers to a disk-shaped biopsy performed with a scalpel angled at 45 degrees, so that the subcutaneous fat is reached at the center of the sample. Punch biopsy refers to the use of a sharp, circular instrument ranging from 1 to 1.5 cm in diameter that removes tissue well into the subcutaneous fat. The resulting defect is typically closed with sutures. Incisional biopsy samples only a portion of a lesion and is frequently employed for larger lesions or those on cosmetically sensitive areas; it may be performed by punch biopsy or elliptical incision. Full-thickness excisional biopsy refers to total removal of a lesion with 1- to 3-mm margins; it can be performed with a punch biopsy instrument or by fusiform (elliptical) excision with a scalpel, followed by primary closure with sutures. Excisional biopsy has long been the recommended technique for lesions suspicious for malignant melanoma, although recent studies suggest that shave biopsy may be sufficient in some cases.

45.3 Common Facial Lesions

45.3.1 Seborrheic Keratosis

Among the most common benign epidermal tumors found on the head and neck, seborrheic keratoses (SKs) are characterized clinically by their stuck-on, waxy appearance (□ Fig. 45.1). Lesions are typically tan to brown and may have a smooth or mammillated surface. Six subtypes have been described, most ranging in size from several millimeters to a centimeter in diameter, although “giant” lesions measuring nearly 10 cm have been reported. Dermatitis papulosa nigra, characterized by numerous 1- to 5-mm hyperpigmented papules on the face of darkly pigmented individuals, is considered by many to be an SK variant. SKs are commonly asymptomatic, but they may be associated with pruritus or more rarely with pain and bleeding, particularly more exophytic lesions prone to traumatization. Although their etiology is not well understood, genetic se-

Fig. 45.1 (a,b) Seborrheic keratoses. (c) Multiple seborrheic keratoses on the face of an African-American woman, also known as dermatosis papulosa nigra.

quencing has revealed a number of associated oncogenic mutations. Advanced age is clearly a risk factor, but data regarding an association with sun exposure are conflicting. Human papillomavirus has been isolated in a subset of lesions. The sudden appearance of numerous SKs is widely thought to be a potential sign of internal malignancy, a paraneoplastic phenomenon known as the sign of Leser-Trelat, although recent studies have cast doubt on this association.

SKs can usually be diagnosed clinically based on their characteristic appearance. Biopsy is typically unnecessary. Dermoscopy can aid in differentiating SKs from melanocytic lesions by enhancing classic features such as comedo-like openings and milium cysts; however, cases of malignant melanoma mimicking SKs have been reported. Treatment of these benign neoplasms is elective, but patients may be bothered by symptomatic or cosmetically conspicuous lesions. A number of treatment modalities have been shown to be effective in removing SKs, including cryotherapy, electrodesiccation and curettage, and shave excision, although these methods are frequently complicated by scarring, pigmentary changes, and recurrence. Laser treatment with 532-nm diode, ablative carbon dioxide, Er:YAG (erbium-doped yttrium aluminum garnet), and Nd:YAG (neodymium-doped yttrium aluminum garnet) models is increasingly being used.

45.3.2 Sebaceous Hyperplasia

Sebaceous gland hyperplasia (SH) is characterized by yellow to flesh-colored papules, most commonly seen on the face (□ Fig. 45.2). Although its incidence increases with age, it may occur at any age, including at birth. Subtypes include senile, linear, diffuse, functional familiar, juxtaclavicular beaded line variant, and giant lesions—plaques or cystlike lesions measuring up to 5 cm. SH represents an increased number of mature sebaceous lobules in the superficial dermis attached to a dilated central pore. Its etiology is unknown, but the incidence is increased in organ transplant recipients and in those taking cyclosporine. SH does not appear to be associated

with Fitzpatrick skin type or solar elastosis, nor is it considered a part of the Muir-Torre syndrome, a rare autosomal-dominant genodermatosis characterized by rarer benign and malignant sebaceous tumors, keratoacanthomas, and internal malignancies.

The diagnosis of SH is typically made clinically. Particular care should be taken in evaluating lesions of the periocular region, the most common site of the rare sebaceous carcinoma. Magnification of SH by dermoscopy or other means typically reveals a central yellow to white ostium with surrounding linear telangiectasia. Successful treatment of SH has been achieved with photodynamic therapy; carbon dioxide, Nd:YAG, and pulsed dye lasers; cryosurgery; bichloroacetic acid; electrodesiccation; and oral isotretinoin.

45.3.3 Trichoepithelioma

Trichoepitheliomas are benign follicular neoplasms most commonly found on the head and neck. Lesions typically appear in childhood or early adulthood as solitary, 2- to 8-mm, firm, flesh-colored papules. The desmoplastic variant, a plaque-like lesion with a central dell, is most often seen on the face of young women. Rarely, multiple lesions that tend to cluster about the central face may be inherited in an autosomal-dominant fashion, alone or in combination with other benign follicular neoplasms, as in Brooke-Spiegler syndrome (□ Fig. 45.3). Inherited forms have been linked to loss-of-heterozygosity mutations in the cylindromatosis *CYLD* gene, whereas sporadic trichoepitheliomas have been linked to mutations in the *PTCH* tumor suppressor gene. The diagnosis can usually be made clinically, but biopsy may be required to differentiate a solitary lesion from basal cell carcinoma. Shave biopsy or curettage is also an effective treatment option for solitary trichoepitheliomas, but impractical for multiple lesions. Some have suggested that Mohs micrographic surgery is warranted for desmoplastic trichoepitheliomas because of their predilection for cosmetically sensitive areas and rare instances of local invasion. Other modalities for the treatment of multiple trichoepitheliomas that

have been described with variable success include dermabrasion; electrosurgery; cryosurgery; ablation with Nd:YAG, Er:YAG, or carbon dioxide lasers; and photodynamic therapy. Medical treatments have included sodium salicylate and prostaglandin A₁, a combination of aspirin and adalimumab, and topical imiquimod.

Fig. 45.2 Sebaceous hyperplasia.

45.3.4 Trichilemmoma

Trichilemmoma is a benign adnexal neoplasm believed to be derived at least partially from the outer root sheath of the hair follicle. Clinically, it appears as a flesh-colored papule or small nodule, most commonly on the central face. Sites of involvement include the cheeks, nose, upper cutaneous lip, and eyebrow, or less frequently the eyelid. Trichilemmoma, particularly the desmoplastic variant, may also arise within a nevus sebaceous (□ Fig. 45.4). Solitary lesions tend to be sporadic, but multiple lesions should raise suspicion for Cowden syndrome, a multiple hamartoma syndrome associated with oral and gastrointestinal papillomatosis, as well as breast, thyroid, and gastrointestinal adenocarcinomas. Autosomal-dominantly inherited mutations of the PTEN tumor suppressor gene appear to underlie Cowden-associated lesions, but the pathogenesis of solitary trichilemmomas is less clear. Early suggestions based on histologic features that trichilemmomas represent old viral warts have not been borne out in more recent polymerase chain reaction-based studies looking for human papillomavirus DNA.

Biopsy may be necessary to differentiate trichilemmoma from basal cell carcinoma (BCC) or squamous cell carcinoma (SCC), or to differentiate Cowden syndrome from other genodermatoses characterized by facial adnexal neoplasms. Treatment is purely elective, and modalities are similar to those mentioned in relation to other adnexal neoplasms, including surgical excision, cryotherapy, electrodesiccation, and ablative laser treatment. Trichilemmal carcinoma, a rare low-grade malignant variant most commonly occurring on the face of elderly patients, is best treated with conservative local excision or Mohs micrographic surgery.

45.3.5 Hemangioma

Hemangiomas are vascular neoplasms that represent benign proliferations of endothelial cells. It is essential to proper management that they be differentiated from vascular malformations—a heterogeneous group of lesions that includes so-called

Fig. 45.3 (a) Multiple trichoepitheliomas. (b) Desmoplastic trichoepithelioma.

port-wine stains—which are composed of structurally abnormal vessels arising from errors of embryogenesis. Infantile hemangiomas are typically not present at birth; they appear within the first month of life, undergo a rapid proliferative phase for 6 months, and then, following a quiescent phase, undergo a more gradual involution beginning at roughly 1 year of age. In contrast, vascular malformations, which are nearly always present at birth, may grow slowly over time with the individual, and do not tend to involute. Both types of lesions—hemangiomas and vascular malformations—may be associated with distinct syndromes that require prompt systemic work-up to prevent or attenuate significant morbidity and mortality.

Infantile hemangiomas are the most common benign tumor of childhood, occurring in up to 10% of white infants, and among the most common vascular neoplasms encountered on the head and neck. Girls, children with light skin types, and premature infants are disproportionately affected. Although no for-

mal classification system exists, a number of subtypes have been described based on characteristics such as as level(s) of skin affected (superficial, deep, or mixed) or on morphological characteristics (localized, segmental, multifocal). Superficial “strawberry” hemangiomas typically appear as solitary, bright red, well-demarcated papules or nodules, whereas deep or mixed tumors involving the dermis or subcutis tend to be more blue or flesh-colored (□ Fig. 45.5). Focal hemangiomas are most often found on the central face at lines of developmental fusion. The presence of five or more focal lesions, or of larger solitary lesions, may indicate an increased risk for involvement of the gastrointestinal tract, particularly the liver. The segmental variety may appear as coalescing papules, a broad plaque, or a large tumor in a segmental, most commonly mandibular distribution.

Large or segmental hemangiomas are more frequently associated with extracutaneous manifestations. Up to one-third of cases may be associated with PHACE syndrome; PHACE is an acronym for a constellation of posterior fossa anomalies, hemangiomas, arterial anomalies, cardiac anomalies (most commonly coarctation of the aorta), and eye anomalies. Vascular tumors involving the lower face and neck may also affect the oropharynx or larynx, potentially resulting in airway compromise. Two other rare vascular tumors distinct from true hemangiomas—the kaposiform hemangioendothelioma and the tufted angioma—can be associated with the Kasabach-Merritt phenomenon, a life-threatening consumptive coagulopathy associated with a decreased platelet count.

By way of contrast, a few well-known vascular malformations and other lesions that are not true hemangiomas bear mention here. The port-wine stain is a typically unilateral capillary malformation present at birth, most commonly in the ophthalmic or maxillary dermatome, that tends to become more prominent with time. Up to one-third of ophthalmic malformations, particularly bilateral lesions, may be associated with ipsilateral vascular malformations of the leptomeninges that can result in seizures and neurologic deficits (Sturge-Weber syndrome).

Fig. 45.4 Multiple tricholemmomas arising in a nevus sebaceus.

Fig. 45.5 (a) Superficial hemangioma. (b) Deep hemangioma.

Fig. 45.6 (a–c) Lentigines.

Another, much more commonly encountered vascular malformation is the so-called salmon patch or stork bite, a capillary malformation present at birth on the central forehead or nape of the neck that tends to fade over the first few years of life. The cherry angioma is a 2- to 4-mm red papule representing a dilated and congested small vessel of the upper dermis that appears during adulthood; it is most frequently found on the trunk but also may appear on the head and neck.

The management of hemangiomas has changed dramatically in recent years. Although “watch and wait” is still an appropriate approach for the majority of focal infantile hemangiomas, β -blockers have joined, if not replaced, corticosteroids as the first-line treatment of severely disfiguring or complicated lesions. Since the first report of the successful treatment of severe infantile hemangiomas with intravenous propranolol, a number of case series and prospective trials have demonstrated the efficacy and relative safety of systemic β -blocker therapy. Treatment is generally well tolerated, but reported side effects have

included hypoglycemia, bronchospasm, and hypotension. In addition to corticosteroids, the use of interferon, vincristine, bleomycin, and cyclophosphamide has also been described. Topical propranolol and timolol, as well as topical corticosteroids, have demonstrated usefulness in hastening the regression of smaller, superficial lesions. Pulsed dye, long-pulsed Nd:YAG, and KTP (potassium titanyl phosphate) lasers are also effective in improving the cosmesis of patients with vascular neoplasms.

45.3.6 Lentigo

Solar or actinic lentigines, colloquially known as age spots or liver spots, are benign pigmented lesions, commonly found on the chronically sun-exposed skin of older, light-skinned adults (□ Fig. 45.6). Their incidence increases with age, affecting 90% of whites older than 50 years of age. The face, neck, forearms, and dorsal hands are most frequently affected. Clinically, lentigines are tan to dark brown or black in color, may appear

mottled, and range from a few millimeters to over a centimeter in diameter. Their borders are well defined but may be irregular. There are typically no surface changes such as scale or infiltration. Individuals who had ephelides (freckles) in adolescence or more than two sunburns after age 20 are at increased risk for lentigines. Like ephelides, lentigines tend to darken in the sun, but they are much more likely to persist year-round.

The diagnosis of lentigines is usually made clinically, but biopsy may be necessary to differentiate them from lentigo maligna, a type of malignant melanoma in situ on chronically sun-damaged skin. Dermoscopy may aid in identifying features concerning for malignancy. Other lesions in the differential diagnosis include nevi and seborrheic keratoses. The treatment of solar lentigines is elective. Ablative cryotherapy is considered first-line treatment, but a wide variety of lasers have also demonstrated benefit. Combination treatment with hydroquinone and topical retinoids produces a less rapid response. The appearance in childhood of multiple facial lentigines, especially on the lips and oral mucosa, may occur as a benign isolated finding but should raise concern for rare familial cancer syndromes such as Peutz-Jeghers syndrome and Carney complex.

45.3.7 Intradermal Nevus

The intradermal nevus (IDN) is a benign melanocytic neoplasm most commonly seen in young children and the elderly. For years, it was widely believed that IDNs were mainly lesions of adulthood, representing the final stage of maturation of acquired melanocytic nevi that “drop down” from the epidermis over time. However, more recent epidemiologic and histologic studies of congenital and acquired nevi suggest that some IDNs may originate within the dermis. Congenital nevi, which are histologically dermal or compound (dermal and epidermal), are present at birth in 1 to 6% of neonates. They are commonly categorized by diameter—ranging from small (<1.5 cm) to medium (1.5 to 20 cm) to large or “giant” (>20 cm), which guides their management. Congenital nevi are typically tan to brown but may also appear blue, gray, or black. Acquired IDNs are usually 2 to 6 mm in diameter. They may be endo- or exophytic, dome-shaped, sessile or pedunculated, smooth or papillated papules (□ Fig. 45.7). They range in color from flesh-colored to dark brown or black. The lesions may be firm or easily compressible. An older patient may relate a history of slow evolution from a

flat, pigmented macule (junctional nevus). The variant most commonly found on the face, known as Miescher nevus, tends to be dome-shaped, firm, smooth, endophytic, and about 5 mm in diameter. Lesions may have overlying vessels or terminal hairs, particularly congenital IDNs. The differential diagnosis of endophytic varieties may include BCC, whereas more exophytic, pedunculated lesions may be mistaken for skin tags (acrochordons) or neurofibromas. Dermoscopy can aid in the diagnosis. Biopsy is often unnecessary but may be required to rule out malignant melanoma or nonmelanoma skin cancer in changing or otherwise clinically concerning lesions.

IDNs are benign, largely asymptomatic lesions, and as such they do not generally require treatment. If removal is desired, biopsy or simple surgical excision is effective for smaller lesions, whereas serial excisions, local, regional, or expanded flaps, and split-thickness or full-thickness skin grafts may be required for larger congenital nevi. Individual and combined laser treatments may improve cosmesis. Although it is well established that individuals with giant congenital nevi (>20 cm) are at increased risk for developing malignant melanoma and neurocutaneous melanocytosis, an association between common acquired nevi or small congenital nevi and melanoma remains controversial.

45.3.8 Actinic Keratosis

Actinic keratoses (AKs), also known as solar keratoses, are common intraepidermal neoplasms with the potential to evolve into SCC. The prevalence in the United States in 2004 was estimated to be 39.5 million. AKs are generally held to exist in a continuum with SCC; however, the annual risk for malignant transformation of an individual AK is unknown, with reports ranging broadly from less than 0.025% to 16%. One recent prospective study puts the annual risk at 0.6%. Cumulative exposure to UV light, fair skin type, and immunosuppression—particularly in organ transplant recipients—are primary risk factors, as are genetic conditions that predispose to UV sensitivity. UVB-specific mutations of the TP53 tumor suppressor gene identified in AKs provide molecular evidence of the pathogenic role of sunlight.

The most common clinical presentation of the AK is a pink to red, scaling papule or plaque on a sun-exposed area, most commonly the face, forearms, or dorsal hands. Lesions are typically

Fig. 45.7 (a) Intradermal nevus. (b) Blue nevus.

2 to 6 mm in diameter but may span several centimeters or occur as multiple discrete papules. The gritty, firmly adherent scale may be more easily felt than seen on a background of chronically sun-damaged skin. Lesions may become hypertrophic, occasionally producing a hyperkeratotic, cone-shaped protuberance known as a cutaneous horn. The differential diagnosis of AK includes SCC, seborrheic keratosis, and verruca vulgaris. The pigmented variant may be confused with BCC or malignant melanoma. Shave biopsy is typically sufficient to make a histologic diagnosis. Actinic or solar cheilosis (sometimes called cheilitis) is a related precancerous neoplasm that occurs on the lower lip. Risk factors are similar to those for AKs. A patient may complain of dry, rough, or painful lips, and physical examination may reveal scaliness, fissures, or ulcerations. Prompt identification of solar cheilosis is particularly important, given the greater risk for transformation into SCC and for metastasis from the lip than from other cutaneous sites.

The treatment of AKs prevents progression to SCC and its associated morbidity and mortality. It also relieves symptoms such as tenderness and pruritus. Cryotherapy is the most common treatment modality in the United States, particularly for solitary lesions. Biopsy, curettage, or surgical excision can each provide the benefit of a definitive diagnosis in addition to removing the lesion. Topical 5-fluorouracil—a chemotherapeutic agent that interferes with DNA synthesis—and imiquimod—a topical immune modulator—are both effective, generally well-tolerated, “field-directed” therapies that are especially useful for larger areas with multiple AKs. Photodynamic therapy, although expensive and not as widely available, is also effective. Systemic retinoids, lasers, chemical peels, and dermabrasion are less well-studied modalities.

Spontaneous remission of AKs occurs in 10 to 25% of lesions annually. This phenomenon, combined with the high prevalence of AKs, the relatively low annual risk that an individual AK will transform into SCC, and the high cost of treatment (estimated at \$1.1 billion in the United States in 2004), has led some to suggest that clinical monitoring might be an acceptable management approach. However, given that most patients have multiple AKs and keep them for many years, their risk for SCC is considerably higher than the individual lesion annual progression rates might suggest. The significant morbidity and mortality associated with SCC, combined with the symptom relief provided, are sufficient to recommend treatment.

45.3.9 Basal Cell Carcinoma

BCC is the most common malignancy in the United States, with estimates of lifetime risk in fair-skinned individuals approaching 1 in 3. It accounts for more than 80% of the approximately 2 million nonmelanoma skin cancers diagnosed each year, and its incidence is rising. Exposure to UV light is the primary risk factor for the development of BCC. Related risk factors include fair skin type, occupations with greater outdoor exposure, and genetic disorders that increase sensitivity to UV light. Ionizing radiation, arsenic, and immune suppression are also established risk factors. The molecular pathogenesis of the majority of BCCs is thought to be associated with deregulation of the hedgehog signaling pathway, which is involved in cell proliferation.

Roughly 80% of BCCs occur on the head and neck, followed by sun-exposed areas of the trunk. There are three clinical BCC variants, each with a different presentation (□ Fig. 45.8). The classic nodular BCC lesion appears as a firm, flesh-colored or “pearly” pink papule or nodule, 2 to 6 mm in diameter, with overlying telangiectasia and rolled borders. Central ulceration or crusting may be present. The differential diagnosis frequently includes hyperplasia of sebaceous glands and intra-dermal nevi. Amelanotic melanoma may have a similar appearance. Superficial BCC presents as an erythematous, scaly patch or thin plaque that is sometimes mistaken for SCC. Both nodular and superficial forms may be pigmented, mimicking melanocytic lesions. Morpheaform BCC, sometimes called fibrosing or infiltrative BCC, often appears as an indurated, scarlike plaque with poorly defined borders. Shave or punch biopsy is sufficient to make an accurate histologic diagnosis in most cases.

BCC is typically a slow-growing tumor. Metastasis is rare, occurring in 0.025 to 0.55% of cases, although larger tumors may have increased rates. However, neglected tumors can be locally invasive and result in significant disfigurement. Standard surgical excision with appropriate margins or electrodesiccation and curettage are generally thought to achieve 5-year cure rates of 95% for small, “low-risk” lesions on the neck, trunk, or extremities with nonaggressive histologic features. Radiotherapy can be an effective treatment modality for patients who are poor surgical candidates or who have inoperable tumors, or as adjuvant therapy for those with deeply invasive or metastatic tumors. Topical imiquimod is an option for the treatment of superficial BCC.

Mohs micrographic surgery is recommended for the treatment of “high-risk” BCC because of improved margin control and lower rates of recurrence. Characteristics of high-risk tumors include the following: tumor diameter larger than 2 mm, location on the ears or central face, neglected or long-standing tumor, incompletely excised or recurrent tumor, aggressive histologic subtype, previous irradiation, and perineural or perivascular invasion. The role of Mohs micrographic surgery in the treatment of low-risk tumors on the body remains controversial. Hedgehog pathway-inhibiting medications have shown promise for the treatment of inoperable and metastatic disease.

45.3.10 Squamous Cell Carcinoma

SCC is the second most common cutaneous malignancy after BCC, accounting for roughly 20% of all skin cancers. An estimated 250,000 new diagnoses are made each year in the United States alone, and evidence suggests that the incidence is rising worldwide, at least in the elderly population. Although not as common as BCC, it is much more likely to metastasize and is responsible for most nonmelanoma skin cancer-related deaths. Risk factors for development are similar to those for AKs—namely, genetic predisposition (fair skin type) and cumulative UV exposure. Men are disproportionately affected at a ratio approaching 3:1. Chronically immunosuppressed recipients of solid organ transplants are at a 65-fold increased risk for developing SCC in comparison with the normal population. SCC also has a propensity to develop in chronic ulcers or scars, or in

Fig. 45.8 (a) Nodular basal cell carcinoma (BCC). (b) Pigmented BCC. (c) Superficial BCC. (d) Nodular BCC, ulcerating. (e) Ulcerative BCC.

areas exposed to occupational or therapeutic irradiation. AKs are considered precursor lesions, although most AKs will never develop into SCC. SCC in situ, also known as Bowen disease, is confined to the epidermis but has the potential to develop into invasive SCC if left untreated.

SCC is most commonly found on the head and neck, especially the cheeks, nose, and ears (□ Fig. 45.9). Clinically, SCC and AKs can be difficult to distinguish from each other. Both typically appear as nonhealing, 2- to 6-mm, pink to red scaling papules or plaques, although SCC is more likely to ulcerate. Lesions may be itchy or painful, or they may bleed with manipulation. The keratoacanthoma variant presents in the same distribution as a rapidly growing, symmetric, crateriform nodule with a central keratotic core. Verrucous carcinoma is rare variant that may present as a warty or cauliflower-like neoplasm within the oral cavity. The differential diagnosis of SCC includes AK, verruca vulgaris, and seborrheic keratosis. The nodular keratoacanthoma may be confused clinically with BCC. The diagnosis can often be made clinically but should be confirmed histologically. Shave biopsy yields adequate tissue in most cases.

Surgical excision is the treatment of choice for SCC. Standard excision with 4-mm margins has been suggested to achieve a 95% cure rate for small, primary, “lower-risk,” invasive SCC of the trunk, extremities, or neck. Other physical modalities, such as electrodesiccation and curettage and cryotherapy, have demonstrated similar cure rates for low-risk tumors. Fractionated radiation monotherapy may be appropriate for early-stage lesions in patients who are unable to tolerate surgery. The authors, however prefer to use radiation therapy as an adjunct to surgery for SCC with perineural involvement. There is limited evidence supporting the use of topical 5-fluorouracil for the treatment of SCC in situ.

Reported recurrence rates following standard excision of low-risk primary SCCs range from 5 to 8% and are substantially increased in “high-risk” tumors (□ Table 45.1). SCCs fulfilling any of following criteria are generally considered to be at high risk for recurrence or metastasis: diameter larger than 2 cm, depth to more than 2 mm, subcutaneous tissue invasion, previous recurrence, tumors arising in scars, or anatomical location on the scalp, ears, eyelids, nose, and lips. High-risk tumors,

Fig. 45.9 (a) Bowen disease. (b) Squamous cell carcinoma. (c) Keratoacanthoma. (d) Actinic cheilitis. (e) Squamous cell carcinoma.

particularly those in cosmetically important areas, are preferably treated with Mohs micrographic surgery for improved margin control and tissue conservation. Perineural invasion, although it occurs in only 2 to 14% of patients with SCC of the head and neck, is associated with higher rates of recurrence and metastasis, most commonly to the parotid gland or regional lymph nodes. Nodal disease may occur in approximately 5% of cases, but reported rates vary widely. Postoperative radiotherapy, sentinel lymph node biopsy, and/or dissection of draining lymphatic basins may be required to achieve lasting local

control of SCC with perineural invasion. Radiotherapy alone may also be used to treat patients with significant medical comorbidities that preclude surgical resection.

45.3.11 Lentigo Maligna

Lentigo maligna (LM) is a form of malignant melanoma in situ—that is, confined to the epidermis—that occurs on the severely sun-damaged skin of light-skinned, elderly individuals. It accounts for 4 to 15% of all melanomas, and 10 to 26% of all head

and neck melanomas. Risk factors for the development of LM include light skin type, age, residence in locales with increased UV exposure, cumulative UV exposure, and a history of severe sunburns. LM is rarely seen in patients younger than 40 years or age, and its incidence increases with age, peaking in the seventh and eighth decades. The nomenclature surrounding this cutaneous malignancy can be a source of confusion. LM is to be differentiated from lentigo maligna melanoma (LMM), which invades the dermis and has a very different prognosis. LM is also distinct from the solar or actinic lentigo, sometimes referred to simply as lentigo, a nearly ubiquitous benign pigmented lesion on the sun-exposed skin of older white adults.

Approximately 90% of LMs occur on the face, with a predilection for the cheek. Clinically, LM is characterized by a slowly growing, asymmetric macule or patch with variegated color and an ill-defined, irregular border (□ Fig. 45.10). Lesions may range in color from tan to dark brown or black. A rare amelanotic variant may present as an ill-defined, erythematous patch resembling SCC or BCC. The differential diagnosis includes solar or actinic lentigo, SK, melanocytic nevus, and LMM. A Wood lamp may aid in defining the lesion margins from the surrounding skin. Excisional biopsy of smaller lesions with 1- to 3-mm margins is ideal but is not feasible for larger lesions, particularly

those in cosmetically sensitive areas. In such cases, incisional or full-thickness punch biopsy of the darkest, most palpable, or otherwise clinically concerning area of the lesion is recommended. Sampling error can occur, however, and multiple punch biopsies may be required to make the diagnosis. Shave biopsy, although commonly practiced, is not traditionally recommended because it can obscure proper evaluation of the Breslow depth, the most important prognostic indicator in melanoma.

Surgical excision of LM is the gold standard of treatment. Complete excision is considered curative, but recurrence with standard excision is relatively common, with rates ranging from 7 to 20%. The 1992 National Institutes of Health consensus statement and the 2012 National Comprehensive Cancer Network clinical practice guidelines advise 5-mm margins for the treatment of malignant melanoma in situ. However, these recommendations are largely based on malignant melanoma in situ of the trunk and extremities. Studies of LM of the head and neck have shown the standard 5-mm margin to be inadequate in up to 50% of cases. Margins of more than 15 mm have rarely been required in studies of staged excisional techniques and Mohs micrographic surgery, which have demonstrated significantly lower recurrence rates. Nonsurgical treatment methods such as cryotherapy, laser ablation, irradiation, and topical imiquimod have much higher recurrence rates and should be used with caution as adjuvant therapy or monotherapy for patients who have unresectable lesions or are unable to tolerate surgery. Incompletely treated, lentigo maligna can progress to invasive LMM. Reported rates vary widely from 5 to 50% but lesional size appears to be correlated with risk. LM that has progressed to LMM carries a prognosis similar to that of other invasive melanoma subtypes.

Table 45.1 Recurrence rates of squamous cell carcinoma after Mohs excision and standard excision

Scenario	Mohs excision	Standard excision
SCC of the lip	3.1%	10.9%
SCC of the ear	5.3%	18.7%
Locally recurrent SCC	10.0%	23.3%
SCC with perineural invasion	0%	47%
SCC larger than 2 cm	25.2%	41.7%
Poorly differentiated SCC	32.6%	53.6%

Abbreviation: SCC, squamous cell carcinoma.

Note: Recurrence rates are significantly lower after Mohs excision in certain circumstances.

45.4 Roundsmanship

- Approximately 80% of cases of nonmelanoma skin cancer and 90% of cases of lentigo maligna are found on the head and neck.
- A macule is a circumscribed, flat lesion with color change that is up to 1 cm in size. A patch has similar characteristics but is

Fig. 45.10 (a) Lentigo maligna (melanoma in situ). (b) Lentigo maligna melanoma.

larger than 1 cm. A papule is a circumscribed, elevated, superficial, solid lesion that is up to 1 cm in size. A plaque has similar characteristics but is larger than 1 cm. A nodule is also elevated and is up to 1 cm in size, but it has more depth than a papule. A mass is a lesion with a depth of more than 1 cm.

46 Mohs Micrographic Surgery

John A. Carucci and Jesse M. Lewin

46.1 Introduction

Skin cancers are the most common human cancers. They can result in significant morbidity and even mortality when left untreated. Depending on histologic type and anatomical location, skin cancers may be amenable to excision or to destruction or ablation by radiation treatment. Skin cancers on the head and neck or selected aggressive or recurrent skin cancers at other anatomical sites may be best treated by Mohs micrographic surgery. Mohs micrographic surgery is the only technique that allows a complete evaluation of the entire peripheral and deep surgical margin. This in turn allows maximal conservation of normal tissue with optimization of function and cosmesis.

46.2 Historical Perspective

In the 1930s, Dr. Frederic E. Mohs, a general surgeon, developed a technique of excisional surgery in which a complete margin of skin cancer was plotted in three dimensions. The procedure was initially termed chemosurgery because it involved chemical fixation in situ before excision. Zinc chloride, used as a fixative, was combined with a permeant and an agglutinant, which were applied to the tissue in vivo while cytologic detail was maintained for microscopic evaluation. After this process, the tumor, along with a narrow margin of healthy tissue, was excised, and frozen sections were generated with the deep and peripheral margins in a single horizontal plane, allowing the tumor to be precisely mapped microscopically. In Mohs' original procedure, this process was repeated the following day until all residual tumor was removed, and the wounds were often left to heal by secondary intention. Later, the process was modified; zinc chloride fixation was replaced with local anesthesia and frozen section processing, which expedited the procedure while maintaining high cure rates. Eventually, in 1985, the term chemosurgery was replaced by Mohs micrographic surgery (MMS) to more accurately describe the process of fresh tissue fixation followed by the microscopic evaluation of layers of tissue. MMS was embraced by dermatologists and has become a technique performed only by dermatologic surgeons with special fellowship training in MMS.

46.3 Technique

Mohs surgeons for the most part perform MMS in an office setting with the patient under local anesthesia. At times, if a particular tumor requires an interdisciplinary approach (e.g., an aggressive tumor infiltrating vital structures in the orbit or involving the parotid gland or facial nerve), MMS may be performed in the operating room with the patient under general anesthesia and in conjunction with other surgical subspecialists, such as otolaryngologists or ophthalmologists.

In order to perform MMS and obtain an excellent repair, the surgeon must ensure that well-trained assistants and a laboratory equipped for processing and reading the fresh frozen sections are available. The tumor is initially identified based upon

a prior biopsy site and preferably photographs and triangulation from the physician who initially performed the biopsy. The site is marked and infiltrated with local anesthesia. The tumor is then debulked with a curet, during which process macroscopically normal tissue can be further distinguished from malignant tissue by means of the surgeon's tactile sensation during curettage. Next, the specimen is excised tangentially, with a 45-degree angle initially. This beveled edge is in direct contrast to the 90-degree edge obtained with a standard excision. The beveled edge is crucial for evaluation of the entire surgical margin after the specimen has been mapped and processed via frozen section (□ Fig. 46.1 and □ Fig. 46.2). Optimal margin control is obtained by examination of the entire perimeter of the specimen and contiguous deep margin. Meticulous mapping allows the directed extirpation of any residual tumor. A key defining feature of MMS is that the surgeon excises, maps, and reviews the specimen personally, minimizing the chance of error in

Fig. 46.1 (a) Specimen preparation. (b) The tumor and surrounding area of clinically normal skin are removed tangentially. (c) The tumor is sectioned before being marked with ink. Black and red ink are used to mark the deep aspect of each section, corresponding to a specified area of the Mohs map.

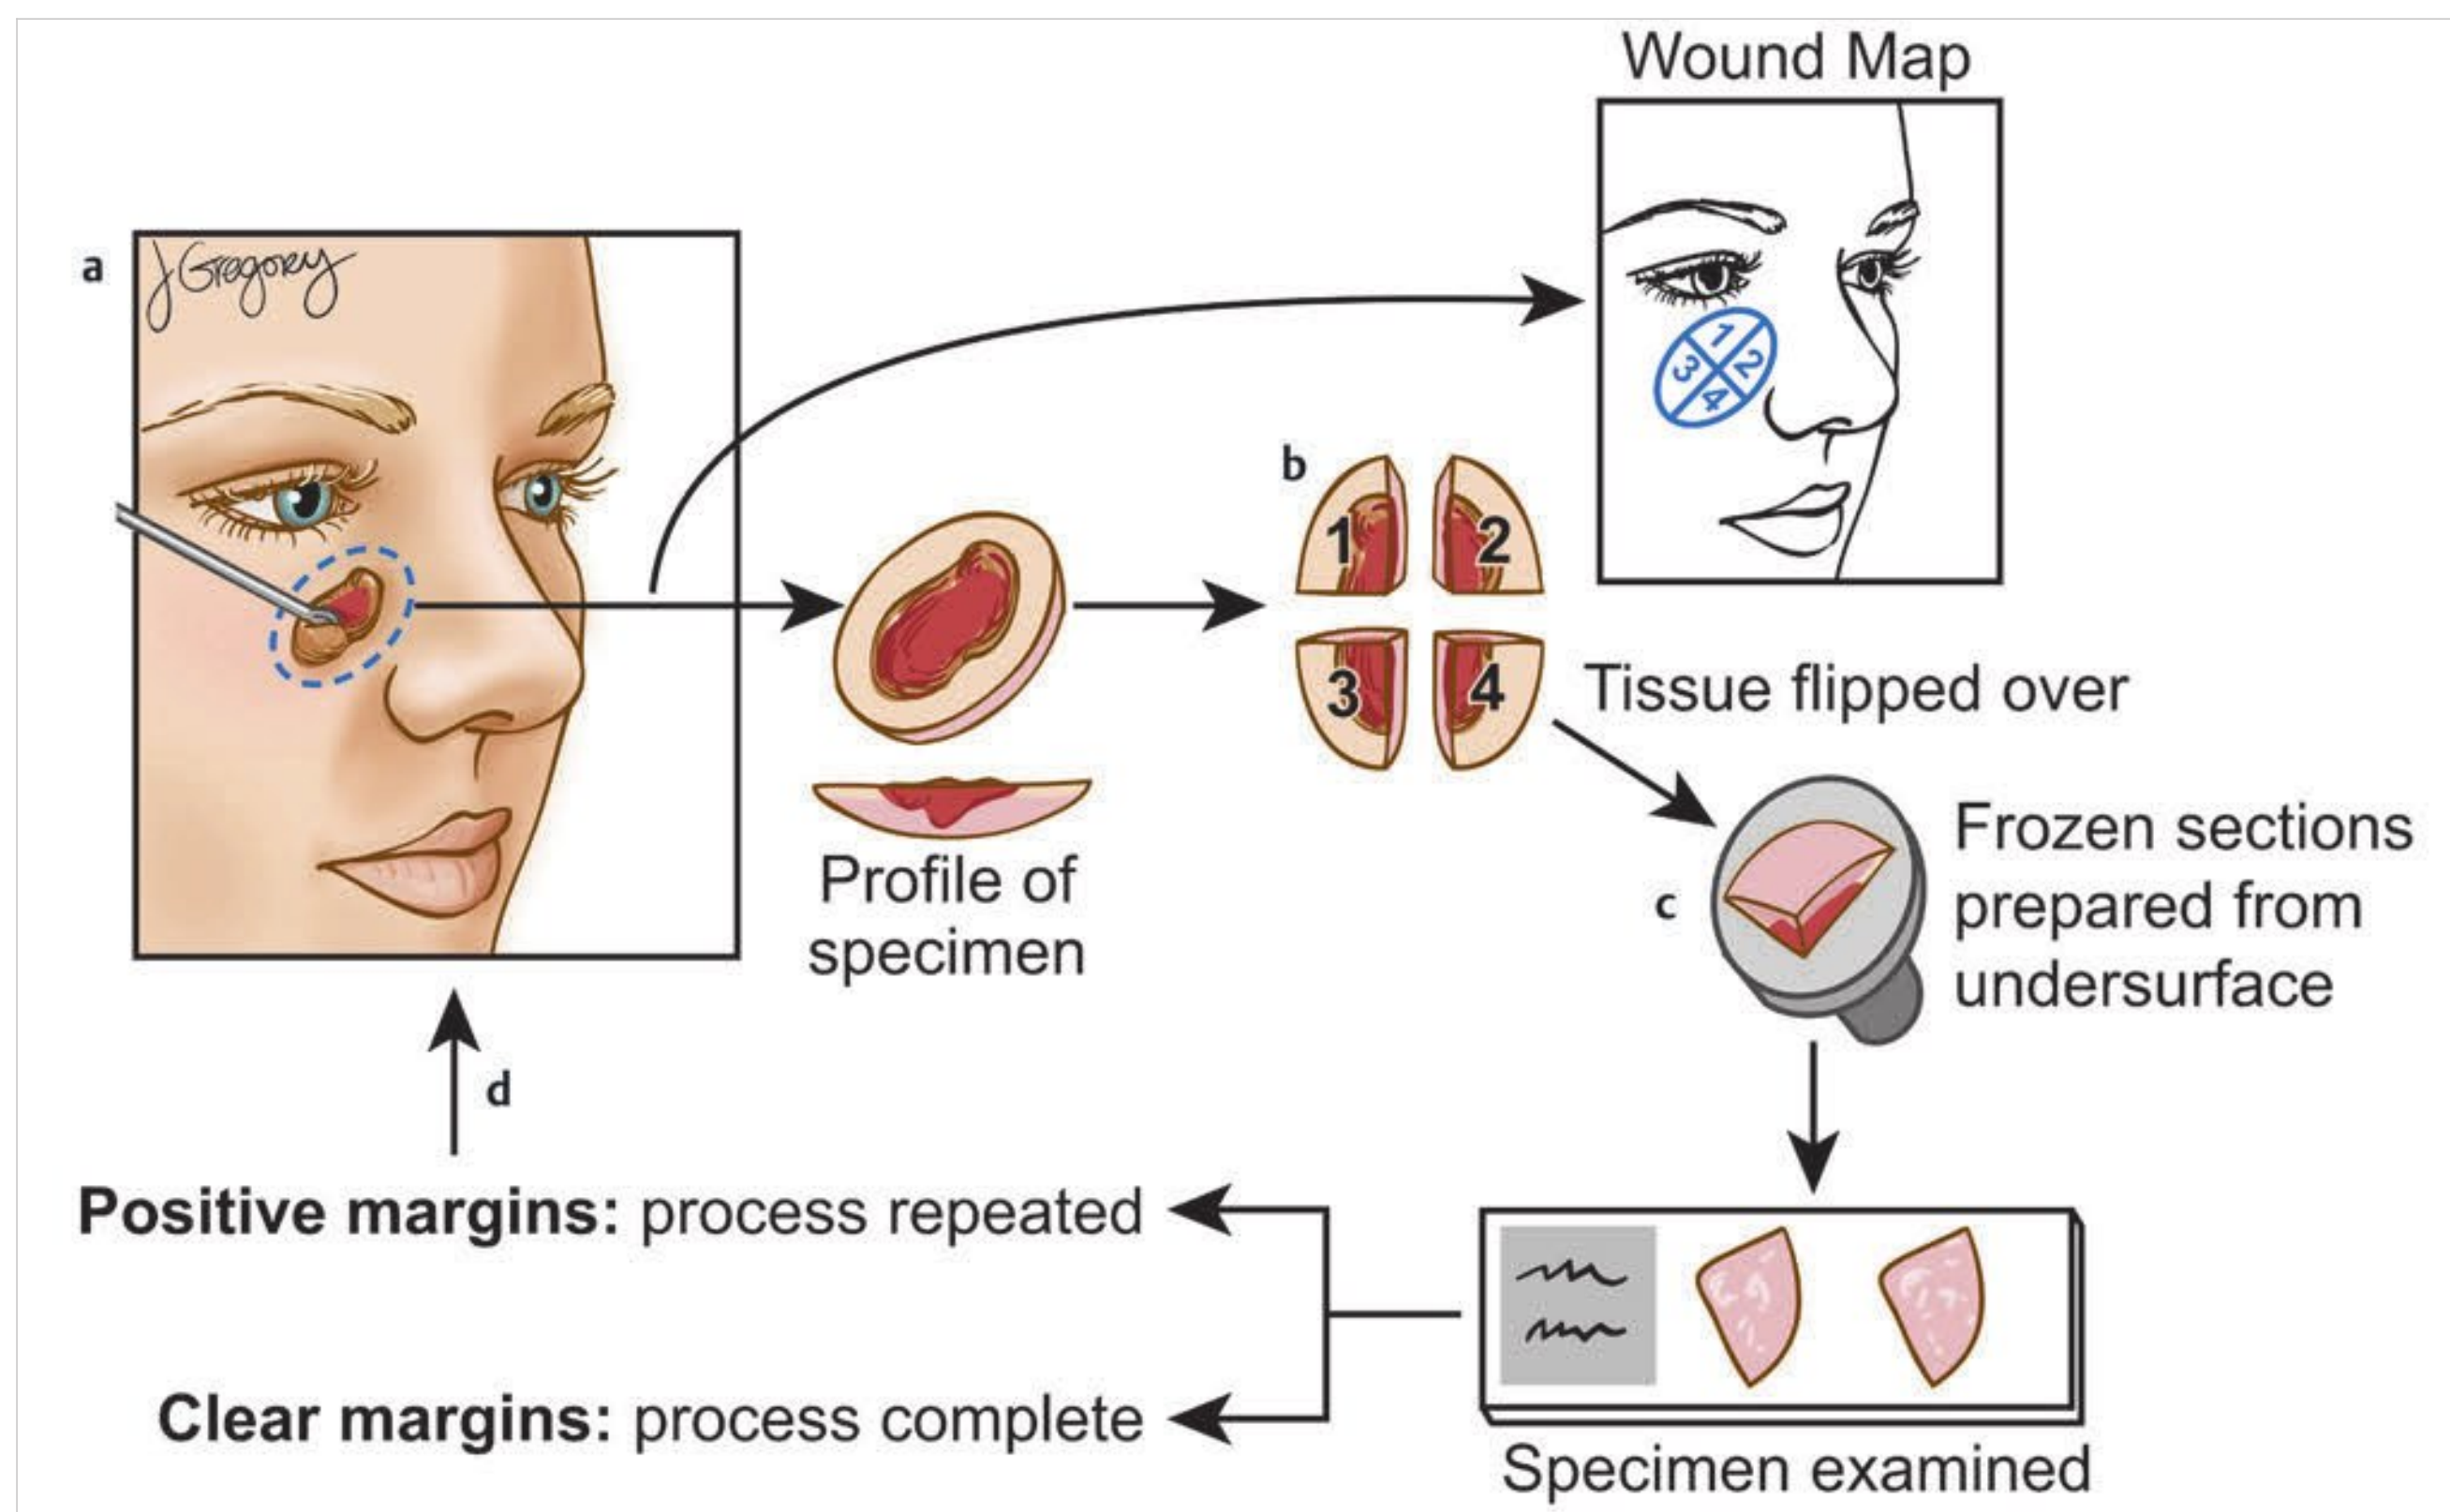

Fig. 46.2 Schematic representation of a Mohs procedure. (a) Initial debulking of the tumor by curettage is followed by tangential removal of the tumor with a margin of clinically normal-appearing skin. (b) The specimen is divided and inked to correspond to the map, allowing precise localization of the remaining areas of positivity. (c) Frozen sections are prepared, allowing visualization of the undersurface and peripheral margin ("worm's-eye view"). (d) Remaining areas of positivity are identified, localized, mapped, and excised until a clear margin is obtained.

tissue interpretation and orientation. If the Mohs surgeon, who is also acting as the pathologist, notes persistent tumor on the margins of a section, it is marked and excised tangentially in an additional stage limited to the area of persistent tumor. This process is repeated until the tumor margins are free of disease. The wound is then usually managed by the Mohs surgeon, who employs measures ranging from secondary intention healing to flaps and grafts, depending on the anatomical location, cosmetic subunits involved, and size of the defect. In some cases, a multidisciplinary approach may be used, and surgical subspecialists from otolaryngology, ophthalmology, and surgical oncology may be involved.

MMS has gained acceptance as the treatment of choice for recurrent skin cancers, as well as for primary skin cancers located at anatomical sites requiring maximal tissue conservation for the preservation of function and cosmesis. This is particularly relevant to dermatologic and head and neck surgeons approaching patients with facial cutaneous malignancies, for whom the desire to avoid disfigurement and functional impairment is paramount and can lead to the inadvertent performance of inadequate standard excisions. MMS allows the surgeon to be flexible in the setting of positive margins and to tailor the reconstruction in real time rather than having to bring the patient back for a second procedure if positive margins are identified by permanent section. As will be discussed in depth in the following sections, it is also crucial to respect the insidious

nature of certain subtypes of aggressive cutaneous malignancies and to approach them knowing the limitations as well as the strengths of MMS.

46.4 Indications

46.4.1 Nonmelanoma Skin Cancer

Each year, approximately 2 million cases of nonmelanoma skin cancer (basal cell carcinoma and squamous cell carcinoma) are diagnosed in the United States. There are more skin cancers in the population of the United States than there are all other cancers combined, and it is estimated that one in five Americans will develop skin cancer during their lifetime (more than 95% will be nonmelanoma skin cancer). As discussed above, MMS facilitates optimal margin control and the conservation of normal tissue in the management of nonmelanoma skin cancer. Although the detailed indications for MMS are beyond the scope of this chapter, the American Academy of Dermatology has outlined general guidelines, which include (1) high risk for local recurrence, (2) areas requiring tissue preservation, and (3) high risk for metastasis. Other treatment modalities, such as simple excision, electrodesiccation and curettage, cryosurgery, topical chemotherapy, and radiation therapy, may be used in other situations.

Fig. 46.3 Basal cell carcinoma (BCC) may extend far beyond what is expected on clinical examination. (a) BCC with perineural invasion involving most of the nasal tip. (b) Paramedian forehead flap repair. (c) Pedicle flap division. (d) Four-month follow-up.

46.4.2 Basal Cell Carcinoma

Basal cell carcinoma (BCC), a malignant neoplasm derived from nonkeratinizing cells that originate in the basal layer of the epidermis, is the most common cancer in humans. The pathogenesis of BCC involves exposure of the skin to ultraviolet (UV) light, particularly the UVB spectrum (290 to 320 nm), which induces mutations in tumor suppressor genes. A latency period of 20 to 50 years has been described between the time of UV damage and clinical onset of the tumor. Thus, in most cases, BCC develops on sun-exposed skin in elderly people, most commonly the head and neck, making it an entity that is often encountered by head and neck surgeons.

Clinically, BCCs may be recognized by their translucency, ulceration, telangiectasia, and rolled borders; however, it is important to note that features may vary for the different clinical subtypes, which include nodular (the most common subtype on the head and neck), superficial, morpheaform, and pigmented BCCs and fibroepithelioma of Pinkus.

For the most part, BCCs tend to be indolent tumors; however, when located on the ear, nose, eyelid, or lip, they are part of the “H” zone where MMS is indicated because of the high recurrence rate and potential to invade locally, resulting in substantial tissue damage to vital structures. One of the most common sites for BCC is the nose, where tumors may extend far beyond what may be expected based on clinical examination (□ Fig. 46.3). In

addition to the clinical subtypes of BCC, there are histologic subtypes that range from less aggressive patterns, such as nodular and superficial, to more aggressive patterns, such as infiltrative, micronodular, and sclerosing or morpheaform. The aggressive subtypes typically are more poorly defined clinically with less predictable radial growth patterns, leading to greater subclinical extension of tumor. When viewed during the traditional “bread loaf” processing of permanent sections, these areas of tumor extension can be missed, leading to a false-negative result.

When BCCs on the face are incompletely excised, these tumors recur between 12% and 41% of the time. It has been demonstrated that MMS has a 99% cure rate for primary BCCs, compared with 91.3% for other methods. In terms of recurrence, the rate of second recurrence of BCCs after treatment with MMS is 5.6% as opposed to 17.6% after standard excision, 9.8% after radiation therapy, and 40% after curettage and desiccation. When the surgeon approaches the patient with a recurrent facial BCC, it is crucial to note that several recent studies have demonstrated greater efficacy of tumor clearance with MMS than with standard excision.

As mentioned briefly above, although most BCCs are indolent, slowly invading tumors, both perineural invasion and metastatic BCC can occur. The estimated incidence of metastatic BCC has been reported to be from less than 0.003% to 0.5%. Perineural invasion, which is defined as the observation of malignant cells in the perineural space of nerves, has been reported in fewer than 0.2% of cases. When perineural invasion is detected, every effort should be made to clear the tumor, preferably by MMS, at times employing an interdisciplinary approach. Patients with gross perineural invasion as indicated by neurologic symptoms will benefit from preoperative magnetic resonance imaging to assess the extent of tumor spread. Classic examples include brow paralysis due to involvement of the temporal branch of the facial nerve and midface paresthesias secondary to involvement of the trigeminal nerve. The estimated incidence of metastatic BCC has been reported to be approximately 0.0028% (28 cases per 1 million diagnoses of BCC) but has been cited to be as high as 0.5%. Relevant to otolaryngologists, more than 80% of metastatic BCCs originate from primary BCCs of the head and neck. Although the topic is beyond the scope of this chapter, studies are under way of molecular pharmacotherapy to target the hedgehog signaling pathway, thought to be responsible for the pathogenesis of BCC, and a new drug, vismodegib, has been approved by the FDA for the treatment of metastatic BCC.

MMS provides definitive surgical management of facial cutaneous malignancies. In addition, another factor to be considered is that the psychosocial implications of head and neck surgery and the resulting reconstruction and scarring cannot be underestimated. Given the morbidity associated with residual tumors after failed standard excisions and treatment with other modalities, and the rare recurrence after MMS, it is important for the surgeon to consider the psychological trauma and anxiety associated with multiple procedures in this region. One large prospective cohort study found that MMS was an independent factor for higher rates of long-term patient satisfaction when compared with standard excision or curettage and desiccation. In terms of guidance for patients following the surgical management of BCC, ongoing total-body skin cancer screenings by a dermatologist, sun protection measures, and skin self-ex-

aminations should be recommended because an estimated 40 to 50% of patients with primary BCC will develop at least one or more BCCs within 5 years.

46.4.3 Squamous Cell Carcinoma

Squamous cell carcinoma (SCC) is a neoplasm of keratinizing cells that shows malignant characteristics, including anaplasia, rapid growth, local invasion, and metastatic potential. More than 250,000 cases of SCC are diagnosed in the United States per year, making it the second most common human cancer after BCC. Whereas the behavior of BCC is determined by histologic phenotype, as described above, the risk for recurrence and morbidity in patients with SCCs is related to the cellular differentiation and depth of invasion of the neoplasm into the reticular dermis and subcutis.

As opposed to BCC, which is thought to arise *de novo*, SCC involving the epidermis alone (termed SCC *in situ*) tends to arise in association with preexisting actinic keratoses, most commonly on sun-damaged skin. Clinically, SCC often presents as an erythematous, scaling patch or a slightly elevated plaque; however, in the immunocompromised host, a more aggressive phenotype may be seen, including metastatic disease. Although SCC *in situ* is considered to have little to no risk for metastasis, invasive SCC can originate in neglected SCC *in situ* (□ Fig. 46.4) and metastasize. The incidence of metastasis of invasive SCC is 3 to 5%. A higher incidence (10 to 30%) is associated with SCC arising on mucosal surfaces (lip, genitalia) and on sites of prior injury (scars, chronic ulcers). It is also important to note that immunosuppressed patients, such as those who have received organ transplants, are a special high-risk group in whom the incidence of SCC is increased more than 60-fold compared with that in the general population. Perineural invasion is associated with a high risk for recurrence and potential metastasis and may be observed in tumors thought to be otherwise low-risk on clinical examination (□ Fig. 46.5).

For SCC on the head and neck, recurrence rates after MMS are lower than after traditional excisional surgery in primary SCC

Fig. 46.4 Squamous cell carcinoma (SCC) may eventuate in local recurrence and metastasis. A patient with untreated SCC that continued to invade locally and subsequently metastasized to regional lymph nodes.

Fig. 46.5 Perineural invasion can occur with squamous cell carcinoma. (a) Perineural invasion in a lesion that appears low-risk otherwise. (b) In this case, perineural invasion involved the supratrochlear nerve, and multiple stages of Mohs surgery were required to achieve a tumor-free plane. (c) Microscopic view of perineural invasion from a Mohs section.

of the ear (3.1% vs 10.9%), primary SCC of the lip (5.8% vs 18.7%), recurrent SCC (10.0% vs 23.3%), SCC with perineural invasion (0% vs. 47%), SCC larger than 2 cm (25.2% vs 41.7%), and poorly differentiated SCC (32.6% vs 53.6%). The literature has reflected variations in the management of patients with SCC and perineural invasion, but several authors encourage interdisciplinary evaluation of these patients by a radiation oncologist for consideration of radiation therapy.

To highlight one anatomical site germane to head and neck surgeons, it is important to note that SCC of the scalp may be particularly aggressive and warrants careful management. This may be due to “field disease” or “field cancerization,” which refers to the confluence of extensive actinic keratoses and SCCs with follicular involvement that is associated with higher-than-expected recurrence rates after superficially destructive measures leading to difficulty achieving negative margins. In addition, the extensive vasculature and lymphatic drainage patterns of the scalp permit penetration and spread of the tumor. One hazard of this lymphovascular network includes the potential for in-transit metastases or foci of cutaneous SCC. In-transit

lesions arise within dermal or subcutaneous tissue that is distinct from the primary tumor site. They occur between the site of the primary or recurrent tumor and the closest regional lymph nodes and are thought to represent local lymphatic metastases (□ Fig. 46.6). It is critical to evaluate these patients for nodal and distant metastases. The in-transit lesions may be removed by either standard excision or MMS, followed by post-operative radiation therapy. MMS can be useful in cases in which there is difficulty distinguishing solitary in-transit metastasis from deep marginal recurrence.

46.4.4 Melanoma

Melanoma, a malignancy arising from melanocytes, is among the most common forms of cancer in young adults. The incidence of melanoma is rising worldwide; in the United States, the estimated lifetime risk for invasive melanoma is 1 in 1,500 for persons born in 1935, 1 in 600 for those born in 1960, and 1 in 62 for those born in 2006 (1 in 34 if in situ melanoma is included). Risk factors for developing melanoma include a history

Fig. 46.6 (a) In-transit metastasis from primary cutaneous squamous cell carcinoma (SCC). (b) In-transit metastasis from SCC in a transplant recipient. Intraoperative view of removal before complete clearance was achieved.

of sunburns and/or heavy sun exposure, blue or green eyes, blonde or red hair, fair complexion, more than 100 typical nevi, any atypical nevi, prior personal or family history of melanoma, and certain genetic mutations. Melanoma has the potential to metastasize to regional lymph nodes and distant organs, including liver, bone, and brain. There are four major subtypes of primary cutaneous melanoma, listed in order of frequency of occurrence from highest to lowest: (1) superficial spreading melanoma (60 to 70%); (2) nodular melanoma (15 to 30%); (3) lentigo maligna melanoma (5 to 15%); and (4) acral lentiginous melanoma (5 to 10%). The prognosis for a patient with melanoma is proportional to the depth of invasion of the tumor; patients with malignant melanoma in situ (tumor confined to the epidermis) have an excellent prognosis and a high cure rate after excision. The term lentigo maligna melanoma refers to melanoma in situ occurring on sun-damaged skin; it is most often encountered on the head and neck and may progress to invasive lentigo maligna melanoma. It is typically a slowly growing

tumor with a centrifugal pattern and thus grows radially as opposed to vertically.

Although wide local surgical excision remains the gold standard in the treatment of melanoma, there is growing acceptance and utilization of MMS for melanoma, particularly malignant melanoma in situ and thin melanomas. Excision margins for melanoma range from narrow (0.5 cm) for melanoma in situ to 2 cm for lesions of more than 2 mm in Breslow depth. For melanoma in situ, the commonly accepted 5-mm margin is based on the National Institutes of Health Consensus expert opinion and on data for melanomas on the trunk and extremities. However, with the growing utilization of MMS for melanoma in situ, new evidence may indicate that 5-mm margins are inadequate for achieving a tumor-free plane. A recent study of 1,120 malignant melanomas in situ excised with MMS followed by frozen section examination of the margins found that 86% of melanomas in situ were successfully excised with a 6-mm margin, whereas a 9-mm margin removed 98.9% of melanomas in situ. Although frozen sections have been shown to be 100% sensitive and 90% specific for detecting melanoma during MMS in some studies, these rates can vary significantly with surgeon ability and the processing technique of a given laboratory. It is important to note that special immunologic stains, including Melan-A/Mart-1, S100, Mel5, and HMB-45, have been used to enhance sensitivity in the detection of malignant melanocytes during MMS. Currently, rapid Mart-1 staining is most often used for this purpose.

Using MMS to accurately define tumor-free margins for melanoma is especially important on the head and neck, where recurrence rates have been shown to be high and function and cosmesis are important. Local recurrence rates after standard excision of melanoma on the head and neck approximate 9 to 13% but have been reported to be as high as 42% (□ Fig. 46.7). For lentigo maligna melanoma after MMS, recurrence rates as low as 1.4% have been reported. Another treatment option is termed staged excision. This refers to debulking of the tumor with a narrow-margin standard excision to confirm depth combined with en face evaluation or peripheral margins. The peripheral specimens are divided and the margins are inked to maintain true orientation; however, tissue is sent for standard formalin fixation and paraffin embedding. A diagnosis of remaining areas of positivity is available within 24 to 36 hours, and any residual melanoma may be removed subsequently in a directed fashion. Once the surgical margins are confirmed to be clear, wound management may involve secondary intention healing, primary closure, skin graft, or flap repair. It is important for patients to be aware that the final size of the surgical defect after the staged excision of a lentigo maligna melanoma on the head and neck can be 2 to 10 times the original lesion size.

46.5 Conclusion

Mohs micrographic surgery is a tissue-conserving surgical technique for excising and mapping high-risk skin cancers. It allows a histologic assessment of the complete circumferential surgical margin with immediate frozen sections or special stains. In addition to the benefits that MMS offers in terms of margin control and conservation of tissue, it has proved to be cost-effective

Fig. 46.7 Melanoma that recurred on the nasal tip after standard excision 4 years earlier. (a) Subtle appearance of recurrence. (b) Significant subclinical extension.

when compared with other modalities used to treat skin cancer. One study determined that the overall cost for MMS and immediate reconstruction by a fellowship-trained Mohs micrographic and reconstructive surgeon may be threefold less than the cost of surgery performed by a colleague from an allied surgical subspecialty in an ambulatory surgical center. In the correct clinical context, MMS provides patients with a treatment modality that leads to the highest cure rates and optimal functional and cosmetic results.

46.6 Roundsmanship

- Mohs micrographic surgery is the only technique that allows complete evaluation of the entire peripheral and deep surgical margin. This in turn allows maximal conservation of normal tissue with optimization of function and cosmesis.
- A key defining feature of MMS is that the surgeon excises, maps, and reviews the specimen personally, minimizing the chance of error in tissue interpretation and orientation.
- The American Academy of Dermatology general guidelines for MMS include (1) high risk for local recurrence, (2) areas requiring tissue preservation, and (3) high risk for metastasis.
- MMS achieves a 99% cure rate (compared with 91.3% for other methods) for primary BCC, and a 94.4% cure rate (compared with 82.4% for standard excision, 90.2% for radiation therapy, and 60% for curettage and desiccation) for recurrent BCC.
- For the following categories of SCC, MMS is associated with higher cure rates than traditional excisional surgery: primary

SCC of the ear (96.9% vs 89.1%), primary SCC of the lip (94.2% vs 81.3%), recurrent SCC (90.0% vs 76.7%), SCC with perineural invasion (100% vs 53%), SCC larger than 2 cm (74.8% vs 58.3%), and poorly differentiated SCC (67.4% vs 46.4%).

47 Grafts in Head and Neck Surgery

Thomas C. Spalla

47.1 Introduction

There will be times during head and neck surgery when reconstruction with one or more grafts becomes necessary. The graft may serve as the ideal reconstructive method for the defect; however, in some cases it may be a necessary, although not ideal, alternative. Regardless, the head and neck surgeon must have a firm understanding of the indications, surgical techniques, and complications that may arise from various grafting techniques.

As with any surgery, the surgeon must do his or her best to convey both the surgery and recovery periods to the patient and caregivers. In elective cases, the surgeon should have a good idea of whether or not grafts will be required for the surgery, although surprises do arise. The consideration of grafts preoperatively is necessary not only for informed consent (e.g., donor site morbidity); it also helps to have any additional instrumentation or personnel available in the operating room to facilitate a smooth operation. Preoperatively, conditions that may increase failure (smoking, diabetes, peripheral vascular occlusive disease, anemia, bleeding dyscrasias) must be examined and, if possible, their effects minimized. There should not be any hesitation to consult with other specialties (e.g., cardiology, endocrinology, hematology) so that the chance for the best possible outcome is maximized.

Grafts consist of numerous types of tissues, both native and foreign, and some of the most common will be discussed below. Each has its own unique indications, limitations, risks, and benefits, and a well-trained surgeon must have a firm comprehension of each of these.

47.2 Skin Grafts

Skin grafts play a large role in the repair of cutaneous defects in the head and neck. Some general principles must be kept in mind when a skin graft is considered as the means of tissue reconstruction. The skin graft is dependent on the recipient site for its blood supply. Ideally, the recipient site is well vascularized to provide a healthy bed on which the skin graft can survive. This tenet prohibits placing skin grafts over areas that are not vascularized, such as bone, cartilage, and bare tendon. However, there may be exceptions in which a small graft (i.e., one with fewer nutritional demands) successfully survives these conditions because of a robust blood supply delivered through the periphery via imbibition and neovascularization. It must also be kept in mind that because of the increased number of cells in the tissue and amount of tissue that is farther from the recipient bed (i.e., more superficial), full-thickness skin flaps require a greater blood supply for their survival. Also, the surgeon must try to match the skin tone and texture of the donor to the recipient site. This allows the best cosmetic result from a skin graft and helps to avoid the creation of a “patched” appearance.

Skin grafts are not limited to external indications. For example, skin grafts can be useful for intraoral defect coverage to decrease wound contracture and allow coverage of a large surface

that might alternatively have been left to undergo a prolonged course of secondary intention healing.

47.2.1 Split-Thickness Skin Grafts

Split-thickness skin grafts (STSGs) include the entire epidermis and a variable amount of dermis. Varying thicknesses can be used depending on the recipient site requirements (□ Fig. 47.1 and □ Fig. 47.2; □ Table 47.1). Thin grafts are often used when surveillance for tumor recurrence is important, and a thinner graft, although less cosmetically acceptable, allows an earlier detection of recurrence.

Keep in mind that the thinner the skin graft, the greater the chance for survival, but the greater the degree of contraction. The surgeon should thus harvest a graft that is larger (by approximately 25%) than the intended recipient site to allow for this contraction and a tension-free inseting.

47.2.2 Full-Thickness Skin Grafts

Full-thickness skin grafts (FTSGs) are helpful in situations in which the recipient site is not excessively large and the atrophic appearance of an STSG might be unfavorable (e.g., nasal tip). Additionally, FTSGs do not contract to the same degree as STSGs and therefore are appropriate in situations in which functional or significant cosmetic defects might result from significant contracture (e.g., eyelid defects).

Once the site of the defect is known and an FTSG is considered, the surgeon should examine the remainder of the patient’s head and neck for an appropriate donor site. Ideally, the donor site should match in color and texture. Areas of prominent sun exposure often match well with recipient sites having similar exposure. Additional points must be kept in mind. The surgeon must ensure the following: Harvesting will not cause undue morbidity; harvesting will not create issues with immediate, or in the foreseeable future, reconstructions; and the selected donor site is free of cancer. Also, if there is concern for early cancer recurrence associated with an aggressive cutaneous malignancy, the surgeon may wish to use an STSG or FTSG as a temporary measure before more definitive reconstruction after an appropriate period of recurrence-free surveillance. Common donor sites include pre- and postauricular skin, upper eyelids, melolabial fold, and the supraclavicular fossae.

As with all surgery, a detailed discussion of the risks, benefits, and alternatives with the patient and/or caregivers is necessary before proceeding because multiple options are frequently available, and the patient’s goals and expectations may not be in line with the surgeon’s. Despite the surgeon’s best attempts at color and texture match, the graft often ends up having some degree of “patchwork” appearance. This is usually most evident at first, while the blood supply is not yet strong, and becomes less noticeable over time (□ Fig. 47.3). The patient must be made aware of this.

FTSGs require a robust blood supply in the recipient site to ensure complete healing, which is often referred to as “take.”

Fig. 47.1 Diagram of the skin demonstrating levels of depth of various skin grafts.

Fig. 47.2 It is essential to tent the split-thickness skin graft away from the dermatome as the harvest progresses.

Table 47.1 Split-thickness skin grafts

Graft	Thickness (in)
Thin	0.008–0.010
Medium	0.011–0.015
Thick	0.016–0.018

Bolstering the reconstruction (□ Fig. 47.4), as detailed above, is necessary to ensure the best chance for a 100% take.

The potential for donor site morbidity is greater with FTSGs than with STSGs. Harvesting an FTSG requires layered closure of the donor site and almost always necessitates some degree of undermining to allow a tension-free repair. This creates some degree of dead space, which makes possible the development of a seroma or hematoma and, subsequently, infection. Meticulous surgical technique will keep this problem to a minimum and should not deter from the use of an FTSG. As with STSGs, additional procedures may be required to give the best possible final outcome.

Fig. 47.3 Lentigo maligna melanoma excised from the nasal dorsum with appropriate margins. Remainder of violated nasal subunits also excised, and defect repaired with a full-thickness skin graft (FTSG). (a) Preoperative view. (b) Intraoperative view showing margins of the lesion and surgical margins extended to incorporate nasal subunits. (c) Surgical specimen. (d) Surgical defect. (e) Supraclavicular FTSG sutured in place. (f) Postoperative view at 5 days. (g) Two-year view shows mild hyperpigmentation of the FTSG.

47.2.3 Dermal Grafts

Dermal grafts are similar to FTSGs except that they lack an epidermal component. They are infrequently used as a way to bulk up the dermal layer. At times, they may be used to raise a depressed scar. Autologous dermal grafts are harvested by first raising an STSG (that is left pedicled to the skin at one end), then excising the dermis and covering with the STSG. The development of allograft dermis has supplanted this technique because it saves time and avoids any donor site morbidity.

AlloDerm (LifeCell, Branchburg, NJ) is cadaver-derived dermis that acts as a framework for tissue ingrowth and thus resists infection and extrusion. It is often used to aid in mucosal reconstruction (e.g., partial glossectomy) and also may be interposed between the parotid bed and superficial muscular aponeurotic system (SMAS) after a parotidectomy in the hope of decreasing the incidence of Frey syndrome. Another unique application of AlloDerm is as a tissue bed and scaffolding for donor site defects after radial forearm free flap harvesting. However, Wax et al did note its potential shortcoming of a prolonged healing time in comparison with an STSG.

47.2.4 Fat Grafts

Fat grafting can be used for improving a variety of soft-tissue deficits. It can be harvested by liposuction or the en bloc resection of subcutaneous fat. The fat in these situations relies on the recipient site for its blood supply. Some amount of loss is expected in the early healing phase, and therefore overcorrection

is recommended. One of the difficulties encountered in fat transfer is resorption, which occurs with time. The timing and degree of resorption likely vary depending on technique, recipient site, graft preparation, and methods used to determine such lasting results. Despite these drawbacks, fat grafting has numerous applications in aesthetic (e.g., lip, nasojugal, malar, or full facial augmentation), functional (e.g., glottis insufficiency), and reconstruction (e.g., parotidectomy bed defect) settings.

47.2.5 Surgical Technique

Split-Thickness Skin Grafts

Most surgeons use a powered dermatome to harvest the STSG because this allows precise control over the thickness of the graft. The donor site is lubricated with mineral oil to prevent sticking and allow the dermatome to glide through the harvest, so that catching and tearing of the skin flap are avoided. Having an assistant gently grasp the ends of the skin with forceps as it passes through the dermatome is helpful to prevent bunching of the skin and subsequent tearing (see □ Fig. 47.2). Once the appropriate amount of skin is harvested, it should be stored in saline-moistened gauze. Do not immerse the graft in saline, or especially water, because this will promote edema within the graft and lead to maceration. Pinpoint bleeding is expected because the capillary loops in the papillary dermis will have been transected. Placing a gauze pad moistened with dilute epinephrine solution (1:100,000 to 1:300,000) is a simple way to slow the bleeding and facilitate the application of a dressing. The donor site may now be dressed with sterile bandaging in a

Fig. 47.4 (a) Skin defect of the right temple repaired with full-thickness skin graft, held in place with peripheral sutures and a tie-over bolster dressing. (b) Eight months later, at the time of repair of a second defect. Note mild hypopigmentation of the skin graft.

manner of the surgeon's preference. Some surgeons prefer a coating of antibiotic ointment followed by a nonadherent dressing and another layer of sterile dressing to act as padding and absorb the serous effusion, which is usually present for the first 48 to 72 hours. Other surgeons simply place a biosynthetic dressing, which permits re-epithelialization beneath its surface and avoids dressing changes in the early postoperative period.

Avoid the temptation to simply measure the recipient site and trim the graft accordingly on the back table. The error of excessive resection will force the surgeon to sew the "scraps" of this graft into the recipient site, fenestrate the remaining graft to allow it to reach the perimeter, or harvest a new graft. All of these situations should be avoided because they will not permit the best possible aesthetic outcome or will lead to additional donor site morbidity (which must be explained to the patient). An easy way to avoid this is for the surgeon to lay the oversized graft on the recipient site and place a tacking suture at the periphery before trimming the graft. Make incremental adjustments in graft size peripherally. Do not attempt to correct the entire graft size with one fell swoop of the knife. A few seconds of patience will pay off nicely in the end. Single-layered closure is all that is necessary at the periphery of the wound.

Preventing the accumulation of fluid (seroma or hematoma) beneath the graft is critical because its survival depends on the nutrition from the wound bed. Therefore, it may be wise to use interrupted sutures at the periphery to allow the egress of fluid beneath the graft. Some surgeons place tacking sutures in the central portion of the graft to help prevent it from lifting off the wound bed, thereby closing any dead space. This technique is particularly helpful with large grafts. Additionally, when larger grafts are used, creating a few fenestrations ("pie crusting") with a No. 15 blade may be helpful in allowing fluid egress. Drain placement is unnecessary, and the interposition of this foreign body prevents revascularization of the portion of the skin graft superficial to it.

No matter the size of the graft, bolsters are extremely helpful in promoting skin graft healing. Bolsters are usually created with fluffed gauze, or similar material, followed by a nonadherent dressing layer that is then coated with antibiotic ointment. This is then sewn over the graft with permanent monofilament suture. Bolsters serve two purposes. First, they eliminate dead space and prevent the formation of seromas beneath the graft; additionally, bolsters decrease the transmission of shear (laterally transmitted) forces across the graft. Shear forces disrupt the newly forming blood supply and may also traumatize the graft or recipient site, causing seromas or hematomas. Bolsters can be bulky and appear unsightly to the patient, but they are invaluable in graft survival and a favorable outcome. In general, bolsters are removed approximately 7 days after surgery unless the patient's clinical picture dictates otherwise. After bolster removal, the wound can be examined and local wound care applied.

Full-Thickness Skin Grafts

Because of the inherent definition of an FTSG, wound closure is necessary at the donor site. This is typically done in a fusiform fashion. Therefore, the surgeon must plan not only for the size of the necessary donor tissue but also for the excision of additional tissues around the donor site to prevent a standing cutaneous deformity.

Once the donor site is selected, a 10 to 15% overestimation of the recipient bed is wise because of the small amount of contracture that will occur. The skin is harvested and subcutaneous fat sharply trimmed away. This improves the chance for survival. The skin may be placed in saline-moistened gauze while hemostasis is obtained at the donor site and layered closure of this wound is performed.

The manner of inseting FTSGs is similar to that for STSGs, but "piecrusting" the graft is rarely indicated because these FTSGs are not generally much smaller than STSGs requiring this technique (e.g., coverage of a large scalp deficit).

Dermal Grafts

Autologous dermal grafts begin with the partial harvest of an STSG (thickness of 0.012 to 0.016 in). However, the STSG is left attached at the distal end. The dermatome width is reduced, and a deeper pass over the site is made (thickness of 0.012 to 0.014 in) to harvest the strip of dermis. The raised STSG may be tacked back down with a single layer of sutures, and a gentle dressing applied.

The dermal graft is then sutured into the recipient bed, typically with a dissolvable suture, with the dermal side facing superficially. In some situations, suturing is unnecessary, if migration is not an issue. AlloDerm is inserted in a similar fashion.

Fat Grafts

Fat grafts may be harvested through liposuction techniques or through open means. The surgeon's preference typically dictates the method chosen.

When liposuction is used, the abdomen is frequently chosen as the donor site because ample abdominal fat is usually present, and this remote site often allows a two-team approach to be used, thereby reducing operating time. During this technique, the surgeon must take care to stay in the subcutaneous tissues and avoid damaging the peritoneum. At the same time, the cannula opening must be directed away from the dermis. After harvest, a pressure dressing is sometimes used to decrease seroma and/or hematoma formation.

Open fat harvest may be performed similarly, with a small incision followed by scissor dissection of the skin away from the subcutaneous fat. The author generally prefers a semicircular umbilical incision if an abdominal fat harvest is being performed to prevent any additional abdominal scarring. If an abdominal lower quadrant incision is used, a left-sided incision is preferable to avoid confusing this scar with an open appendectomy incision. Also, marking the patient in an upright position with undergarments on is helpful to camouflage the position of the final scar.

47.2.6 Follow-up

If any sites of duskininess are seen, close follow-up is warranted. Local wound care (gentle cleansing with saline or peroxide to remove any crusting and the application of an antibiotic ointment) should be instituted, and any conditions that may contribute to this should be carefully reexamined and corrected. For example, seroma formation under the graft will decrease its ability to receive an adequate blood supply and therefore should be drained. Additionally, conditions such as tobacco use or uncontrolled diabetes may also lead to wound-healing issues and need to be managed post-operatively to maximize the chance for a successful outcome. Photography can be helpful in documenting and tracking the extent of the problem, and it serves as a means of future education for the surgeon and students. If sites of necrosis are seen, the aforementioned measures should be taken, but the area(s) of necrosis should be sharply excised so that they do not act as a growth medium for bacteria. Regrafting, or local tissue reconstruction, is not recommended at this time because the factors responsible for initial failure may still be present and lead to a repeat event, which is disheartening for both patient and surgeon. Rather, the area is reconstructed by allowing secondary intention healing of this site, and reconstruction at a later time is considered. An exception to this would be a moderate-size or large failure in an area where secondary intention would create functional impairment or a significant distortion of anatomical structures. In such situations, if the reasons for failure cannot be corrected or are unclear, then an alternative method of reconstruction should be considered to avoid a repeat situation.

As with all scars, the avoidance of ultraviolet light is critical in preventing long-lasting pigmentary changes. A sunblock or sunscreen of with a sun protection factor (SPF) of 30 or higher is recommended for the year after surgery. After successful healing, methods to improve the final aesthetic result can be considered. Camouflage with cosmetics is very helpful in both the short- and long-term management of residual aesthetic imperfections. A full discussion regarding dermabrasion is beyond the scope of this chapter, but dermabrasion to the periphery of the graft, as well as the facial subunit, can be considered to provide a better blending of color and texture. Also, certain laser and light applications may improve the final outcome by improving the surrounding skin. In general, these techniques are not covered by insurance companies, so they may not be a realistic option for many patients.

47.3 Cartilaginous Grafts

47.3.1 Nasal Cartilage

Septum

The quadrangular nasal septal cartilage is an invaluable source of graft material for the head and neck surgeon. The head and neck surgeon's familiarity with septoplasty makes the harvesting of this cartilage a rapid and low-risk procedure. In an otherwise normal and unoperated septum, the surgeon can expect to obtain a sheetlike piece of cartilage that is approximately 1 mm in thickness. It is easily cut into a desired shape and may be scored or morselized depending on the desired application.

One of the more common applications of the nasal septal cartilage graft is to improve a dysfunctional nasal valve. The size and shape of the cartilage allow it to be cut into rectangles (3 x 14 x 1 mm) easily and interposed between the upper lateral cartilages and the septum to widen the internal nasal valve. This technique can also be used to widen the middle vault of the nose and bolster upper lateral cartilages that may have been disrupted and have since collapsed into the nose. The nasal septal cartilage also is easily fashioned into batten grafts, which help resist external valve collapse.

Upper and Lower Lateral Cartilages

The upper and lower lateral cartilages of the nose are not generally considered primary autologous donor sites, primarily because of the aesthetic, and possibly functional, changes that may occur. However, during rhinoplasty, these cartilages may be trimmed (e.g., cephalic trim of the lower lateral cartilages). These remnants should be saved in moist saline gauze until the end of the case. In some instances, they can be crushed or morselized and used to camouflage minor irregularities, particularly of the nasal tip.

47.3.2 Auricular Cartilage

Auricular cartilage, generally harvested from the conchal bowl, is another frequently used source of graftable cartilage. Unlike nasal septal cartilage, auricular cartilage is bowl-shaped and therefore does not lend itself to certain applications. However, this shape is quite useful in nasal applications such as lower

lateral cartilage reconstruction, alar rim grafts (in layered reconstruction), and butterfly grafts (to improve the internal nasal valves). The ability to simultaneously harvest auricular cartilage while the recipient site is being prepared is another advantage of this site. Unlike nasal septal cartilage, auricular cartilage is fairly weak. It is thinner and more flexible and is not suitable for situations in which resilience is required; in older patients, it may be quite brittle. The morselization of auricular cartilage may lead to its destruction and an appearance of moist, wet dust.

Pre- and postauricular harvest is possible (□ Fig. 47.5). It is recommended that some form of bolstering technique (e.g., dental rolls or mattress sutures; see □ Fig. 47.5) be used when the donor ear is closed. This helps to reduce the possibility of a hematoma, which can lead to subsequent infection and chondritis, with a resultant “cauliflower” ear deformity.

47.3.3 Costal Cartilage

Costal cartilage is often used in situations of significant nasal and auricular reconstructions. It offers a reliably large piece of cartilage that can be carved to suit a host of reconstructive needs. One of the best-known uses for costal cartilage is in microtia repair. The creation of delicate features through cartilage carving requires expertise, and it is recommended that the surgeon practice this technique with substitute materials in his or her free time to gain mastery. However, no amount of ex vivo practice can reliably predict long-term postoperative results. The details of these techniques are covered in Chapter 52.

Costal cartilage can be harvested simultaneously in a two-team approach, thereby decreasing operative time. Donor site morbidity must be considered when costal cartilage is used. A chest wall scar may become unsightly, and its placement in a female patient must be carefully considered. During harvest, the possibility of pleural injury is real and may lead to a pneumothorax. If one is identified during surgery, purse-string closure of the defect over a red rubber catheter under negative aspiration should lead to a safe outcome. As with any costal harvest, a postoperative chest X-ray is performed to detect a pneumothorax. If one is identified postoperatively, a chest tube should be placed and any appropriate consultation for management made. Other considerations include a possible unsightly chest scar, chest wall pain, atelectasis, and pneumonia. Therefore, thorough informed consent is especially stressed in cases of elective and cosmetic surgery.

47.3.4 Homografts

When the surgeon identifies a reconstructive situation in which the use of cartilage would be beneficial, another option remains a possibility. Irradiated cadaveric cartilage may be used, and its use depends on several factors. If the patient or caregiver will not consent to the harvest of autologous cartilage, or if the additional risks of autologous cartilage harvest outweigh the possible benefits, cadaveric cartilage may be used. Although some report significant resorption in long-term follow-up, others have not found the rate to be as high.

In addition to resorption concerns, there exists a concern for warping of the homograft cartilage, as well as the fear of viral

Fig. 47.5 (a) Anterior approach to concha cavum harvest. The surgeon is elevating beneath the perichondrium; dissection is aided through hydrodissection with 1% lidocaine and 1:100,000 epinephrine. (b) Closure of the anterior approach. Mattress sutures with 4-0 plain gut were used to close the dead space and prevent an auricular hematoma.

transmission (although the author is unaware of any reported cases). It is easy to see why many surgeons prefer to harvest autologous cartilage.

47.4 Composite Grafts

Composite grafts contain two or more layers of tissue, and therefore, even more so than FTSGs, require a robust recipient site blood supply. For this reason, proper patient selection and minimization of patient comorbidities (smoking, glucose control, blood thinners) are crucial for graft viability.

A common indication for the composite graft is in nasal ala reconstruction. The root of the helix offers a reliable and aesthetically pleasing source for this reconstruction. Graft placement is similar to that for the FTSG. Meticulous hemostasis and surgical technique cannot be overemphasized.

47.5 Osseous Grafts

Osseous grafts are useful in a variety of head and neck reconstructions. These grafts can be placed with vascularized or nonvascularized methods. Free tissue transfer is covered in Chapter 49.

47.5.1 Nonvascularized Osseous Grafts

Split calvaria may be readily harvested for use in head and neck reconstruction, such as in a nasal cantilever graft for severe saddle nose deformities. An oscillating saw can be used to incise the outer calvaria, with care taken to prevent penetration through the inner calvaria and injury to the dura mater, which can result in an epidural or subdural hematoma. It is recommended that the surgeon, when harvesting calvaria, avoid suture lines to minimize the risk for dural injury.

Iliac crest offers a viable source of autologous bone. Oral surgeons frequently use the iliac crest for alveolar bone grafts when deficient native tissues preclude implant placement.

The ribs offer an alternative, although less often utilized, bone stock. As with cartilaginous rib harvest, the risks of this technique are real, and the bone stock at this site is generally less robust than that at the calvaria or iliac crest.

47.6 Implants

A variety of implant materials exist that offer flexibility in head and neck reconstruction without any donor site morbidity. No matter what the material, the risks for infection and rejection are greater than with any autologous material, and therefore the judicious use of foreign material and aseptic technique are mandatory.

47.7 Roundsmanship

- Split-thickness skin grafts (STSGs) include the entire epidermis and a variable amount of dermis, depending on the thickness.

- Full-thickness skin grafts contract less than STSGs.
- Dermal grafts can be used to raise a depressed scar. These grafts are harvested after an STSG has been raised. The STSG is left pedicled and then sutured back in position after the dermal graft has been taken.
- Composite grafts contain two or more layers of tissue, such as skin–cartilage or dermis–fat grafts.

48 Reconstruction of Facial Soft-Tissue Defects

Anthony P. Sclafani and James A. Sclafani

48.1 Introduction

The reconstruction of facial defects may be required after facial soft-tissue trauma or extensive infection, but it is most commonly required after the removal of skin cancers. Although any area of the body may be affected by these insults, the particular functional, psychological, and emotional significance of the facial appearance makes the seamless reconstruction of facial defects exceptionally important. The repair of such defects should (1) restore or maintain normal function of the affected and adjacent facial structures and (2) restore the integrity and appearance of the affected area(s) without (3) damaging or adversely affecting neighboring tissues.

48.2 Incidence of Disease

As noted, the most common reason for facial reconstruction is the repair of a defect caused by the removal of a skin cancer. In 2006, 3.5 million nonmelanoma skin cancers were diagnosed in the United States, affecting 2 million people. Basal cell carcinoma is the most common form, while squamous cell carcinoma accounts for approximately about one-fourth of cases. Nonmelanoma skin cancers were the fifth most common cancer in Medicare patients and accounted for 4.5% of Medicare costs for skin cancer in 2006. Approximately 100,000 cases of melanoma are diagnosed annually. Melanoma, by virtue of different treatment recommendations, typically generates larger defects. Approximately 80% of nonmelanoma skin cancers occur on the head, face, and neck, and 80% of these are on the nose. Other commonly affected areas in the head and neck are the auricles and upper lip.

48.3 Terminology

Soft-tissue defects of the face involve damage to or the destruction and loss of one or more parts of the facial envelope. A partial-thickness skin defect does not fully extend through the dermis (□ Fig. 48.1); because there is a reservoir of basal cells, such a defect can generally be managed expectantly, although in some cases, excision of the remaining dermis (converting the defect to a full-thickness skin defect) with repair is a good option. If, especially in traumatic cases, the skin has been incised in an oblique fashion and one side of the laceration has been undermined more than the other side, a trapdoor deformity (in which the flap is depressed relative to the surrounding skin) may develop.

In order to camouflage facial scars maximally, it is helpful to align them, as much as possible, with relaxed skin tension lines (RSTLs). RSTLs (□ Fig. 48.2) represent the facial skin's natural tendency to fold in a direction perpendicular to the dominant vectors of facial muscle contraction. Although RSTLs may fall within existing wrinkles, they exist in the absence of these and

can be best demonstrated by asking the patient to animate individually each part of the face.

The simplest of skin defect repairs is conservative care. As mentioned earlier, this may be appropriate in cases of partial-thickness injuries and includes cleansing and conservative débridement (when necessary); generally, occlusive or semioclusive dressings are applied, which promote faster healing by speeding epithelial migration over the remaining dermis. In cases of small, inconspicuous full-thickness defects, healing by secondary intention may be acceptable. This relies on the natural contractile properties of the wound in addition to epithelial migration from the wound edges. In general, wounds healed by this method generate hypopigmented, depressed scars; however, small defects, especially in concave areas such as the alar crease or the region immediately adjacent to the medial canthus, can undergo healing by secondary intention with excellent cosmetic results. Healing by secondary intention should be avoided in areas of significant cosmetic importance and in areas of highly mobile aesthetic units, such as the eyelids and lips.

Primary closure, in which the wound edges are advanced together and all injured layers of the skin are sutured, is typically the preferred method of repair, if possible. Simple closure is reserved for situations of minimal dermal separation and is performed with a single layer of sutures. Layered closure includes multiple layers of sutures (epidermal and at least one dermal layer). Complex closure may require some undermining of the wound edge and/or deeper (e.g., facial or muscular) layers of sutures. Ideally, the closure should align with RSTLs (□ Fig. 48.3).

Skin grafts (□ Fig. 48.4) may be required to repair skin defects and are characterized by thickness. Split-thickness skin grafts (STSGs) include the epidermis and a portion of the dermis; thin STSGs are 0.005 to 0.012 inches thick, whereas thick STSGs are 0.018 to 0.030 inches in thickness. STSGs are generally more viable and leave less of a cosmetic defect because the donor site can be allowed to re-epithelialize. However, repaired areas may be thinner and depressed, and they may contract more than those repaired with full-thickness skin grafts (FTSGs). FTSGs, on the other hand, contain epidermis and the full thickness of dermis. FTSG donor sites are typically closed primarily with a resultant scar, so that they must be placed in inconspicuous areas with significant skin laxity/redundancy. However, wounds repaired with FTSGs undergo less contraction and are less likely to be depressed than are those repaired with STSGs.

Cartilage grafts are frequently used to rebuild or reinforce structure, especially in the nose or ear. Septal cartilage typically yields flatter cartilage grafts, whereas conchal cartilage grafts are often chosen to take advantage of the natural curve of the concha.

Other types of grafts include composite grafts, which contain two or more distinct tissue types, such as skin–cartilage or mucosa–cartilage grafts. Dermis–fat grafts, harvested by first removing the overlying epidermis (either by dermabrasion or by raising an STSG) and then harvesting the dermis and the

Fig. 48.1 Layers and blood supply of the skin.

underlying fat as a unit, can be used to add bulk volume to areas of tissue deficit. A skin–cartilage graft is typically harvested from the concha or helix of the ear.

All grafts are separated from their natural blood supply during harvesting and are nourished initially through a process of serum imbibition, in which nutrients present in the serum are transferred passively from the wound bed to the graft. Generally within 72 to 96 hours, microvascular connections between the recipient site and the graft develop (arterial connections slightly earlier than venous ones) to support the graft.

Skin flaps are partially elevated segments of skin that maintain an intact bridge to the surrounding skin through which blood supply flows. Skin flaps can be categorized as random skin flaps (relying on blood flow through the subdermal vascular plexus) or axial flaps (based over and fed by a specific artery). Flaps can also be described by the way they are moved to repair a skin defect. An advancement flap is moved unidirectionally into an adjacent defect, whereas a rotation flap pivots around a defect. A transposition flap is moved over surrounding intact skin to reach its intended recipient site, and an interpolation flap crosses under or over surrounding skin to reach its final location, leaving a pedicle.

48.4 Applied Anatomy

The repair of facial skin defects most commonly relies on random skin flaps. The subdermal plexus is the principal blood supply in random flaps. The extensive vascular interconnections found in the subdermis allow opening of choke vessels to shunt blood through the diminished flap base, or pedicle, toward the flap tip. Some flaps, such as the forehead flap (based over one or both supratrochlear arteries), are axial in nature.

48.5 The Disease Process

48.5.1 Etiology

Skin defects may be a result of trauma but are more commonly due to the excision of skin lesions. Traumatic injuries should be carefully prepared, ensuring the removal of any necrotic tissue or debris. Bite wounds should be treated cautiously with appropriate antibiotic coverage (amoxicillin/clavulanic acid); animal bites, if not grossly contaminated, can be closed, but injuries from human bites should be treated with antibiotics and undergo delayed closure to prevent infection.

Fig. 48.2 Relaxed skin tension lines.

Fig. 48.3 Primary closures should be aligned as closely as possible to relaxed skin tension lines.

Fig. 48.4 (a-d) Types of skin grafts.

The majority of malignant skin lesions are nonmelanoma skin cancers. In the United States in 2006, more than 3 million non-melanoma skin cancers were diagnosed. Melanomas are less common, occurring at a rate of approximately 100,000 per year.

48.5.2 Pathogenesis

The incidence of skin cancer among Medicare recipients increased from 1.1 million cases in 1992 to over 2 million in 2006. This tremendous increase is expected to continue. These numbers reflect cumulative skin damage induced by sun exposure. The role of the immune system is highlighted by the increased incidence of nonmelanoma skin cancers in patients with chronic immunosuppression.

48.5.3 Natural History and Progression

Skin defects, whether resulting from traumatic wounds or the removal of skin lesions, are typically best repaired as soon as possible. Open skin wounds of the head and face, if they are not contaminated and are treated with local wound care and antibiotics as appropriate, infrequently become infected because of the excellent blood supply of the skin in these areas. However, these wounds will undergo progressive contraction during healing by secondary intention, which may distort surrounding tissues; moreover, the resultant scars are usually thin, pale, and waxy and will appear noticeably different from the surrounding normal skin.

48.5.4 Potential Disease Complications

Unrepaired skin defects can distort surrounding facial structures if allowed to contract. This may be as simple as a stellate scar with mild puckering of the skin in its immediate area. More problematic is the contracted scar that causes eyelid malposition or ectropion, lip malposition generating asymmetry or a “snarling” appearance, or retraction/notching of the nasal ala.

48.6 Medical Evaluation

48.6.1 Presenting Complaints

Patients with skin defects typically present acutely, either in an emergent setting after a traumatic injury or semiemergently after a planned skin excision by a dermatologist or surgeon. A thorough history should be obtained, with specific inquiries regarding any conditions that would be expected to impair proper healing. The length of time between skin injury and presentation should also be determined; traumatic wounds of the face should ideally be closed within 12 hours of injury, although this time should be shorter in areas with less robust vascularity. The mechanism and instrument of injury should be determined, as well; grossly contaminated wounds should undergo delayed closure, and any foreign bodies expected (e.g., glass shards or road debris in cases of motor vehicle accidents) should be anticipated. Finally, intercurrent injuries (e.g., intracranial or cervical injuries) as well as existing medical conditions should be managed first.

48.6.2 Clinical Findings, Physical Examination

A careful examination of the wound is essential to determine both the timing and method of wound care. The area should be gently cleaned and any blood clots removed. Grossly contaminated, open wounds can be irrigated with a warm saline solution pulsed through a 20-mL syringe fitted with an 18- or 20-gauge plastic intravenous catheter. The wound should be evaluated for its depth, as well as the viability of remaining attached skin, laceration of any vascular structures, exposure of any underlying cartilage or bone, and proximity to vital or highly mobile structures. Sharp débridement can be performed at this point if needed to assess the wound, but in general, this should be minimized and restricted to the removal of obviously devitalized or necrotic tissues and grossly contaminated tissues. The proximity of the defect to mobile structures (e.g., margins of the lips or eyelids, nasal alae) should be noted. If a traumatic flap of skin has been created, the edges should be inspected because these cuts are typically beveled and are more likely to develop a pincushion deformity (in which the skin on the concave aspect of a curved skin cut contracts and is raised compared with the skin on the convex side of the cut). These margins should be resected to generate perpendicular wound edges and prevent pincushioning.

48.7 Treatment

48.7.1 Medical Treatment

In cases in which the wound will be allowed to heal secondarily, rapid wound healing affords optimal appearance and patient comfort. After the wound has been appropriately cleaned and appropriate hemostasis ensured, a moist dressing should be applied. In the face, gentle wound care and coverage with an antibiotic ointment is generally sufficient and acceptable to the patient. Based on the size of the defect, these wounds may take 6 to 10 weeks to fully heal, but as noted earlier, acceptable cosmetic results may be achieved.

48.7.2 Surgical Treatment

Before any defect is reconstructed, a number of conditions need to be met. A simple, common sense paradigm of wound closure should be employed in determining the best method of wound repair (□ Fig. 48.5). The wound should be not infected; if infection is present (gross contamination should be assumed in cases of human bites), oral or intravenous antibiotics should be begun and antibiotic irrigation of the wound instituted for at least 48 hours before repair of the wound. If a tumor was removed, complete and proper oncologic resection should be ensured; if this is uncertain or if there is a high likelihood of recurrence, an STSG may be applied for wound coverage without impairing surveillance for recurrence. Partial-thickness wounds and small full-thickness wounds in cosmetically unimportant areas or in concave areas (e.g., the alar crease) can be allowed to heal by secondary intention with good cosmetic results, but they may take several weeks to heal. In other cases, the local tissue should be assessed for laxity; if sufficient, primary closure should be

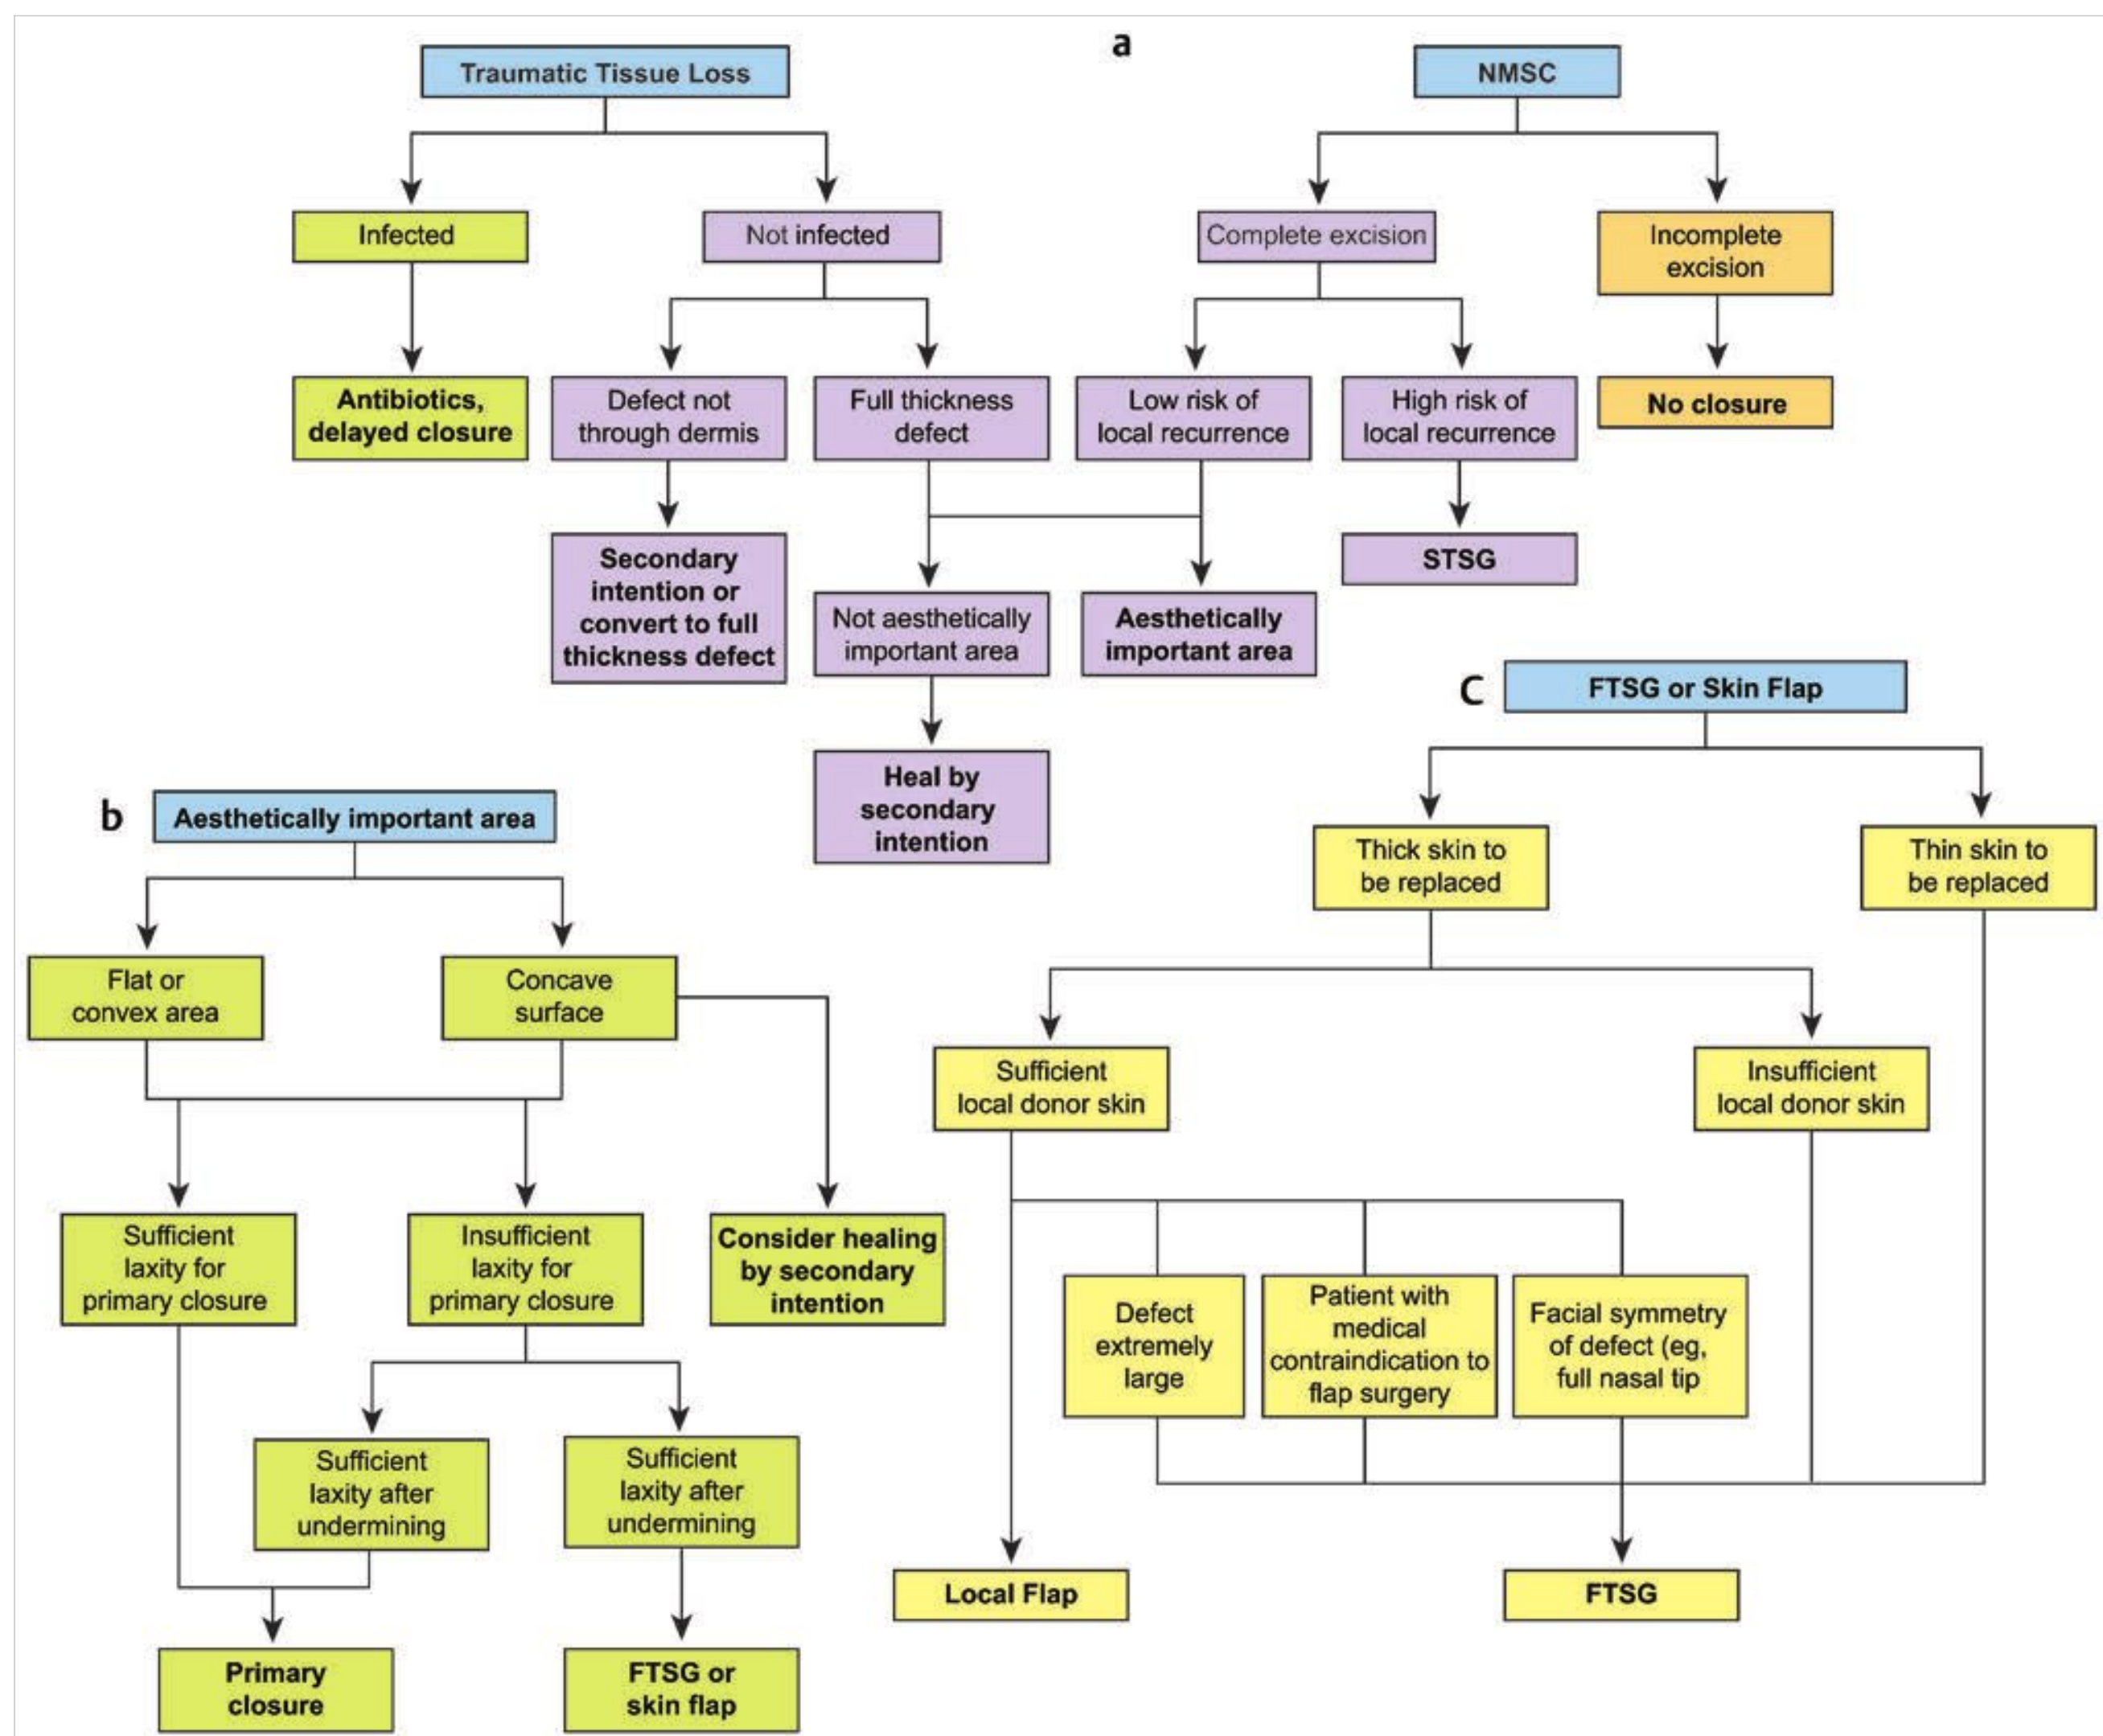

Fig. 48.5 Decision tree to determine the appropriate method of wound closure. (a) Traumatic lesion versus electively excised lesion. (b) Determining healing by secondary intention, primary closure, or full-thickness skin graft or local skin flap. (c) Choosing between FTSG and local flap. FTSG, full-thickness skin graft; NMSC, nonmelanoma skin cancer; STSG, split-thickness skin graft.

performed. Undermining in a subcutaneous plane peripherally from the defect can improve local tissue laxity, but care should be taken to avoid undermining too close to mobile structures (e.g., lower eyelid), which may be distorted by tissue movement. If primary closure is still not possible without producing unacceptable tension of the wound closure, either an FTSG or a skin flap may be used. Generally, the closer to the defect a graft is harvested, the closer the skin match. FTSGs for the face are most commonly harvested from the postauricular sulcus, but if sufficient laxity is present, they can also be harvested from the preauricular, non-hair-bearing area or (in patients with deep nasolabial folds) from the nasolabial crease. Contralateral eyelid skin can be used to repair eyelid defects, and this is often the best method of repair for eyelid defects. Larger FTSGs can be harvested from the supraclavicular fossa. On the nose, FTSGs are generally not used unless the defect is symmetrically located, especially on the nasal tip.

If there is sufficient adjacent donor tissue, a local skin flap (see Box Types of Facial Skin Flaps (p.381)) can be used to repair the defect. The specific flap design is chosen based on the size, shape, and orientation of the defect and its proximity to aesthetic unit borders, where scars can be hidden. The simplest flap is the advancement flap (□ Fig. 48.6), in which there is a unidirectional movement of the tissue. One or two relaxing incisions are made along or parallel to RSTLs, and the flap is moved in the same vector while the surrounding tissues are undermined to allow tissue movement. Advancement flaps are particularly helpful in the forehead, where the natural transverse creases are excellent places in which to hide the relaxing incisions. Near the base of the flap, the tissue adjacent to the flap may bunch into a “dog ear” or standing cone deformity, reflecting the shorter length of the flap than of the defect itself. A Burrows triangle, which in essence removes part or all of this skin excess, can be used to correct the deformity.

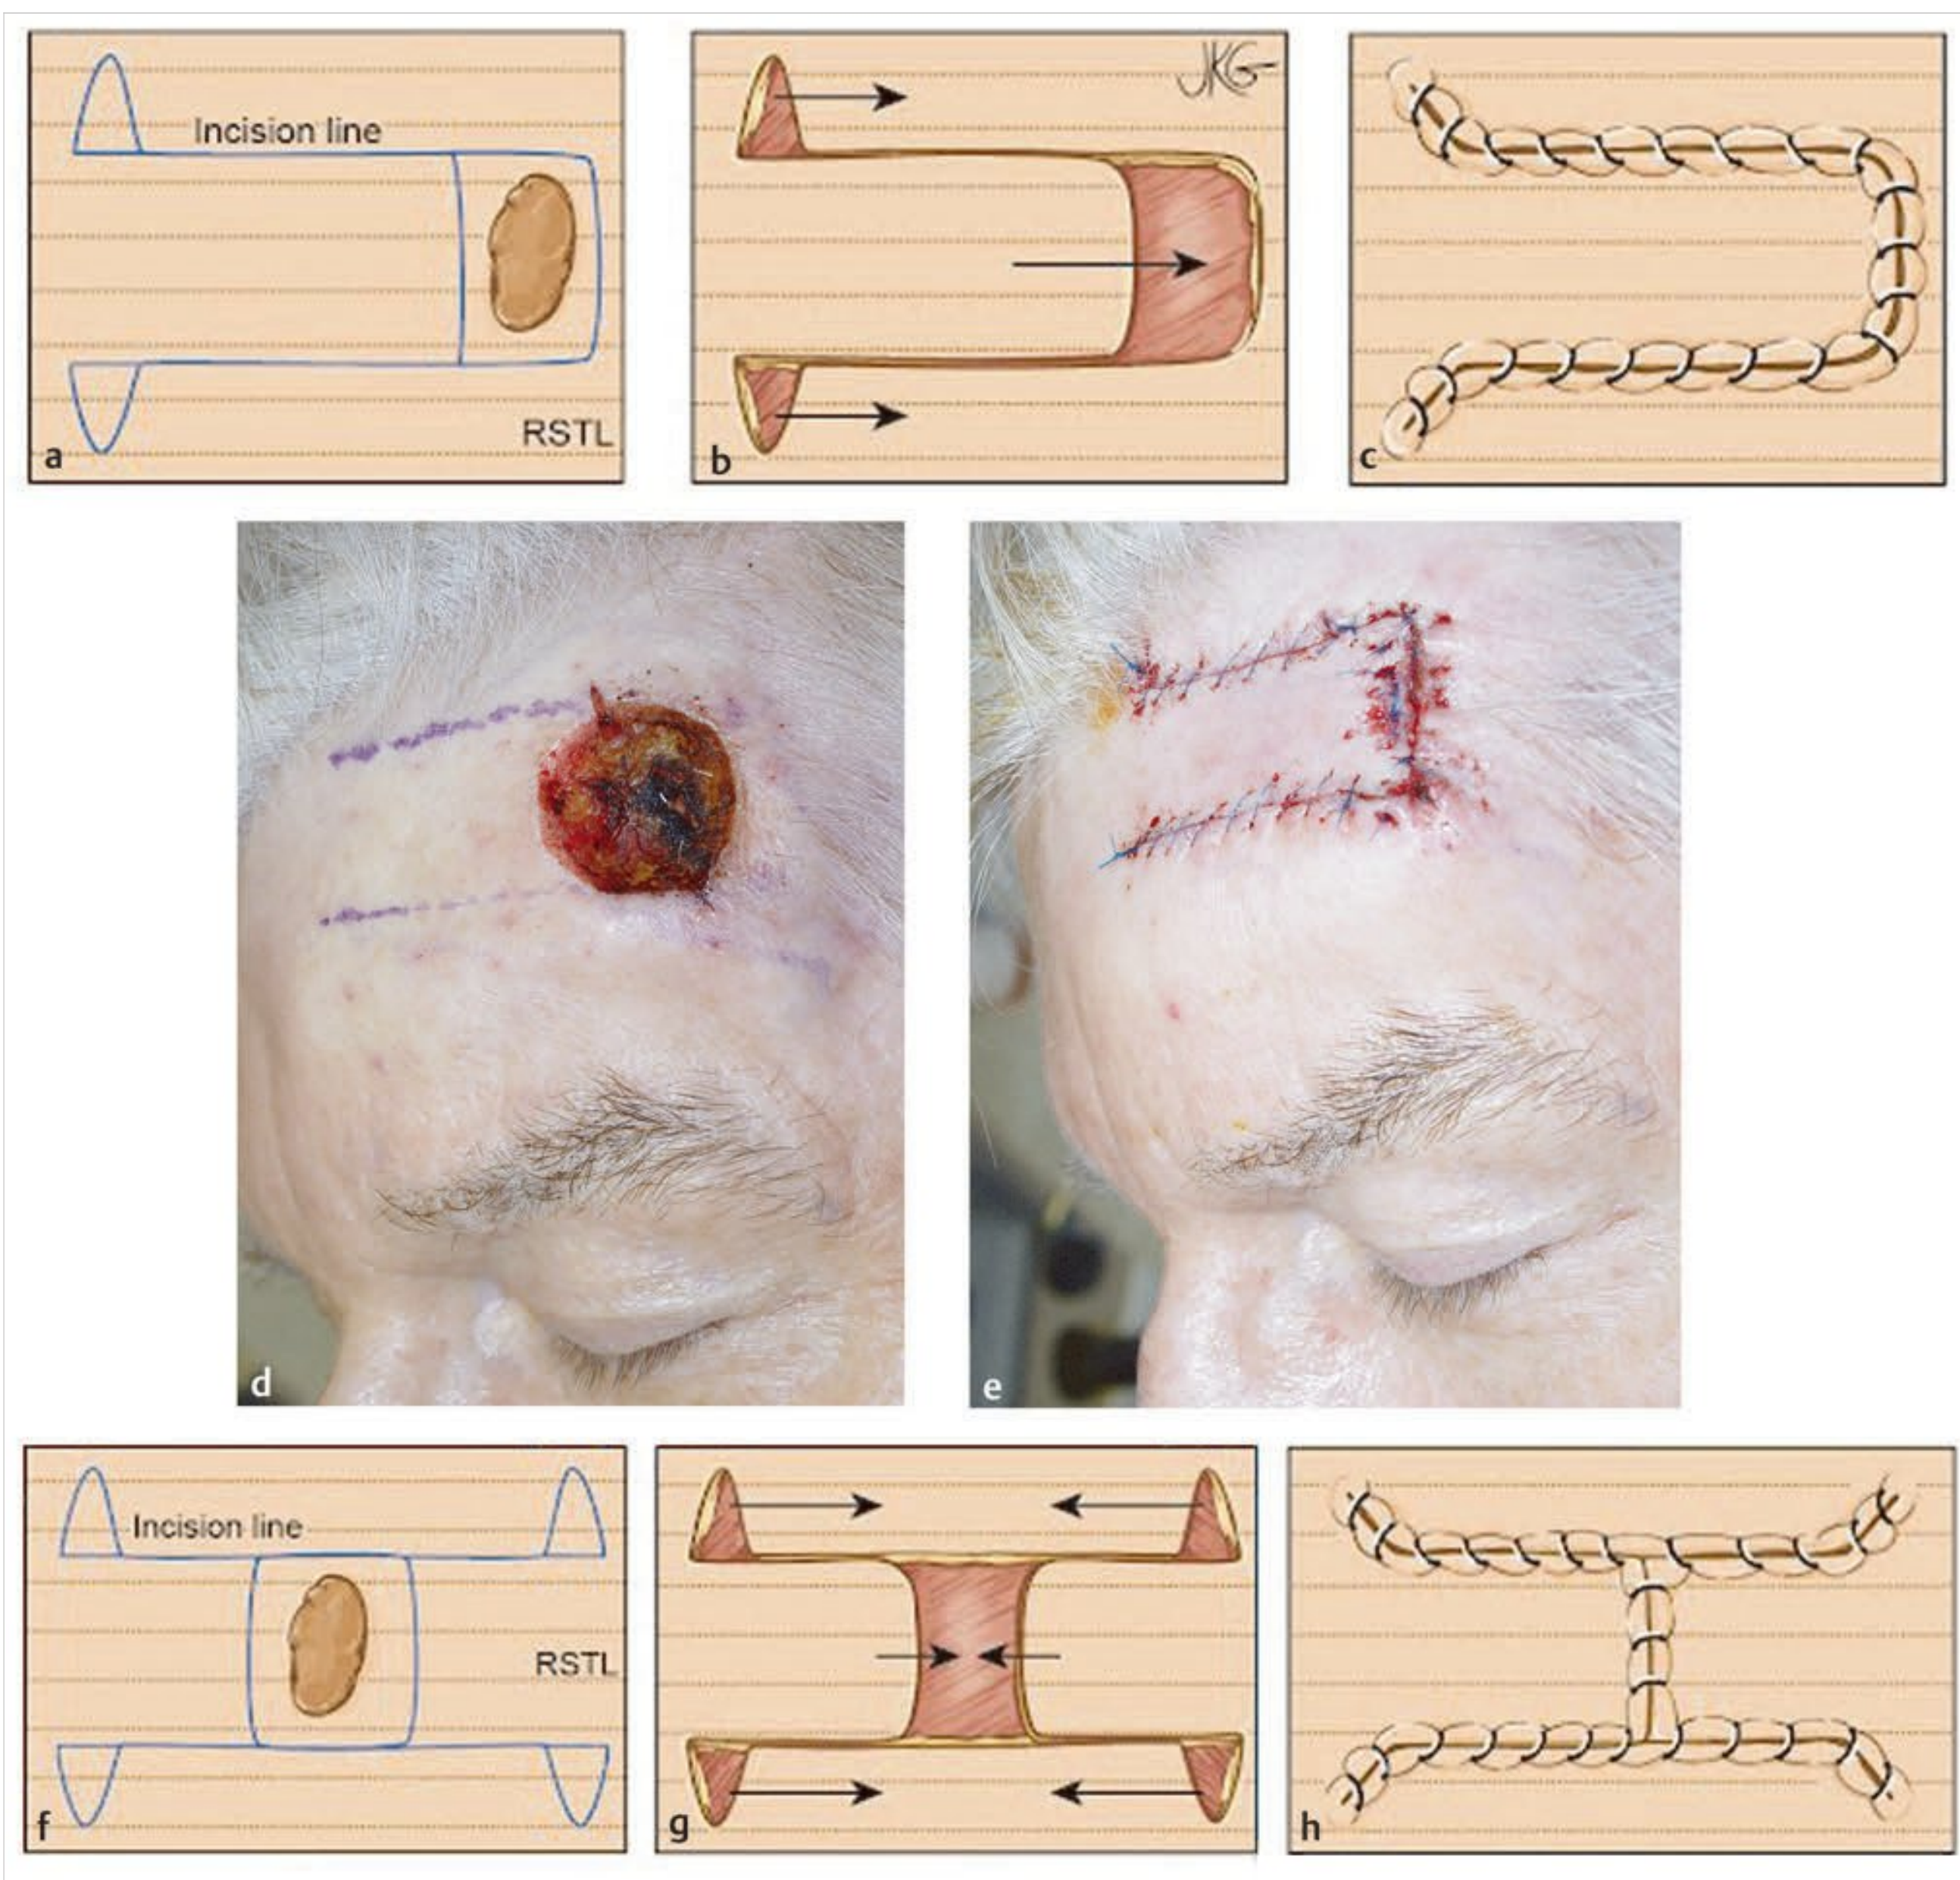

Fig. 48.6 Advancement flap. (a–c) Schematic of advancement flap. (d) Patient with a forehead defect closed with (e) advancement flap. (f–h) Bilateral advancement flaps can be used; Burrows triangles can be excised as necessary. RSTL, relaxed skin tension line.

Types of Facial Skin Flaps

- Advancement flap
 - Unidirectional movement into defect
- Rotation flap
 - Pivots around an axis
- Transposition flap
 - Transfer flap over normal intervening skin
- Interpolation flap
 - Flap with non-inset pedicle

A rotation flap (□ Fig. 48.7) pivots around a point adjacent to its base after a curvilinear incision is extended to a length approx-

imately four times the distance from the pivot point to the distal aspect of the defect. Again, a Burrows triangle may be needed to correct the standing cone deformity. Rotation flaps are quite useful in the cheek, where the RSTLs are curvilinear. An O-T closure is essentially the use of bilateral rotation flaps when tissue rotational laxity is adequate and there is an aesthetic boundary or RSTL in which to hide the scars. O-T closures are very useful in the lips and the superior forehead (□ Fig. 48.8).

In transposition flaps, such as rhombic and bilobed flaps, tissue is transferred across a bridge of intact skin to be inserted into the defect. Transposition flaps are based on geometric patterns. The classic rhombic flap (□ Fig. 48.9) visualizes a rhombus with two 60-degree and two 120-degree angles. The

Fig. 48.7 Rotation flap. (a–c) Schematic of a rotation flap. (d) Patient with extensive defect of the temple repaired with (e) advancement flap above the brow combined with a temple rotation flap. This required excision of a Burrows triangle along the lateral orbital rim. (f) Patient 3 weeks after repair. RSTL, relaxed skin tension line.

rhombus is ideally oriented with its short axis parallel to RSTLs. An incision, equal in length to the short axis, is made from the defect margin as an extension of the short axis, and a back cut is then made equal in length and parallel to the side of the rhombus. The outlined flap is elevated, the donor site is advanced and closed primarily after wide undermining, and the flap is transposed into the defect. The Dufourmental modification (□ Fig. 48.10) is used when the defect is relatively narrow and conversion to a rhombus would sacrifice a significant amount of normal skin. Instead, a narrow rhom-

boid is drawn around the defect. The first limb of the flap is angled to bisect the angle formed by the short-axis extension and the extension of the adjacent rhomboid side. The back cut is equal and parallel to the side of the rhombus. The flap generated is narrower than the standard rhombic flap; in order to facilitate closure, a Webster M-plasty is performed at the base of the defect, which serves to narrow the defect size. The rhombic flap allows alignment of the incisions with RSTLs fairly easily, but it leaves scars that are somewhat unnaturally sharp-angled.

Fig. 48.8 O-T closures. (a) Preoperative markings around an upper lip defect indicate incisions along the vermilion border, undermining of the upper lip, and planned Burrows triangle along the right philtral column. (b) After closure, incisions lie along the vermilion border and on the right philtral column. (c) Two weeks after repair. (d) Forehead defect with transverse forehead rhytids marked. (e) Immediately after O-T repair, with Burrows triangle excised superiorly. (f) Four weeks after repair.

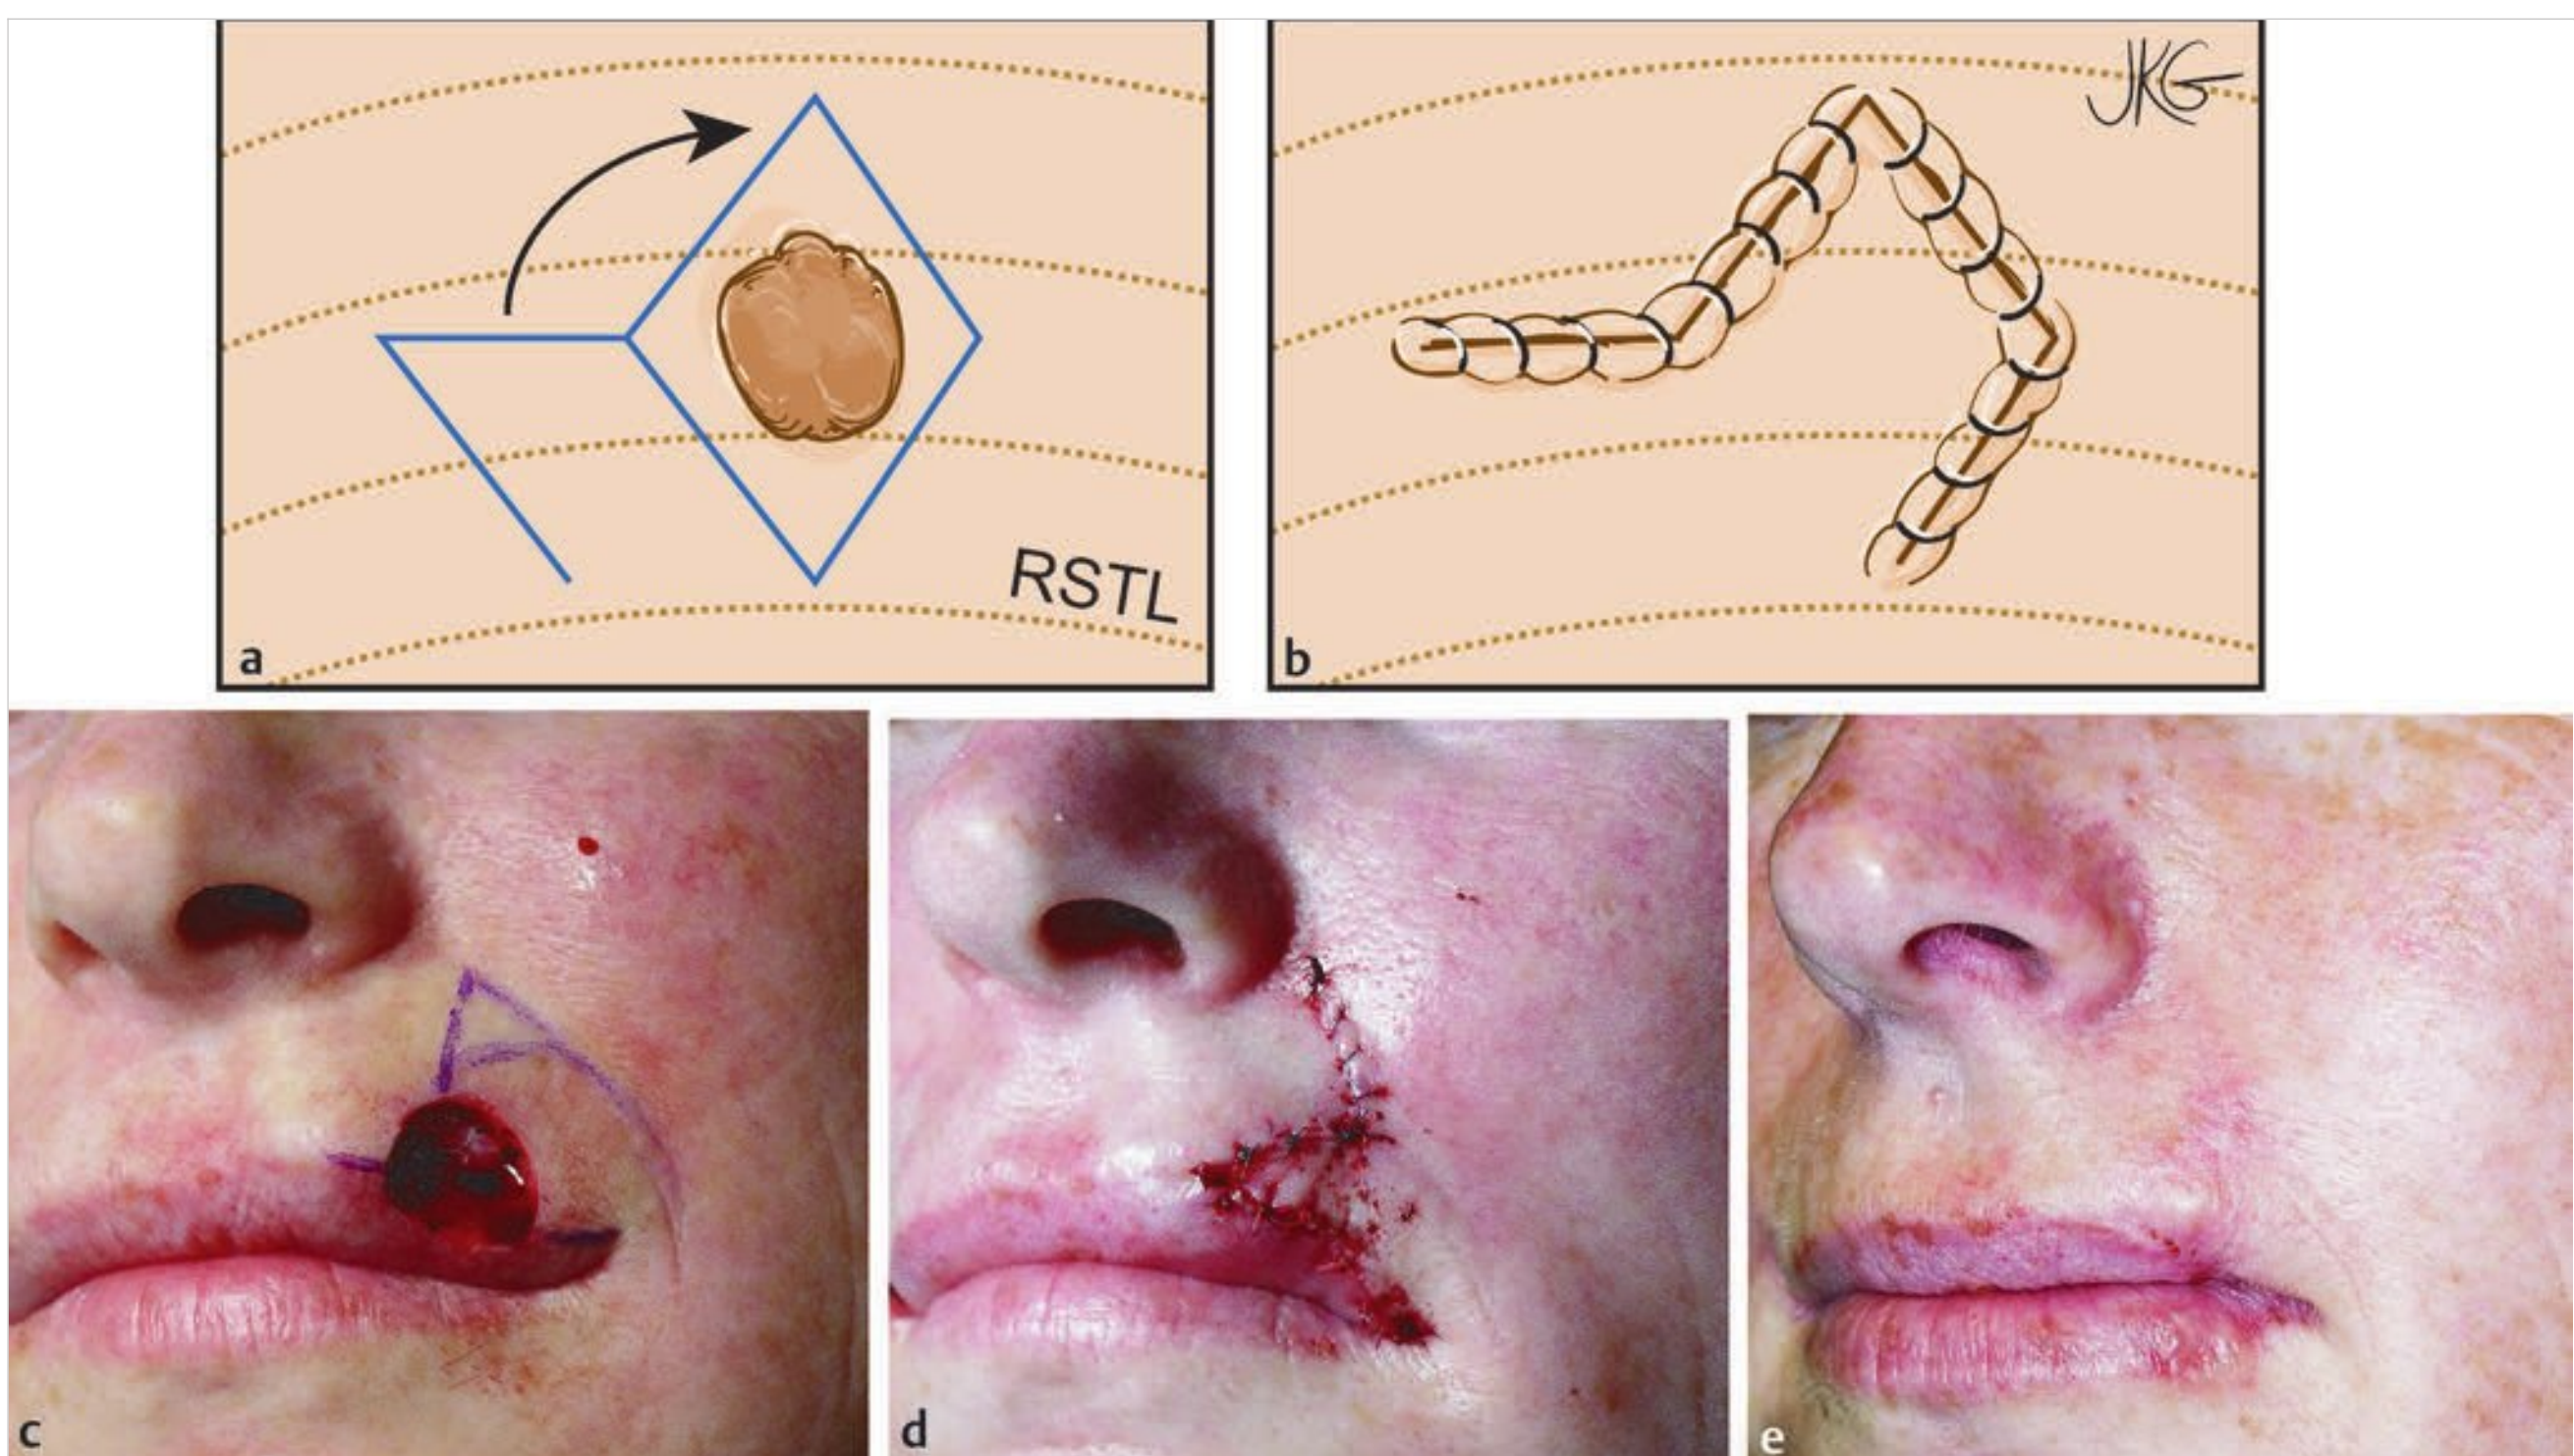

Fig. 48.9 Rhombic flap repair. (a,b) Schematic of a rhombic flap. (c) Defect of the right upper lip with rhombic flap drawn to lie in the nasolabial fold. (d) The rhombic flap is rotated clockwise into the defect, and the donor site closed primarily. (e) Three weeks after rhombic flap repair. RSTL, relaxed skin tension line.

Fig. 48.10 (a,b) Schematic of a Dufourmental rhombic flap repair. RSTL, relaxed skin tension line.

Fig. 48.11 Bilobed flap repair. (a–c) Schematic of a bilobed flap repair. The curvilinear lines represent arcs extending through the distal aspect of the defect as well as the center of the defect and curving around a defined pivot point. The first flap is drawn to be 80% of the width of the center of the defect, while the secondary flap is drawn to be 75% of the width of the center of the primary flap. The primary flap closes the defect, the secondary flap closes the primary flap donor site, and the secondary flap donor site is closed primarily. (d) Patient with nasal tip defect and bilobed flap drawn. (e) Bilobed flap rotated in place. (f) Four weeks after bilobed flap repair of nasal tip defect, with mild primary flap pincushioning that required subsequent intralesional corticosteroid injection.

Fig. 48.12 (a) Defect of the alar crease and superior nasolabial fold. (b) Island pedicle flap with attached adjacent subcutaneous tissue advanced into defect. (c) Island pedicle flap advanced and sutured in place. (d) One week after repair of defect with island pedicle flap.

Bilobed flaps are most commonly used in lower nasal repairs less than 2 cm in diameter or in the occipital region. The bilobed flap (□ Fig. 48.11) is aptly named because it is composed of a rotation/transposition flap with two lobes. A pivot point is chosen, and two arcs are drawn around this; the first extends through the center of the defect, and the second runs tangentially through the outer aspect of the defect. The first lobe is

designed to be directly adjacent to the defect with its apex abutting the outer arc, and it should create no more than a 45-degree angle from the defect. The diameter of the primary lobe should be about 80% of the width of the defect. The second lobe also runs at less than 45 degrees from the first lobe, with a diameter that is approximately 75 to 80% the width of the first lobe. The surrounding tissues are undermined widely, and the

Fig. 48.13 Paramedian forehead flap. (a) Through-and-through defect of the right ala. Markings for cheek flap advanced into the alar crease and right paramedian forehead flap. Internal lining reconstructed with a septal flap and alar support re-created with a cartilage graft. (b) One week after paramedian forehead flap, with pedicle attached at the origin of the right supratrochlear artery. (c) One week after pedicle division (3 weeks after first stage of forehead flap).

donor site for the second lobe is closed primarily; this is facilitated by elevating the lobe as an extended flap with an angle of (no more than) 30 degrees at its distal end. The primary lobe is transposed into the defect while the second lobe is moved into the defect from the primary lobe. A bilobed flap allows the tissue to be shared over a wider area at the cost of a somewhat more complex scar. Rhombic and bilobed flaps are generally useful in closing defects up to 2 cm. Points of significant tension occur at the distal aspect of the flap, as well as at the point where the donor site meets the defect.

An island pedicle flap (□ Fig. 48.12) transfers a segment of skin vascularized by a subcutaneous pedicle that can be tunneled under adjacent tissue and avoids removing or distorting tissue adjacent to the defect.

Facial defects larger than 2 cm may require larger flaps, including cervicofacial flaps. Incisions for these flaps can be hidden in the pre- or postauricular crease and along the anterior border of the sternocleidomastoid muscle. Large nasal defects can be repaired successfully with a forehead flap. A midline forehead flap is based over both supratrochlear arteries and consequently has a wide base, which limits its arc of rotation and reach. The paramedian forehead flap (□ Fig. 48.13) is based on a single supratrochlear artery and has a much narrower pedicle; a narrower pedicle allows more effective rotation and a longer reach of the flap, and it can be used to reconstruct the nasal tip and columella. These flaps can be extended behind the frontal hairline, if necessary, but the use of hair-bearing skin for reconstruction often necessitates subsequent laser hair removal. The flap is turned and sutured to the distal aspect of the defect, while the pedicle from the brow area remains in place until blood supply to the distal end of the flap develops and crosses the scar from the surrounding skin. The donor site is generally closed primarily.

48.7.3 Complications (see Box Complications of Skin Defect Repair)

Contraction around areas allowed to heal by secondary intention can lead to tissue distortion if it occurs near mobile structures, such as the eyelids or lips. Repair of skin defects is generally quite successful, and although always possible, flap failure from arterial compromise or venous engorgement is uncommon. Because tissue has been lost, there is always some tension on the skin closure. Scars may become hypertrophic, widened, or hyperpigmented. With typical postoperative swelling, there may be some compromise to the superficial layers of skin of the distal flap (epidermolysis). The flap itself may stay swollen and raised (pincushioning) as excessive fibrosis develops (and may require corticosteroid injections), or less commonly, the flap may be depressed below the surrounding skin (trap door deformity). Finally, preexisting telangiectasia may become more prominent, or the scar may remain persistently erythematous after flap surgery and require laser treatment.

Complications of Skin Defect Repair

- Flap failure
- Scar issues (hypertrophy, keloid, dyspigmentation, depressed or widened scars)
- Dehiscence (secondary to excessive wound tension, infection, poor vascularity)
- Epidermolysis (if leads to deeper loss)
- Pincushioning/trap door deformity
- Scar retraction or distortion of surrounding skin

48.8 Roundsmanship

- Skin defects should be repaired with the method that most effectively fills the defect while generating the simplest scar.
- Repair should be performed only when there is no infection and complete resection of any malignancy is certain.
- Undermining of surrounding tissues facilitates tensionless closure.
- Incisions used to harvest flaps should be placed at the borders of aesthetic units and so that they blend maximally into relaxed skin tension lines.

49 Myocutaneous and Free Flap Reconstruction

Grigory Mashkevich

49.1 Introduction

Complex defects of the head, neck, and upper aerodigestive tract often necessitate the transfer of regional or distant tissue in order to restore lost volume and function. Regional myocutaneous flaps and free flaps can provide the optimal bulk and three-dimensional configuration to match virtually any defect in the head and neck region. In previously irradiated patients with head and neck cancer, this method of reconstruction provides healthy, well-perfused tissue capable of withstanding the rigors of wound healing in a compromised tissue bed. Flap surgery requires meticulous planning with a targeted set of goals aimed at restoring volume and diminishing any functional impairment with respect to speech and swallowing.

49.2 Incidence of Disease

Regional and free flap repair is necessary in a small percentage of patients with head and neck cancer, trauma, or congenital anomalies. This method of reconstruction is typically reserved for large wounds, existing or anticipated, that are not amenable to primary closure.

49.3 Terminology

Free tissue or free flap reconstruction is a surgical procedure during which a segment of tissue, with its own intact vasculature, is harvested from a donor area and transferred to a recipient site. The artery and vein(s) perfusing the flap are cut in the donor region and sutured to recipient vessels in the head and neck via a process called microvascular anastomosis. In contrast, regional tissue transfer mobilizes healthy tissues from areas immediately adjacent to the head and neck. These areas include the anterior chest wall (pectoralis major flap) and posterolateral chest wall (latissimus dorsi flap). Regional flaps are most commonly transferred in a pedicled fashion. During pedicled transfer, the base of the flap at the site of perfusing blood vessels is progressively narrowed. This allows greater arching and mobilization of the flap while the connection of the perfusing blood vessels to their source is retained. The term composite refers to flaps containing multiple tissue types (skin, fat, muscle, and/or bone). Myocutaneous and osteocutaneous flaps are examples of composite flaps.

49.4 Applied Anatomy

The anatomy of the regional and free flaps most commonly used for head and neck reconstruction is outlined in □ Fig. 49.1 and □ Table 49.1. The salient points about each flap are discussed in the surgical section of this chapter. The pertinent head and neck anatomy includes recipient blood vessels, which are selected based on availability. In oncologic cases, tumor involvement, previous surgeries, and prior fields of radiation therapy determine vessel access. The facial and lingual arteries

are most commonly used for arterial anastomosis. The facial artery can be readily identified on the posterior surface of the submandibular gland. The lingual artery has a close relationship with the hypoglossal nerve, which lies immediately superficial to it at the anterior aspect of the external carotid. The external jugular, common facial, and internal jugular veins are the largest-caliber veins in the neck. They are optimal for venous anastomosis owing to their location, length, and availability in the majority of cases. The anterior jugular veins should be avoided because of their proximity to the tracheotomy site (if one is needed). In a vessel-depleted neck, ipsilateral transverse cervical vessels or contralateral neck vessels are alternative choices. Transverse cervical vessels can be found in the lower portion of the neck, below the level of the omohyoid muscle (level IV). These vessels are commonly spared during neck dissections and lie outside most fields of radiation to the head and neck, making them less susceptible to radiation-induced intraluminal stenosis.

49.5 The Disease Process

49.5.1 Etiology

The extirpation of oncologic disease is the leading cause of large head and neck defects requiring reconstruction with regional and distal flaps. Trauma and congenital deficits are less common etiologies.

49.5.2 Pathogenesis

The evolution of surgical defects in the head and neck is determined by the tumor location and the need to obtain clear margins. Wounds may result in large losses of sensate skin or mucosa, cranial nerve damage, and impairment of critical functions such as speech and swallowing.

49.5.3 Natural History and Progression

Flap transfer to a recipient site leads to the gradual development of vascular interconnections between the flap and surrounding tissues. Initially, flap survival depends solely on perfusion through the vascular pedicle of the flap. At about 3 weeks, sufficient circulation is established across the flap borders such that transferred tissue may survive without its pedicle. This rule does not apply in settings of previous radiation therapy, in which the circulation in the recipient tissue bed is poor and longer periods of time are required for healing.

49.5.4 Potential Disease Complications

Flap failure can present as arterial or venous obstruction. The most common cause of each is thrombus formation. Multiple factors can lead to this event, including poor vessel geometry (kinking or twisting), a poorly executed anastomosis (insufficient vessel preparation and cleaning, or inadvertent placement of sutures spanning the vessel lumen), or underlying medical

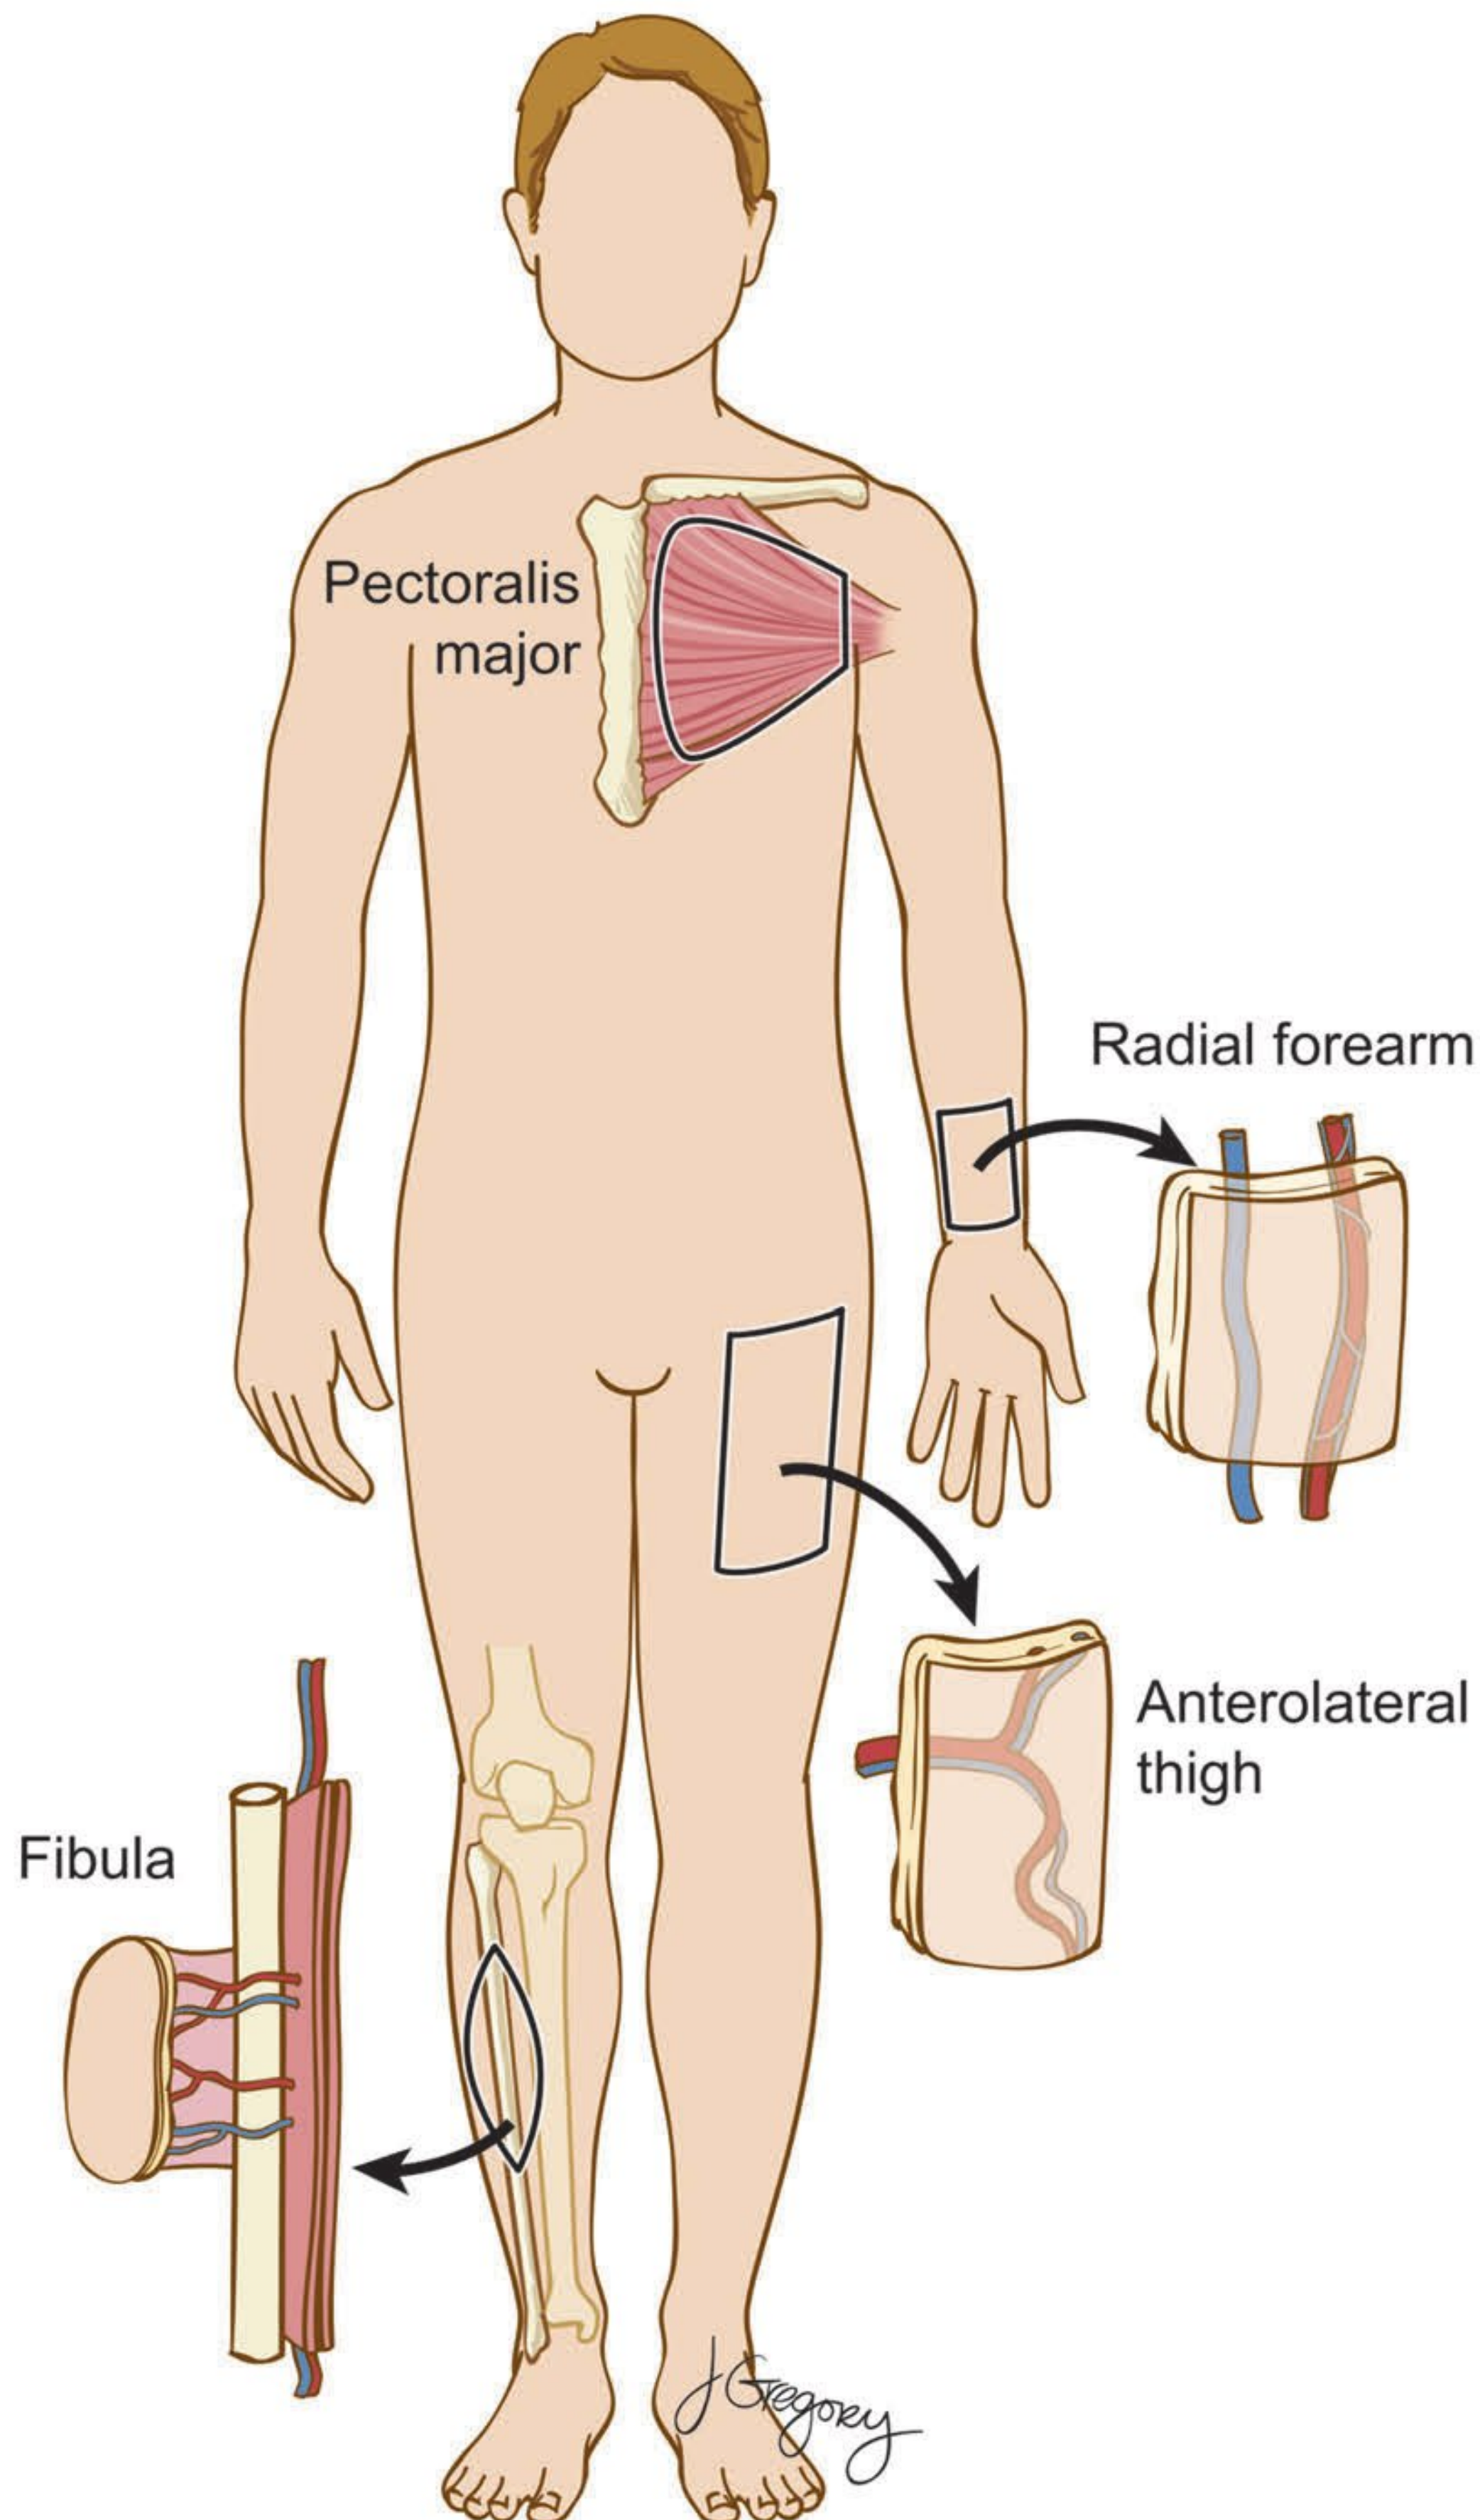

Fig. 49.1 The most commonly used flap donor sites for head and neck reconstruction.

Table 49.1 Regional and distal flap anatomy

Flap source	Flap type	Artery	Vein	Nerve	Defect
Pectoralis major	Pedicled, regional, or free flap	Pectoral branch of thoracoacromial and lateral thoracic	Venae comitantes	Lateral and medial pectoral nerves	Soft tissue ^a
Latissimus dorsi	Pedicled, regional, or free flap	Thoracodorsal	Thoracodorsal	Thoracodorsal (motor)	Soft tissue ^a

^aBone can be incorporated in rare circumstances.

problems predisposing to a hypercoagulable state. Clot formation is most common within 72 hours of the creation of a microvascular anastomosis. Insufficient arterial flow through the flap manifests as pale tissue, absent blood flow on needle pricking, and missing arterial Doppler signal. Venous obstruction results in engorged tissues, with continuous dark venous oozing on needle pricking and a single-phase “water hammer” signal on Doppler ultrasound in the initial stage of flap failure. Both scenarios necessitate urgent return to the operating room for reexploration of the blood vessels, clot evacuation, and revision of the anastomosis. If the revision is performed within 4 to 6 hours, the success rate approaches 50%

49.6 Medical Evaluation

A patient undergoing regional and free flap transfer must receive a comprehensive medical evaluation, with specific emphasis on cardiovascular and pulmonary health. The patient’s condition must be optimized to withstand long operative times under general anesthesia. Any risk factors adversely affecting wound healing should be assessed, including poor nutritional status, smoking, previous radiation therapy, connective tissue disorders, peripheral vascular disease, and diabetes.

49.6.1 Presenting Complaints

The presenting complaints revolve around the disease process requiring flap reconstruction. Flap-related preoperative concerns typically include the length of hospital stay, potential disfigurement of the donor site, and speech and swallow results following the operation. These must be addressed in sufficient detail in order to establish appropriate expectations and reduce preoperative anxiety.

49.6.2 Clinical Findings, Physical Examination

A general physical examination of all potential donor sites is required in order to assess any evidence of previous trauma or

surgery. Either of these may preclude flap harvest at a site because of concerns about potential vascular trauma. Particular to the radial forearm, an Allen test is done to ensure that the ulnar artery can supply the entire palmar arch on its own. During this test, performed on the nondominant hand of the patient, the radial and ulnar vessels are occluded and the patient is asked to make a fist several times, thereby exsanguinating the hand and thenar eminence. This is followed by release of the ulnar artery pressure and an assessment of the capillary refill time, judged by observing the return of a pink hue to the thumb. A time of less than 5 seconds indicates sufficient circulation and an adequate contribution by the ulnar artery to the distal aspect of the palmar arch. In poorly cooperating patients, or in those with dark skin color, the Allen test can be performed instead with a pulse oximeter.

Examination of the thigh focuses on skin laxity and the degree of subcutaneous tissue bulk. Excessive thigh fat may prevent the use of this site in soft-tissue defects around the airway because of concerns for potential compromise. In certain defects, such as total glossectomy, bulk may be desirable and is a positive feature of this site. A pinch test can determine whether a patient’s thigh has sufficient laxity, with generally 8 to 10 cm of excess skin considered a desirable amount.

Examination of the leg focuses on palpation of the dorsalis pedis and posterior tibial pulses. Signs of peripheral vascular disease may consist of weak or absent pulses, cyanosis of the digits, and hair loss in the distal lower extremity. Any examination findings must be corroborated by vascular imaging (see below), which is the single most important determinant of suitability of the fibula as a donor location.

49.6.3 Testing

For a fibular free flap, magnetic resonance (MR) angiography can precisely assess the vascular anatomy of the leg. Certain congenital configurations or peripheral vascular disease involving the peroneal artery can be detected by MR angiography and preclude the use of this flap.

Table 49.2 Defect location and flap selection

Defect site	Location	Appropriate flap/reconstruction
Orbit	Orbital exenteration without eyelid preservation	Split-thickness skin grafting followed by osseointegrated implants and globe prosthesis
	Orbital exenteration with eyelid preservation	Orbit obliteration with RFFF followed by ocular prosthesis fitted into the upper and lower fornix
Maxilla	Superior maxilla with orbital exenteration	Orbit considerations as above; ALT or RAFF in cases of cavity obliteration; rib or split calvaria for infraorbital rim grafting
	Inferior maxilla and hard palate	Dental obturator or FFF
Oral cavity	Partial glossectomy	RFFF or thin ALT
	Hemiglossectomy	RFFF or thin ALT
	Near-total glossectomy	Bulky ALT or RAFF
	Buccal mucosa	RFFF or thin ALT
	Through-and-through cheek	RFFF or thin ALT for inner lining; cervicofacial rotation or folded portions of RFFF or ALT for external lining
Mandible	Anterior	FFF or serratus–rib free flap
	Lateral	FFF or spanning reconstruction plate covered by RFFF, thin ALT, or PMCF
Oro- and hypopharynx	Pharyngeal wall	RFFF or thin ALT
	Laryngopharynx	RFFF or thin ALT

ALT, anterolateral thigh free flap; FFF, fibular free flap; PMCF, pectoralis myocutaneous flap; RAFF, rectus abdominis free flap; RFFF, radial forearm free flap.

49.6.4 Differential Diagnosis

The determination of an optimal flap donor site depends on the location of the head and neck defect and the degree of missing tissue bulk. The majority of soft-tissue reconstructions in the head and neck can be achieved with radial forearm, anterolateral thigh, or rectus abdominis free flaps. A pectoralis major myocutaneous flap is an excellent second choice. It can become a primary option in patients who are poor candidates for free tissue transfer, for anatomical or health reasons. Bony reconstruction of the mandible is best achieved with a fibula free flap. Alternative flap choices include radial osteocutaneous, serratus–rib, scapula, and iliac crest flaps. Each has its pluses and minuses with respect to bone stock, length of the vascular pedicle, and ease of harvesting. Facial skeletal and palate defects are best repaired with prosthetics, obturators, or a combination of free bone and cartilage grafts with a soft-tissue flap cover.

49.7 Treatment

49.7.1 Medical Treatment

Several anticoagulants can be used for the prevention of thrombus formation in the postoperative setting. These include dextran and aspirin, which are equally efficacious. Aspirin at a dose of 81 mg is continued daily for 4 weeks following the operation to help maintain vessel patency. Broad-spectrum antibiotics, pain medications, and stool softeners are given in the immediate postoperative setting.

49.7.2 Surgical Treatment

Preoperative defect anticipation and intraoperative wound assessment are critical in assisting with flap selection and design. Potential flap choices, based on anticipated defect location and size, are listed in □ Table 49.2.

Each potential flap site has its advantages and disadvantages. The strengths of each site play an important role when one is planning to resurface a defect in the head and neck. The details of flap dissection are beyond the scope of this chapter; however, salient points about anatomy, flap design, and harvest are reviewed below for some of the flaps more commonly used in head and neck reconstruction.

The pectoralis major anatomy is shown in □ Fig. 49.2. Flap design takes into consideration the first two intercostal perforators emanating parasternally (□ Fig. 49.3). These perforators supply the deltopectoral flap, which is a region of tissue extending from the sternum to the shoulder. This cutaneous flap can be used for coverage in cases of pectoralis major failure and should be preserved. Once incised, the pectoralis major muscle is identified and detached from the anterior chest wall. The pedicle (pectoral branch of the thoracoacromial artery) courses on the undersurface of the muscle and is easily identified. The lateral muscle attachments to the humerus, as well as the lateral thoracic vessels, are divided to improve the arc of rotation. A generous subcutaneous tunnel is then created under the deltopectoral flap, allowing passage of the pectoralis major into the neck. Care is taken to handle the skin paddle gently in order to avoid shearing the perforating vessels feeding it through the pectoralis major muscle. This flap can reach as high as the mid-

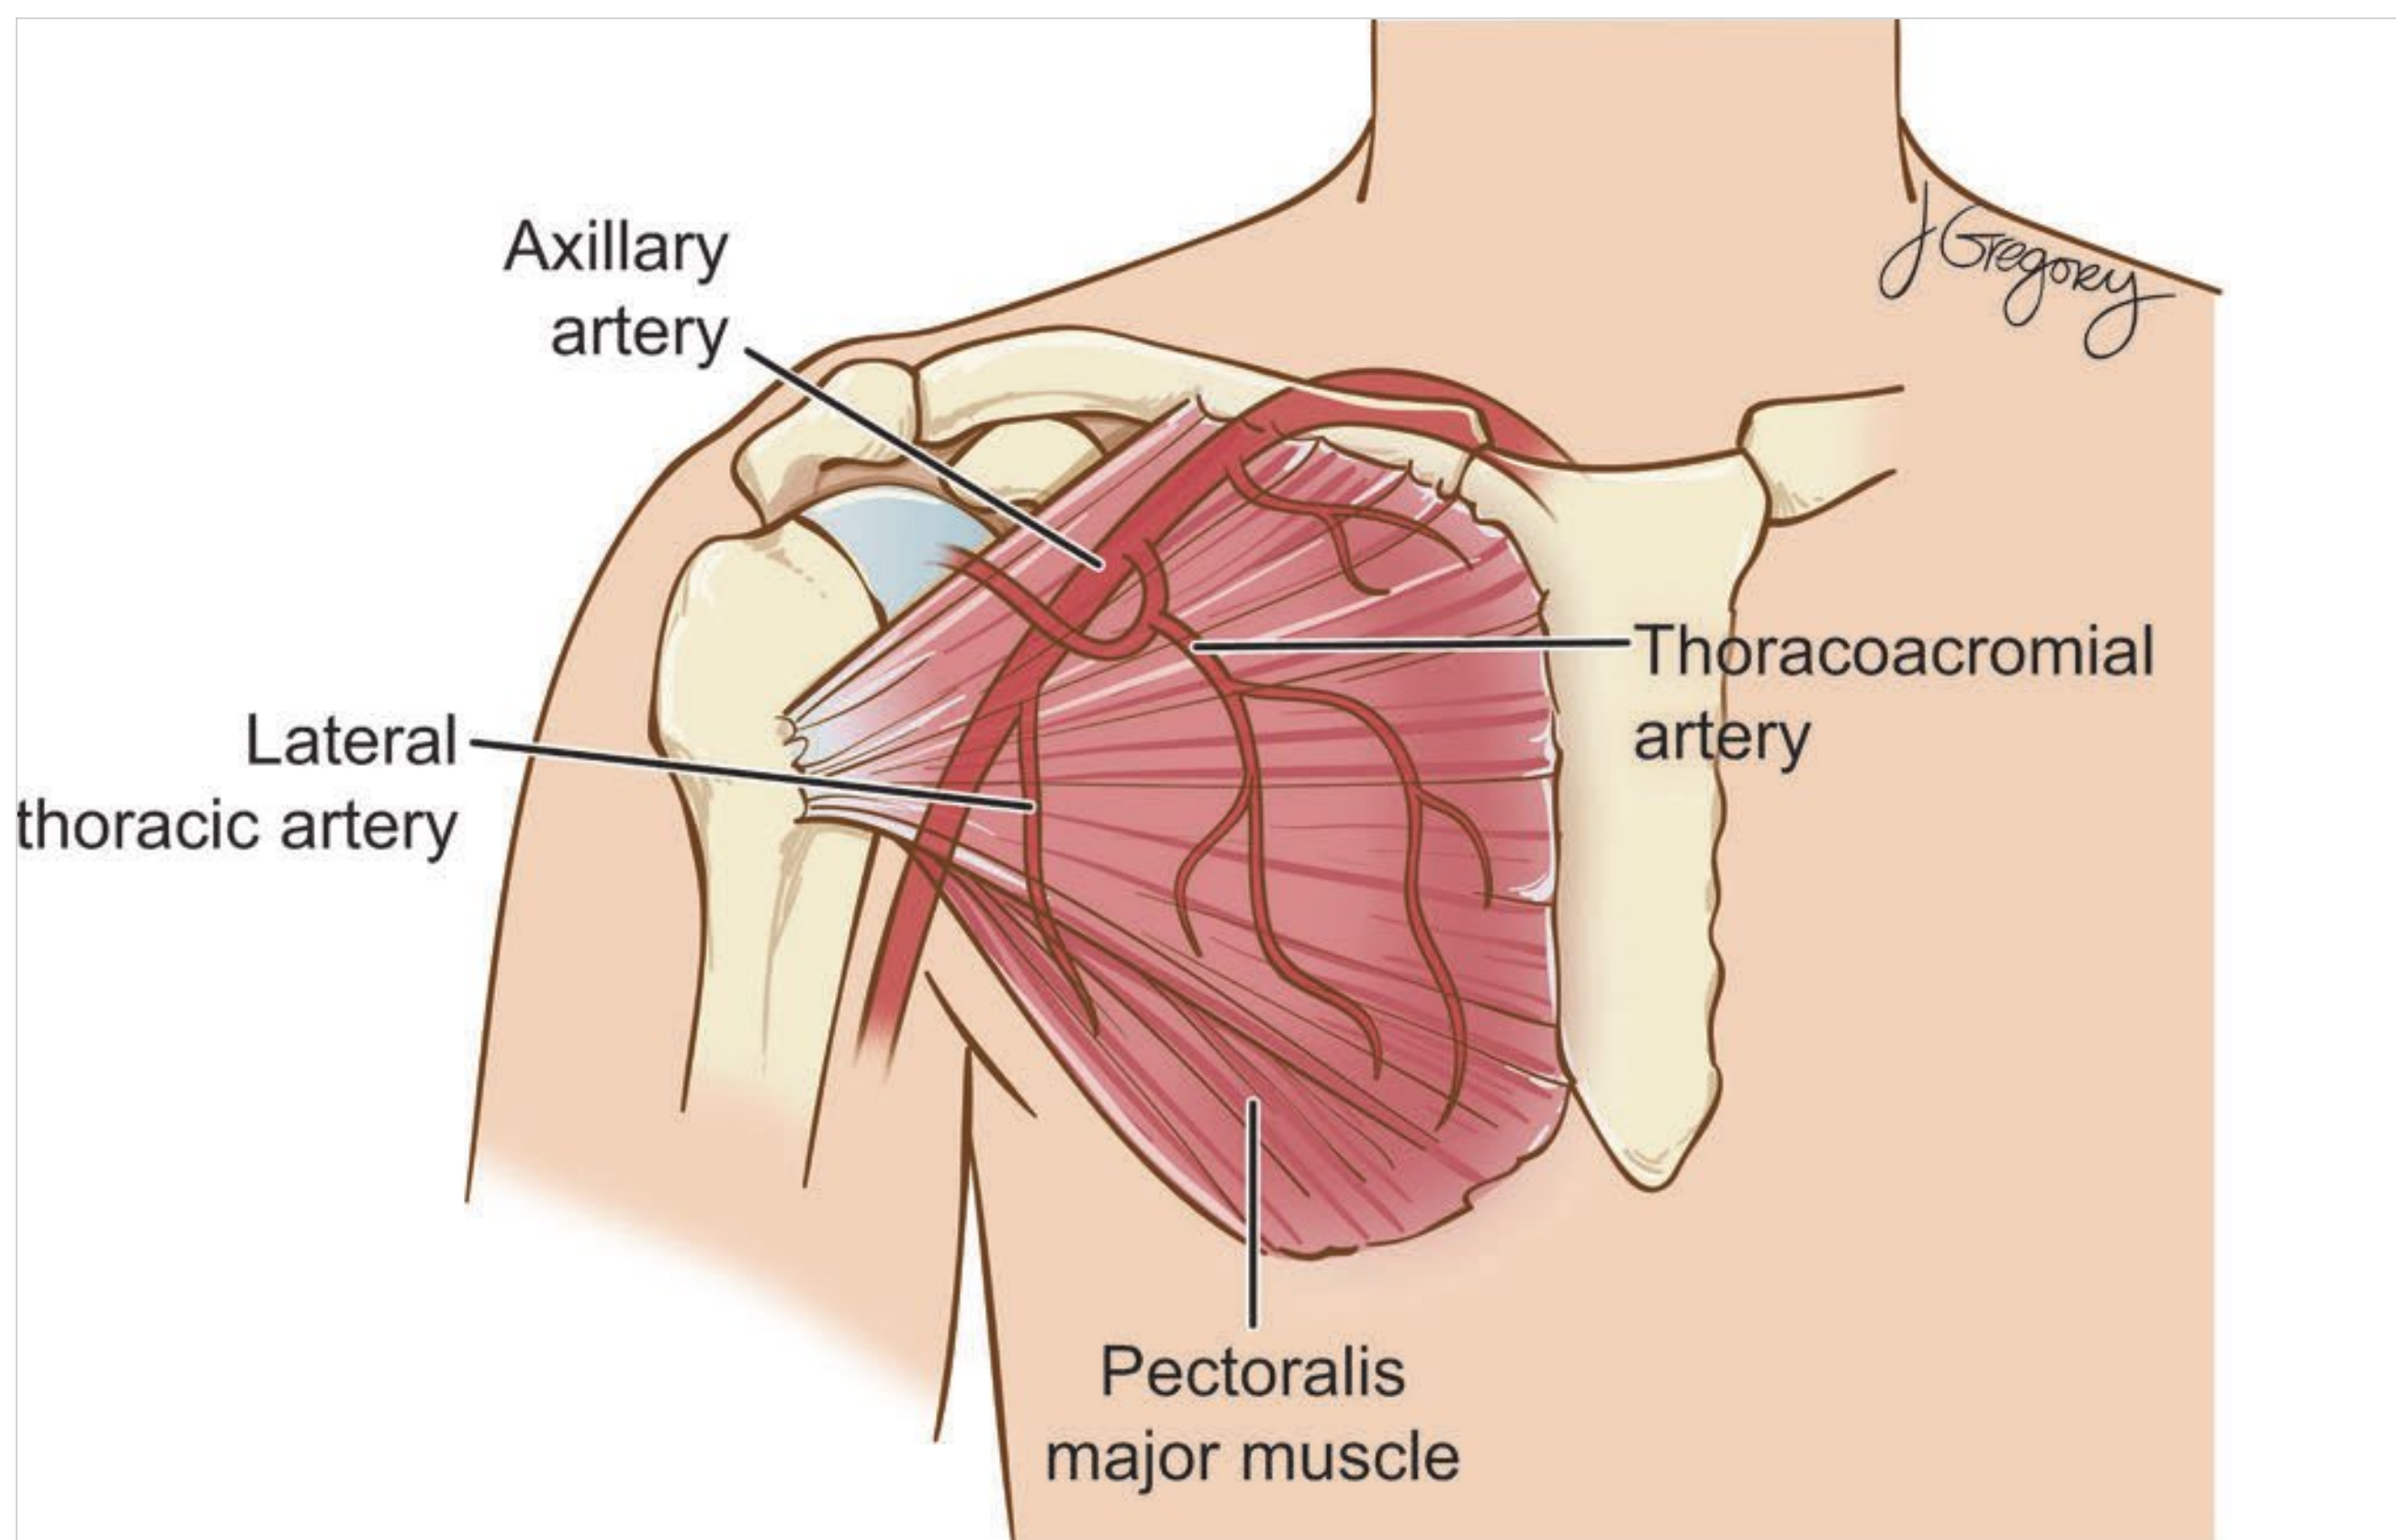

Fig. 49.2 Pectoralis major myocutaneous flap anatomy.

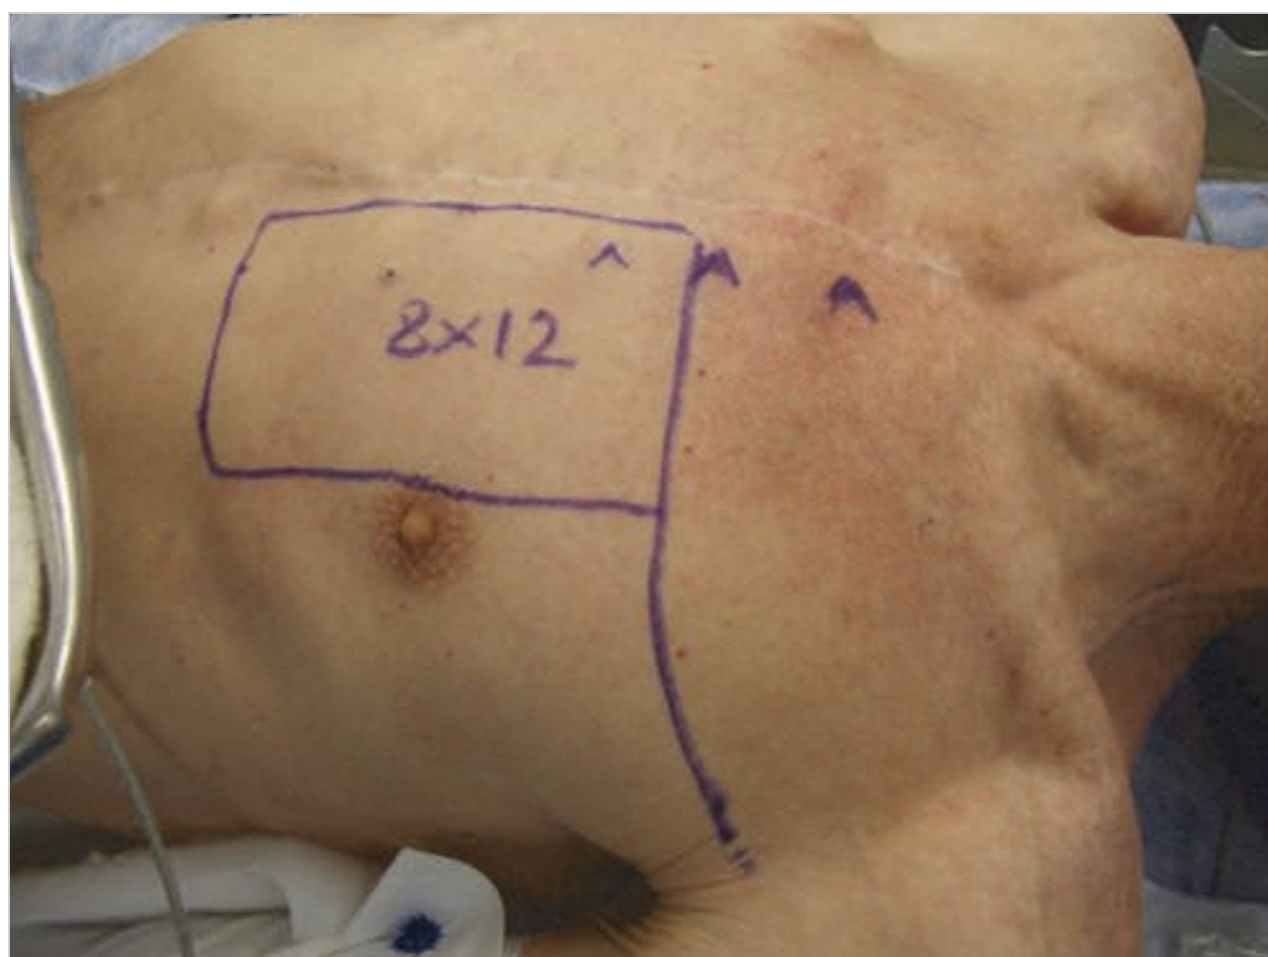

Fig. 49.3 Pectoralis major myocutaneous flap design.

Fig. 49.4 Oral tongue reconstruction with a radial forearm free flap. The highly pliable skin paddle is able to conform to the original shape of the reconstructed left tongue and floor of mouth.

face; however, tension on the pectoralis major flap increases the risk for skin ischemia and breakdown. Partial skin loss can occur in as many as half of all pectoralis flaps. The resulting chest wall defect can be closed primarily in most situations.

The radial forearm free flap has several anatomical advantages that make it an ideal soft-tissue flap for numerous head and neck defects. The middle to distal skin of the forearm has a high degree of pliability, allowing it to conform to complex soft-tissue deficits in the head and neck. These commonly include

defects of the tongue (□ Fig. 49.4) and pharynx (□ Fig. 49.5). The other attractive feature of this flap is its long vascular pedicle and redundant venous drainage. In a vessel-depleted neck, the pedicle can reach to the opposite side for anastomosis with recipient vessels. The venous outflow through the cephalic vein and deep venous system, accompanying the radial artery, readily intercommunicates via a number of small vessels and a single large vein in the proximal forearm. The redundancy of the venous outflow allows the selection of either vein for the

microvenous anastomosis. The skin paddle design is anatomically centered on the radial vasculature of the forearm (□ Fig. 49.6). The medial border of the skin paddle is restricted at the palmaris tendon, to avoid potential exposure of the ulnar vessels. Important steps in flap elevation include early identification of the cephalic vein, preservation of the distal superficial branch of the radial nerve, and dissection of the communicating vein in the proximal forearm. Inclusion of the lateral antebrachial cutaneous nerve, which travels along the cephalic vein, provides a sensory nerve for reinnervation in the head and neck

Fig. 49.5 Pharynx reconstruction with a radial forearm free flap. The skin paddle of the flap is tubed and sutured to itself to re-create the conduit between the oropharynx and esophagus. Part of the skin paddle is brought outside to provide coverage above the laryngectomy stoma.

region. A split-thickness skin graft is used for closure of the forearm wound. Long-term problems related to flap harvest may include sensory loss in the distribution of the superficial radial nerve, scar contracture with limitation of hand extension, and visible deformity. Grip strength and range of motion are rarely affected to any significant extent.

The main advantage of the anterolateral thigh flap over the radial forearm flap is reduced donor site morbidity. Most thigh defects following flap harvest can be closed primarily, thereby avoiding a skin graft. Flap design depends on identification of the perforating vessels from the flap pedicle—the descending branch of the lateral circumflex femoral artery. These perforators lie close to a line drawn between the anterior superior iliac spine and anterolateral patella. After redundant skin of the thigh has been pinched together, the medial and lateral borders of the flap can be marked (□ Fig. 49.7). In older patients, skin paddles measuring 250 to 350 cm² can be elevated while primary closure in the thigh is achieved. Elevation of the anterolateral thigh flap requires meticulous dissection of the perforating vessels traversing the vastus lateralis muscle. Alternatively, this flap can be raised by keeping a portion of vastus lateralis muscle attached to the undersurface of the skin and fat, thereby eliminating tedious perforator dissection. The anterior lateral thigh flap pedicle is similar to that of the radial forearm flap, in that it is long and can reach to the opposite side of the neck if such need arises. Morbidity related to this flap is minimal, even in cases of muscle sacrifice. Gait disturbances are rare.

The fibula free flap is the optimal source of tissue for bony reconstruction of the head and neck, especially the mandible.

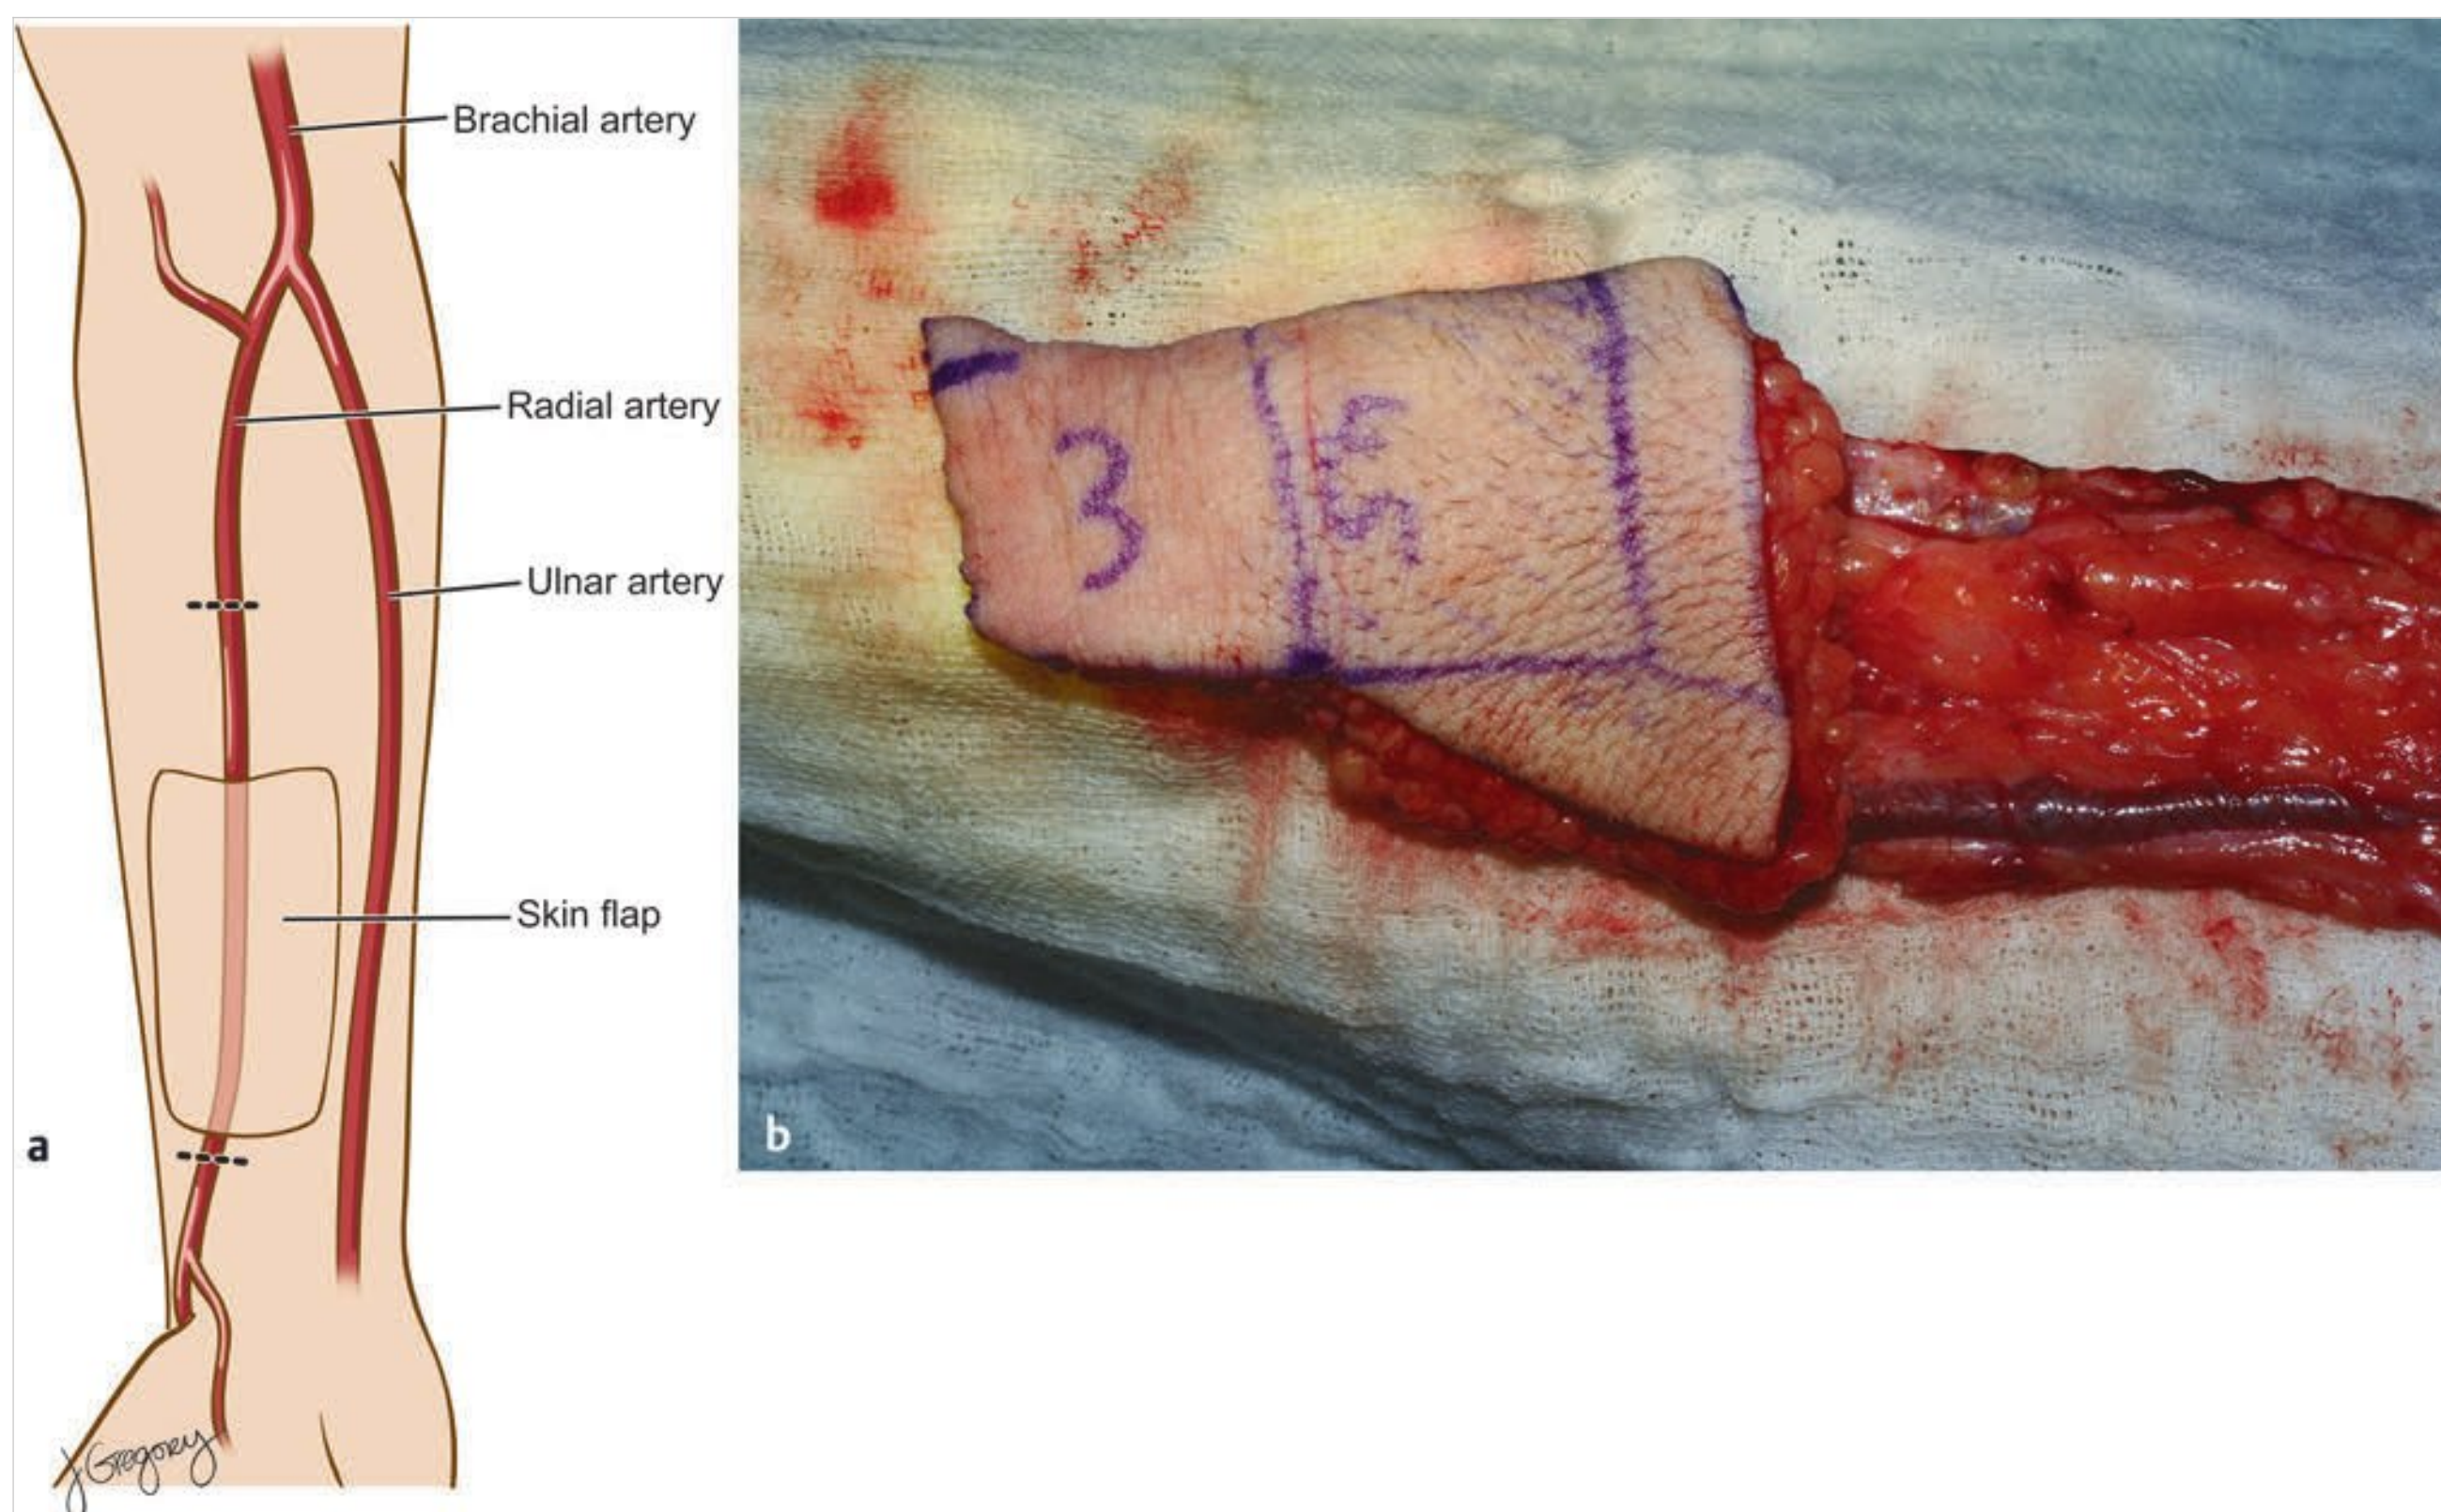

Fig. 49.6 (a) Radial forearm free flap design and (b) after harvest.

Favorable anatomical characteristics of this flap include an available bone length of up to 25 cm, strong cortical bone capable of supporting osseointegrated implants, and a reliable vascular pedicle. In addition, a large area of lateral leg skin can be harvested with this flap, up to 300 cm² (□ Fig. 49.8). Harvesting beyond this amount risks partial skin loss. The fibular skin paddle can be used for resurfacing most tongue, cheek, and associated external defects. Fibular bone can precisely reconstitute

any segmental mandible defect. Fibular contouring is performed with closing osteotomies. Each osteotomy segment, which relies on vascular supply from the periosteum, needs to be 3 cm or larger to preserve sufficient blood flow. Following the osteotomies, a reconstruction plate is applied to stabilize the fibula within the mandibular defect.

Complications of free flap transfer include flap failure (as previously discussed), bleeding (□ Fig. 49.9), infection, wound

Fig. 49.7 Anterolateral thigh free flap design.

Fig. 49.9 Hematoma evacuation on the first postoperative day.

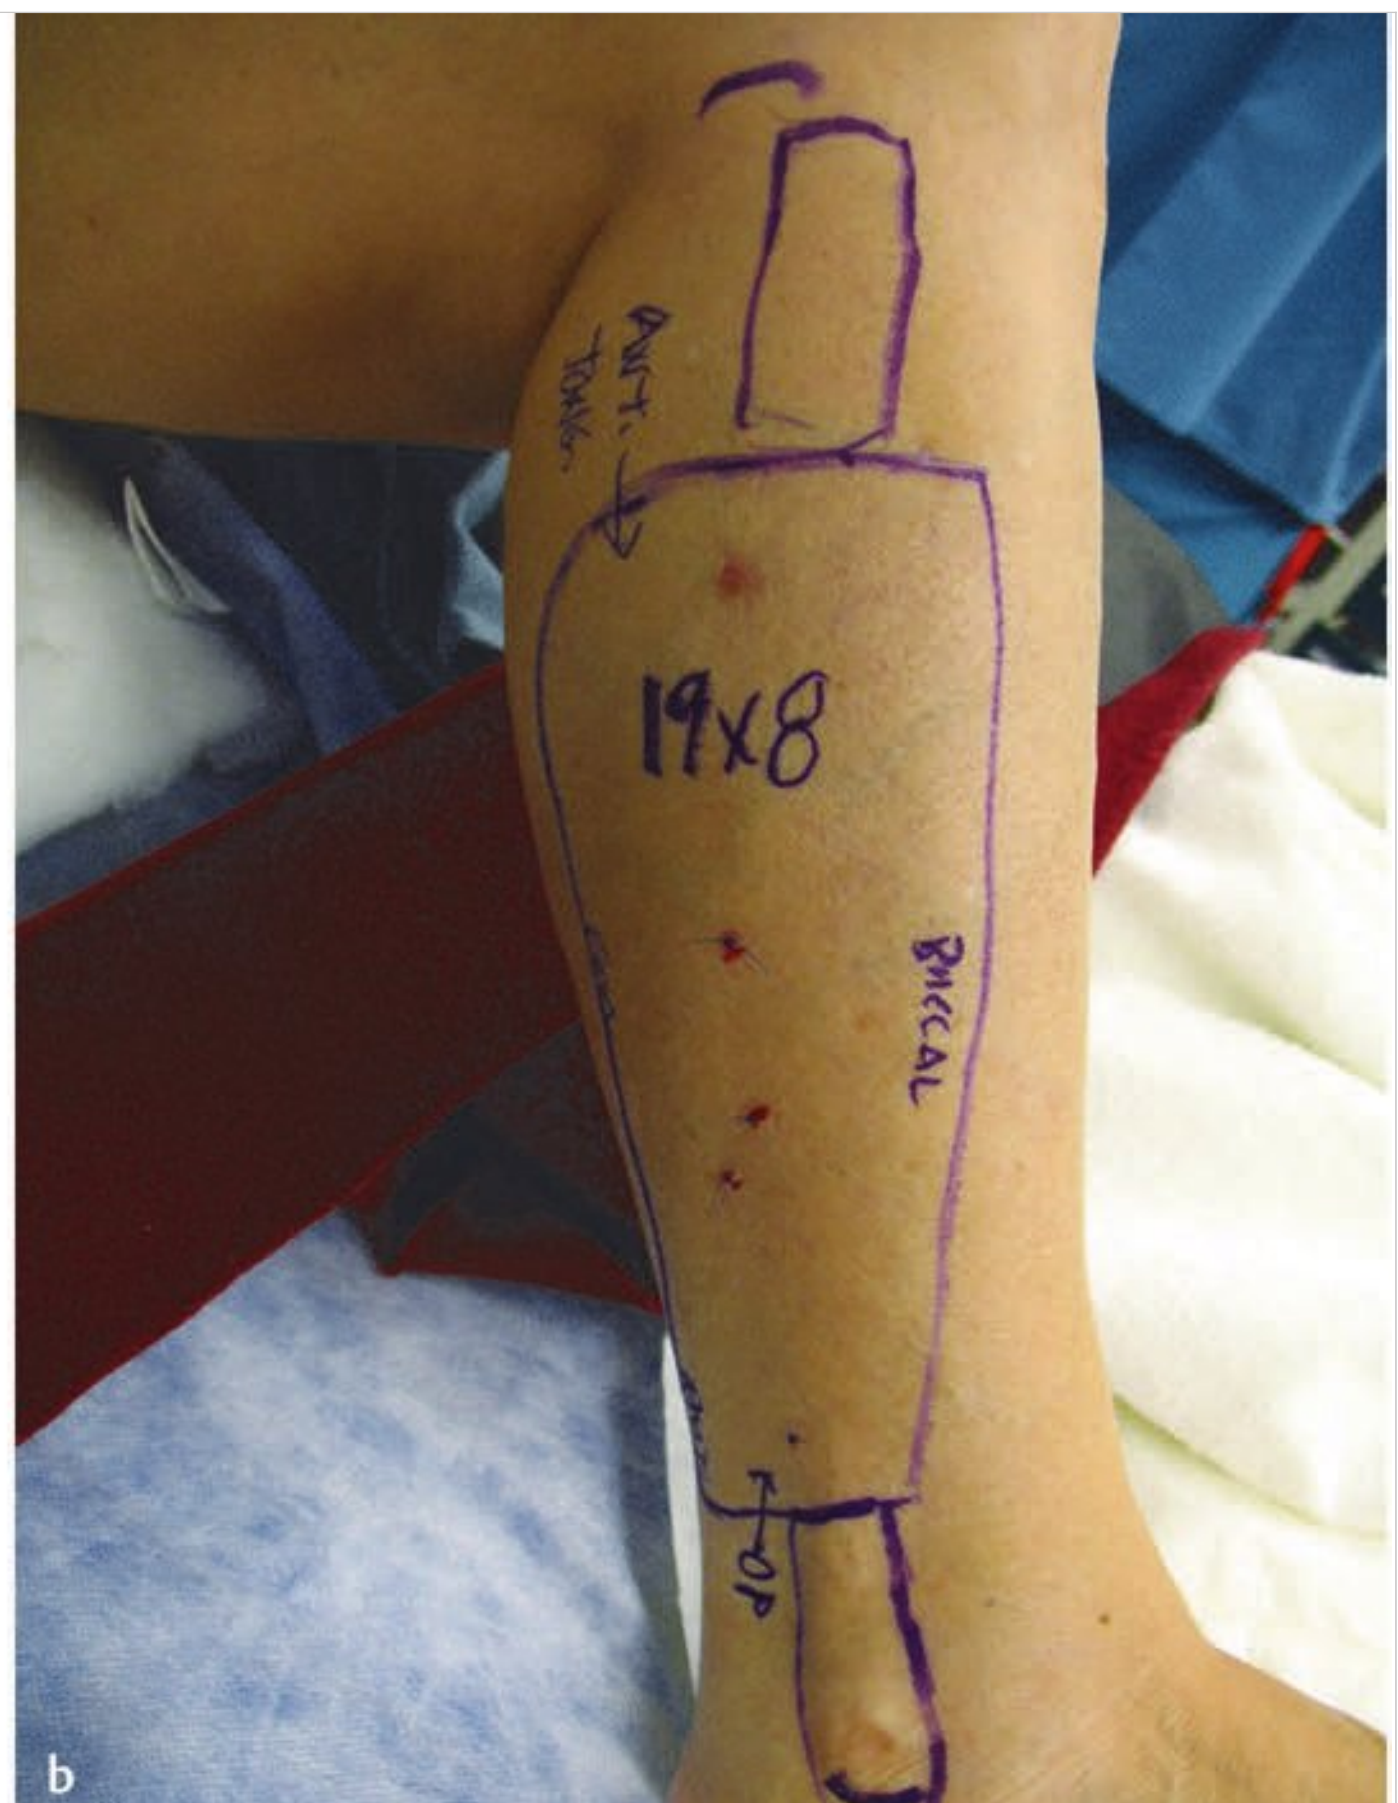

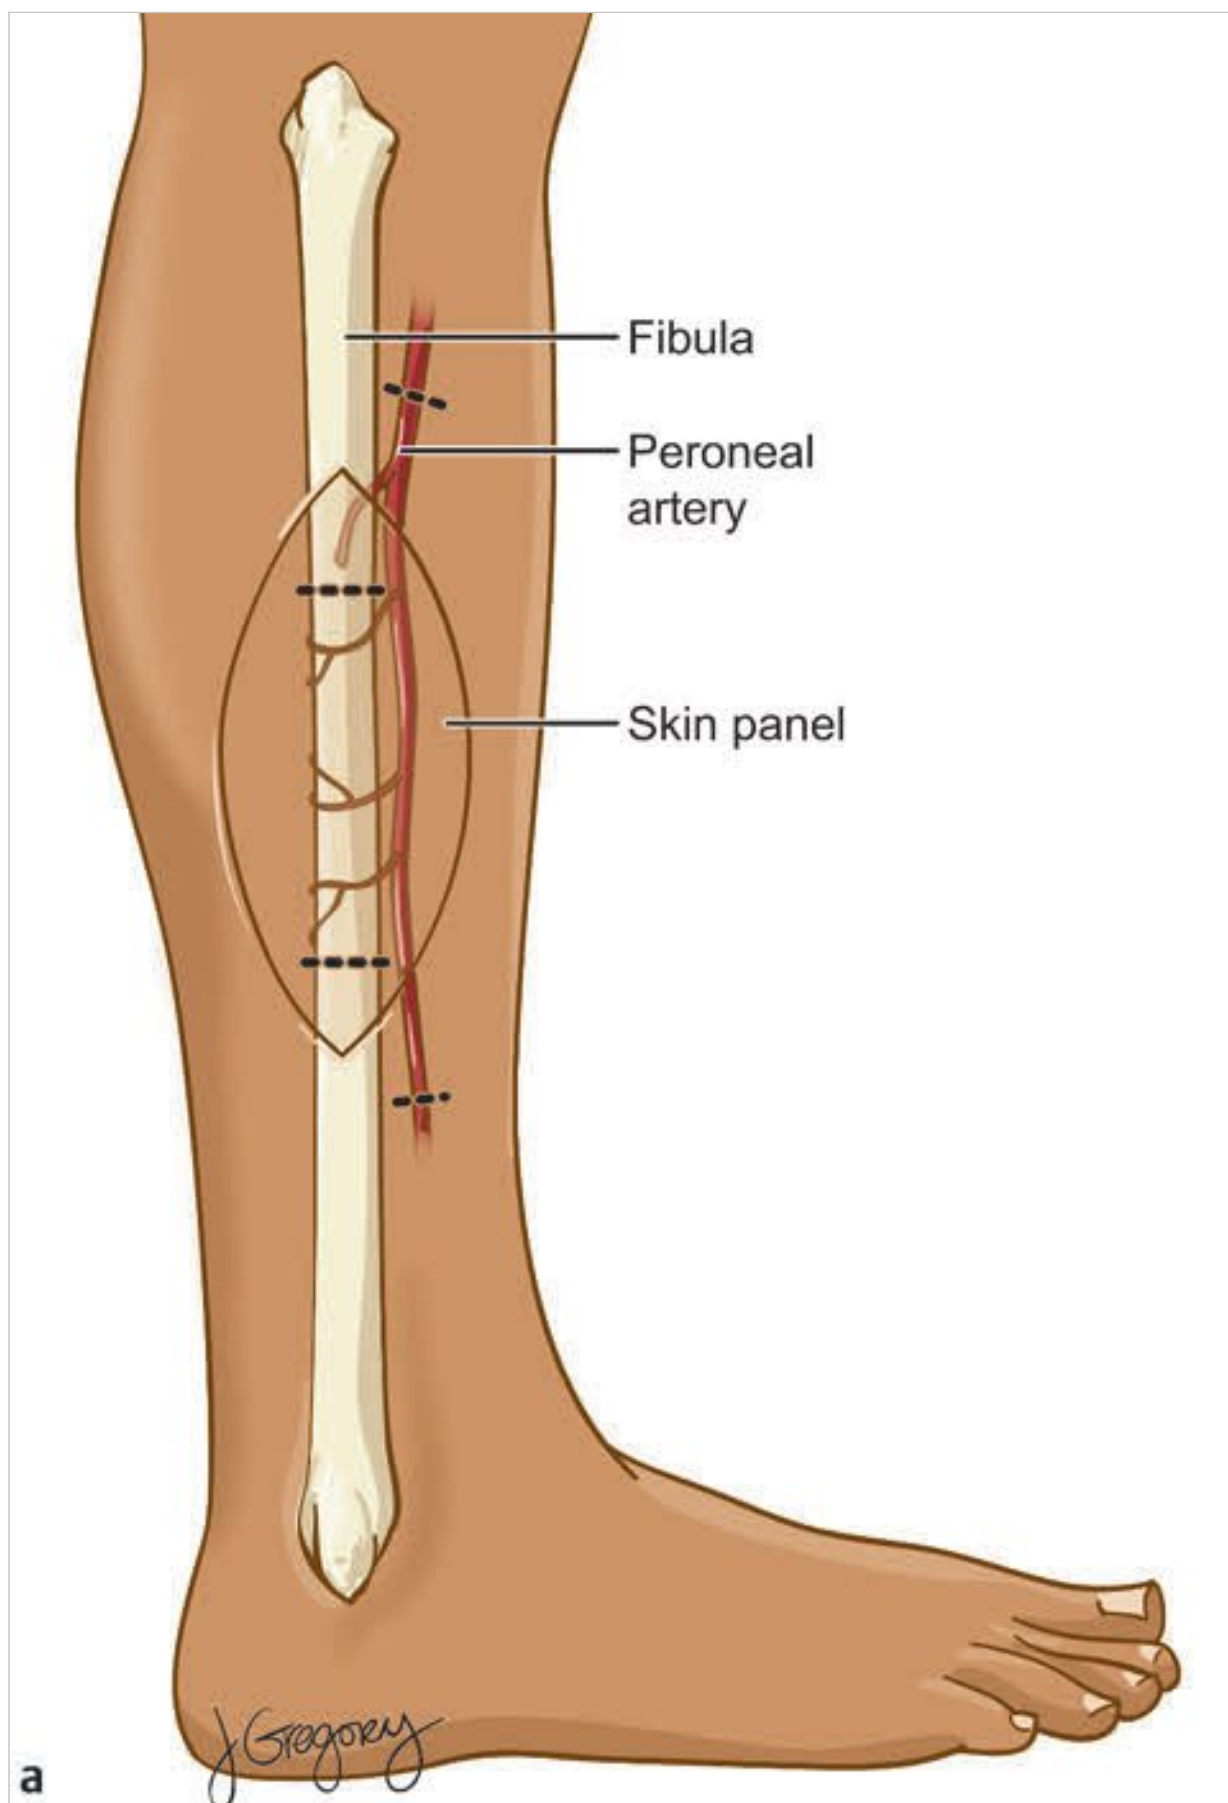

Fig. 49.8 (a,b) Fibula free flap design.

dehiscence, fistula formation, hardware exposure, excessive bulk, and several others. Soft-tissue flap revisions may be necessary to improve tissue contour and function. In applicable cases, revisions can be delayed until after the end of radiation therapy.

49.8 Prognosis

The overall success rate for free tissue transfer in the head and neck approaches 95% in several large series reported in the literature. The perioperative mortality is approximately 1%. The rate of medical complications, most commonly caused by cardiac and pulmonary manifestations, is about 20%. Surgical complications, such as wound infection, breakdown, and fistula formation, are significantly higher in patients with a history of previous radiation therapy.

49.9 Roundsmanship

- Flap selection depends on the missing tissues and the volume requirements of a head and neck defect.

- Free flaps are the optimal choice for the reconstruction of large head and neck defects.
- Free flap reliability approaches 95%
- Effective elevation of a pectoralis major myocutaneous flap requires sectioning of the lateral thoracic artery and preservation of the first two intercostal perforators.

50 Tissue Expansion

Grigorly Mashkevich and Kenneth M. Wong

50.1 Introduction

Over the past 30 years, tissue expansion has become an increasingly useful adjunct in reconstructive surgery, especially in the region of the head and neck. Although the concept of tissue expansion has been known since ancient times, Neumann, using a rubber balloon gradually filled with air, first applied this technique in reconstructive surgery in 1957. Following publications by Austed and Radovan, tissue expansion gained wide acceptance during the 1970s and 1980s. Its safety and efficacy were well documented in the decades that followed. The technique of tissue expansion has been applied successfully to a wide range of clinical problems, including breast reconstruction, repair of burn wounds, pediatric plastic surgery, and head and neck reconstruction. Tissue expansion provides several distinct advantages, such as excellent color and texture match and the retention of cutaneous sensory function. For these reasons, tissue expansion continues to serve as a valuable tool for the reconstructive surgeon.

50.2 Incidence of Disease

Although exact data on the number of tissue expansion procedures performed are lacking, the use of tissue expansion has been well documented and published. In the head and neck region, the most frequent application has been for large scalp and neck wounds.

50.3 Terminology

A distinction should be made between long-term tissue expansion and intraoperative tissue expansion because they differ in technique and the process of expansion. Long-term tissue expansion involves placing an expander device under the skin in the appropriate area. The wound is allowed to heal for 2 weeks, and expansion is carried out in serial fashion over several weeks with sterile technique and saline injection. The expander is then removed in another surgical procedure and the wound reconstructed with the newly expanded tissue. Intraoperative tissue expansion, on the other hand, is performed synchronously with reconstruction of the wound. Intraoperative tissue expansion is carried out in cyclical fashion, with three cycles of expansion and deflation. A large Foley catheter or specific expander device is used. The balloon is inflated underneath the area to be expanded, left for 3 minutes, and deflated. The flap is then incised and used to reconstruct the wound in one setting.

50.4 Applied Anatomy

A thorough understanding of head and neck anatomy and the histologic layers of the skin is important in tissue expansion, especially when the expanders are placed. The skin comprises the epidermis and dermis, which are situated over the subcuta-

neous tissues. The dermis is further separated into papillary and reticular layers. All tissue components of the skin undergo physiologic changes during tissue expansion. Knowledge of the different layers in the head and neck is important in terms of the placement of expanders. In the scalp region, the tissue layers include the skin, connective tissue, galea aponeurosis, loose areolar tissue, and periosteum. An important layer in the facial region is the superficial musculoaponeurotic system (SMAS), which connects to the galea superiorly and platysma inferiorly.

50.5 The Disease Process

50.5.1 Etiology

Tissue expansion can address wounds in need of soft-tissue coverage, such as those resulting from burns, trauma, or cancer. In the head and neck region, tissue expansion can additionally be used for scar revision, the treatment of male pattern baldness, the release of contractures, and even the repair of cleft lip and microtia. In the pediatric population, tissue expansion can assist in the management of various disorders, including congenital nevi, hemangiomas, lymphangiomas, arteriovenous malformations, and congenital anomalies.

50.5.2 Pathogenesis

Although not a disease process, long-term tissue expansion results in mechanical, physiologic, and histologic changes (“biological creep”) within the different tissue layers. The epidermis and dermis exhibit the most drastic changes.

Epidermal thickness remains the same or increases. Although the stratified layers remain intact, metabolic and mitotic activities increase. After expansion, the epidermis usually returns to normal, with hyperpigmentation and dryness the most common side effects.

Increased metabolic activity and physiologic changes are also observed in the dermis, which can lose 30 to 50% of its thickness. Fibroblast activity is enhanced, resulting in increased collagen synthesis. The basal layer of the dermis thickens and myofibroblasts increase in number, which can lead to flap contracture after flap transfer. The number of hair follicles remains the same, but the density decreases as the surface area increases. Adipose tissue and muscle tend to atrophy with tissue expansion. Adipose tissue can lose up to 50% of its thickness. Nerves lengthen with gradual expansion. One major advantage of long-term tissue expansion is neovascularization. Capillaries proliferate, leading to a lengthening of venules and arterioles. Increased vascularity improves flap survival and resistance to infection.

Tissue gain during intraoperative tissue expansion occurs via a different process. Intraoperative tissue expansion increases skin length through the process of mechanical creep, which involves the disruption and realignment of collagen and elastin fibers, displacement of adjacent tissue, and shifting of intersti-

Fig. 50.1 Various shapes of tissue expanders. (Image provided courtesy of Mentor Corporation, Santa Barbara, CA.)

tial fluids. About 1 to 3 cm of additional flap length can be obtained through this approach.

50.5.3 Natural History and Progression

Many different shapes, sizes, and volumes of tissue expanders are used in long-term expansion (□ Fig. 50.1). Common shapes include rectangular, crescent, and circular. Tissue expanders consist of an expandable chamber composed of silicone elastomers and an injection port. In the head and neck area, remote injection ports can be optimally placed away from sensitive areas of the face. In long-term expansion, progression occurs in a biphasic manner. There is a period of tissue resistance during the initial stages, which is followed by a rapid increase in compliance. Expansion should be continued until there is about twice the amount of tissue needed to cover a defect. On the other hand, intraoperative expansion, for reasons previously outlined, occurs much more rapidly and is performed in one setting.

50.6 Medical Evaluation

50.6.1 Presenting Complaints

Patient motivation is an important factor in the decision to proceed with tissue expansion. The patient should be prepared for multiple procedures and frequent office visits. The surgeon must counsel patients and caregivers with respect to the time course of expansion, expected physical appearance, and interim social functioning. During the later stages of the process, the physical appearance caused by the expanded tissue may interfere with work and social activities. Proper patient education before the process begins can help minimize expected anxiety. The surgeon should also inquire about any history of smoking, diabetes, or radiation because any of these may adversely affect wound healing and outcome.

50.6.2 Clinical Findings, Physical Examination

The wound should be measured, and the shape and size of the expander chosen appropriately. The shape of the expander should match the shape of the anticipated flap. If a large rotation flap is expected, then a crescent or circular expander is selected. Rectangular expanders are most commonly used for straight advancement flaps. The area of the base of the expander should be 2.5 to 3 times the area of the defect. The actual amount of tissue that can be used is only a fraction (about 35%) of the increased surface area.

50.6.3 Testing

Standard preoperative medical testing should be performed based on the patient's medical history, including electrocardiography, chest X-ray, and all necessary laboratory work. All required medical clearance should be obtained before any procedures are performed.

50.6.4 Differential Diagnosis

When dealing with a wound defect, the surgeon should weigh all the available reconstructive options. These include healing by secondary intention, primary reapproximation, local or regional flaps, split-thickness or full-thickness skin grafts, and microvascular free flaps. Tissue expansion can be an adjunct to any of these interventions by increasing the amount of available tissue. The advantages of tissue expansion include good color, texture and bulk match, minimal donor site morbidity, minimal scarring, and retention of sensory and adnexal function. Disadvantages include temporary cosmetic deformity during the expansion phase, prolonged period of expansion, need for multiple procedures, and complications associated with the implant and placement.

50.7 Surgical Treatment

Multiple procedures are needed for long-term tissue expansion. Once an expander with the appropriate size and shape has been selected, several technical considerations guide its insertion in the operating room. The incision is placed away from the site of expansion to minimize the chance of wound dehiscence and implant extrusion. The pocket for the expander should be large enough to accommodate it without resistance and folding. The injection port should be positioned in an optimal location, with patient comfort and visibility for the serial injections taken into account.

The area of expansion in the head and neck determines the tissue plane in which the expander is positioned. In the facial region, the expander is placed subcutaneously, superficial to the SMAS, to protect the facial nerve. In the neck, the expander can be placed either superficial or deep to the platysma muscle. When the expander is placed in the deeper plane, care must be taken to position the device away from the marginal branch of the facial nerve. The expander is placed between the galea and pericranium in the scalp and forehead. Superficial placement in the scalp region can lead to alopecia.

Fig. 50.2 Patient with bilateral microtia requiring long-term expansion of the postauricular tissue of the scalp to limit the need for skin graft. Impending necrosis developed at the end of the expansion cycle. The expander was removed and the expanded tissue successfully used for postauricular coverage after elevation of the auricular framework.

Complications associated with long-term tissue expansion occur in approximately 10% of adult patients and up to 30% of pediatric patients. These include hematoma, seroma, exposure or extrusion, infection, numbness due to neurapraxia, migration, and very rarely leakage of the device. Exposure and infection are the most common side effects. Their management depends on when they occur during the expansion process; if the device is exposed or infected early, implant removal is the most prudent course of action, whereas an implant can be left in place for an additional round of expansion and antibiotics con-

tinued to prevent infection if the device is exposed near the end of the expansion process (□ Fig. 50.2). Implant capsule formation can limit the pliancy of the expanded skin, and capsulectomy may be necessary.

50.8 Prognosis

When performed correctly, tissue expansion has excellent cosmetic and functional results. It has become a valuable tool, especially in the reconstruction of the head and neck region.

50.9 Roundsmanship

- There are two types of tissue expansion: long-term and intraoperative.
- Physiologic and histologic changes (“biological creep”) occur during long-term expansion, whereas mechanical changes accompany intraoperative expansion, known as “mechanical creep.”
- The size of expander should be approximately 2.5 to 3 times the size of the defect.
- Expanders should be removed if complications occur early in the expansion process. Expansion can be continued or shortened with late complications.

51 Treatment of Facial Paralysis

Grigorly Mashkevich

51.1 Introduction

Facial paralysis is a challenging problem for both patients and physicians. This potentially disabling condition can arise from multiple causes, and a thorough understanding of the differential diagnosis and available treatment options is required. Optimal cosmetic and functional rehabilitation in patients with facial paralysis depends on an individualized treatment strategy performed in a multidisciplinary setting.

51.2 Incidence of Disease

The incidence of facial paralysis varies greatly based on its etiology. This information is provided in sections that follow.

51.3 Classification of the Disease Process

The House-Brackmann scale is a reliable tool for grading facial nerve dysfunction (□ Table 51.1). This scale is not applicable to patients with facial nerve synkinesis. Other scales have been developed to help assess the physical and psychological impact of facial paralysis on afflicted individuals.

51.4 Applied Anatomy

The facial nerve enters the temporal bone via the internal auditory meatus and travels within the tight bony confines of the fallopian canal. Most inflammatory conditions cause pressure-induced paralysis in this portion of the nerve. Upon its exit from the stylomastoid foramen, the facial nerve penetrates the substance of the parotid gland, by which it is well protected in the preauricular region. Within the gland, it divides into five major branches, which exit the periphery of the gland deep to the superficial muscular aponeurotic system (SMAS). Anterior to the parotid gland, distal facial nerve branches substantially intercommunicate and innervate the midfacial musculature with redundancy.

51.5 The Disease Process

51.5.1 Etiology, Pathogenesis, Natural History, and Progression

Congenital

Birth Trauma

Several factors during the birth of a child may lead to facial nerve injury and associated paralysis. These include the use of forceps during the delivery, birth weight of more than 3.5 kg (7.7 lb), and first pregnancy. A contributing factor may be compression molding of the fetus while it passes through the birth canal. In this setting, the facial nerve is susceptible to stretch injury and requires time to regenerate. The overall prognosis is excellent, with up to 90% of children achieving complete recovery of their facial nerve function without surgical or medical intervention. In the rare instances in which transection injury is strongly suspected, surgical exploration may be warranted.

Mobius Syndrome

Mobius syndrome, first described in the 19th century, is characterized by concomitant facial and abducens nerve palsies. These may arise as a result of peripheral nerve underdevelopment or agenesis, as well as from poorly functioning brainstem nuclei. Additional cranial nerves may be affected in this syndrome. Clinically, patients struggle with facial movement and have extreme difficulty expressing emotion. Accompanying problems include oral incompetence, drooling, poor self-esteem, and social isolation—all of which exacerbate the challenges to persons with this condition. In this patient group, free muscle transfer has been successfully used for the rehabilitation of facial movement. Ideally, such intervention is performed before school entry in an attempt to avoid the psychological trauma caused by peer ridicule during the early formative years.

Melkersson-Rosenthal Syndrome

Melkersson-Rosenthal syndrome is the constellation of recurrent facial paralysis, facial swelling, and tongue fissures. Although the typical care of recurrent flare-ups includes steroid

Table 51.1 House-Brackmann grading scale for facial nerve dysfunction

Grade	Impairment	Deficits
I	Normal	Normal facial movement
II	Slight	Normal resting tone, complete eye closure, slight weakness with movement
III	Moderate	Mild facial asymmetry at rest, complete eye closure with effort, moderate weakness with movement
IV	Moderate–severe	Disfiguring asymmetry at rest, incomplete eye closure, some facial movement
V	Severe	Disfiguring asymmetry at rest, incomplete eye closure, slightly noticeable facial movement
VI	Complete	Absent facial movement

and anti-inflammatory medications, controversy remains over the management and prevention of facial palsy. Isolated case reports describing facial nerve decompression (opening its biologic bony confines to prevent nerve pressure during bouts of swelling) suggest that long-term resolution of facial nerve dysfunction is possible with this more aggressive approach.

Hemifacial Microsomia

Hemifacial microsomia comprises a spectrum of congenital facial anomalies arising from underdevelopment of one side of the face. This syndrome is marked by hemifacial soft-tissue deficiency and poor development of the lower jaw, maxilla, and external ear. In cases of accompanying facial weakness or paralysis, reconstructive surgery can be planned together with craniofacial repair directed at correcting jaw and ear abnormalities. The restoration of facial symmetry and smile can be especially effective with free muscle transfer because it provides a secondary benefit of facial augmentation.

Infectious

Bell Palsy

Bell palsy is also known as idiopathic facial paralysis. However, recent evidence suggests that herpes simplex virus is the most likely agent responsible for Bell palsy. The incidence of this condition approaches 30 per 100,000 people. Typically, the onset of paralysis occurs over a period of 24 to 72 hours and may be accompanied by other symptoms, such as pain around the ear, decreased taste, and diminished hearing on the affected side. Although the overwhelming majority of patients recover their facial nerve function, a small minority are left with a movement deficit, marked by aberrant facial movements (synkinesis). Steroids and antiviral medicines have been found helpful in improving functional recovery of the facial nerve in the acute stages of Bell palsy. In selected instances, in which electrical activity of the nerve is severely depressed during the first 2 weeks (see testing below), surgical decompression of the nerve's bony channel should be considered. In those with poor recovery and synkinesis, chemodenervation (paralysis) with botulinum toxin A and intensive physical therapy offer a promising rehabilitative option.

Ramsay Hunt Syndrome

Ramsay Hunt syndrome (herpes zoster oticus) is caused by reactivation of the varicella-zoster virus (human herpesvirus 3) within the facial nerve and is accompanied by vesicle formation and ear pain (zoster oticus). Other symptoms, such as hearing loss, tinnitus, vertigo, nausea, and vomiting, may be present, as well. These are thought to arise from irritation of the vestibulocochlear nerve, which is situated adjacent to the inflamed facial nerve in the temporal bone. Although no randomized studies exist on the treatment of this infrequent condition, a combination of steroids, antivirals, and pain medications can be used to control inflammatory injury of the facial nerve. This regimen is based on experience in the treatment of Bell palsy (with steroids), as well as the treatment of zoster infections in other parts of the body (with antiviral medications). The prognosis for facial nerve recovery is poor in Ramsay Hunt syndrome,

with chronic neuralgia (pain) commonly persisting following the resolution of infection.

Otitis Media/Mastoiditis

Otitis media/Mastoiditis is an acute infection of the middle ear and mastoid that in rare cases (fewer than 1%) may result in facial nerve paralysis. Swelling around the nerve and toxic substances released by bacteria are thought to be the causative factors behind facial nerve involvement. Successful treatment consists of the prompt recognition and eradication of infection. This includes broad-spectrum antibiotics and myringotomy with placement of a ventilation tube, so that a bacterial specimen can be obtained for culture. A mastoidectomy (removal of infection in the adjacent mastoid bone) may be performed in selected cases of associated mastoiditis. The prognosis for complete facial nerve recovery is excellent with the above interventions.

Cholesteatoma

Cholesteatoma is a slow-growing skin cyst that over time causes destruction in the ear by exerting pressure on surrounding structures and causing flare-ups of chronic infection. The incidence of facial paralysis in a setting of cholesteatoma approaches 3%. Prompt recognition of this disease process and surgical eradication are critical in successfully releasing pressure from the facial nerve and removing the source of chronic infection and inflammation. Poor prognostic factors for recovery include extension of a cholesteatoma into the petrous apex (deep portion of the temporal bone) and delayed surgical treatment. Patients who undergo early intervention are more likely to recover their facial nerve function completely.

Lyme Disease

Lyme disease is caused by *Borrelia burgdorferi*, a bacterium transmitted to humans through the bite of infected ticks. Typical symptoms and signs in acute stages of Lyme disease include headache, weakness, fever, and erythema chronicum migrans (a characteristic target-shaped rash that develops at the site of a tick bite). Although the incidence of accompanying facial paralysis reaches 11% it completely resolves in 99.2% of patients. A high index of suspicion for Lyme disease should arise when a patient presents with a recent history of tick bites during the summer months in areas where the disease is endemic; the national risk map is available on the U.S. Centers for Disease Control and Prevention Web site (<http://www.cdc.gov/lyme/stats/maps/interactiveMaps.html>). Lyme titers should be obtained for confirmation and antibiotic therapy instituted, following guidelines published by the Infectious Diseases Society of America (<http://www.idsociety.org/lymedisease.htm>).

Other

A number of additional infectious processes can impair facial nerve function, including HIV infection, tuberculosis, infectious mononucleosis, and others. These conditions typically have other associated symptoms in affected individuals, and a high index of suspicion is required to make the diagnosis. Previous history and risk factors for exposure influence the decision to

pursue these diagnostic possibilities in a setting of facial paralysis. The mainstay of management is targeted medical therapy, unless associated mastoiditis is identified on work-up. In this instance, mastoidectomy should be performed to control the infection and swelling around the facial nerve.

Systemic and Neurologic

Conditions in this category include autoimmune diseases, diabetes, sarcoidosis, Guillain-Barré syndrome, multiple sclerosis, and others. Infrequently, these can present with isolated facial paralysis. A correct diagnosis and prompt medical intervention form the initial treatment strategy, with anticipated recovery of facial movement in most cases.

Traumatic

Traumatic injuries to the head and cranium are one of the most common causes of acquired facial paralysis. In instances of blunt trauma, in which no lacerations or fractures occur, the facial nerve retains its continuity and is expected to recover. In a setting of suspected nerve laceration (penetrating trauma through facial skin and soft tissues), immediate surgical exploration with nerve repair is warranted. Ideally, this would take place within 3 days of injury, during which time the distal portion of the facial nerve can still be stimulated and thus identified during surgery.

When facial trauma results in a temporal bone fracture, accompanying facial nerve injury occurs in 10 to 25% of cases. Temporal bone fractures follow several patterns, defined with respect to the long axis of a temporal bone: longitudinal (80%), transverse (10%), and mixed (10%). Facial nerve paralysis occurs more frequently in transverse (50%) than in longitudinal (20%) fractures. Full recovery is expected in patients with a delayed onset of facial paralysis. In contrast, up to 50% of those with an immediate onset recover poorly. In many cases of significant facial trauma, concomitant acute conditions may delay examination and testing of the facial nerve. However, delayed surgical exploration, even months after the injury, can still be performed with reasonable success rates of functional improvement and recovery.

Iatrogenic injury to the facial nerve can occur during facial, bony, or intracranial surgery. The extent of nerve damage largely dictates the type of repair. In severe cases, nerve repair may not be possible, and other rehabilitative methods must be utilized (□ Fig. 51.1).

Neoplastic

The extirpation of cancer invading or situated in the vicinity of the facial nerve may require significant nerve manipulation during surgery and possibly partial or complete transection. The most common tumors affecting the facial nerve are acoustic neuroma (vestibular schwannoma), glomus tumors, facial neuroma, and carcinoma of the parotid gland. When the facial nerve continuity is maintained during surgery, postoperative recovery is closely monitored. Stimulation of the nerve at the end of the procedure may provide useful prognostic data. Steroid medications are typically not given in this setting because several studies have clearly shown lack of benefit. Following

surgery, electromyography (EMG) can be utilized to assess reinnervation of the facial musculature. Depending on the stage of recovery, as well as individual challenges and concerns, several simple procedures are considered to aid with eye closure, facial symmetry, and oral competence (□ Fig. 51.2).

51.5.2 Potential Disease Complications

In the setting of an intact or repaired facial nerve, the resolution of paralysis depends on axonal regeneration and regrowth into the facial musculature. Aberrant regeneration of facial nerve axons can be characterized by misdirection of fibers or sprouting of axons to innervate multiple facial muscles. This can result in synkinesis, which is an involuntary contraction of the facial muscles during facial mimetic movement (□ Fig. 51.3). Other complications of facial paralysis include excessive globe dryness and exposure keratopathy, oral incompetence and drooling, and chronic cheek biting.

51.6 Medical Evaluation

In an acute setting, the medical evaluation should address a number of differential possibilities, as outlined in □ Fig. 51.4 and □ Fig. 51.5.

51.6.1 Presenting Complaints

Patients with facial paralysis experience a range of difficulties pertaining to appearance, speech, and swallowing. Periocular complaints may include blurry vision, excessive tearing, and discomfort or pain. Perioral deficits depend on the age of the patient and corresponding facial tone. These can include drooling, food spillage, and cheek biting. Facial asymmetry at rest and with movement can be a significant source of embarrassment and lead to social withdrawal.

51.6.2 Clinical Findings, Physical Examination

During the initial visit, a detailed examination of facial appearance at rest and with movement is photographed and videotaped. On physical examination, patients with facial paralysis display characteristic tissue sagging and lack of facial movement (□ Fig. 51.6 and □ Fig. 51.7). The eye examination typically reveals lagophthalmos, or an inability to fully close the eye. The Bell phenomenon, which is an upward rolling of the globe on attempted eye closure, is an important finding denoting an added level of protection against dryness. Signs of excessive eye dryness and irritation include redness of the conjunctivae and mucoid or purulent drainage. Examination of the oral cavity may reveal drooling of saliva due to commissure incompetence and inner cheek trauma from biting.

51.6.3 Testing

In a setting of acute facial paralysis, electrodiagnostic testing can help identify patients who may benefit from surgical decompression of the facial nerve. Electroneurography of the facial nerve measures compound facial muscle action potential

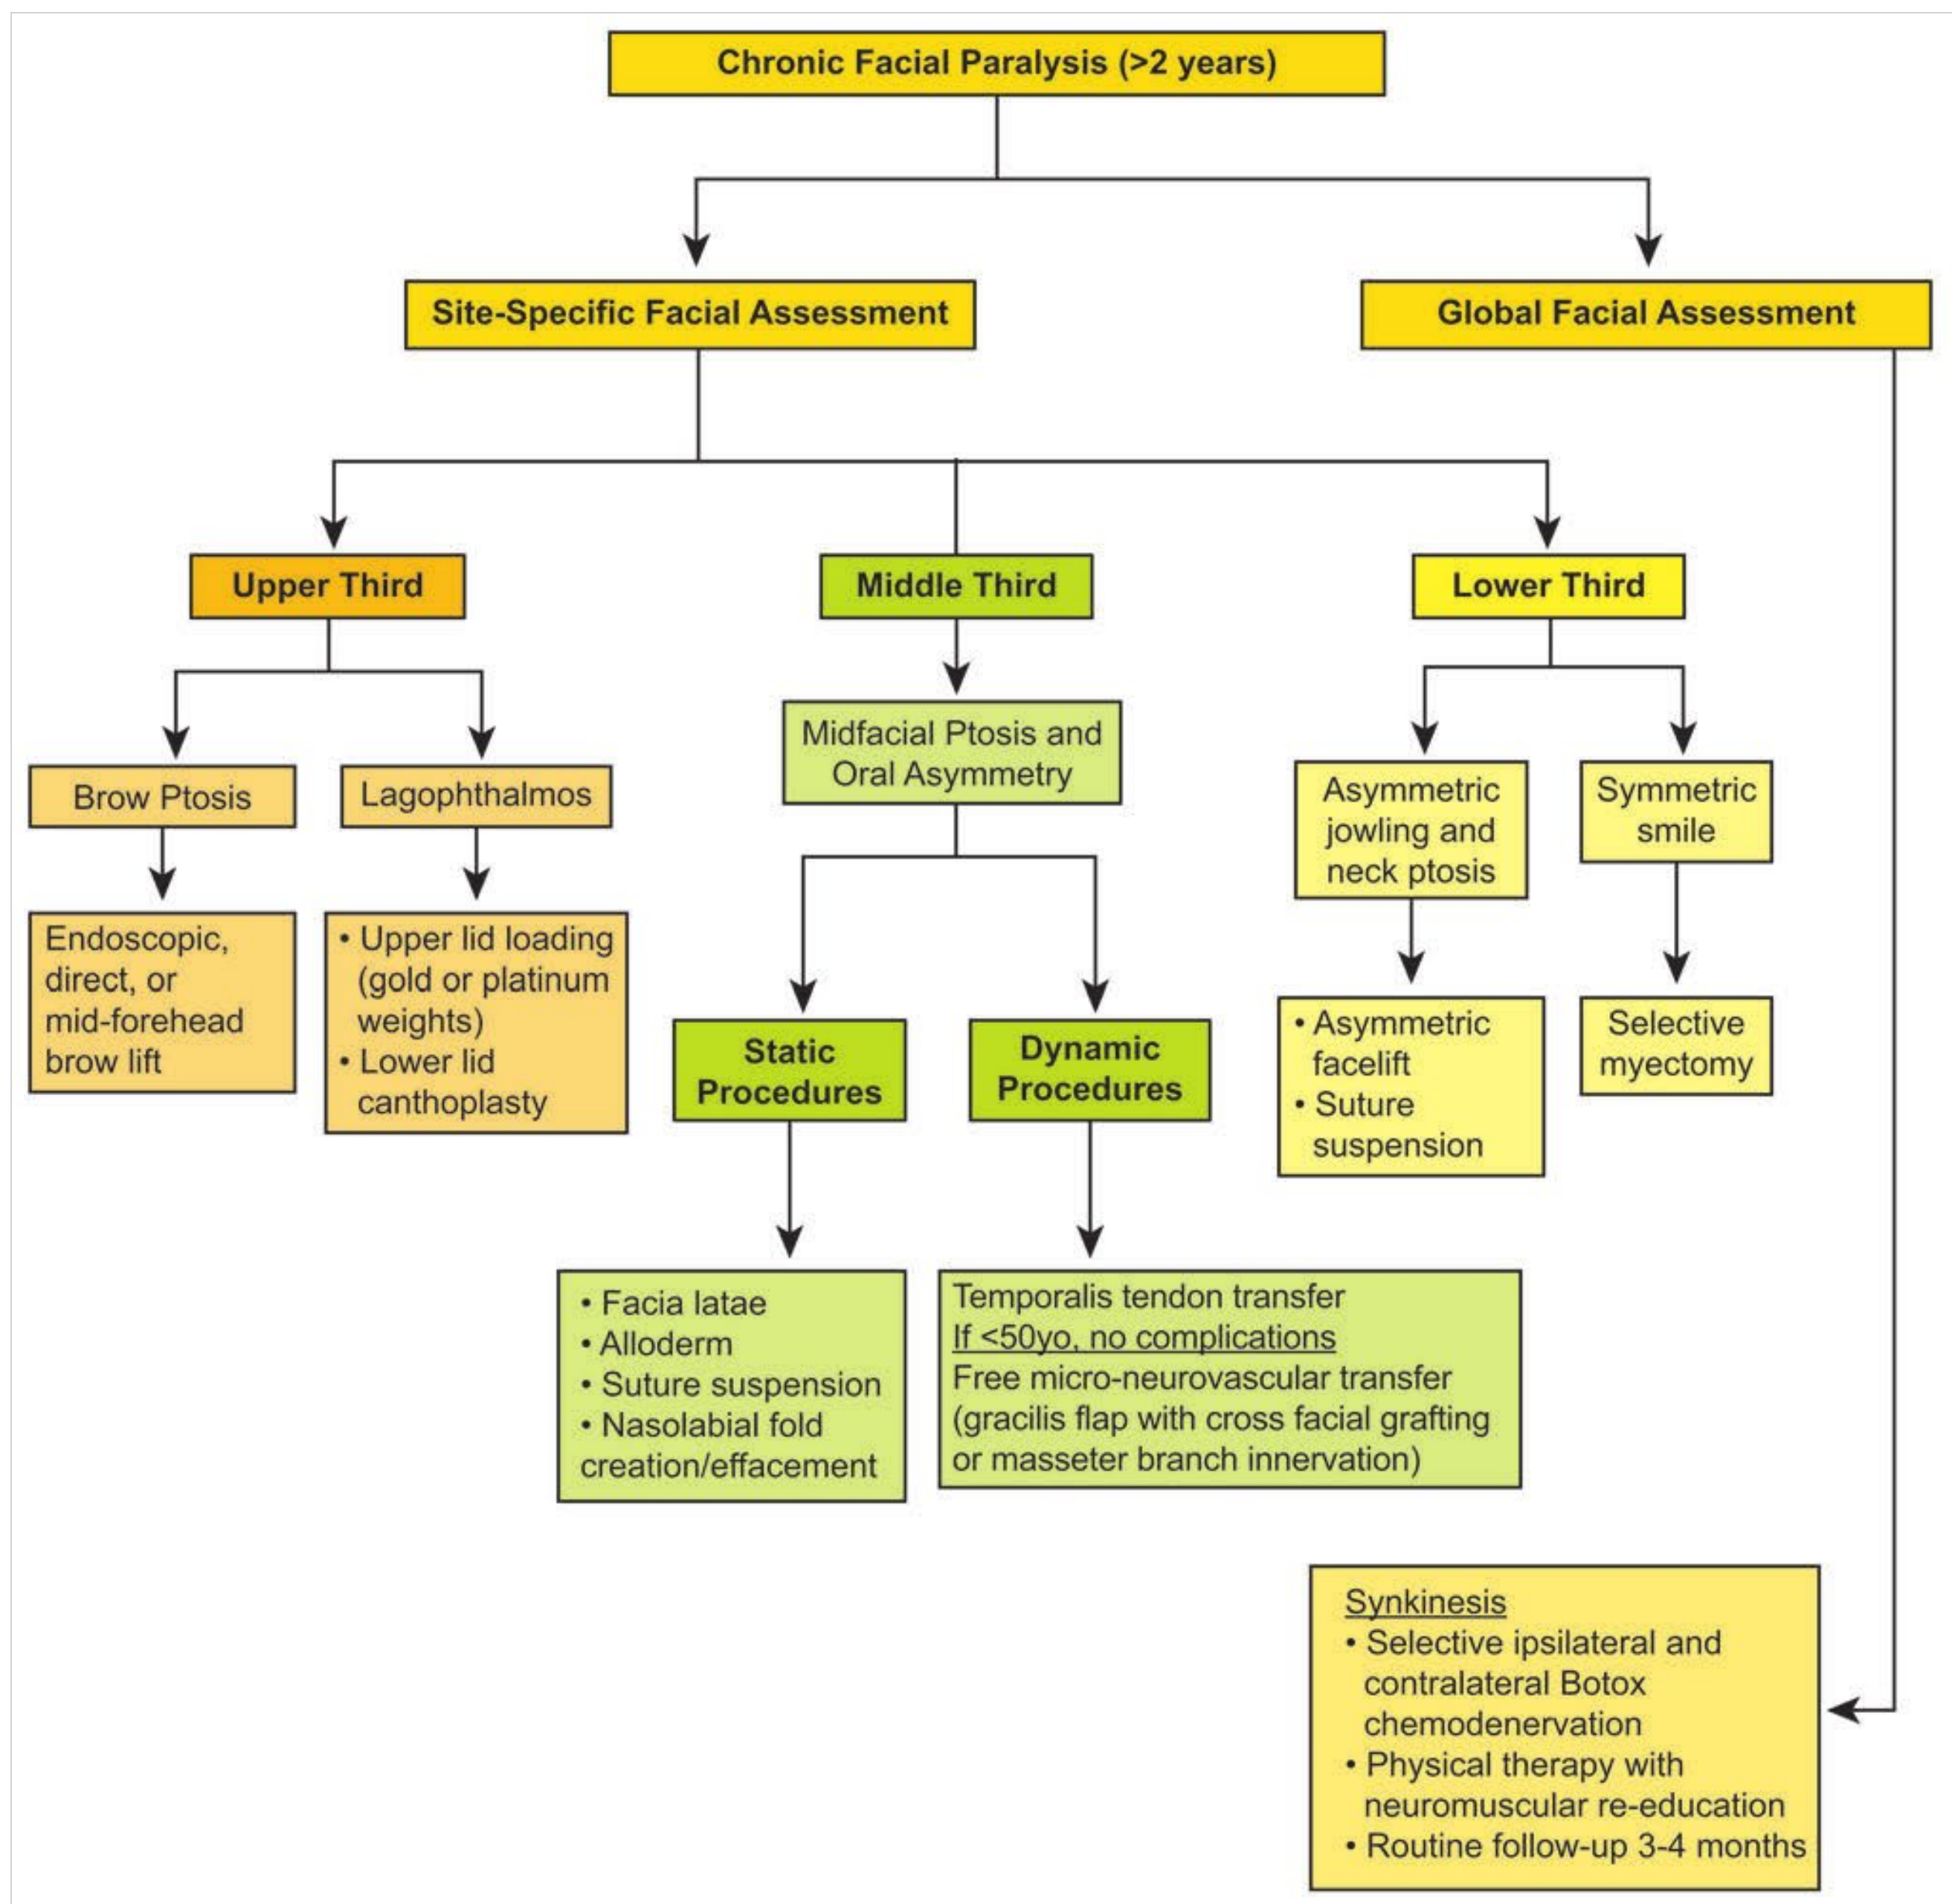

Fig. 51.1 Management strategies for chronic facial nerve paralysis of longer than two years' duration.

upon stimulation of the nerve at the stylomastoid foramen. Measurements from the paralyzed and healthy sides of the face are compared. In cases of more than 90% degeneration, decompression of the facial nerve may be indicated. In cases of paralysis lasting beyond 3 weeks, facial EMG can provide prognostic data. This test is performed by inserting a needle into one of several larger facial muscles, such as the orbicularis oculi and orbicularis oris, and recording action potentials. Polyphasic configuration of the action potentials indicates early reinnervation and impending return of facial function. Blood tests may be ordered depending on the level of suspicion for any number of infectious and systemic disease processes (see □ Fig. 51.4).

51.6.4 Differential Diagnosis

The differential diagnosis of facial paralysis is reviewed in an earlier section of this chapter (The Disease Process) and in □ Fig. 51.4 and □ Fig. 51.5

51.7 Treatment

51.7.1 Medical Treatment

The medical treatment of facial paralysis depends on the underlying etiology. Specific treatment guidelines are outlined in □ Fig. 51.4. All patients with facial paralysis receive

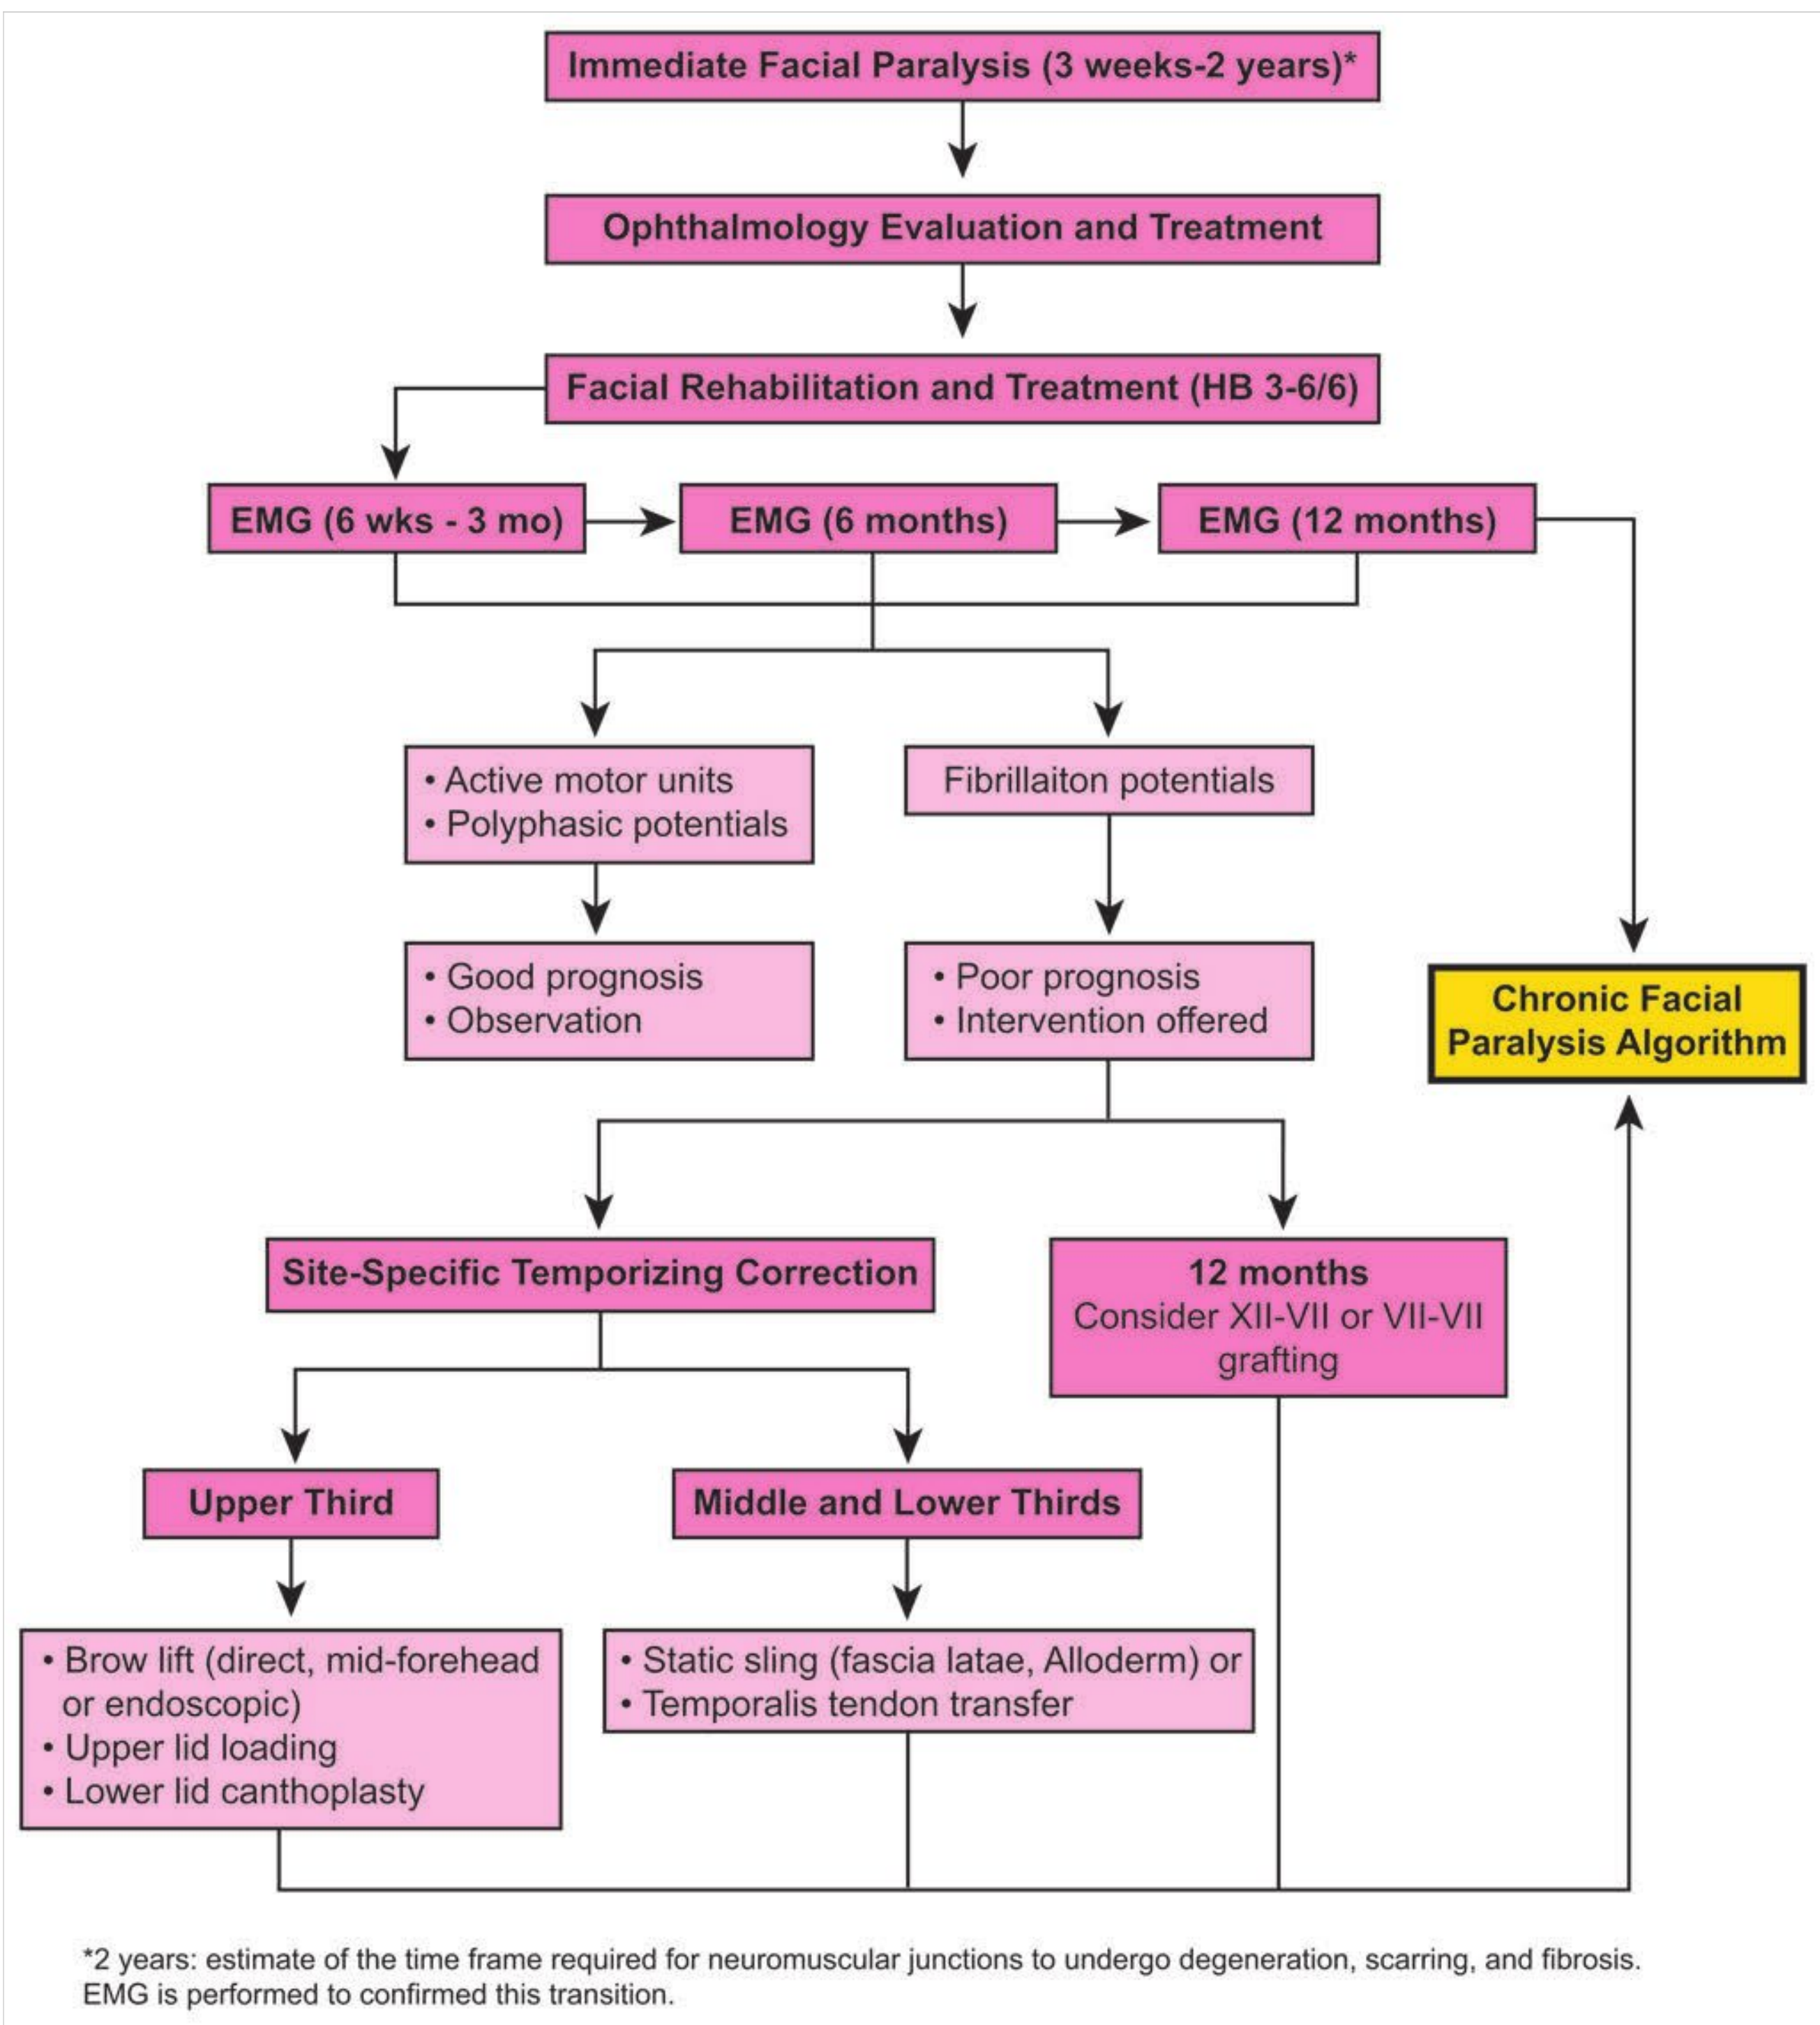

Fig. 51.2 Management strategies for intermediate facial nerve paralysis of 3 weeks' to 2 years' duration. EMG, electromyography.

eye care with natural tears and ointment until full resolution of lagophthalmos.

51.7.2 Surgical Treatment

The treatment options for facial paralysis and associated movement disorders are numerous and vary based on individual

deficits, needs, and preferences. An individualized plan of care is formulated together with the patient. In many cases of facial paralysis, multiple treatments may be necessary in order to achieve optimal aesthetic and functional results. Specialty services, such as ophthalmology, otology, and physical therapy, are consulted on an as-needed basis.

Fig. 51.3 Right facial synkinesis, or lip pucker. Note simultaneous contraction of the right orbicularis oculi, orbicularis oris, and platysma

Acute Facial Paralysis (0–21 Days)

Identifiable causes of acute paralysis are treated expediently with appropriate medical therapy, following proper identification of the cause (see □ Fig. 51.4). In rare instances, surgical intervention may be necessary to control infection and/or swelling around the facial nerve.

In a setting of facial nerve transection, several reconstructive options are available for immediate facial nerve repair, which minimize the sequelae of paralysis and promote the return of facial nerve function (see □ Fig. 51.5). Tension-free approximation is critical in achieving a successful neuroorrhaphy. Identified

nerve ends can be mobilized for distances of several centimeters by releasing attachments to surrounding soft tissues. Larger gaps can be repaired with either regional (great auricular) or distal (lateral antebrachial cutaneous or sural) nerve grafts. Nerve stumps are approximated with fine, interrupted monofilament sutures (e.g., 9–0 nylon) placed under microscopic magnification.

Intermediate Facial Paralysis (21 Days–2 Years)

During this stage, facial nerve recovery is monitored with serial EMG examinations, which provide useful prognostic data. In the setting of a poorly recovering facial nerve, several procedures can be considered to restore facial appearance and rehabilitate function around the eye and mouth (see □ Fig. 51.2). In the early stages, at 6 weeks to 3 months, the placement of gold or platinum weights aids upper eyelid closure, and static sling suspension of the midface and lip can be performed with minimal associated downtime. These procedures do not interfere with the recovering facial nerve. In the later stages, if the facial nerve continues to display poor recovery on EMG, consideration is given to nerve transfer procedures designed to maintain neurologic input to the facial muscles. A graft from a nearby nerve, most commonly the hypoglossal nerve (cranial nerve XII), can provide such input. This ultimately allows the preservation of tone in the native facial musculature—usually, however, at the expense of causing synkinesis (involuntary simultaneous movement of multiple facial muscles). As an alternative, definitive reconstruction with a vascularized gracilis muscle transfer is also considered at this stage.

Chronic Facial Paralysis (More than 2 Years)

Paralysis

The management of chronic facial paralysis depends on numerous factors, including patient preferences and desires. Depending on the situation, medical considerations may limit available procedures. For example, older and frailer patients are poor candidates for nerve and muscle transfer procedures. Reconstructive options range from static suspensions to dynamic reanimation via muscle transfer to the paralyzed side (see □ Fig. 51.1). Both have their merits and serve a useful purpose in the aesthetic and functional rehabilitation of patients with facial paralysis.

Static slings are the simplest solution with the quickest recovery time. They reposition ptotic tissues of the face and aid in functional aspects, such as lip closure and the prevention of food spillage. Autologous fascia, homologous tissue (AlloDerm; LifeCell Corporation, Branchburg, NJ), sutures, and various manufactured materials (Gore-Tex; W. L. Gore & Associates, Newark, DE) can be used for this purpose. Static slings may relax and stretch over time, potentially requiring additional tightening.

Muscle transfer allows the restoration of symmetry and movement on the paralyzed side. These are more extended procedures with longer recovery times than those of static slings. Transfer of the temporalis muscle, however, requires the patient to bite down in order to activate the smile. The procedure of choice to regain involuntary smile is a two-stage transfer of the

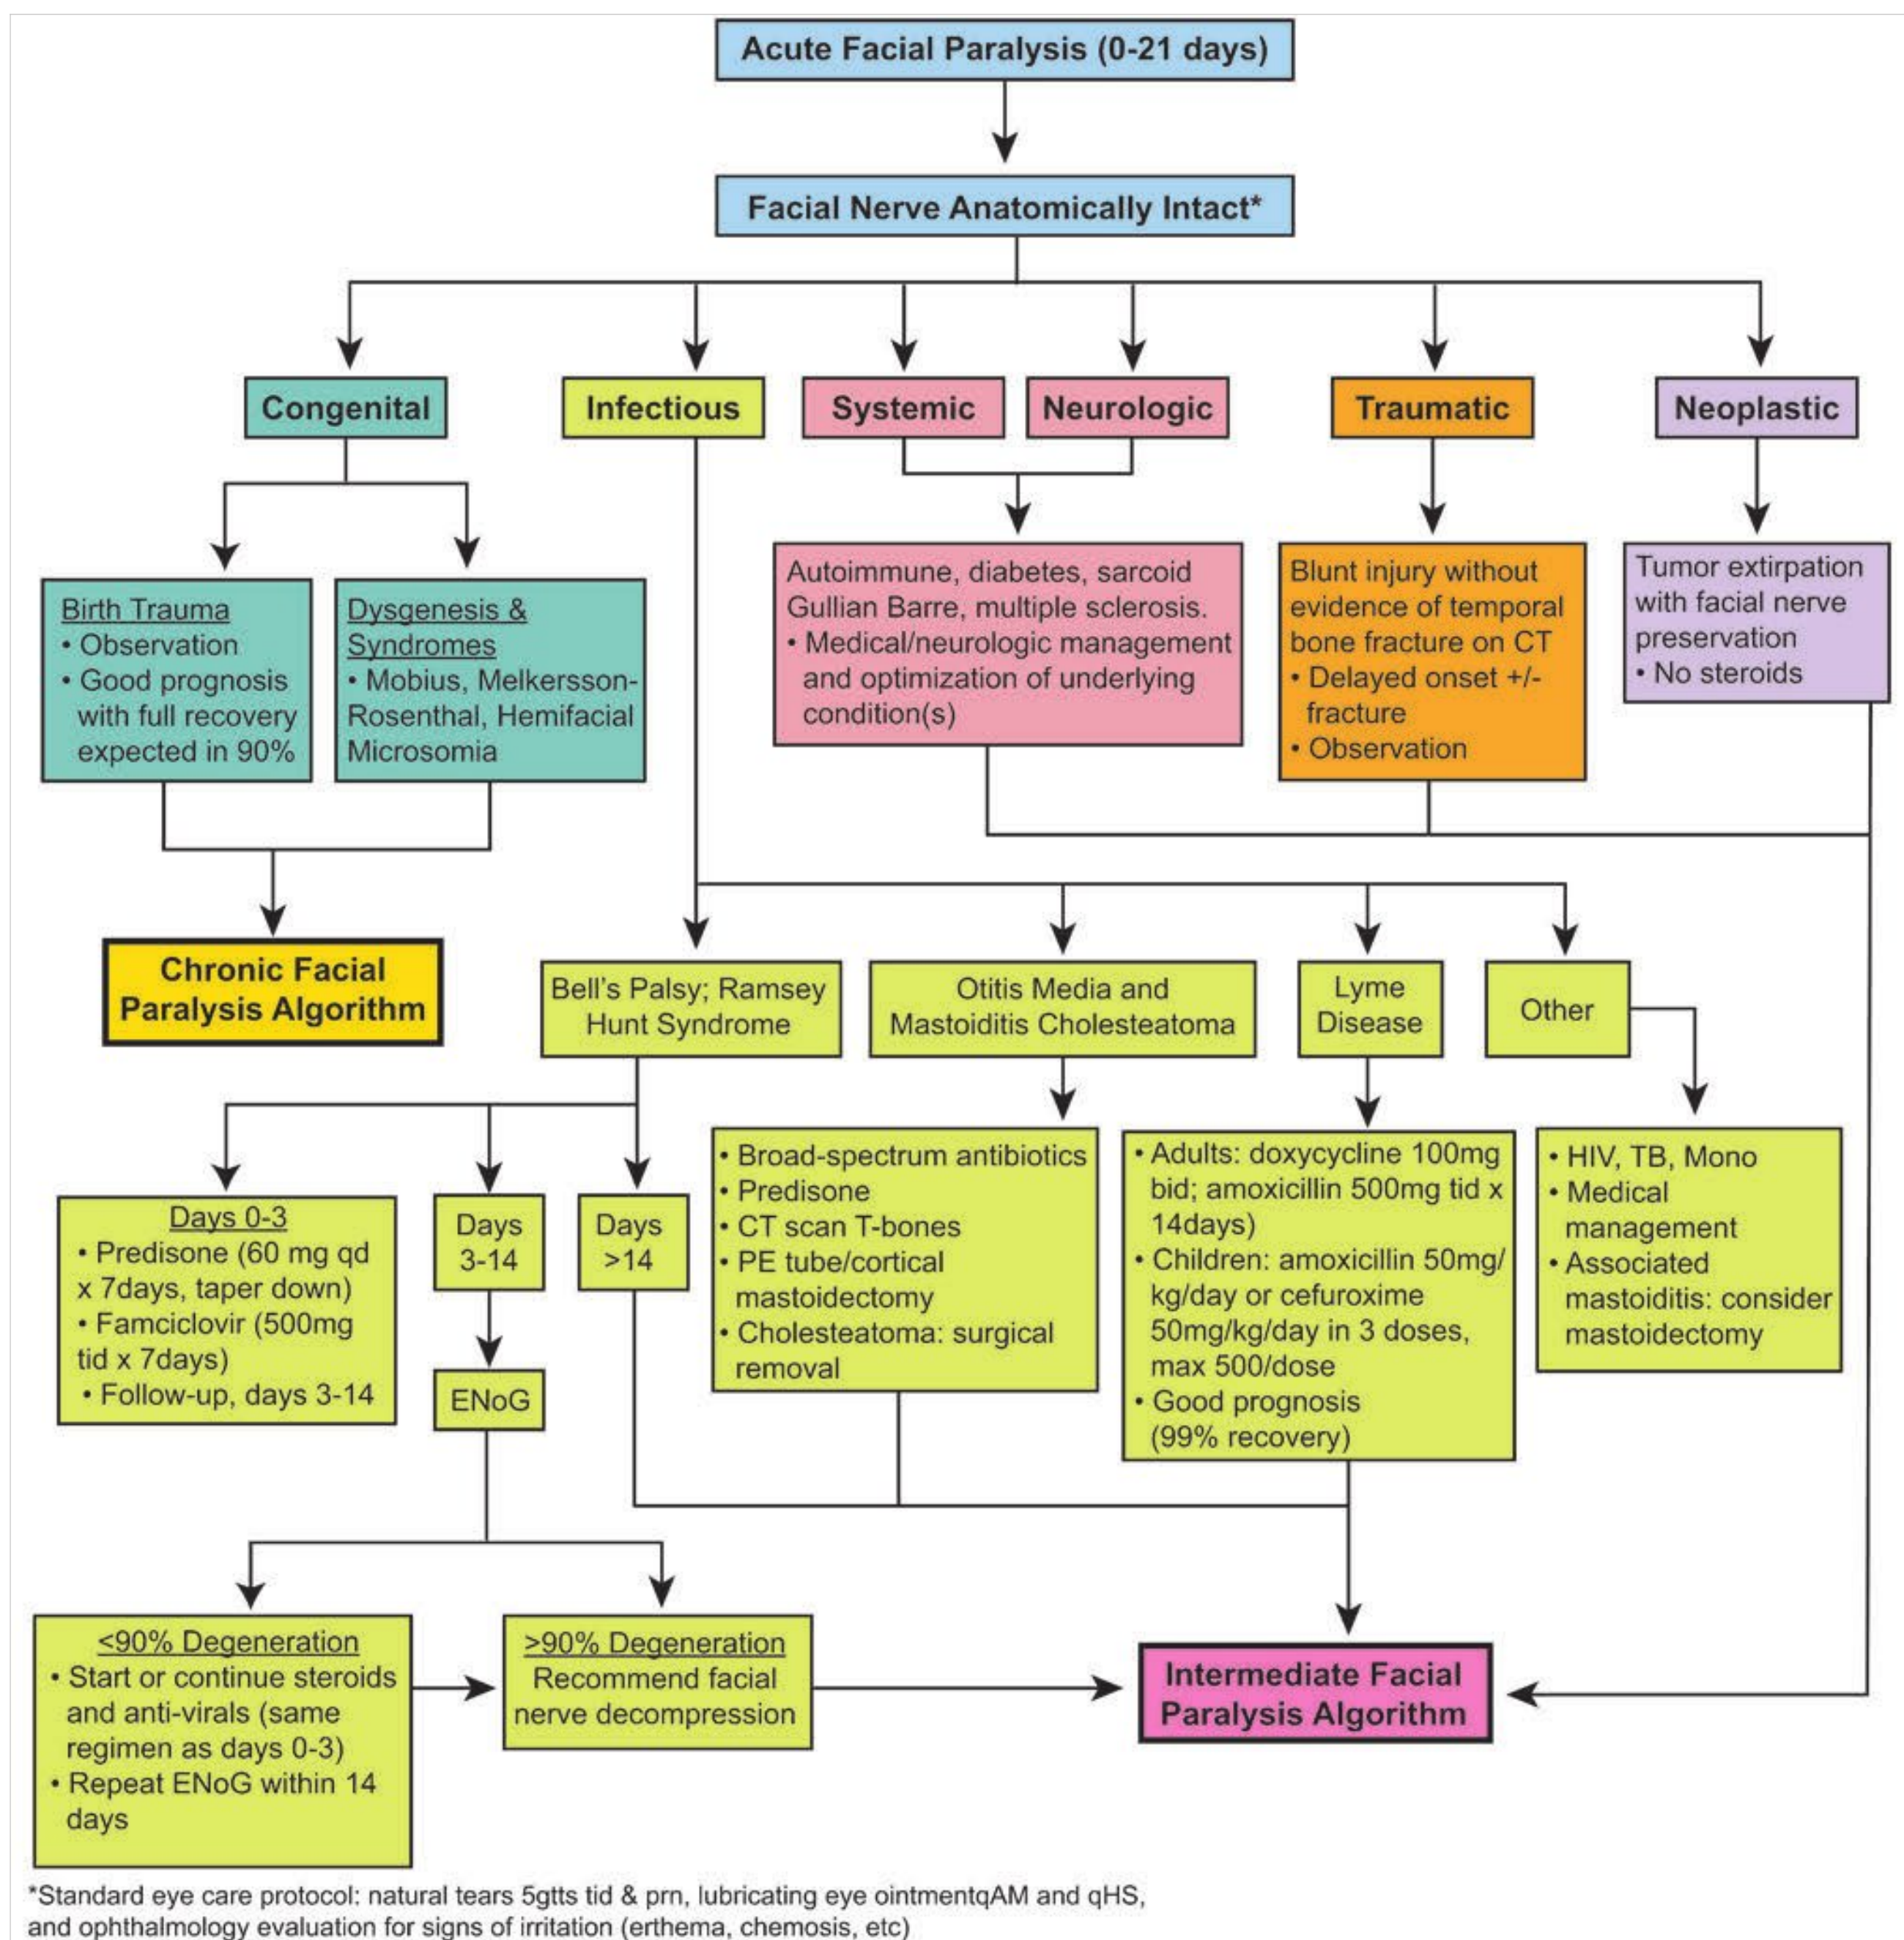

Fig. 51.4 Differential diagnosis and management of acute facial nerve paralysis with an intact facial nerve, 0 to 21 days' duration.

gracilis muscle. During the first operation, a smile-specific branch of the facial nerve is identified on the healthy facial side. This branch is then grafted across to the paralyzed side with a long nerve, such as the sural nerve (□ Fig. 51.8, □ Fig. 51.9, □ Fig. 51.10). Approximately 6 to 9 months later, following axonal regeneration and the development of a Tinel sign, a segment of the gracilis muscle is transferred to the paralyzed side and connected to the previously grafted nerve (□ Fig. 51.11). In approximately 6 months, the transferred muscle becomes functional and provides movement on the paralyzed side. The gracilis transfer affords better precision with respect to the smile an-

gle and greater excursion (movement) of the commissure (corner of the mouth) in comparison with the temporalis transfer.

Synkinesis

Synkinesis is the poorly coordinated, simultaneous, and involuntary contraction of several facial muscles during purposeful movement of the face. For example, while eye closure is attempted, the corner of the mouth may move also, generating an unwanted smile (see □ Fig. 51.3). Such poor coordination results from random axonal regeneration within the recovering

Fig. 51.9 Dissected facial nerve branch responsible for commissure elevation. This branch is cut and sutured to the sural nerve graft.

facial nerve. The successful management of synkinesis depends on selective chemodenervation with a paralytic agent (botulinum toxin A) in combination with facial physical therapy. The effects of botulinum toxin injections wear off, and the injections must be repeated every 3 to 4 months. Other therapies, such as radio-frequency ablation, may reduce the required frequency of such injections but are still investigational at this juncture.

51.8 Prognosis

The prognosis for recovery of facial movement varies with the disease etiology and timing of presentation. Many patients with infectious or systemically based cases of facial paralysis recover fully with appropriate treatment. Outcomes in the surgical rehabilitation of chronic facial paralysis are more difficult to quantify and depend on numerous patient- and procedure-related factors.

Fig. 51.10 The sural nerve graft is passed within the upper gingivo-buccal sulcus to the paralyzed side of the face.

51.9 Roundsmanship

- Patients with facial paralysis require an individualized approach to achieve optimal cosmetic and functional outcomes.
- Recovering facial nerve can result in synkinesis. The optimal treatment of synkinesis includes chemodenervation with botulinum toxin A and physical rehabilitation.
- An assessment of the facial zones (forehead; periocular, perioral, and cervical regions) helps define the surgical goals in patients with chronic facial paralysis.

Fig. 51.11 Gracilis muscle graft, harvested and ready for inset. Note facial access incision for graft placement (upper left corner).

- Chronic facial paralysis can be managed with static repositioning or dynamic reanimation. The choice of surgery depends on the individual patient's presentation, needs, and goals.

52 Correction of Congenital Auricular Deformities

Anthony P. Sclafani and Anthony M. Sclafani

Congenital auricular deformities describe a wide range of anomalous auricular forms, from prominent to completely absent ears. These deformities may be associated with other congenital syndromes but most often are found in isolation. Although the correction of these deformities addresses the patient's physical appearance, they should not be considered cosmetic; these procedures are performed to restore a normal appearance of the ears and are rightly classified as reconstructive surgeries. The procedures can be performed at any age, but ear deformities are best corrected in childhood, before the patient has suffered psychologically from social stigmatization and has developed a sense of physical "self."

52.1 Incidence of Disease

The exact incidence of congenital auricular deformities is unknown, and this figure is most likely underreported because affected patients may simply style their hair to camouflage the deformity. Approximately 5% of Caucasians in the United States have protruding ears. The 2011 American Society for Aesthetic Plastic Surgery survey estimated that just slightly fewer than 27,000 "cosmetic" ear surgeries were performed; 59% of patients with prominent ears have a family history of the condition, and transmission is thought to be autosomal-dominant with variable penetrance. Cases of microtia/anotia, easily evident at birth, are more reliably reported, with a general incidence in the United States of approximately 1 in every 7,000 to 8,000 live births. Ethnic and national differences in incidence have also been described, with Hispanics, Asians, and Navajo Native Americans more commonly affected in the United States. Microtia is more common in boys (60 to 70% of cases) than in girls. More cases of microtia are noted on the right side (60%) than the on left (30%); approximately 10% of cases are bilateral.

52.2 Terminology

Terms to understand include those that refer to the structures of the normal auricle (listed below), as well as those pertaining to specific deformities and their associated abnormalities. The term anotia refers to the total absence of any external ear, whereas microtia describes an imperfectly formed auricle ranging from grade I (small but relatively normally shaped ear) and grade II (abnormally sized and formed auricle with some recognizable components of the auricle) to grade III microtia (skin and cartilage remnants only). Grade III microtia has been subdivided into lobule remnant and conchal remnant subtypes, in which only skin approximates a malpositioned earlobe (lobule remnant) or skin and malformed cartilage approximate an earlobe and inferior conchal bowl (conchal remnant). Aural atresia is to the absence of an external auditory canal, tympanic membrane, and intact ossicular chain and is frequently seen together with microtia. Hemifacial microsomia is a condition in which some or all parts of a hemiface are underdeveloped, also seen

not infrequently together with microtia. Cryptotia refers to a mild auricular deformity in which the superior helical rim is tucked under temporal skin and does not project away from the head. A variety of common names have been used to phenotypically describe the prominent auricle, such as lop ear, bat ear, satyr ear, shell ear, and cup ear, among others. It is more valuable to identify the specific defects of the malformed ear because these features will be directly addressed during otoplasty.

52.3 Applied Anatomy

Surgeons performing procedures on the auricle should be familiar with the normal structures and forms of the natural auricle, such as the helix, antihelix, scaphoid fossa, fossa triangularis, conchal bowl, tragus, antitragus, lobule, helical root, cauda helix, and postauricular crease (□ Fig. 52.1). The auricle is composed of fibroelastic cartilage, and although flexible in youth, it becomes more rigid over time. The arterial supply to the auricle is from the posterior auricular artery and superficial temporal arteries, which are both terminal branches of the external carotid artery systems (□ Fig. 52.2).

Rudimentary muscles help maintain the auricular position, and in some individuals they have a slight ability to move the auricle. Sensory nerves to the auricle are from the auriculotemporal nerve (from the mandibular division of the trigeminal nerve), the great auricular nerve (from C2 through C4 roots), the Arnold nerve (branch of the vagus nerve), and twigs of the facial nerve (□ Fig. 52.3). Both the neural and vascular supply to the auricle follow a radial pattern, allowing a circumferential ring blockade around the base of the ear to anesthetize the entire auricle.

52.4 The Disease Process

52.4.1 Etiology

No specific causes of auricular malformation have been conclusively proved. Auricular prominence can occur sporadically, although about 60% of patients have a positive family history. Transmission between generations is as an autosomal-dominant trait with incomplete penetrance. Conversely, microtia appears to occur more commonly in certain countries (e.g., Finland and Ecuador) and cultures, suggesting some limited genetic role.

52.4.2 Pathogenesis

The external ear develops separately from the middle ear and inner ear. The auricle is formed from the tissues of the first and second branchial arch, with the first arch contributing the first three hillocks of His, while the fourth through sixth hillocks originate from the second arch; these are present by day 38 of gestation. The tragus and the root and body of the helix

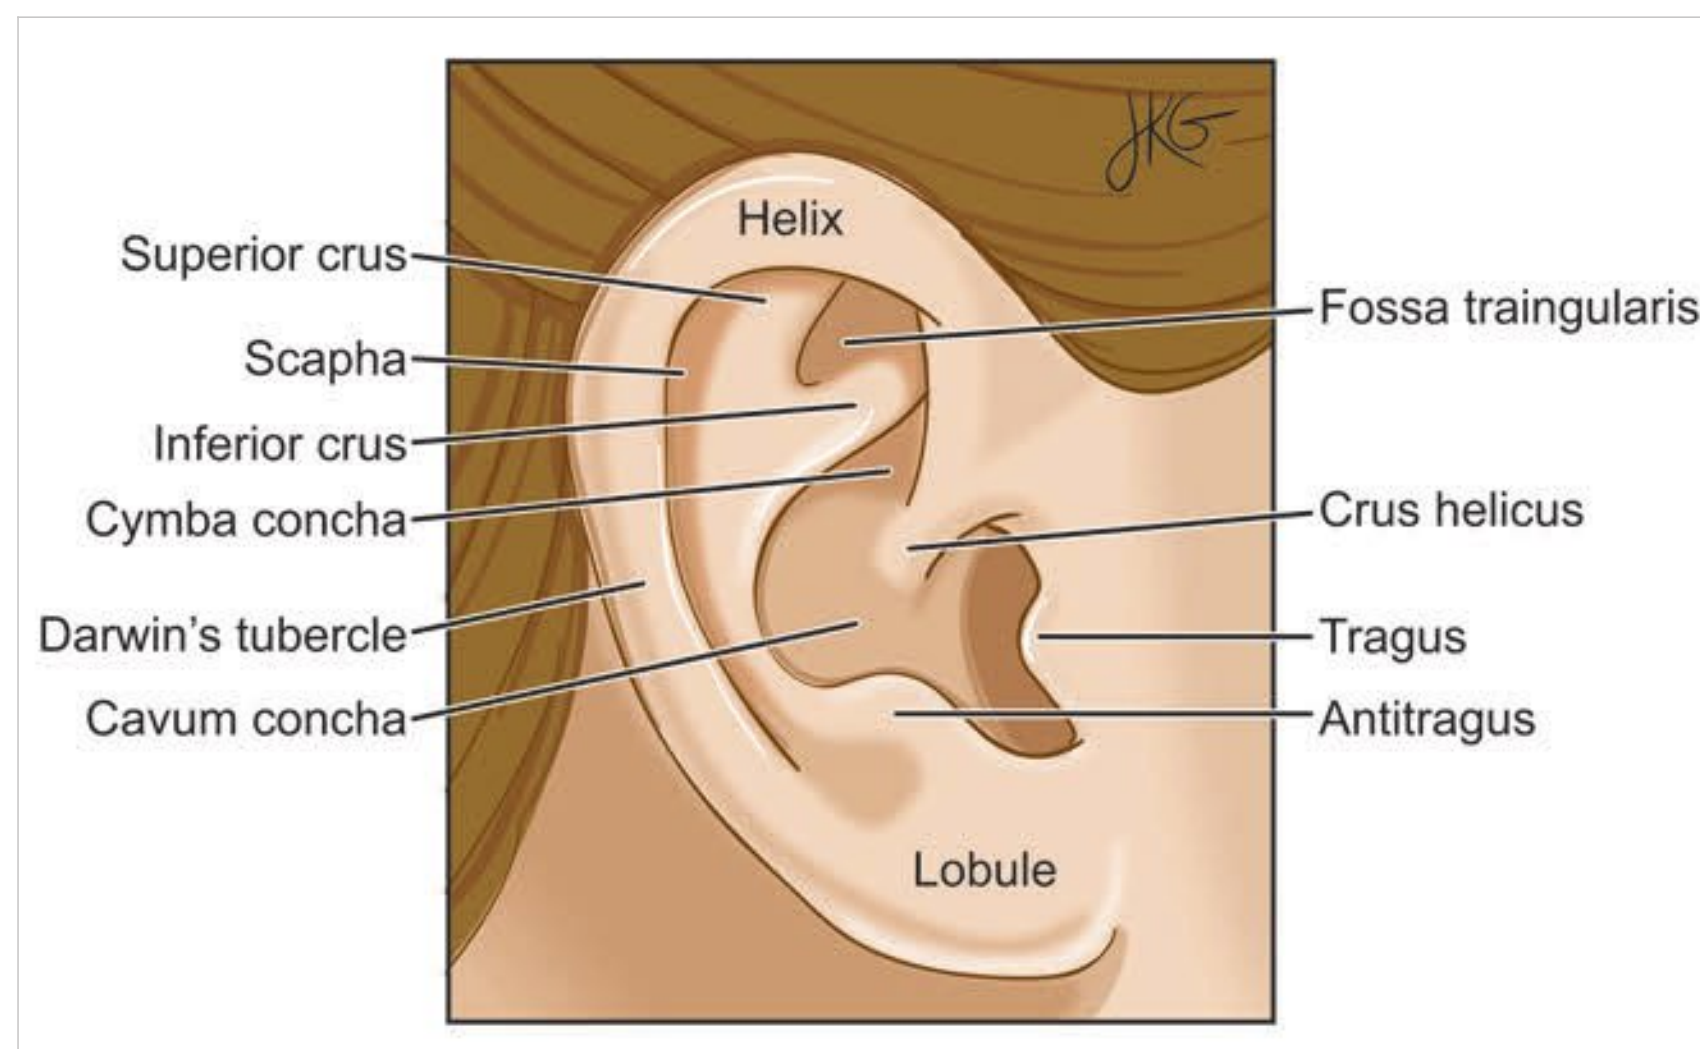

Fig. 52.1 Normal auricular landmarks.

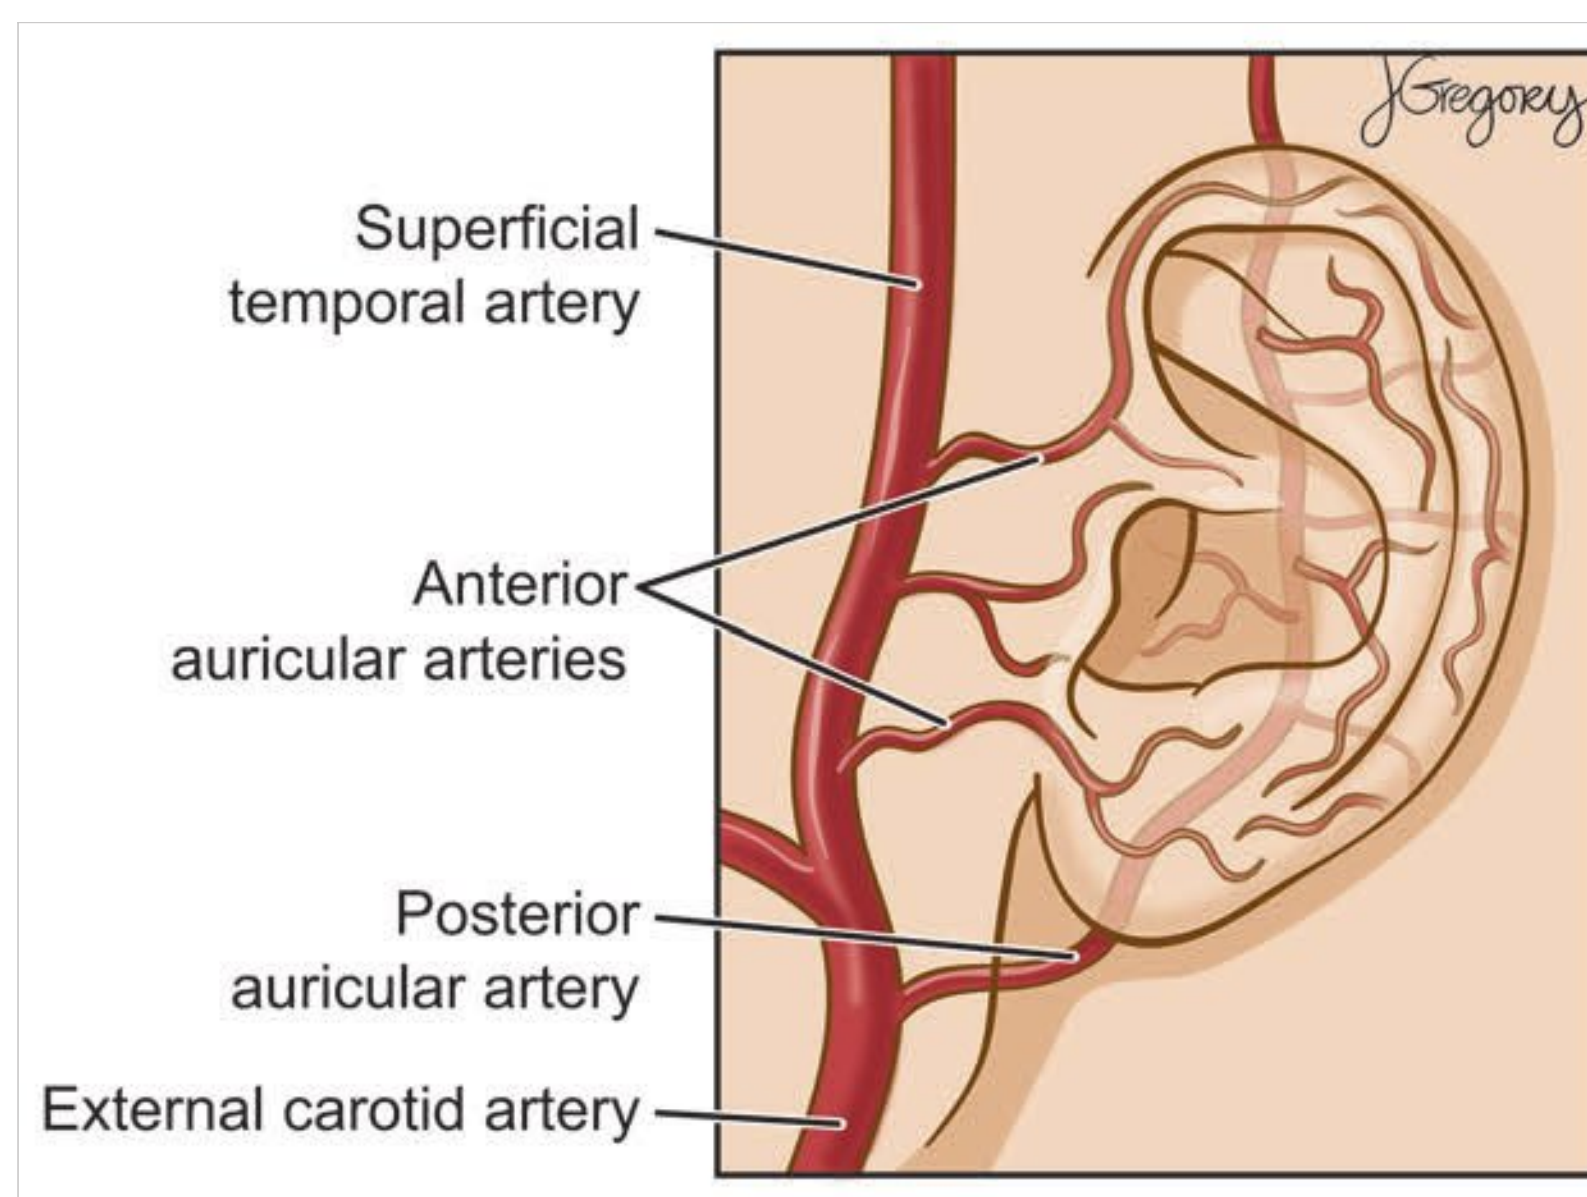

Fig. 52.2 Auricular blood supply.

develop from first-arch tissue, while the remainder of the auricle originates from the second arch. The auricle develops between weeks 6 and 16 of gestation. The helix is believed to grow rapidly during weeks 8 through 12 and ultimately overhangs the rest of the auricle; during weeks 13 through 16, the antihelical curl develops and medializes the helix. It is thus reasonable to assume that the deformities seen in prominent ears form during weeks 10 through 16, whereas microtia deformities are a result of more significant, earlier gestational abnormalities and can be attributed to anomalous development of hillocks 2 through 5.

An alternative theory of auricular embryogenesis holds that the tragus and helical root develop from the first arch; the antihelix, conchal bowl, lobule, and antitragus develop from the second arch; and the remainder of the helix as well as the scaphoid fossa are derived from the free ear fold, a swelling just above and behind the developing arches. This theory relegates the hillocks of His to incidental findings.

52.4.3 Natural History and Progression

The auricle grows after birth and attains approximately 85% its adult size by 5 to 6 years of age. Without intervention, congenital auricular deformities do not improve over time.

52.4.4 Potential Disease Complications

Prominent ears do not progress or cause a physical debility. However, the social stigma of deformed ears can cause significant emotional distress. Children rarely suffer from teasing by peers before the age of 6 years, and surgery can be delayed until that time, when the patient will be more mature and cooperative. Microtia likewise does not worsen; however, microtia is typically associated with aural atresia and its associated maximal conductive (60 dB) hearing loss. In cases of bilateral microtia, auditory rehabilitation with bone-anchored hearing aids is essential to allow appropriate auditory cortical development.

Fig. 52.3 Auricular sensory innervation. CN, cranial nerve.

52.5 Medical Evaluation

52.5.1 Presenting Complaints

Although microtia is immediately recognized at birth, patients frequently do not present until the age of 3 or 4 years because the family has been advised that no treatment is possible until the age of 5 or 6 years. Parents typically style the child's hair long to camouflage the deformity.

Patients with unilateral microtia, despite the maximal conductive hearing loss, rarely suffer from auditory deprivation because hearing in the contralateral ear is usually normal. The child should receive preferential classroom seating (front of class, unaffected ear toward the teacher). Aggressive and early

treatment for even transient cases of childhood hearing loss (e.g., otitis media with effusion) is justified. By contrast, patients with bilateral microtia should be fitted with a bone stimulation hearing aid early to facilitate normal speech development. Patients with prominent ears have hearing loss no more commonly than do other patients.

Children with microtia younger than 5 years of age may be aware of the "different" appearance of their ears but typically are too young to demonstrate any anxiety about this difference. By 7 years of age, patients with microtia have become acutely aware of the abnormal appearance of their ears(s) and may have already suffered the taunts and teasing of classmates. In contrast, patients with prominent ears, despite a lesser degree of deformity, may present earlier with psychological issues and

Fig. 52.4 Interrelations of auricular structures.

by age 6 or 7 may be unwilling to participate socially because of embarrassment.

52.5.2 Clinical Findings, Physical Examination

Children with auricular anomalies should be assessed in a uniform manner. The anterior–posterior auricular position should be 5 to 6 cm lateral to the lateral canthus, and the top of the helix should be at the level of the eyebrow; deviations from these should be noted. Auricular position can be affected by craniofacial anomalies, including hemifacial microsomia. This may occur in as many as 40% of patients with microtia and can involve maxillary or zygomatic width, but it is most commonly seen as mandibular asymmetry. This can be demonstrated by asking the patient to bite down on a tongue blade placed horizontally across the posterior teeth and observing the tilt of the blade. The basic outline of the auricle should be a smooth helical margin that extends from the helical root down into the earlobe. The shape and depth of the conchal bowl should be examined; the superior and inferior crura of the antihelix run into the common crus to form a gentle Y-shaped curve extending from the margin of the conchal bowl toward the helical rim. These basic structures thus define the scaphoid fossa and fossa triangularis; the tragus and antitragus define the incisura intertragica. The conchal bowl is separated into the cymba conchae and the concha cavum (see □ Fig. 52.1).

Furled auricles should manually be re-formed and the true height and width of the auricle noted. These dimensions should be 5 to 6 cm and 2.5 to 3.5 cm, respectively, and represent the amount of useable native cartilage available. The interrelation of the structures themselves should be evaluated: the auriculocephalic angle (between the head and the auricle, as seen from above) should be no more than 25 degrees; from the same vantage point, the conchomastoid angle should be about 90 degrees, while the antihelix should also turn away 90 degrees from the conchal bowl (□ Fig. 52.4). Overall, the ear should protrude from the head no more than 10 to 12 mm superiorly, 16 to 18 mm in the midpoint of the helical rim, and 20 to 22 mm at the lobule. The inclination of the long axis is similar but not

Fig. 52.5 The inclination of the auricle should be roughly parallel to that of the nasal dorsum.

equal to that of the nasal dorsum (inclined about 20 to 30 degrees off vertical; □ Fig. 52.5).

Obviously, patients with microtia will have significantly fewer, if any, normal landmarks. The auricular remnant can be assigned a grade from I to III. Grade I microtia is a small ear with relatively normal features and proportions; an auricle with grade II microtia may have a few recognizable features of a normal auricle but is clearly “deformed.” An auricle with grade III microtia typically has only a vestigial remnant, which can be categorized as a conchal remnant (mimicking a conchal bowl) or the more common lobule remnant (with a small, skin-covered, malformed block of cartilage at the superior end of a fleshy “lobule” remnant).

52.5.3 Testing

Patients with auricular deformities should be photographed before any surgical intervention. Standard frontal, lateral, and oblique views should be supplemented by posterior views (to assess the lateral projection of the ears) as well as close-up views of the ears. All patients should have a preoperative audiologic assessment for documentation as well as assistance in determining the need and feasibility of surgical aural rehabilitation (in cases of microtia/atresia). High-resolution computed tomography (CT) of the temporal bones should be obtained when the child is old enough to cooperate with the test to aid in further determining the candidacy of the patient for aural atresia repair. This is done preoperatively in our institution through the cooperative efforts of the facial plastic surgeon and the otologist. The patient with microtia should be assessed for evidence of other congenital deformities, especially hemifacial microsomia, congenital facial nerve impairment, and Goldenhar and Nager syndromes. Consultation with a geneticist and screening for cervical spine deformities (X-rays or CT of the neck) and renal anomalies (ultrasound) may be appropriate.

52.5.4 Differential Diagnosis

The diagnosis of microtia is fairly self-evident because the deformity is obvious and has been present since birth. Prominent ears also are simple to diagnose, but the surgeon should be aware that cranial anomalies can cause malposition and prominence of the ears; more commonly, postauricular inflammatory swelling may cause the ear to protrude.

52.6 Treatment

52.6.1 Medical Treatment

Although there is no medical treatment per se for an advanced-grade microtia, minor auricular deformities can sometimes be partially or fully corrected noninvasively. Especially within the first year of life, the auricular cartilage is quite soft and pliable. Taping and splinting prominent or folded auricles during the first several months of life can aid in correcting, or at least improving, the contour of the auricle.

A prosthesis can be made, with the contralateral ear used as a template, and be either glued in place or mounted with osseointegrated implants. A well-made prosthesis, although artificial and requiring maintenance, can look quite realistic.

52.6.2 Surgical Treatment

Otoplasty

Prominent auricles can be reshaped and repositioned by otoplasty. Ely described the first case of otoplasty in New York City in 1881, when he excised full-thickness portions of conchal bowl. In 1903, Morestin described many techniques currently in use, while Lockett used cartilage incisions and sutures to form the antihelix in 1910. Modern otoplasty maneuvers fall into two distinct categories: cartilage-cutting and cartilage-sparing techniques.

Cartilage-cutting techniques are powerful steps that can significantly remodel and reposition the auricle; however, these techniques can lead to unnatural, sharp edges when cuts through firm cartilage are seen through thin auricular skin. Cartilage-sparing techniques avoid sharp angles by relying mainly on sutures and postoperative fibrosis to bend, fold, and maintain the corrected shape and position of the auricular cartilage. The utility of this approach can be limited in adult patients, whose cartilage is stiffer and less pliable than that of pediatric patients.

Most otoplasty procedures use a postauricular approach, although an anterior approach can be used for anterior cartilage scoring. In this technique, a fine rasp or wire brush is used to make parallel longitudinal partial-thickness cuts through the cartilage of the lateral surface of the antihelix. Subsequent contractile forces, in addition to postoperative splinting, then promote cartilage warping and the creation of a more convex lateral surface. Again, cartilage irregularities are sometimes visible through thin lateral auricular skin.

Both cartilage-cutting and cartilage-sparing procedures access the auricular cartilage via a postauricular incision and fusiform skin excision. The skin on either side of the incision can be elevated and retracted for adequate exposure from the helical rim to the mastoid periosteum. Skin excision should be conservative and planned so as to allow the scar to fall into the postauricular sulcus.

Cartilage-cutting procedures may involve the exposure and removal of an overly convex conchal bowl cartilage that bows excessively and does not rest flat against the mastoid cortex. Other modifications include parallel incisions on either side of the apex of the antihelical curve, followed by sutures placed between the two larger segments; the strip of antihelical apex is

allowed to ride over the sutured cartilage segments to camouflage the sharp angle formed by the junction of the two larger cartilage segments. Cartilage-sparing procedures are more commonly used. These are used to form a more defined antihelix, medialize the conchal bowl, correct prominence of the superior pole of the auricle, or correct earlobe prominence. Mustardé described mattress sutures placed between the sides of the antihelical fold and tied sufficiently tightly to better define the antihelix. The antihelix should be manually folded by the surgeon, and a 2-0 silk suture can be passed through the cartilage and across the antihelix about 1 cm below its apex (□ Fig. 52.6) to mark the site for the two to four mattress sutures. The postauricular dissection is then exposed, and the entry and exit sites of the sutures as they pass through the cartilage are noted. These marking sutures are removed, and horizontal mattress sutures of a 3-0 or 4-0 braided, nonabsorbable suture material are placed at these sites (□ Fig. 52.7) and tied while an assistant folds the antihelix appropriately. Three to five sutures are placed along the length of the common and superior crura of the antihelix. Suture bites should be wide enough to allow a gentle, rolling antihelical curve; however, sutures should not be placed too superiorly along the superior crus to avoid a “tent pole” deformity (in which the superior crus of the antihelix extends crisply up across the scaphoid fossa to the helix).

The conchal bowl can be sutured more medially to reduce its lateral extension in cases of prominence. If the mastoid surface of the conchal bowl is significantly rounded, partial-thickness cartilage excision is performed to “flatten” this surface of the cartilage. Horizontal mattress sutures are placed through the conchal cartilage extending away from the mastoid and tied to a suture bite of mastoid periosteum. It is important that the suture pull the conchal bowl posteriorly as well as medially; mastoid sutures placed too anteriorly will cause the anterior lip of the conchal bowl cartilage to move anteriorly and compromise the external auditory meatus.

Further contouring of the auricular position and shape can be performed with directed sutures for specific purposes. One

Fig. 52.6 Silk sutures placed to mark the sites for Mustardé sutures.

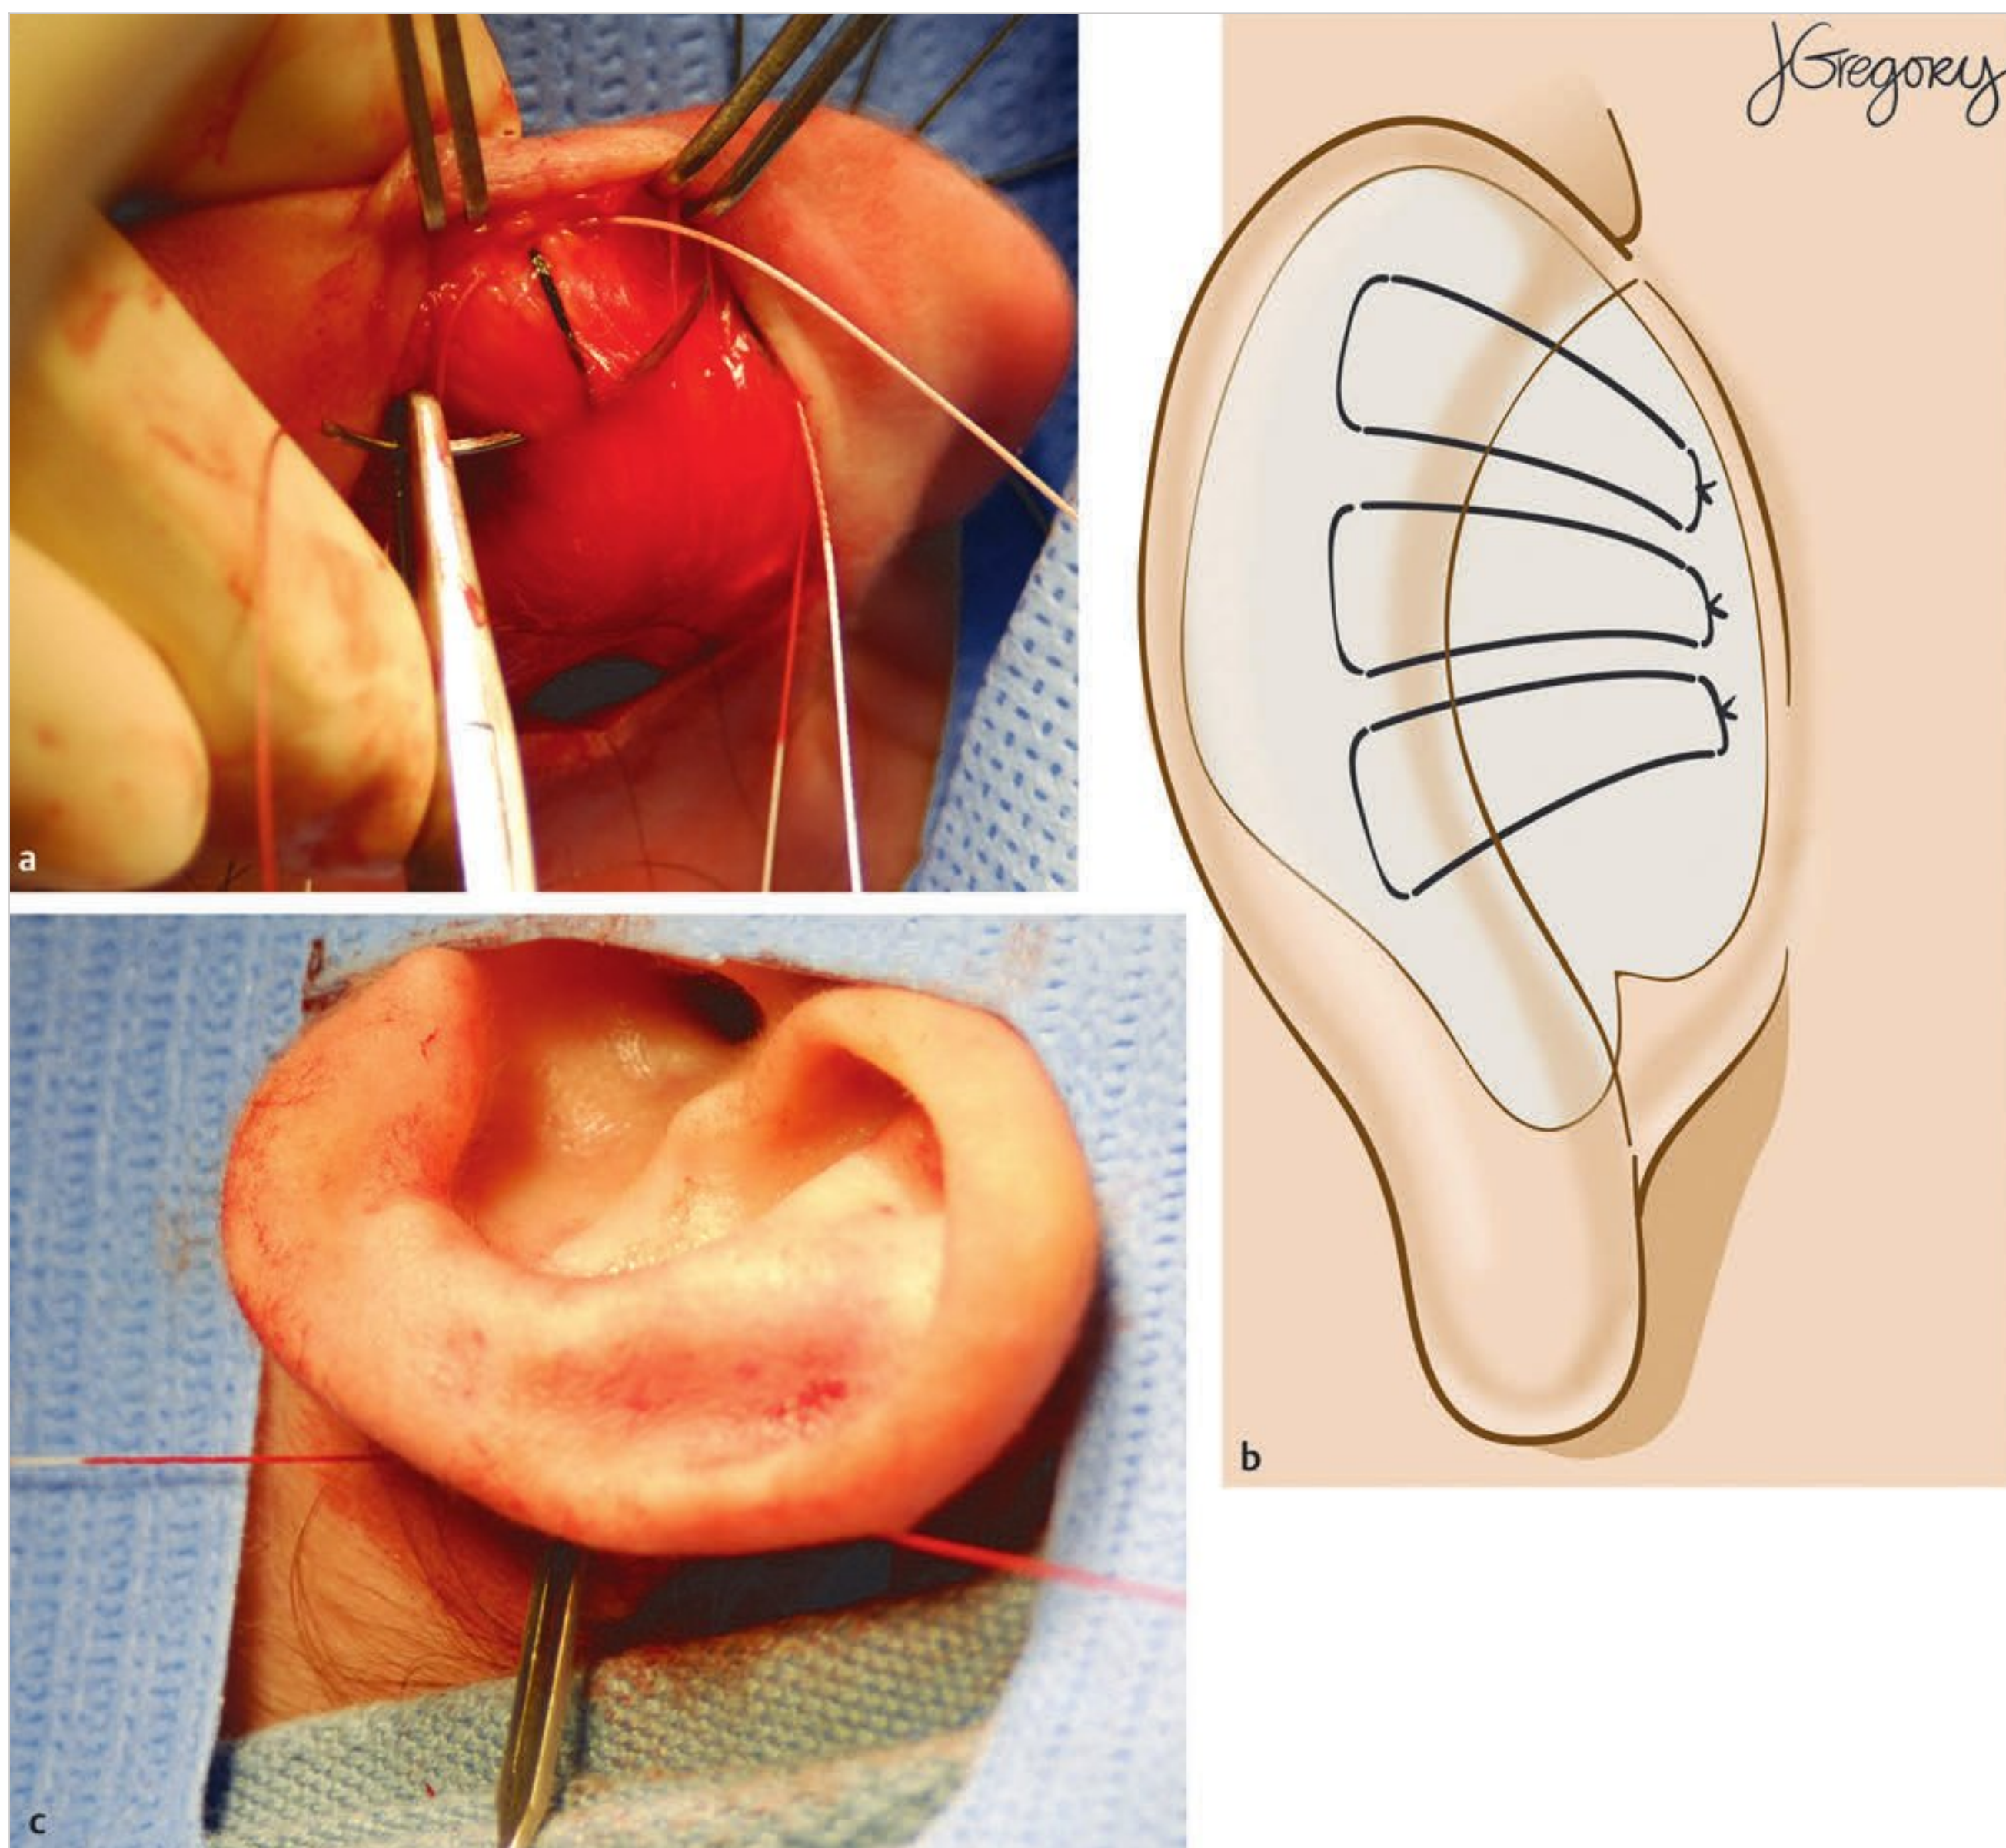

Fig. 52.7 Placement of conchohelical (Mustardé) sutures. Horizontal mattress sutures are (a,b) placed and then (c) tied while an assistant holds the antihelix in an appropriately folded position.

common finding after antihelical and conchal bowl correction is persistent prominence of the superior auricular pole. This can be fixed more medially with similar mattress sutures passed between the cartilage of the fossa triangularis and the temporalis fascia. Also, inferior pole prominence can occur, manifested by an overly lateral earlobe. This may be due to excessive soft tissue on the medial aspect of the earlobe (best treated by conservative skin excision from the medial surface of the earlobe) or to a prominent or laterally oriented cauda helix. This can be treated either with conservative cartilage excision or with an additional mattress suture between the cauda helix and conchal bowl.

It is important that both during and after placement of the cartilage sutures, the repositioned and re-formed cartilage not be stretched or pulled, but instead gently manipulated. Care should be taken to ensure that sutures do not tear through

cartilage. Once the auricle has been repositioned, the postauricular skin is redraped and any excess skin is conservatively excised. The wound may be drained with a sterile rubber band (if necessary), and the skin is closed with a running 4-0 chromic suture. A form-fitting, lightly compressive dressing is made from cotton soaked in mineral oil, packed lightly to fill the newly created concavities, underneath a mastoid dressing. The dressing and drain are removed on postoperative day 1, and an elastic athletic headband is worn over both ears constantly; after the first week, this is worn at nighttime only for the next 3 weeks (□ Fig. 52.8).

Auricular Reconstruction

Most surgeons who treat microtia surgically generally follow the techniques described by Tenzer and Brent; Nagata has

Fig. 52.8 (a) Before and (b) after otoplasty.

described a somewhat different technique but also used autologous rib cartilage to create the auricular framework. More recently, a synthetic material (Medpor; Porex Surgical, Newnan, GA) has been used, but management is problematic if it becomes infected after aural atresia repair is performed.

Stage 1

Reconstruction with autologous rib requires a staged approach. Surgery is generally begun after the patient is 6 to 7 years of age, so that adequate costal cartilage is available. A piece of clear X-ray film is placed over the normal ear, and the outline of the auricular structures is traced. The position and orientation of the normal ear relative to the temporomandibular joint, lateral canthus, and superior orbital rim are also drawn. Small perforations are made in the X-ray film with a needle along each of these marks to preserve them even after the template has been sterilized.

A 7- to 8-cm incision is made across the lower ribs approximately two finger breadths above the contralateral costal margin. The inferior oblique and rectus abdominis muscles are transected. The perichondrium over the seventh rib is incised and elevated, and this plane is followed medially until the synchondrosis of the sixth and seventh ribs is exposed. This entire section of the seventh rib with the synchondrosis and a portion of the sixth rib is then harvested en bloc after the deep perichondrium has been fully elevated; this will form the core of the auricular framework. An 8- to 9-cm segment of cartilage from the eighth rib is similarly harvested; this segment is used to form the helix. It is generally necessary to thin this segment to facilitate forming the convexity of the helical rim; the remaining cartilage can be used to form the tragus or to deepen the conchal bowl, or it can be “banked” subcutaneously in the temporal region and retrieved for use to provide additional auricular lateralization in the third-stage procedure.

During cartilage harvest, the perichondrium is carefully elevated circumferentially; although this is relatively simple to do on the anterior surface, particular care should be taken to remain between the cartilage and the perichondrium when working on the posterior surface. After the cartilage harvest, the integrity of the posterior perichondrium and parietal pleura

Fig. 52.9 Carved costal cartilage framework next to template based on the contralateral ear for microtia repair.

should be confirmed by filling the wound with warm sterile saline and noting the absence of any air leak (bubbles) during positive pressure ventilation. If these are present, the pleural violation should be identified and a soft red rubber catheter inserted into the pleural space while a purse-string suture is placed around the tear in the pleura. Suction should be applied and the suture tightened and tied as the catheter is withdrawn. Transected muscles are then reapproximated with an absorbable braided suture, and the wound is drained and closed.

The harvested cartilage pieces are then carved and sutured to form the auricular framework. Ideally, the synchondrosis between the fifth and sixth ribs forms the superior and inferior crura, fossa triangularis, and superior part of the scaphoid fossa; the remainder of the scaphoid fossa, common antihelical crus, conchal bowl, and inferior auricle are formed with the bulk of the seventh rib. The eighth rib is sutured to this inner-base framework to form the helix. Additional pieces of cartilage can be sutured to the framework to form additional bulk and support for a tragus. Clear, permanent monofilament 4-0 or 5-0 buried sutures are used to fix these cartilage segments in position based on the X-ray template (□ Fig. 52.9).

Next, the template is again used to confirm the desired position of the constructed auricle. An incision is made in the skin so that a subcutaneous pocket for the framework can be developed and any malformed remnant cartilage removed. It is essential that this skin be elevated just below the dermis and any hair follicles to produce a thin flap that can wrap delicately around and highlight the curves of the framework. Clearly superfluous remnant skin is resected after proper placement and positioning of the framework. Another pocket is developed above the deep temporal fascia well superior to the planned position of the superior helix, and the unused cartilage segments are “banked” for use during auricular elevation and a resorbable suture placed to keep these segments away from the main pocket. The framework is placed, and then a small, flat,

Fig. 52.10 (a) Before and (b) after framework placement and lobule transposition for microtia repair.

open-channel drain is placed to drain the area around the framework; once the framework has been placed on suction, the shape of the framework can be seen and checked for proper placement. Skin incisions are closed with resorbable monofilament sutures. A lightly compressive dressing is applied and maintained for 4 days while the drain is kept on low suction and is removed when the drainage decreases to less than 5 mL/d.

Stage 2

After 6 to 8 weeks, the earlobe is created. Remnant skin (in some cases, skin and cartilage) is generally located anteriorly, running vertically and crossing the desired conchal bowl position. A V-shaped incision is made based inferiorly around the microtia remnant, with the base kept as wide as possible inferiorly. A back cut is made extending up the lower part of the auricular framework. The most inferior portion of the framework is elevated, the remnant is transposed posteriorly and bivalved, and the framework is tucked into the flap. The skin incisions are then closed in layers with monofilament resorbable sutures. Alternatively, this stage can be performed at the same time as the framework construction and placement (□ Fig. 52.10).

Stage 3

At 6 to 8 weeks after stage 2 (12 to 16 weeks after stage 1), the skin approximately 5 mm beyond the helical rim framework is

incised. The auricular framework is then progressively elevated, while a generous cuff of soft tissue is left covering the medial aspect of the cartilage. The previously banked cartilage is retrieved and sutured to the medial–anterior aspect of the framework and covered with a soft-tissue flap elevated from the framework. Further wide undermining superiorly and posteriorly is performed and allows the occipital and temporal skin flap to be advanced anteriorly and inferiorly, respectively, to bring the edge of the flap up to the postauricular sulcus. A full-thickness skin graft is harvested from the inguinal region and used to cover the medial surface of the elevated auricle, and the donor site is closed primarily. An antibiotic/petroleum gauze bolster is sutured in place over the skin graft and removed after 1 week.

Additional Procedures

After the first three stages, patients who seek hearing restoration can undergo aural atresia repair. At that time or at a subsequent surgery, an anteriorly based skin flap can be raised from the conchal bowl (which can then be deepened) and wrapped around previously placed cartilage for tragus reconstruction, or simply used as the lateral tragal surface while a composite graft from the contralateral conchal bowl is used for tragal structure and medial surface coverage. Also, patients whose remnant skin was based too superiorly will have an elevated earlobe after stage 2; this can be transposed to a more symmetric, lower position if needed.

Complications

Otoplasty

In general, complications of otoplasty are fairly uncommon (see Box Complications of Otoplasty and Auricular Reconstruction (p.417)). Most are related to technique: cellulitis, chondritis, hypertrophic scar/keloid, suture failure, suture bridging, telephone ear, and recurrence. Cellulitis can occur and is generally caused by typical skin flora. Chondritis is marked by deep pain in addition to swelling and erythema that develop 3 to 5 days after surgery. Drainage, culture, and antibiotics (including coverage for *Pseudomonas* in cases of suspected chondritis) should be instituted as soon as the diagnosis is suspected. Excessive skin resection is generally the cause of “suture bridging,” the visible span of sutures across the postauricular crease, whereas excessive skin closure tension may predispose to the development of hypertrophic or keloid scars. Uneven reduction of the auricular prominence can cause a “telephone ear” deformity, in which the superior and inferior poles project farther from the head than does the midportion of the auricle; careful inspection of the intraoperative result should identify this unwanted result. Recurrence of auricular deformity is uncommon (approximately 2%) and is generally a result of suture failure.

Complications of Otoplasty and Auricular Reconstruction

Complications of otoplasty

- Recurrence of deformity (2%)
- Telephone ear
- Suture bridging
- Hypertrophic scar/keloid
- Cellulitis
- Chondritis

Complications of auricular reconstruction

- Pneumothorax
- Atelectasis/pneumonia
- Cartilage exposure
- Blunting/loss of postauricular sulcus
- Hematoma
- Chondritis

Auricular Reconstruction

Pneumothorax is rare, and particular attention to remaining in the proper plane during cartilage harvest is essential. We rou-

tinely obtain a chest X-ray in the recovery room, as well as 6 hours later. Atelectasis is more common because patients splint postoperatively as a result of transection of the intercostal muscles. Patients should be given adequate analgesics, and early ambulation should be required. Skin breakdown and cartilage exposure can occur, generally early after placement of the framework. At this early stage, healing by secondary intention is rarely sufficient to close the wound; the cartilage should be conservatively débrided in order to remove devitalized tissue and covered with a local skin flap or (if there is minimal local skin laxity) a temporoparietal fascia flap. Loss of lateralization and blunting of the postauricular sulcus can develop if excessive skin graft contracture occurs; we prefer to advance the posterior skin flap into the apex of the postauricular crease and use the skin graft to cover only the medial surface of the auricle.

52.7 Roundsmanship

- The correction of prominent ears can be performed after the age of 6 years, by which time the ears have attained approximately 85% of their adult height.
- Cartilage-cutting techniques are more likely to produce sharp edges.
- Auricular prominence should be checked after each suture is placed, and even correction along the length of the auricle should be ensured.
- Methods of microtia reconstruction use cartilage segments of multiple ribs to construct different parts of the auricle.

53 Primary Rhinoplasty

Anthony P. Sclafani and James A. Sclafani

53.1 Introduction

Rhinoplasty is the deliberate alteration of the form, shape, and often the function of the external nose. Although generally performed for cosmetic reasons, rhinoplasty can also be performed to improve nasal respiration or to repair congenital, traumatic, or otherwise acquired deformities. Each step in any procedure on the external nose should be performed with the dual effects on appearance and breathing kept in mind. Whereas an open reduction of a nasal fracture includes the creation of incisions in the nasal bones, which can then be repositioned, rhinoplasty includes additional contouring of the nose by altering the nasal bridge (by augmenting or reducing the size and/or width of the bones and cartilages) or the position, orientation, and shape of the nasal tip.

53.2 Incidence of Disease

Although it does not treat a specific “disease,” primary rhinoplasty can be performed in a number of common scenarios: the dorsal “bump,” the “large” nose, the deviated nose, the bulbous tip, and the overprojecting or underprojecting nasal tip are frequent indications for rhinoplasty. Rhinoplasty is the second most common facial plastic surgical procedure; more than 126,000 rhinoplasties were performed in 2011.

53.3 Terminology

In a discussion of the nose, movement from the glabella toward the nasal tip is described as caudal; movement in the opposite direction is cephalic. When the position of the nasal tip is discussed, projection refers to the degree the tip extends away from the face, whereas rotation denotes the upward (as viewed laterally) pivoting of the nasal tip (based at the nasal alae); de-projection and de-rotation refer to the opposite. The nose is often discussed in thirds; the upper third of the nose runs from the articulation of the nasal bones with the nasal process of the frontal bone and ends at the caudal margin of the nasal bones (□ Fig. 53.1). The middle third of the nose continues caudally from the nasal bones to the anterior septal angle (the dorsal aspect of the most caudal portion of the septum). The lower third of the nose comprises the nasal tip.

There are two types of approach to rhinoplasty: endonasal rhinoplasty is performed solely through incisions placed within the nose, whereas an open or external rhinoplasty uses internal nasal incisions combined with one across the columella. Osteotomies are bony incisions through the dorsal or lateral bones of the nose in order to reshape, reduce, or reposition the nasal bones. Open reduction of a nasal fracture differs from rhinoplasty in that it is limited to osteotomy and repositioning of the nasal bones, whereas rhinoplasty involves active reshaping of the nose to a new form.

53.4 Applied Anatomy

The nasal bones extend inferiorly from the nasal process of the frontal bones and articulate laterally with the ascending process of the maxilla and with each other medially. Inferiorly, the paired upper lateral cartilages have a trapezoid shape and insert on the internal aspect of the lower (caudal) nasal bones for approximately 2 to 3 mm. Laterally, the upper lateral cartilages

Fig. 53.1 The nasal bones are relatively narrow, with the ascending portion of the maxilla comprising significant portions of the nasal side walls. The maxillary crest sits along the nasal floor, upon which rests the quadrangular septal cartilage. The nasal process of the frontal bone articulates with the nasal bones superiorly.

are bound to the free margin of the piriform aperture (the caudal end of the bony nasal opening); they fuse with the dorsal nasal septum medially. The dorsal septum extends slightly more caudally than the lower aspect of the upper lateral cartilages, ending at the anterior septal angle (□ Fig. 53.2).

Each lower lateral cartilage is an inverted V- or U-shaped cartilage, wider at the lateral crus, narrowing at the bend of the intermediate crus, and running inferiorly as the thinner medial crus. The most inferior part of the medial crus typically curves backward and has a fibrous attachment to the caudal septum, which serves as one of the three major tip supports. The cephalic end of the lateral crus extends for 1 to 3 mm over the caudal aspect of the upper lateral cartilage, and the fibrous attachment of these two areas forms the second major tip support, known as the scroll. The third major mechanism of tip support is the actual strength, integrity, and resilience of the lower lateral cartilages (□ Fig. 53.3).

The shape, position, and orientation of the nasal tip are chiefly determined by the tip supports. The major and minor tip supports are listed in the Box Major and Minor Tip Support Mechanisms (p.419). These classifications may vary from patient to patient, and in certain cases, minor tip supports may be

major ones, and vice versa; each patient should be assessed individually (□ Fig. 53.4).

Major and Minor Tip Support Mechanisms

Major supports of the nasal tip

- Length and strength of the lower lateral cartilages
- Attachment of the upper lateral cartilages to the lateral crura of the lower lateral cartilages
- Attachment of the foot plates of the medial crura of the lower lateral cartilages to the caudal septum

Minor supports of the nasal tip

- Fibrous attachment of the domes of the lower lateral crura to each other (interdomal ligament)
- Nasal skin
- Membranous septum
- Anterior septal angle
- Posterior septal angle
- Sesamoid cartilage and fibrofatty tissue of the alae

Fig. 53.2 The upper lateral cartilages insert on the undersurface of the nasal bones, fuse medially with the septal cartilage, and are attached to the lower lateral cartilages by fibrous tissue (inset). The lower lateral cartilages angle cephalically and do not run along the rim of the nostril. Fibrofatty tissue and sesamoid cartilage comprise the dense tissue of the nasal lobule. The nasal tip skin is thinnest over the rhinion. LLC, lower lateral cartilage.

Fig. 53.3 The nasal tip support can be compared to a tripod, with each lateral crus of the lower lateral cartilages serving as one leg of the tripod and the fused medial crura serving as the third leg of the tripod.

Functionally, an important area is the internal nasal valve. This is the cross-sectional area formed by the caudal end of the upper lateral cartilage, the nasal septum, the floor of the nose, and the inferior turbinate. This area serves as a variable resistor to nasal airflow. Excessive narrowing of this area by enlargement of the turbinate, septal deviation, or weakness or collapse of the upper lateral cartilage and/or the cephalic end of the lower lateral cartilage can lead to internal nasal valve collapse or stenosis.

53.5 The Disease Process

53.5.1 Etiology

Nasal deformity can be congenital, developmental, or acquired and may involve any or all of the areas of the nose. Dislocation of the septum during birth can, if left uncorrected, lead to deviated growth of the nose, and the septum should be gently repositioned as soon as possible. Cleft lip and cleft palate deformities are associated with typical patterns of distortion of the lower two-thirds of the nose. The onset of puberty is associated with significant nasal growth, and during this time subtle deviations may become more obvious. Most adults will recall at least one episode of “significant” nasal trauma during childhood. Adult nasal trauma may lead to malpositioning and subsequent malunion of the nasal bone and to fracture of the septum with displacement. Fractures of the caudal end of the nasal bone may weaken the attachment of the upper lateral cartilage, with subsequent collapse of the internal nasal valve. Injury of the nasal

Fig. 53.4 The interdomal (Pitanguy) ligament (long arrow) and the anterior septal angle (short arrow) seen through an external approach rhinoplasty.

septum (caused by traumatic, surgical, induced [e.g., intranasal cocaine abuse], or inflammatory/infectious [e.g., Wegener granulomatosis or syphilis] processes) can result in collapse of the nasal dorsum and subsequent nasal tip distortion. Unsuccessful rhinoplasty can also lead to an unacceptable nasal appearance.

53.5.2 Pathogenesis

Deformed noses lack a smooth contour, symmetry, and organic integration with the other facial structures. A complete discussion of facial aesthetics is beyond the scope of this chapter, but in general, the length of the nose should be appropriate for the rest of the face. The nose should begin superiorly at approximately the level of the upper eyelid crease and end at a nasal tip that projects away from the face by roughly 55 to 60% of the distance from the nasal root to the lateral alae. There should be a smooth and gentle sweep, beginning at the superomedial orbital rim and extending down along the side of the nose, that widens slightly at the ala (□ Fig. 53.5). The ala should extend laterally to a point along a vertical line dropped from the medial canthus. From a basal (“worm’s eye”) view, the nasal tip should comprise approximately half of the width from ala to ala.

Asymmetry of the nasal bones, either from true asymmetry of the bones or from asymmetric malpositioning, will make the upper third appear deviated. Excessive bowing of the middle nasal third can make the nose look “crooked,” even if the nasal bones are symmetrically placed (□ Fig. 53.6). This may be due to medial collapse of the upper lateral cartilages or to a deviated dorsal septal cartilage. Lack of an appropriate “supratip break” (a visible step-off just above the midline of the cephalic edge of the nasal tip, where the nasal tip is seen to project 1 to 2 mm

Fig. 53.5 A gentle sweep from the superior–medial orbital rim along the side of the nose widens at the ala in an aesthetic nose.

Fig. 53.6 The two nasal side walls course gently from the orbital rims to the alae in a symmetric fashion in the aesthetic nose.

above the nasal dorsum) will make the nose appear longer and will accentuate a dorsal hump. From the frontal view, the alar rims should approximate a “gull in flight” (□ Fig. 53.7).

Viewed laterally, the rim of the ala should extend no more than 1 to 2 mm along a line bisecting the nasal opening; a greater distance is evidence of alar retraction. Similarly, the lower border of the nasal opening on this view should be no more than 1 to 2 mm below this line; greater distances indicate a hanging columella. An irregularity or bump along the nasal tip, referred to as a bossa, may be multiple and is frequently (but not always) an effect of a poorly performed rhinoplasty.

53.5.3 Natural History and Progression

Although most nasal deformities are fixed in nature, those that progress indicate some loss of structural integrity and support and should be investigated thoroughly. A collapsing bridge may indicate loss of dorsal septal support from an overly aggressive septal submucous resection, or indicate progression of a septal perforation or other significant septal process. Progressive widening of the nasal bones can occur in the presence of an enlarging neoplasm of the nasal cavity or of severe nasal polyposis. The nasal tip can become broader and more prominent in the setting of active rosacea. There is a natural tendency of the nose to appear longer with age as the nasal skin envelope loses elasticity. Especially in the setting of prior nasal surgery, the internal nasal valve may cause progressive nasal obstruction.

53.5.4 Potential Disease Complications

Nasal deformities and nasal obstruction are not life-threatening, nor will they typically worsen other conditions.

Fig. 53.7 On the frontal view, the alar rims together form a “gull in flight.”

53.5.5 Disease Grading

Saddle nose deformity, which is a depression of the middle and upper thirds of the nose, is qualitatively described as major or minor. Otherwise, there is no universally accepted and used grading of nasal deformity. Much more important are a careful examination and description of the deformity and an understanding of the state of the underlying structures.

53.6 Medical Evaluation

53.6.1 Presenting Complaints

Whether a patient presenting for rhinoplasty requests specific changes to his or her nose or simply asks the physician to “make my nose look better,” it is imperative to help the patient define the surgical goals. The patient should be asked to indicate precisely the changes desired while inspecting the nose in a mirror and using the end of a cotton applicator as a pointer. This simple exercise will help the patient develop a more precise surgical goal. The surgeon should assist the patient in this process by helping to define appropriate parameters for change, but the patient must be comfortable that the choices and desires will be respected. Patients should be questioned about nasal obstruction (unilateral or bilateral), as well as any symptoms of sinusitis.

53.6.2 Clinical Findings, Physical Examination

A complete discussion of facial aesthetics can be found in Chapter 38. However, the surgeon should critically examine the patient’s face and should assess the patient’s general facial structure. Is there any facial bone deficiency or asymmetry? Is there underdevelopment of the cheeks or the chin, both of which will cause the nose to look larger? Is the nasal root at the appropriate height? Does the dorsum project sufficiently and smoothly, and is there a sufficient supratip break? Is the nasal length appropriate and is tip projection sufficient? This is easily assessed with the “3–4–5 right triangle” rule (□ Fig. 53.8). The nose is viewed from the side, and a vertical line extending inferiorly from the low point of the nasal root is visualized. A horizontal line perpendicular to this vertical line and passing through the high point of the nasal tip is also visualized. These lines form two sides of a right triangle, while the third line connects the nasal root to the nasal tip and runs along the nasal dorsum. The vertical side of the triangle is assigned a value of 4; the horizontal side should be approximately three-fourths of the length of the vertical side, and the nasal tip projection (horizontal line) should be approximately three-fifths (55 to 60%) of the nasal dorsal length (third side).

The nasal tip, seen from a basal view (□ Fig. 53.9), should approximate an equilateral triangle, with the nasal tip comprising about one-third of the width of the entire nasal base. The nasal alae should lie along or just within vertical lines dropped down from the medial canthi.

An important part of the examination of the nose is palpation. The nasal bones should be palpated for symmetry, contour, and angulation. The bridge of the nose should be assessed for incomplete contact of the nasal bones in the midline (an “open roof” deformity). The middle and lower thirds of the nose should be checked for adequate support, and the tip should be palpated for underlying symmetry.

The internal nose should also be examined by anterior rhinoscopy and (when appropriate) nasal endoscopy. The condition of the septum and inferior turbinates, including the nasal mucosa, should be noted.

Fig. 53.8 The “3–4–5 right triangle” rule.

53.6.3 Testing

Although testing is generally not performed before rhinoplasty, those patients in whom nasal valve collapse or obstruction is suspected should undergo functional testing. To test nasal function and possible nasal valve collapse during respiration, a Cottle maneuver can be performed; the skin just lateral to the ala is stabilized (not drawn laterally) and the patient is asked to inspire deeply. Alternatively, a fine curet or the tines of a forceps can be placed inside the nose gently to stabilize the site of suspected collapse. If the nasal obstruction is decreased with either method of stabilization, the site of the collapse can be identified. Acoustic rhinometry or rhinomanometry can supplement the functional assessment of the nose. Radiographic assessment is rarely necessary, but computed tomography may be helpful in cases of suspected sinusitis.

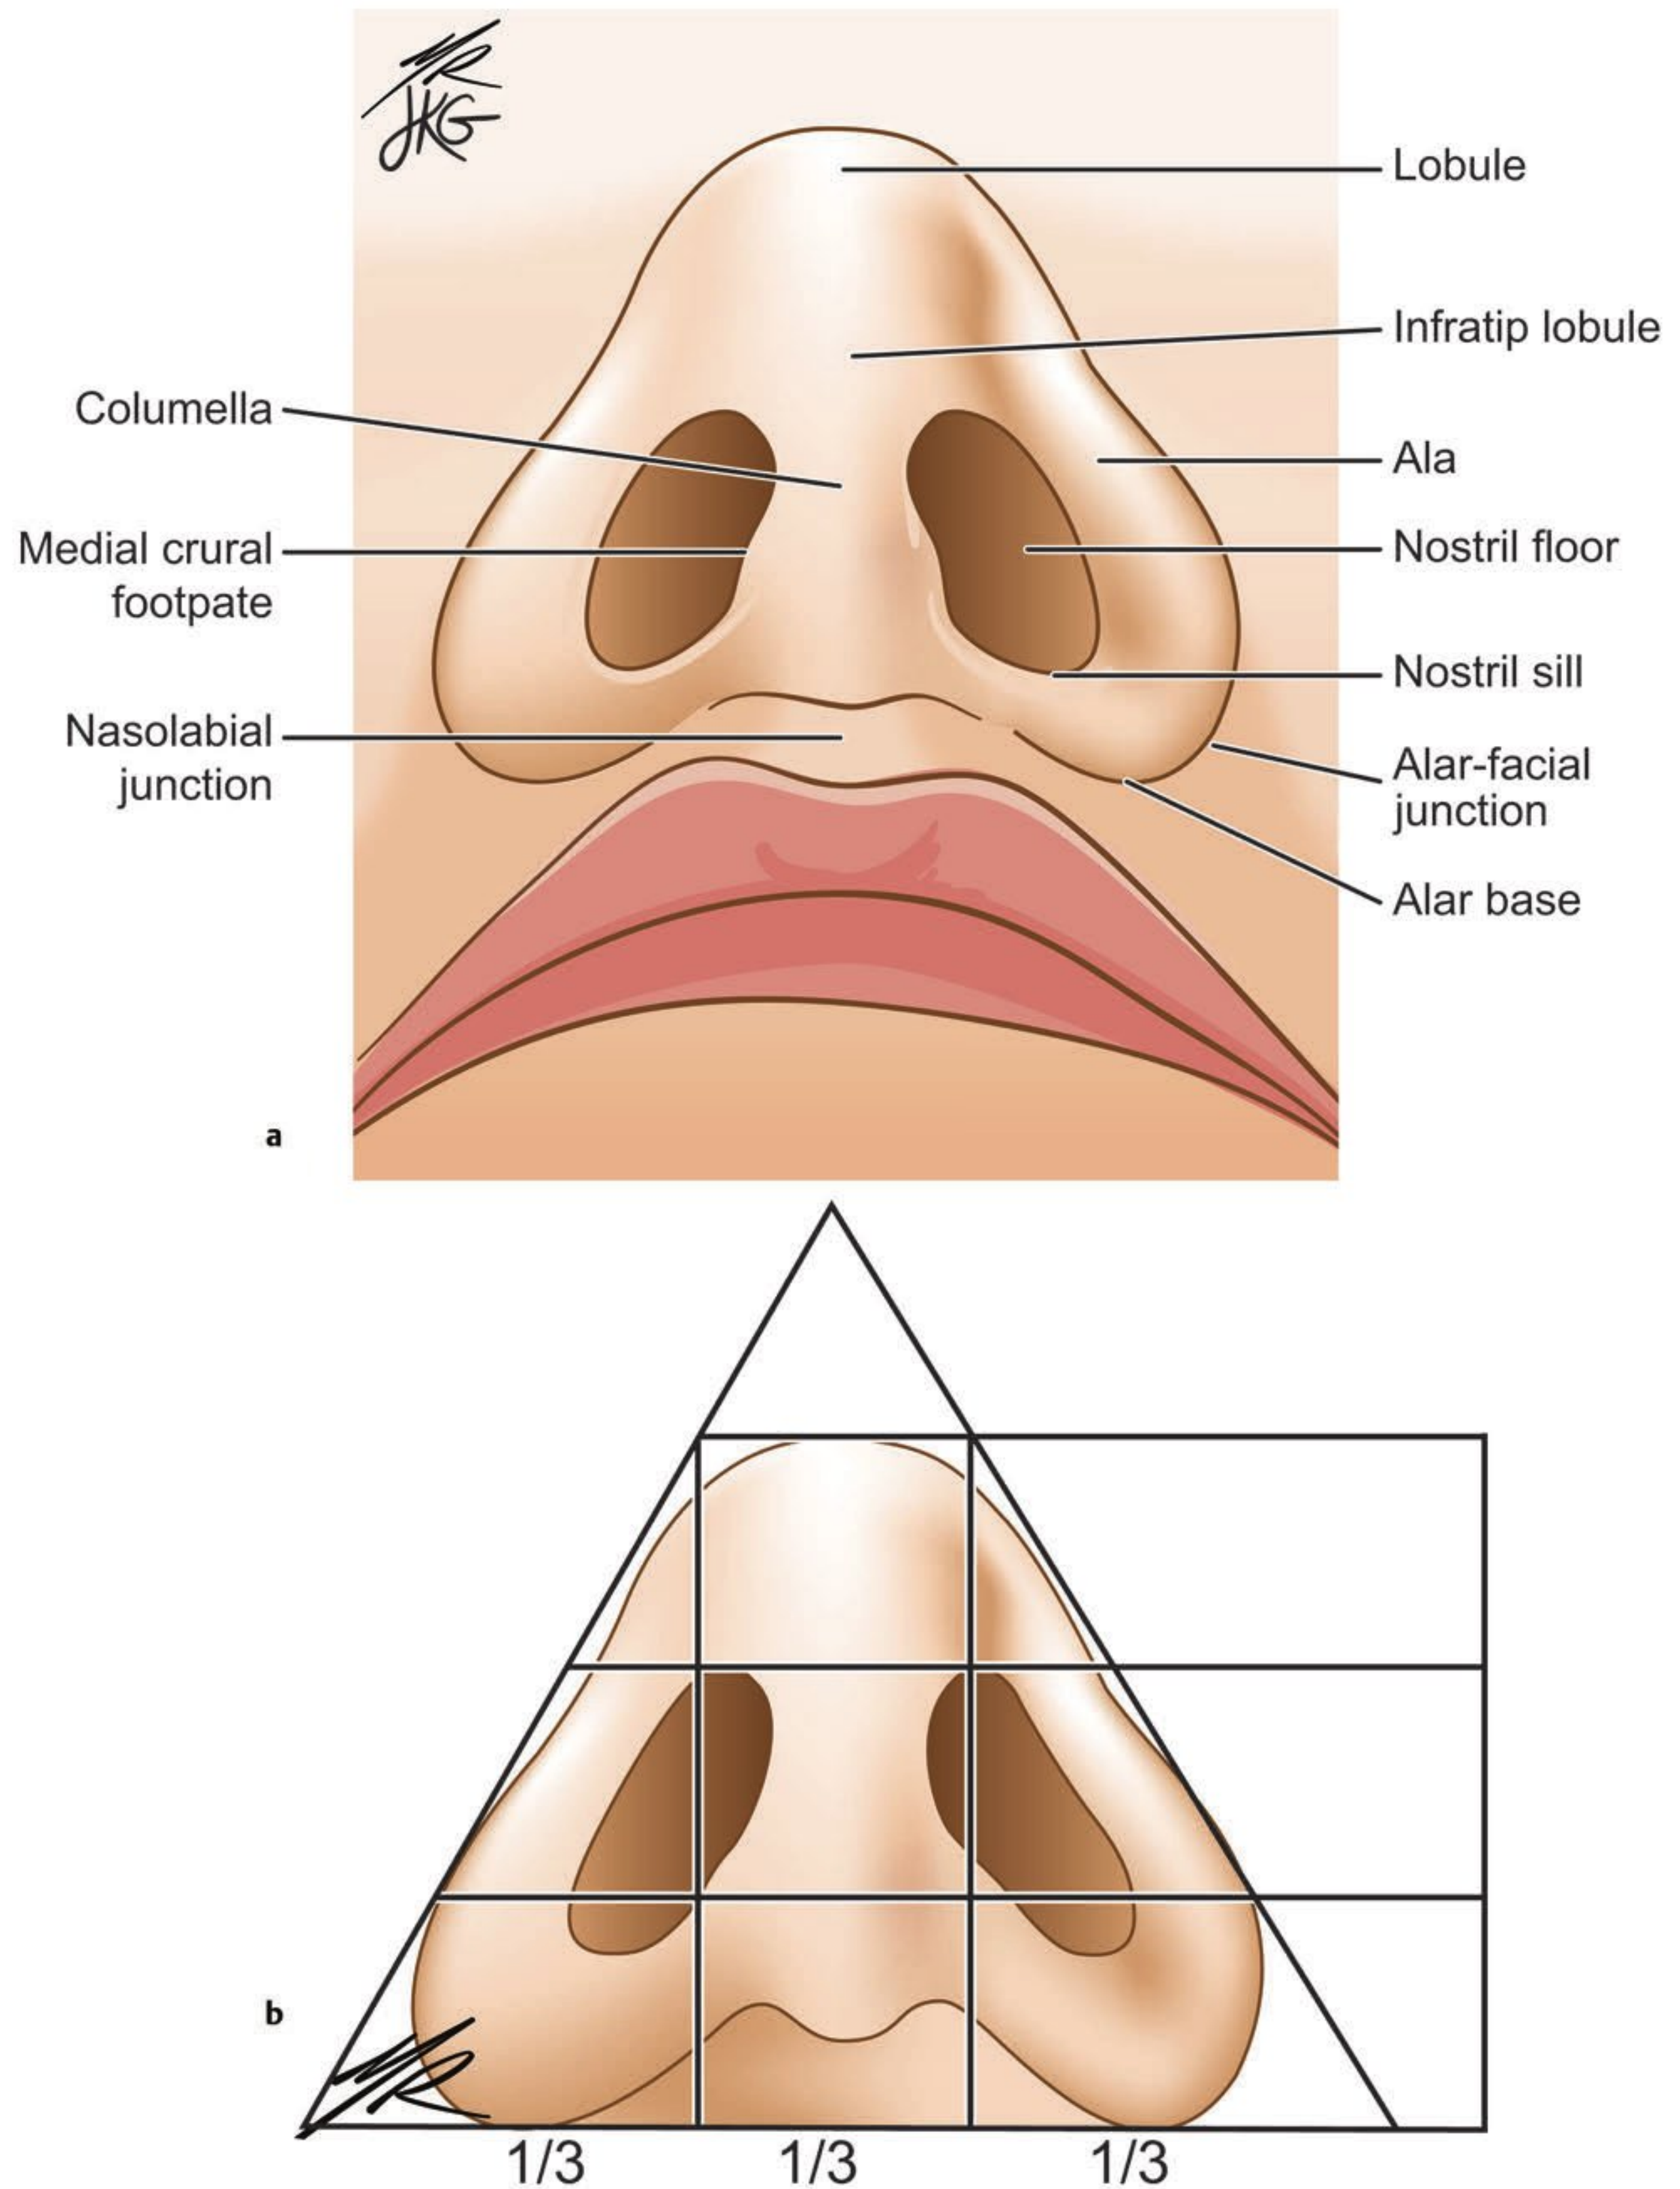

Fig. 53.9 (a) The structures of the nasal tip. (b) The lobule comprises one-third of the nasal tip height, and the nasal tip is approximately one-third the width of the nasal base.

53.6.4 Photography

Photographic assessment is imperative in rhinoplasty, as in all cosmetic interventions. Standardized photographs are invaluable in documenting the degree of preoperative deformity, as well as the postoperative changes. All photographs should be taken with the patient in front of a nonreflective background and in a “head neutral” position (with the gaze focused on a site at eye level). Right and left lateral and 45-degree oblique views, as well as a frontal projection, should be obtained; all views should include the top of the head to the thyroid notch. A close-up, “worm’s eye” view should be taken of the nasal base.

53.6.5 Differential Diagnosis

One of the most significant preoperative duties of the surgeon is to assess the appropriateness of the patient for surgery. Patients who show inordinate concern for minor deformities or who attribute social, personal, financial, or employment difficulties to the appearance of their nose will be disappointed with even the best surgical results if these other concerns continue after surgery. It is essential to identify these patients preoperatively. In questionable cases, a preoperative psychiatric evaluation may be helpful.

53.7 Treatment

53.7.1 Medical Treatment

There is no way to alter the shape of the nose with medication. However, it is essential that a trial of nonsurgical management of nasal obstruction be made with topical nasal corticosteroid sprays. If nasal allergies contribute to nasal obstruction, these should be appropriately managed, as well. Confirmed cases of sinusitis should be treated with antibiotics and all evidence of sinusitis eliminated before rhinoplasty. In the case of chronic sinusitis that fails to resolve with appropriate antibiotic therapy, endoscopic sinus surgery can be performed at the same operative setting before the rhinoplasty. However, rhinoplasty should be deferred to another time if there is any concern for significant sinus bleeding, orbital penetration, or cerebrospinal fluid leak.

53.7.2 Surgical Treatment

Rhinoplasty can be performed through either an endonasal or an external approach. An endonasal approach keeps all incisions within the nasal vestibule. Simple access to the nasal dorsum is accomplished by making an intercartilaginous incision that is placed at the intersection of the caudal upper lateral cartilage with the lateral crus of the lower lateral cartilage (□ Fig. 53.10a). Blunt or sharp undermining is performed above the upper lateral cartilage until the nasal dorsum is reached. When minimal changes to the nasal tip are planned, a transcartilaginous incision can be used. This approach moves the intercartilaginous incision more caudally and is located directly above the planned incision in the lateral crus. After the lateral crus is incised, the cephalic portion of the lateral crus is excised; generally, this provides a modest increase in definition of the nasal tip (□ Fig. 53.10b). As an alternative, a retrograde dissec-

tion can be performed after an intercartilaginous incision is made and the same cephalic portion of the lateral crus is excised (□ Fig. 53.10c). Finally, a delivery approach to the tip can be used; this combines an intercartilaginous incision that connects to a transfixion incision (a through-and-through incision of the membranous septum directly in front of the caudal septum) with a marginal incision (which follows the caudal margin of the lower lateral cartilage beginning near the foot plate of the medial crus, extends into the dome, and then follows the caudal margin of the lateral crus; □ Fig. 53.11). Once these incisions are made, the nasal tip and alar skin are dissected off the perichondrium of the lower lateral cartilage. The skin of the nasal margin is retracted with a hook cephalically, while a hook placed at the intercartilaginous incision retracts the lateral crus caudally until it can be delivered up and onto the caudal nasal margin. This approach provides wider exposure of lower lateral cartilage for more aggressive resection or suturing (□ Fig. 53.12). Regardless of the treatment of the tip, these approaches all use the intercartilaginous incision to access the nasal dorsum.

An external approach (“open rhinoplasty”) differs from these approaches in that it uses marginal incisions in each nasal vestibule, which are then connected by a broken-line incision across the midportion of the columella. This allows the skin and soft tissue of the nasal tip to be elevated off the perichondrium of the nasal tip cartilages (see □ Fig. 53.4).

Nasal Tip

Changes to the nasal tip can be made by incising, excising, suturing, or grafting the nasal tip cartilages. The changes can be predicted by understanding the concept of the nasal tip tripod (see □ Fig. 53.3). The nasal tip is visualized as a tripod, with the apex at the nasal tip. Each lateral crus serves as a leg of the tripod, and the two medial crura (together) serve as the third leg. Changes to any leg of the tripod will affect the tip position and projection in a predictable way.

Typical contouring changes to the tip include resection of a cephalic strip (a portion of the cephalic edge of the lateral crus), sutures to sharpen the angle of the cartilage in the area of the dome or to bind the two domes, and complete splitting of the cartilage (in a cephalic-caudal direction) at or near the dome. Cephalic strips are resected by carefully incising the cartilage of the lateral crus, with care taken to preserve an intact strip of caudal lateral crus; 5 to 8 mm of width of remaining crus should generally be left in place, although the precise amount necessary is determined by the resilience of the cartilage and its relative impact on tip support in the individual patient. After the cartilage is incised, it is dissected free of the underlying vestibular mucosa. It is essential to respect any natural asymmetries of the alar cartilages and leave symmetric portions of cartilage remaining. The resection of cephalic strips will weaken the lateral limbs of the tripod, and the apex will rotate cephalically; conversely, the resection of a portion of the medial crura will not only decrease tip projection but also rotate the tip downward. Further narrowing of the nasal tip can be effected with an interdomal suture, a mattress suture through both domes to narrow the domal angles (□ Fig. 53.13).

More aggressive management of the tip can include vertical dome division, in which the lateral crus is divided from the

Fig. 53.10 (a) The site of the intercartilaginous incision can be demonstrated by opening a nasal speculum and pressing gently cephalically. This will bring the caudal edge of the upper lateral cartilage into relief. (b) A transcartilaginous incision transects the mucosa over the midportion of the lateral crus; the mucosa is dissected off the cephalic portion of the crus, the cartilage is transected at the level of the mucosa and cut, and the cephalic portion is removed. (c) Alternatively, an intercartilaginous incision is used, and retrograde dissection is performed to excise a cephalic portion of the lateral crus.

medial crus just lateral to the dome. Sutures are placed to secure the two medial segments and also to stabilize the lateral crura to the medial crura (□ Fig. 53.14). Postoperative healing in the nasal tip will cause more significant narrowing and rotation of the nasal tip due to a weakened alar arch.

A powerful technique that both narrows the nasal tip and increases projection and rotation is the lateral crural steal procedure. The vestibular mucosa is dissected free from the alar cartilage at the dome and for a distance lateral to it, and the desired additional tip projection is measured lateral to the existing dome and marked. This area of cartilage is then lightly crushed with a forceps to allow further contouring. A mattress suture is placed, spanning this new dome symmetrically; as the suture is tightened, additional lateral crus is “stolen” and added

to the medial limb of the tripod. The tip is narrowed, and the shift of cartilage from the lateral to the medial segment leg increases projection and rotation. With or without cartilage shifting or resection, mattress sutures at the nasal tip can be placed to narrow the angle at each dome and/or to narrow the space between the domes.

Cartilage grafts (harvested from septal, conchal, or rib cartilage) can be used to add support to the nasal tip structures. A columellar strut can be carved and placed between the medial crura for additional medial tripod support of the tip; if needed, the graft can be wider at the posterior septal angle to correct a retracted columella. In patients who have severe nasal tip asymmetry or deformities of the alar cartilages at the domes, or in patients who require additional tip definition, a shield graft

Fig. 53.11 Incisions to access the nasal tip. Marginal (blue), intercartilaginous (red), and transcolumellar (green) incisions.

Fig. 53.12 Delivery of the lateral crus.

Fig. 53.13 A mattress suture through both domes narrows each domal angle and brings the domes together to refine the nasal tip.

can be placed in a precise pocket caudal to the medial and intermediate crura (endonasal approach) or sutured directly to the medial and intermediate crural segments (external approach). The nasal tip skin then will redrape over this additional cartilage, accentuating the contours of the tip; depending on how much above or below the natural dome the shield graft is allowed to extend, projection and apparent rotation can also be affected.

Spreader grafts (□ Fig. 53.15) are rectangular grafts that can be placed between the dorsal upper lateral cartilages and septum unilaterally or bilaterally (through either an endonasal or an external approach) after the upper lateral cartilages have

been separated from the dorsal septum. These grafts can help open the internal nasal valve and are useful in addressing middle nasal vault asymmetries caused by deviation of the dorsal septum. An alar batten graft can be placed from the piriform aperture to the septum over the junction of the lateral crus and the upper lateral cartilage; the lateral crus can be sutured to this graft to stabilize it and prevent valve collapse. Occasionally, a rim graft can be placed caudal to the lateral crus to extend the alar margin in cases of alar retraction. Premaxillary grafts are sometimes placed in front of the premaxilla to treat a deep nasolabial angle. Many other grafts can be placed for specific regions.

Fig. 53.14 Vertical dome division with resuturing of the cephalic ends of the cartilage segments can significantly narrow the nasal tip.

Fig. 53.15 The nasal tip and dorsum as seen from above (caudal on left, cephalic on right). Spreader grafts (held in the forceps) can be placed (unilaterally or bilaterally) into discrete pockets (long arrow) lateral to the septum (short arrow).

Nasal Dorsum

After the nasal tip has been exposed and treated, the nasal dorsum is fully addressed. Sharp or blunt undermining elevates the soft tissues above the perichondrium of the upper lateral cartilages and the dorsal septum. When the caudal edge of the dorsal nasal bones is reached, a periosteal elevator is used to elevate the periosteum off the dorsal aspect of the nasal bones. Cartilaginous dorsal humps are resected sharply (□ Fig. 53.16), and violation of the underlying nasal mucosa is avoided when possible to prevent valvular stenosis. Larger bony humps can be

Fig. 53.16 Cartilaginous dorsal excess is excised incrementally with a No. 11 blade.

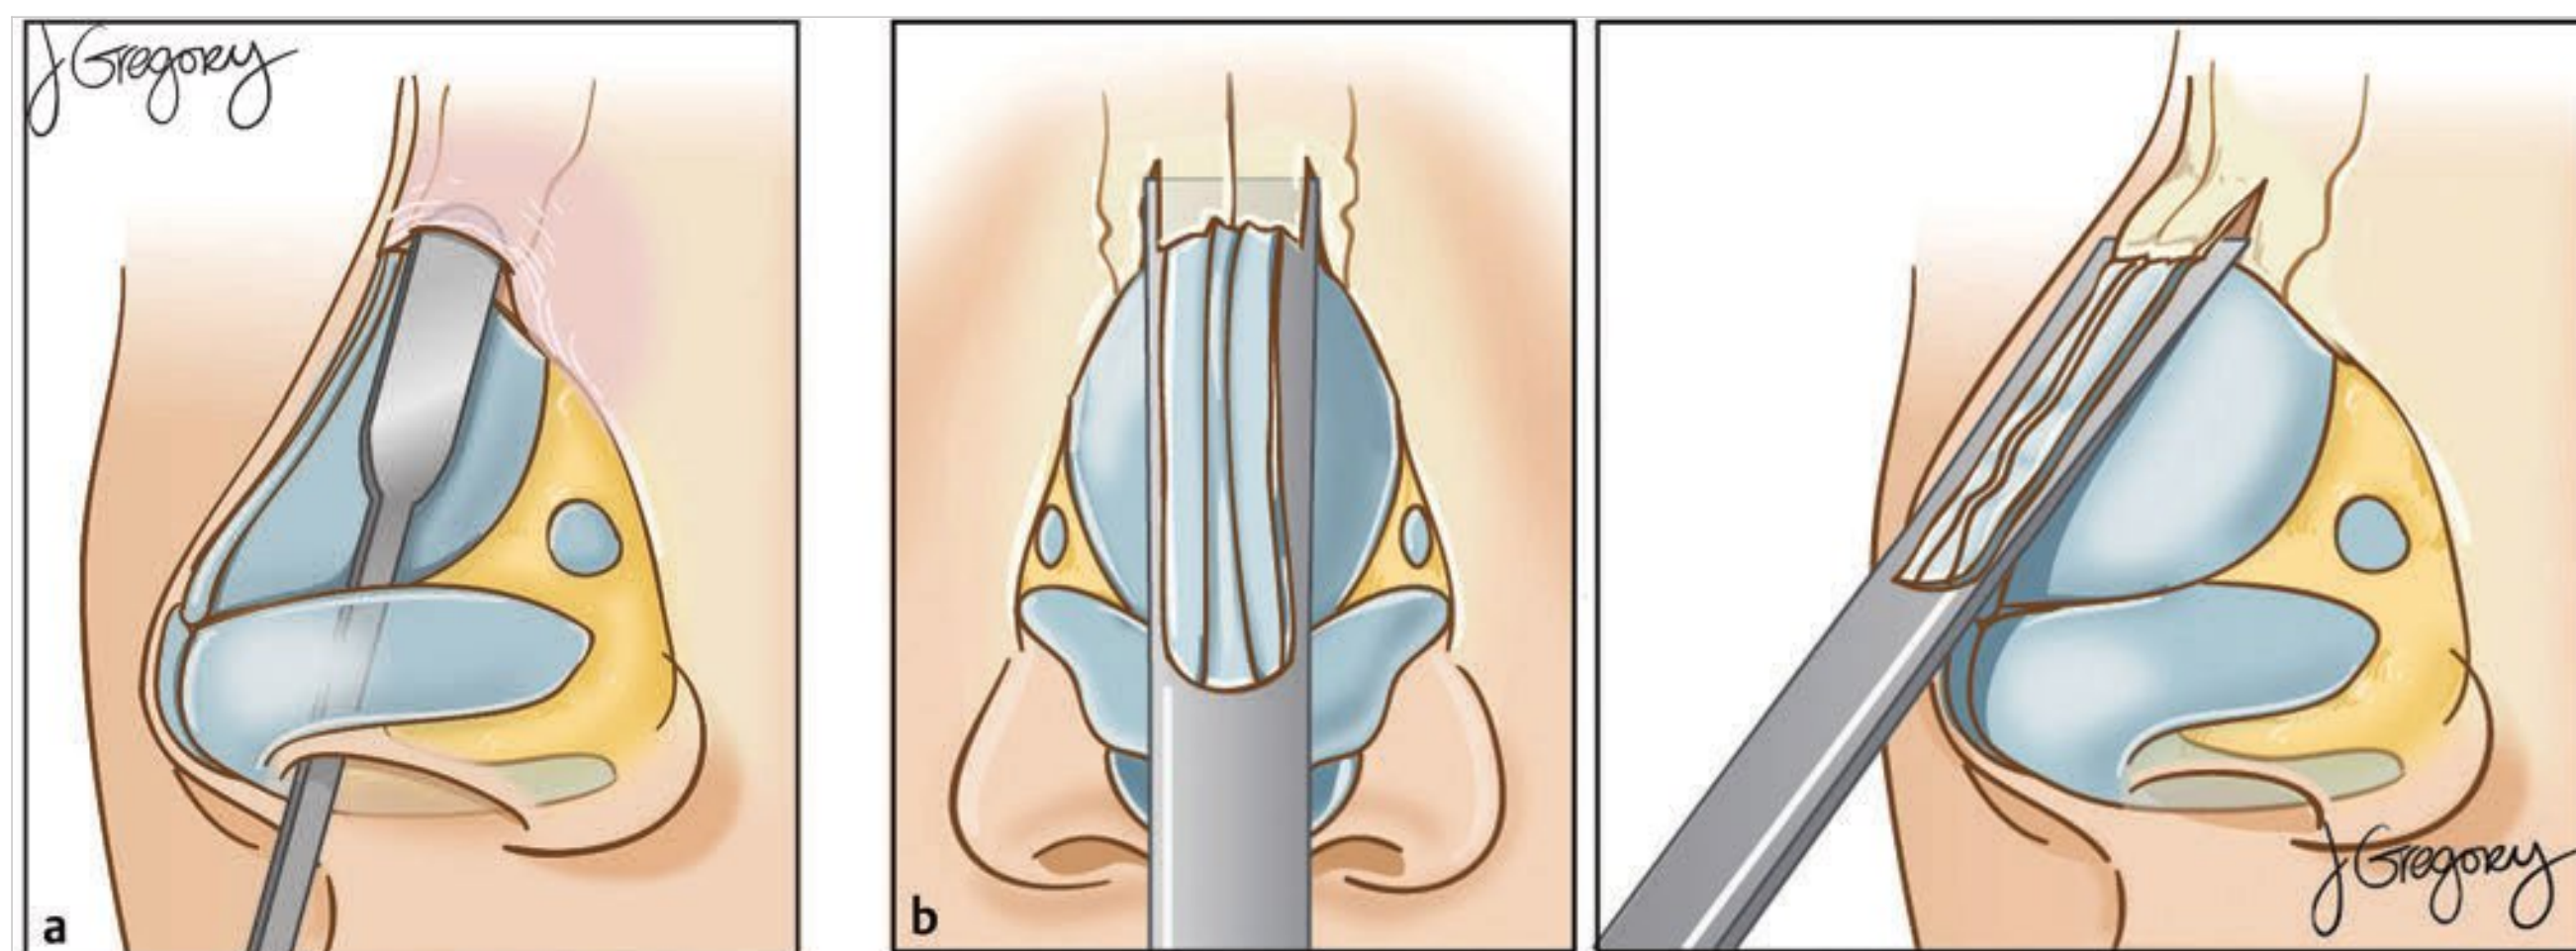

Fig. 53.17 (a) After the periosteum is elevated from the midline nasal bones, (b) an osteotome is used to remove larger dorsal humps.

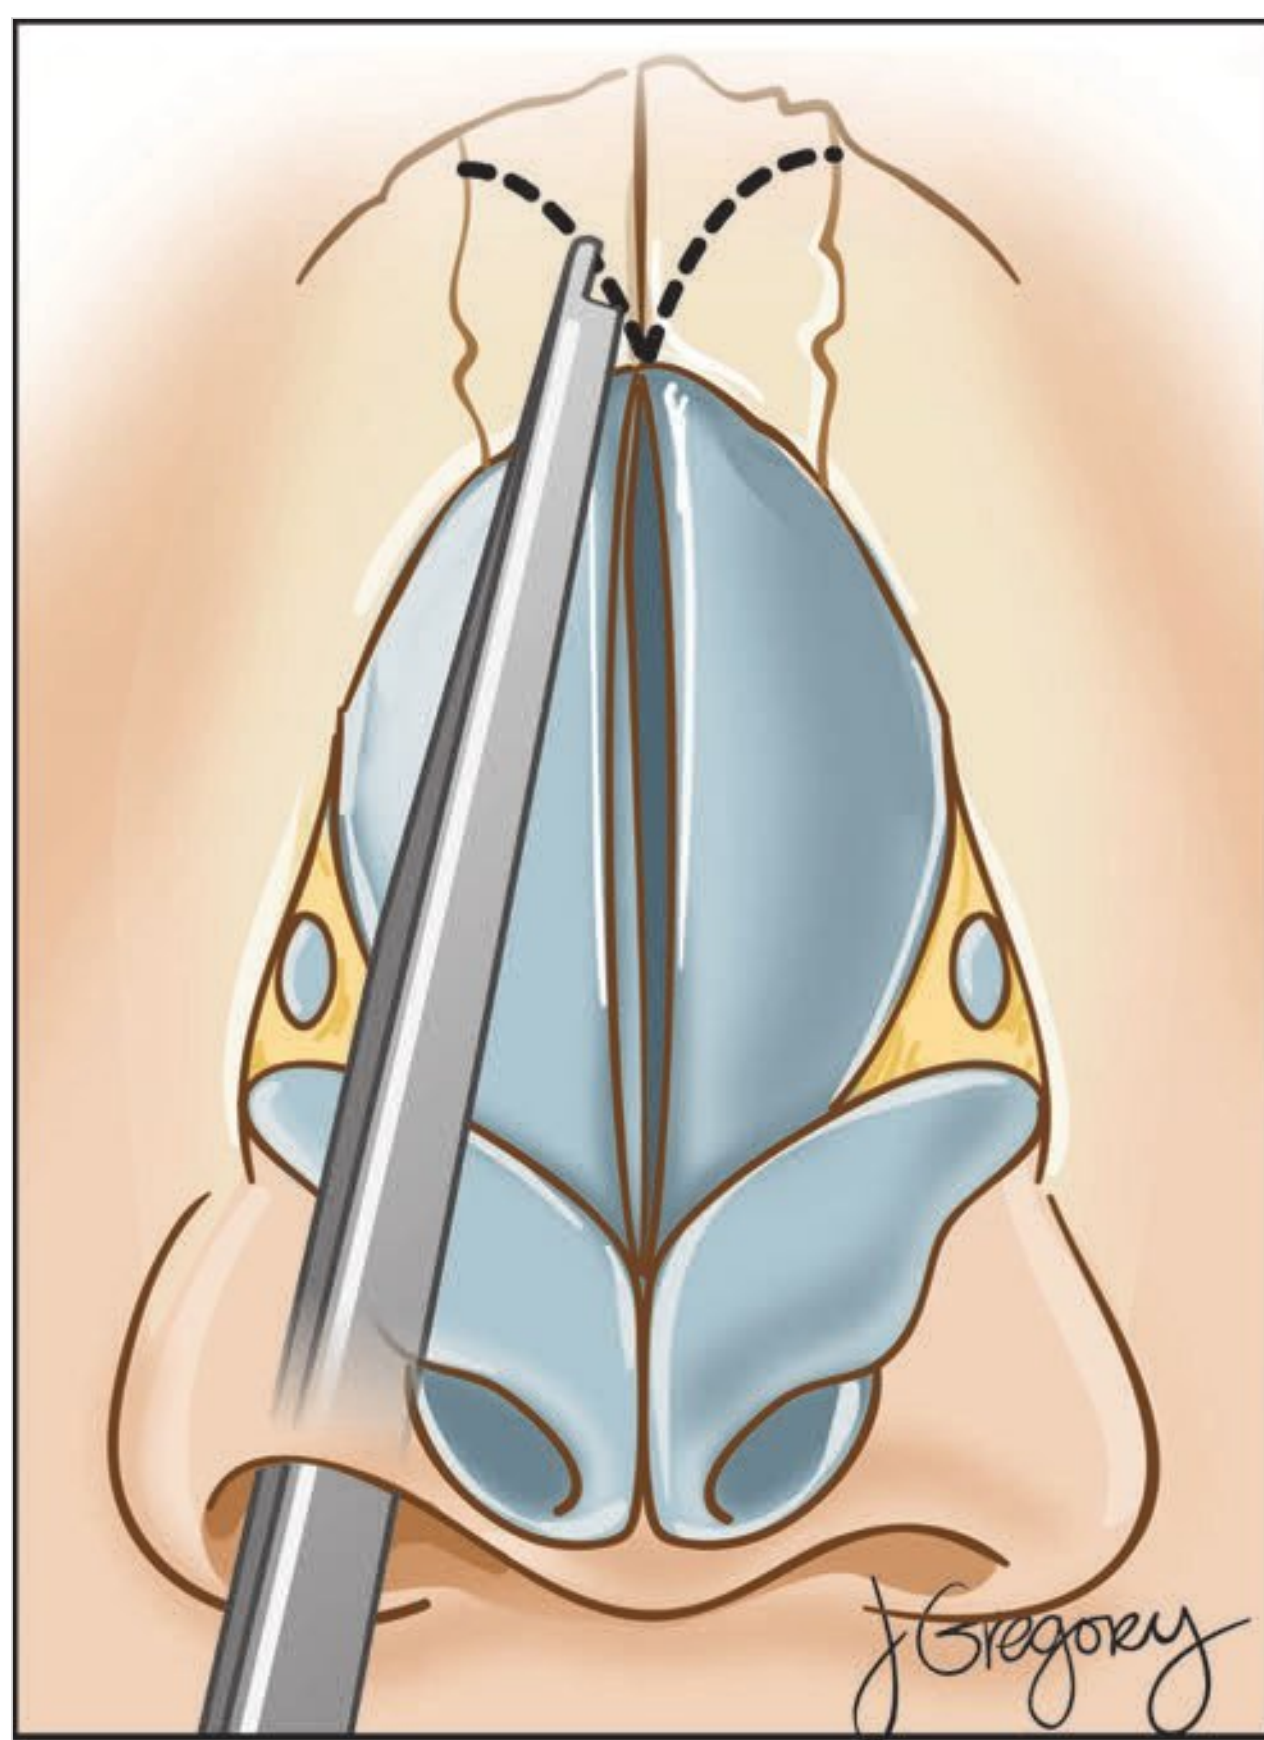

Fig. 53.18 Medial oblique osteotomies facilitate complete medialization of the nasal bones.

removed with an osteotome (□ Fig. 53.17), whereas smaller humps can be filed down incrementally with rasps. Typically, removal of a bony hump creates an “open roof” (incontinuity of nasal bones across the bridge) almost to the root of the nose; if not, single-guarded osteotomes can be used to complete bilateral osteotomies separating the nasal bones medially (□ Fig. 53.18). When a large cartilaginous hump is removed,

spreader grafts may be placed bilaterally between the upper lateral cartilage and the dorsal septum to prevent the development of internal nasal valve collapse.

Lateral osteotomies (□ Fig. 53.19) are required to close an open roof or narrow a nasal bridge. These are performed by incising the mucosa just lateral to the anterior insertion of the inferior turbinate, elevating the soft tissues along the nasomaxillary junction and then performing the osteotomy. A triangle of bone (“Webster triangle”) is preserved at the inferolateral aspect of the piriform aperture to prevent medial alar collapse postoperatively. The osteotomy progresses superiorly until it communicates with the medial osteotomy (□ Fig. 53.20).

An inward rotation of the osteotome will help connect the two osteotomies if the medial osteotomy remains in the paramedial position. The nasal bones are then freely mobile and can be manipulated into the appropriate position. In cases of asymmetrically shaped or excessively wide nasal bones, an intermediate osteotomy can be performed after the medial osteotomy but before the lateral osteotomy by sliding the osteotome medially from the piriform aperture incision along the caudal edge of the bone. A unilateral osteotomy of this kind can adjust a misshapen nasal bone, whereas bilateral intermediate osteotomies can help narrow an overly wide nasal bridge.

Alar Base Modifications

The alar width should harmonize with both the nasal tip width and dorsal width, and it roughly should fall between vertical lines dropped from the medial canthi; from a basal (“worm’s eye”) view, the nasal alae and tip should form an equilateral triangle. Widened alae may be a result of thickened alar walls, rounded and widened alar apertures, or both (see □ Fig. 53.17). Alar base reductions are typically performed after tip-plasty and dorsal narrowing. Incisions are made along the nasal crease and into the vestibule. Triangular or wedge-shaped excisions are made to reduce the inner size or outer size (or both) of the ala, with the incision carried into the nasal vestibule or along the alar crease as needed. Deep absorbable sutures are placed to align the segments, and the vestibular incision is also closed with absorbable sutures; the external closure is performed with

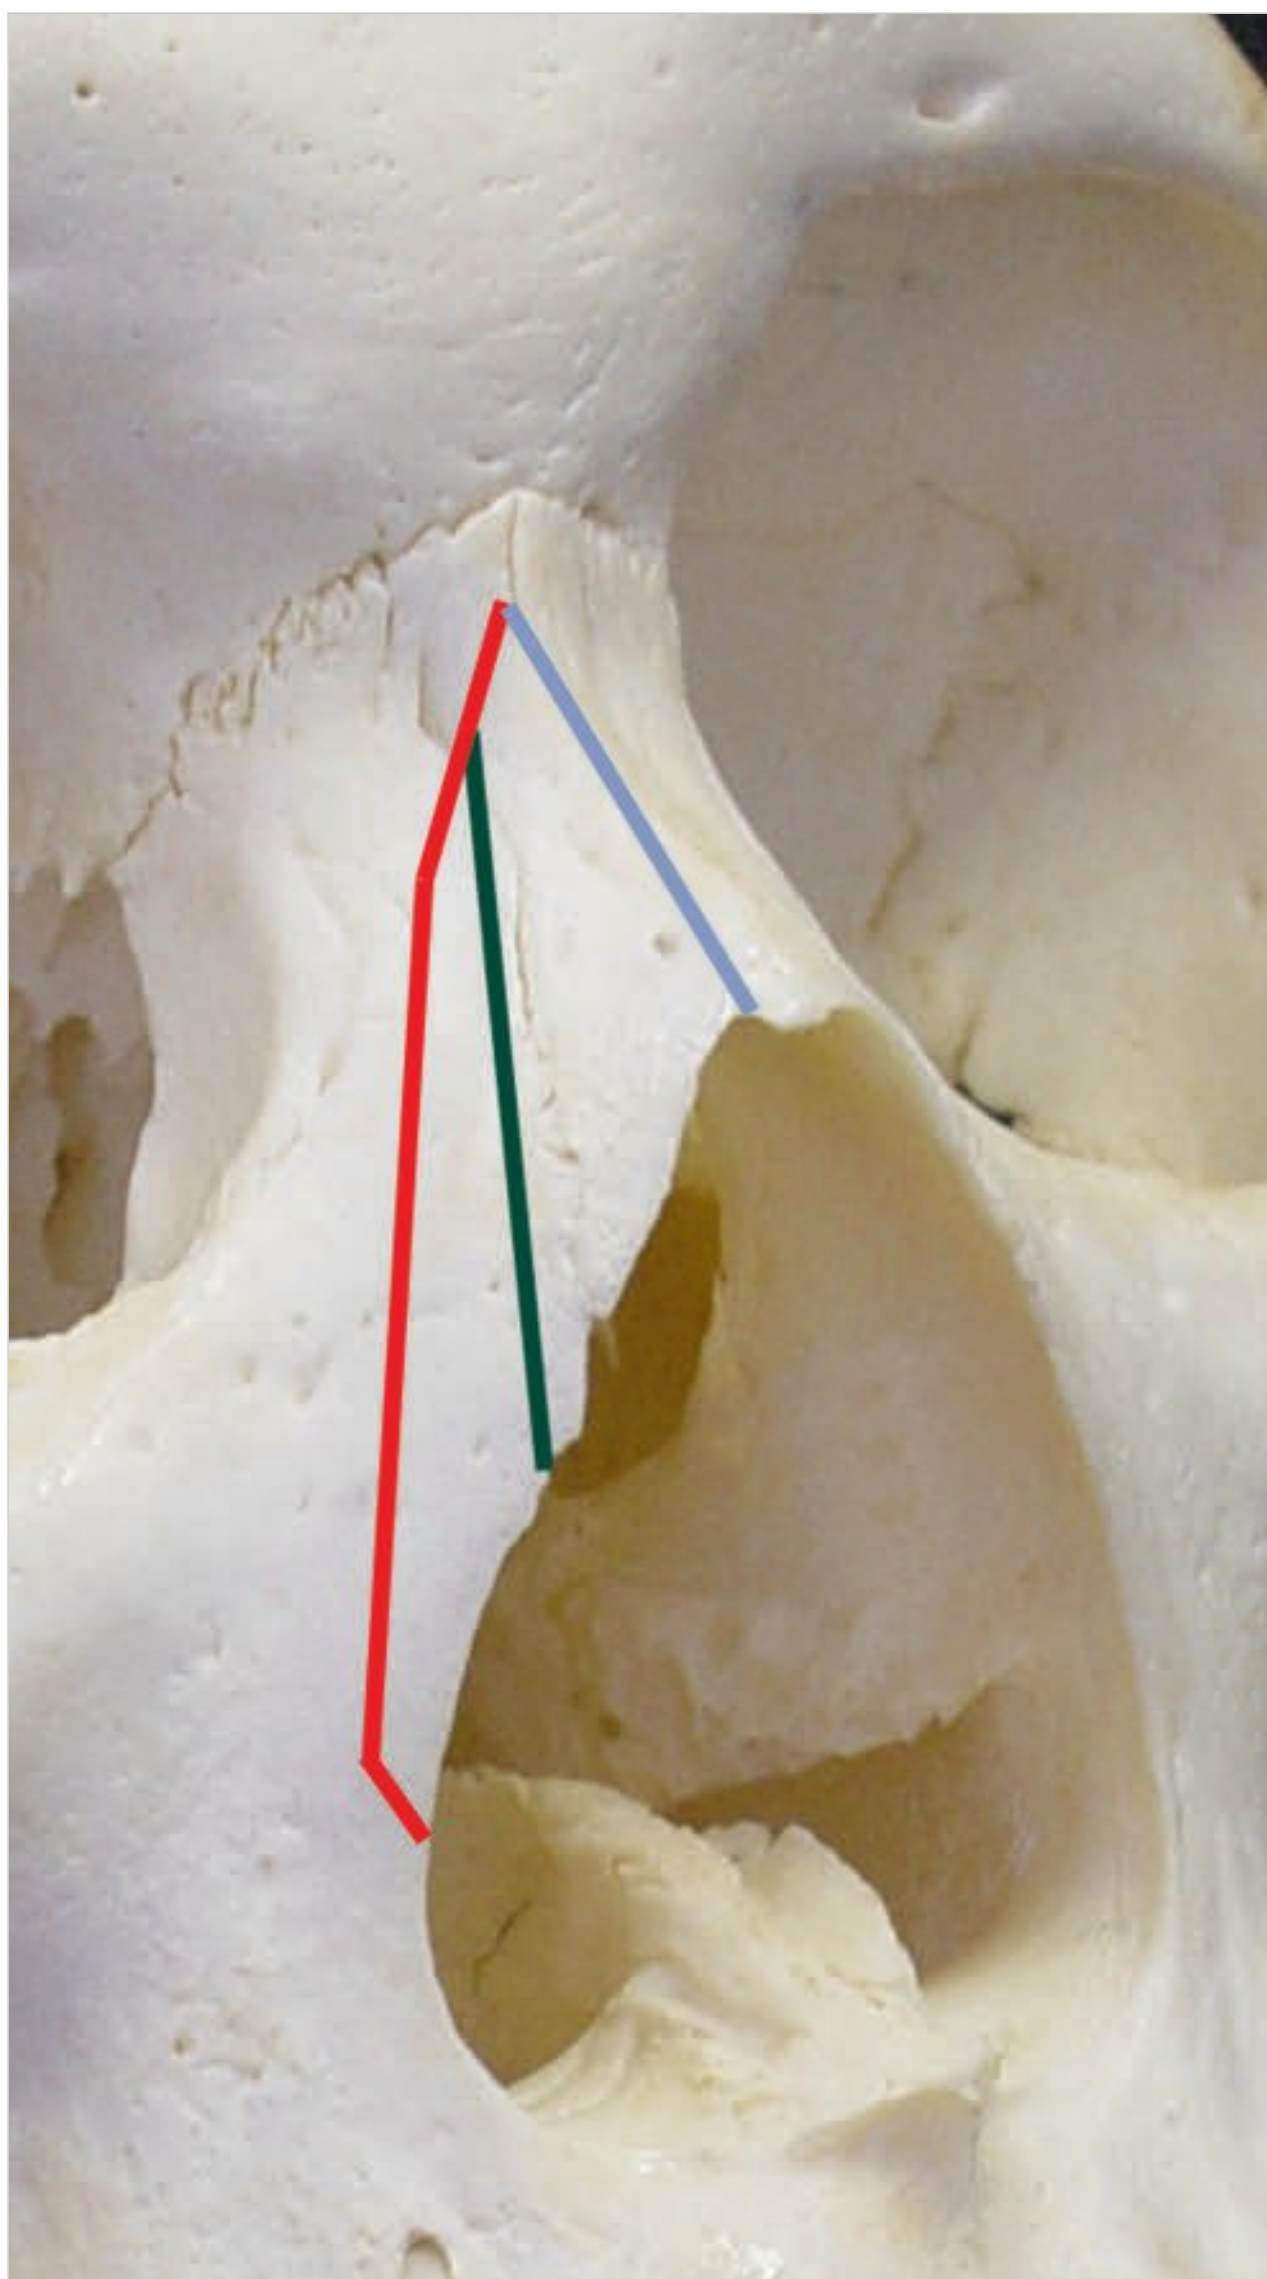

Fig. 53.19 Osteotomies are used to reshape or reposition nasal bones. Medial osteotomies are paramedian in location, whereas lateral osteotomies run mainly through the ascending portion of the maxilla and typically preserve a bone triangle at the lateral caudal piriform aperture. Intermediate osteotomies run between these two and can be used in cases of excessively wide or misshapen nasal bones.

5–0 or 6–0 monofilament permanent sutures (□ Fig. 53.21 and □ Fig. 53.22).

Postoperative Care

After internal nasal incisions are closed with resorbable sutures and columellar incisions are closed with permanent monofilament sutures, a cast is applied to the nasal dorsum. Columellar sutures and the nasal cast are removed in 7 days, and the nasal tip and dorsum are further taped for an additional 7 days.

Complications

Complications (see Box Complications of Rhinoplasty) are infrequent but may occur. Bleeding should occur in fewer than 2 to 5% of cases, and infection is rare. Incomplete osteotomies may leave an open roof deformity. Excessively high lateral osteoto-

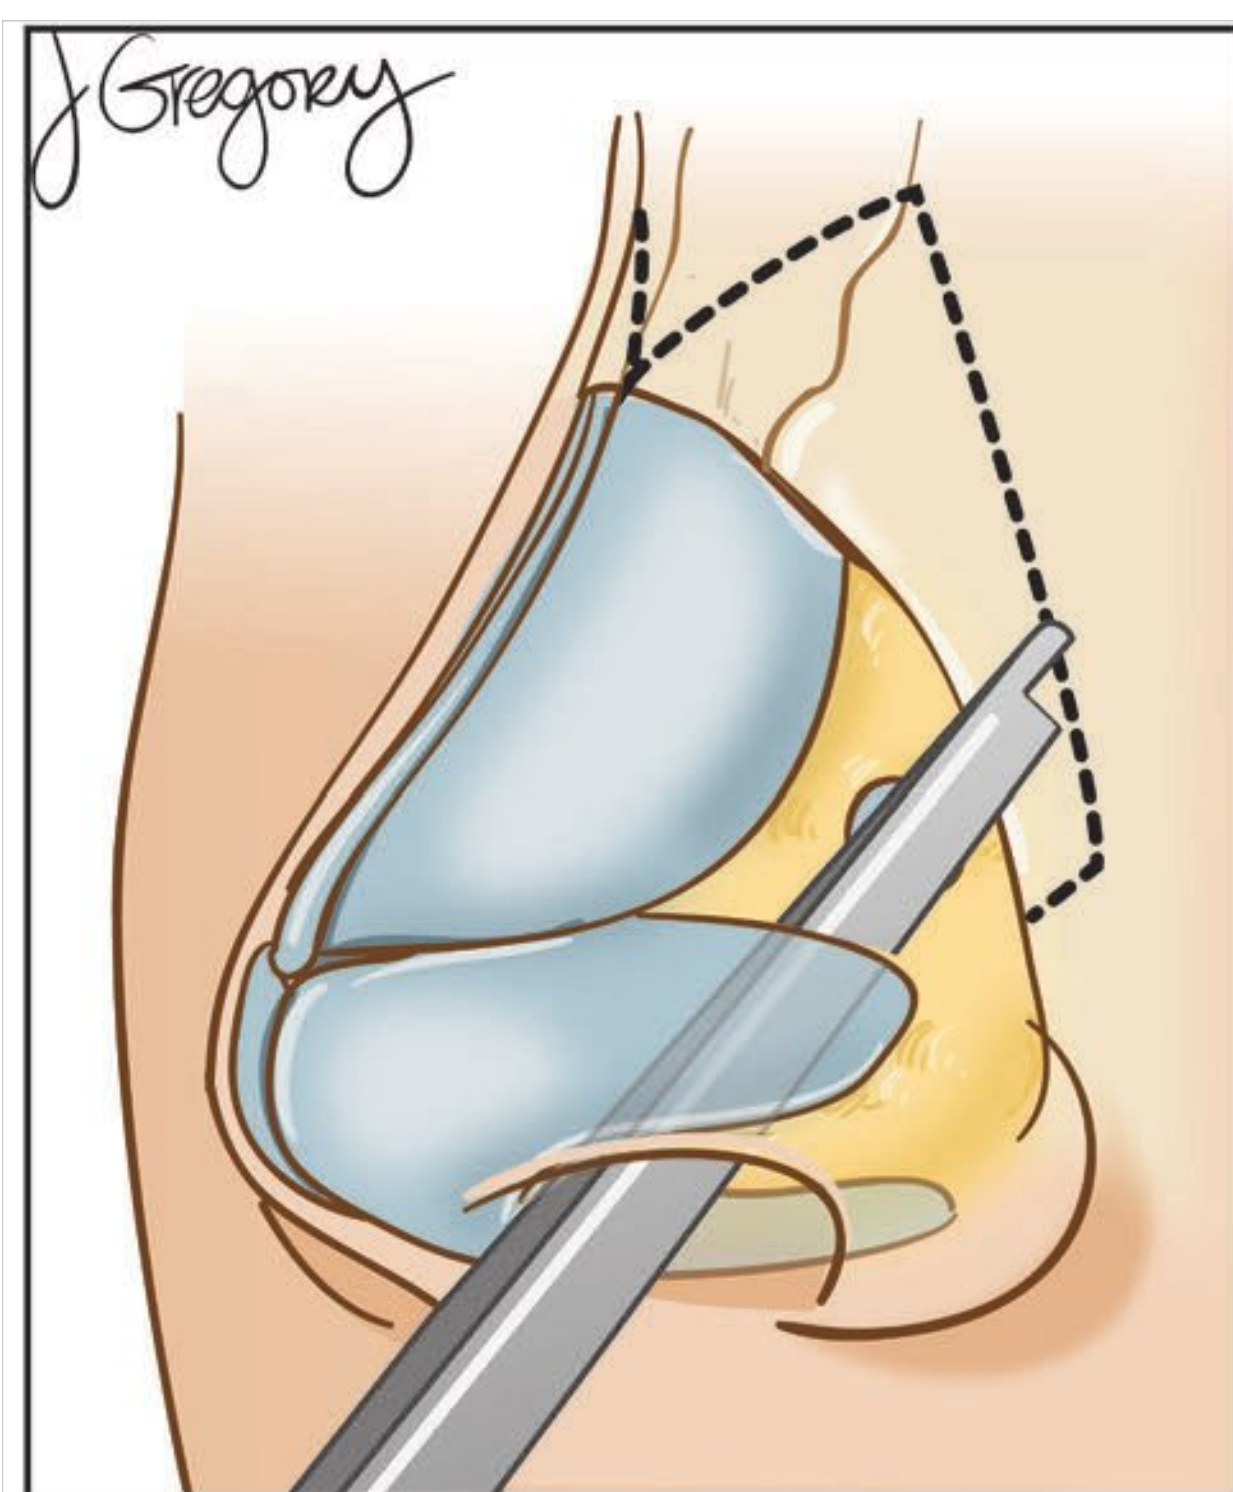

Fig. 53.20 A lateral osteotomy incises the nasal bone from the piriform aperture to the medial osteotomy.

Fig. 53.21 Alar base reductions can be performed to reduce excessive (a) nasal sills, (b) alar margins, or (c) nares.

mies can lead to a “rocker deformity,” in which the upper portion of the nasal bones protrudes when the lower portions are medialized because the lateral osteotomy has been carried

across the concave portion of bone above the nasal root. Nasal obstruction can be a result of excessive dorsal narrowing, an untreated septal deviation or turbinate enlargement, or an internal or external nasal valve collapse/stenosis. Soft-tissue thickening in the nasal tip, excessive bony dorsal reduction, inadequate cartilaginous dorsal resection, or loss of tip support all can lead to a “pollybeak” deformity. Irregularities of the tip may develop early or late because of excessive cartilage resection or damage and postoperative fibrosis, especially in patients with thin skin, and these bossae will be visible. Disruption of the internal nasal valve, failure to address septal deformity or turbinate enlargement, and even overly narrowing the nose can cause nasal obstruction. In general, rhinoplasty is a successful operation, and patient satisfaction rates should be in the 90% range (see □ Fig. 53.22; □ Fig. 53.23 and □ Fig. 53.24). Revision surgery, because of the prior surgery, may be successful in only 80% of cases.

Complications of Rhinoplasty

- Septal hematoma
- Septal perforation
- Saddle nose deformity
- Residual hump
- Deviated nose
- Open roof deformity
- Rocker deformity
- Bossa
- Pollybeak deformity
- Nasal tip overrotation/underrotation/projection
- Nasal obstruction
- Epistaxis
- Nasal valve collapse/stenosis
- Alar retraction
- Hanging columella

Fig. 53.23 (a) Preoperative and (b) postoperative views of rhinoplasty with dorsal reduction and conservative refinement of the nasal tip.

Fig. 53.24 Preoperative (a,c) and 7-year post-operative (b,d) views of external rhinoplasty to straighten and reduce the nasal dorsum and refine the nasal tip.

53.8 Roundsmanship

- Major and minor tip supports maintain the position of the nasal tip. Know them.
- Understand the tripod concept.
- Rhinoplasty should never sacrifice function for form.
- The height of nose (nasal root to nasolabial angle) is generally not changed. The position of the nasal tip and dorsum are generally based on the nasal height.
- Remember the 3–4–5 right triangle view of the nose.

54 Revision Rhinoplasty

Alexander Ovchinsky

54.1 Introduction

Rhinoplasty is rightfully considered by many to be one of the most difficult facial plastic procedures. The tridimensional anatomy of the nose, involving multiple tissue layers with various anatomical properties (skin, bone, cartilage, and nasal mucosa), and the central location of the nose in the face make rhinoplasty a technically demanding task with variable final outcomes. These factors undoubtedly account for a fairly high revision rate of rhinoplasty surgery compared with other surgical cosmetic procedures.

In cases of dissatisfaction after rhinoplasty for aesthetic and/or functional reasons, revision rhinoplasty may be indicated to improve the patient's nasal appearance and function. Compared with primary rhinoplasty, revision rhinoplasty is an even more challenging operation because the main goal of this procedure is to modify functional and/or cosmetic defects or complaints after a previous procedure that was unsuccessful according to the patient's estimation.

54.2 Incidence of Disease

The revision rate of rhinoplasty surgery is known to be in the range from 10 to 15% nationwide. This fairly high incidence of revision surgery compared with that of other facial plastic procedures may be due to the intricacy and complexity of the nasal anatomy, requiring a high level of surgical expertise to consistently achieve good results. In addition, involvement of various tissues with very different physiologic and anatomical properties, such as bone, cartilage, skin, and mucosa, makes the healing process less predictable and more difficult to fully control.

54.3 Terminology

The terminology used in the description of normal nasal anatomy has been presented in earlier chapters. The term saddle nasal deformity describes a nasal dorsal height that is lower than normal, whereas dorsal hump indicates an excessive height of the nasal dorsum. Polybeak deformity indicates excessive fullness in the supratip region, which creates a beaklike appearance of the nasal profile. Inverted-V deformity is excessive narrowing or pinching of the cartilaginous midvault caudal to the bony–cartilaginous junction and may indicate the presence of internal nasal valve collapse. A Cottle maneuver is the test for internal nasal valve collapse, in which the upper lateral cartilage is manually supported on the undersurface while change in the patient's nasal breathing is assessed.

There exist multiple descriptions for postoperative nasal tip deformities, such as tip bossa and boxy, bifid, or bulbous tip. A bossa of the nasal tip is a knuckling of the lower lateral cartilages (LLCs) at the nasal tip due to contracting healing forces acting on overly weakened cartilages. Certain types of patients, especially those with thin skin and strong tip cartilages that are widely placed, are especially at risk. Columellar show describes

the length of the columella visible on the profile view (normally 2 to 4 mm).

54.4 Applied Anatomy

An overview of nasal anatomy may be found elsewhere in the body of this text.

54.5 The Disease Process

54.5.1 Etiology

The dorsal abnormalities frequently necessitating revision surgery are saddle nasal deformity, persistent dorsal hump, and persistent dorsal asymmetry and deviation. The most common etiologies for saddle nasal deformity include overly zealous reduction of the nasal dorsum during primary surgery (□ Fig. 54.1), inward collapse of flail nasal bones after osteotomy, and overly aggressive septoplasty with excessive resection of the bony and cartilaginous septum, leading to the loss of dorsal support (□ Fig. 54.2). Overly zealous reduction of the bony dorsum relative to reduction of the cartilaginous dorsum leads to the polybeak deformity (□ Fig. 54.3). Other etiologies of polybeak deformity include insufficient reduction of the cartilaginous dorsum, as well as extensive postoperative fibrosis in the supratip region (more common in patients with thick skin).

Insufficient cartilaginous midvault support due to overly reduced upper lateral cartilages (ULCs) or inadvertent detachment of the ULC from its attachment to the undersurface of the caudal nasal bone during dorsal hump reduction may lead to the inverted-V deformity and internal nasal valve collapse with resultant nasal airway obstruction.

Nasal tip deformities can occur after overly aggressive LLC reduction leading to a loss of cartilage strength and gradual deformity due to forces of postoperative scarring and fibrosis, after division of the LLC leading to a loss of continuity and weakness, or after poor surgical technique with asymmetric reduction or suturing (see □ Fig. 54.3). Excessive columellar show commonly results from the placement of a disproportionately large columellar strut or tip graft, buckling of the medial crura, or an excessively long caudal septum pushing the columella out. Additionally, columellar show should be distinguished from alar retraction, which, albeit occasionally an anatomical variant, most commonly results from inadequate alar support or excessive scarring.

54.5.2 Pathogenesis

Although some post-rhinoplasty deformities are purely cosmetic in nature, others may result in significant functional problems. Inverted-V deformity and saddle nasal deformity may result in internal nasal valve collapse and nasal obstruction. Significant nasal tip irregularities and weakness of the LLCs may cause alar stenosis and collapse, especially on inspiration, thus resulting in external nasal valve compromise (see □ Fig. 54.3).

Fig. 54.1 (a,b) A patient with a history of prior nasal trauma and rhinoplasty who presented with saddle nose and open roof deformities, irregular and widened nasal bones, a ptotic nasal tip, and pinched lower lateral cartilages with external nasal valve stenosis. (c,d) Twelve months after revision rhinoplasty with dorsal costal cartilage graft, bilateral batten grafts, columellar strut, and lateral osteotomies.

Excessive resection of the nasal septum during primary septorhinoplasty results in a gradual loss of nasal support, progressive dorsal saddling, and nasal obstruction. Alternatively, insufficient correction of a preexisting septal deviation or failure to perform septoplasty during primary rhinoplasty when indicated will leave the patient with persistent nasal airway obstruction.

54.5.3 Natural History and Progression

The postoperative nasal appearance and function may initially be normal in patients with underlying structural deficits. With time, however, weakened, overresected cartilages buckle under the influence of subcutaneous fibrosis and scarring. Progressive subcutaneous fibrosis in the supratip region leads to the polybeak deformity, whereas progressive alar soft-tissue scarring, if not resisted by strong cartilaginous support, causes alar notching and collapse in more severe cases (see □ Fig. 54.3). Incorrectly performed osteotomies (i.e., incomplete osteotomies or osteotomies carried too far superiorly beyond the nasofrontal junction) commonly fail to correct nasal bony deviation. Failure to perform osteotomies to close an open roof after dorsal hump reduction results in open roof deformity and progressive scarring of the dorsal skin into the gap between the nasal bones (see □ Fig. 54.1). Onlay grafts placed during the primary surgery

(bone or cartilage autografts or allografts) may warp, shift, become infected, or be resorbed.

Because many postoperative changes occur gradually over time as a consequence of progressive bony–cartilaginous remodeling and the forces of scar contracture and fibrosis, the “final” result of rhinoplasty is typically described at 1 year or more after surgery. However, even after that, some (generally subtle, but possibly dramatic when significant structural integrity has been compromised) changes in nasal appearance and function may still take place over the following months to years.

54.5.4 Potential Disease Complications

As already discussed, the potential complications of rhinoplasty are primarily of two types: functional due to nasal obstruction and cosmetic due to persistent or worsened nasal deformity.

54.6 Medical Evaluation

54.6.1 Presenting Complaints

Patients evaluated for revision rhinoplasty most commonly present with aesthetic and/or functional nasal complaints that can be broadly subdivided into two categories: uncorrected or

Fig. 54.2 (a,b) Patient with complaints of persistently deviated nasal dorsum, “low-set” nasal profile, and ptotic tip after rhinoplasty. (c,d) Fourteen months after revision rhinoplasty with costal cartilage dorsal graft, columellar strut, lateral and medial osteotomies, and tip refinement.

poorly corrected problems that were present before the original surgery and new problems that have occurred as a result of the previous rhinoplasty. The former include persistence of a dorsal hump because of insufficient reduction, persistence of a nasal dorsal deviation and an uncorrected septal deviation resulting in persistent nasal obstruction, and persistent tip irregularities that were insufficiently addressed or not addressed at all. The latter include open roof deformity, saddling of the nasal dorsum, inverted-V deformity, tip asymmetry and bossa, excessive columellar show, alar notching and retraction, internal and external nasal valve collapse, and various deformities due to poorly placed, designed, shifted, or warped nasal grafts.

54.6.2 Clinical Findings, Physical Examination

A thorough examination of the external nasal anatomy, which includes an evaluation of the nasal appearance on frontal, lateral, oblique, and base views, and careful palpation of the nasal bony–cartilaginous framework are performed. This commonly allows an accurate assessment of the existing problems and gives the surgeon an idea about what was done during the primary surgery. In a cephalic to caudal direction, the nasal bones and cartilaginous midvault are examined for deviation, excessive width or pinching, asymmetry, step-offs, and the presence of a dorsal hump or inverted-V deformity. The Cottle maneuver assists in confirming internal nasal valve collapse. The nasal tip is examined for adequacy of projection, rotation, and support, as well as for the presence of tip asymmetry, deviation, or alar

weakness. Anterior rhinoscopy and nasal endoscopy are routinely performed, particularly in patients with nasal obstructive symptoms, to better evaluate the internal nasal anatomy and rule out other potential causes of nasal obstruction, such as nasal polyps, sinusitis, and nasopharyngeal lesions.

54.6.3 Testing

Standard preoperative photography is always required before revision rhinoplasty. It should document the frontal and basal views, and the right and left 90-degree lateral and 45-degree oblique views. Rhinomanometry, an objective test for nasal airway resistance and obstruction, may be helpful in some instances to diagnose and document the degree of obstruction but is not routinely performed. This test, however, may come in handy when a patient reports significant nasal obstruction and there is no objective evidence of the cause of obstruction on examination. Computer imaging is frequently used as preoperative consultation tool; it greatly facilitates communication between surgeon and patient but should never be considered to be a guarantee of surgical outcome.

54.6.4 Differential Diagnosis

Nasal deformities are multifactorial in etiology, and they may be congenital or arise from prior surgery or trauma. The surgical planning is largely based on the deformity at hand rather than its possible etiology. However, revision rhinoplasties are usually more time-consuming and technically demanding

Fig. 54.3 (a–c) Progressive saddle nose deformity, tip ptosis, and alar notching with internal nasal valve stenosis developed in this patient after prior rhinoplasty. (d–f) Six months after revision rhinoplasty with dorsal costal cartilage graft, columellar strut, and bilateral batten grafts.

because of the altered nasal anatomy and scarring from the primary procedure. Patients should always be asked for their consent to the possible harvest of a cartilage (auricular or rib) and/or calvarial bone graft because there may not be any suitable or sufficient septal cartilage remaining after the original surgery.

54.7 Treatment

54.7.1 Medical Treatment

Medical treatment has limited application in cases in which the main problem is structural (i.e. loss of support, deviation,

other). However, there is a role for medical therapy in attempts to decrease nasal mucosal edema and hyperreactivity. Intranasal, as well as oral, steroids and antihistamines may be used in various combinations for this purpose. Steroid injections into the areas of excessive scarring (most commonly in the supratip region) assist in improving nasal appearance; injectable triamcinolone is commonly used, administered no more frequently than every 3 weeks.

Nasal alloplastic implants placed during the primary surgery may become infected, necessitating treatment with oral or intravenous antibiotics. Although unlikely to salvage the implant,

Fig. 54.4 (a,b) Severe bony–cartilaginous saddle deformity after prior nasal trauma and subsequent rhinoplasty. (c,d) Eighteen months after revision rhinoplasty with a dorsal onlay graft of diced costal cartilage wrapped in AlloDerm (LifeCell Corporation, Branchburg, NJ).

these help reduce the infectious load and optimize the patient for a revision procedure.

54.7.2 Surgical Treatment

Revision rhinoplasty is an indicated treatment for most of the nasal conditions, whether functional or cosmetic, that arise as a result of or that persist in spite of a prior rhinoplasty. Revision rhinoplasty surgery is usually a more demanding and difficult procedure from the surgeon's perspective because of the altered nasal anatomy, obliteration of the normal tissue planes by post-operative fibrosis, and frequently insufficient donor septal cartilage after prior septoplasty. The use of alloplastic materials, such as e-polytetrafluoroethylene (e-PTFE), silicone, and porous high-density polyethylene implants, remains a viable albeit controversial option in revision rhinoplasty and thus should be discussed with patients preoperatively. In secondary or tertiary revisions, when the defect is mainly cosmetic and not functional, many surgeons advocate a "minimalistic" approach by using various onlay grafts to camouflage the defect rather than undertaking a formal reconstructive rhinoplasty, which would be much more-time consuming and less predictable.

It is important to consider preoperatively whether the revision surgery is appropriate. Some post-rhinoplasty patients become so obsessed with their nasal appearance that they may desire revision after revision in the pursuit of perfection and an unrealistic goal. It is the responsibility of a surgeon to discuss all surgical limitations with patients and to carefully select

operative candidates by excluding those with unrealistic expectations, psychiatric problems, or body dysmorphic disorder.

A persistent dorsal hump due to underreduction during a primary surgery can be corrected by further dorsal reduction with dorsal rasps or an osteotome for bony humps and a scalpel for cartilaginous reduction.

Correction of a persistent nasal deviation commonly requires revision osteotomies. Lateral osteotomies alone are frequently adequate; however, medial and/or intermediate osteotomies may be necessary in cases of thick, severely deviated, or asymmetric nasal bones (see □ Fig. 54.2). One should determine the reason for the failure to correct the nasal deviation during the primary surgery because failure to correct this during a revision procedure will likely lead to persistent dorsal deformity. Several common reasons for persistent dorsal deviation after a primary rhinoplasty include incorrectly performed osteotomies (either incomplete osteotomies or asymmetric osteotomies), failure to correct bony septal deviation (so that midline positioning of the nasal bones is not possible), and uncorrected deviation of the cartilaginous dorsum. Open roof deformity results from a failure to perform osteotomies after dorsal hump reduction and is usually corrected by lateral osteotomies.

Saddle nasal deformity is usually corrected by the placement of dorsal onlay grafts, which may be autografts, homografts, or allografts (see □ Fig. 54.1, □ Fig. 54.2, □ Fig. 54.3, □ Fig. 54.4). Autologous materials, which include septal, auricular, or costal cartilage grafts and calvarial bone grafts, are usually the preferred option; however, there are several inherent problems

related to the use of autologous grafts, such as donor site morbidity, resorption, and warping (with most cartilage grafts, especially costal cartilage). Homografts (including irradiated cadaveric rib cartilage grafts) have been used with variable success because of reported resorption of the graft. The use of allografts, such as e-PTFE, silicone, and porous high-density polyethylene, avoids donor site morbidity and issues of insufficient graft availability; however, alloplastic materials are prone to migration, extrusion, foreign body reaction, and infection, which may exacerbate the nasal deformity and necessitate implant removal.

Asymmetries of the cartilaginous dorsum are commonly due to uncorrected deviation of the dorsal septal cartilage, asymmetric or weak ULCs, or asymmetrically placed onlay grafts during the primary surgery. Dorsal septal deviations are difficult to correct because simple excision of the deviated septal cartilage will undoubtedly lead to a loss of nasal support and saddle nose deformity. Numerous surgical techniques exist for the reconstruction of dorsal septal deviations, including spreader graft placement to brace and straighten the deviated cartilage (with or without prior cartilage scoring), complete removal of the cartilaginous septum and extracorporeal reconstruction of the cartilage pieces over a resorbable polydioxanone mesh that is then placed in the anatomical position and secured to the ULCs, or replacement of the septal cartilage with a costal cartilage L-shaped graft. In some instances, a simple detachment of the ULCs from the septal cartilage allows the release of septal tension forces and correction of the septal deviation. Asymmetry of the ULCs is usually corrected by the placement of a ULC onlay graft or a unilateral spreader graft; occasionally, an oversized ULC may be trimmed conservatively without sacrificing the support. Weakness of the ULC, either congenital or secondary to ULC overresection or detachment from the bony–cartilaginous junction, commonly leads to midvault weakness, inverted-V deformity, and internal nasal valve collapse. This can be corrected by the placement of spreader grafts, which are cartilaginous grafts placed between the ULCs and dorsal septal cartilage. Spreader grafts provide additional support to the cartilaginous midvault and increase the cross-sectional area of the internal nasal valve, thus improving its patency and relieving nasal obstruction. An asymmetric or shifted dorsal onlay graft may be repositioned or replaced altogether.

Polybeak deformity, or excessive fullness in the supratip region, results from excessive postoperative fibrosis in the supratip, underreduction of the cartilaginous dorsal hump, overresection of the bony dorsum, or progressive nasal tip ptosis postoperatively. Thus, a polybeak deformity should be corrected based on the primary causative factor with the cautious excision of subdermal scar and fibrosis, addition of structured tip grafts to provide a more substantial base upon which the skin and soft-tissue envelope can be draped, further reduction of the cartilaginous dorsum, and augmentation of the bony dorsum or correction of the nasal tip ptosis.

Nasal tip deformities usually result from excessive weakness of the LLCs from overresection, disruption of continuity, asymmetric LLC suturing, extensive scarring of the nasal tip skin, or a combination of these. The end result may be a bifid tip, bossae, alar collapse, excess or deficiency of columellar show, severely overrotated tip creating the appearance of a foreshortened nose, or an underprojected or droopy tip.

Tip bifidity, or divergence of the dome areas of the LLCs, usually results from the failure to properly secure the domes as a single unit; the domes are then pulled apart by the forces of scar contracture. The correction of a bifid tip requires resuturing the domes together with a nonabsorbable suture (Ethilon [Ethicon, Somerville, NJ] or polypropylene). There exist multiple techniques to correct nasal tip bossae, including direct excision of the bossae and reestablishment of the continuity of the LLCs with sutures and camouflage of the bossa with either an onlay or a tip graft. Alar collapse commonly occurs because of excessive weakening of the lateral crura of the LLCs secondary to overresection (i.e., excessive cephalic trim) or loss of continuity (in cases of LLC division). Occasionally, weak LLCs may collapse under the forces of scar contracture as a result of marginal incisions alone. Alar collapse usually leads to external nasal valve stenosis, in which the alar soft tissues collapse during inspiration under negative pressure, causing nasal obstruction. Reestablishing the strength of the LLC lateral crura with alar strut grafts (cartilage grafts placed on the undersurface of the lateral crura between the crura and the vestibular mucosa) or with alar batten grafts (onlay cartilage grafts placed over the lateral crura) improves alar support and usually corrects external nasal valve stenosis (see □ Fig. 54.1).

Excessive columellar show is caused by buckling of the medial crura, poor placement of the columellar strut or tip graft, or an overly long caudal septum. Alar retraction will make the columella more visible on the profile view. Buckled medial crura may be corrected with sutures or with excision of the buckled segment and the reestablishment of medial crural continuity with a permanent suture. Another option is to suture the medial crura onto the caudal septal cartilage, as in the so-called tongue-in-groove technique, which usually corrects medial crural deformity and adds to tip support. Poorly placed columellar strut or tip grafts need to be replaced or repositioned. Alar retractions are more difficult to correct; mild retraction may be corrected with an alar rim cartilage graft, whereas more severe retraction may require a composite graft (usually from the contralateral auricle). Insufficient columellar show is corrected by adding volume caudal to the medial crura with either a columellar strut or a tip graft. A premaxillary plumper graft, a diced cartilage graft placed into the pocket created at the base of the columella and in front of the anterior nasal spine, can also improve columellar show and creates an illusion of increased tip rotation.

An overrotated nasal tip and a foreshortened nose are the stigmata of unsuccessful rhinoplasty, or multiple rhinoplasties (□ Fig. 54.5). They commonly result from the combination of overresection of the caudal septal cartilage, overly aggressive cephalic trim of the LLC lateral crura, and excessive lateral repositioning of the domes combined with skin contracture forces pulling the tip cephalad. The correction of a foreshortened nose requires de-rotation of the nasal tip, lengthening of the supratip region, the creation of an illusion of lengthening by placing a columellar strut or a tip graft, or a combination of the above techniques. Extended spreader grafts, which extend from the bony–cartilaginous junction to beyond the caudal extent of the septal cartilage and are connected to the columellar strut, recreate a new L-shaped nasal support structure upon which the final tip position is set. The addition of a tip graft assists with lengthening the nose, thus creating an illusion of more de-rotation, and can aid in camouflaging tip irregularities.

Fig. 54.5 (a) Patient with cleft lip nasal deformity who previously underwent two rhinoplasty surgeries, with overrotated nasal tip and “short nose.” (b) Six months after revision rhinoplasty with bilateral extended spreader grafts, columellar strut, and tip refinement.

Underrotated or ptotic nasal tips occur from weakening and failure to reconstruct tip support structures during the primary surgery. Thick and heavy nasal tip skin and weak LLCs are the predisposing risk factors for postoperative tip ptosis. The ptotic tip needs to be resupported either with a strong columellar strut or by suturing the LLCs to the caudal septal cartilage, as in the tongue-in-groove technique.

54.8 Prognosis

As for primary rhinoplasty, there is a definitive revision rate for secondary rhinoplasty that averages about 15%. Proper patient selection is the key factor to a successful revision rhinoplasty; only patients with realistic expectations of the surgical outcome and with nasal deformities that are deemed correctable on preoperative evaluation should be offered a revision surgery. It is a universally recommended and accepted practice not to embark on a revision surgery too soon after the primary rhinoplasty; a year should be allowed to elapse before revision surgery is attempted, particular if the tip needs to be revised. This amount of time allows most of the postoperative changes to mature and gives the patient enough time to get used to the new nose; this latter factor alone helps significantly decrease the number of patient requests for a revision procedure.

54.9 Roundsmanship

- Revision rhinoplasty surgery is required in 10 to 15% of patients after primary rhinoplasty. This high revision rate is

mainly due to the intricacy of the nasal anatomy, complexity of the surgical technique, and difficulty of controlling the healing process in various tissues with different anatomical characteristics, such as bone, cartilage, mucosa, and skin.

- Alteration of the nasal anatomy during primary rhinoplasty surgery makes revision rhinoplasty a more technically demanding procedure with a less predictable final outcome.
- Only patients with correctable deformities and realistic expectations should be offered a revision procedure.
- An accurate assessment of the problem in question and careful surgical planning, which frequently includes auricular or costal cartilage or calvarial bone graft harvest, is imperative for optimizing the surgical outcome.
- All major structural revisions should be delayed for at least 1 year after the primary surgery. This allows enough time to elapse for scar maturation and for the nose to acquire its final shape.

55 Special Considerations in Rhinoplasty

Grigorly Mashkevich

55.1 Introduction

Rhinoplasty changes the shape and/or function of the nose. In several clinical scenarios, special considerations are required for the planning and execution of this operation. These include patients with cleft lip/palate deformities and those of ethnic extraction, particularly of Middle Eastern, African, Asian, or Hispanic descent. Some of the nuances of rhinoplasty surgery pertinent to these groups of patients are addressed in detail in the sections that follow.

55.2 Incidence of Disease

The incidence of cleft lip and palate deformity varies depending on the population. In Caucasians, the incidence reaches 1 in 1,000 live births. The rate in the African population is approximately half of that, and the rate among Asians is twice as high.

55.3 Terminology

Cleft rhinoplasty is designed to restore appropriate height and symmetry to the affected side of the nasal tip in patients with history of cleft lip deformity. Ethnic rhinoplasty reflects a surgical modification of the nasal appearance in patients of ethnic extraction. Ethnic rhinoplasty has an implicit goal of maintaining the ethnic nasal appearance and avoiding “Westernization rhinoplasty.”

55.4 Applied Anatomy

A cleft nose is marked by deformity limited to the nasal tip and affecting the lower lateral cartilage on the side of the cleft. This cartilage is typically flattened and lowered in comparison with the contralateral lower lateral cartilage (□ Fig. 55.1). Because of the underlying cleft defect, the base of the nostril is widened; the columella and ala are situated farther apart on the cleft side, while the nasal septum is deviated to the noncleft side. The premaxilla is also frequently deficient.

Within each ethnic group, patients undergoing rhinoplasty display consistent external nasal features. These nasal features are listed for persons of Middle Eastern and African descent in □ Table 55.1.

55.5 The Disease Process

55.5.1 Etiology

The etiology and evolution of cleft deformity are outlined elsewhere in this textbook. Ethnic nasal structure and appearance represent variations of normal and occur because of inherent genetic differences between clustered populations.

55.5.2 Pathogenesis

If not surgically corrected, a nasal cleft deformity will lead to persistent flattening of the lower lateral cartilage on the affected side. This configuration can result in nasal obstruction at the level of the vestibule and external nasal valve. Despite growth and development, an obvious tip deformity will persist on the cleft side.

The external nasal appearance of persons of non-Caucasian lineage exhibits several defining characteristics, which are listed for selected groups in □ Table 55.1. For instance, persons of Middle Eastern extraction commonly have large dorsal humps and underrotated nasal tips. On the other hand, persons of African descent may have weak and underprojecting nasal bones, with large and thick nasal tips.

Fig. 55.1 Cleft lip and nose deformity (a) before and (b) after cleft lip and nose repair.

Table 55.1 Characteristics of the external nasal appearance in patients of Middle Eastern or African extraction

Nasal appearance	Middle Eastern	African
Skin and soft-tissue envelope	Thick skin and subcutaneous tissues of the tip	Thick skin and subcutaneous tissues of the tip
Upper third	Overprojecting bony dorsum and radix, dorsal widening	Underprojecting bony dorsum and radix, dorsal widening
Middle third	Widening of the osseous and cartilaginous vaults	Widening of the osseous and cartilaginous vaults
Nasal tip	Amorphous and hanging nasal tip, variation in width	Amorphous and wide nasal tip
Nostrils	Variable degree of alar flaring	Alar flaring

55.5.3 Natural History and Progression

The growth and development of ethnic nasal appearances are genetically driven, resulting in the unique features listed for selected groups in □ Table 55.1.

55.5.4 Potential Disease Complications

Potential complications in cleft noses include persistent external deformity and nasal airway obstruction at the level of the external nasal valve. Ethnic noses are not a form of disease and are without inherent structural problems that can lead to complications such as nasal obstruction. Most commonly, patients of ethnic extraction desire nasal surgery to improve their external appearance.

55.6 Medical Evaluation

The complete evaluation of children with cleft deformity is reviewed elsewhere in this textbook.

The initial consultation for an ethnic rhinoplasty allows the surgeon to discuss the patient's concerns and goals for surgery. The concept of maintaining an ethnic identity should be clearly communicated during the initial and subsequent visits. A surgeon should be cautious with patients requesting drastic changes in their nasal appearance because this may lead to unnatural results and "Westernization" changes. Such results may become a strong source of dissatisfaction in such patients.

Digital photography and morphing are used to convey proposed changes. These are shown and discussed as a point of reference, without implicit guarantees of the result. If needed, before and after photographs of previous surgical patients can be used to clarify differences in rhinoplasty goals between Caucasian and ethnic noses.

55.6.1 Presenting Complaints

Children with a cleft nose present primarily with cosmetic and functional deficits related to lip and palate clefting. The accompanying nasal deformity, although not a primary complaint of parents, must be noted, documented, and addressed during cleft surgery.

Patients who seek ethnic rhinoplasty present with complaints related to their appearance, which may include concerns

about any of the features listed for the selected groups in □ Table 55.1.

55.6.2 Clinical Findings, Physical Examination

The clinical findings and examination of the child with a cleft deformity are reviewed in the pathogenesis section of this chapter. The findings pertaining to patients undergoing ethnic rhinoplasty are listed in □ Table 55.1. As in all patients, nasal palpation should be performed to determine the inherent strength of the lower lateral cartilages, document any evidence of previous nasal surgery, and assess potential cartilage grafting sites, such as the septum and ear. Any reports of nasal obstruction should be evaluated during the physical examination by assessing valve competence and nasal allergies.

55.6.3 Testing

No special testing is required for patients with a cleft deformity beyond documenting appropriate growth and development in the first several months of life.

55.7 Treatment

55.7.1 Medical Treatment

The medical treatment of a child with a cleft deformity is discussed elsewhere in this textbook and is not applicable for the cleft nose defect. Ethnic patients with valve obstruction due to inherently weak lower lateral cartilages may benefit from external stents, such as Breathe Right nasal strips (GlaxoSmithKline, Philadelphia, PA). Patients with nasal obstruction due to underlying allergies should undergo allergy testing and be treated with corticosteroid sprays.

55.7.2 Surgical Treatment

The main goal of cleft rhinoplasty is reconfiguration of the lower lateral cartilage with restoration of nasal symmetry and projection on the affected side. Cleft rhinoplasty should accompany cleft lip repair in children at about 3 months of age. Infants are judged to be surgical candidates based on the "rule of 10s":

Fig. 55.2 Patient of Middle Eastern extraction (a) before and (b) 6 months after rhinoplasty. Note the maintenance of a strong radix and dorsum, with only a partial dorsal reduction and concomitant tip rotation.

Table 55.2 Surgical maneuvers commonly performed in Middle Eastern and African ethnic rhinoplasty

Surgical maneuvers	Middle Eastern	African
Skin and soft tissue envelope	Conservative removal of fat in the supratip region; postoperative monitoring and conservative steroid injections	Moderate–aggressive removal of fat in the supratip region; postoperative monitoring and conservative steroid injections
Upper third	Maintenance of high radix during dorsal hump reduction; elevation of the tip to enhance a visual illusion of dorsal hump reduction	Augmentation grafting of the radix and dorsum
Middle third	Osteotomies for dorsal narrowing; placement of spreader grafts to avoid internal valve collapse and an inverted-V deformity	Osteotomies for dorsal narrowing
Nasal tip	Cartilage-sparing maneuvers; preferential use of suture techniques for the dome region; placement of strong supports (columellar strut or septal extension graft, shield or cap grafts)	Cartilage-sparing maneuvers; preferential use of suture techniques for the dome region; placement of strong supports (columellar strut or septal extension graft, shield or cap grafts)
Nostrils	Alar base reduction in some cases	Alar base reduction in the majority of cases

weight over 10 lb, hemoglobin level over 10 g/dL, and age over 10 weeks. During cleft rhinoplasty, the skin overlying the deformed lower lateral cartilage is undermined, and a suspension suture is placed through the dome region. The lower lateral cartilage is sutured in a more cephalic and medial position (see □ Fig. 55.1). This suture is bolstered for several weeks with a silicone button. Definitive cleft rhinoplasty can be offered starting at age 16 for those patients with persistent nasal deformity and/or airway obstruction. An open rhinoplasty approach via a transcolumellar incision affords the best visualization of the lower lateral cartilages. These can be modified with suture and cartilage-grafting techniques to achieve desired tip symmetry and airway patency.

Ethnic rhinoplasty (□ Fig. 55.2) addresses some of the visual characteristics particular to the ethnic nasal appearance. Native nasal harmony must be kept in mind when ethnic rhinoplasty is performed. This surgery has a goal for appearance that differs from what is desirable in Caucasian rhinoplasty. Like any other rhinoplasty operation, ethnic nasal surgery must incorporate the patient's goals and concerns. However, one of the primary

objectives of ethnic rhinoplasty is the avoidance of surgical “Westernization.” Excessive reshaping of the nose to match the ideal Caucasian nose creates an unnatural appearance in ethnic patients. Such a result generates a relative discord between the nose and the face. The surgical goals of ethnic rhinoplasty for Middle Eastern and African patients are listed in □ Table 55.2.

Several undesirable outcomes may complicate ethnic rhinoplasty. These include the same problems seen in Caucasian rhinoplasty, which are discussed in detail in a different section of this textbook. Particular to ethnic nasal surgery is surgical “Westernization,” which is best avoided by understanding the native visual characteristics of ethnic noses.

55.8 Prognosis

Favorable outcomes are expected in most properly executed cleft and ethnic rhinoplasties. Errors leading to complications are best avoided by meticulous planning and precise execution. An understanding of native visual characteristics in ethnic noses should help avoid surgical “Westernization.”

55.9 Roundsmanship

- Special considerations are important in the planning and execution of rhinoplasty surgery in patients with cleft deformities and in those of ethnic extraction.
- Cleft rhinoplasty should accompany cleft lip and palate repair at 3 months of age.
- Ethnic rhinoplasty addresses important visual characteristics in patients of Middle Eastern, African, Hispanic, and Asian backgrounds.

- The avoidance of surgical “Westernization” in ethnic patients is an important goal of ethnic rhinoplasty.

56 Surgical Treatment of the Aging Face

Anthony P. Sclafani and James A. Sclafani

56.1 Introduction

Modern surgery of the aging face was first reported in the early 1900s and was clouded in secrecy, with patients seeking to maintain anonymity and surgeons attempting to keep their techniques to themselves. Over the past 100 years, these procedures have become better designed, defined, and described by surgeons and accepted by the public at large. The procedures have become increasingly refined, with better and longer-lasting results, as well as smaller, less conspicuous scars and less morbidity.

56.2 Incidence of Disease

In 2008, 132,000 facelifts and 44,000 forehead lifts were performed in the United States. These procedures can be performed individually or in concert, depending upon the aesthetic needs of the patient.

56.3 Terminology

Browlift and foreheadplasty are distinct and separate terms. The browlift procedure elevates the brow only, whereas the foreheadplasty additionally treats rhytids of the forehead. Neither facelift nor rhytidoplasty is an accurate description of the procedure, which neither “lifts” the face nor solely treats wrinkles (rhytids). A better description is facialplasty, but the term facelift is used herein because of its common use. Similarly, a midfacelift rejuvenates and recontours the midface (the area between the lower eyelids and the nasolabial folds) and does not simply “lift.”

56.4 Applied Anatomy

The soft-tissue anatomy of surgical facial rejuvenation includes the skin, superficial musculofascial layer, facial muscles, and nerves.

56.4.1 Skin

Elevation of the skin, when performed, is done by elevating the skin flap with a small amount of subcutaneous fat on the flap. This provides protection to the subdermal plexus of vessels. Elevation of this plane is relatively easy in the midface and lower face but is more difficult in the forehead, where the muscles are more intimately attached to the skin. Similarly, the skin is fairly firmly attached to slips of muscle from the sternocleidomastoid (SCM) muscle laterally and often requires sharp dissection.

56.4.2 Musculofascial Layers

Beginning in the forehead, the fascial layer of the galea aponeurotica covers and envelops the frontalis muscle. Posteriorly, this layer continues into the occipitalis muscle fascia; inferiorly,

the galea fuses with the periosteum about 2 cm above the orbital rim, while laterally the galea fuses with multiple layers of fascia just medial to the superior temporal line (most superior attachment of the temporalis muscle). Anatomically, the galea becomes contiguous with the SMAS (superficial musculoaponeurotic system), a fascial tissue that covers and envelops the facial muscles, at the zygomatic arch, where they fuse with the periosteum. Inferiorly, the SMAS is contiguous with the platysma muscle, whereas medially it sends fibrous slips superficially to the overlying skin. Laterally, this tissue is less mobile than medially and covers the parotidomasseteric fascia.

56.4.3 Facial Muscles

Important muscles encountered or modified during foreheadplasty include the paired frontalis muscles (brow elevators that originate posteriorly from the galea and course inferiorly to intermingle with each other in the midline and with the orbicularis oculi muscles more laterally); orbital portion of the orbicularis oculi muscles (brow depressors); paired corrugator and depressor supercillii muscles (brow medializers and depressors, respectively, originating from the superomedial orbital rim); and the midline procerus muscle (brow depressor originating from the nasal bones).

In the midface, most muscles are out of the immediate surgical field; however, the zygomaticus major muscle, coursing from the midportion of the zygomatic arch to the nasolabial fold and modiolus, is a landmark in the deep plane facelift. Similarly, the orbital portion of the inferior orbicularis oculi muscle, depending on the surgical approach, may require mobilization or modification.

In the lower face, the platysma is the inferior extension of the SMAS and runs from the clavicle to interdigitate with the facial muscles and SMAS just above the mandibular border. Starting in the lateral neck, this muscle extends to meet the muscle from the opposite side in the midline. Generally, these are fibrously bound together near the chin but dehiscence more inferiorly, a state that worsens with age. Laterally, the SCM muscle runs from the mastoid inferomedially; especially superiorly, slips of fascia and muscle extend from this muscle to insert on the skin.

56.4.4 Nerves

Motor Nerves

The facial nerve is the only motor nerve within the surgical field of forehead, face, and neck rejuvenation procedures. After the nerve emerges from the stylomastoid foramen and branches at the pes anserinus, five main branches innervate the facial muscles. These branches become increasingly more superficial medially, where in particular the temporal and buccal branches have significant interconnections. The temporal branch runs superiorly to innervate the forehead and lateral orbicularis and corrugator muscles. The temporal branch crosses the zygomatic arch, usually in one to three branches, within the fusion of the SMAS and periosteum, and then runs on the undersurface of

the galea into the forehead. Often, an upper and a lower buccal branch of the facial nerve run medially, parallel to the Stensen duct, to innervate the midfacial muscles from their deep surface. More inferiorly, the marginal mandibular nerve extends medially in the area of the mandibular border, usually dipping below the mandible before ascending over it to innervate the depressor anguli oris muscle. The temporal and marginal mandibular nerves are the motor nerves most at risk for injury during surgery.

Sensory Nerves

The supraorbital and supratrochlear nerves (branches of the ophthalmic division of the trigeminal nerve, V₁) supply sensation to the brow and forehead posteriorly to the crown. These nerves emerge from notches or foramina along the superior orbital rim accompanied by arteries and veins, run posteriorly, and branch and become more superficial peripherally. The supratrochlear nerve is generally found between 15 and 20 mm lateral to the midline, while the supraorbital nerve emerges approximately 23 to 26 mm from the midline. The infraorbital nerve (branch of the maxillary division of the trigeminal nerve, V₂) emerges from a foramen in the maxilla just below the orbital rim, accompanied by associated arteries and veins; this foramen is generally near the midpupillary line. The mental nerve (branch of the mandibular division of the trigeminal nerve, V₃) exits a bony foramen in the mandible below the canine tooth and is generally not encountered during a facelift unless a chin implant is being placed. The great auricular nerve (from C2 and C3) emerges around the Erb point (a point on the posterior aspect of the SCM muscle 6.5 cm below the external auditory canal) and crosses the middle one-third of the SCM muscle with multiple branches to innervate the lower portion of the auricle and mastoid area. The great auricular nerve is the most commonly injured nerve during facelifts.

56.5 The Disease Process

56.5.1 Pathogenesis

Facial aging is a complex concert of multiple processes that occur at different times and rates and to different degrees in individual patients. Skin aging occurs and is characterized by collagen loss, disorder, and degradation; loss of elasticity; dermal thinning; decreased integrity of the dermal–epidermal bond; and dyschromia (age spots, or mottled pigmentation). Fat in the face is organized in discrete compartments that undergo differential descent and/or atrophy with aging; midfacial fat is more likely to atrophy and descend as the fibrous support in this fatty tissue degrades, while fat accumulation in the submental region further ages the face. In addition to contributing to facial wrinkles because of repetitive contraction (e.g., “smoker’s lines” around the mouth), some muscles may have an elevated tone (e.g., horizontal forehead lines that resolve when the patient’s eyes are closed and the patient is no longer subconsciously elevating the eyebrows). Finally, facial bony resorption can occur and contribute to facial aging.

Each patient must be critically examined and the factors contributing to the undesirable appearance identified. Treatments

should be designed to address these specific causes of facial aging.

56.5.2 Etiology

As our bodies age, our appearance is affected. Genetics clearly plays a major role in aging, and a full discussion of this topic is beyond the scope of this chapter. Disorders such as cutis laxa and Ehlers-Danlos syndrome produce a prematurely aged appearance due to a loss of normal elastin or collagen integrity, respectively. Clearly, several exogenous factors contribute to aging, as well. Tobacco use, excessive sun exposure, fluctuations in weight, and poor nutrition all lead to premature aging.

56.5.3 Natural History and Progression

It is self-evident that over time, our faces and bodies will continue to age. Patients frequently present asking, “It is time for a facelift?” When to undergo a facial rejuvenative procedure is an intensely personal decision for patients, but the surgeon can aid them in this decision by asking them to consider the similarity of their appearance to that of older relatives, as well as understanding that the overall sum of the multiple aging processes ongoing will determine the progression of aging. For example, in the study of Guyuron et al, the maintenance of facial volume was associated with a younger appearance in older patients; conversely, younger subjects with more facial fat appeared older.

56.6 Medical Evaluation

56.6.1 Presenting Complaints

A complete history and physical examination should be completed for every patient seeking facial rejuvenation. A frank and unpressured discussion with the patient should elicit from the patient the specific features he or she seeks to improve. It is important to discuss the patient’s motivation for this surgery because proper patient selection is key to success. Patients who choose surgery to improve their personal life, win the approval or love of a spouse or significant other, or gain a promotion at work seek results that surgery cannot give. Patients with body dysmorphic disorder will express dissatisfaction with their appearance out of proportion to their actual deformity. These patients should be identified preoperatively, and a referral for psychiatric evaluation is appropriate. Patients with body dysmorphic disorder suffer from an unrealistic body image and will not be satisfied with the results of even the most skillfully performed surgery. Appropriate patients express a reasonable dislike of noticeable signs of aging and seek to improve their appearance to bolster their self-esteem or to “just look better.” A complete medical and surgical history should be obtained; the surgeon should specifically inquire about any history of facial trauma, prior facial surgery, peripheral vascular disease, bleeding disorder, or collagen vascular skin disorder. A list of prescription, over-the-counter, and homeopathic medications used by the patient should be obtained, and tobacco and alcohol use should be assessed.

56.6.2 Clinical Findings, Physical Examination

The patient seeking rejuvenation of the face should undergo a comprehensive facial examination in a systematic way. Although patients may request treatment of a specific area, other parts of the face will impact the appearance of that area, and treatment should be planned in a way that achieves maximal improvement. For example, a patient who desires treatment of fat deposits of the neck may benefit from a chin implant if the projection of the chin is weak.

The patient should be assessed while seated upright with the head in a neutral position and eyes closed. Rhytids of the forehead and glabella should be noted, as should the position of the frontal hairline, which should be no more than 5 to 6 cm above the brows. Hair density should also be evaluated. The position of the eyebrows should be noted relative to the orbital rim and then lifted to an aesthetically pleasing position, and the amount of elevation required should be noted. Ideally, the male brow runs fairly horizontally at or slightly below the orbital rim, whereas in women the brow should arch and peak a few millimeters above the rim at or just medial to the lateral canthus. The medial and lateral brow should lie on the same horizontal plane. The medial brow should begin along a vertical line drawn from the nasal ala through the medial canthus, and the lateral brow should end on a line running tangentially from the ipsilateral ala through the lateral canthus.

The midface should show smooth contours, rising from a slight concavity below the lower eyelid, then falling to blend into the lower face. Ideally, there is only minimal depression inferiorly at the nasolabial fold, defining the boundary between the cheek and the perioral area; this depression is more defined superiorly as an extension of the alar crease but then ideally fades inferiorly. The ideal point of highest prominence of the midface should be at a point identified at the intersection of the extension of the lateral orbital rim and the zygomatic arch. Slight definition may be present below the malar arch, but a severe depression imparts a gaunt appearance.

The lower face extends below the oral commissure and ideally has a defined, smooth jawline extending from the mandibular angle to the chin. The neck should be smooth, without “bands” or “cords.” The cervicomental angle (formed by the intersection of a line from the chin running along the submental area and a second line running along the anterior aspect of the neck on a lateral view) ideally should be 90 degrees but can be blunted by a low hyoid bone, an accumulation of submental fat, and platysmal bands.

56.6.3 Testing

As patients undergoing facial rejuvenative procedures are generally older, a complete medical evaluation should be performed, preferably by the patient’s primary care physician. The surgeon should describe the planned procedure to the primary care physician and discuss the required perioperative care. Before surgery, a complete series (full-face frontal and bilateral oblique and lateral views) of photographs should be obtained.

56.6.4 Differential Diagnosis

Although the changes addressed with this surgery are generally self-evident, it is important to rule out conditions that may either mimic aging or cause compensatory changes that in turn will age the appearance of the patient. Patients with upper eyelid ptosis will use frontalis muscle contraction to provide additional upper eyelid lift at the expense of heavy horizontal wrinkles of the forehead. Likewise, enlargement or ptosis of the submandibular gland will mimic jowling. The facial skeleton should be addressed in older patients with bony facial aging or patients with congenitally hypoplastic bony features who demonstrate premature aging.

56.7 Medical Treatment

The surgeon best serves patients by presenting them with a range of options, from subtle to dramatic changes with minimal to extensive procedures, and allowing them to choose the procedure(s) that most suit their needs. Although minimally invasive treatments cannot remove redundant skin or elevate soft tissues, some changes can be sufficient for the patient who is not prepared to undergo more involved procedures. Botulinum toxin A, a neurotoxin approved by the FDA for treatment of glabellar lines in 2002, acts by blocking acetylcholine release at the neuromuscular junction. Treatment of the brow depressors, in the face of moderately increased tone of the frontalis muscle, with help elevate the brow. Botulinum toxin A can be used to reduce platysmal banding. Although it is generally safe and associated with minimal bruising, complications of botulinum toxin A result from its spread to and effect on nontarget muscles, such as the levator palpebrae muscle; its effect on this muscle causes ptosis (when it is injected around the eyes). Serious complications are generally limited to inappropriate use of the neurotoxin, the use of adulterated or unapproved toxin, or its use by inadequately trained injectors.

Soft-tissue fillers, such as autologous fat, hyaluronic acid derivatives, poly-L-lactic acid, porcine collagen, and calcium hydroxylapatite, have been used to fill both folds and wrinkles, as well as to restore facial volume. These “volume lifts” can smooth areas of the face and restore a more youthful appearance. Adverse effects associated with soft-tissue fillers include bruising, lumpiness or palpability, granuloma formation, and infection.

56.8 Surgical Treatment

56.8.1 Forehead

Multiple procedures are used currently to raise the eyebrows and smooth the forehead. The most predictable technique, the direct browlift, is the simplest and quickest to perform but can leave visible scars, and it addresses only brow position. A mid-forehead lift can additionally smooth the forehead but requires a visible scar. The coronal foreheadplasty hides the scar at or within the hairline and allows smoothing of the forehead as well as brow repositioning, but it requires a long incision and an increased recovery time. An endoscopic foreheadplasty can yield similar results with smaller scars and a much shorter recovery, but it requires dedicated endoscopic equipment and is

less effective in cases of severe brow ptosis. Finally, a temporal lift, performed either through a limited open approach or endoscopically, can reposition the lateral brow and easily be combined with a facelift, but it has limited benefit in the midbrow and medial brow.

Direct Browlift

The direct browlift is a simple procedure that can be performed under local anesthesia to reposition the lateral two-thirds of the eyebrows. It is best reserved for patients with severe brow asymmetry, such as those with unilateral facial paralysis (□ Fig. 56.1). The best candidate for this procedure is a fair-skinned man with thick eyebrows to provide maximal camouflage for the scar. The amount of brow elevation is directly marked as an ellipse resting on the upper brow hairs. This skin is then excised; the exposed orbicularis oculi muscle fibers inferiorly are then sutured superiorly to the fibers of the frontalis muscle. A layered skin closure is then performed. A modification of this technique, the indirect browlift, places the excisions in preexisting horizontal forehead creases 1 to 2 cm above the brows.

Midforehead Lift

The midforehead lift uses a broken line incision in an upper forehead crease between the midpupillary lines. The frontalis

Fig. 56.1 (a) Patient with a right brow paralysis after tumor resection (note lack of rhytids on the right side of the forehead). The severity of the brow ptosis caused significant visual field reduction. (b) One week after direct browlift, there is improved symmetry of the brows and no visual field cut.

muscle is incised, and inferior dissection below the galea is performed until the corrugator supercilii and procerus muscles are identified; these can then be divided to smooth the glabella. The frontalis muscle is redraped superiorly, excess muscle is excised, and the muscle/galeal layer is closed. The skin is then redraped and the excess excised, followed by layered dermal and epidermal closure. The midforehead lift is a good option in patients who are bald or have severely thinning or receding hairlines and also have a deep forehead crease in which the scar can be hidden; however, its effectiveness in lifting the brow lateral to the midpupillary line is limited.

Coronal Foreheadplasty

The coronal foreheadplasty uses a much more significant incision, which runs from the top of one helical root over the crown to the other helical root. Laterally, the skin is elevated below the temporoparietal fascia (which is contiguous with both the SMAS and the galea), through which runs the temporal branch of the facial nerve, whereas between the temporal crests the plane is subgaleal. The dense periosteal attachments of the temporoparietal fascia and the galea are divided sharply at the temporal line. The dissection transitions to a subperiosteal plane approximately 2 cm above the orbital rim (where the galeal leaves fuse densely with the periosteum), and dissection proceeds to the orbital rim. The forehead flap can be “turned down” to expose the corrugator and procerus muscles inferiorly, which are then divided. The frontalis muscle is scored below the deepest transverse crease. The flap is then advanced superiorly, redundant skin is excised, and the galeal and skin incisions are closed after the wound is drained. The midforehead lift and the coronal foreheadplasty require a certain degree of overcorrection because the point of fixation is at the galeal closure (at the coronal incision), not at the brow (point of interest), and there is some “stretch back” of the flap over time. Midforehead lift requires elevation to about 150% of the desired elevation, and the coronal foreheadplasty typically requires 200 to 250% overcorrection.

Temporal Lift

The temporal portion of the coronal foreheadplasty can be performed in isolation to elevate the lateral brow. An open incision within the hair-bearing temple, supplemented by inferior dissection under direct vision or assisted with endoscopes, is performed inferiorly to the orbital rim. The attachments at the superior temporal line are divided down to the orbit, with release of the orbital retaining ligament in this process. The lateral brow is then elevated, and extra skin is removed and closed in layers under tension.

Endoscopic Foreheadplasty

Endoscopic foreheadplasty combines a number of features of these procedures but relies on a more functional understanding of brow dynamics. A number of 1- to 2-cm sagittal incisions (two to four, typically) are made in the hair-bearing scalp between the temporal lines. One additional incision is made in each temple, as in the temporal lift. The central incisions are

used to develop a subperiosteal (less commonly, subgaleal) plane down to the orbital rim and glabella, while the temporal incisions allow a sub-temporoparietal fascia dissection medially to the superior temporal lines and inferiorly to the zygomatic arches and lateral orbital rims. During this dissection, care must be taken to protect the temporal branches of the facial nerve, which runs in the overlying temporoparietal fascia. This plane is relatively avascular, but a bridging vein (zygomaticotemporal vein, the so-called “sentinel” vein) crosses between the temporoparietal fascia and temporalis muscle and pierces the underlying deep temporal fascia in close proximity to the temporal branches. Cautery is best avoided, but if necessary (because of bleeding or for the enhanced exposure required during a midface lift; see below), it should be done at the deep origin of the vein. The dense fibrous attachments at the superior temporal line are divided down to the orbital rim. The periosteum is opened at the orbital rim (after the arcus marginalis, the periosteum of the rim of the superior orbit, has been identified). This incision should extend across the midline continuously between one lateral canthus to the other. In the glabella, the corrugator and depressor supercillii and the procerus muscles are identified and divided while the branches of the supraorbital and supratrochlear nerves are protected. With this release, the forehead flap is freely mobile and can be advanced superiorly as needed. Early failures of the endoforeheadplasty were most likely due to failure to provide sufficiently long (>6 weeks) brow support to allow the periosteum/galea to become sufficiently adherent to the deep structures to resist gravitational descent. Moreover, residual corrugator and depressor supercillii and procerus muscle function will also pull the brow inferiorly. However, with bone-anchored sutures or resorbable fixation devices, which can provide this needed long-term support, the postoperative brow position is quite predictable, and significant overcorrection is unnecessary. Temporally, the elevated temporoparietal fascia is advanced superiorly and sutured to the deep temporal fascia and the wound closed. Recovery is quite quick, with patients often returning to work within a week (□ Fig. 56.2).

Midface lift

The endoscopic foreheadplasty can be extended by incising the periosteum of the superior edge of the zygoma and continuing subperiosteal elevation along the zygoma to the inferolateral orbital rim, then inferiorly into the midface. Special elevators allow dissection around the infraorbital nerve and inferiorly to just above the tooth roots. A suture is then passed through the midfacial fat and fixed superiorly to the deep temporal fascia at the temporal incision. This provides superolateral elevation of the midface.

An alternative approach to the midface is through the lower eyelid. Either by a transconjunctival or a transcutaneous approach, the periosteum is incised at the infraorbital rim (similar to the approaches used for midfacial fractures) and elevated on both sides of the infraorbital nerve to just above the maxillary tooth roots, between the nasal side walls medially and the masseter muscle laterally. After the periosteum and the lower end of the dissection have been incised, bone-anchored fixation devices as well as sutures to the orbital rim are used to mobilize and secure the periosteum and midfacial fat superiorly. Lateral

Fig. 56.2 (a) Moderate brow ptosis with lipoma of the left forehead. (b) After endoscopic browlift (with resection of the forehead lipoma), the forehead is notably smoother, and the brows are in a more relaxed position.

canthal suspension is important in these cases to avoid causing an ectropion.

Although the endoscopic approach requires no eyelid incision and has a low incidence of postoperative lid malposition, there is a 1 to 2% risk for injury to the frontal or buccal branches of the facial nerve. Moreover, correction of a “tear trough” deformity (hollowing and concavity of the lower eyelid below the medial orbital rim) is not possible with this approach. Conversely, lid malposition at a rate of up to 19% has been reported in the transpalpebral approach, although this should be considerably lower with the use of bone-anchored fixation. The choice of approach depends upon surgeon preference and the specific needs of the patient.

56.8.2 Lower Face

Submental Liposuction

Many surgeons combine submental liposuction with other, more invasive procedures, such as facelift, neck lift, and platysmaplasty, to achieve maximum contouring of the neck and lower face. The aesthetic goals of younger patients with elastic skin and isolated submental or jowl fat deposits can be met with submental liposuction alone. Postoperative contraction of the skin in patients with good skin tone can provide subtle yet satisfying definition of the cervicomental angle. Older patients

with increased laxity will likely benefit from submental liposuction in combination with another, more invasive procedure.

The procedure involves small stab incisions in the submental and subauricular regions. Pretunneling with progressively larger blunt-tipped cannulas without the use of suction elevates the subcutaneous plane before insertion of the liposuction cannula. A wetting solution of 0.1% lidocaine with 1:1,000,000 epinephrine can be injected before or during the pretunneling procedure. Aspiration liposuction is then conducted with 1 atm of negative pressure. The open face of a blunt-tipped, single-port cannula is oriented away from the dermis and a bimanual technique is used; the surgeon's nondominant hand guides the cannula through the subcutaneous fat layer in skin rolled and compressed by the dominant hand. Liposuction is performed conservatively, with a small amount of fat left on the flap to protect the subdermal plexus blood supply. The aspiration is typically done between the two SCM muscles laterally and as far inferiorly as the thyroid notch. Overlapping subauricular and submentally based fan patterns are used to avoid visible ridges and achieve a smooth contour. Care is taken to ensure uniform fat removal so that the flap redrapes naturally with peripheral tapering. After closure of the incisions, an elastic neck garment with fluff is applied for proper compression.

SMAS Facelift

The SMAS facelift is typically conducted after submental and subjowl fat deposits have been addressed with liposuction, as discussed above. An incision beginning in the temple, wrapping around the ear, and ending in or at the occipital hairline is made and may incorporate the previously made liposuction incisions. In women, the incision can be hidden behind the tragus (□ Fig. 56.3). A subcutaneous dissection over the cheek and lateral neck is then performed, extending 4 to 10 cm from the tragus and preauricular incision. With scissors, a skin flap can be elevated in the occipital region while care is taken to avoid injury to the great auricular nerve. After the earlobe has been freed, the scissors can be directed toward the lower neck through the superficial subcutaneous plane. A vertically oriented strip of SMAS is incised approximately 2 cm anterior to the skin incision, exposing the parotidomasseteric fascia, and may curve around the earlobe. The SMAS is elevated (□ Fig. 56.4) below the zygoma inferiorly to the junction of the platysma. Anterior to the parotid, if dissection is performed it must remain superficial to the masseter to avoid facial nerve branches. Inferiorly, the lateral aspect of the platysma is then identified and a minimal subplatysmal elevation is conducted. The SMAS–platysma flap is then secured with a superoposterior vector of traction and multiple sutures. After the SMAS–platysma flap has been realigned and sutured, excess SMAS and skin can be excised, with care taken not to put undue tension on the flap. This superolateral traction typically affects the lower cheek, jowl region, and anterior–superior neck. The incisions are then closed in a two-layer fashion, with careful attention paid to the hair-bearing skin. Improvements in the jawline and neck contour are seen relatively quickly.

Rhytidectomy with Lateral SMASectomy

Rhytidectomy with lateral SMASectomy was described as an alternative to the SMAS flap rhytidectomy, which required

discrete elevation of the SMAS. Before the introduction of rhytidectomy with lateral SMASectomy, extensive SMAS dissection anterior to the parotid gland was thought necessary to effect significant change in the overall facial contour. However, this dissection was known to put facial nerve branches at higher risk. Advocates of the lateral SMASectomy approach argued that extensive SMAS dissection was not necessary in most patients and that its risks outweighed the long-term benefits. Lateral SMASectomy is essentially the removal of a portion of the SMAS overlying the anterior edge of the parotid gland. The direction of the SMASectomy is oriented so that the vectors of SMAS closure lie perpendicular to the nasolabial fold (□ Fig. 56.5). This closure effectively brings the mobile medial SMAS up to the level of the more fixed lateral SMAS. Care is taken to remain below the malar eminence and in a plane superficial to the deep fascia and the parotid parenchyma, in order to minimize the risk for injury to the facial nerve branches. This rapid and relatively safe technique produces contouring of not only the nasolabial fold, but also the jowl and jawline. The lateral SMASectomy also generates a more superiorly oriented vector of lift.

Deep Plane Facelift

For the deep plane facelift, standard temporal, preauricular, and postauricular incisions are made that may extend into the temporal hairline and over the occiput. A short subcutaneous flap is elevated that extends up to about 3 cm anterior to the tragus and remains posterior to a line drawn from the angle of the mandible to the lateral canthus. A J-shaped vertical strip of SMAS is then excised, with care taken to stay posterior to the course of the temporal branch of the facial nerve. The sub-SMAS plane is entered and elevated inferiorly, and the osseocutaneous and fasciocutaneous ligaments are divided down to the subplatysmal plane approximately 3 to 5 cm below the margin of the mandible. The division of these ligaments allows complete mobilization of the deep plane flap. The flap is also elevated over the medial extent of the zygomaticus major muscle in a superior to inferior fashion to avoid injury to the zygomatic branch of the facial nerve. The subplatysmal flap can be elevated far medially, but it does not have to be carried across midline (□ Fig. 56.6). Traction is then applied to the platysma–SMAS flap in a superolateral direction, and suturing is done to create an initial vector parallel to the mandibular ramus. Redundant skin may be excised at this point without creating tension in the flaps. Closure is conducted in multiple layers.

Corset Platysmaplasty

Platysmaplasty is considered to be particularly useful in patients with platysmal banding in order to establish a more defined cervicomental angle and jawline. Ideal candidates include those with good skin elasticity, moderate neck ptosis, and thin skin. The procedure can be conducted under local anesthesia in qualified patients, removing the morbidity associated with general anesthesia. Like many other techniques, platysmaplasty is often employed in conjunction with submental liposuction. This union not only allows improved defatting of the neck but also aids in undermining the cervical skin in a relatively atraumatic fashion. Corset platysmaplasty can be used in concert with laterally based facelift techniques.

Fig. 56.3 (a) The standard facelift incision wraps around the ear. For a patient with a low hairline, the incision can be carried into the frontal and occipital hairline; for a patient with a higher hairline, the incision runs along the hairline. (b) The postauricular portion of the incision runs along the posterior conchal bowl when the ear is reflected forward, so that when the ear is in its normal position, the scar will fall into the postauricular sulcus. (c) In a male patient or a patient with a laterally displaced tragus, the incision is positioned in the pretragal crease to avoid draping beard hair onto the tragus or pulling the tragus more laterally, respectively. (d) When possible, the preauricular incision is placed on the inner aspect of the tragus to better camouflage the scar.

With the patient in the upright position, the anterior borders of the SCM muscles and the jawline, jowls, left and right bands of the platysma muscle, and thyroid cartilage are identified and marked out on the skin. The classic submental stab incision used during submental liposuction is extended approximately 4 cm after the completion of liposuction. After soft-tissue

bridges have been divided between the dermis and underlying platysma, the medial edges of the platysma are identified and skeletonized. Each side of the muscle can then be horizontally transected at the level of the hyoid, and a running suture is used to bring the two edges of the platysma together in the midline from the submental zone down to the thyroid notch.

Fig. 56.4 In an SMAS facelift, a skin flap is raised toward the nasolabial fold and in the lateral neck; an incision is then made in the SMAS, and an SMAS flap is elevated in the same direction. The SMAS flap is then advanced posterosuperiorly and sutured. SMAS, superficial muscular aponeurotic system.

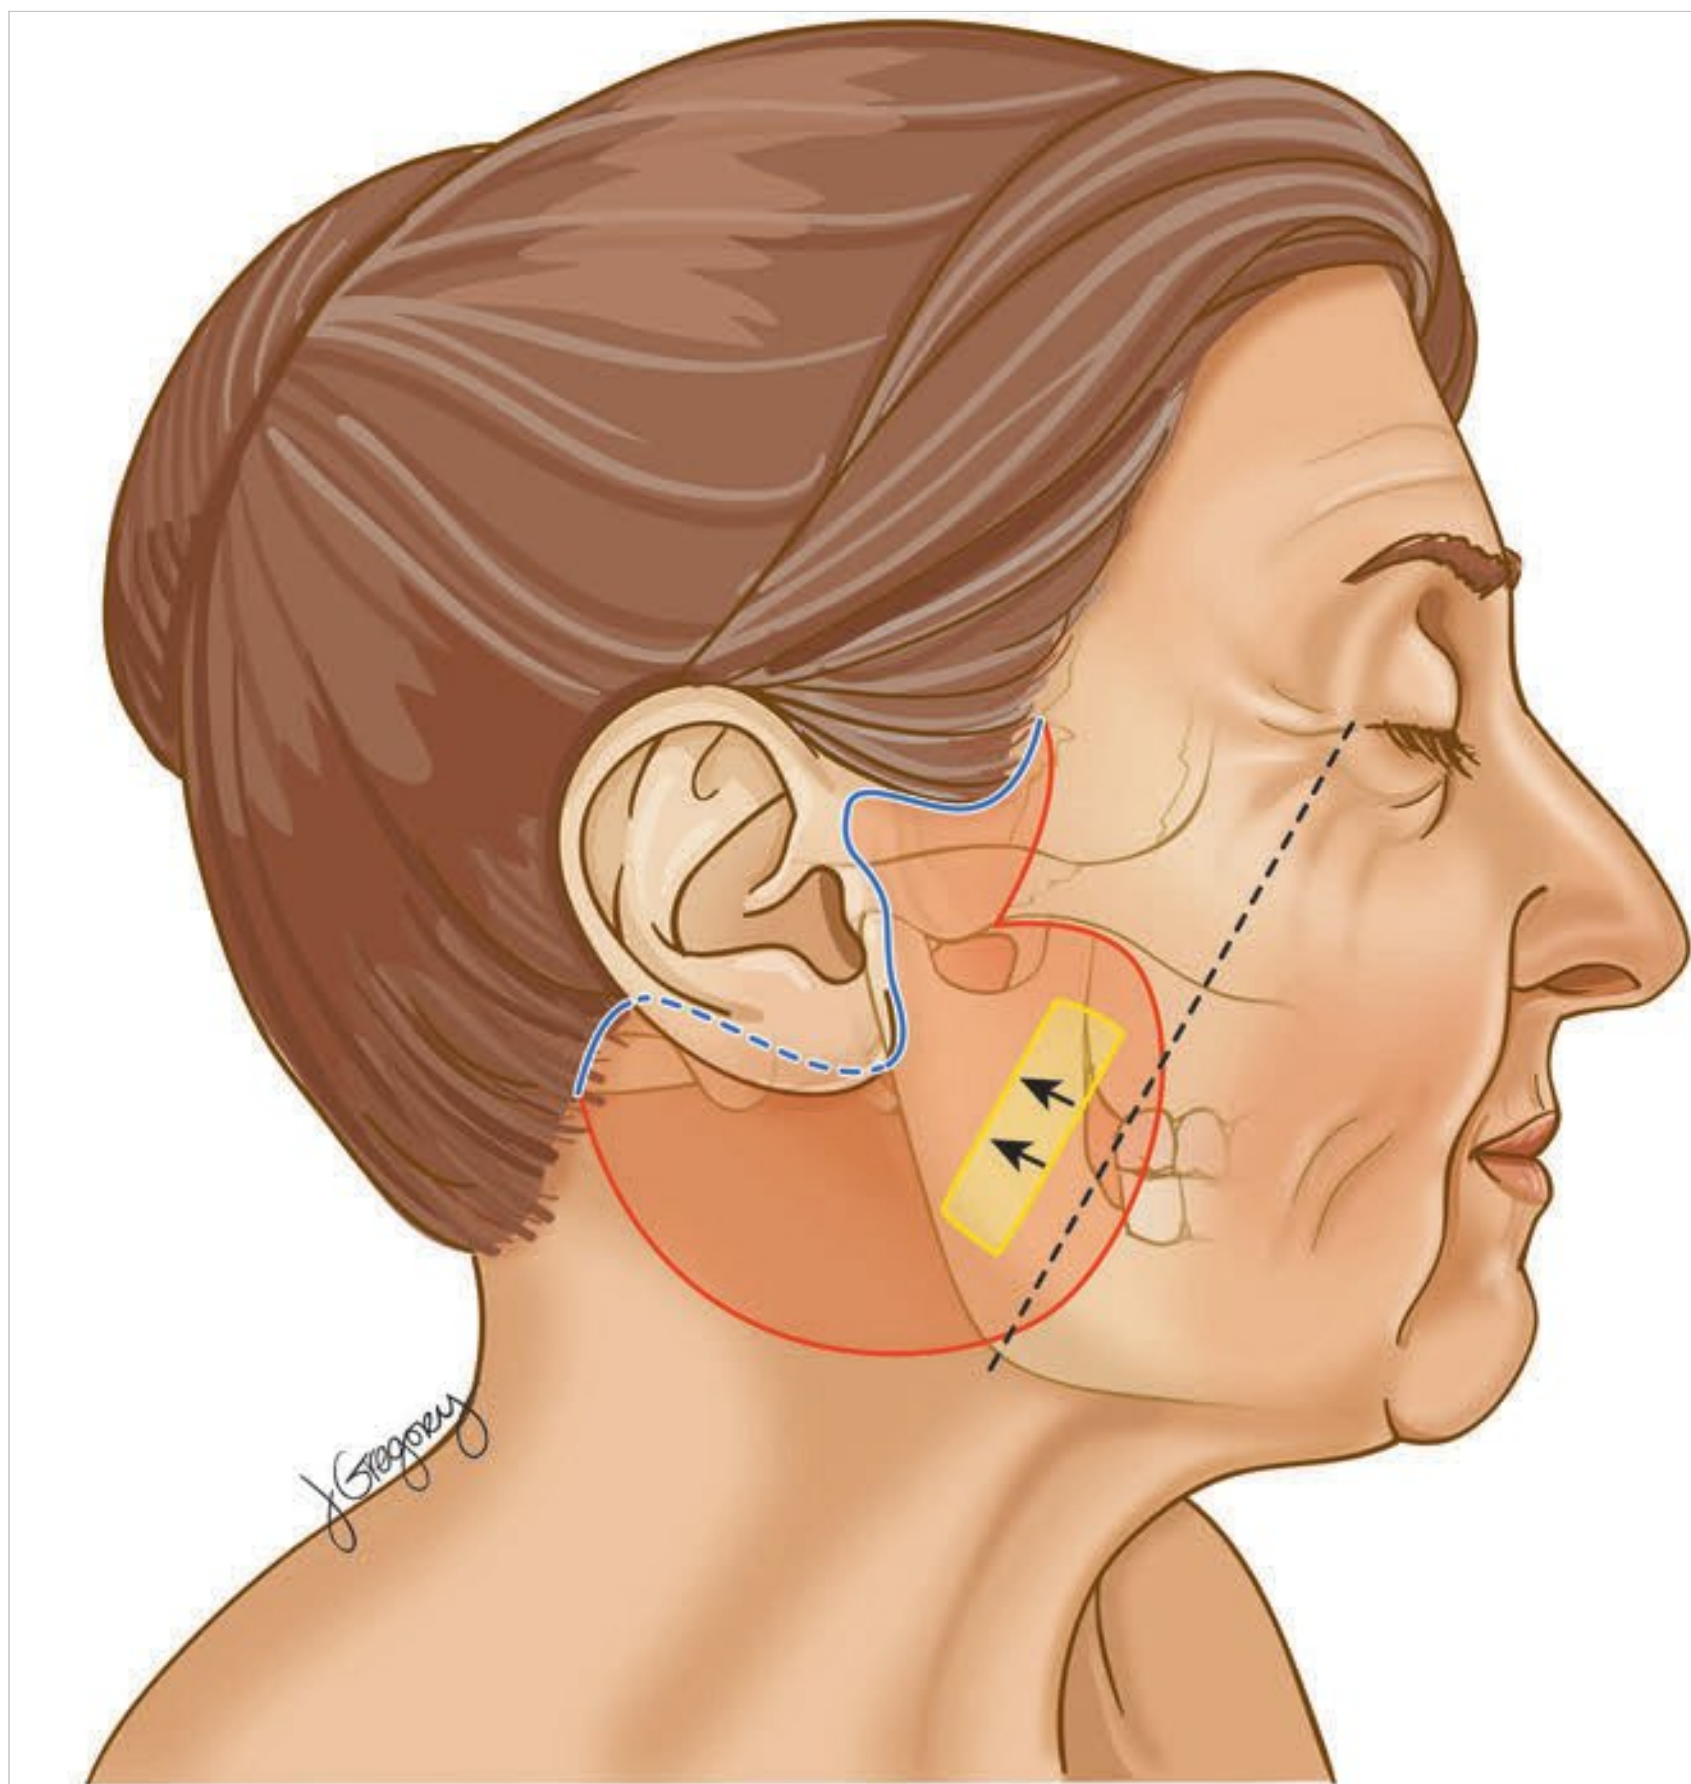

Fig. 56.5 A lateral SMASectomy is better reserved for patients with mild cervical skin laxity. A skin flap is raised, and a 1-cm strip of SMAS is excised from the angle of the mandible to the malar arch (directed toward the lateral canthus). The SMAS is sutured in a mostly superior direction.

Fig. 56.6 A deep plane facelift relies on a relatively small skin flap, which allows access to the preauricular SMAS. The SMAS is incised and an SMAS flap is elevated as the surgeon identifies and progresses medially over the zygomaticus major muscle. The composite flap is then advanced posterosuperiorly.

The running suture is then returned superiorly with wider tissue bites and tied in the submental region (□ Fig. 56.7).

Submental W-Plasty

Submental W-plasty is a technique employed in patients with significant skin laxity who are not candidates for a traditional facelift and neck lift procedure. It is typically reserved for older men with severe cervical skin laxity who are committed to maintaining a beard to camouflage the scar. The procedure involves the direct vertical excision of redundant submental skin and subcutaneous fat and closure of the vertical scar with a running W-plasty. The platysma is then plicated in the midline, allowing the skin to redrape properly. Tension is also removed by closing the incision with alternating deep dermal buried absorbable sutures at the midpoints of the limbs. The epidermis can be closed with eversion of the edges with interrupted non-absorbable sutures (□ Fig. 56.8).

Significant bleeding is uncommon in any of these procedures (rare in surgery of the forehead and midface), but as with any surgical procedure, it is possible. Patients should be specifically warned to avoid anticoagulants such as aspirin and nonsteroidal anti-inflammatory drugs for at least 2 weeks before surgery and for 1 week after surgery. Male gender, use of general anesthesia, intraoperative hypertension, and postoperative nausea and vomiting all increase the risk for hematoma. Hemostasis should be meticulously ensured before wound closure, and

sealants such as platelet gel should not be relied upon to control bleeding. Drains are often used to ensure the adequate evacuation of any serum or small amounts of blood after a coronal or endoscopic forehead procedure or facelift. Hematomas typically present with pain out of proportion to the surgery and may be associated with external bruising and swelling or buccal ecchymosis. Active bleeding (expanding hematoma) requires reoperation to achieve hemostasis. Large, stable hematomas can be managed in the operating room or at the bedside by opening the facelift incision in the postauricular area and evacuating the clots (□ Fig. 56.9). Small (<1 cc) hematomas can be watched for 7 to 10 days and aspirated with a needle as the clot begins to break down. Hematomas are more common in men (7 to 9%) than in women (1 to 2%).

Complications of Facelift and Forehead-plasty

- Hematoma (1–7%)
- Sensory nerve injury (7%)
- Motor nerve injury (0.5–2.6%)
- Alopecia (1–2%)
- Infection (<0.2%)
- Poor scarring
- “Pixie ear” deformity
- Skin slough

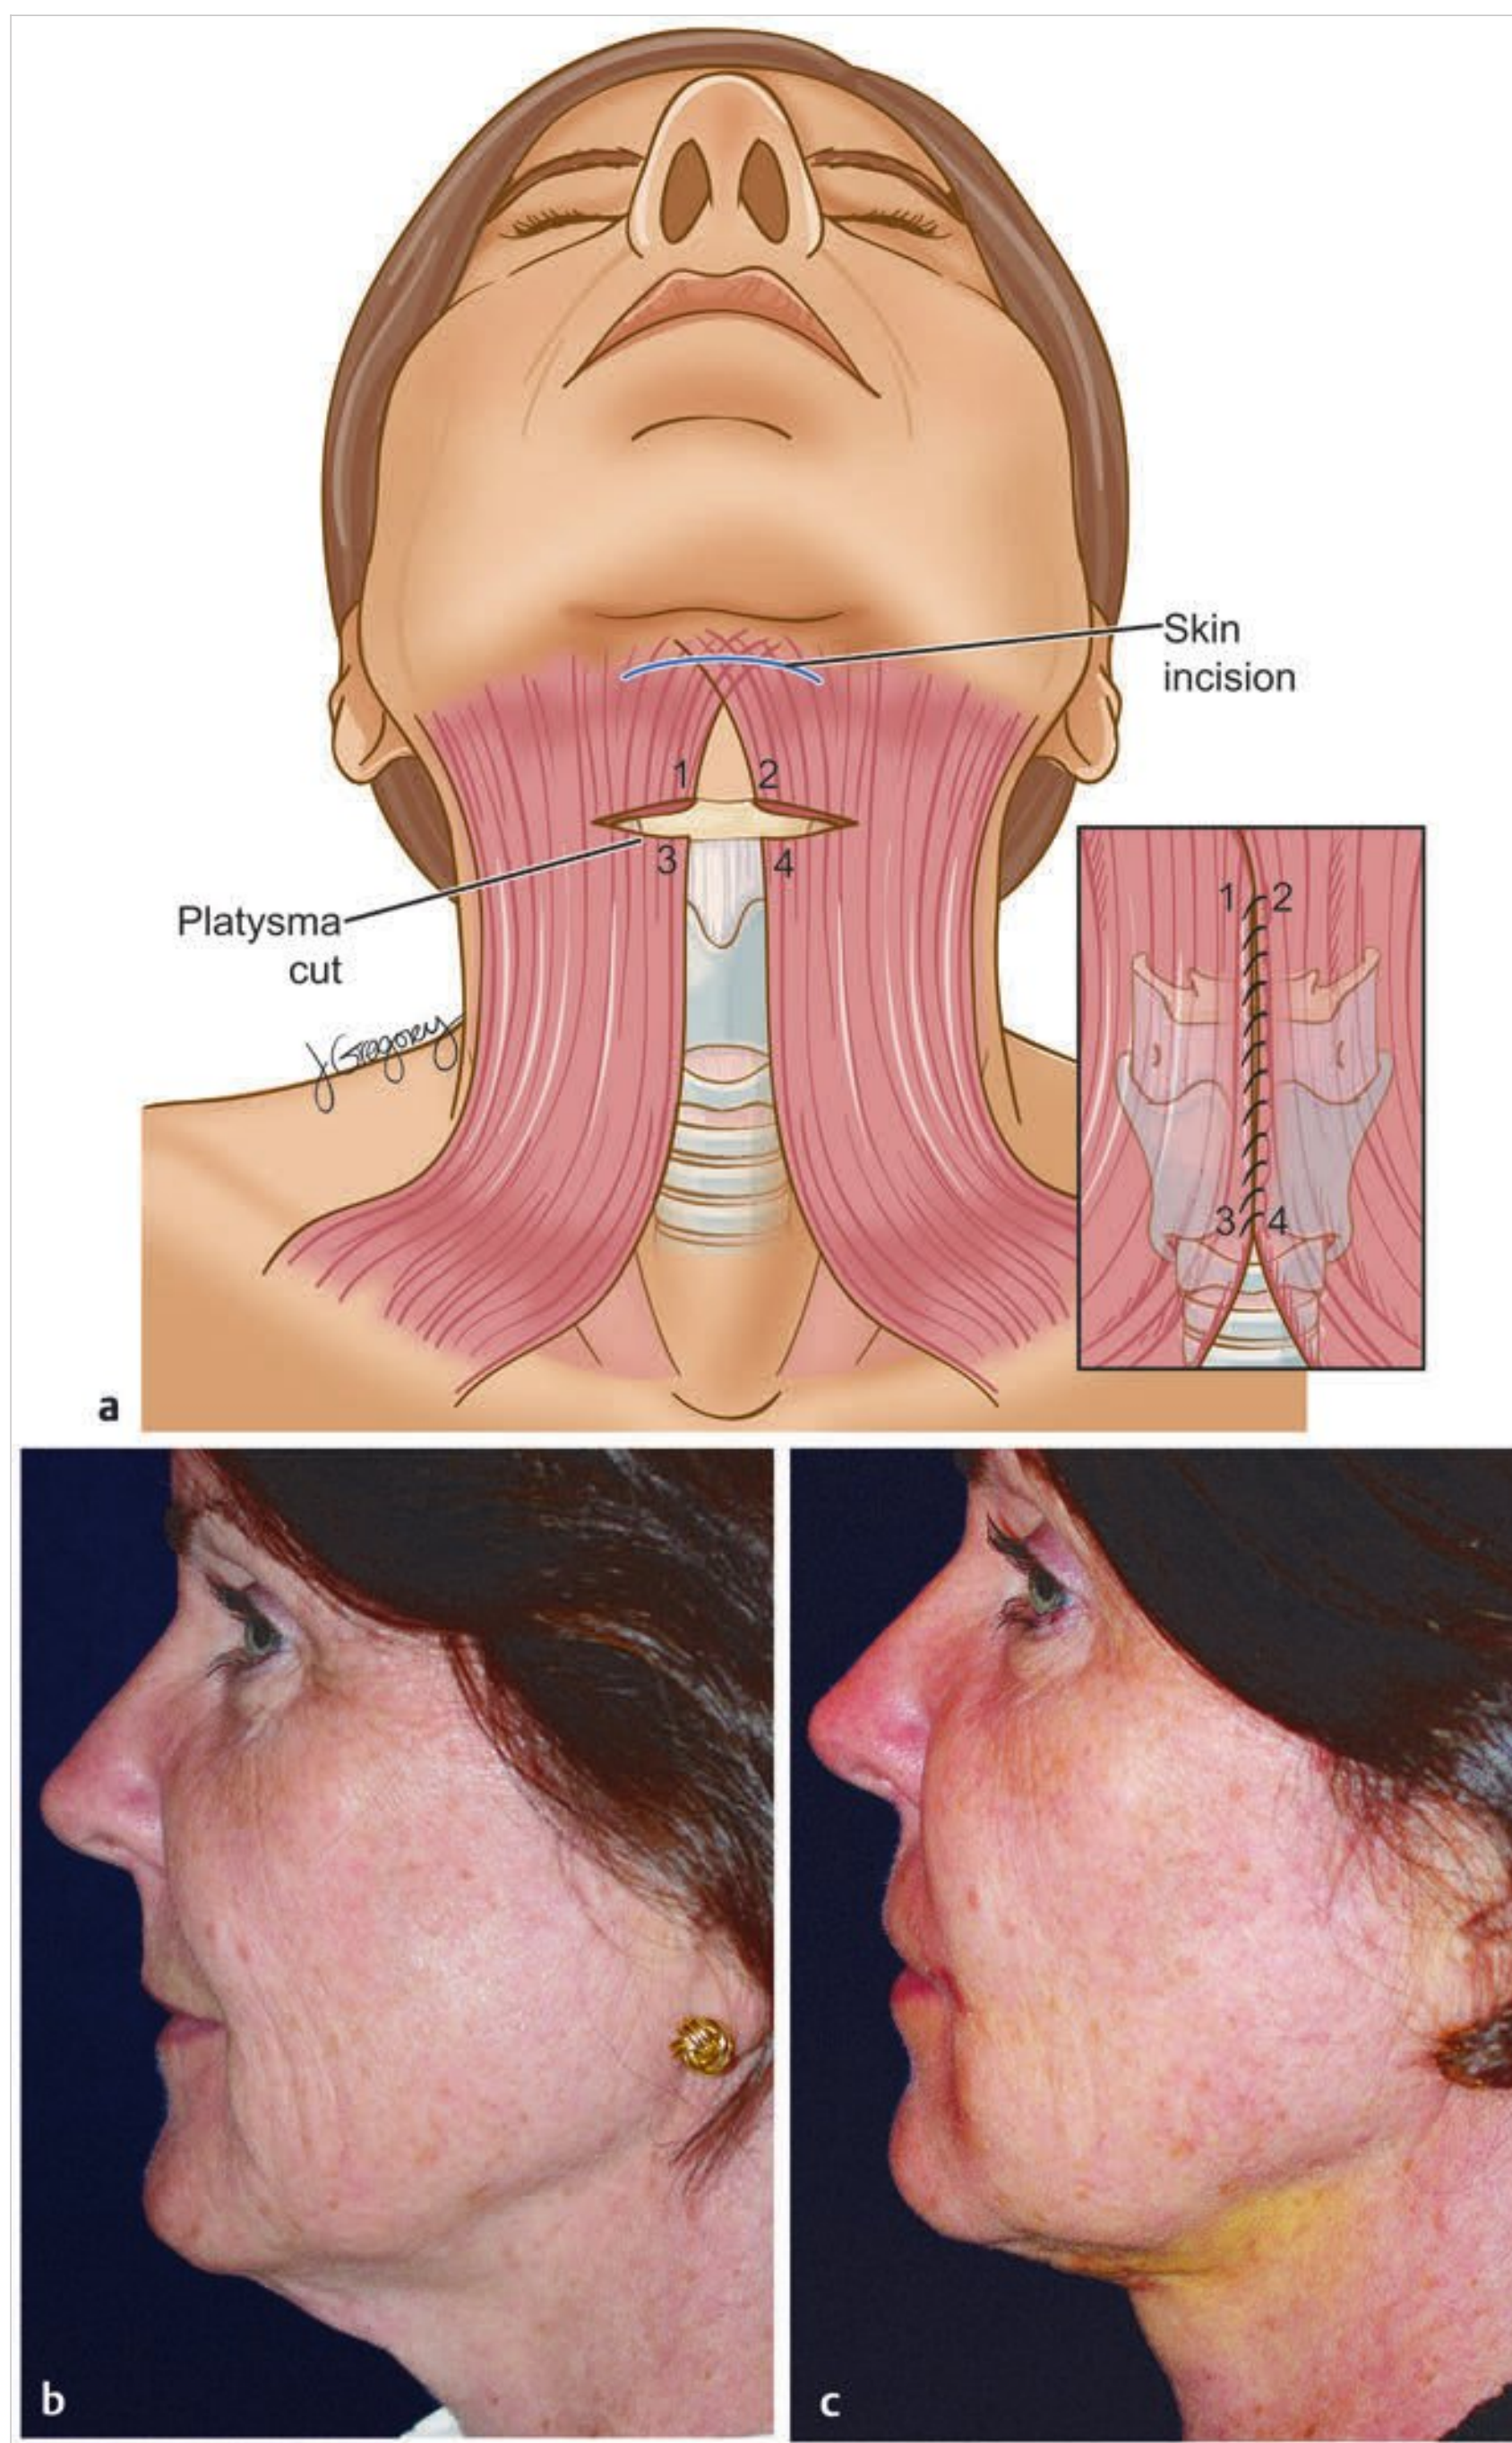

Fig. 56.7 (a) Platysmaplasty is performed through a submental incision and involves identification of the medial edges of the platysma and transverse platysmal transection at the level of the hyoid. The platysmal edges are sutured together. (b) Patient before platysmaplasty. (c) One week after platysmaplasty.

56.8.3 Infection (<0.2%)

Infection after a facelift or browlift is rare but is more common in patients with poorly controlled diabetes or on immunosuppressive therapy. Untreated hematomas provide an excellent environment for the development of infection, and they should be evacuated as soon as possible. Patients with small hematomas that are being observed for clot lysis before aspiration should be treated with prophylactic antibiotics selected to cover the predominant bacteria, staphylococci. Obvious abscesses should be drained and cultured.

56.8.4 Motor Nerve Injury (0.5–2.6%)

Motor nerve injury is uncommon; the nerve most commonly affected is the marginal mandibular nerve. This nerve loops down below the mandibular margin and then ascends again medially to innervate the depressor anguli oris muscle. Injury to this nerve will result in an inability of the patient to evert the lower lip when smiling. The nerve may be injured directly or during liposuction contouring of the lateral jawline. Injuries to the temporal branch of the facial nerve can occur during the superior dissection of a facelift or the temporal dissection of a forehead procedure. Injury is best avoided by remaining in the appropriate surgical plane: below the temporoparietal fascia

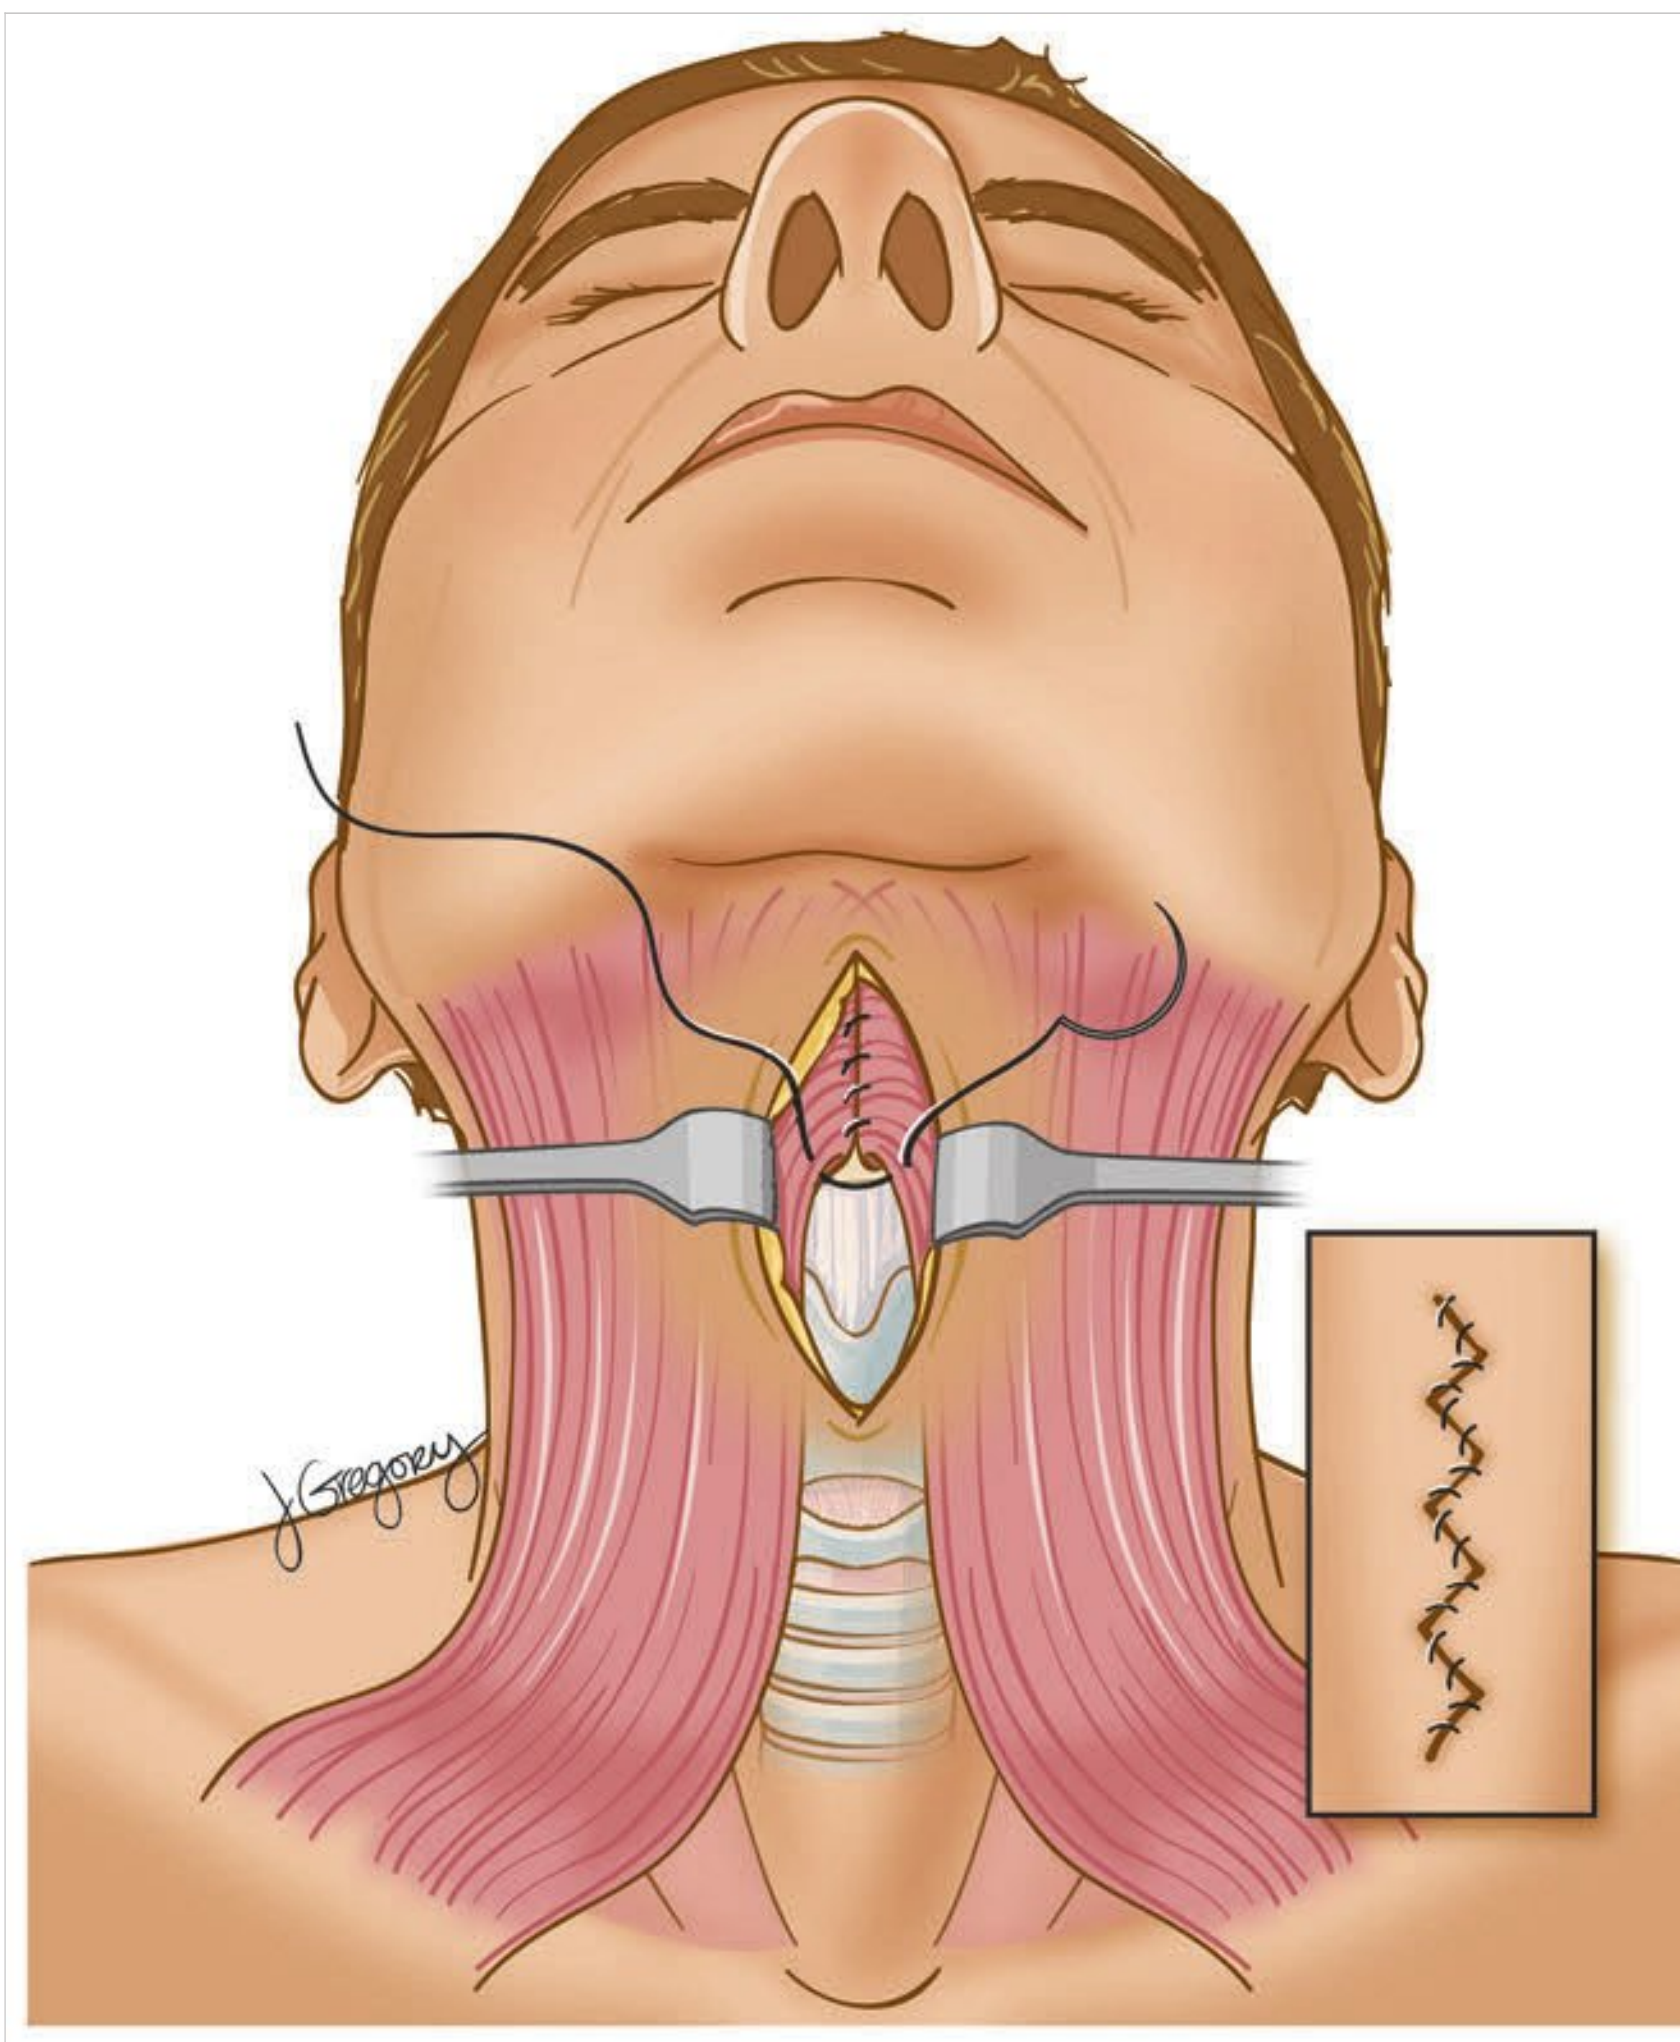

Fig. 56.8 Submental W-plasty involves direct skin excision, platysmal tightening, and W-plasty skin closure.

during dissection above the zygomatic arch and above the SMAS/temporoparietal fascia during the facelift dissection. The buccal branch of the facial nerve can be injured (□ Fig. 56.10) during anterior dissection in deep plane facelifts or during mid-facelifts. Even when the proper plane is maintained, these nerves may be injured by excessive traction, clamping, or cautery; hemostasis is best avoided because attempts to control bleeding may cause nerve injury.

If nerve transection is identified intraoperatively, tensionless microscopic neurorrhaphy with 7–0 nylon sutures should be performed and can be expected to maintain tone and some active (but diminished) muscular function. If paralysis is noted postoperatively, adequate time for the resolution of all anesthesia must be allowed before a motor nerve paralysis is diagnosed. If persistent, it is important to remember that most of these injuries are transient and related to blunt nerve trauma or traction, and they often recover spontaneously. The injuries should be observed serially, and electrical stimulation should be used for monitoring. Nerve exploration and neurorrhaphy are indicated for cases in which there is an absence of electrical activity. Supportive care, such as gold weight placement and ophthalmic lubricants, is provided as indicated.

56.8.5 Sensory Nerve Injury (7%)

The great auricular nerve is the most commonly injured nerve, with injury in up to 7% of cases. After emerging from the Erb point, the nerve runs deep to the platysma posterior to the external jugular vein, and it can be injured during inferior facelift dissection. Injury to this nerve will cause anesthesia of the earlobe and the inferior half of the auricle. Although total transection of either the supraorbital or supratrochlear nerve is uncommon during forehead procedures, focal areas of hypesthesia may be noted over the forehead and frontal scalp after endoscopic foreheadplasty. These are typically small (<1 cm) areas that may be permanent but generally become smaller over time.

56.8.6 Alopecia

Alopecia after surgery for an aging face can be a disconcerting but transient effect of shock to the hair follicles (telogen effluvium). Patients generally recover in 3 to 4 months. More problematic is permanent alopecia.

Alopecia after facelift may occur in 1 to 2% of patients. When hair-bearing skin is incised, the blade of the knife should be

Fig. 56.9 Early pretragal hematoma after facelift (arrows).

angled parallel to the angles of the hair shafts to avoid injury to the follicles. Flaps should be redraped, and continuity of the hairline should be restored when the flap is replaced and closed without excessive tension. Widened scars, even if properly positioned, will cause obvious alopecia. Small areas of postoperative alopecia may be treated with microfollicular hair grafts, whereas large areas may require excision and flap repair.

Alopecia after foreheadplasty depends upon the specific procedure. Most problematic is alopecia after a coronal foreheadplasty, and it is important to maintain the angle of the scalpel parallel to the hair follicles to avoid transecting hair roots and to preserve maximal postoperative hair density. Alopecia can occur around the incisions of an endoforeheadplasty; this was more common (6 to 10%) with the use of transcutaneous fixation screws, but the use of permanent bone-anchored devices has reduced the rate considerably (1 to 3%).

56.8.7 Poor Scarring

Scars that are too wide or hypertrophic will be obvious. They are more common in the postauricular area and are best prevented by a tensionless closure after SMAS support. Layered closure also reduces tension on the epidermal closure. Proper scar placement is essential for maximal camouflage (□ Fig. 56.11).

Fig. 56.10 Mild right upper lip weakness indicating buccal branch weakness.

Fig. 56.11 Treatment of hypertrophic scars after a facelift complicated by the poor placement of incisions.

Hypertrophic scars are treated with intralesional corticosteroid injections, which may be supplemented with the use of topical silicone gel sheeting. Widened scars, if the surrounding skin is lax, can be excised and the local skin advanced for closure. Inferior traction of the flap can distort the earlobe, pulling its insertion inferiorly and blunting its normally rounded shape. The risk for this pixie ear deformity, a telltale sign of facelift surgery, can be reduced by suturing the dermis of the inferior facelift flap superiorly to the conchal bowl perichondrium for support, as well as ensuring adequate SMAS support to the skin flap.

56.8.8 Skin Slough

Facelift surgery generates a large, medially based skin flap on each side of the face. The distal flap is located at the wound closure in the periauricular area, and this is the area of the flap with the most tenuous blood supply. Patients with compro-

Fig. 56.12 (a) Before and (b) after SMAS facelift.

mised vasculature are at increased risk for skin slough in these areas; the most common precipitating factor is tobacco use. Patients undergoing facelift surgery must stop all tobacco use at least 6 weeks in advance of the surgery to reduce the vasoconstrictor effects of nicotine; in cases in which the surgeon suspects that the patient has been smoking, a blood or urine test for cotinine, a nicotine metabolite, can be performed. Evidence of recent tobacco use is an indication to delay the surgery. Additionally, a hematoma or other fluid collection may impair revascularization of the flap and lead to flap necrosis. In patients in whom impaired vascularity of the flap is suspected, a deep plane facelift should be strongly considered because the flap is more robust. The treatment of a skin slough is conservative, with expectant wound care and judicious débridement. Healed areas of skin slough are more likely to develop a hypertrophic scar. After full healing of the skin slough, the surgeon should consider revision of the scars.

56.9 Prognosis

The longevity of an aesthetic facial procedure depends not only upon the specific procedure and expertise of the surgeon but

also upon the patient's ability to heal, skin care, lifestyle (e.g., smoking), and state of skin aging.

Forehead procedures maintain their effect over a longer period of time if the brow depressor muscles (corrugator supercilii, depressor supercilii, procerus, and orbital portion of the orbicularis oculi) are neutralized (e.g., by transection or the continued use of botulinum toxin A). However, brow procedures rarely “need” to be repeated because most of the cosmetic benefit is maintained over time.

Midfacial procedures performed subperiosteally rely on adherence of the periosteum to bone, a dense bond that stretches little and so maintains midface elevation. However, atrophy of the midfacial fat may prompt additional treatment (autologous fat transfer or injection of fillers) of the area to maintain an appropriate proportion of midfacial volume.

Facelift procedures, which rely on soft tissue–soft tissue adhesion, do have a limited “lifespan” because this scar tissue will soften and stretch over time. As a rule of thumb, deeper procedures “last” longer than those performed more superficially. The benefits of a subcutaneous facelift may be lost after a year or two, whereas an SMAS procedure may not need to be revised for 7 to 10 years in younger patients or for 5 to 7 years in older patients (□ Fig. 56.12).

56.10 Roundsmanship

- In forehead rejuvenation procedures in general, greater elevation is required the more distal the point of fixation is from the brow.
- Modern facelift procedures rely on the SMAS to maintain elevation.
- The most commonly injured nerve during a facelift is the great auricular nerve; the most commonly injured motor nerves are the marginal mandibular and temporal branches of the facial nerve.
- The temporal branch of the facial nerve runs within the temporoparietal fascia; maintaining dissection below this fascia protects the nerve from injury.

- Brow elevation during endoscopic browlift depends on adequate myotomies of the muscles that depress the eyebrows.

57 Blepharoplasty

YuShan L. Wilson and Grigorly Mashkevich

57.1 Introduction

The eyes are often the focus of attention of many patients seeking facial rejuvenation. Periorcular aging manifests as a combination of brow descent, excess skin formation in the upper and lower lids, and orbital fat herniation. These processes are influenced by both heredity and age. Blepharoplasty is an operation designed to reduce redundant skin and fat in the aged periorcular region. This surgery is most often performed for cosmetic reasons, but it can also correct functional deficits associated with reduced visual fields.

57.2 Incidence of Disease

Periorbital aging affects all individuals starting in their late twenties and early thirties. Blepharoplasty is one of the most frequently requested aesthetic facial procedures.

57.3 Terminology

Dermatochalasis is an acquired condition of excessive eyelid skin laxity that is related to genetic predisposition, natural aging, and environmental factors. Dermatochalasis is accompanied frequently by prolapsed orbital fat (□ Fig. 57.1). Steatoblepharon denotes the prolapse of orbital fat through either true herniation or pseudoherniation from behind a weakened orbital septum. Aesthetically, this manifests as fullness of the eyelids, or “bags.” Blepharochalasis is a disorder of the upper eyelids characterized by recurrent attacks of unilateral or bilateral lid edema, ultimately resulting in loss of skin elasticity and atrophic changes. Mainly young or middle-aged women are affected. Festoons are redundant folds of the orbicularis oculi

muscle in the lower lid that drape onto themselves, creating a hammock-like baggy appearance. Malar bags are soft-tissue prominences on the lateral edge of the infraorbital ridge and zygomatic prominence. They typically remain stable with facial animation but may worsen during smiling.

57.4 Applied Anatomy

The eyelids are composed of an outer and an inner lamella (□ Fig. 57.2). The outer lamella consists of the skin and orbicularis oculi muscle, while the inner lamella includes the tarsus and conjunctiva (often, the orbital septum and tarsus are considered a middle lamella). The upper eyelid extends superiorly to the eyebrow, while the lower lid extends below the inferior orbital rim to join the cheek. The skin of the eyelids is the thinnest in the body, often less than 1 mm in thickness. The upper eyelid skin crease (superior palpebral sulcus) is formed by the insertion of the levator muscle aponeurotic fibers into the skin (8 to 9 mm in men and 9 to 11 mm in women).

In the midpupillary line, the upper lid margin should be situated more than 2 mm above the light reflex in the pupil, with smaller distances denoting upper lid ptosis. This distance is also referred to as margin reflex distance. The lower eyelid margin should rest at the level of the lower limbus.

The tarsus is composed of thick fibrous tissue and is present in both the upper and lower eyelids. It provides integrity and stability to the eyelids and contains sebaceous meibomian glands. The tarsus is an important landmark in eyelid surgery because incisions are often marked in comparison to its position.

The levator palpebrae superioris muscle is the major elevator of the upper eyelid. It originates from the superior orbital apex

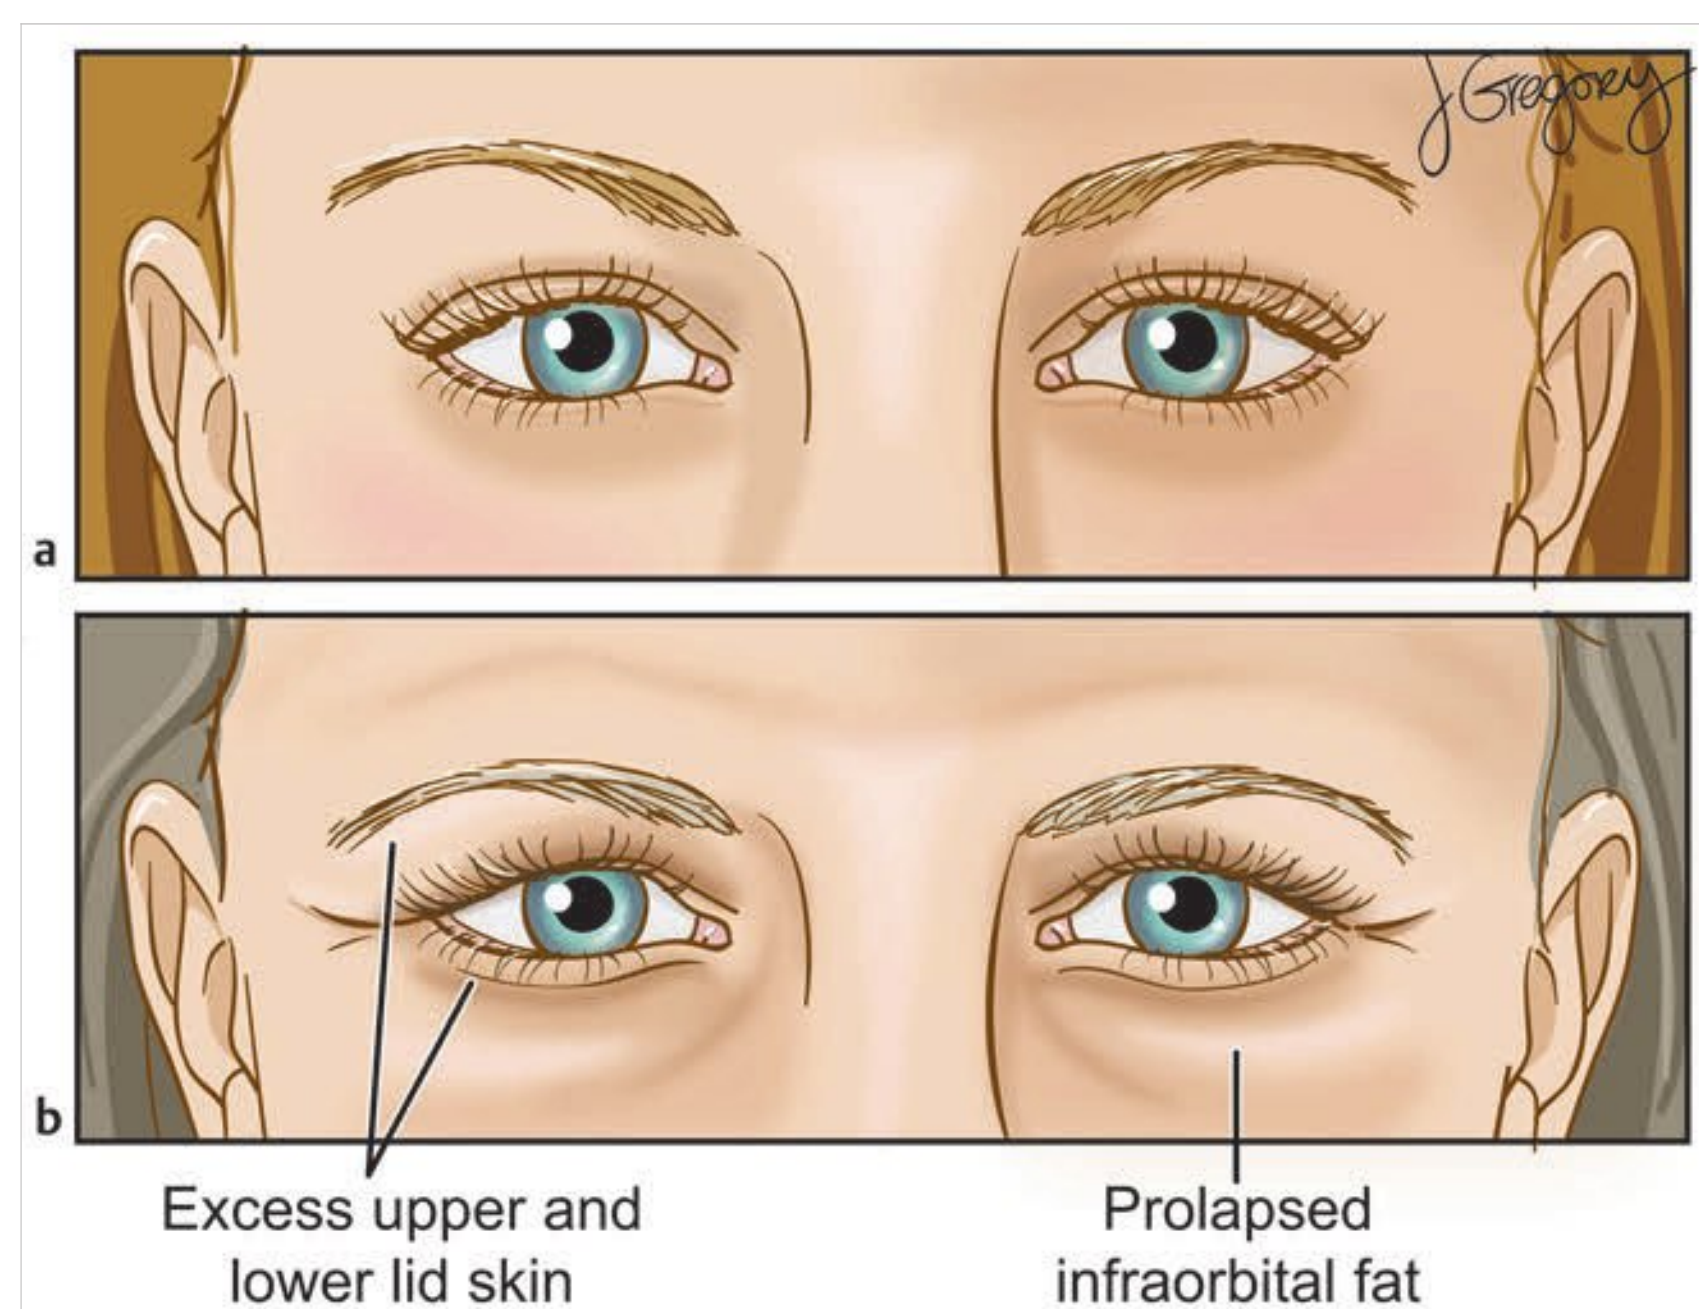

Fig. 57.1 (a,b) Aging-related changes in the periorbital region.

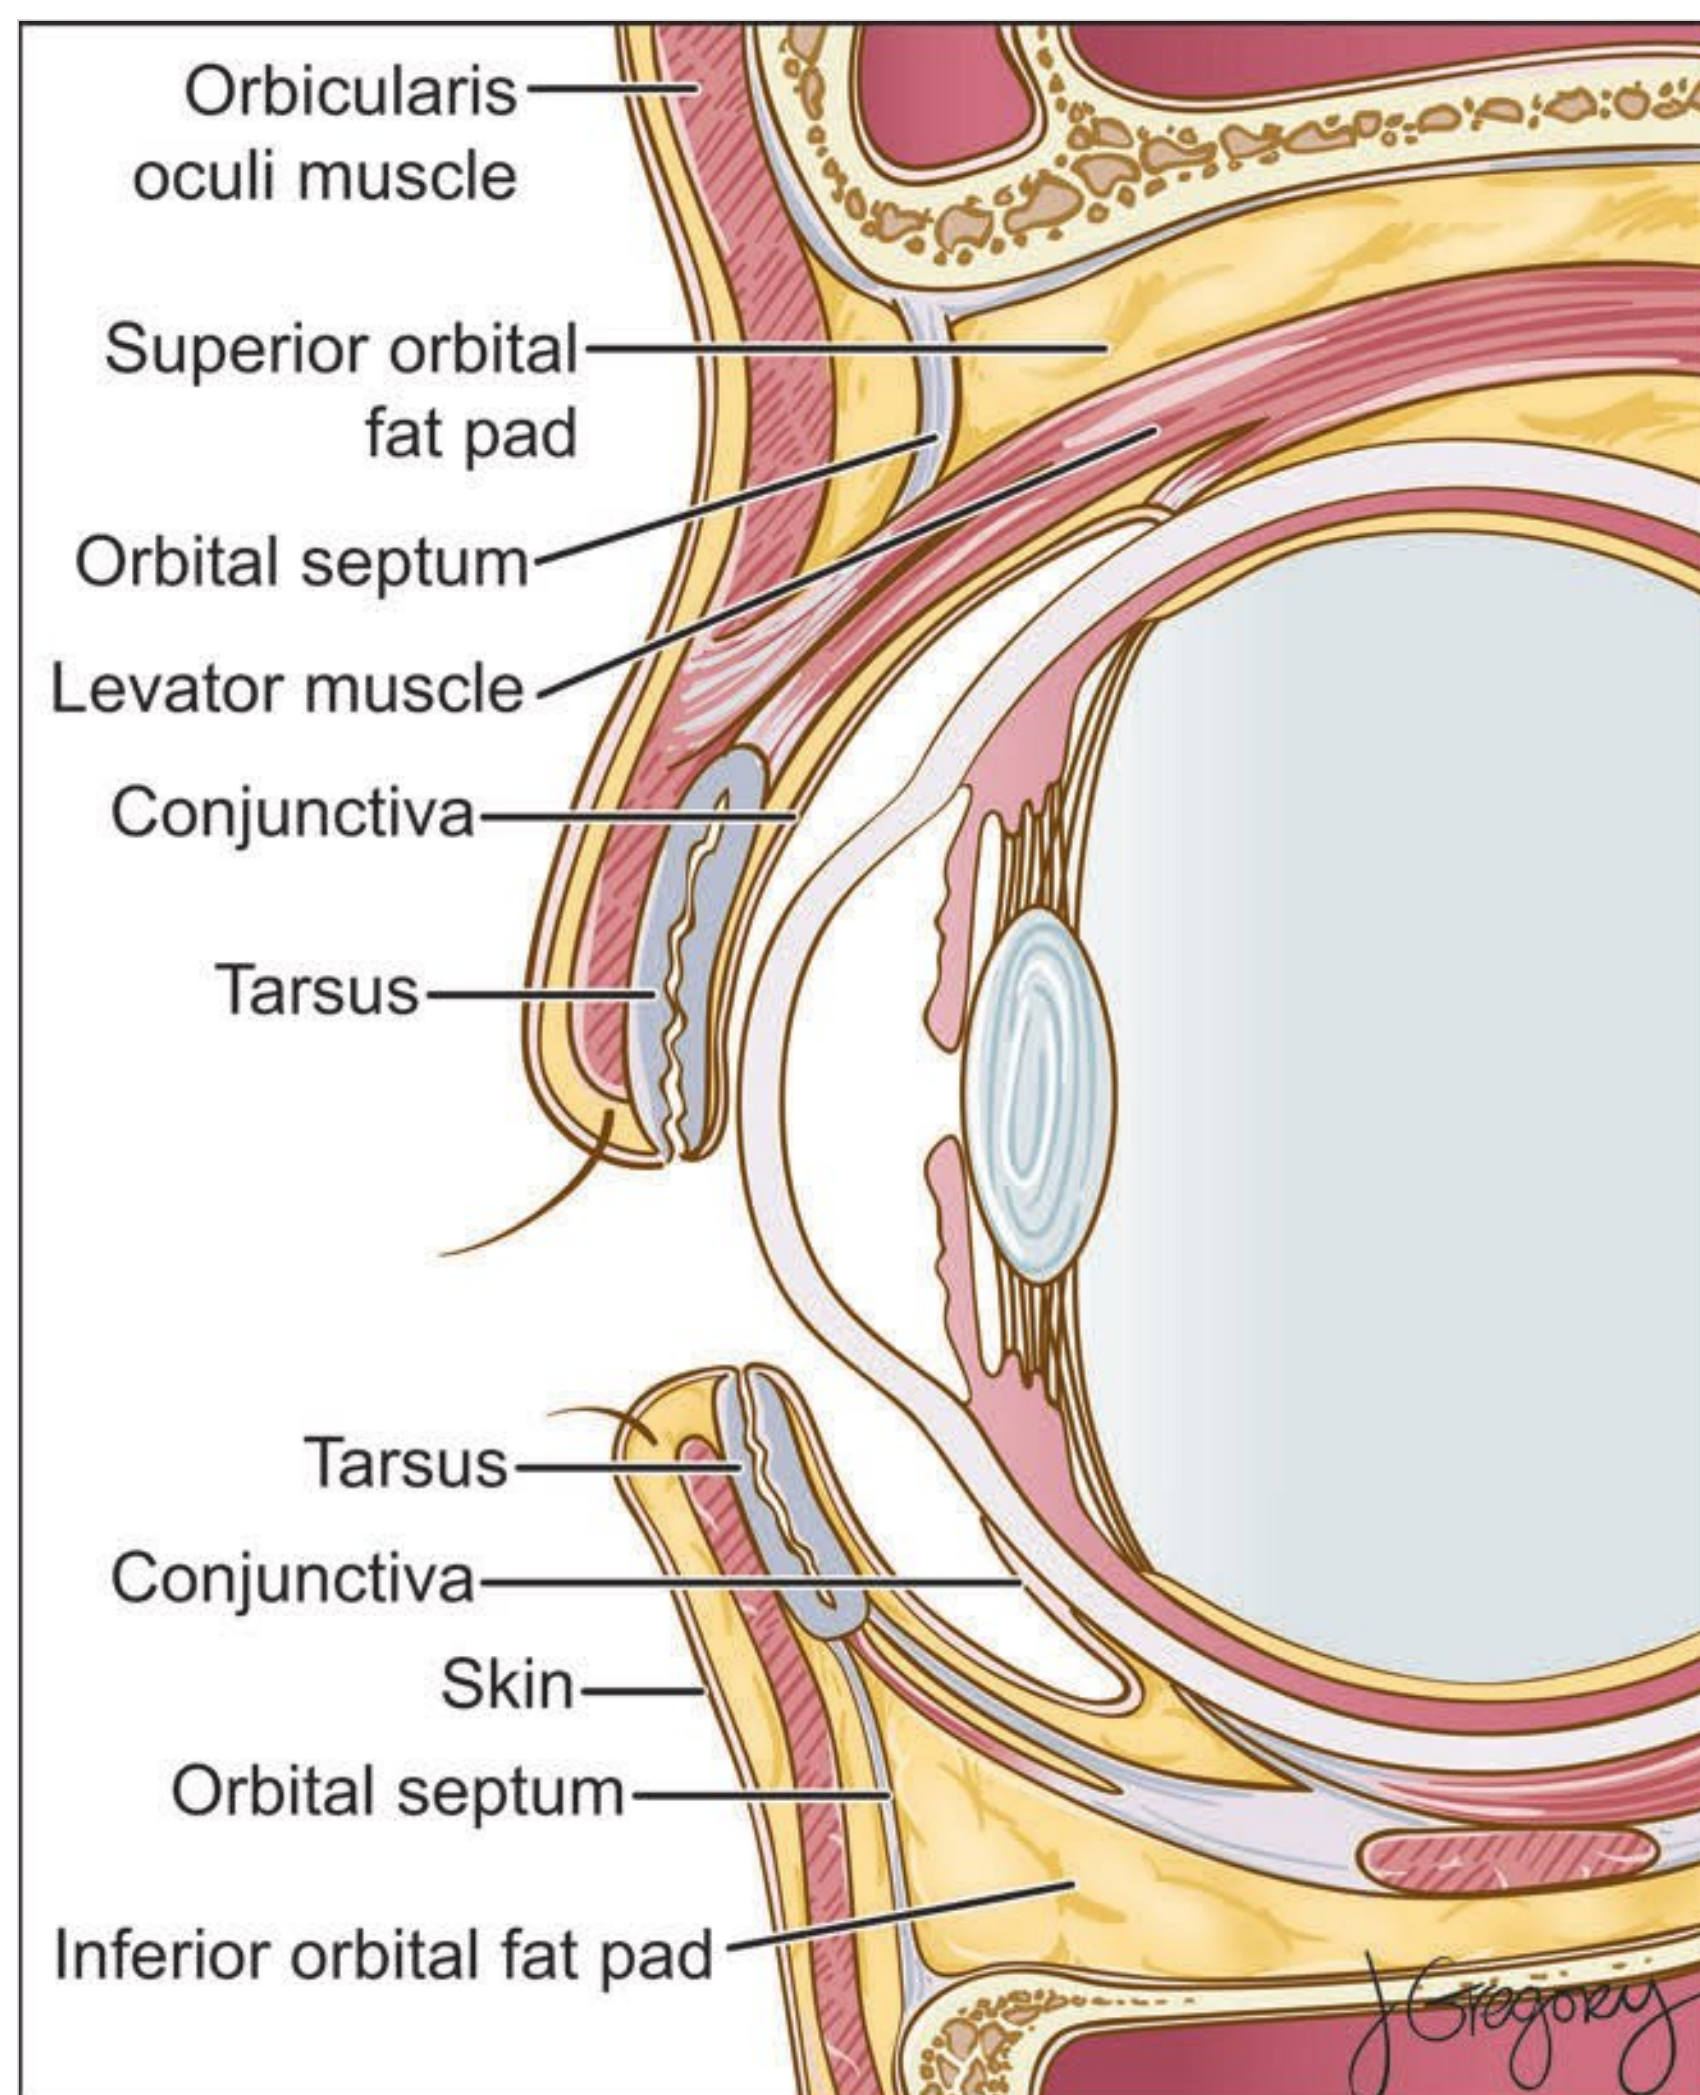

Fig. 57.2 Cross-sectional eyelid and orbital anatomy.

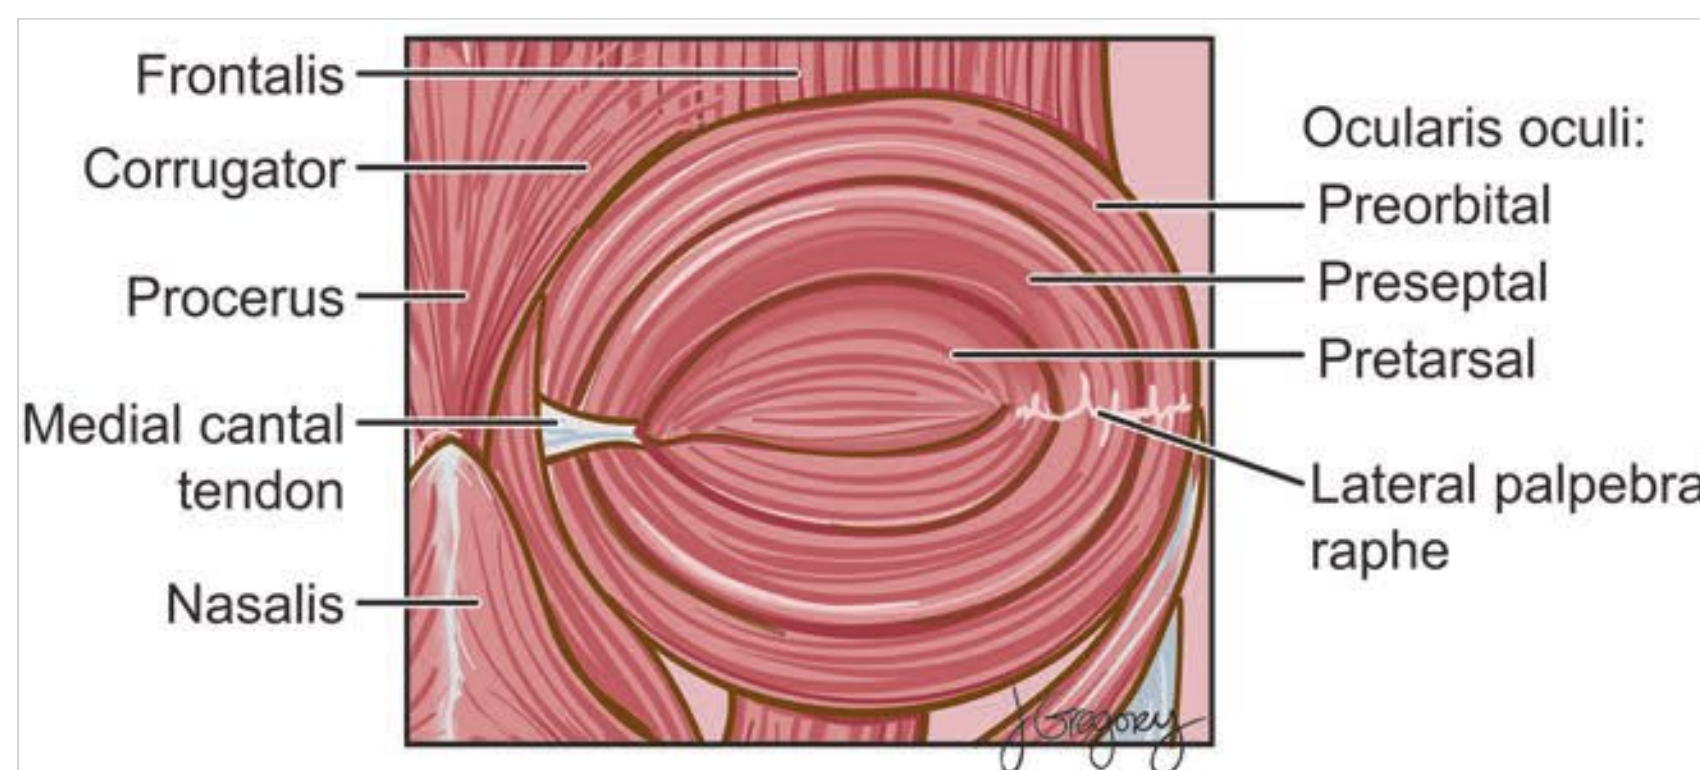

Fig. 57.3 Periorbital musculature.

and inserts into the upper lid. This attachment results in the superior eyelid crease that is a nearly ubiquitous feature in Caucasian eyelids.

The orbicularis oculi muscle is one of the muscles of facial expression, innervated by the temporal and zygomatic branches of the facial nerve. These branches are orientated horizontally and innervate the muscle from its undersurface. The muscle (□ Fig. 57.3) is composed of orbital and palpebral segments, with the latter further subdivided into preseptal and pretarsal

components. The palpebral segment is primarily responsible for blinking and voluntary winking, while the orbital segment generates forced closure. Medially, muscle heads of the pretarsal orbicularis unify to form the medial canthal tendon, which inserts into the anterior lacrimal crest. Laterally, these muscle fibers condense to become the lateral canthal tendon, which attaches to the Whitnall tubercle.

Immediately beneath the surface of the preseptal orbicularis lies the orbital septum. The orbital septum is a connective

tissue structure that attaches peripherally to the periosteum of the orbit at the arcus marginalis. It serves as a boundary retaining the orbital contents. There are two upper eyelid fat pads—medial and central—with the lateral compartment occupied by the lacrimal gland. The lower eyelid fat pads are divided into medial, central, and lateral compartments. The inferior oblique muscle separates the medial and central fat compartments.

The Asian eyelid has distinct anatomical differences from the Caucasian eyelid. In the Asian upper eyelid, the lower insertion point of the levator aponeurosis leads to a smaller or absent upper lid fold. An upper eyelid skin crease is absent in approximately 50% of Asian persons. This variant is viewed as less desirable in the Asian culture because of the appearance of a heavier eyelid. Absence of the crease is often associated with medial epicanthal hooding.

57.5 The Disease Process

57.5.1 Etiology

The upper eyelid is one of the first facial features to exhibit signs of aging, typically starting in the late twenties. A combination of genetic predisposition and environmental influences contributes to this process, which results in eyelid skin laxity, weakening of the orbital septum, and fat atrophy and herniation.

57.5.2 Natural History and Progression

The youthful eyelid is smooth and free of rhytids or redundant folds. The lateral orbital rim is free of skin draping or hooding. The lower eyelid exhibits a smooth gentle convexity and blends seamlessly into the skin of the upper cheek. With aging, excessive skin forms in the upper and lower lids. The orbital septum weakens, allowing variable amounts of orbital fat to bulge. With the descent of the malar fat pad and sagging of the orbicularis oculi muscle, the bony outline of the infraorbital rim becomes more prominent. These changes give rise to a fatigued and aged periocular appearance.

57.5.3 Potential Disease Complications

Advanced dermatochalasis may result in superior and lateral visual field disturbances, secondary to obstruction by redundant upper eyelid skin.

57.5.4 Disease Grading

There is no formalized disease grading system for dermatochalasis and steatoblepharon. Emphasis is placed on description of the deformity and photographic evaluation of the aging-related changes.

57.6 Medical Evaluation

57.6.1 Presenting Complaints

As with any aesthetic procedure, it is imperative to establish a reasonable and rational motivation for the treatment. Patients

who request eyelid surgery with the goal of attaining a more youthful appearance are good candidates. The most common complaint voiced by patients is a tired appearance. Patients with significant dermatochalasis may complain of difficulty seeing, especially when looking up.

57.6.2 Clinical Findings, Physical Examination, Testing

Medical conditions that would contraindicate any facial rejuvenation surgery should be elicited. Medications, vitamins, and herbal supplements that might interfere with clotting must be identified. These need to be discontinued at least 7 days before any planned eyelid procedure. A thorough ophthalmologic history, with attention to vision, dry eye, and recurrent ocular infections such as conjunctivitis, styes, chalazia, and herpes, must be obtained.

Eyelid evaluation begins with a general examination of the skin type—dry or oily, thin or thick. Any preexisting asymmetries or concomitant brow ptosis should be noted and discussed with the patient. Brow elevation surgery may be necessary to achieve the optimal cosmetic outcome.

Upper lid redundancy is best evaluated with the patient's eyes closed. The skin may be grasped with forceps in a medial to lateral direction to estimate the amount of skin that can be resected safely. Medial and central fat pseudoherniation can be evaluated while gentle pressure is applied to the globe. Excessive lateral fullness should alert the examiner to the possibility of a ptotic lacrimal gland.

Testing the lower lid tone determines the vulnerability of this structure to postoperative malposition. Tone may be assessed with the “snap” test (□ Fig. 57.4), during which the lower lid is grasped gently between the thumb and forefinger, pulled away from the globe, and released. A normal lid will “snap” back to

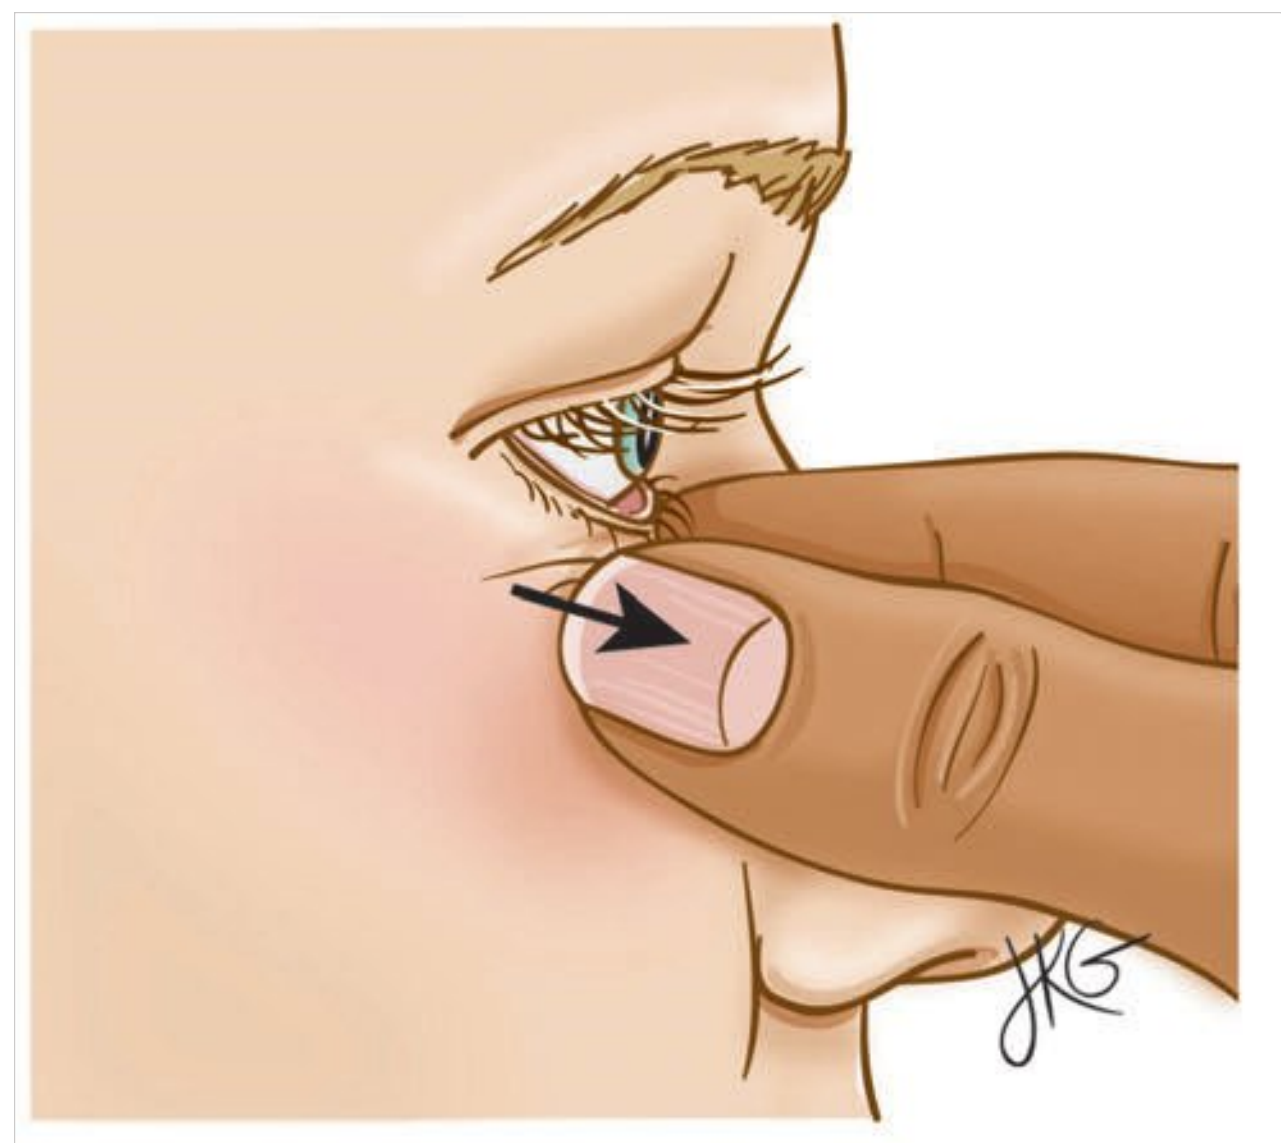

Fig. 57.4 The lower lid skin is grasped between the thumb and forefinger and pulled away from the globe. The time and ease with which the lid returns to its normal position indicate the lower lid tone.

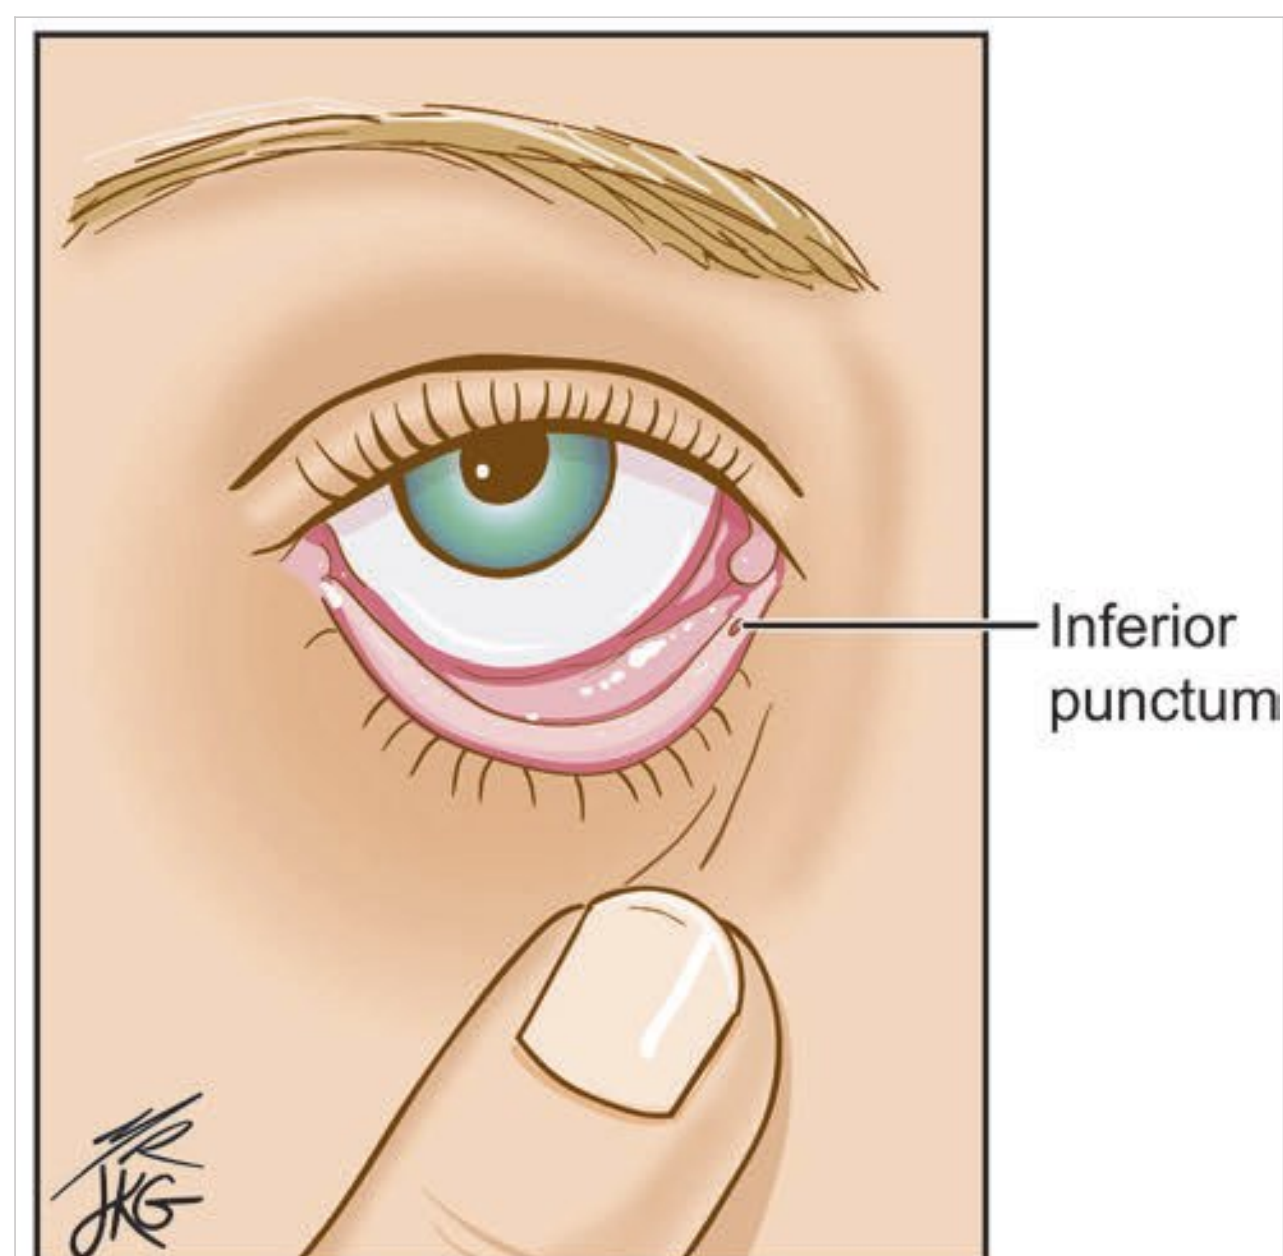

Fig. 57.5 Lower lid laxity can be assessed by distracting the lid inferiorly and allowing it to recoil.

contact the globe like a spring. Slower returns indicate a poor lid tone. Similarly, a lid distraction test (□ Fig. 57.5) can be performed, in which the lid is pulled inferiorly; the return of the lid to its normal position should be brisk. The worst response is failure of the eyelid to return until the patient blinks.

Pseudoherniation of fat in the lower lid can be ascertained by having the patient gaze upward and then to the right and left. Grasping the skin with forceps while the patient is looking upward identifies the amount of lower lid laxity.

The Schirmer test, which determines the level of tear production, is obtained in all patients interested in blepharoplasty. This test is performed by placing a strip of filter paper in the conjunctival sac of the lower eyelid for 5 minutes. The wet portion of the paper is then measured. Values above 15 mm denote a normal level, whereas readings below 5 mm indicate severe dryness. Blepharoplasty is relatively contraindicated in patients with severe dryness because such a procedure may precipitate a dry eye syndrome (persistent ocular pain and discomfort, with the potential for corneal ulceration). For patients in the intermediate category (5 to 15 mm), correlation of the Schirmer test result with the potential development of eye dryness after surgery is less clear. In this group, conservative skin excision may be undertaken.

57.6.3 Photography

As with all aesthetic surgery, preoperative photographic documentation is essential. Close-up 1:5 ratio photographs should include the following: frontal views with the eyes open, gazing upward, and closed; oblique and lateral views with the eyes open. These close-up photographs should include the eyebrow superiorly and the nasal ala inferiorly. A 1:10 full-face view is also appropriate. Pictures should be taken in good lightning without flash because flash photography may wash out finer details.

Fig. 57.6 The lower limb of the upper blepharoplasty incision runs in the supratarsal crease, while the upper limb is determined by the amount of redundant skin.

57.6.4 Differential Diagnosis

Upper eyelid ptosis may present concomitantly with dermatochalasis. This eyelid rim malpositioning cannot be treated with an upper lid blepharoplasty. Depending on the etiology, appropriate ptosis repair should precede blepharoplasty surgery.

57.7 Treatment

57.7.1 Medical Treatment

Although a multitude of facial rejuvenation products are available on the market, a discussion of their proposed mechanisms and efficacy is beyond the scope of this chapter. In general, superficial rhytids respond well to chemical peels and laser resurfacing, whereas redundant skin and prolapsed fat are best managed by surgical means.

57.7.2 Surgical Treatment

Blepharoplasty can be performed safely as an outpatient procedure with local anesthesia and with or without intravenous sedation. The procedure begins with marking of the eyelids. All makeup is removed, and the skin is cleansed with alcohol to remove natural skin oils. With the patient in the supine position, the brow is gently pushed toward the orbital rim to counteract the effect of gravity. The upper lid skin is then gently grasped with forceps, with one blade at the superior lid crease and the other grabbing just enough redundant skin to smooth the lid. The upper medial incision should not pass more medially than the nasal-orbital junction. Laterally, it is extended into a natural crease between the orbital rim and eyelid. Medially and laterally, the sinuously shaped markings join at 30-degree angles (□ Fig. 57.6). A 30-gauge needle is used to infiltrate 1 to 2 mL of 1% lidocaine with 1:100,000 epinephrine, buffered with 8.4% sodium bicarbonate, subcutaneously. At least 10 minutes is allowed to pass for maximal anesthesia and vasoconstriction. Following the incisions, the redundant skin is removed sharply

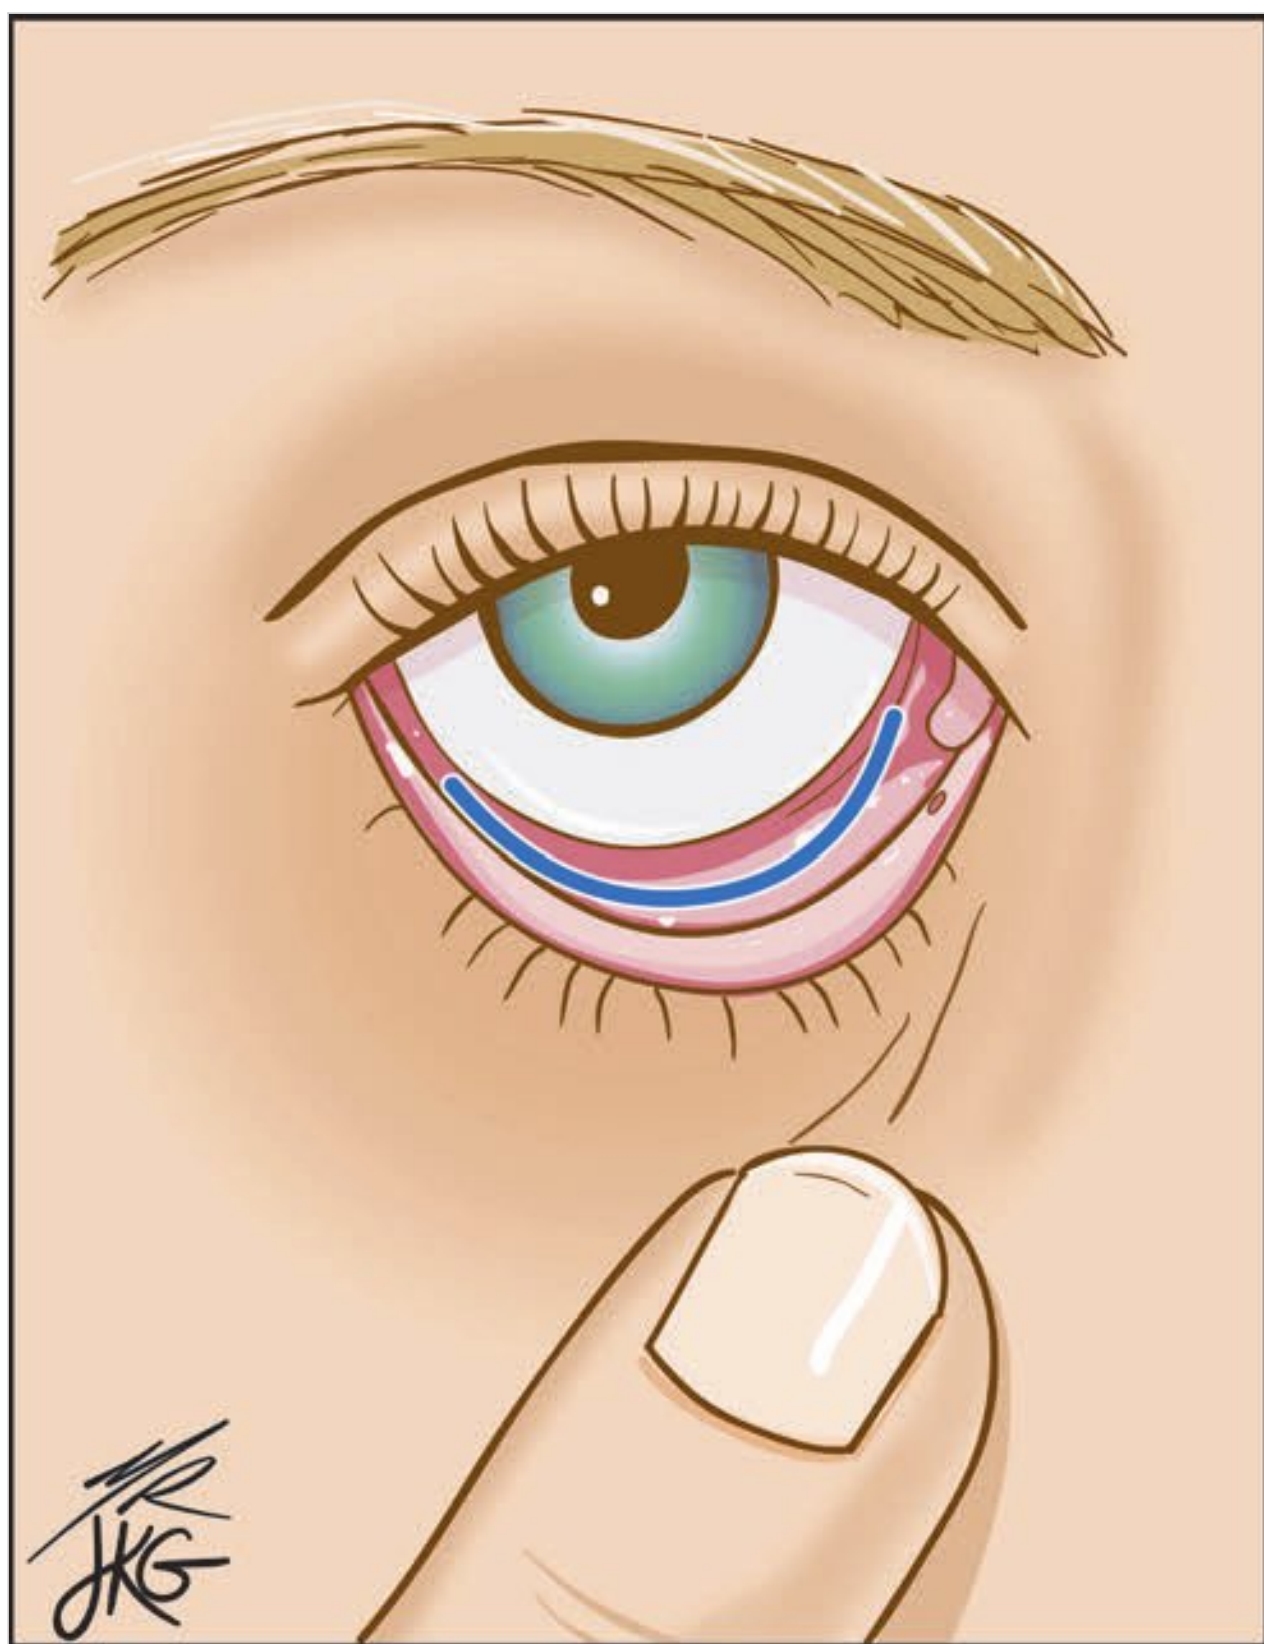

Fig. 57.7 The transconjunctival lower blepharoplasty incision is placed just below the lower border of the tarsus, dividing the capsulopalpebral fascia and lower lid retractors and allowing exposure of the orbital septum.

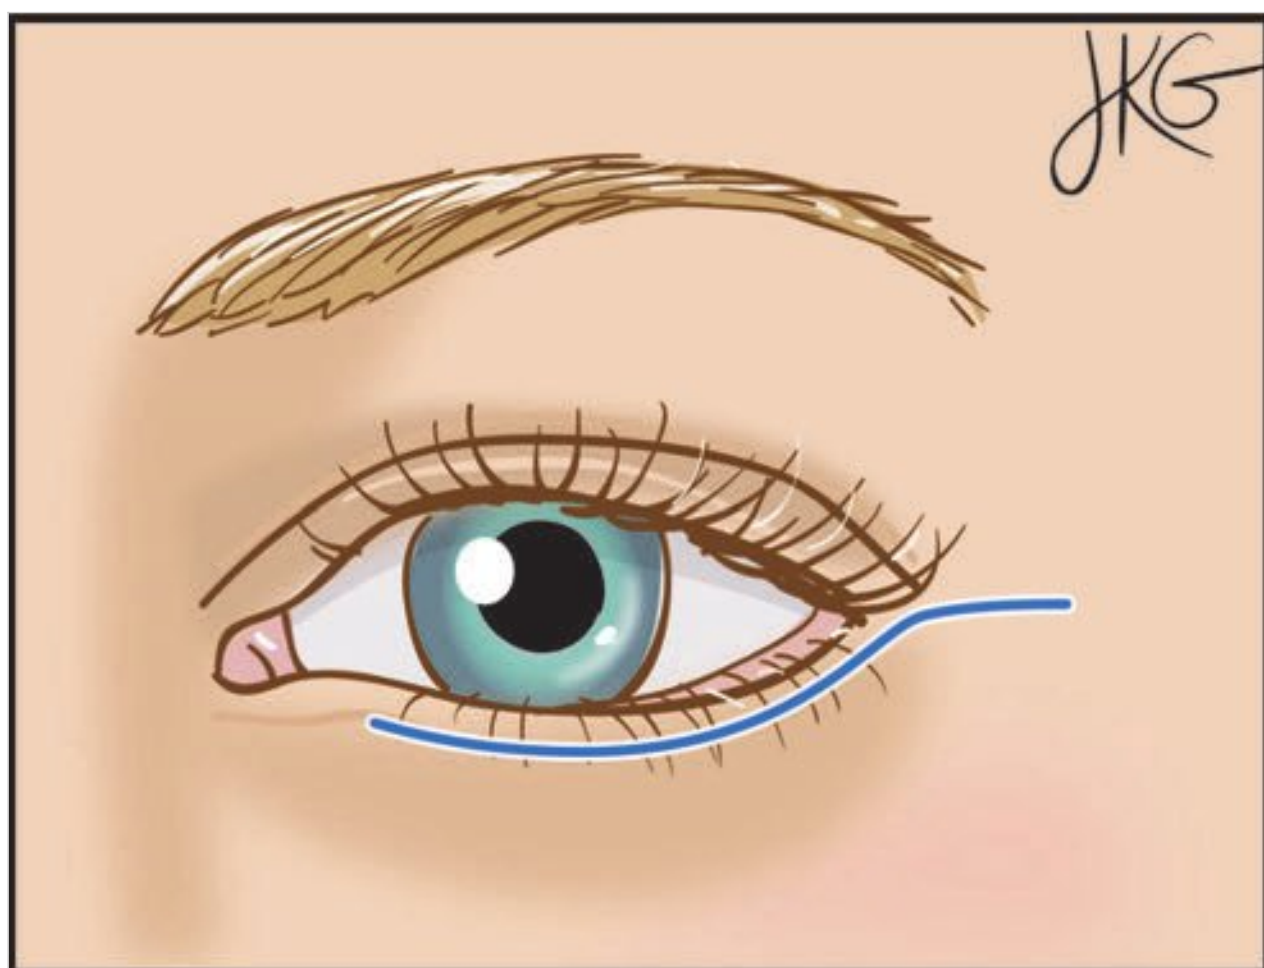

Fig. 57.9 Transcutaneous lower blepharoplasty with a subciliary incision.

with Stevens scissors. The lateral aspect of the orbicularis can be trimmed for additional debulking and to induce lateral brow elevation. The excision exposes the orbital septum.

Redundant pseudoherniated fat is trimmed conservatively through buttonhole incisions in the orbital septum. Excessive fat removal may result in retraction of the lid and a pronounced

overhang of the orbital rim, thereby producing the effect of an aged appearance. Each excised segment of fat is set aside so that a comparable amount can be removed from the contralateral eyelid.

Meticulous hemostasis before closure significantly reduces the risk for postoperative bleeding. Wound closure begins at the lateral edge of the incision, which is the area of greatest tension. This part of the incision is reapproximated with several interrupted mattress sutures. The rest of the wound is closed in a subcuticular fashion with a 6–0 nonabsorbable monofilament suture.

Lower lid blepharoplasty can be performed via either of two surgical approaches: (1) transconjunctival (see □ Fig. 57.2; □ Fig. 57.7 and □ Fig. 57.8) or (2) transcutaneous with a skin–muscle flap (□ Fig. 57.9 and □ Fig. 57.10). The transconjunctival approach avoids an external scar and carries a lower incidence

of ectropion. For the transconjunctival approach, the conjunctiva and cornea are first anesthetized with 0.5% tetracaine hydrochloride ophthalmic solution. Subconjunctival injection with local anesthetic solution follows. Corneal protectors are placed to protect the eye from injury. A Desmarres retractor is then introduced to retract the lower lid margin, and an incision is made 3 to 4 mm below the tarsus. A preseptal plane is identified and developed via blunt dissection with cotton-tipped applicators. Fat pads are visualized while gentle pressure is applied to the globe. As with the upper eyelids, care should be taken to avoid aggressive fat removal because this may result in a hollow, or skeletonized, appearance. For patients with a tear trough deformity, repositioning and suturing of the orbital fat can also be performed through this exposure. The transconjunctival incision is approximated with several 6–0 fast-absorbing gut sutures. External skin redundancy can be addressed with a “pinch excision.” One to three millimeters of redundant skin inferior to the ciliary margin is pinched with forceps and sharply excised with Iris scissors. The orbicularis muscle is not excised during this maneuver.

During a transcutaneous approach, a subciliary incision is made parallel and approximately 2 to 3 mm below the palpebral margin. A skin–muscle flap is then lifted to expose and incise the orbital septum. Depending on the individual needs, all three fat pads can be addressed in a similar manner as during the transconjunctival approach. The inferior oblique muscle, which separates the medial and central fat compartments, is identified to help prevent inadvertent injury. Following fat excision, any redundant skin is trimmed conservatively. If surgery is performed with the patient under conscious sedation or local anesthesia, asking the patient to gently open the mouth while gazing upward helps prevent cutaneous overresection. Lower lid support is reestablished by placing a vertical suspension suture in the lateral aspect of the orbicularis muscle, tied to the lateral orbital rim periosteum at the region of the lateral orbital tubercle.

57.7.3 Postoperative Care

Wounds are left uncovered and are lubricated with an antibiotic ophthalmic ointment. During the first two postoperative days, cold compresses are placed at hourly intervals for 20 minutes while the patient is awake. Acetaminophen with or without codeine is often sufficient to relieve discomfort. Patients are instructed to avoid any medications that can produce vasodilation (including alcohol) or increase the risk for bleeding, such as aspirin-containing products and nonsteroidal anti-inflammatory drugs. In addition to analgesics, antibiotic eye drops and lubricants are given. Sutures are removed on the fifth postoperative day, at which point makeup can be applied to the lid skin. Contact lenses may also be used at this time. Most patients are able to return to their normal level of activity by the seventh postoperative day. Light exercise can start 2 weeks after surgery, with full exercise resumed at 6 weeks.

57.7.4 Complications

Fortunately, serious complications of blepharoplasty are uncommon; however, several lesser complications and minor sequelae may occur following this procedure. The eye can sustain

injury at any time during an eyelid procedure. Trauma from excessive pressure, cautery, or ill-positioned sutures can occur. The transconjunctival approach carries a greater risk for corneal abrasion. These injuries are extremely painful and can lead to ulcers. Abrasions are treated conservatively with ophthalmic drops or ointment, with ophthalmologic consultation. Postoperative problems that generally resolve after the second postoperative week include eyelid ecchymosis, tearing, contact lens difficulty, contact dermatitis, and a sensation of tightness. Long-dormant chalazia may be reactivated in the first few weeks following surgery. This relatively painless swelling is localized to the upper lid margin and is best treated with warm compresses and antibiotics.

Orbital hematoma after blepharoplasty remains rare. When encountered, it constitutes a true surgical emergency because increasing pressure within the orbit can damage the optic nerve and result in blindness. Any sudden increase in pain during the immediate postoperative period should raise suspicion of this possibility. Surgical intervention should be timely, with opening of the wound, removal of clots, and achievement of hemostasis. If the patient experiences decreasing vision or if the ocular pressure approaches 80 mm Hg, lateral canthotomy and inferior cantholysis are urgently performed to decompress the orbit and preserve vision. The development of lid hematoma in the immediate postoperative period also necessitates reopening the wound and establishing hemostasis. If discovered at a later time, the hematoma should be allowed to liquefy and can be aspirated with a needle in 7 to 9 days. If the clot is not removed, a firm nodular scar may form in this area.

The most common functional problem after blepharoplasty is dry eye syndrome. This is often preventable by obtaining a thorough history and identifying complaints of ocular itching, foreign body sensation, and burning. All patients undergo an ophthalmologic evaluation before blepharoplasty, which includes a Schirmer test. If despite these precautions a patient develops dry eyes following blepharoplasty, attention should be directed toward maintaining corneal protection with artificial tears, a nocturnal lubricant, and lid taping.

Persistent diplopia after blepharoplasty usually indicates injury to the inferior oblique muscle. Diplopia as a consequence of mild trauma to the muscle is often temporary, but transection may cause permanent ocular dysmotility requiring surgical intervention.

Problems of lid position may also arise after blepharoplasty. Typically, the lower lid margin rests at the corneal limbus, but minimal scleral show may be a normal variant. Postoperative displacement of the lower lid by 1 mm can often be seen. If moderate scleral show is noticed postoperatively, initial treatment consists of upward massage and closed-eye squints to strengthen the orbicularis oculi. More extensive scleral show, ectropion, or lateral lower lid rotation (“hound dogging”) requires a more aggressive approach with horizontal lid shortening and potentially skin grafting.

Blepharoptosis, or upper lid ptosis, can be noticed postoperatively. Often, this is secondary to unrecognized preoperative lid ptosis or due to levator injury during blepharoplasty. Lagophthalmos, or inability to close the palpebral fissure after blepharoplasty, is usually a temporary phenomenon. After the completion of blepharoplasty, it is normal to see palpebral separation of up to 4 mm. Greater distances substantially increase

the postoperative risk for lagophthalmos. If this is noticed intraoperatively, a strip of resected skin can be replaced before conclusion of the procedure.

At times, aesthetic concerns after blepharoplasty are not viewed as complications by the surgeon, but they may be considered as such by the patient. Patients may voice complaints of persistent malar bags and animated lateral wrinkling. Because these are not correctable by blepharoplasty, such misunderstanding is best avoided by adequate preoperative awareness, patient education, and realistic expectations.

57.8 Roundsmanship

- Blepharoplasty targets excessive periorbital skin and fat.

- Lower blepharoplasty approaches include transconjunctival and transcutaneous approaches.
- The inferior oblique muscle separates the medial and central fat compartments of the lower eyelid.
- Aggressive fat excision may result in orbital hollowing, accentuating an aged appearance.

58 Facial Implants

Alexander Ovchinsky

58.1 Introduction

Alloplastic materials have long been used for the correction of functional and aesthetic facial problems. The recent development of new, biocompatible materials has further broadened the application of implants in facial plastic surgery. The major advantages of alloplasts are the following: abundance of implant materials; lack of need for a donor site, with related morbidity; and ease of customizing the implant according to the individual patient's needs by selecting from numerous sizes and shapes or by generating, with computer assistance, a custom implant based on the patient's anatomy.

The disadvantages are based on the fact that all alloplastic implants are foreign bodies with all the potential complications of such.

Thus, an ideal implant should be (1) nontoxic; (2) nonantigenic; (3) noncarcinogenic; (4) biocompatible with the host tissues; (5) infection-resistant; (6) easily shaped, molded, and carved and able to maintain its form and volume permanently; and (7) cost-effective.

58.2 Incidence

Alloplastic implants are commonly used in midfacial augmentation procedures as malar, submalar, shell, or tear trough implants (□ Fig. 58.1); in rhinoplasty surgery for dorsal augmentation or as L-shaped structural implants; and in mandibular augmentation (□ Fig. 58.2). A total of 8,789 malar implant procedures were done in 2009, comprising 0.6% of all cosmetic

Fig. 58.1 Mandibular implants (silicone). Top left: extended anatomical chin implant. Top right: extended conform anatomical chin implant. Bottom left: prejowl implant. Bottom right: mandibular angle implant.

surgeries; 73% of the malar implant procedures were in women. Nearly \$23 million was spent on malar implant surgery in 2009. A total of 13,000 chin implant surgeries were performed in 2009, which accounted for 0.9% of all cosmetic surgeries; 52% of these were in women and 48% in men. The total annual spending on chin augmentation surgery in 2009 was nearly \$27 million.

58.3 Terminology

Facial implants are differentiated based on their application (malar, submalar, mandibular, other) or their composition. Various synthetic materials have been used for facial implants. Silicone implants have been used in clinical practice since the middle of the 20th century; silicone has a fairly high degree of chemical inertness and stability, and it is not allergenic. Tissue reaction to solid silicone implants is characterized by the formation of a fibrous tissue capsule without tissue ingrowth into the implant. Expanded polytetrafluoroethylene (Gore-Tex; W. L. Gore Associates, Flagstaff, AZ) has found wide application in facial augmentation because of its limited soft-tissue ingrowth

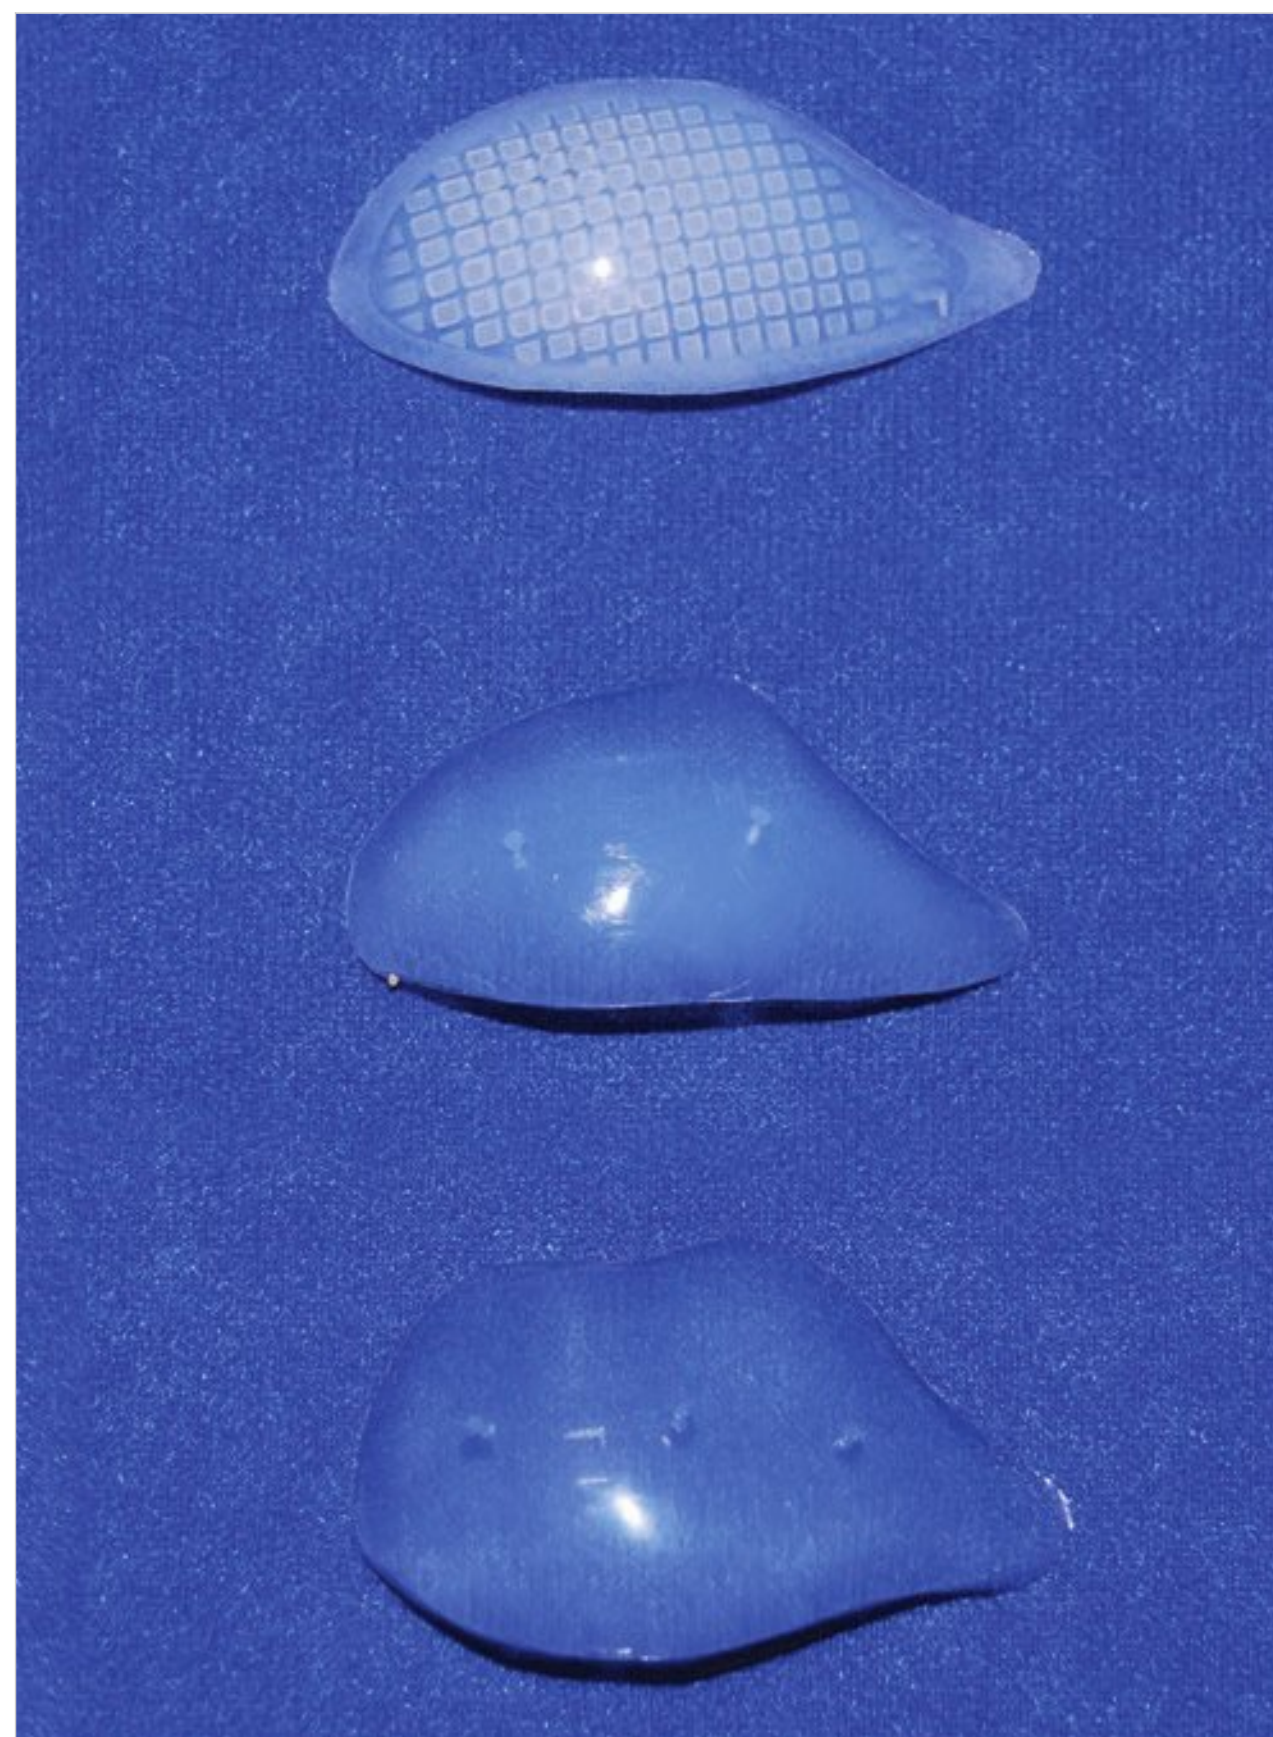

Fig. 58.2 Malar implants (silicone). Top: conform malar shell implant. Middle: malar shell implant. Bottom: combined submalar shell implant.

and minimal inflammatory reaction. The material allows for partial incorporation of the host's soft tissues, thus making it less susceptible to infection or migration, while not significantly compromising the ease of implant removal, if necessary. Porous polyethylene (Medpor; Porex Surgical, Newnan, GA) permits extensive tissue ingrowth into the implant pores, which provides additional stability but may make implant removal very difficult. Medpor is a very rigid material and therefore tolerates thin soft-tissue coverage poorly. Mesh polymers include Marlex, a high-density polyethylene (Marlex Pharmaceuticals, New Castle, DE); Mersilene, a polyester fiber mesh (Ethicon, Somerville, NJ); and Dacron, a condensation polymer obtained from ethylene glycol and terephthalic acid (Dow Corning, Midland, MI). Mesh polymers are easily folded and shaped and allow extensive soft-tissue ingrowth through the mesh network. This minimizes the risk for migration and infection but may make removal of the implant more difficult.

58.4 Applied Anatomy

Nasal dorsal implants are placed over the paired nasal bones (bony dorsum) and paired upper lateral cartilages (cartilaginous dorsum). An implant is placed directly over the bony-cartilaginous framework, underneath dorsal soft tissues. Nasal implants that are L-shaped are placed over the nasal dorsum (longer part of the L) and into the columella between the medial crura of the lower lateral cartilages (shorter part of the L).

The mandible consists of the central symphysis and the bilateral mandibular bodies, rami, angles, and coronoid and condylar processes. The alveolar process of the mandible forms its superior portion and supports the lower dentition, which is innervated by the inferior alveolar nerve. The condylar process articulates with the glenoid fossa of the temporal bone to form the temporomandibular joint. The mental nerve, the terminal branch of the inferior alveolar nerve, exits through the mental foramen, located between the first and the second premolars about 1 cm above the lower mandibular border. Mandibular implants are used to augment many of these anatomical areas and may be used unilaterally in cases of mandibular asymmetry or hemifacial microsomia. For example, anatomical chin implants are used to augment the symphyseal area primarily, whereas extended anatomical chin implants augment both the mandibular symphysis and the parasymphysial and body regions. Prejowl implants provide augmentation to the area of the mandibular body just medial to the jowl without adding any volume to the symphyseal region. Mandibular angle implants serve to augment the body and ramus of the mandible and are commonly used in patients with hemifacial microsomia.

The anatomy of the midface is primarily defined by the relationship between the zygoma and the soft tissues of the cheek and infraorbital region. The zygomatic bone is a tetrapod and consists of the body of the zygoma with four articulating processes: the zygomaticotemporal, zygomaticofrontal, zygomaticomaxillary, and zygomatico-orbital processes. The zygoma defines the cheek prominence and plays an important role in achieving the triangular shape of a youthful face. The masseter muscle is attached to the inferior aspect of the zygoma body and zygomatic arch. The zygomaticus major and minor muscles

of facial expression also originate from the inferior aspect of the zygoma and insert into the area of the upper lip and oral commissure. Several fat compartments have been described in the area of the midface; the malar, buccal, and suborbicularis oculi fat pads are the most important ones. Various important anatomical structures, such as branches of the facial and trigeminal (infraorbital and zygomaticofacial) nerves, parotid duct, and branches of the facial artery are located in the midface region.

58.5 The Disease Process

58.5.1 Etiology

Saddle nasal deformity is usually a result of nasal trauma or prior nasal surgery (secondary to overzealous reduction of the nasal dorsum or aggressive septoplasty leading to the loss of nasal dorsal support); some Asian and African-American patients may have a congenitally low dorsum, as well. Systemic diseases, such as Wegener granulomatosis and syphilis, and illicit drug use (cocaine snorting) may lead to the loss of nasal support and dorsal saddle deformity.

Mandibular deformities necessitating the use of implants are usually of developmental etiology. Microgenia and micrognathia lead to a small-appearing chin on the frontal view, and the profile may be improved with a mandibular implant. Hemifacial microsomia may be an isolated finding or a component of a syndromic condition (e.g., Treacher Collins syndrome, Crouzon syndrome) and commonly requires unilateral augmentation of the affected parts of the mandible.

A hypoplastic zygoma, either developmental or due to trauma, frequently benefits from augmentation. Soft-tissue voids in the infraorbital region due to midfacial ptosis and atrophy may also be improved with malar implants.

58.5.2 Pathogenesis and Natural History

Most facial deformities necessitating augmentation are cosmetic in nature, and their correction is aimed primarily at improving of the overall facial balance. Saddle nasal deformity, when severe, may result in symptoms of nasal obstruction.

58.5.3 Potential Complications

Complications related to facial implants can be broadly subdivided into two main categories. Immediate complications are related primarily to the surgical placement of an implant and include hematoma, bleeding, and neural injury leading to either motor or sensory deficits. Later complications, related mainly to the foreign body nature of the implant, include infection, foreign body reaction, implant migration or extrusion, and poor scarring of the access incisions.

58.5.4 Disease Grading

Most facial implants come in a variety of sizes, depending on the degree of augmentation needed. The selection of implant

size is based primarily on the patient's needs and the surgeon's expertise. Many manufacturers offer implant sizers, which are sterilizable rubber replicas of the various implant sizes. Sizers provide good visual assistance during preoperative patient consultations and during selection of the correct implant size for a given patient.

58.6 Medical Evaluation

58.6.1 Presenting Complaints

Patients may feel that certain areas are disproportionately small or deficient (e.g., a small or "weak" chin, flat cheekbones, or a "low" nasal dorsum). Patients with microgenia frequently dislike a poorly defined or blunted cervicomental angle; they may also complain of a "big nose," not realizing that a disproportionately small chin may be the main underlying etiology.

58.6.2 Clinical Findings, Physical Examination

Midfacial hypoplasia may be secondary either to an insufficiently developed malar bone (type I) or to atrophy and ptosis of the midfacial soft tissues (type II). The former requires a malar shell implant to augment the zygoma and create a higher arch of the cheekbone. The latter may be corrected with a submalar implant, which augments soft-tissue deficiency below the malar arch without additional augmentation of the zygoma. The combined bony–soft tissue deficiency (type III) requires placement of a malar–submalar implant to address both problems simultaneously.

Saddle nose deformities present as a low, wide nasal dorsum and may be bony, cartilaginous, or a combination of bony and cartilaginous. The nose appears widened because of the lack of dorsal height.

Patient with micrognathia have class II occlusion on physical examination and are best treated with orthognathic surgery. However, patients with normal occlusion and microgenia are best served with a chin implant. In patients with hemifacial microsomia, the degree of mandibular asymmetry may vary. Isolated mandibular angle–ramus deficiency is common, but in some cases the whole hemimandible may be hypoplastic.

58.6.3 Testing

No specific testing is required except for a routine preoperative work-up. Computer imaging may be a useful consultation tool to communicate the proposed changes to the patient.

58.6.4 Differential Diagnosis

Saddle nasal deformity may be a result of prior trauma, surgery, or loss of septal support due to inhaled drug use or a systemic condition (i.e., Wegener granulomatosis, neoplasm, or syphilis). Midfacial and mandibular hypoplasias are usually developmental conditions, whether isolated or part of a craniofacial syndro-

me, or may result from the aging process. Soft-tissue aging of the neck may exacerbate a mild chin deficiency.

58.7 Surgical Treatment

The basic principles of malar, nasal, and mandibular augmentation are in fact very similar. Selecting an implant of appropriate shape and size is very important in achieving a pleasing facial contour. Nasal dorsal implants can be placed via closed or open rhinoplasty approaches, depending on the particular problem at hand and the surgeon's preference. Surgical access for malar augmentation is usually through a gingivobuccal incision; however, transconjunctival or subciliary approaches may also be used. Mandibular implants can be introduced intraorally through a gingivobuccal incision or through the open approach via submental incision. With all implants, the dissection is carried on top of the bone in the subperiosteal plane. In the chin, a small strip of periosteum over the symphysis may be left intact, thus making the central portion of the implant supraperiosteal and the lateral portion subperiosteal. It is of paramount importance to create a precise pocket to fully accommodate the implant without undue tension or buckling, but at the same time to avoid excessive undermining to minimize the risk for implant migration and shifting. One should be aware of the location of the mental and infraorbital nerves in order to avoid injury during the dissection or introduction of the implant.

The implant is typically soaked in an antibiotic solution and then placed into the pocket. The area is evaluated for symmetry and the presence of palpable edges, and all needed adjustments are carried out. The wound is thoroughly irrigated with saline or an antibiotic solution, hemostasis is verified, and the incisions are closed. If the implant pocket is precise, it is usually not necessary to suture the implant. However, some surgeons prefer suturing implants either to the periosteum (mandibular implants) or to the overlying skin (malar and nasal dorsal implants) for additional security. A compression dressing is placed to minimize the chance of hematoma and to further stabilize the implant in the immediate postoperative period.

Surgical complications usually involve injury to the sensory (infraorbital and mental) nerves with resultant hypesthesia, which may be transient or permanent depending on the degree of injury. Weakness of the marginal mandibular nerve may occur during mandibular implant placement as a consequence of overzealous retraction and nerve compression; this is almost always a temporary problem. There is a potential for injury to the facial nerve branches during dissection over the masseter muscle and malar implant placement. Other surgical complications include hematoma, seroma, infection, and bad scarring. Long-term complications related to implants themselves were discussed earlier in this chapter.

58.8 Prognosis

The surgical success rate is universally good, with only small percentage of patients developing postoperative complications necessitating implant removal. Although challenging, facial im-

plant procedures provide the patient with improved facial harmony that is long-lasting.

58.9 Roundsmanship

- Many different types of facial implants are available to create a variety of changes.
- Long-term implant-related complications include infection, foreign body reaction, migration, and extrusion.
- Detailed facial analysis and proper implant selection lead to optimal surgical outcome.

59 Management of Aging Skin

Tova Fischer Isseroff and Alexander Ovchinsky

59.1 Introduction

As the “Baby Boom” generation ages and genetic breakthroughs uncover the etiology of many disease mechanisms, aging has come to be considered a disease process that can be treated, rather than the inevitable final pathway of all humans. Physicians have occupied themselves with discovering ways to help their patients live longer and feel better about themselves, all the while modifying chronic diseases and affecting lifestyle choices. The social renaissance in the 1960s and 1970s brought with it a surge in the acceptance and willingness of physicians to perform and of patients to request cosmetic surgery. The search for the fountains of youth generated an outpouring of new surgical techniques and dialogue. In addition, nonsurgical approaches to facial rejuvenation have peaked as the sale of over-the-counter and specialty products to reverse the signs aging has reached a market high, and as the offerings of aesthetic surgeons, dermatologists, and aestheticians in the realm of facial resurfacing have burgeoned.

59.2 Incidence of Disease

The incidence of aging is directly proportional to the lifespan of a given population; the specific appearance of an aged individual depends on a host of factors, including but not limited to genetic predisposition, diet, and environment.

59.3 Terminology

When analyzing a face, the physician observes for rhytids (skin wrinkles) and other obvious changes in the skin. Dynamic wrinkles are amenable to treatment with a neuromodulator because they are produced by mimetic musculature and can be reduced by weakening the underlying muscle. Static wrinkles need to be

addressed separately because they may overlie areas of actinic keratosis, premalignant warty lesions that occur on the sun-exposed areas of the face. Skin tone and color are graded with standardized grading scales, such as the Fitzpatrick Scale (□ Table 59.1) and the Glogau Wrinkle Scale (□ Table 59.2). Skin rejuvenation techniques, which may be ablative or nonablative, are all aimed at improving the quality, texture, and appearance of the skin and are usually performed on skin that has aged or undergone actinic damage, acne scarring, or hypertrophic scarring. The ablative modalities employ different mechanisms of skin injury: chemical peels cause caustic injury, dermabrasion causes mechanical injury, and lasers cause thermal injury. Each rejuvenation procedure has its own vocabulary and instructions, which are essential for the operator to understand and use in communication.

59.4 Applied Anatomy

The skin is composed of three basic layers. The outermost layer of skin is the epidermis; the dermis is deeper and is composed of the superficial papillary layer and the deeper reticular layer (□ Fig. 59.1). Injury limited to the epidermis and papillary dermis, the end-product of most resurfacing procedures, results in a wound that heals without scarring, whereas injury to the deeper reticular layer usually heals with scar formation.

59.5 The Disease Process

59.5.1 Etiology and Pathogenesis

Multiple theories have been proposed to explain the aging process. The free radical theory is the basis of many over-the-counter serums, creams, and dietary supplements. This theory postulates that free radicals, routinely produced during cell metabolism, build up as the body ages and then interfere with

Table 59.1 Fitzpatrick Scale of skin types

Type	Description
Type I	White or freckled skin; blue or hazel eyes; blond or red hair; always burns, never tans
Type II	Fair skin; blond, red, or brown hair; usually burns, tans less than average
Type III	White to olive skin; sometimes burns mildly, tans average
Type IV	Brown skin; rarely burns, tans with ease more than average
Type V	Intermediate brown-colored skin; Asian, Latin, or Indian; brown skin; tans easily
Type VI	Black skin; never burns

^aApproximate age range; severity of wrinkles depends upon other factors in addition to age.

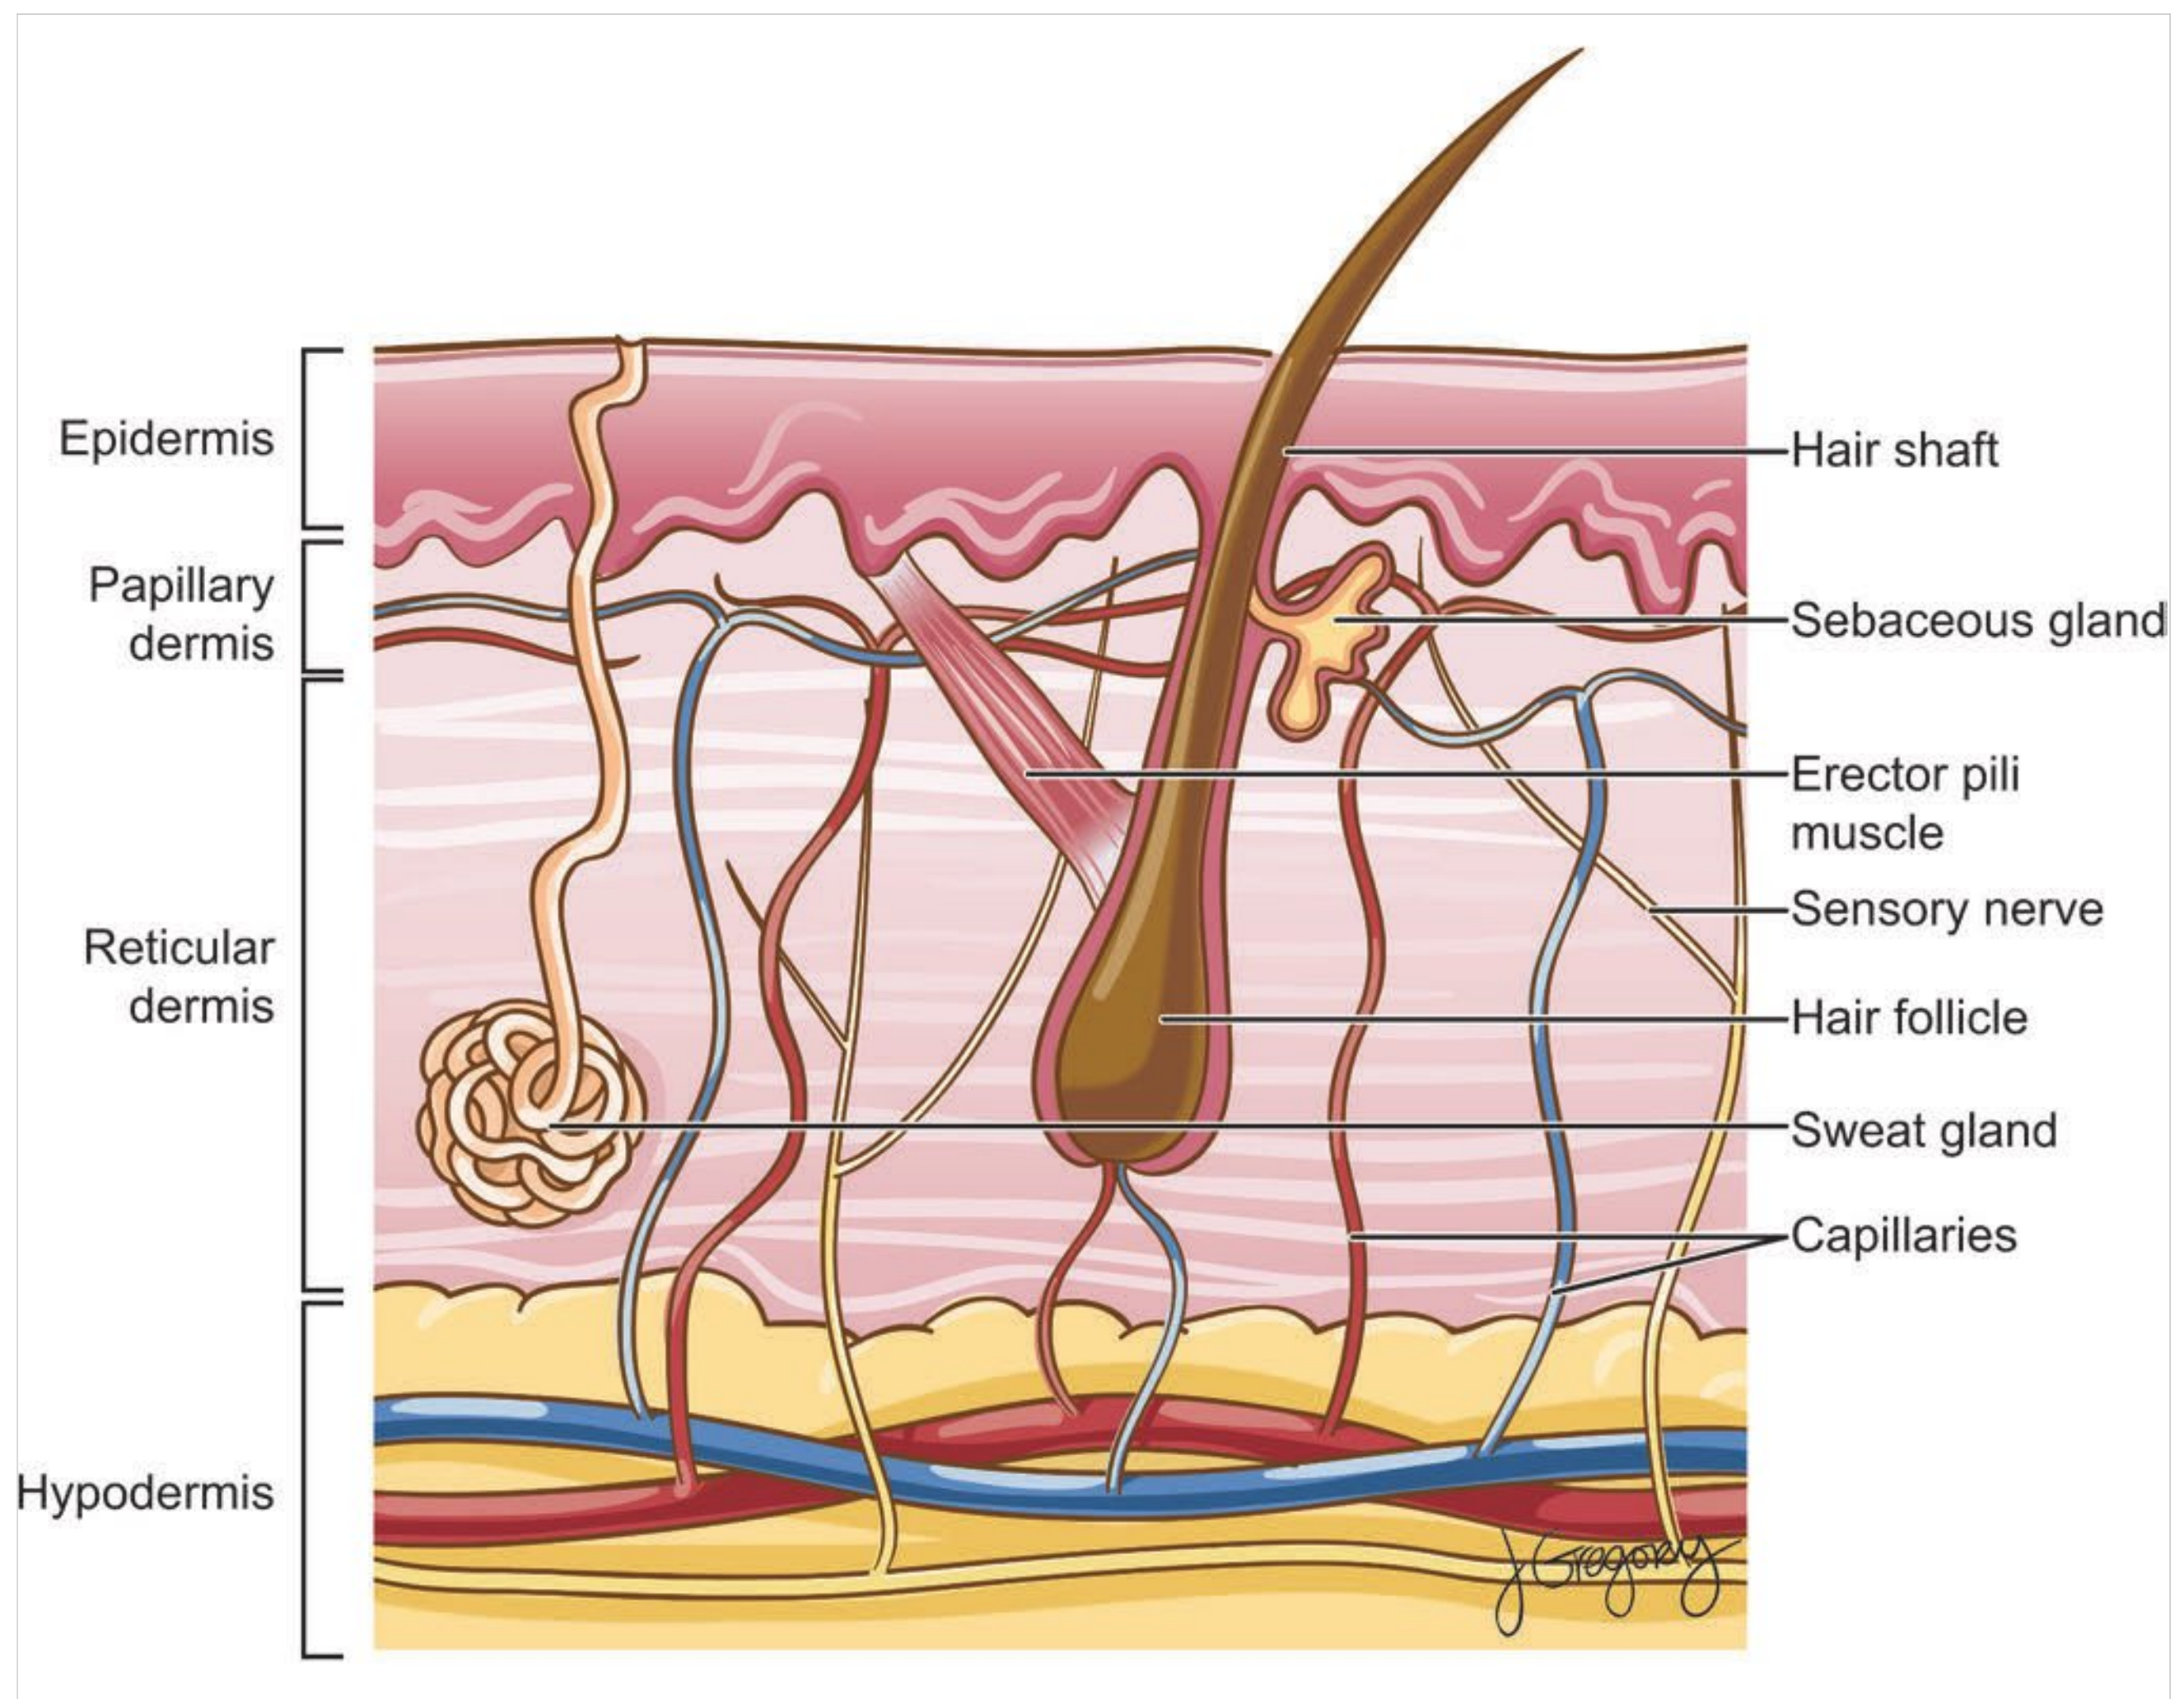

Fig. 59.1 Layers of the skin.

cellular respiration and energy production in the mitochondria, damaging the cell. A second theory centers on the decline in hormonal levels that naturally occurs as one ages. Female menopause and male andropause both lead to a decline in sexual hormone levels, which give the characteristic appearance of youth to those in their peak reproductive years. The cell senescence theory states that cells have a finite ability to replicate and with each replication lose a telomere protein. The telomere sequence determines the cell's age capacity. Yet another theory involves inflammation and an increase in cellular stress that occurs as certain chemicals and hormones naturally build up in the body. Histologically, aging skin shows a loss of epidermal cell differentiation and degeneration of the underlying elastic network. The amount of collagen in the dermis decreases, dermal fibers degenerate, and the dermal-epidermal junction flattens. Lymphocytes infiltrate the dermis, and melanocytes become unevenly distributed, causing mottled pigmentation.

59.5.2 Natural History and Progression

A common end point for all humanity is aging. As hormone levels begin to decline, the body and face begin to show signs

of aging. Wrinkles develop in dynamic and static locations, areas that are dependent or have been damaged by the sun. Smoking, diet, skin care, and genetics can alter facial appearance, as well.

59.5.3 Potential Disease Complications

Aging skin can cause physical and psychological distress. Skin laxity around the eyes can result in visual changes by affecting the palpebral fissure. Patients can become very distressed about their cosmetic appearance and the loss of their youthful glow.

59.5.4 Disease Grading

Grading systems and classifications are used to standardize and provide interphysician reliability with regard to physical examination and treatment, as well as guidance in determining an appropriate treatment modality for a specific patient (see □ Table 59.1 and □ Table 59.2).

Table 59.3 Brody relative and absolute contraindications to chemical peels

Relative contraindications	Darker skin type (Fitzpatrick IV–VI); history of keloid formation; history of herpes; history of cardiac abnormality; history of facial radiation therapy; marked quantity of vellus hair; telangiectasia
Absolute contraindications	Unrealistic patient expectations; physical inability to perform adequate postoperative care; significant renal and hepatic dysfunction; HIV infection; significant immunosuppression; emotional instability/mental illness; Ehlers-Danlos syndrome; scleroderma; collagen vascular disease; recent isotretinoin treatment; anticipation of inadequate photoprotection

Source: Adapted from Table 29.3. In: Cummings C, Haughey B, Thomas JR, et al, eds. Cummings Otolaryngology: Head and Neck Surgery. Philadelphia, PA: Elsevier Mosby; 1998:693–713.

59.6 Medical Evaluation

59.6.1 Presenting Complaints

Patients seeking a consultation for facial rejuvenation have complaints related to their aged appearance, whether a specific area with noted physical changes or the overall appearance. Changes in skin texture and laxity, pigmentation, and susceptibility to bruising and blemishing can also cause dissatisfaction.

59.6.2 Physical Examination, Laboratory Studies, and Imaging

A thorough social and medical history must be obtained from a patient seeking any cosmetic procedure. Any history of previous surgery, previous facial treatments, or trauma, medication use, allergies, and the likelihood of scar formation must all be taken into account when a specific treatment modality is considered. A history of sun exposure, whether remote or recent, is crucial in evaluating the degree of photodamage to the skin. Chronic medical conditions may preclude the use of certain treatment modalities, such as collagen vascular diseases and scleroderma, which are absolute contraindications to the use of chemical peels (□ Table 59.3). A history of immunosuppression indicates a poor prognosis for healing after treatment, as does active smoking. A patient's expectations, functional status, and ability to care for himself or herself, and to comply with follow-up after a treatment, will also affect the readiness of a clinician to perform a certain procedure.

Examination of the face should be performed consistently, in a systematic and meticulous fashion. Careful attention must be paid to skin laxity, texture and coloration, and blemishes; the location of wrinkles; and the strength of bony structures. The face must be observed when active and in repose to study the movement of individual muscle groups. Photographic documentation, important for both consistency and postoperative comparison, should use standardized lighting and poses. No crucial laboratory tests are needed before intervention, other than preoperative screening.

59.6.3 Differential Diagnosis

Rare medical conditions, such as Hutchinson-Guilford syndrome (Progeria) appear as premature aging; however a simple history and physical exam will make this diagnosis evident.

59.7 Medical Treatment

The medical treatment of aging skin is divided into three basic categories. Skin resurfacing is discussed here; neuromodulation and injectable fillers are covered separately. Chemical peels chemically ablate differing thicknesses of the skin to reduce the effects of aging and sun damage.

Although the technique itself is easy to learn, experience is necessary to predict how different skin types and areas of the face will respond to peels. The concentration of the solution used and the length and number of applications determine the depth of peel. Peels work by causing protein precipitation or keratolysis.

When compared with photoaged, nonrejuvenated skin, skin that has undergone chemical peeling exhibits new bands of dermal collagen and ordered cellular differentiation in the epidermis, free of irregularities and actinic keratosis. Melanin granules are evenly distributed and bleached. The dermal–epidermal matrix is linearly oriented, with elastotic fibers paralleling the new collagen. There is decreased lymphocytic infiltration. Wrinkles are effaced by the new layers of connective tissue. Chemical peeling can decrease precancerous skin lesions.

Pretreatment with tretinoin is applied for 2 to 4 weeks before the peel; this thins the epidermis (allowing deeper penetration of the chemical peel) and increases the rate of dermal collagen production (speeding improvement and recovery after the peel).

A superficial chemical peel is generally suitable for all Fitzpatrick skin types and Glogau category I skin. Low concentrations of chemical agents are used to exfoliate the stratum corneum and epidermis to stimulate regrowth and temper superficial photodamage; these include 40 to 99% glycolic acid; 10 to 20% trichloroacetic acid; Jessner solution (a mixture of salicylic acid, lactic acid, ethanol, and resorcinol); and salicylic acid. A medium-depth chemical peel (□ Fig. 59.2) causes controlled injury down to the papillary dermis in a single application; it uses 35% trichloroacetic acid combined with Jessner solution, solid carbon dioxide, or glycolic acid. It is appropriate for patients with Glogau category II skin, actinic keratosis, or mild acne scarring. A deep chemical peel wounds the skin down to the midreticular dermis and is effective in rejuvenating severely photoaged skin with deep rhytids; it is used for patients with Glogau category III or IV skin. A Gordon-Baker peeling solution (a combination of 88% phenol, septisol, croton oil, and distilled water) is most commonly used because it reliably and consistently produces the expected result. The phenol produces rapid denaturation and irreversible coagulation of the keratinocytes. It is this keratinocyte coagulation that limits the depth of penetration of the

Fig. 59.2 Patient (a) before and (b) after 35%trichloroacetic acid peel. Note the smoother and more even complexion and the effacement of fine lines after treatment.

peel; pure phenol penetrates less deeply because it has a greater coagulative effect.

Before application of the solution, the face is first cleansed to remove oils and exfoliate desquamated cells, and then the solution is applied with saturated gauze or a brush. A deep peel is a major surgical procedure, and both preoperative medical clearance and intraoperative intravenous sedation and hydration are necessary, as well as intraoperative monitoring and oxygen support. Phenol is cardiotoxic, nephrotoxic, and hepatotoxic, so hydration and extension of the application time to more than 1 hour for the entire face limits the toxic side effects of the preparation. Deep peels can be occluded (zinc oxide tape is applied to cover the phenol solution immediately after application in order to increase penetration of the solution in deeply wrinkled faces) or nonoccluded (which involves more skin cleansing and the application of greater amounts of peel solution, but no taping).

The skin heals within slightly different time frames depending on peel depth. After a deep peel, healing of the skin occurs in four phases. Inflammation is evident immediately, with erythema occurring as the epidermis separates and gradually sloughs off with the use of soaks and compresses. Coagulation then follows, and re-epithelialization begins on day 3 and continues into days 10 to 14, at which point fibroplasia commences and new collagen is formed. This phase lasts until about 4 months postoperatively. Patients must be informed that there is a higher potential for pigmentary disturbance and textural damage from chemical peels. All patients are advised to wear

sunscreen at all times after the peel, and makeup may be necessary to camouflage certain areas, as well.

Dermabrasion is a mechanical method of removing the epidermis and regenerating the collagen of the papillary layer without injuring the underlying reticular layer. The new collagen that is produced supports a new epidermis. This technique is best used for skin with actinic damage, aging, or scarring. Dermabrasion wounds, just like chemical peels or laser wounds, heal by re-epithelialization from the wound margins and epidermal appendages that remain (such as pilosebaceous glands). Because the skin of the face is rich in sebaceous glands, it is an excellent skin surface for this procedure. The preoperative application of tretinoin, as in chemical peels, has been shown to shorten healing time by approximately 3 days. Additionally, chilling the skin before abrasion creates a rigid surface that can then be abraded evenly. Dermabrasion may use wire brushes or wheels covered with diamond chips. Microdermabrasion, in which small aluminum or glass particles are blown over the skin, produces an effect similar to that of superficial chemical peels.

Dermabrasion is done in an outpatient setting, and preoperative and intraoperative anxiolytics and painkillers are administered to make the patient more comfortable, as well as local anesthesia. Once the skin is solidified by the cooling agent or distended by the injection of a dilute anesthetic, abrasion is performed. Adequate depth through the epidermis is made evident by the loss of pigmentation, and depth to the papillary dermis is identified by punctate bleeding. Once the papillary

dermis is entered further, faint bands of collagen become visible, and when this is destroyed, abrasion down to the reticular layer is complete. Postoperative occlusive dressings, especially biosynthetic dressings, speed healing time by keeping wounds moist and allowing wound fluid and growth factors to have maximum contact with the skin. Steroids reduce edema and discomfort, and as with any other procedure that removes epidermis, antiviral prophylaxis should be started 2 days before treatment and continued until epithelialization is complete. Patients are restarted on tretinoin at that time and are advised that they must use sunscreen when going outside. Most patients are able to resume daily activities after 7 to 10 days; however, it takes approximately 4 to 6 weeks for erythema to fade fully.

Light-based skin rejuvenative therapies depend upon the different effects caused by different levels of absorbed energy. The energy delivered is affected by the wavelength (□ Fig. 59.3) used; shorter wavelengths impart more energy (□ Fig. 59.4). Once in contact with a surface, the energy is differentially absorbed, reflected, scattered, or transmitted, according to the tissue qualities and the presence of chromophores in the skin corresponding to the wavelength of the light (□ Fig. 59.5). The light energy absorbed by the tissue will cause photodynamic, electromagnetic, and thermal effects to differing degrees (□ Fig. 59.6).

Fig. 59.3 Wavelength, frequency, and amplitude of light. The energy delivered increases as frequency increases.

Laser resurfacing can be ablative or nonablative. Ablative laser resurfacing is accomplished with the carbon dioxide laser or the erbium:yttrium-aluminum garnet (Er:YAG) laser. Lasers produce effects by a process of photothermolysis, in which the laser's specific wavelength corresponds to a peak in the absorption curve of the chromophore. Unwanted effects are limited by choosing an absorption peak well separated from the absorption curve of other chromophores, such as hemoglobin and

Fig. 59.5 Light energy striking a surface can be absorbed, reflected, scattered, or transmitted.

Fig. 59.4 Spectrum of light. KTP, potassium titanyl phosphate; Nd:YAG, neodymium:yttrium-aluminum garnet; PDL, pulsed dye laser; UV, ultraviolet.

Photodynamic Effects	Thermal Effects		
	Low	Medium	High
Biochemical substances activated	Proteins denatured	Tissues coagulated	Tissues vaporized

Fig. 59.6 Low levels of energy may affect biological systems in a nonlethal way, whereas higher levels may destroy, coagulate, or simply vaporize tissues.

melanin. Both the carbon dioxide and Er:YAG lasers use water as the selected chromophore because more than 90% of the epidermis is water. When the laser hits the target tissue, laser energy is absorbed by water molecules, where it is then converted to heat, vaporizing water and tissue alike. Ideally, only a limited amount of heat is transferred to the adjacent collagen-containing tissue, preventing unwanted tissue injury. Laser safety is of the utmost importance for the operator, support staff, and patient. This includes the use of protective eyewear, nonflammable drapes, laser masks, and a smoke evacuator, in addition to the removal of alcohol-based makeup and moisturizers. Intravenous, regional, or topical anesthesia is used.

The carbon dioxide laser uses a continuous wavelength of 10,600 nm. Over the past half century it has been reconfigured to provide a short pulse duration, ideal for resurfacing. The water absorbance of the Er:YAG laser is 10 times that of the carbon dioxide laser, owing to a wavelength of 2,940 nm. This causes more precise tissue thinning and less adjacent thermal injury, coupled with a faster healing time. However, less tissue tightening occurs with this laser because there is less thermal effect on adjacent tissue. Postoperative edema, recovery time, resultant hyper- and hypopigmentation, and scarring are significantly less when the erbium laser is used. Owing to the inherent differences and advantages of these two laser types, some combine both laser wavelengths in order to provide the benefit of the pooled result.

Many surgeons pretreat the skin with tretinoin, and all should advise patients to avoid sun exposure before resurfacing because it exacerbates postoperative hyperpigmentation due to melanocyte activation. As the laser vaporizes the epidermis, the tissue appears pink when the papillary dermis is entered; after more laser passes, the tissue color changes to a chamois yellow, which indicates reticular dermis and the need to stop skin ablation. Postoperatively, the use of occlusive dressings shortens healing time to 5 to 7 days. Strict sun avoidance is necessary for approximately 2 to 3 months until all of the postoperative erythema has subsided in order to decrease the risk for hyperpigmentation.

Nonablative lasers selectively affect the dermis and spare the epidermis. Minimal recovery is needed, which makes it a

preferred choice for many patients. However, multiple treatment sessions are necessary, and the results are not as dramatic as those with ablative lasers or deep peels. The 1,320-nm neodymium:yttrium-aluminum garnet (Nd:YAG) laser provides the optimal wavelength for specifically targeting the dermis. It has been effective in wrinkle reduction and in treating acne scars through a process of stimulated dermal collagen deposition. The 1,450-nm diode laser has good dermal penetration, as well, and has achieved good results in reducing rhytids. Fractionated lasers work by creating multiple microscopic areas of thermal injury, around which the uninjured tissue promotes rapid healing. Re-epithelialization occurs within 24 hours, and erythema usually resolves within a week.

Intense pulsed light (IPL) is a noncoherent, polychromatic filtered light source used for photothermolysis. Initially approved by the FDA in 1995 for the treatment of leg telangiectasia, its benefits were soon noted in the treatment of photoaging and vascular lesions and in hair removal. Specially designed filters in the treatment head manipulate the wavelengths emitted in order to provide selective thermolysis based on the target tissue's absorption (e.g., vasculature vs epidermis). Multiple pulses to a given area allow thermal relaxation of the target tissue between pulses; relaxation time depends on tissue and skin type (Fitzgerald skin type, ethnicity). IPL is effective in treating facial telangiectasia and poikiloderma of sun-exposed areas, as a photorejuvenation modality, and for hair removal. Treating the entire face can reduce mottled pigmentation and freckling and can smooth the skin. Studies have shown an increase in the transcription of types I and III collagen and of elastin following IPL treatment.

Photodynamic therapy (PDT) is a nonablative photorejuvenation technique that employs the combination of a light source and the creation of reactive oxygen to biologically damage and change the underlying skin. A photosensitizing agent, such as aminolevulinic acid (5-ALA), is applied topically and penetrates abnormal keratin in cutaneous tissue and creates endogenous protoporphyrin IX, an activated oxygen intermediate. When an appropriate light source is then applied, the activated photosensitizer causes cell destruction and death. The damage inflicted must surpass the cellular repair mechanisms in order for

destruction to be complete, known as the photodynamic response. The effectiveness of PDT depends on the photosensitizer used, the light source, and the oxygen status of the target tissue. PDT uses include the treatment of selected nonmelanotic skin cancers, acne and sebaceous hyperplasia, various infectious and inflammatory skin conditions, and actinic keratosis, in addition to cosmetic photorejuvenation.

The side effects of all of the above procedures include hypopigmentation and hyperpigmentation, poor cosmesis, scarring, and infection. Patients with a history of herpesvirus infection are required to take prophylaxis after the procedure in order to prevent reactivation of the infection. Phenol is cardiotoxic, nephrotoxic, and hepatotoxic, and certain groups of patients are not eligible for deep peels. Dermabrasion can make patients more prone to milia outbreaks and acne flares, as well as persistent erythema, all of which can be managed with topical or oral agents. After laser resurfacing, patients frequently develop contact dermatitis in reaction to certain ointments; in this case, the use of those ointments should be stopped and the face treated with a corticosteroid cream. The development of scattered purpura is a unique side effect of both PDT and IPL treatment, although the incidence is low and it usually resolves on its own. Stinging pain is also a side effect of IPL, which can be reduced with the application of topical anesthetic cream before treatment.

59.7.1 Prognosis

Superficial chemical peels do not penetrate the epidermis and have no clinically noticeable recovery time. Medium-depth peels, superficial dermabrasion, and ablative laser resurfacing have a healing time of approximately 5 to 7 days. Repetitive peeling is often necessary to produce the full desired effect. Re-

sults from deep and medium peels usually last for over 1 year. Barring the occurrence of side effects, the peels are effective in rejuvenating photoaged and actinic skin. Use of the Nd:YAG nonablative laser has been shown to be most effective in patients who have Fitzpatrick type I or II skin with mild, moderate, or severe rhytids.

59.8 Roundsmanship

- Skin resurfacing can be performed chemically with chemical peels, mechanically with dermabrasion, or thermally with ablative lasers.
- The strength (concentration) of the peeling solution, the duration of the application, and the condition of the treated skin determine the depth of a chemical peel.

60 Facial Soft-Tissue Fillers and Neuromodulators

Anthony P. Sclafani and Anthony M. Sclafani

60.1 Introduction

Facial wrinkles may be a result of skin laxity, subcutaneous muscular contraction, volume loss, or dermal atrophy. Skin fillers were developed to help correct volume deficiency and focal dermal thinning. Other procedures, such as facelift and chemical or laser skin peel, address these issues only partially, and if performed overly aggressively, they may lead to a “tight,” “surgical” appearance. Silicone oil injections have had a lengthy if poorly controlled history as a facial treatment, in terms of both material and technique used. Beginning in 1981, a number of materials were introduced in the United States as facial wrinkle fillers, such as collagen, hyaluronic acid (HA) derivatives, calcium hydroxylapatite (CaHA) and poly-L-lactic acid (PLLA); many more materials are available worldwide, but reliable clinical evidence is somewhat lacking.

The neurotoxins commonly in use in the United States are all toxins isolated from *Clostridium botulinum* bacteria. Originally isolated in 1895, botulinum toxin A (BTxA) was first used in the 1970s for the treatment of strabismus. In 1992, its use for the treatment of periorcular wrinkles was first described; since then, BTxA has acquired a \$2 billion market worldwide.

Soft-tissue fillers and neurotoxins offer the potential to significantly rejuvenate the face with a minimally invasive approach, but they have risks and must be administered properly by adequately trained medical professionals.

60.2 Incidence of Disease

Skin aging due to dermal or soft-tissue atrophy or to hyperkinetic lines will occur to varying degrees, and each patient needs to be addressed individually. Generally, facial aging worsens with age. Hyperkinetic lines and shallow rhytids due to dermal atrophy may become noticeable during a person’s thirties, whereas soft-tissue atrophy and more severe rhytids may become noticeable only in a patient’s forties or fifties. Hyperkinetic lines, such as crow’s-feet (□ Fig. 60.1), may develop because of patterns of facial expressivity or involuntary muscle contraction. Patients with fair skin are more prone to these changes. Women, smokers, and individuals with frequent significant fluctuations in weight are also more likely to develop these signs of premature aging.

60.3 Terminology

The term rhytid refers to any skin wrinkle. Dermal atrophy, or thinning, usually is a result of repeated skin folding during animation and will manifest as a fine etched line. Skin folds, such as nasolabial folds, are due to an overhang of skin and soft tissue above a fixed point and may be due to skin and soft-tissue descent or to subdermal atrophy below the fold. Hyperkinetic lines (see □ Fig. 60.1) occur because elevated muscle tone prevents full relaxation of the overlying skin; over time, dermal atrophy may result from this, even in the absence of muscle contraction. Facial soft-tissue atrophy refers more broadly to the

different loss of soft-tissue (mainly fat) volume in the face. This volume loss will alter the shape of the face, lead to a loss of the gentle convexities of youth, skeletonize parts of the face (most notably the infraorbital rim), allow the facial skin to sag, and generally age the face. Soft-tissue fillers are generally categorized as either volumizers (effecting beneficial action by occupying space), stimulators (increasing facial volume by stimulating collagen deposition), or both.

60.4 Applied Anatomy

Clinically relevant muscles in the upper face include the frontalis, corrugator and depressor supercilii, procerus, and orbicularis oculi muscles; see Chapter 56 (Surgical Treatment of the Aging Face) for a more complete discussion. An important midfacial muscle is the zygomaticus major, originating from the medial malar arch and inserting on the modiolus. The levator labii superioris alaeque nasi muscle originates from the nasomaxillary junction and inserts on the dermis of the lateral ala and upper lip. The orbicularis oris muscle runs circumferentially to serve as the sphincter of the mouth. It interrelates with other perioral muscles at the modiolus and is attached to the dermis of the lips intimately, although a potential space exists between muscle and dermis at the vermilion border. In addition to the orbicularis muscle in the lower face, the mentalis originates from the mentum and inserts (often with a midline cleft) into the chin pad, while the depressor anguli oris originates from the medial mandible and assists in depressing and evert-ing the lateral lower lip.

There are multiple fat compartments in the face that are separated by delicate septa and may undergo atrophy or descent at different times and rates. Most significantly, the deep midfacial fat compartment may undergo early atrophy and produce significant facial aging.

Fig. 60.1 Crow’s-feet are caused by hypertonic contraction of the lateral orbicularis oculi muscle with folding of the overlying skin.

60.5 The Disease Process

60.5.1 Etiology

Dermal atrophy may be caused by genetic disorders such as cutis laxa or Ehlers-Danlos disease, but most dermal atrophy is a result of chronologic aging and photoaging. As the skin ages, the dermal collagen thins and loses its organization; the dermal rete pegs become more blunted. Photoaging, caused by damaging ultraviolet light, demonstrates elastin breakdown and can cause chronic heliodermatitis, marked by perivascular inflammation and extracellular pigment accumulation. These changes are clearly exacerbated by excessive sun exposure, tobacco use, and weight fluctuation. The exact mechanism of fat atrophy is unknown.

60.5.2 Disease Grading

The Glogau Wrinkle Scale can be used to classify the severity of facial wrinkles (see Box The Glogau Wrinkle Scale (p.476)).

The Glogau Wrinkle Scale

- I: No wrinkles
- II: Wrinkles in motion
- III: Wrinkles at rest
- IV: All wrinkles

60.6 Medical Evaluation

Before treatment, the skin should be evaluated. Treatments should not be performed in areas of active infection. New, non-inflammatory skin lesions should be examined, and referral to a dermatologist should be considered. A thorough medical history should be elicited, especially any medications taken or history of bruising or bleeding.

60.6.1 Presenting Complaints

Patients requesting treatment of facial rhytids and folds may complain about specific lines and folds but more commonly ask that “laugh lines,” “crow’s-feet,” or frown lines be treated. Alternatively, patients may be even less specific, requesting that a “sad,” “tired,” “angry,” or “gaunt” appearance be treated. The physician should help the patient to determine the specific deformities he or she finds most bothersome before initiating treatment.

60.6.2 Clinical Findings, Physical Examination

A complete aesthetic analysis is appropriate for each patient, even when the patient requests specific nonsurgical treatment. It is important for the physician to appreciate and point out to the patient the limitations of minimally invasive treatments. Rhytids should be assessed with the patient in animation as well as at rest; lines present at rest represent areas of dermal

and subdermal thinning, will not respond completely to neurotoxin treatment, and should be considered for soft-tissue augmentation.

60.7 Medical Treatment

60.7.1 Soft-Tissue Fillers

Most facial soft-tissue fillers are approved for the correction of facial wrinkles and folds, such as the nasolabial folds. Other common problems treated include forehead wrinkles and glabellar lines between the brows; so-called marionette folds (lines running from the mouth corners down the sides of the chin) and the prejowl sulcus (relative depression between the chin and jowl along the lower mandibular border) are also commonly treated. Lip volume augmentation was an early use for soft-tissue fillers; an expanding area of use now is for general facial (especially midfacial) volume restoration. Larger volumes can be injected into the cheek or temples and lateral brows (below or within the normal soft tissue) to restore facial fullness. Additionally, deeper injections can be placed at the posterior edge of the mandibular angle to better define the jawline.

Each filler has its own particular qualities and risks, and the specific material used should always be tailored to the intended site and application. In general, fillers with larger particles require deeper placement; a filler placed more superficially provides a greater degree of correction than a similar volume of a more deeply placed filler (□ Fig. 60.2).

Collagen

Zyderm and Zyplast, when available, were based on bovine collagen. Individual collagen fibers were treated to remove the most immunogenic peptide portion and then suspended in saline with (Zyplast) or without (Zyderm) chemical cross-linking to increase persistence of the effect. Patients treated with these bovine collagen-based fillers required allergy skin testing beforehand. Human collagen-based products (Cosmoderm and Cosmoplast) obviated the need for skin testing. Zyderm and Cosmoderm were injected into the mid dermis, whereas Zyplast and Cosmoplast required injection into the deep dermis or subdermis. Because the collagen fibers were suspended in saline, significant overcorrection was necessary to achieve the desired result after resorption of the water. The clinical effect of these materials persisted for 2 to 4 months. Porcine collagen, cross-linked into a three-dimensional matrix, was more recently introduced and provided a volumizing effect for up to 12 months, but all of these materials were removed from the market by their manufacturers.

Hyaluronic Acid Products

HAs were first approved in 2003 and have become the predominant class of soft-tissue filler. HA is a naturally occurring polysaccharide that gives resilience to the skin, but levels decrease with age. HA is highly conserved evolutionarily, and commercially available HA, produced by streptococci, is identical to human HA. This HA is treated to cross-link the polysaccharide chains and increase persistence of the clinical effect. As the thickness and viscosity of these materials increases, the depth

Fig. 60.2 Larger-particle soft-tissue fillers require placement in the deep dermis or subdermis.

of placement also increases, with thicker fillers placed at the dermal–subdermal junction to avoid vascular compromise and palpability. HAs can maintain a clinical effect for up to 12 months (□ Fig. 60.3). These fillers are predominantly “volumizers,” but there is some experimental evidence of the induction of neocollagen formation around the implants, which may explain subtle increases in persistence of the effect after multiple treatments.

Calcium Hydroxylapatite

Originally introduced as a bulking agent for the bladder neck, CaHA was later used for augmentation of the paralyzed vocal fold. CaHA was approved in 2006 by the FDA for the treatment of facial wrinkles and folds. CaHA microbeads are suspended in a gel carrier. After a subdermal injection, the gel carrier is resorbed and replaced over time by a small amount of fibrous tissue around the individual microbeads. Over time, the microspheres dissolve and are resorbed, but CaHA produces a clinical effect for 12 to 15 months.

Poly-L-Lactic Acid

PLLA was approved by the FDA in 2004 for patients with facial lipoatrophy as a result of highly active antiretroviral therapy (HAART) for HIV infection and was approved in 2009 for cosmetic facial uses. PLLA is provided as a sterile powder, which must be suspended and thoroughly mixed to avoid clumping. This is then injected subdermally, stimulating a fibrous response and thickening the dermis. Generally, three to six treatments, separated by intervals of 4 to 6 weeks, are necessary to produce clinically significant effects. Clinical benefit has been shown to persist for at least 24 months, at which time the PLLA beads are substantially resorbed and metabolized.

Silicone Oil

Silicone oil injections were popularized, and in some cases abused, from the 1940s to the 1960s. Currently, no silicone oil

is FDA-approved for cosmetic indications, and any treatments performed are so-called off label (see below). A large-scale review of silicone treatments by Webster et al showed that an appropriate microdroplet technique (injecting minute amounts in multiple sites and avoiding large deposits of material) could provide permanent correction of facial wrinkles safely and effectively. However, as a permanent filler, silicone oil injections are more prone to delayed complications, even several years or decades after treatment.

Injection Techniques

Soft-tissue fillers should be injected safely, with the compliance of the treated skin always taken into consideration and excessive injection as well as intravascular injury (especially in the glabella) avoided. Intradermal injections meet greater resistance and cause more immediate and visible skin change than do subdermal injections. In general, blanching of the skin or visibility of the needle through the skin indicates an injection that is too superficial. Injections can be done either with a series of individual skin punctures or by linearly threading the needle in the correct plane and injecting upon withdrawal. The edges of injected material should be “feathered” to blend in with the surrounding tissues and generally can be massaged to produce a smooth effect.

60.7.2 Neuromodulators

Currently, three commercially available botulinum toxin A (BTxA) products are approved for cosmetic facial indications: onabotulinum toxin (Botox Cosmetic; Allergan, Irvine, CA); abobotulinum toxin (Dysport; Medicis Pharmaceutical Corporation, Scottsdale, AZ); and incobotulinum toxin (Xeomin; Merz Pharmaceuticals, Greensboro, NC). All are BTxA preparations, but they differ slightly in associated properties and in how they are dosed. Botox, Dysport, and Xeomin units are different and not interchangeable. However, once injected, all associated proteins are released and the “naked” BTxA protein is liberated (Xeomin has no associated hemagglutinins). BTxA is composed of a

Fig. 60.3 (a) Deep nasolabial folds, marionette folds, and thin lips age the perioral area. (b) After treatment with a hyaluronic acid product, the lines have been smoothed and the mouth area rejuvenated.

heavy and a light chain joined by a disulfide bond. The heavy chain facilitates entry into the nerve ending; once it is internalized, a conformational change occurs, and the light chain of the molecule cleaves a portion of and inactivates soluble NSF attachment protein (SNAP)-25, a molecule essential for vesicle binding and acetylcholine release, as well as synaptobrevin and syntaxin. The process inactivates this particular synapse (□ Fig. 60.4). Over time, additional neural sprouting will allow the resumption of neuromuscular transmission. A number of points along the target muscle are treated, eliminating or decreasing muscle tone and eliminating muscle contraction. Weakening of the treated muscle generally becomes apparent

in 2 to 7 days, and the full effect may take up to 14 days (□ Fig. 60.5). Clinical effects typically last 3 to 4 months.

In the face, it is especially important to consider the effect of both target muscle tone and voluntary action, as well as the now-unopposed action of the target muscle's antagonist. The treatment of glabellar furrows (the only FDA-approved cosmetic use of BTxA) by injecting the depressor and corrugator supercilii and procerus muscles, or the effacement of crow's-feet by treating the lateral orbicularis oculi, will reduce or eliminate wrinkles in these areas but will allow frontalis contraction to alter the shape and position of the eyebrows; this can be done selectively to raise the brows and improve brow shape. The frontalis itself can be treated to eliminate transverse forehead rhytids; however, the frontalis muscle within 2 cm of the brows should not be treated to avoid a brow ptosis. Other muscles and areas treated include the levator labii superioris alaeque nasi to reduce an overly "gummy" smile, the depressor anguli oris to reduce the depth of marionette folds, the mentalis muscle to reduce wrinkles on the chin, and the paramedian platysma muscle to relax and efface platysmal bands.

60.8 FDA Considerations

It is important to remember that all soft-tissue fillers and neurotoxins approved by the U.S. Food and Drug Administration are indicated for specific purposes and locations. Properly trained physicians may use these materials in ways not specifically addressed by the FDA, but these uses are considered "off label." It is the physician's responsibility to be well trained, take proper precautions, use the materials in a way consistent with general medical practice and based on sound scientific reasoning, and discuss with the patient that the treatment is "off label." Common practice does not replace the need to discuss potential risks with each patient.

60.9 Postoperative Care

The soft-tissue fillers and neurotoxins described in this chapter are all considered minimally invasive treatments. These procedures are easily performed in the office with (at most) local or regional anesthesia. They are generally associated with little to no discomfort afterward. Typically, cold compresses are applied to the treated area for 30 minutes to a few hours after treatment. Generally, patients are advised to avoid manipulating the treatment area for 3 to 4 hours afterward. Patients treated with a neurotoxin are additionally advised to avoid head hanging or lying down for the same time period to avoid excessive spread of the toxin. Patients treated with PLLA are asked to massage the treated area several times a day for several weeks to minimize lumpiness.

60.10 Complications

60.10.1 Soft-Tissue Fillers

The injection of any material across the skin barrier may cause infection. Materials with a longer persistence of effect present

Fig. 60.4 Botulinum toxin A works at the motor end plate, inhibiting the release of acetylcholine by cleaving SNARE proteins. BN, botulinum neurotoxin; SNAP, soluble NSF attachment protein; SNARE, SNAP receptor.

greater problems when colonized by bacteria because a foreign body is present for a longer time; in these cases, treatment with antibiotics, often for several months, may be required. Allergic reactions to commonly used fillers (except bovine collagen) are rare. Migration of material is uncommon, but particulate fillers like CaHA and PLLA may form localized accumulations secondary to muscle contraction (especially in the lips) and should not be used in these areas. Intravascular injection or injections causing the constriction of arterial or venous flow in a localized area can lead to skin necrosis, most commonly seen in the glabella. Arterial occlusion causes immediate blanching of the skin. The injection should be stopped immediately if this is noted. Hyaluronidase should be injected to dissolve the injected material (if HA is being used). Warm compresses, topical nitroglycerin, and hyperbaric oxygen may be used to limit the degree of skin and soft-tissue necrosis if vascular occlusion is noted. Venous obstruction may also occur if the injected material compresses the venous outflow from a particular area. Venous occlusion is typically characterized by prolonged edema and ecchymosis with later (2 to 5 days) wound breakdown. Conservative wound care and patient support are essential to minimize tissue damage and patient anxiety if vascular occlusion occurs. Good technique and

aesthetic judgment are needed to ensure proper placement of the filler. Other potential complications include localized acne eruptions, cold sores, nodule formation, and asymmetry.

60.10.2 Neurotoxins

BTxA treatment is contraindicated in patients who are pregnant or breastfeeding and in those with preexisting neuromuscular disorders, such as myasthenia gravis. Inadvertent action on nontarget muscles can lead to facial distortion, asymmetry, or disability. Most commonly seen is eyelid ptosis (1 to 2%) as toxin injected into the glabella diffuses through the orbital septum to affect the levator palpebrae superioris. Eyelid ptosis typically lasts for only 2 to 3 weeks, even without treatment, but (if not contraindicated) the application of α -adrenergic eyedrops, such as 0.5% apraclonidine or 2.5% phenylephrine, will stimulate contraction of the Müller muscle to compensate for the loss of levator function. Excessive treatment of the medial frontalis with inadequate paralysis of the lateral frontalis can lead to the laterally overly arched “Mephisto” brow (□ Fig. 60.6). This is easily managed with supplemental BTxA treatment to the lateral frontalis, which will allow the lateral brow to drop into a

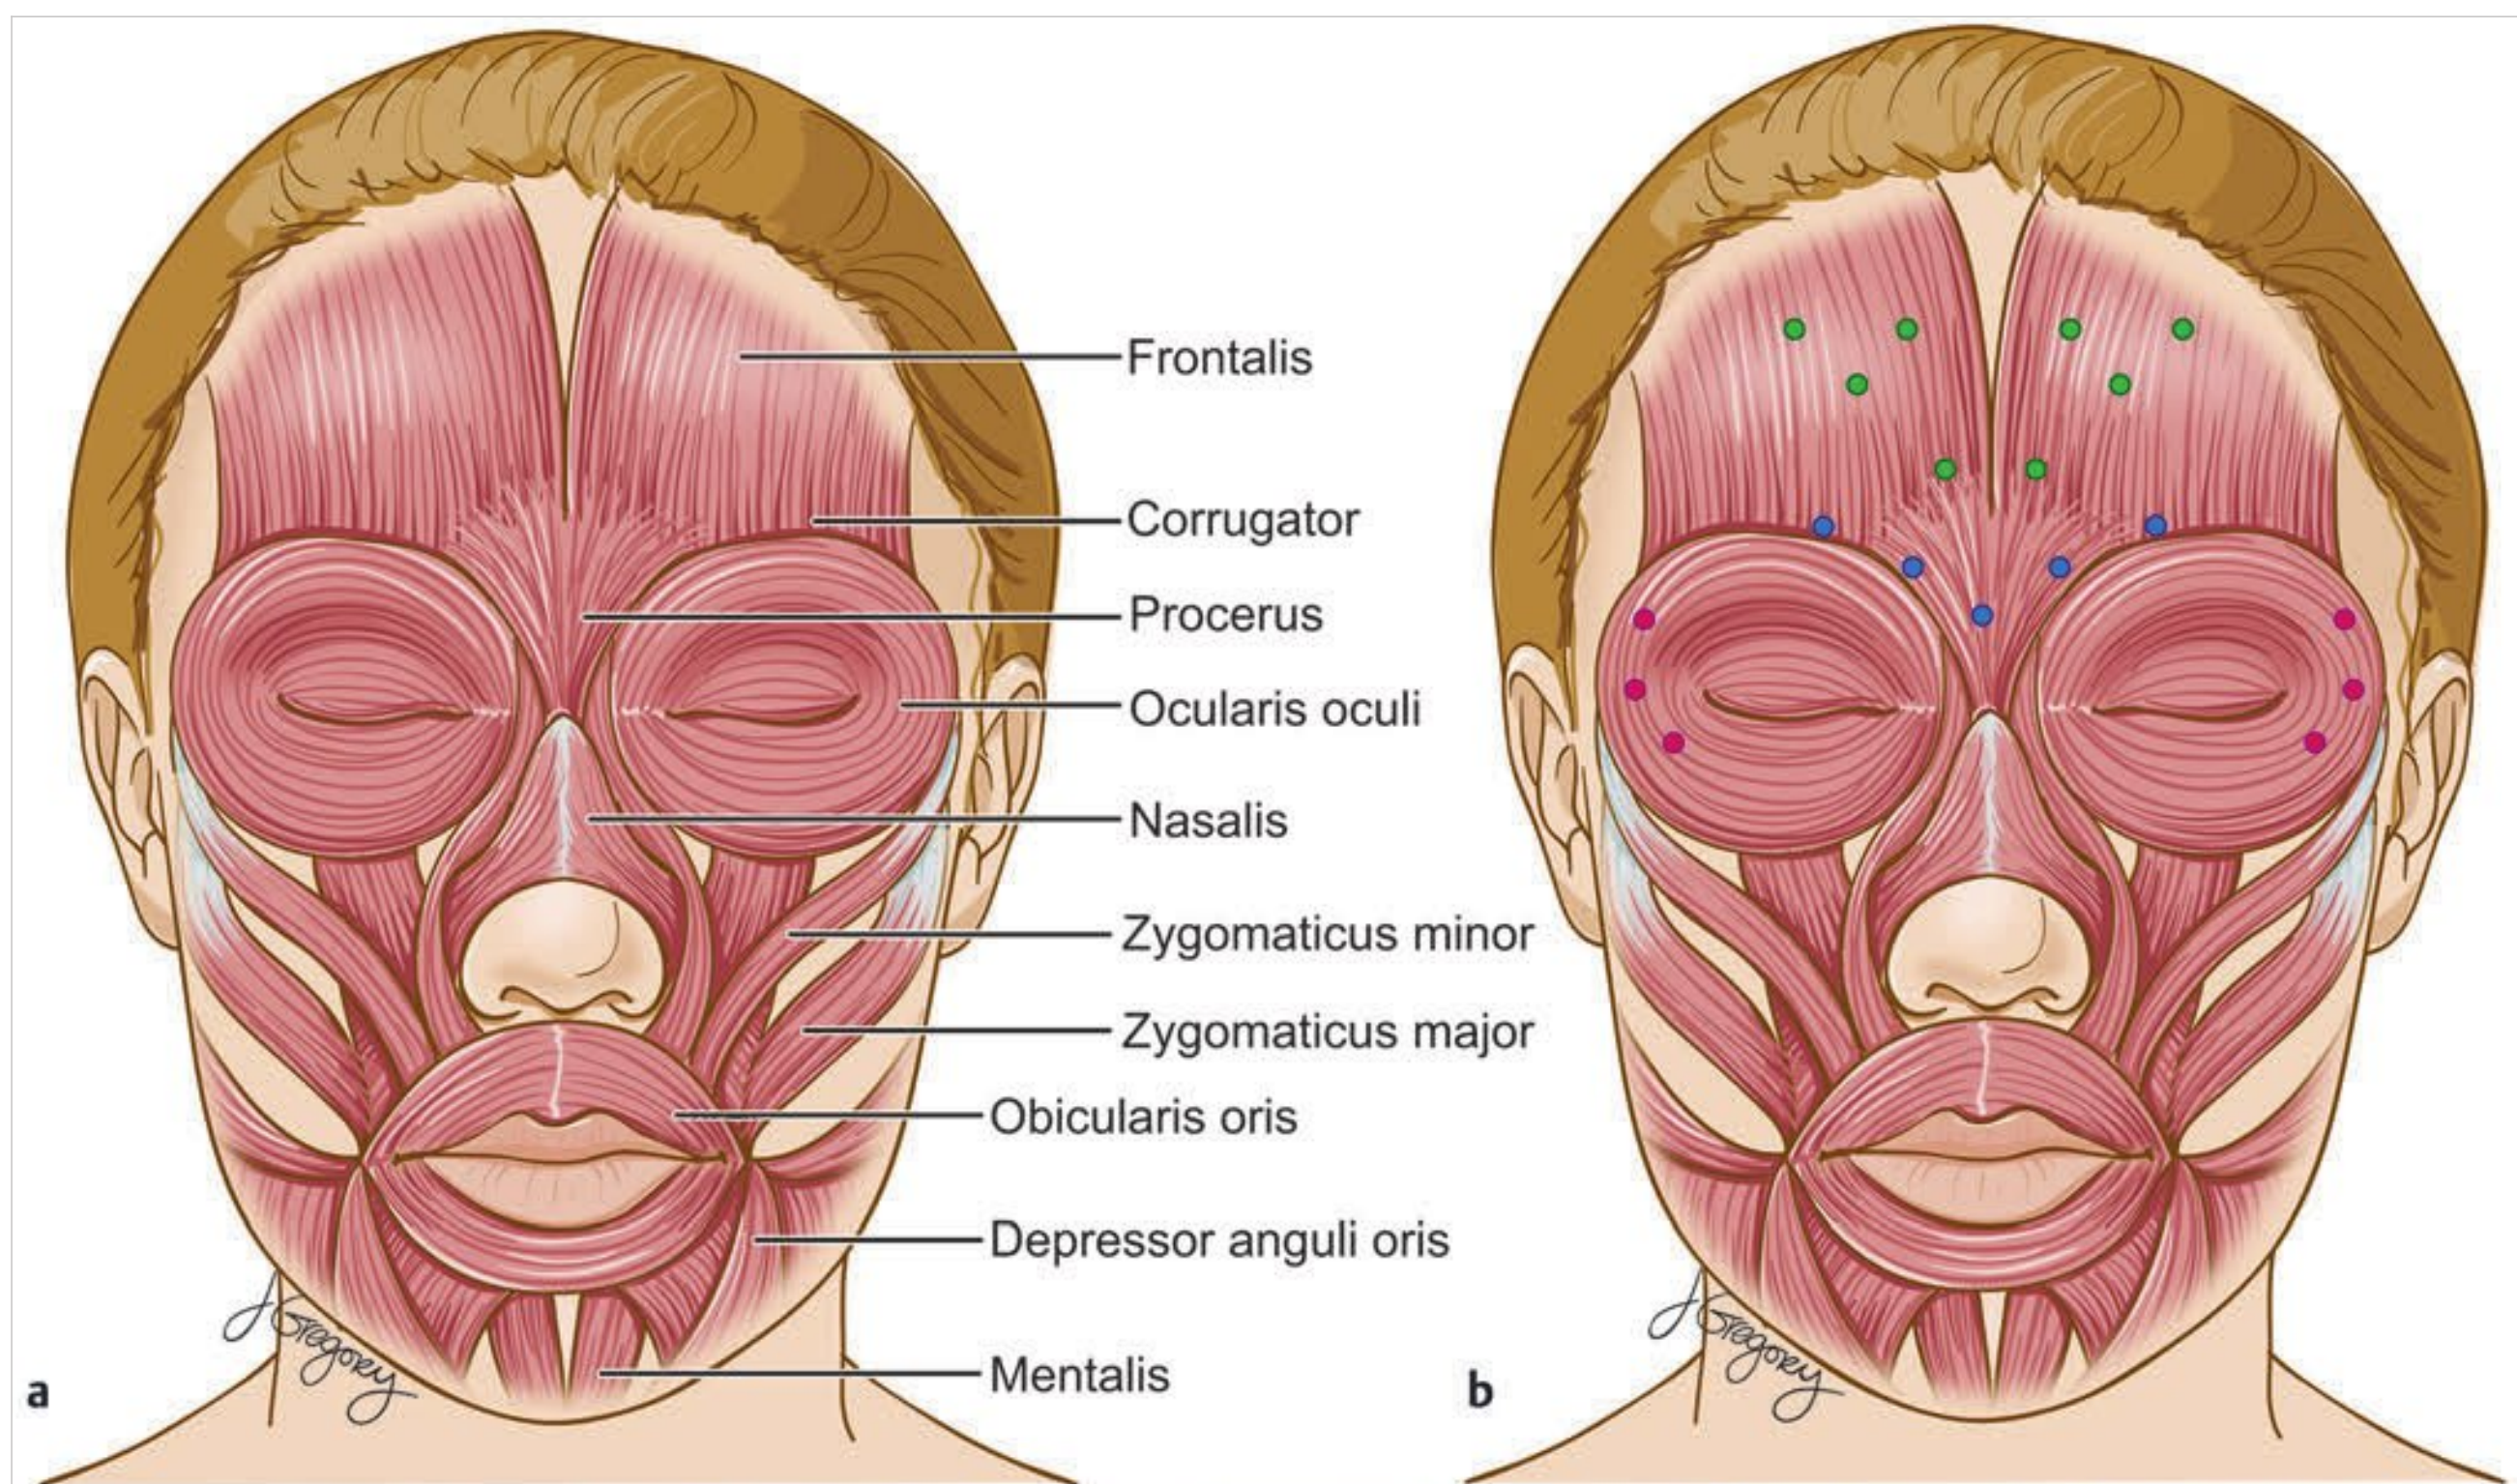

Fig. 60.5 (a) The facial muscles run in predictable, discernible areas in close proximity. Specifically targeting certain muscles can reduce hyperkinetic lines without altering resting facial expression. (b) Botulinum toxin A injections sites for horizontal frown lines (green dots), glabellar furrows (blue dots), and crow's-feet (red dots). (c) Hyperkinetic lines in the glabella and crow's-feet are created by contraction of the depressor and corrugator supercillii and procerus muscles and the orbicularis oculi muscle, respectively. (d) After treatment with botulinum toxin A in the glabella and the areas with crow's-feet, despite maximal effort the patient is unable to create rhytids. The patient declined treatment for "bunny lines" at the sides of the nose.

more appropriate position. The treatment of inferomedial crow's-feet may also paralyze the zygomaticus major muscle and alter the patient's smile. Dysphagia may occur if platysmal injections affect deeper muscles. Anti-BTxA antibodies may develop (generally associated with the much larger doses required to treat cervical dystonia) but do not seem to alter the clinical effect. Allergic reactions are uncommon.

60.11 Roundsmanship

- Soft-tissue fillers can smooth lines and change relative volumes in different facial units.
- Smaller-particle, less viscous fillers are appropriate for intradermal injections, whereas larger, more viscous fillers (typically longer-lasting) should be injected just below the dermis.

Fig. 60.6 (a) Before treatment with botulinum toxin A to the glabella at indicated sites. (b) Good result at rest after treatment of the glabella and forehead. (c) “Mephistopheles” brow due to an imbalance of medial and lateral frontalis muscle activity, which allows the lateral brow to be elevated disproportionately; correction is by treatment of the lateral frontalis muscle.

- Soft-tissue fillers can achieve volume augmentation by volumizing directly, by stimulating a fibrous response that augments dermal thickness, or both.
- Botulinum A toxin acts by inhibiting presynaptic acetylcholine release and produces a localized flaccid paralysis.
- Recovery after botulinum toxin A treatment occurs by the sprouting of additional neuronal twigs.

61 The Evolution of Pediatric Otolaryngology–Head and Neck Surgery

Robin A. Dyleski

The specialty of otolaryngology encompasses the medical and surgical management of diseases and conditions involving the head and neck. In recent years, the specialty has branched out into various areas of interest, such as facial plastic and reconstructive surgery, otology and neurotology, otolaryngic allergy, voice and laryngology, rhinology, head and neck cancer, and pediatric otolaryngology. Each of these subspecialties evolved to fill a niche created by various advances in technology and the need for dedicated specialists with distinct areas of expertise to care for certain subsets of patients.

Pediatric otolaryngology is a relatively new subspecialty, formally recognized for the last 25 to 30 years. It is a field dedicated to providing care mainly to infants and children younger than 18 years of age. Fellowship training in pediatric otolaryngology has been available in a formal manner for the last two to three decades; previously, this training was available only as an apprenticeship or as a focused interest. Although there has been interest in the care of otolaryngologic problems in children for decades (with pediatric patients comprising a large component of the typical general otolaryngologist's practice), pediatric otolaryngology took hold as a recognized subspecialty as a consequence of technologic advances in the survival of preterm newborns. These paralleled the development of dedicated children's hospitals providing subspecialized pediatric care in anesthesiology, cardiothoracic surgery, pulmonary medicine, critical care medicine, neonatology, and genetics to address the unique problems of sick children. Advances in neonatal medicine have saved the lives of many children who would not otherwise have survived but have left them with secondary problems.

Pharmacologic and technical advances have been instrumental in the development of pediatric otolaryngology as a subspecialty. The introduction of mechanical ventilators and advanced monitoring equipment for use in children in the early 1960s was an important step leading to the development of pediatric

intensive care units. This progress in pediatric critical care led to the use of prolonged oral and nasotracheal intubation in infants and children instead of the then-standard tracheotomy with mechanical ventilation. As a result, otolaryngologists specializing in pediatric care became indispensable to physicians specializing in pediatric critical care for managing their patients' airways. The rising use of prolonged endotracheal intubation in the 1960s and 1970s was associated with increased rates of subglottic stenosis in these sick children.

The management of children with subglottic stenosis was radicalized with advances in endoscopic evaluation technology. In the mid 1960s, Harold H. Hopkins in England and Karl Storz in Germany collaborated to devise a unique rod–lens optical system in which fiber optics were used to transport light. A series of glass rods improved resolution and provided a brighter illumination system, resulting in a smaller-diameter instrument with a wider viewing angle. Hopkins and Storz introduced the new illumination system into pediatric bronchoscopy in 1968.

One of the pioneers in endoscopy in the United States, Dr. Sylvan Stool, was given a set of these new endoscopic instruments by Dr. C. Everett Koop (later to become the U.S. Surgeon General) in Philadelphia. Soon afterward, airway endoscopy in children was revolutionized by these instruments, and the development of accessories such as specialized endoscopic scissors and forceps (including optical forceps in which a telescope was incorporated) made possible procedures and interventions that could not have been performed previously. Advanced light sources, endoscopic cameras (allowing video and digital capture of the procedure and digital photo documentation), and microinstruments have permitted improvements in care and are routinely used today. Today's modern laryngoscopes, bronchoscopes, forceps, and cameras have brought pediatric otolaryngology to its current level.

62 The Otolaryngologic Examination of Children

Robin A Dyleski

62.1 Introduction

As in all areas of otolaryngology, an appropriately detailed and focused history and examination are the basis of an accurate diagnosis and the subsequent treatment of pediatric illnesses and diseases. Because of the inability of many young children to readily and accurately communicate their symptoms and reliance upon their caregivers for this information, this information may be difficult to acquire. In addition, although the pediatric patient's examination is basically similar to the head and neck examination in older children and adults, there are a number of ways in which the examination of young children can be facilitated to make the process easier for the child, caregiver, and examiner.

62.2 Approaching the Young Patient

Many children are frightened by a visit to a doctor's office, and an otolaryngologist's office is no different, especially given the amount of unfamiliar equipment and instruments that are often visible in the otolaryngologist's examining room. Engaging the young child and gentle reassurance at the outset of the encounter is often calming and leads to great rewards during the examination phase.

With some children, no special approach will be needed, whereas others will favorably respond to explanations of what each of our diagnostic tools is and how they work. When a non-threatening approach is used, the child can be fully examined without the examination becoming a traumatic event for all.

62.3 The Examination

Many physicians will proceed with the examination after obtaining the history, review of systems, and related family and social histories. The examination of the pediatric patient begins during the verbal parts of the encounter. Important facets of the child's condition should be observed, such as the following: presence and quality of the child's speech, the child's interactions with others, his or her breathing pattern while awake or asleep, the presence of stridor and other airway noises, possible swallowing functions for liquids and/or solids (snacks), and gait. These components sometimes can be observed only in a clandestine manner because children are highly likely not to speak when you need to hear their voice or speech, diminishing the information obtained in the examination.

62.3.1 Conducting the Examination

Although many children will readily sit in the examination chair themselves, others will require assistance from their caregiver. Many children will have to be held on the parent's lap for reassurance, and the parent's assistance may be needed for restraining them, so that the examination can proceed and the

children will be prevented from becoming injured if they are unable to remain still. There are a number of ways that children can be held to facilitate their examination.

The basic position for a child during examination is seated across one parent's thigh. If necessary, the child's legs can be restrained by the parent's thighs by having the parent cross his or her ankles; at the same time, the child's torso and arms are held with one hand and the head is steadied against the parent's chest by the parent's other hand. This technique can be used for infants and relatively calm children until the age of 4 or 5 years during many therapeutic maneuvers (cerumen removal) and diagnostic evaluations (fiber-optic laryngoscopy). When a child who is completely uncooperative with the examination is much older than 4 or 5 years, it becomes increasingly difficult to "hold" him or her in this way.

Other, more constraining apparatus is available for children who cannot be suitably held with the "parent lap hold" technique. In one method used for smaller children, a sheet is used to wrap their arms and legs close to the body in "papoose" style. This device consists of a board on which the patient is placed with the arms by the sides; strong Velcro straps are wrapped over and immobilize the patient. The papoose maneuver gives ready access to the head, which is carefully stabilized by a parent or nurse to allow the uncooperative child to be treated or examined. Wrapping the child snugly in a sheet often can provide similar results. With the child stabilized, the examination or even minor procedures may proceed safely without inadvertent injury to the moving child.

62.3.2 Otologic Examination

Most pediatric otolaryngologic examinations include a thorough examination of the outer ear, ear canal, and tympanic membrane with a hand-held otoscope—either an operating otoscope or a pneumatic otoscope with an insufflation bulb. Regardless of which is chosen, the otoscope is held with the first three fingers, while the fourth and fifth finger are braced against the child's temple (□ Fig. 62.1). Should the child move suddenly, the instrument cannot penetrate more deeply into the canal.

The insufflating otoscope is the preferred instrument because it allows evaluation of the mobility of the tympanic membrane and enhances the detection of middle ear effusions. A tuning fork evaluation of hearing and the Weber and Rinne tests are performed in older children with suspected hearing impairment, as indicated. Microscopic examination is performed when indicated.

62.3.3 Nasal Examination

The nasal examination is usually performed via anterior rhinoscopy; often, the otoscope with either the nasal tip or the large ear speculum is used. Attention to the size, color, and contour of the turbinates, septum, secretions, and nasal airway patency are important facets of the nasal examination in children. The

Fig. 62.1 The hand holding the otoscope is braced against the temple, maintaining the distance between the instrument and the ear.

examination may include a comparison of nasal examinations in the decongested and nondecongested states. Observation for intranasal secretions, prominent blood vessels, polyps, masses, and foreign bodies is made. In some children, flexible nasopharyngoscopy may be needed to visualize completely the nasal and nasopharyngeal structures.

62.3.4 Oral Examination

The oral examination includes inspection of the lips, mucosal surfaces, tongue, floor of the mouth, and oropharynx. This may be performed with a flashlight or headlight. Generally, children are cooperative with this part of the examination and readily open the mouth in anticipation of the “tongue stick.” Tongue shape and movement, the floor of the mouth, palatine tonsil size, uvula shape, and soft palate contour and mobility are noted. The superior aspect of the epiglottis is often seen during the normal oral examination in children.

62.3.5 Neck Examination

The neck examination in children focuses on the presence of any swellings, masses, or asymmetries. The location, firmness, mobility, and size of any mass are noted. Lymph node size, consistency, and position are compared with those in the opposite side of the neck. The thyroid gland is palpated for enlargement and masses. The neck skin is inspected for any congenital lesions, pits, or sinus tracts.

62.3.6 Airway Examination

The laryngeal and hypopharyngeal airway is examined when indicated with flexible fiber-optic laryngoscopy. This is safely accomplished in children in the office setting through either an anesthetized nostril or the oral cavity (in infants without teeth). The flexible fiber-optic laryngoscope may also be used to inspect the nose and nasopharynx for masses, polyps, and adenoid size. The procedure usually will require the child to be restrained by the parent, papoose board, or a sheet wrapped around the child. This is the most invasive portion of the head and neck examination and will require that older children be able to remain still during the examination. An explanation of the process and the adequate use of topical nasal anesthetics are usually all that is necessary for older children to permit the examination to proceed.

The entire airway from the nostrils to the subglottic area can be visualized with the fiber-optic laryngoscope. The color and condition of the mucosal membranes, the presence of any masses, and the configuration and appearance of the nasal structures, adenoids, eustachian tube orifices, oropharynx, hypopharynx, and larynx should all be assessed in this examination.

62.4 Roundsmanship

- The pediatric ear, nose, and throat (ENT) examination should include observation of the child while the history is being elicited, when details of the patient’s speech, apparent hearing, gait and coordination, swallowing, and breathing can be assessed.
- The pediatric ENT examination should be performed in a calm, nonthreatening manner.
- An uncooperative patient can be restrained by the caregiver or a papoose to prevent inadvertent injury to the patient and allow the examination to proceed.
- Parts of the examination requiring restraint should be reserved for the end of the evaluation.

63 Special Considerations in Pediatric Anesthesiology

Rebecca L. Bagdonas

63.1 Introduction

Pediatric anesthesiology encompasses the pre-, intra-, and post-operative care of neonates through adolescence. Although many anesthetic techniques and pharmacologic agents are the same in both pediatric and adult populations, there are many differences with regard to their use and application. Children differ from adults in many respects, including anatomy, physiology, and most commonly seen diseases. In the care of a child, consideration of the concerns of the parent plays an important role because the interaction with the child's parent can be even more complex than the interaction with an adult patient.

63.2 Preoperative Concerns

The immune system of the young child is not fully developed, making children more susceptible to communicable diseases such as upper respiratory infections, strep throat, conjunctivitis, and otitis media. Often, these diseases are the very reason for the operative procedure (e.g., tonsillectomy or the placement of tympanostomy tubes).

Upper and lower respiratory tract infections, even 2 to 4 weeks before surgery, often lead to an increase in airway secretions, hypoxemia, and airway hyperreactivity, raising the risk for intraoperative laryngospasm and bronchospasm. The duration and symptoms of these common viral infections must always be evaluated because the severity of the upper respiratory symptoms may mean the difference between proceeding with and postponing the surgery. Additionally, an assessment of the child's birth history, including method of delivery (vaginal vs cesarean delivery, with reasons for the latter), prematurity versus full-term gestation, birth weight, perinatal hospitalization (including neonatal intensive care), and any genetic, cardiac, or pulmonary conditions, is of the utmost importance in planning safe anesthesia. It is important to determine if the patient has had any problems with prior anesthetics or if there are familial problems with anesthesia, especially symptoms compatible with malignant hyperthermia.

63.3 Pediatric Airway Anatomy, Metabolism, and Anesthetic Agents

The general shape of the pediatric airway is different from that of the adult airway. The pediatric airway is more conical than the adult airway, which is more cylindrical. In children, the airway is positioned more anteriorly and cephalad. The pediatric larynx and epiglottic cartilage are thinner and more collapsible. The narrowest point in the larynx of a child is at the cricoid cartilage (until the age of 5 years), as opposed to the vocal cords in an adult. Infants have a relatively large tongue for the size of their mouth and a relatively larger occiput, which can make positioning for airway support more difficult. In addition, neonates have fewer lung alveoli, decreased lung compliance, and

increased chest wall compliance, which lead to decreased lung functional residual capacity (FRC) and resultant decreased oxygen reserves, culminating in hypoxemia and atelectasis during periods of apnea.

Alveolar ventilation in neonates, infants, and toddlers is greater than in adults. This, combined with increased blood flow to vessel-rich organs such as the brain and heart, leads to faster induction with inhaled anesthetics and a more rapid emergence from anesthesia. The minimum alveolar concentration (MAC) of inhaled anesthetics is at a peak in the infant period. The MAC decreases from infancy onward.

Cardiac output in neonates and infants relies on the heart rate, as opposed to the stroke volume. The pediatric patient has a relatively immature and noncompliant left ventricle that is unable to increase the cardiac output. The heart rate is more significant than the mean arterial blood pressure. The heart rate peaks in the neonatal period; rates of 120 to 160 beats/min are normal. The normal heart rate decreases as the child ages, with heart rates of 100 to 120 beats/min observed in infants and of 80 to 100 beats/min in 3- to 5-year-olds.

Temperature regulation is extremely important in children. The ratio of body surface area to weight is increased in neonates, and they have few fat stores; these characteristics, combined with the cold environment of the operating room and unheated anesthetic gases, render them more susceptible to hypothermia. It is important to monitor the body core temperature with a temperature monitor, to use body-warming devices like the Bair hugger blanket (Arizant, Eden Prairie, MN), and to warm the ambient operating room temperature for these patients. Hypothermia results in respiratory depression, delayed emergence/awakening from anesthesia, and increased pulmonary vascular resistance. The anesthesiologist must also monitor the patient for hyperthermia, or unexpected increase in body core temperature. Hyperthermia is an important indicator of malignant hyperthermia (although it is usually a late sign in the development of the disease).

Separation anxiety and generalized fear of the operating room are common in the pediatric population. Thus, many hospitals and ambulatory surgery centers permit the child's parent to be present during the induction of general anesthesia ("parent-present induction"). The parent's role is to reassure the child in the unfamiliar operating room environment, which permits a calmer and smoother anesthetic experience for the child. In some cases, a preoperative sedative may be used, such as midazolam (0.5 mg/kg orally 30 minutes before the procedure), to calm the child. This is commonly done for children with a high level of anxiety or for those with certain medical conditions, such as congenital heart disease. Another option is intramuscular ketamine for highly anxious children.

63.4 Intraoperative Management

Standard anesthesia monitoring is applied for all pediatric patients and includes three- or five-lead electrocardiography, pulse oximetry, noninvasive blood pressure monitoring,

capnography, and temperature monitoring. Inhalational induction is administered by face mask with a combination of oxygen, nitrous oxide, and anesthetic gas. Sevoflurane is the most commonly used volatile anesthetic; it provides a smoother induction because it is less likely to cause airway irritability and cough than the other volatile anesthetics. After the child is asleep, the intravenous (IV) line is placed (especially in ambulatory patients), and other medications, such as atropine, analgesics/narcotics, and propofol, are administered before endotracheal intubation.

It is important to use the proper size of endotracheal tube in children because airway irritation and swelling from the use of an oversized tube leads to increased airway resistance after extubation. Uncuffed endotracheal tubes are often used in pediatric patients for this reason. The leak around the endotracheal tube is confirmed and optimally is between 18 and 24 cm H₂O. General formulas for endotracheal tube size include $(4 + \text{age})/4$ or a size similar to the size of the distal phalanx of the pinky finger. After the endotracheal tube is secured, the patient's eyes are taped closed, the stomach is decompressed with a catheter, and all pressure points are padded.

A commonly used neuromuscular relaxant, succinylcholine, is much less frequently used in pediatric than in adult patients. Although it is a reliable depolarizing muscle relaxant and can quickly terminate laryngospasm, it is much more likely in children to cause hyperkalemia, rhabdomyolysis, muscle/masseter spasm, and cardiac arrhythmias (including bradycardia leading to cardiac arrest). It is also known to be a triggering agent in malignant hyperthermia.

The maintenance of anesthesia involves IV fluid management, the administration of inhalational gases, and the IV administration of medications such as antibiotics, steroids, antiemetics, and narcotics. Fluid management is crucial in pediatric cases because there is a slim margin of error in pediatric fluid balance. The calculation of maintenance fluids in children is based upon the patient's weight. The 4–2–1 rule is followed for all cases of standard pediatric fluid maintenance and for determining the fluid deficit incurred while the child's status is NPO (nil per os): 4 mL/kg/h for the first 10 kg + 2 mL/kg/h for the next 10 kg + 1 mL/kg/h for weight over 20 kg.

In neonates, hypovolemia manifests as hypotension, but without concurrent tachycardia. Neonates also require dextrose in their IV fluids, whereas older infants and children can receive isotonic fluids, such as lactated Ringer solution or normal saline. Excess free water, associated with hypotonic fluids, can easily lead to hyponatremia, seizures, coma, and death if liberally administered, especially when there is a protracted loss of electrolyte-rich fluids (e.g., prolonged emesis).

As the surgical procedure nears completion, preparations are made for emergence and extubation. Narcotics may be titrated; the patient is weaned off the ventilator, spontaneous ventilation resumes, and reversal agents for muscle relaxation agents are given (if appropriate). It is extremely important to extubate the patient while either deeply anesthetized or in the fully awakened state to decrease the risk for laryngospasm (spasm of the laryngeal musculature that can lead to total airway obstruction). The in-between stage of anesthesia, often referred to as "stage II," is a dangerous time for extubating the patient because the airway is the most reactive at this time. IV lidocaine (1 mg/kg) is also beneficial to decrease the likelihood of laryngospasm.

If laryngospasm occurs, positive-pressure ventilation via mask is applied and will frequently cause the episode to cease. If the laryngospasm is refractory to positive pressure, succinylcholine may be given as a rescue drug. Once the airway patency is reestablished and ventilation restored, the patient is observed as oxygen saturation is maintained without support and taken to the postanesthesia care unit (PACU). In the PACU, the monitors are replaced, supplemental oxygen is given, and the vital signs are closely monitored.

Children undergo ambulatory surgery more commonly than in the past, when inpatient stays were frequent. Postoperative discharge criteria include adequate pain control, absence of nausea and vomiting, ability to void and ambulate, and adequate oral intake of fluids. Special consideration is given to premature and very young infants. Premature children who are less than 46 weeks past conception age are at increased risk for central apnea after general anesthesia because of the immature neurologic development of premature children. These patients require airway monitoring for at least 12 hours after anesthesia. When the child is between 46 and 60 weeks past conception age, the required monitoring period is at least 6 hours unless there are coexisting significant neurologic, cardiac, or pulmonary conditions, which require at least 12 hours of observation.

63.5 Pain Management

Many drugs in the pain management arsenal for adults may be used in the pediatric population. These medications include fentanyl, morphine, codeine, and oxycodone. Oxycodone is an excellent oral medication for children who require postoperative pain management. Acetaminophen is frequently given as a rectal suppository (30 to 40 mg/kg) at the time of induction and is noted to reduce narcotic requirements postoperatively. Codeine may be administered either orally (with or without acetaminophen) or rectally at a dose of 1 mg/kg every 6 hours as needed. Up to 10% of people lack the enzyme required to convert codeine into morphine, so that the effectiveness of codeine is not uniform, and this must be considered in patients whose pain is inadequately controlled with codeine. Conversely, an estimated 1 to 7% of patients are "ultra-high metabolizers," with DNA mutations in cytochrome P-450 2D6 that enhance the conversion of codeine to morphine and lead to elevated blood levels of morphine; the minimum doses of codeine should be used, especially in patients undergoing adenotonsillectomy for obstructive symptoms.

63.6 Fasting and NPO Guidelines

The preoperative fasting status (nil per os, or NPO) is very different in children than in adults. In general, patients are kept NPO to decrease the risk for aspiration and pulmonary complications during anesthesia. Neonates and infants up to 3 years old are physiologically more prone to dehydration and hypovolemia than older children are, and therefore their NPO requirements are shorter to reduce the risk for significant dehydration during the fasting period. Babies may be given clear liquids such as water, Pedialyte (Abbott Laboratories, Columbus, OH), or clear apple juice up to 2 hours before the onset of general anesthesia; this has been demonstrated to increase gastric

Table 63.1 NPO guidelines for children undergoing general anesthesia

Patient age	Clear liquids	Breast milk	Formula/full liquids
Birth–6 months	2 h	4 h	6 h
6–36 months	2 h	6 h	6 h
>36 months	2 h	6 h	6–8 h

emptying, leading to a lower gastric residual volume and lower risk for aspiration. Human breast milk is also quickly absorbed and moved from the stomach into the small intestine; it requires a 4-hour fasting period. Infant formula and nonhuman milk require a 6-hour NPO period in children up to 36 months old. At 36 months and older, children are expected to fast for a minimum of 8 hours for all full liquids (such as milk) and all solids; however, clear liquids (in limited quantities) may be given up to 2 hours before the anesthetic (□ Table 63.1).

63.7 Complications of Anesthesia

The most commonly seen complications in the pediatric population are respiratory in origin, with laryngospasm encountered most often. Other potential perioperative problems in children undergoing anesthesia include bronchospasm, “postintubation croup,” and negative-pressure pulmonary edema (also called postoperative pulmonary edema, or POPE). Bronchospasm is an abnormal spasm or constriction of the bronchi and bronchioles. Bronchospasm is often seen in persons who have hyperreactive irritable airways, with patients who have asthma and those who have had a recent viral respiratory illness at greatest risk. It manifests with wheezing, hypoxemia, and poor ventilation despite an adequate airway because it is due to spasm in the bronchi and larger bronchioles. Bronchospasm is treated with inhaled bronchodilators and the subcutaneous injection of terbutaline, a β_2 -agonist. In refractory cases, an isoproterenol infusion can be used to break the airway spasm, in addition to the continued administration of inhaled anesthetic agents, which have potent bronchodilator properties.

“Postintubation croup” predominantly affects children ages 1 to 4 years and manifests as inspiratory stridor and a harsh cough following intubation for a surgical procedure. It is caused by localized edema or mucosal swelling in the airway, primarily subglottic, resulting from the presence of the endotracheal tube. In most cases it is self-limited and may respond to nebulized racemic epinephrine or IV steroids. The risk for postintubation croup increases with the use of inappropriately large endotracheal tubes, repeated attempts at intubation with subsequent airway trauma, repeated manipulation of the endotracheal tube, relatively long surgical procedures, and certain head and neck procedures.

Negative-pressure pulmonary edema (POPE) is an uncommon, potentially life-threatening condition caused by upper airway obstruction. POPE occurs most often during the induction of or emergence from anesthesia and affects mostly healthy patients without underlying cardiopulmonary pathology. It is estimated to occur in up to 10 to 15% of patients who have an episode of upper airway obstruction requiring intervention.

Risk factors for upper airway obstruction include a history of obstructive sleep apnea, the presence of known airway lesions, and anatomically difficult intubations, as well as nasal, oral, and laryngeal surgical procedures. POPE results from the generation of a highly negative intrathoracic pressure by forceful inspiration against an obstructed airway or closed glottis (sometimes from laryngospasm). The result of the negative intrathoracic pressure is a transudation of pulmonary interstitial fluid into the alveolar space. Signs and symptoms of respiratory distress include oxygen desaturation, hypoxemia, and chest retractions. Copious pink, frothy secretions and sputum are the hallmark of POPE and are seen in the endotracheal tube. Rales and wheezing are heard on auscultation, secondary to the fluid-filled airways. Tachycardia, bradycardia, hypertension, and diaphoresis are also often present. A chest X-ray demonstrates diffuse, bilateral interstitial and alveolar infiltrates and areas of “whiteout” in the lung fields. POPE is treated with supplemental oxygen, positive-pressure ventilation using positive end-expiratory pressure (PEEP) in intubated patients, or continuous positive airway pressure (CPAP) in extubated patients. The routine administration of diuretics has not been proved to correct POPE, but it may aid in the management of systemic fluid overload. The main goals are to reverse hypoxemia and decrease the fluid in the lungs. Resolution is usually rapid after diagnosis and the start of treatment, and most cases resolve within 24 hours or sooner. Prompt diagnosis and treatment are essential to avoid long-term sequelae.

63.8 Surgery-Specific Anesthesia Concerns

Tonsillectomy and adenoidectomy: Although it is such a common operation, children undergoing tonsillectomy and adenoidectomy (T+A) are at high risk for perioperative airway problems. The T+A procedure is best performed when the child is as free from respiratory symptoms as possible, and postponement is recommended if the patient has an acute infection or upper respiratory infection. Major complication of T+A include postoperative bleeding, laryngospasm, and POPE. Postoperative bleeding from the tonsillar fossa is a true emergency, and control of the hemorrhage is mandatory, with general anesthesia usually required. Patients with oropharyngeal hemorrhage are treated as though they have a full stomach and undergo rapid-sequence induction to minimize the risk for aspiration. After the airway is secured and the hemorrhage controlled, the stomach is suctioned to reduce the risk for aspiration at extubation.

Tympanostomy tubes: The induction of anesthesia via inhalation and the maintenance of anesthesia with a face mask comprise the technique usually used for the placement of tympanostomy tubes in children. Depending upon the presence of comorbid conditions and the ease or difficulty of face mask ventilation in the child, the placement of an IV line may be needed for the administration of medication.

Emergence delirium: Emergence delirium is seen in the pediatric population and is a side effect of sevoflurane administration. Studies have shown that the administration of IV propofol at the end of the case after the termination of sevoflurane will reduce the likelihood of emergence delirium.

63.9 Roundsmanship

- The normal neonatal heart rate is 120 to 160 beats/min; in infants, the normal rate is between 100 and 120 beats/min, while the normal heart rate of 3- to 5-year-olds is 80 to 100 beats/min.
- Endotracheal tube selection for children is approximated by the formula $(4 + \text{age})/4$.
- Standard pediatric fluid maintenance for children with NPO status is calculated as follows: 4 mL/kg/h for the first 10 kg + 2 mL/kg/h for the next 10 kg + 1 mL/kg/h for weight over 20 kg.
- Premature children who are less than 46 weeks past conception age are at increased risk for central apnea after general anesthesia and require airway monitoring for at least 12 hours after anesthesia. Children between 46 and 60 weeks past conception age should be monitored postoperatively for at least 6 hours unless they have coexisting significant neurologic, cardiac, or pulmonary conditions, which require at least 12 hours of observation.
- Bronchospasm is treated with inhaled bronchodilators and the subcutaneous injection of terbutaline. In refractory cases, isoproterenol infusion can be used to break the airway spasm.
- Postoperative pulmonary edema (POPE) is treated with supplemental oxygen, positive-pressure ventilation using

positive end-expiratory pressure (PEEP) if the patient is intubated, or continuous positive airway pressure (CPAP) if patient has been extubated.

64 Common Genetic Syndromes in Otolaryngology

Morgan R. Bliss, Harlan R. Muntz, and Alan F. Rope

64.1 Introduction

A syndrome is a nonrandom pattern of anomalies that can be attributed to an identifiable genetic or environmental etiology or is heritable. A syndrome may have more than one etiology, with dozens of genes identified that are connected to that syndrome. No single feature is ever pathognomonic for a syndrome because syndromes are characterized by variable expression. The human genome consists of 46 human chromosomes containing approximately 23,000 protein-encoding genes, and knowledge of the pathophysiology of genetic syndromes is rapidly improving. Some syndromes have yet to be named. The initial definition of a syndrome requires astute observers to publish case series or reports of individuals with multiple anomalies. Most consider an anomaly to be associated with a syndrome if it occurs in 10 to 15% of individuals with the syndrome.

One study showed that in 119 infants with multiple congenital anomalies involving otolaryngologic defects, 51% were due to an unknown cause, 25% to a chromosomal anomaly, 10% to an identified mendelian condition, 3% to a known exposure to a teratogen, and 10% to a recognized pattern of defects of unknown cause. In mendelian inheritance, monogenic dominant or recessive traits are inherited from parents in a predictable manner. Recessive traits require two alleles for expression, whereas dominant traits are expressed if one allele is inherited. X-linked traits may be dominant or recessive, but they will be expressed in males regardless of whether they are dominant because males have a single X chromosome. The trait will be expressed in females with two recessive X-linked alleles.

Most genetic disorders are polygenic and multifactorial and do not demonstrate mendelian inheritance patterns. Another reason for alterations in expected mendelian inheritance is incomplete penetrance. Penetrance is the proportion of individuals carrying a specific genotype who demonstrate the expected phenotype. Incomplete penetrance may be due to environmental factors or to other genes that regulate the expression of one gene. Variable expression of genes also complicates the picture of genetic heritability. Variable expression can cause differing phenotypes in individuals with the same genotype.

The otolaryngologist is an integral part of the multidisciplinary team required to optimally treat patients with genetic syndromes. Up to 3% of infants are born with a major anomaly that is diagnosed in the first year of life. Of infants with a syndrome, 84% will have an otolaryngologic anomaly. Some of the genetic syndromes associated with the most prominent anomalies of the head and neck include the following: Down syndrome (trisomy 21), 22q11 deletion syndrome (velocardiofacial syndrome), Treacher Collins syndrome, Beckwith-Wiedemann syndrome, and ocular–auricular–vertebral spectrum (OAV). An understanding of the pathophysiology, associated anomalies, and new developments in treatment avoids delays in diagnosis and leads to optimal outcomes.

64.2 Down Syndrome (Trisomy 21)

Down syndrome (trisomy 21) is the most common chromosomal syndrome (□ Fig. 64.1). The incidence is considered to be about 1 in 700 to 1 in 1,000 live births, although Resta reports that it would affect 1 in 629 births without any prenatal intervention. Of the cases, 94% are due to trisomy of chromosome 21, which occurs during meiosis I, but occasional cases are due to translocation or mosaicism. The major risk factor for Down syndrome is advanced maternal age; whereas the risk is only 1 in 1,500 for mothers younger than 25 years of age, the risk increases to 1 in 10 for mothers older than 45 years of age. Other risk factors include a previous pregnancy complicated by trisomy and chromosomal translocations, inversion, or aneuploidy in either parent.

Typical features of Down syndrome (see □ Fig. 64.1) include characteristic craniofacial features: flat occiput, brachycephaly, upward-slanting palpebral fissures, hypertelorism, flat nasal bridge, stenotic external auditory canals, macroglossia, narrow palate, hypotonia, developmental delay, intellectual disability, excessive skin at the nape of the neck, hypertrophic tonsils, xerodermia, and single palmar creases with short metacarpals

Fig. 64.1 Down syndrome.

and phalanges. Up to 60% of patients have associated cardiac anomalies. Affected individuals have an increased incidence of duodenal atresia, Hirschsprung disease, and imperforate anus, and 5% of patients have some type of gastrointestinal anomaly.

Hearing loss in individuals with Down syndrome is common; it may be conductive or sensorineural. A recent study of 432 children with Down syndrome in Utah found that 46.1% of the children had a conductive hearing loss. Past reports have found up to a 60% rate of conductive hearing loss in patients with Down syndrome. This is often due to serous otitis media, although up to 40% of children will have a persistent conductive hearing loss after the placement of pressure equalization (PE) tubes. The treatment and diagnosis of serous otitis media are complicated by stenotic external auditory canals, which are present in 40 to 50% of cases. A study from 2001 conducted at Cincinnati Children's Hospital found that 83% of children with Down syndrome younger than 2 years of age required PE tubes for chronic ear disease and persistent middle ear effusions. A study from 2003 showed that children with Down syndrome had a 3.6 times greater chance of having normal hearing when PE tubes were in place than when they were not. Eustachian tube dysfunction is common and may lead to the need for several tympanostomy procedures. Dysfunction of the eustachian tube is due to the poor quality of its cartilage and narrow diameter, and to hypotonia of the tensor veli palatini. Congenital sensorineural hearing loss also occurs in 3.6% of affected individuals.

Children with Down syndrome should have a newborn hearing screen with auditory brainstem response (ABR) and otoacoustic emission (OAE) testing and follow-up testing every 6 months up to the age of 3 years. Frequent examination under the microscope until 2 to 3 years of age is recommended in children with stenotic external auditory canals. Individuals with Down syndrome and any degree of hearing loss benefit from early intervention with hearing aids in order to improve the development of speech and cognition.

There are many anatomical sites that can lead to obstruction and airway difficulties in individuals with Down syndrome. Infants and young children with Down syndrome have difficulty controlling the tongue, resulting in tongue thrusting. This leads to problems with latching on during feeding and to glossoptosis; macroglossia is occasionally seen. Mandibular and maxillary hypoplasia, hypertrophic tonsils and adenoids, and general hypotonia may contribute to obstructive sleep apnea. Sleep apnea affects the majority of individuals with Down syndrome and increases the risk for pulmonary hypertension, even in the absence of cardiac anomalies. Parental observation is not a sensitive test for sleep apnea in this patient population. Adenotonsillectomy is the first-line treatment for children with sleep apnea, but 50% of children with Down syndrome will continue to have an abnormal sleep study after this surgery. Children with persistent apnea should begin continuous positive airway pressure (CPAP) therapy or should undergo further studies, such as cine sleep magnetic resonance (MR) imaging and sleep endoscopy, to evaluate the precise airway level of persistent obstruction. Further surgeries can then be tailored to the problematic anatomical location.

Subglottic and tracheal stenosis is common in children with Down syndrome, and an endotracheal tube two sizes smaller than expected should initially be used to size the

airway. Intraoperatively, pulmonary hypoplasia can lead to difficulties with ventilation. Atlantoaxial instability is another factor complicating management of the airway in children with Down syndrome. Cervical flexion and extension spine films are helpful but are not entirely reliable predictors of this anomaly in young children because of incomplete calcification of bone. For this reason, hyperextension of the neck should never be performed, and overall movement of the head during surgical procedures should be minimized. Furthermore, a complete neurologic examination should be conducted in the preoperative period to obtain a baseline.

Ideally, the approach to caring for a patient with Down syndrome begins prenatally. Screening may take place in the first or second trimester of pregnancy with serum testing and ultrasound. Prenatal diagnosis allows the medical staff to prepare for possible complications at delivery, and the family and caregivers to prepare for early aggressive interventions to optimize outcome. Echocardiography at birth is essential to detect congenital cardiac anomalies and plan possible cardiac procedures that may prevent long-term sequelae of undetected cardiac anomalies. Other screenings at birth should include a newborn hearing screen and screening for hypothyroidism. Up to 30% of children with Down syndrome will ultimately develop thyroid dysfunction; hypothyroidism is more common than hyperthyroidism. The thyroid-stimulating hormone and free T₄ levels should be checked at birth and 6 months of age, and then annually.

Patients with Down syndrome may require a psychological or psychiatric evaluation for the diagnosis and treatment of coexisting depression, anxiety, autism, or attention deficit. Developmental delay and intellectual disability are typical of the diagnosis, and children require regular evaluation to determine placement in appropriate educational classrooms and activity groups. Diet should be managed with consideration for the increased incidence of constipation and obesity.

Aggressive intervention is required not only at the time of initial diagnosis but also throughout the life of a person with Down syndrome. Even in the absence of other congenital anomalies, many individuals with Down syndrome will develop problems later in life: cardiac valve anomalies; autoimmune disorders; neoplastic processes such as leukemia, lymphoma, and testicular tumors; cataracts; and an increased rate of infections. The close surveillance required to detect multiple possible disease processes highlights the importance of a primary care provider who is able to coordinate care throughout the child's life and ensure that all appropriate tests and specialist consultations are carried out. Epidemiologic and outcomes research is rapidly expanding in this area, and dedicated physicians will ensure that individuals with Down syndrome are monitored and treated according to the most current evidence-based practices.

64.3 Chromosome 22q11.2 Deletion Syndrome (Velocardiofacial Syndrome)

Chromosome 22q11.2 microdeletions are responsible for what is commonly called DiGeorge syndrome, velocardiofacial

Fig. 64.2 Velocardiofacial syndrome in a patient with a bulbous nasal tip; narrow nares; small, cupped ears; and short, upward-slanting palpebral fissures.

syndrome, and a number of other well-characterized phenotypes (□ Fig. 64.2). This is due to the highly variable expression of the same genotype. DiGeorge syndrome classically manifests with conotruncal cardiac anomalies, varying degrees of immune dysfunction/immunodeficiency, and distinctive facial features. Immunodeficiency may be seen with either a normal or an absent thymus, but some children without a thymus may have a normal immune system. Velocardiofacial syndrome is characterized by velopharyngeal insufficiency and/or incompetence, conotruncal cardiac anomalies, learning disabilities, and characteristic facial features. The incidence of the 22q11.2 microdeletion is 1 in 4,000 to 5,000 live births, and 85 to 90% of cases are due to a spontaneous deletion. This results in aberrant development of the third and fourth pharyngeal arches and pouches. The diagnosis is confirmed by fluorescence in situ hybridization (FISH) testing of targets in the critical region of chromosome 22q11.2.

In general, DiGeorge syndrome and velocardiofacial syndrome are actually the same entity, although some consider DiGeorge syndrome to be a worse phenotype. The 22q11.2 microdeletion causes a wide range of phenotypes, but approximately 50% of patients will have some major cardiac anomaly. Although this is easily diagnosed in infancy, other phenotypic traits are more difficult to detect until later in life. Velopharyngeal insufficiency and incompetence, as well as speech and language delay, may not be recognized until the child begins to attend school or day care. Chronic middle ear disease may also be present. A retrospective review from Children's Hospital of

Philadelphia found that 76% of cases with 22q11.2 microdeletion had velopharyngeal insufficiency. In the absence of cardiovascular malformations or the Robin anomaly, this condition is very challenging to ascertain in the neonatal period. Affected individuals may demonstrate only abnormal palpebral fissures, hypertelorism, unusual ears, and a small mouth, but these are not specific for 22q11.2 deletion syndrome, and a high index of suspicion is required for early and accurate diagnosis. Hypocalcemia secondary to hypoparathyroidism in infancy can be a particularly important trait that allows a clinician to fit the clinical picture together.

Other otolaryngologic manifestations are variably expressed. Typical nasal anomalies include a bulbous nasal tip, a thickened nasal bridge, narrow nares, and a prominent nasal root. The most common auricular abnormality is an overfolded helix. The ears may also be small, posteriorly rotated, and protuberant, with a thickened helix or cupped shape. Common eye abnormalities include hooded eyelids, epicanthal folds, hypertelorism, and short, upward-slanting palpebral fissures. There are over 180 reported symptoms of 22q11 microdeletion, so this list is not exhaustive. Currently, there is no proven explanation for the large degree of variability in the expression of this genotype.

Sensorineural hearing loss is not a typical manifestation of 22q11.2 deletion syndrome, but conductive hearing loss is common. This is often due to chronic otitis media resulting from the palatal abnormality. Chronic otitis media is present in 40 to 75% of patients with 22q11.2 deletion syndrome.

Delayed speech and language development is one of the most pervasive features of 22q11.2 deletion syndrome and is due to a combination of overall developmental delay, velopharyngeal insufficiency/incompetence, and conductive hearing loss. Velopharyngeal insufficiency/incompetence is detected by hypernasality on perceptual analysis and by constant nasal air loss during phonation. In individuals with 22q11.2 deletion syndrome, velopharyngeal insufficiency/incompetence is most often due to a short velum, atonic velum, and/or a deep cavum, resulting in the inability of the soft palate to touch the posterior pharyngeal wall during speech. Other speech-related symptoms include poor articulation and overall unintelligibility. Overt cleft palate is present in a minority of cases, but a submucous or occult cleft may also contribute to difficulties in speech and swallowing.

Behavioral problems range from isolation to impulsiveness, hyperactivity, anxiety, and emotional lability. It is postulated that the inability to communicate effectively exacerbates these behavioral characteristics. Patients benefit from intervention with tympanostomy tubes and speech therapy.

Surgical procedures of the palate should be tailored to individual needs. Medially displaced carotid arteries are more common in 22q11.2 deletion syndrome than in the general population, and MR imaging of the neck has been suggested before pharyngoplasty, although this is controversial. Pulsation of the posterolateral pharyngeal wall is not sensitive or specific for abnormal orientation of the vasculature. Surgical options for the correction of velopharyngeal insufficiency include pharyngeal flap, sphincter pharyngoplasty, augmentation pharyngoplasty, and palatoplasty. Symptom improvement can be achieved non-surgically with a palatal obturator or lift.

Fig. 64.3 Some classic features of Treacher Collins syndrome are mandibular hypoplasia with retrognathia, downward-slanting palpebral fissures, and auricular deformities.

The outcomes of pharyngeal flap in a small group of children who had 22q11.2 deletion were compared with outcomes in a small group of children who had nonsyndromic, nonleft velopharyngeal insufficiency, and both groups were found to have excellent results 2 years after surgery, with no significant difference in quality of outcome. The patients with 22q11.2 microdeletion took longer to achieve excellent postoperative results than the nonsyndromic patients. Other studies have found that children with 22q11.2 deletion syndrome tend to require more revision procedures than nonsyndromic cases.

Velopharyngeal insufficiency may also affect the ability to swallow, and failure to thrive is common in infancy. A poor suck reflex and nasopharyngeal regurgitation may be due to the shortened or hypotonic palate. Airway anomalies are not a major manifestation of 22q11 microdeletion, although the degree of retrognathia should be considered in planning intubation and sedation/anesthetic procedures. Other laryngotracheal anomalies are more common in this population than in the general population, and any signs of airway obstruction or respiratory distress merit endoscopy for further evaluation.

Deaths in early childhood are almost always due to severe congenital heart disease or associated complications. This highlights the importance of lifelong aggressive medical monitoring and interventions to optimize overall health.

Fig. 64.4 Mild cases of Treacher Collins syndrome may manifest only mild depression of the zygoma and downward-slanted palpebral fissures.

64.4 Treacher Collins Syndrome

Treacher Collins syndrome occurs in 1 in 25,000 to 1 in 50,000 live births and is inherited in an autosomal-dominant pattern with variable penetrance. Spontaneous gene mutations are the cause in 57% of cases. Deformities are due to the dysfunction of neural crest cells, resulting in the abnormal development of bone, cartilage, and connective tissue. Classic features include malar and mandibular hypoplasia with retrognathia, coloboma of the lateral one-third of the lower eyelid, sparse or absent eyelashes of the lower eyelid, and downward-slanting palpebral fissures. Auricular deformities are present in 85% of patients, as are middle ear deformities (□ Fig. 64.3). Mild phenotypes may be detectable only by mild depression of the zygoma and by subtle downward slanting of the palpebral fissures. Some cases are detected only when computed tomography demonstrates the malar anomaly (□ Fig. 64.4).

The airway requires special attention in individuals with Treacher Collins syndrome. Airway compromise is present at birth in 47% of cases. In most mild cases, the airway can be managed conservatively in infancy without tracheostomy. Positive-pressure mask ventilation, placement of a nasopharyngeal airway, and prone positioning may be sufficient to relieve symptoms of mild airway obstruction due to retrognathia and mandibular hypoplasia. Choanal atresia is also present in 11% of patients with Treacher Collins syndrome and complicates the already-difficult airway. A retrospective review of 30 individuals with Treacher Collins syndrome found that only 13% required tracheostomy in infancy and only 7% required emergent tracheostomy later in childhood. A smaller, earlier study from a

different institution reported a 41% rate of tracheotomy in patients with mandibulofacial dysostosis, including individuals with Treacher Collins syndrome or Nager syndrome.

Obstructive sleep apnea is common in individuals with Treacher Collins syndrome, and polysomnography is suggested to obtain a baseline and evaluate severity. Adenotonsillectomy is an effective intervention for many individuals with Treacher Collins syndrome affected by obstructive sleep apnea, but many will continue to require the use of CPAP, and severe cases may require tracheostomy. Mandibular advancement with distraction osteogenesis may be performed before 10 years of age and enables decannulation in some children with airway obstruction and tracheostomy. Choanal atresia or stenosis also requires early repair. Genioplasty and hyoid advancement are reserved for refractory airway obstruction in children older than 12 years.

Conductive hearing loss is common, and one study of 46 cases found that the severity of hearing loss correlates with the degree of auricular deformity. Individuals with Treacher Collins syndrome should be counseled regarding the risks and benefits of auricular reconstruction versus an auricular prosthesis such as a bone-anchored hearing aid or a conventional hearing aid. Reconstructive surgery has typically achieved poorer outcomes for hearing in patients with Treacher Collins syndrome than in those with nonsyndromic cases of microtia. Prompt intervention for hearing loss within the first year of life enables children to begin to develop language. Speech and articulation are a challenge in almost 75% of children with Treacher Collins syndrome. Hyponasality occurs in most children with Treacher Collins syndrome because of the small size of the nasopharynx and oropharynx. However, almost one-third of affected children also have a cleft palate or velopharyngeal insufficiency and will instead demonstrate hypernasal speech. The timely repair of a cleft palate is more complicated in this population because of the coexisting difficult airway. The average age of children undergoing cleft palate repair is 2.1 years. Articulation problems also occur and are due to malocclusion and the posterior position of the tongue.

Individuals with Treacher Collins syndrome require multi-stage surgical treatment. Correcting the malar hypoplasia is one of the most challenging aspects of reconstruction because of the partial or complete resorption of grafts. Eyelid coloboma is corrected with a transposition flap from the upper to the lower eyelid, and downward-slanting palpebral fissures are corrected with bone grafting and lateral canthopexy at the time of the malar reconstruction. Rhinoplasty is performed in the teenage years to correct the prominent dorsal hump. Counseling affected individuals about realistic expectations for surgical outcomes is important. Many will require revision procedures to obtain an acceptable result, and some individuals have some residual dysmorphic features despite a full course of aggressive surgical treatment.

Affected individuals who are treated by a multidisciplinary team do well and are able to participate in all aspects of society into adulthood. Intellectual impairment is not expected with this disease process. Individuals with Treacher Collins syndrome may benefit from early diagnosis and airway management, foresight in overall surgical planning, and therapy to improve speech and manage the psychosocial aspects of coping with a rigorous treatment process.

64.5 Beckwith-Wiedemann Syndrome

Beckwith-Wiedemann syndrome (□ Fig. 64.5) occurs in approximately 1 in 13,700 live births. The diagnosis is suggested clinically by the presence of three major features or of two major features and one minor feature of the syndrome. Major features include abdominal wall defects, macroglossia, macrosomia, anterior ear lobe creases or postauricular pits, visceromegaly, omphalocele, Wilms tumor, hepatoblastoma, hemihyperplasia, and specific renal abnormalities. Children are at risk for tumors, with an estimated 7.5% risk of tumor development within the first 8 to 10 years of life. Minor features include polyhydramnios, preterm delivery, neonatal hypoglycemia, nevus flammeus, cardiac anomalies, midface hypoplasia, suborbital creases or prominent mandible, diastasis recti, and advanced bone age. Other notable manifestations in the head and neck include prominent occiput, flattened nasal dorsum, and downward-slanting palpebral fissures.

Many features of the syndrome are attributed to the altered expression of genes located at chromosome 11p15.5, and 85% of cases are due to a spontaneous mutation. The diagnosis may be suspected during pregnancy by an increased rate of growth in the second half of pregnancy. Infants are typically in the 97th percentile for height and weight and the 50th percentile for head size. The presentation of some affected infants is similar

Fig. 64.5 Macroglossia and macrosomia are major features of Beckwith-Wiedemann syndrome.

to the presentation of infants affected by maternal diabetes (large for gestational age, hypoglycemia). Dysmorphic features are more prominent during infancy and childhood and gradually normalize in most cases throughout adulthood. The most common associated tumors are Wilms tumor, hepatoblastoma, rhabdomyosarcoma, adrenocortical carcinoma, and neuroblastoma.

There is a great degree of variability in expression, and some cases may not be diagnosed until adulthood. Affected individuals without obvious major features of the syndrome are still at increased risk for tumor development, and a high index of suspicion is needed to reach a diagnosis in children with atypical phenotypes so that effective tumor surveillance can be initiated. Tumor surveillance consists of detailed physical examinations coupled with serial abdominal ultrasound examinations (every 6 to 12 weeks until the age of 8 years) and the measurement of alpha fetoprotein levels (every 6 to 12 weeks until the age of 5 years). Rhabdomyosarcoma is the most common malignant tumor of the head and neck in individuals with Beckwith-Wiedemann syndrome, but fortunately these are rare, even in this population.

Acute management is often needed in infancy for several associated features. Abdominal wall defects are present in 60 to 75% of cases, and severe defects are repaired soon after birth. Severe hypoglycemia is present in 30% and must be controlled tightly to avoid complications. Macroglossia is present in more than 80% of affected individuals, and infants with significant macroglossia occasionally require tracheostomy. Macroglossia is due to hypertrophy/hyperplasia of both the anterior tongue and the base of tongue. Because of the diffuse tongue involvement, anterior tongue reduction may not be adequate to relieve symptoms. Affected individuals who are less symptomatic from macroglossia may benefit from a period of observation before surgical management because spontaneous resolution has been reported as the facial skeleton grows to accommodate the large tongue. In some patients with macroglossia and upper airway obstruction, the upper airway symptoms may be relieved with adenotonsillectomy alone. The surgical correction of severe upper airway obstruction in Beckwith-Wiedemann syndrome is essential to prevent the long-term sequelae of cor pulmonale, failure to thrive, and premature death.

Macroglossia causes additional speech and articulation problems. Children with Beckwith-Wiedemann syndrome typically have a normal IQ, but speech therapy may not be enough to help them to communicate effectively unless a tongue reduction is performed. Macroglossia resulting in constant anterior protrusion of the tongue can trigger teasing, and tongue reduction is indicated to achieve a better cosmetic outcome. Feeding difficulties due to macroglossia may be managed conservatively with changes in dietary consistency or the use of a nipple with a larger aperture.

Hearing loss is not a common feature of Beckwith-Wiedemann syndrome, but several cases of conductive hearing loss have been reported. These cases have been associated with the intraoperative finding of stapedial foot plate fixation, but more research is needed to determine whether this disease process is affected by 11p15.5 dysregulation. Hemihypertrophy/hemihyperplasia occurs in some patients with Beckwith-Wiedemann and is due to mosaicism of the dysregulated genes. Facial asymmetry may require surgical reconstruction in severe cases, but

most cases are mild and will gradually improve throughout childhood.

64.6 Ocular–Auricular–Vertebral Spectrum

Hemifacial microsomia is part of the ocular–auricular–vertebral (OAV) spectrum. Goldenhar syndrome is the most specific phenotypic variant of this association. Cardinal features include auricular anomalies, typically located on the side of the face affected by microsomia; epibulbar dermoids; vertebral anomalies; coloboma of the upper eyelid; preauricular skin tags; unilateral parotid agenesis; and congenital facial nerve palsy (□ Fig. 64.6). The severity of the mandibular microsomia correlates with overall disease severity. The estimated incidence is 1 in 5,600 live births, and the etiology is unknown. Males and females are equally affected. One-third of patients demonstrate dysmorphic features on both sides of the face, and the other

Fig. 64.6 (a) Epibulbar dermoids are seen in patients with Goldenhar syndrome. (b) Microtia, often with an anomalous course of the facial nerve, is common in Goldenhar syndrome, as is hemifacial and hemimandibular microsomia.

two-thirds are affected on only the right or left side, with equal rates noted for the two sides. The OAV spectrum is a genetically heterogeneous disorder. Although several cases of Goldenhar syndrome have been associated with chromosomes 5p15 and 14q32 deletions, other cases with similar phenotypes have been identified in patients with trisomy 18, trisomy 7, trisomy 9, and terminal deletion of 22q, but there is no localization to any region. Although most cases are spontaneous, family pedigrees have supported autosomal-dominant and autosomal-recessive patterns of inheritance. Maternal factors, including a diabetic state and the use of retinoic acid, thalidomide, or cocaine, are associated with the phenotype, as well. Because most anomalies involve first and second branchial arch derivatives, hemorrhage from the stapedia artery during the course of development results in the typical features. The overlapping features of the OAV spectrum and CHARGE (coloboma of the eye, heart defects, atresia of the nasal choanae, retarded growth, genital and/or urinary abnormalities, ear abnormalities and deafness) syndrome have led to speculation that the aberrant development of neural crest cells plays a role in pathophysiology.

Extracraniofacial anomalies occur in more than half of patients with hemifacial microsomia, and affected individuals with more severe craniofacial manifestations are more likely to have anomalies of the skeleton, heart, lungs, central nervous system, or gastrointestinal tract. Extracranial skeletal findings are common in patients with hemifacial microsomia, and 40 to 60% of patients will have a skeletal anomaly. The most common skeletal deformities are of the vertebrae and ribs. The most common extraskelatal association is cardiac, and 25 to 50% of patients with hemifacial microsomia have a cardiac anomaly. The most common reported cardiac anomalies are ventricular septal defects.

Conductive or mixed hearing loss is the most common type of hearing loss associated with OAV spectrum and occurs in 70 to 75% of patients. Affected individuals may present with microtia, atretic auditory canals, malformed or fused ossicles, and absence of the round window. There is an increased incidence of chronic otitis media, and individuals may benefit from the placement of longer-lasting ventilation tubes. Occasionally, affected individuals have profound sensorineural hearing loss due to malformations of the inner ear, and they may have findings of dysplastic cochleas and semicircular canals. Ear surgery should never be performed on patients with OAV spectrum before a radiologic evaluation of the course of the facial nerve has been obtained because the location of the facial nerve is often atypical. Individuals with OAV spectrum have poorer outcomes overall than do patients with nonsyndromic cases of microtia or atresia after surgical reconstruction of the ear. The complex abnormal anatomy and growth of the surrounding facial skeleton are important factors.

Speech development is typically not affected by the auricular anomalies because hearing is usually preserved on one side. Rare patients who have bilateral hearing loss benefit from a conventional hearing aid or a bone-anchored hearing aid, and patients with profound bilateral sensorineural hearing loss benefit from a cochlear implant. Asymmetric weakness of the tongue musculature often causes articulation problems, and speech therapy is an important component of treatment. Coordination problems with the tongue also can affect feeding. Affected neonates who cough or choke during feeds should be

evaluated for tracheoesophageal fistula because this is more common in individuals with OAV spectrum.

Craniofacial reconstruction is indicated only in severe cases and may be limited to mandibular distraction osteogenesis. Le Fort I repositioning of the maxilla and free flap reconstruction of the mandible have also been described. Reported outcomes of all of these procedures are variable, and some cases require multiple revision surgeries to obtain a cosmetically and functionally acceptable result.

64.7 Conclusion

The common theme among all of these described syndromes is phenotypic variability, and a thorough physical examination and history are required to make an accurate diagnosis and initiate appropriate treatment and screening. Patients require more frequent visits to primary care providers and specialists, and coordination with a multidisciplinary team ensures that all appropriate tests are done while redundant and excessive tests and procedures are avoided. Early intervention for hearing, speech, and airway management may optimize individual outcomes.

Affected individuals may benefit from psychosocial counseling to manage the stresses of dealing with a disfigurement, as well as neurocognitive testing to diagnose behavioral disorders or developmental delay that requires special attention. Prenatal diagnosis helps families to begin learning about the disease process and necessary interventions, and it helps caregivers to plan for potentially life-saving interventions at the time of delivery.

This overview only touches on some of the most common syndromes of interest to the otolaryngologist. In practice, the otolaryngologist must be well versed in the full spectrum of genetic syndromes because patients with myriad syndromes will require evaluation and treatment by this specialist. Consultations are commonly needed for individuals with genetic syndromes to manage the difficult airway, chronic upper airway infections, and hearing loss and to treat speech and swallowing problems. A thorough knowledge of the anatomical anomalies and associated features of a variety of syndromes will help the otolaryngologist to avoid the pitfalls of inappropriate management.

Human genome mapping and the field of proteomics are rapidly changing what is known about the pathophysiology of syndromes. Advances in radiology and surgical technology are also constantly evolving and leading to improved outcomes. Clinicians should be up to date on the recent literature in order to provide the best outcomes, which a multidisciplinary approach helps to ensure.

64.8 Roundsmanship

- No single feature is ever pathognomonic for a syndrome because syndromes are characterized by variable expression.
- An otolaryngologic anomaly will be found in 84% of syndromic infants.
- An endotracheal tube two sizes smaller than expected should initially be used to size the airway of a patient with Down syndrome.
- Hemifacial microsomia is part of the ocular–auricular–vertebral (OAV) spectrum.

65 Congenital Malformations of the External and Middle Ear

David J. Crockett and Jeremy D. Meier

65.1 Introduction

Throughout the evolutionary process, the ear has developed into a complex organ with many structures necessary for the transmission of sound. This chapter discusses the embryology and the most common congenital malformations of the external and middle ear. The primary responsibility of these structures is to assist with the transmission of auditory information from the environment to the inner ear. Malformations or deformities can lead to functional and aesthetic complications for the patients affected.

65.2 Embryology

The embryology of the external and middle ear is a complex process. Malformations of these structures usually occur from genetic or environmental influences during embryologic development. For this reason, appreciating the embryologic process will aid in understanding the malformations discussed in this chapter.

All structures of the ear develop concurrently with one another and with other head and neck structures. Development of the inner begins first, at around the end of the third week of gestation, and the inner ear develops independently of the middle and external ear. Sometime in the fourth week of gestation, the external and middle ear start to form. The first pharyngeal pouch (endodermal) principally forms the tubotympanic recess. Throughout the remainder of the developmental process, the tympanic cavity continues to expand, eventually surrounding the ossicles and their support structures. The ossicles generally lie completely within the tympanic cavity by the eighth month of development.

Neural crest mesenchyme of the first (Meckel cartilage) and second (Reichert cartilage) branchial arches is principally responsible for the development of the ossicles. The head of the malleus and the short and long processes of the incus are formed from Meckel cartilage. The long process of the incus, handle of the malleus, and stapes superstructure are formed from Reichert cartilage. The vestibular surface of the stapes foot plate and the annular ligament are formed from mesoderm of the otic capsule.

The first branchial cleft (ectodermal), between the first and second branchial arches, forms the external auditory canal. This epithelium invaginates, and by approximately the 28th week of gestation the core has canalized, creating the external auditory canal and allowing access to the tympanic membrane. The tympanic membrane is composed of ectoderm from the first branchial cleft laterally, endoderm from the first pharyngeal pouch medially, and a central layer composed of neural crest mesenchyme.

The auricle begins development at around the fifth week of gestation. Three hillocks are noted to arise from the first

branchial arch and three from the second branchial arch. The six hillocks are associated with the formation of distinct auricular structures in the adult: hillock 1, tragus; hillock 2, helical crus; hillock 3, ascending helix; hillock 4, horizontal helix and portions of the scapha and antihelix; hillock 5, descending helix and portions of the scapha and antihelix; hillock 6, antitragus and portion of the helix (□ Fig. 65.1).

65.3 Common Malformations of the External Ear

As previously discussed, the external ear and middle ear develop separately from the inner ear because their embryologic origins are different. Alterations in the normal embryogenesis, through genetic and environmental agents, will lead to various malformations of the external and middle ear. A few of the common malformations are discussed.

Fig. 65.1 Illustration of the auricle, depicting the classic concept of particular development from specific hillocks of His: hillock 1, tragus; hillock 2, helical crus; hillock 3, ascending helix; hillock 4, horizontal helix and portions of the scapha and antihelix; hillock 5, descending helix and portions of the scapha and antihelix; hillock 6, antitragus and portion of the helix.

Fig. 65.2 (a) Oblique, (b) lateral, and (c) posterior views of a prominent ear. An overly large conchal bowl and poorly defined antihelix produce lateral prominence and pseudoptosis of the auricle. (d) Lop ear with abnormal folding of the superior helix.

65.3.1 Anomalies of the Auricle: Prominent Auricle and Lop Ear

Varying degrees of severity of auricular malformation have been discussed in the literature. Anotia, microtia (auricular hypoplasia), and prominent ear (□ Fig. 65.2) are common anomalies of the auricle. The functional and aesthetic concerns resulting from these malformations can cause significant distress to a patient.

A prominent or protruding ear is a fairly common defect. If the antihelix fails to unfold during the embryologic develop-

mental process, the helix will continue to overhang and protrusion will persist, resulting in a lop ear. Various minor auricular anomalies can also occur. The most common abnormalities include increased angle between the auricle and the scalp (the normal angle between the ear and the head is between 15 and 25 to 30 degrees), underdevelopment of the antihelix, excessive conchal cartilage, and earlobe deformity (mainly protrusion).

Otoplasty is defined as the surgical repair, restoration, or alteration of the auricle. The auricle nears completion of growth in childhood, and it is safe to correct deformities of the external ear during this stage of life. Multiple surgical techniques have

Fig. 65.3 (a, c) Before and (b, d) after otoplasty.

been described to correct such deformities (□ Fig. 65.3). The Mustardé suturing technique is used to create an antihelical fold and involves placing several horizontal mattress sutures along the scapha. The Furnas technique involves placement of a conchomastoid suture that reduces the conchal bowl and allows retraction of the auricle. More aggressive techniques that include cartilaginous incisions have been developed by Pitanguy and Farris. Common complications of otoplasty include inadequate correction, chondritis, hematoma, and “telephone ear” deformity (caused by too much flexion of the midportion of the antihelix and inadequate flexion of the superior and inferior poles). Otoplasty is discussed in more detail in Chapter 52 (Correction of Congenital Auricular Deformities).

65.3.2 Preauricular Pits and Skin Tags

Preauricular cysts, fistulas, and sinuses (also called “pits”) commonly occur in the pediatric population. It is thought that these

arise from developmental defects of the first branchial cleft and first branchial arch. The location of these defects is usually anterior to the auricle close to the anterior border of the ascending limb of the helix. Sinuses are usually intimately associated with the adjacent helical cartilage, and inadequate excision may result in recurrence. The standard technique involves an elliptical cutaneous incision around the pit followed by dissection of the tract near the root of the helix. The elliptical incision can be extended to allow a supra-auricular approach, which improves access and so allows a more adequate excision.

Preauricular skin appendages are also common. These are small tags that occasionally contain cartilage. They are often found anterior to the auricle at the level of the supratragal incisura (□ Fig. 65.4). Presumably, these preauricular appendages arise as a consequence of excessive growth during the developmental process. Simple excision, if desired by the patient or family, may be performed.

Fig. 65.4 Multiple preauricular skin tags.

Fig. 65.6 Aural atresia is frequently associated with microtia. What appear to be a small conchal bowl and external auditory meatus end in a blind pouch.

65.3.3 First Branchial Cleft Anomalies

As previously discussed, the first branchial cleft develops into the external auditory canal and the outer layer of the tympanic membrane. Maldevelopment may lead to cystic lesions, sinus anomalies, and fistulas. Sinuses arising from the first branchial cleft are of two major types. Type I lesions (□ Fig. 65.5) are duplications of the external auditory canal; they exist as fistulous tracts and usually lie in close association with the lower pole of the parotid gland. Type II lesions are superficial sinuses or cysts in the anterior neck below the angle of the mandible. They are usually noticed earlier in childhood than type I lesions. Recurrent infection can be associated with both lesions. If aural discharge persists in the absence of middle ear disease, this anomaly should be suspected, especially if there is a history of a neck lump or abscess. If surgery is indicated, complete excision is recommended because of high recurrence rates. There is often

Fig. 65.5 (a) Pre- and (b) intraoperative views of a type I first branchial cleft cyst.

an intimate relationship of the cyst or sinus with branches of the facial nerve, requiring tedious dissection with possible partial parotidectomy.

65.3.4 Aural Atresia

Congenital aural atresia has a reported incidence of 1 in 10,000 to 1 in 20,000 births. Approximately one-third of these children will have bilateral aural atresia to some degree. Atresia of the ear canal with middle ear anomalies can occur in isolation or may be associated with other anomalies, such as microtia (□ Fig. 65.6). As mentioned previously, the ear canal is formed from the first branchial groove. If canalization is arrested during the developmental process, a stenotic or membranous atretic canal may result. Atresia of the bony canal is secondary to malformation of the tympanic bone during development.

The evaluation and treatment of aural atresia include a detailed hearing assessment to determine the need for immediate amplification. Computed tomography (CT) of the temporal bone is indicated to evaluate the middle ear and facial nerve anatomy when surgical reconstructive options are being discussed and to identify potential cholesteatoma. In unilateral atresia, a maximal conductive hearing loss is present, but immediate intervention is unnecessary if there is normal hearing in the

Fig. 65.7 Various degrees of microtia and anotia. (a) Grade I. (b,c) Grade II. (d) Grade III. (e) Anotia. (f) Nearly complete anotia.

contralateral ear. A hearing aid may be used in canal stenosis. Complete canal atresia requires a bone conduction hearing aid. Early amplification is necessary in bilateral atresia. A bone conduction hearing aid can be fitted after the first few months of life.

Should surgery be desired, it can be done as early as 6 to 7 years of age, generally after microtia repair so that the reconstructive procedure can be performed in unscarred tissues. Although it is difficult, the objective of the atresia surgery is to create a pathway that allows sound to reach the cochlea in a functional manner. Not all children are candidates for canal atresia repair. Jahrsdoerfer proposed a 10-point grading scale to predict the likelihood of a good hearing outcome after canal-plasty. This scale assesses for the following: stapes present, middle ear space adequate, facial nerve position normal, malleus–incus complex present, mastoid well pneumatized, incus–stapes connection present, round window normal, external ear appearance normal, and oval window patent. Each parameter is awarded 1 point, except for stapes present, which is awarded 2 points. Children with a score of 8 points or more are considered to have the best chance of a good outcome.

65.3.5 Microtia

Microtia is graded based on the severity of the malformation of the external ear (□ Fig. 65.7a–d). Anotia (□ Fig. 65.7e, f) is complete absence of the pinna. Meurman classified the severity of

microtia on a three-grade scale. Grade I indicates a small, malformed auricle with most of the characteristic components present. Grade II indicates an auricle with a vertical remnant of cartilage and skin and a smaller anterior hook. Grade III denotes an auricle that is almost entirely absent except for a misplaced lobule and a smaller skin and cartilage remnant; a grade III auricle is often described as a “peanut ear.”

Repair of the microtia and concomitant atresia requires coordination between an otologist and a facial plastic surgeon. Most physicians generally agree that 6 years is an appropriate age at which to proceed with microtia reconstruction because the normal contralateral pinna has reached about 85% of full adult size and can be used as a model. At this age, the patient has adequate donor cartilage for the surgery and is usually more prepared from a psychological standpoint. If the microtia is unilateral, waiting for additional growth is sometimes preferred because the harvested cartilage is thicker and more amenable to sculpting. Construction of an ear with autologous rib cartilage is discussed in more detail in Chapter 52 (Correction of Congenital Auricular Deformities).

In addition to reconstruction with autogenous cartilage, certain implants, such as porous high-density polyethylene (Medpor; Porex Surgical, Newnan, GA) implants, have been used to create the framework structure for the auricle. These implants are placed under a temporoparietal fascial flap and covered with a skin graft. The choice of reconstructive material is discussed preoperatively with the patient and family.

Fig. 65.8 High-riding jugular bulb of the right temporal bone.

Surgery is not the only reconstructive option for these patients. Auricular prosthetics have been found to be an adequate reconstructive option. Hearing can be improved with the use of a bone-anchored hearing aid in patients with canal atresia.

65.4 Common Malformations of the Middle Ear

65.4.1 Ossicular Chain Anomalies

The ossicles are derived from the first and second branchial arches. Deviation from normal embryologic processes will result in aberrant development of the ossicles. Anomalies vary widely, from minor morphological defects to rudimentary ossicular masses. Although ossicular deformities often occur simultaneously with deformities of the external auditory canal or tympanic membrane, they may occur alone because the ossicles develop through a different embryologic process.

Children who have ossicular chain anomalies often present with a unilateral conductive hearing loss in the range of 40 to 60 dB. These children frequently are identified during routine school audiometry. In a child without a history of trauma, middle ear effusion, or infection, the clinician should suspect a congenital ossicular malformation. Many surgical techniques have been developed to improve the hearing of these patients, and the overall prognosis is good. Because it is difficult to determine the exact deformity before surgery, the surgeon must be prepared to perform various ossicular reconstructive techniques depending on the findings during middle ear exploration. The most common abnormalities include fixation of the stapes, abnormalities of the stapes superstructure, ankylosis of the incudostapedial joint, and fixation of the malleus head to the tympanic ring.

65.4.2 Vascular Anomalies

Multiple vascular anomalies may occur within the middle ear. These anomalies are especially important to any surgeon operating on the ear in order to avoid inadvertent injury to the vessel. The internal carotid artery may assume an anomalous course and enter the middle ear in the hypotympanum.

Patients may present with pulsatile tinnitus, conductive hearing loss, and otalgia. The vessel may appear as a reddish mass medial to the inferior portion of the tympanic membrane. In a similar manner, the sigmoid sinus and the jugular bulb can present in abnormal locations. A high-riding or enlarged jugular bulb may present as a bluish mass medial to the inferior portion of the tympanic membrane (□ Fig. 65.8). Failure to identify an anomalous carotid artery or high-riding jugular bulb during middle ear surgery or even a myringotomy can lead to devastating consequences.

Another rare congenital vascular anomaly is a persistent stapedia artery. The stapedia artery is the embryologic remnant of the second branchial arch artery. The artery normally regresses at approximately the 10th week of gestation. A persistent stapedia artery arises from the internal carotid artery in the hypotympanum and courses through the crura of the stapes to the fallopian canal, geniculate ganglion, and dura. Like other vascular anomalies, a persistent stapedia artery can cause difficulties with surgery involving the middle ear, especially the stapes.

65.4.3 Congenital Cholesteatoma

Cholesteatomas are expansile lesions composed of stratified squamous epithelium and desquamated keratin that may develop within the temporal bone. They may be acquired or congenital. Multiple complications may arise as a result of the presence of a cholesteatoma. Infection, facial nerve paralysis, hearing loss, bone destruction, and intracranial complications can all occur.

Congenital cholesteatoma has been defined as an embryonic rest of epithelial tissue in the middle ear in a patient without tympanic membrane perforation and without a history of otorrhea or prior ear procedures. On physical examination, congenital cholesteatomas often appear as a white mass in the anterior–superior quadrant of the tympanic membrane. CT is used to characterize the size, location, and extent of the cholesteatoma for surgical planning (□ Fig. 65.9). The mean age of patients at presentation is 4.5 years, and a 3:1 male-to-female preponderance has been noted. The pathogenesis of these lesions is not fully understood. Treatment is similar to that for acquired cholesteatomas.

Fig. 65.9 Congenital cholesteatoma of the right temporal bone.

65.5 Conclusion

When the clinician is evaluating patients with malformations of the external or middle ear, a thorough understanding of the embryology and developmental processes is necessary. These malformations can lead to functional and aesthetic complications and concerns for the patients affected. Multiple procedures and therapies have been developed to address these complications. An improved understanding of congenital anomalies will assist in the diagnosis and treatment of those affected.

65.6 Roundsmanship

- The head of the malleus and the body and short processes of the incus are formed from Meckel cartilage, whereas the long process and lenticular process of the incus, handle of the malleus, and stapes superstructure are formed from Reichert cartilage. The vestibular surface of the stapes foot plate and the annular ligament are formed from mesoderm of the otic capsule.
- Type I first branchial cleft cysts are duplications of the external auditory canal and run lateral to the facial nerve. Type II cysts run inferiorly toward the angle of the mandible and may be lateral or medial to the facial nerve.
- Meurman classified microtia into three grades based on the presence or absence of normal external auricular landmarks. Know these!
- The most common congenital ossicular abnormalities include fixation of the stapes, abnormalities of the stapes superstruc-

ture, ankylosis of the incudostapedial joint, and fixation of the malleus head to the tympanic ring.

66 Evaluation, Management, and Special Techniques in Pediatric Otolaryngology

Robin A. Dyleski, Nancy King, and Christopher J. Linstrom

66.1 Eustachian Tube Development

The eustachian tube (ET) is an organ that runs between the middle ear and the nasopharynx. It regulates pressure in the middle ear while protecting the middle ear from nasopharyngeal sounds and secretions and clearing middle ear secretions into the nasopharynx.

The ET lumen widens at both ends and narrows in its midsection (isthmus). The distal cartilaginous portion ends in the nasopharynx at a prominence known as the torus tubarius. The proximal osseous portion opens onto the anterior wall of the superior portion of the middle ear about 4 mm above the floor. The osseous portion is open at all times. The fibrocartilaginous portion is closed at rest but opens during swallowing or Valsalva maneuver. Muscles associated with the ET include the tensor veli palatini, levator veli palatini, salpingopharyngeus, and tensor tympani; these aid in opening and closing the cartilaginous portion of the ET.

The ET in children is immature and therefore less functional than it is in adults. The length of the pediatric ET averages about 18 mm, about half the length of the adult ET. Perhaps more importantly, the direction of the tube varies from horizontal to 10 degrees from horizontal in the child. Additionally, the tensor veli palatini is less efficient. This combination of anatomical differences leads to a decreased ability to clear middle ear secretions, appropriately ventilate the middle ear, and protect the middle ear from the bacterial flora migrating from the nasopharynx. This has been theorized to account for the increased incidence of pediatric otitis media. The ET reaches full size by the age of 7 years, and the incidence of otitis media generally decreases after this age.

66.2 Acute Otitis Media and Otitis Media with Effusion

Otitis media (inflammation of the middle ear and mastoid space) is the most common reason for sick visits in pre-school-age children. Otitis media can be described, based on duration, as follows:

Acute: 0 to 3 weeks

Subacute: 3 to 12 weeks

Chronic: longer than 12 weeks

Acute otitis media (AOM) is defined as the presence of fluid in the middle ear accompanied by acute symptoms such as otalgia, fever, and irritability. Recurrent AOM is defined as three or more episodes within 6 months, or four episodes within 12 months.

Otitis media with effusion (OME) is the presence of fluid in the middle ear space without signs or symptoms of an acute ear infection. OME is considered a separate entity from AOM; it is

characterized by an acute onset of signs and symptoms, the presence of middle ear effusions, and signs and symptoms of middle ear inflammation.

OME can occur as a postinflammatory response to AOM, viral infection, or ET dysfunction. The persistent fluid collection can result in multiple sequelae, most commonly a conductive hearing loss due to decreased mobility of the tympanic membrane (TM).

Chronic suppurative otitis media is the persistence of purulent fluid behind the TM that is unresponsive to medical therapy.

66.2.1 Epidemiology

Children in the 7- to 36-month age range are most likely to develop AOM. Children with multiple episodes of AOM tend to have their first episode within the first year of life. Children who have not had AOM by the age of 3 years are unlikely to develop severe or recurrent otitis media.

OME will occur in 50% of children in the first year of life and persist in 30 to 40% usually in an asymptomatic manner. The incidence of OME peaks in the second year of life during the winter months, in association with an upper respiratory infection; full resolution occurs within a few months without any medical or surgical intervention.

Children with craniofacial abnormalities affecting the ET are at greater risk for developing otitis media, including those with cleft palate, midface deformities, skull base deformities, or nose and paranasal sinus abnormalities. Other craniofacial abnormalities associated with otitis media include Down syndrome, Apert syndrome, and mucopolysaccharidoses.

Other children who may be more prone to otitis media include those with immunodeficiencies or nasal obstruction (e.g., chronic allergies, adenoid hypertrophy, sinonasal tumors).

66.2.2 Pathophysiology

Otitis media in the child is related to dysfunction of the ET. The immature ET is more horizontally aligned than the adult ET, leading to less effective drainage of the middle ear space. Edema of the ET due to an upper respiratory infection or allergies only compounds the problem. Congenital abnormalities of the palate musculature may also affect ET function.

66.2.3 Microbiology

The most common pathogens responsible for pediatric otitis media in descending order are *Streptococcus pneumoniae* (30 to 50%), *Haemophilus influenzae* (20 to 30%), *Moraxella catarrhalis* (10 to 20%), and group A streptococci (1 to 5%). One-third of *H. influenzae* and 100% of *M. catarrhalis* bacteria are β -lactamase-positive.

66.2.4 History

Common signs of AOM include otalgia, fever, irritability, and otorrhea (indicating a ruptured TM). Additional symptoms, such as facial paralysis, vertigo, and swelling behind the ear, may be indicative of a complicated AOM, and computed tomography (CT) may be required to determine if further intervention is required (see later section on complications of otitis media). Most children also have hearing loss. A child with OME may simply have hearing loss. A child with a ruptured TM secondary to AOM may have little to no pain, some hearing loss, and low-grade fevers.

66.2.5 Physical Examination

External Ear Examination

If the auricle is rotated forward and is erythematous and edematous with obliteration of the posterior auricular sulcus, there is concern for coalescent mastoiditis (see later section on acute coalescent mastoiditis)

Pneumatic Otoscopy

A normal TM (□ Fig. 66.1) should be translucent, with the middle ear landmarks clearly visible. The TM can be in normal position, retracted, or bulging. AOM and OME can be present with a retracted or bulging TM. The color of the TM may be yellow, opaque, or bluish, indicating fluid in the middle ear. Hyperemia is not specific for infection and may simply be a sequela of crying or coughing. An air–fluid level can often be seen, or air bubbles that indicate the presence of fluid in the middle ear. Effusions can be categorized as serous (thin and watery), mucoid (thick and viscous), or purulent (presence of pus). Pneumatic otoscopy should show the TM to be mobile. Decreased motility

of the TM with positive or negative pressure can be an indication of fluid sitting behind the TM, limiting its motion.

A TM perforation can be a result of increased pressure caused by persistent fluid in the middle ear. In this case, fluid is often seen coming from the perforation (otorrhea). Clinically, the patient generally describes some relief of symptoms after the perforation occurs because the pressure behind the TM is released and the effusion is allowed to drain.

66.2.6 Management of Acute Otitis Media

AOM has a spontaneous resolution rate of 60% within 24 hours and of 80% within 48 to 72 hours. Once a diagnosis of AOM has been confirmed, an appropriate course of action is determined. The American Academy of Pediatrics and the American Academy of Family Physicians, together with experts in otolaryngology, have created guidelines for the evidence-based management of AOM.

Observation

In selected children with dependable follow-up, watchful waiting for 48 to 72 hours with only pain management is an option. Children between the ages of 6 months and 2 years with mild to moderate symptoms, uncomplicated AOM, or an uncertain diagnosis would be appropriate candidates for this strategy.

Medical Treatment

If medical treatment is appropriate, amoxicillin is the first-line medication for most children, dosed at 80 to 90 mg/kg/d. Other options include cefdinir and clindamycin. Symptomatic relief should occur within 48 to 72 hours of the initiation of antibiotic-

Fig. 66.1 Normal right tympanic membrane.

Fig. 66.2 Types of tympanostomy tubes. (a) Armstrong grommet. (b) Mini-grommet. (c) Feuerstein split.

ics. If no improvement is seen, the diagnosis of AOM should be reconfirmed. For AOM refractory to amoxicillin, the guidelines recommend amoxicillin/clavulanate for additional coverage. For patients who are allergic to penicillin, a cephalosporin (penicillin-allergic patients show 10 to 15% cross reactivity when treated with cephalosporins), trimethoprim/sulfamethoxazole, or a macrolide is recommended. Levofloxacin, azithromycin, or clarithromycin can also be tried in penicillin-allergic patients.

66.2.7 Management of Otitis Media with Effusion

In May of 2004, the American Academy of Otolaryngology-Head and Neck Surgery, the American Academy of Family Physicians, and the American Academy of Pediatrics revised the guidelines for the management of OME. The highlights are reviewed here.

- OME should be differentiated from AOM. OME is defined as the presence of fluid in the middle ear without signs or symptoms of AOM.
- Pneumatic otoscopy should be the primary diagnostic method, with confirmation by tympanometry. The laterality of OME, duration of the effusion, and any associated symptoms should be documented.
- Watchful waiting for 3 months after the onset of the effusion or the diagnosis is appropriate in most children because 75 to 90% of cases of residual OME after AOM resolve spontaneously within 3 months.
- If OME persists for 3 months or longer, significant hearing loss with associated speech or language delay is noted, or learning problems are suspected, a hearing test should be performed.
- If no hearing loss is found, children with OME should be reexamined every 3 to 6 months until the effusion disappears.
- If hearing loss is present, placement of a pressure equalization tube should be the initial procedure. Repeated tube insertion should be accompanied by adenoidectomy. Surgical candidates include children who have OME lasting 4 months or more with persistent hearing loss, children with persistent OME who are at risk regardless of hearing status, and children who have OME and structural damage to the TM or middle ear.

Fig. 66.3 Triune tube (Grace Medical, Memphis, TN).

- In children at risk, such as developmentally delayed children with Down syndrome or children with cerebral palsy, who are more likely to have baseline speech or language delay, OME should be addressed earlier.
- Antibiotics, antihistamine decongestants, and steroid medications have not been shown to aid in the resolution of OME.

Tympanostomy Tube Selection

Tubes can be separated into three categories: short-term, mid-term, and long-term. For most normal children with chronic serous otitis media, a short-term tube is sufficient to ventilate the middle ear until ET function improves with age. Mid-term and long-term tubes are reserved for children who are expected to be tube-dependent for a long period of time. Children who fall into this category include those who have Down syndrome, are receiving their second or third set of tubes, or have long-standing ET dysfunction.

Short-term tubes generally reside in the TM for 6 to 24 months. Some popular types are shown in □ Fig. 66.2.

Mid-term tubes typically remain in place and function for 18 to 20 months and are shown in □ Fig. 66.3.

Long-term tubes are placed when there is a greater likelihood of recurrent disease and generally provide effective function for 2 to 3 years (□ Fig. 66.4).

The incidence of complications, such as chronic TM perforation and granulomas, increases the longer a tube is left in place.

Myringotomy and Tube Placement Technique

1. Position the microscope and patient appropriately.
2. Place the largest ear speculum that will fit atraumatically into the external auditory canal.
3. Cerumen in the external auditory canal is removed, and visualization of the TM is maximized.

Fig. 66.4 T-tube.

4. Examine the eardrum and note the normal landmarks and any abnormalities in the drum.
5. If the patient is not under general anesthesia:
 - a) Ear canal injection:

A solution of 1% lidocaine with 1:100,000 epinephrine can be injected at the cartilaginous–bony junction at 12 o'clock, 3 o'clock, 6 o'clock, and 9 o'clock through a 25-gauge needle. Inject slowly to prevent infiltration into the middle ear. Anesthetic in the middle ear can cause delayed vertigo if the solution crosses the round window or temporary facial paralysis if the patient has a dehiscence facial nerve canal.

- a) Topical phenol:

A wisp of cotton saturated with 100% phenol and applied discretely to the TM at the proposed myringotomy location produces excellent anesthesia with no postoperative complications. Alternatively, phenol can be administered with a phenol applicator (straight-handled otologic instrument with a “forked” tip that, when dipped, holds a small amount of phenol between the tines and allows discrete and focused application). The myringotomy is then made through the white coagulum created.

1. The myringotomy knife is inserted through the TM, and the incision is created in the location of choice. The length of the myringotomy incision should be about the diameter of a No. 5 suction vent to ensure easy tube insertion.
2.
 - a) Myringotomy location:
 1. Epithelial migration of the squamous portion of the drum is believed to be responsible for tube extrusion. Migration begins at the umbo and radiates outward.
 2. Migration is fastest in the anteroinferior and posteroinferior quadrants.
 3. As the posterosuperior quadrant contains the ossicles, the anterosuperior quadrant is the ideal place for myringotomy and tube placement.
 4. The inferior quadrants are more easily accessible and are often used.
 - b) Myringotomy direction:
 1. Radially oriented incisions parallel epithelial migration.
 2. Circumferential incisions run perpendicular to epithelial migration, leading to a faster extrusion rate.
 - c) Hemostasis can be achieved with oxymetazoline-soaked pledgets, if necessary.
 - d)
3. Suction the middle ear contents with a No. 5 suction vent through the myringotomy.

- a) Mucoïd secretions are sometimes difficult to evacuate; saline irrigation may be of value. Alternatively, a second counter-incision can be made through the TM to allow air to enter the middle ear space.
 - b) The tympanostomy tube is grasped with an alligator forceps, and the anterior edge of the inner flange is inserted into the myringotomy incision. The tube is then released. With either an alligator forceps or a Rosen pick, the lagging edge is gently pushed until it “pops” through the myringotomy incision (□ Fig. 66.5).
4. Ensure patency of the tube by gently suctioning it with the thumb off the suction vent.
 5. Administer otic antibiotic drops.

Tube Management

An audiogram should be obtained after tympanoplasty and compared with the pretreatment test to ensure improvement in hearing. The patient should be seen every 3 to 6 months and then yearly in order to visually examine the tubes and determine their location (in place, extruded, in the external auditory canal), their patency, and the status of the middle ear. Audiography is repeated as clinically necessary.

If the tubes persist longer than they are clinically needed and have shown no signs of spontaneous migration from the TM, removal of the tubes can be considered.

Factors to consider before tube removal:

- Recurrent/chronic drainage: Drainage from the ears is an indication that the tubes are clinically necessary. In this case, the tubes should be left in place.
- ET function: In the case of unilateral tube persistence, the contralateral ear can be examined to determine the maturity of the ET. If the contralateral TM is retracted, indicating continued poor ET function, the tubes are still clinically needed.

Complications of Tubes

Persistent Tympanic Membrane Perforation

After tube removal, the patient should observe water precautions and return for an examination in 3 months. In most cases, the perforation will be smaller or healed. If the perforation persists, repair of the TM is necessary.

Paper Patch Technique (□ Fig. 66.6)

For dry perforations smaller than 3 mm, a paper patch is sufficient.

1. Position the patient reclining in the chair.
2. Examine the external auditory canal and TM, documenting the size and location of the perforation.
3. The edges of the perforation are de-epithelialized with a myringotomy knife or otologic needle. Make sure to remove only a minimal amount to avoid enlarging the perforation.
4. Use a right angle hook to sweep circumferentially around the medial portion of the perforation margin.
5. Rice (cigarette) paper or paper tape (Micropore strip tape; 3 M, St. Paul, MN) is used. The paper patch is trimmed to approximately twice the size of the perforation. The underside of the paper patch is moistened with sterile water or a non-steroidal antibiotic drop.

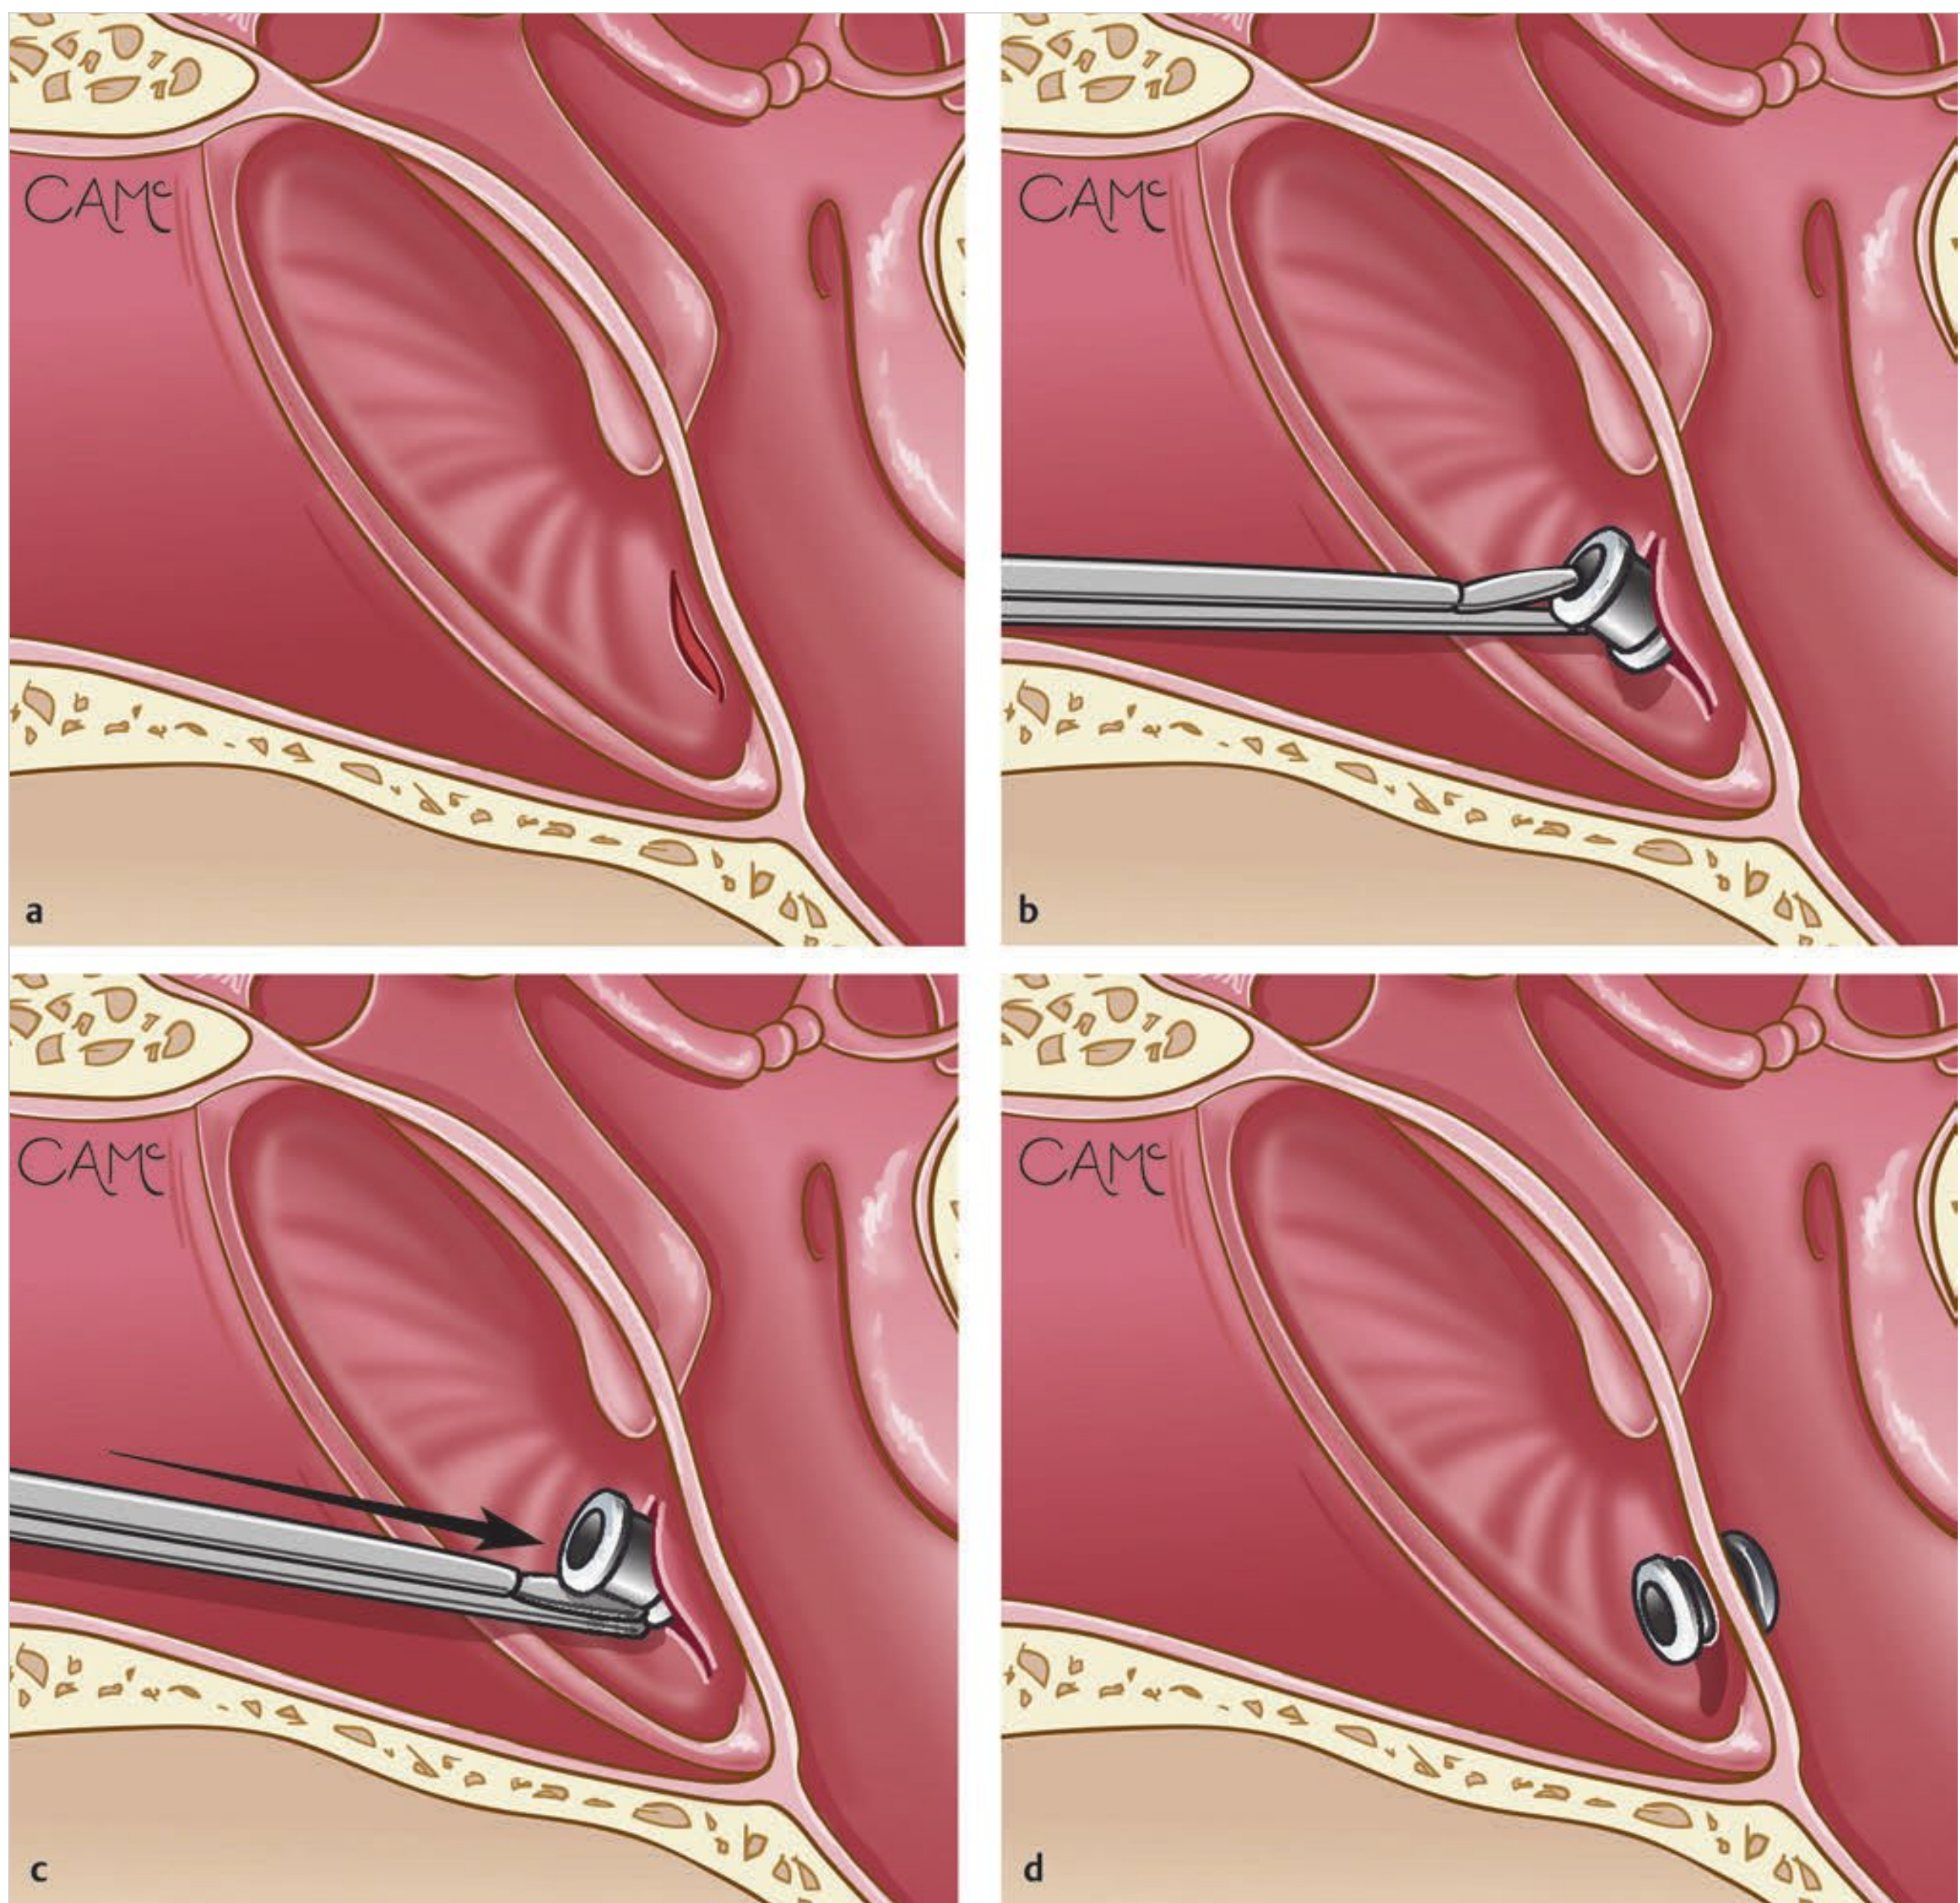

Fig. 66.5 Myringotomy with placement of a tympanotomy tube. (a) A radial incision is made in the tympanic membrane. (b) The anterior flange is placed through the myringotomy and then released. (c) A forceps or a pick is used to “pop” the posterior flange of the tube through the myringotomy until (d) the tube is in an appropriate position.

6. Place the paper patch over the perforation with an alligator forceps.
7. Smooth it against the TM with a cerumen curet.

For larger perforations, a formal tympanoplasty is needed.

66.2.8 Complications of Otitis Media

Facial Paralysis

The facial nerve, as it travels through the middle ear and mastoid bone, may be affected by adjacent infection. Facial paralysis can occur as a complication of AOM and should be addressed

immediately to prevent permanent facial paralysis. It often resolves after myringotomy and tube placement, along with intravenous (IV) antibiotics. Should facial paralysis occur in the setting of acute coalescent mastoiditis (see below), a mastoidectomy should be performed urgently.

Acute Mastoiditis

Technically, all cases of AOM are accompanied by an acute mastoiditis because the mastoid cells are simultaneously inflamed. This process does not carry any additional symptoms beyond those of an AOM. The condition improves with improvement of the otitis media.

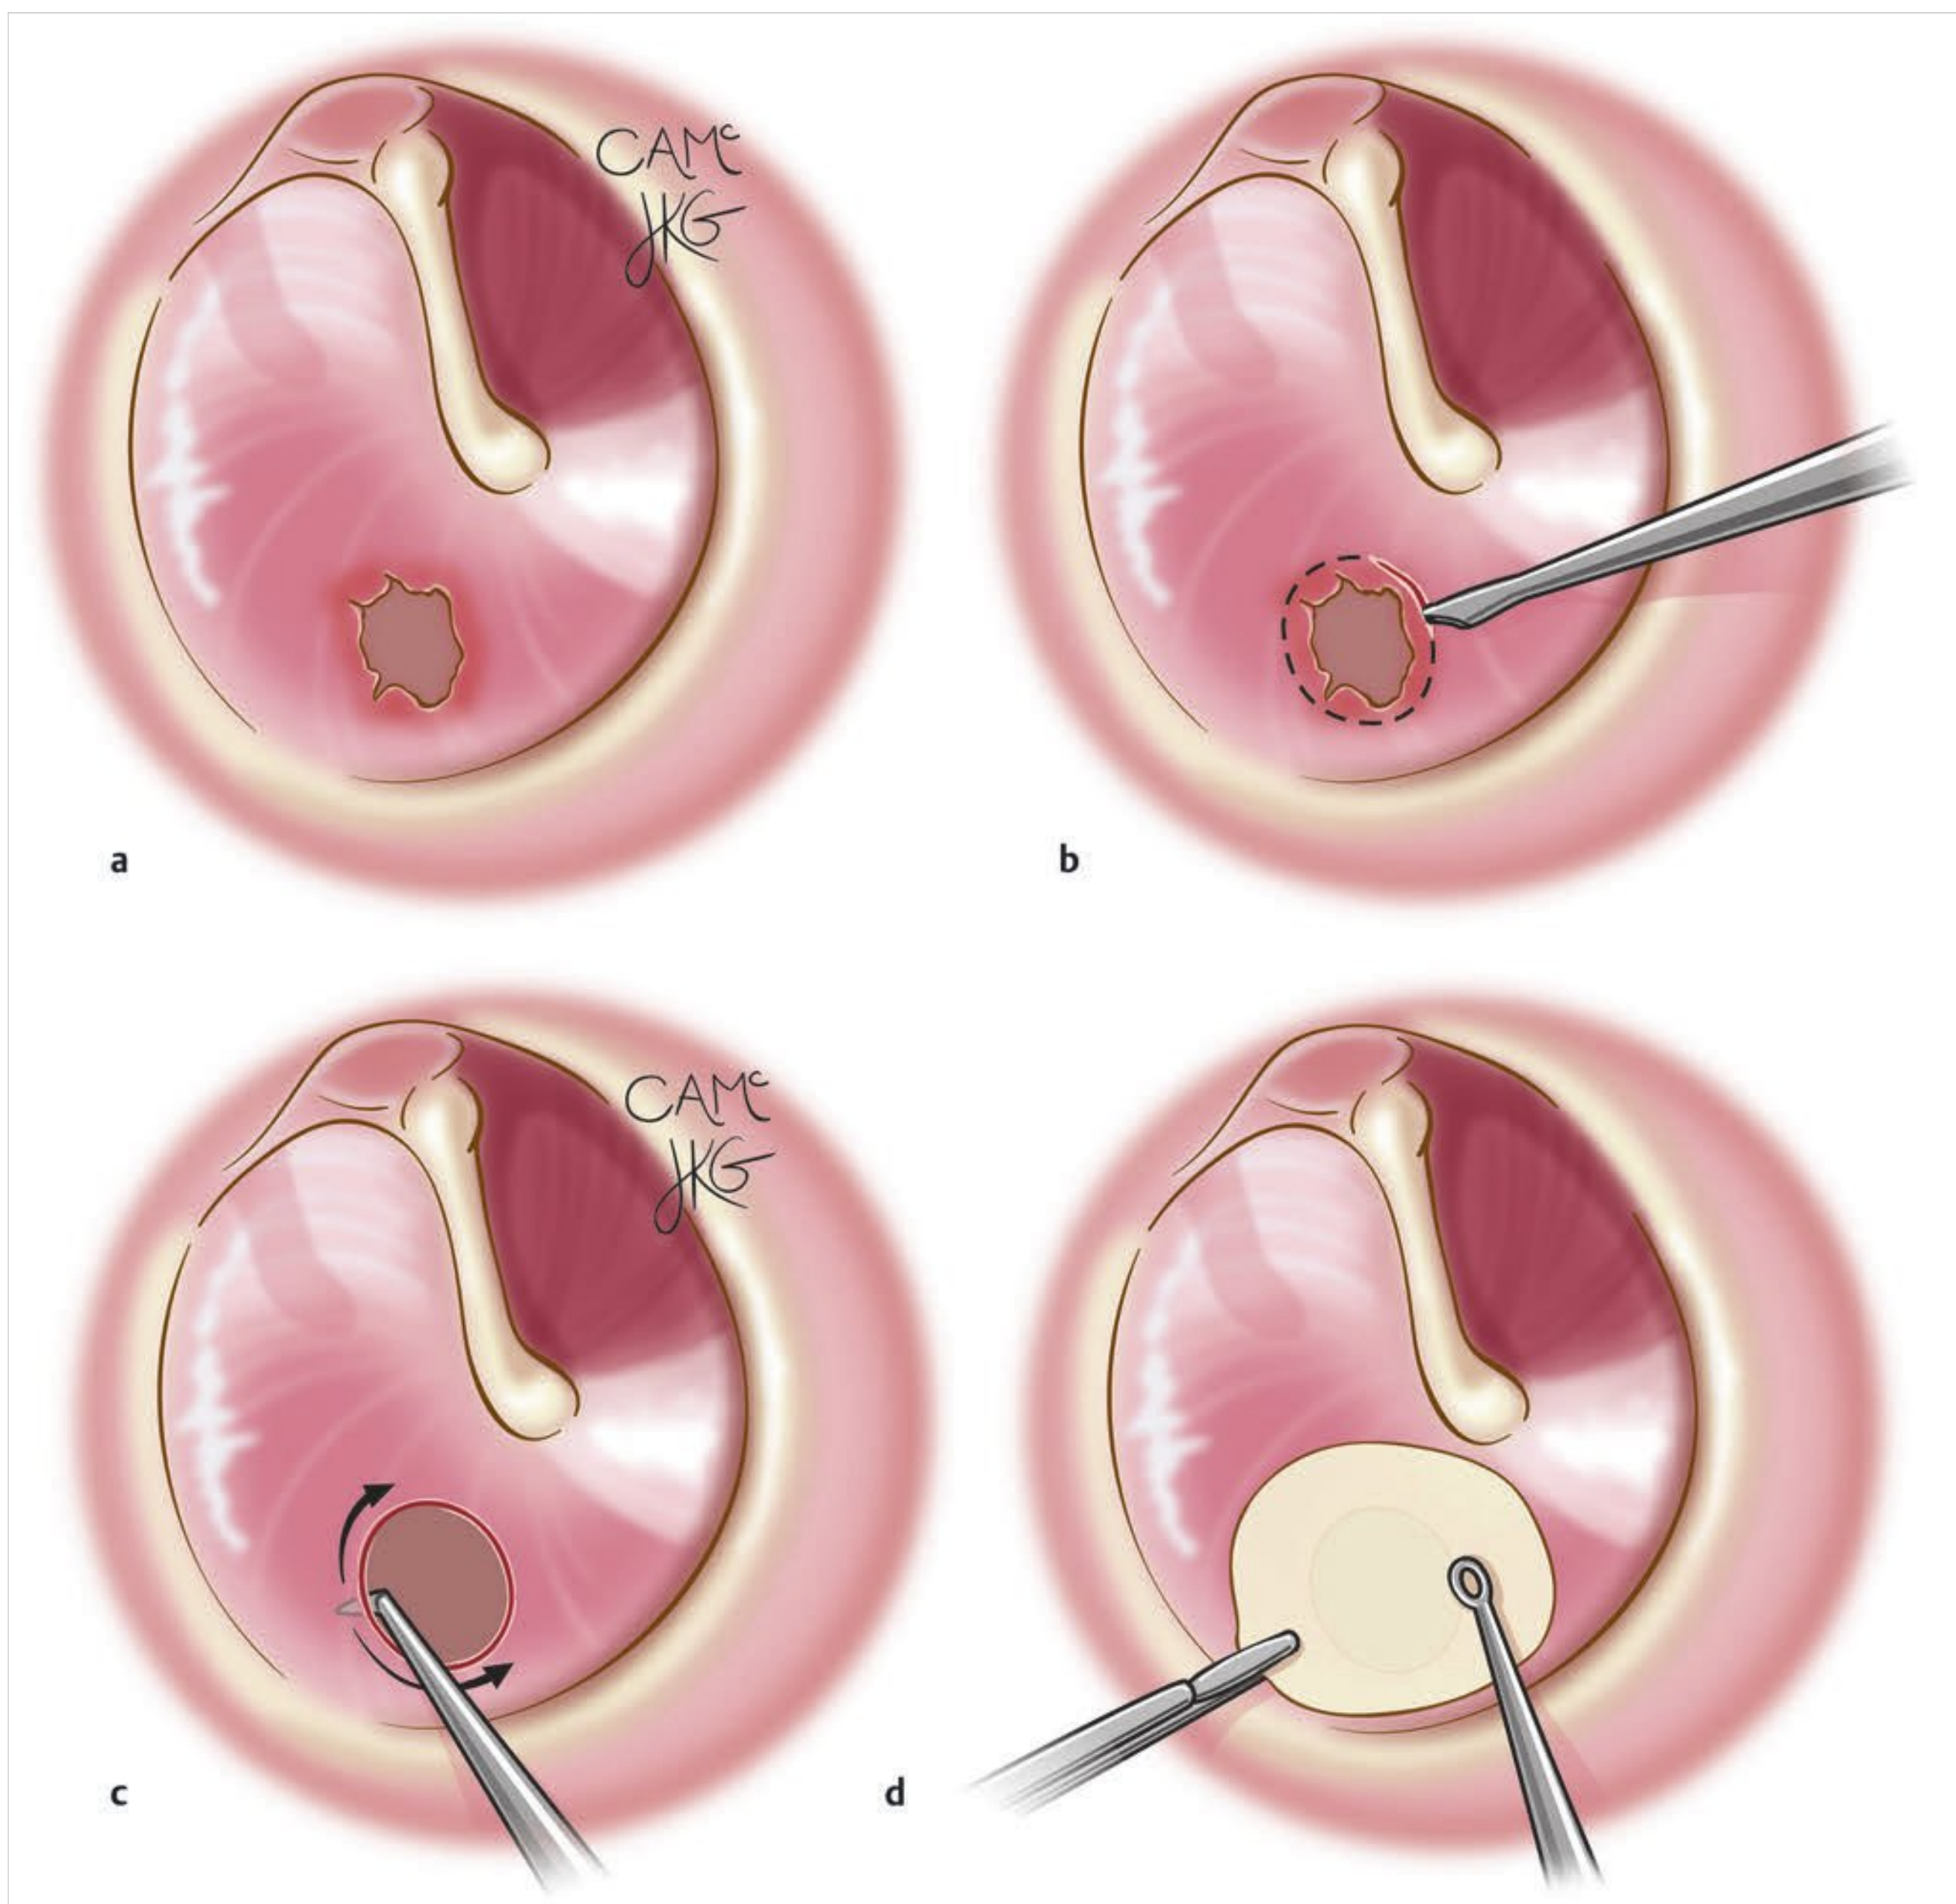

Fig. 66.6 (a) Small, dry tympanic membrane perforations may be closed effectively with a paper patch technique. (b) The perforation edge is de-epithelialized with a myringotomy knife or otologic pick, with minimal tissue removed. (c) The undersurface of the perforation edge is abraded with a right angle hook. (d) The moistened paper patch is applied directly over the perforation.

Acute Mastoiditis with Periosteitis

Acute mastoiditis with periosteitis involves inflammation and infection of the mastoid air cells extending to the periosteum, but without involvement of bone. Findings include inflammation and erythema of the postauricular area, displacement of the pinna inferiorly and anteriorly, and fluid in the middle ear (□ Fig. 66.7). The postauricular crease may or may not be absent. Treatment with IV antibiotics and tube placement to facilitate drainage of the middle ear leads to resolution.

Acute Coalescent Mastoiditis

Also known as acute mastoid osteitis, acute coalescent mastoiditis is an infection that causes bony destruction. This usually presents in children 4 years of age or younger (mostly boys) who have had unrelieved symptoms of AOM and/or mastoiditis for 2 to 4 weeks. Coalescent mastoiditis tends to develop in children with well-developed mastoid air cells and children with no prior otologic disease. Pain may be localized to the posterior auricular area. The mastoid may be tender to percussion, there may be overlying erythema, and the posterosuperior external

Fig. 66.7 (a) Posterior and (b) oblique views of the postauricular sulcus in a patient who has acute mastoiditis with periosteitis show protrusion and inferior displacement of the auricle, along with erythema of the postauricular sulcus.

Fig. 66.8 Temporal bone computed tomographic scan showing loss of septa between the mastoid air cells, suggesting coalescent mastoiditis.

auditory canal may be sagging. These signs are usually present, but not always. The children look toxic with persistent high fevers. CT of the temporal bone should be obtained to clarify the extent of the disease (□ Fig. 66.8).

Early acute coalescent mastoiditis may respond to tube placement and IV antibiotics. However, a simple mastoidectomy may be required. If acute coalescent mastoiditis is found in the setting of facial nerve paralysis, mastoidectomy should be performed urgently and 3 to 6 weeks of IV antibiotics initiated.

Acute coalescent mastoiditis may be accompanied by acute petrositis, indicating that infection has spread to the petrous portion of the temporal bone. Gradenigo syndrome is a triad of suppurative otitis media, ipsilateral ocular pain, and sixth cranial nerve paralysis.

Simple Mastoidectomy Technique

A safe technique for mastoidectomy in children is informed by an understanding of the differences between the adult and pediatric temporal bone. In children 2 years of age or younger, pneumatization has not progressed to the mastoid tip, resulting in a more superficially located stylomastoid foramen (□ Fig. 66.9 and □ Fig. 66.10). This puts the facial nerve at increased risk for surgical injury in the pediatric patient. Unless it is impossible to obtain in a gravely ill patient, preoperative audiography should be performed to document conductive and sensorineural hearing.

1. The patient is placed in a supine position with the head turned away from the affected ear. The postauricular crease is infiltrated with local anesthetic (□ Fig. 66.11).
2. Because of the more superficial location of the stylomastoid foramen in children, the postauricular incision is not carried down as far inferiorly as in adults. The incision is also made 6 to 8 mm posterior to the postauricular sulcus (□ Fig. 66.12).
3. The incision is carried down to the loose areolar tissue over the temporalis fascia and mastoid periosteum (□ Fig. 66.13a).
4. The superior boundary is the linea temporalis. A T incision is made along the linea temporalis from the zygomatic root to the occipitomastoid suture and from the linea temporalis to the mastoid tip with a monopolar cautery. An elevator is used to elevate the soft tissue off the bone (□ Fig. 66.13b).
5. Self-retaining Weitlander retractors are placed to improve exposure, and key landmarks are identified: spine of Henle, cribriform area, and linea temporalis.
6. The MacEwen triangle is identified, which serves as a landmark for locating the mastoid antrum. The MacEwen triangle is bounded by the posterior border of the external auditory canal, the anterior line of the zygomatic arch, and a line that connects the two (□ Fig. 66.14). The antrum is 15 mm medial to this. Under a 200- to 250-mm microscope, a cutting bur is used to remove the outer cortex of the mastoid beginning at a line along the linea temporalis. Copious irrigation is used to prevent excessive heat transfer to underlying structures. The tegmen is identified by a pinkish color seen through a thin bony covering and carefully respected. Posteriorly, as the cortex is removed, the bluish tint of the sigmoid sinus can be

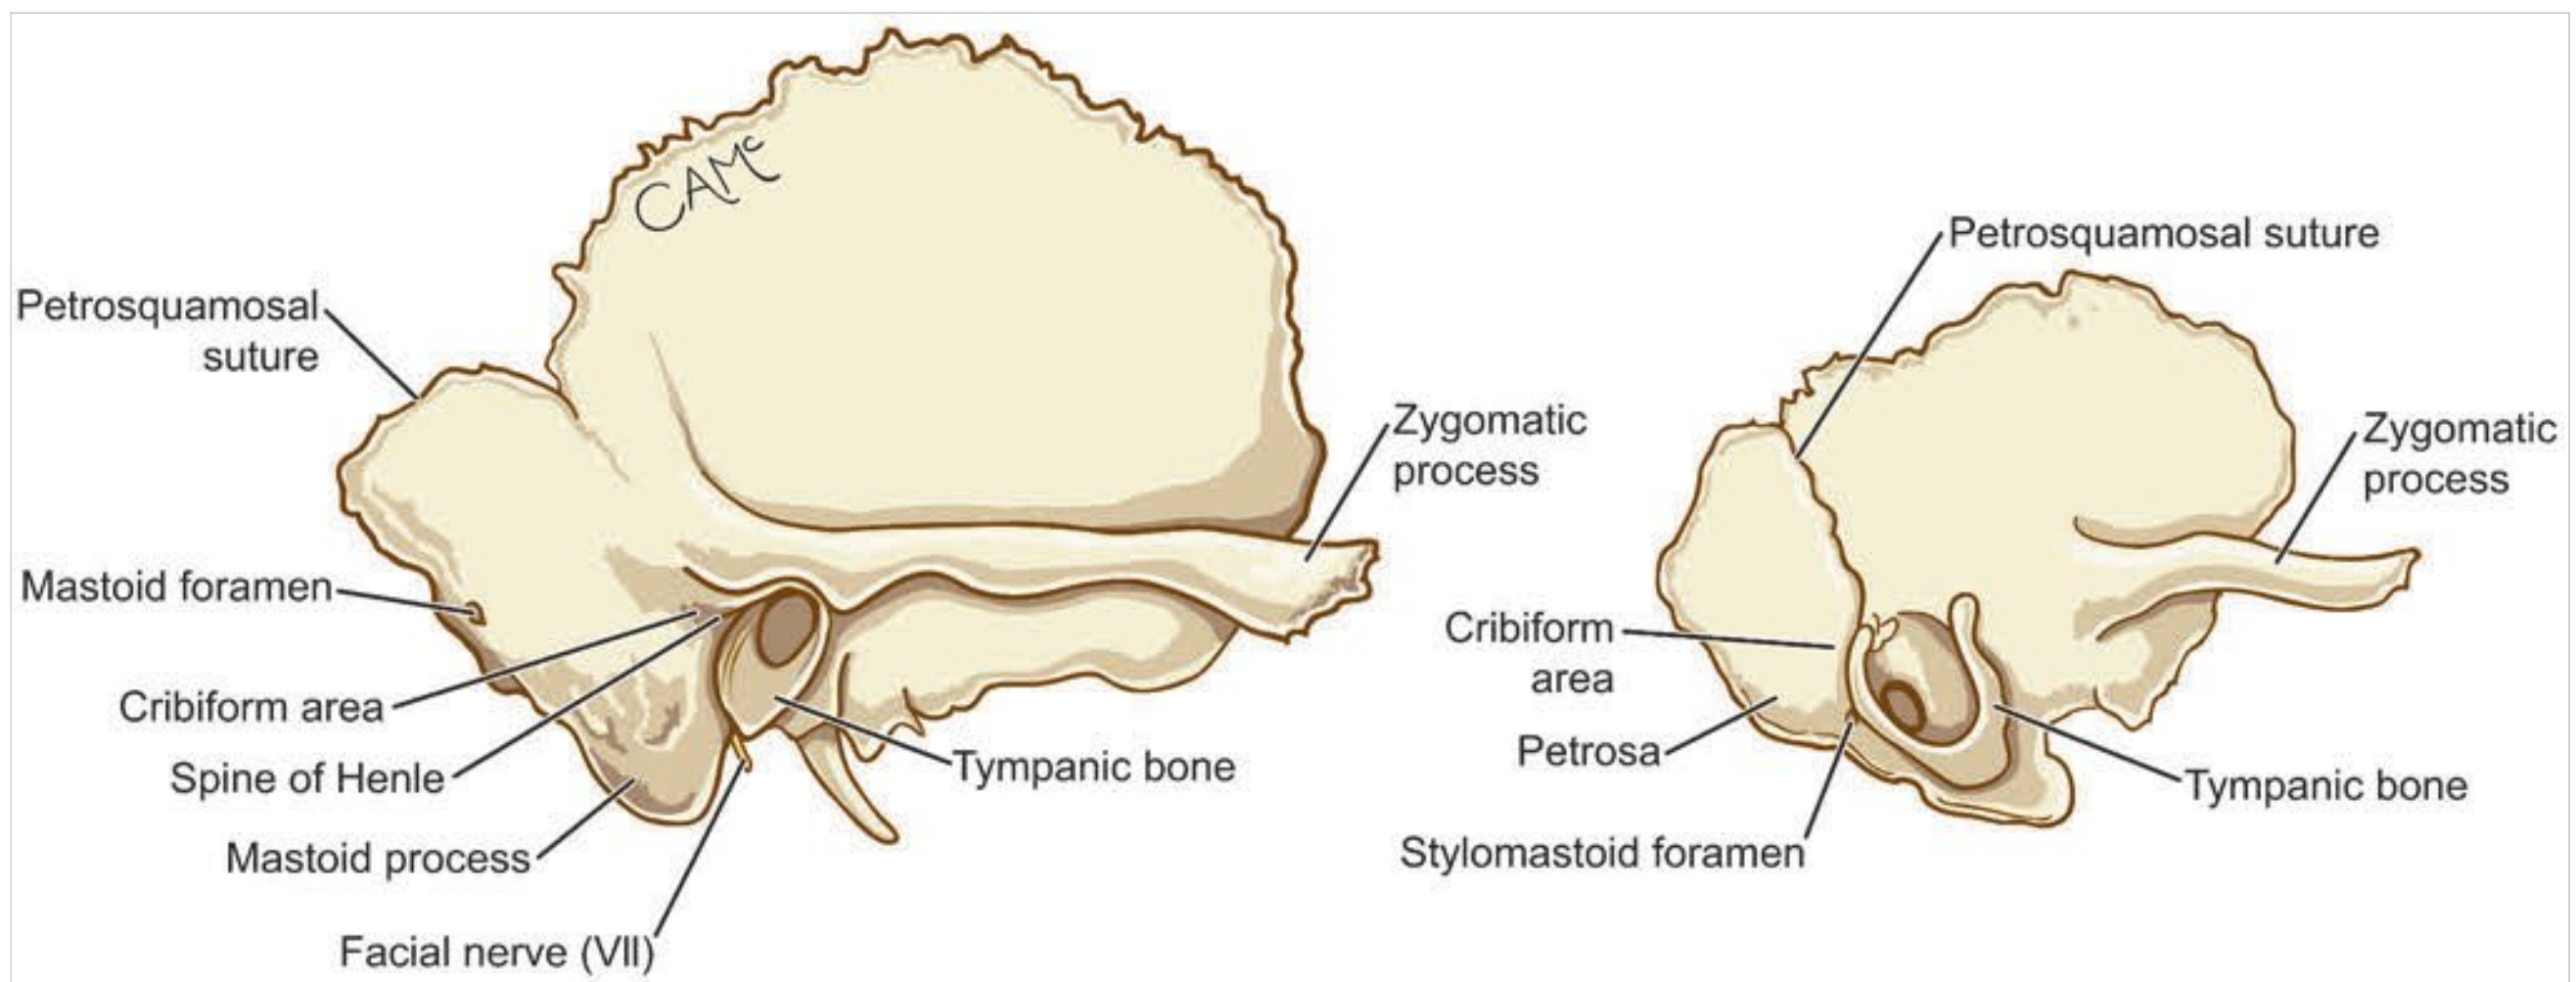

Fig. 66.9 Differences between the adult and pediatric mastoid bone. In children, the mastoid is far less pneumatized and the tympanic ring is much less developed.

Fig. 66.10 Normal mastoid structures.

Fig. 66.11 Mastoidectomy. The postauricular sulcus is infiltrated with 1% lidocaine with 1:100,000 epinephrine.

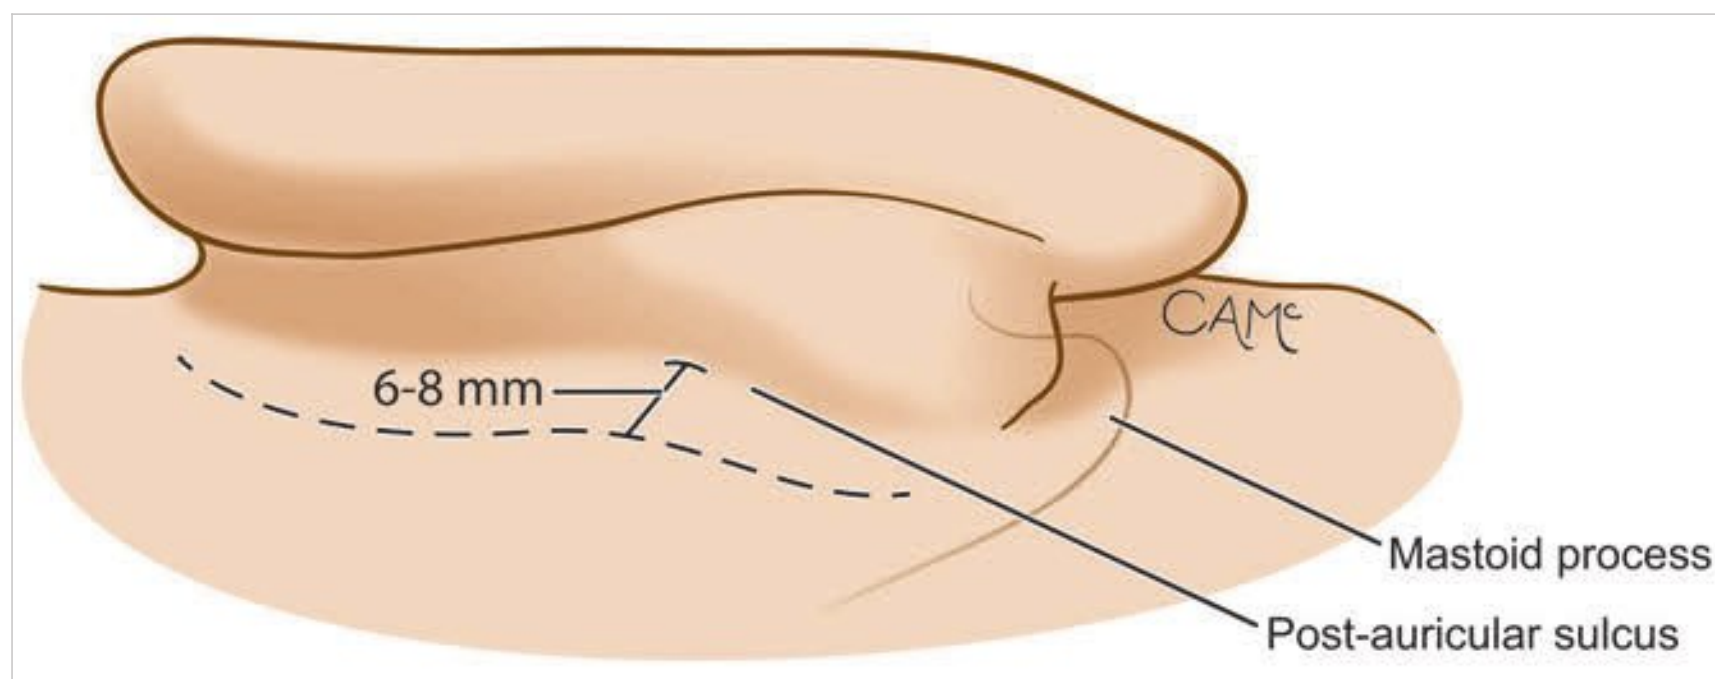

Fig. 66.12 Mastoidectomy. The postauricular sulcus incision is moved 6 to 8 mm posteriorly, and the incision does not extend as far inferiorly as in the adult to avoid facial nerve injury.

seen as the bowl is progressively developed from the mastoid tip to the posterior aspect of the linea temporalis dissection. Anteriorly, bone is removed up to a few millimeters posterior to the spine of Henle. More air cells are opened as the bowl is progressively saucerized (□ Fig. 66.15).

7. The Körner septum, a thin plate of bone representing the petrosquamous lamina, is penetrated to fully open the mastoid antrum. Once this is done, the aditus ad antrum is inspected, identifying the lateral semicircular canal, fallopian canal, chorda tympani, and short process of the incus (□ Fig. 66.16).
8. A tympanostomy tube should be placed in a patient with acute coalescent mastoiditis.

66.3 Evaluation and Management of Speech Delay in Children

The development of normal speech and language is evaluated as a component of the developmental milestones that are monitored by pediatricians during routine well-child visits. Early intervention to determine the nature and cause of speech delays is important in children who have either normal hearing or impaired hearing to help them reach their full potential. When hearing impairment is identified and treated before 6 months of age, there is a greater likelihood of normal speech and language development.

In the United States, nearly all states have legislated newborn hearing screening programs that test the hearing of newborn children before discharge from their birth hospital. The few states without legislated programs have voluntary programs to screen for hearing loss in infants. The Year 2007 Position

Statement of the Joint Committee on Infant Hearing stresses the following points:

1. The definition of hearing loss has been expanded to include neural hearing loss (e.g., “auditory neuropathy/dyssynchrony”).
2. Separate protocols are recommended for neonatal intensive care units (NICUs) and well-infant nurseries. NICU infants admitted for more than 5 days are to undergo auditory brainstem response (ABR) testing as part of their screening, so that neural hearing loss will not be missed.
3. Referrals from the NICU should be made directly to an audiologist for rescreening and comprehensive evaluation, including ABR testing.
4. For rescreening, a complete screening of both ears is recommended, even if only one ear failed the initial screening.
5. For all infants (NICU infants and well infants) readmitted during the first month of life with a condition associated with potential hearing loss (e.g., severe hyperbilirubinemia or culture-positive sepsis), a repeat hearing screening is recommended before discharge.
6. Only audiologists with expertise in evaluating newborns should provide audiology diagnostic and auditory habilitation services (selection and fitting of amplification device).
7. For infants in whom hearing loss is diagnosed, amplification should be fitted within 1 month of the diagnosis.
8. For infants with confirmed hearing loss, a genetics consultation should be offered to their families.
9. Every infant with confirmed hearing loss should be evaluated by an otolaryngologist with knowledge of pediatric hearing loss and should have at least one examination to assess visual acuity performed by a pediatric ophthalmologist.
10. All infants with any degree of bilateral or unilateral permanent hearing loss should be eligible for early intervention services.

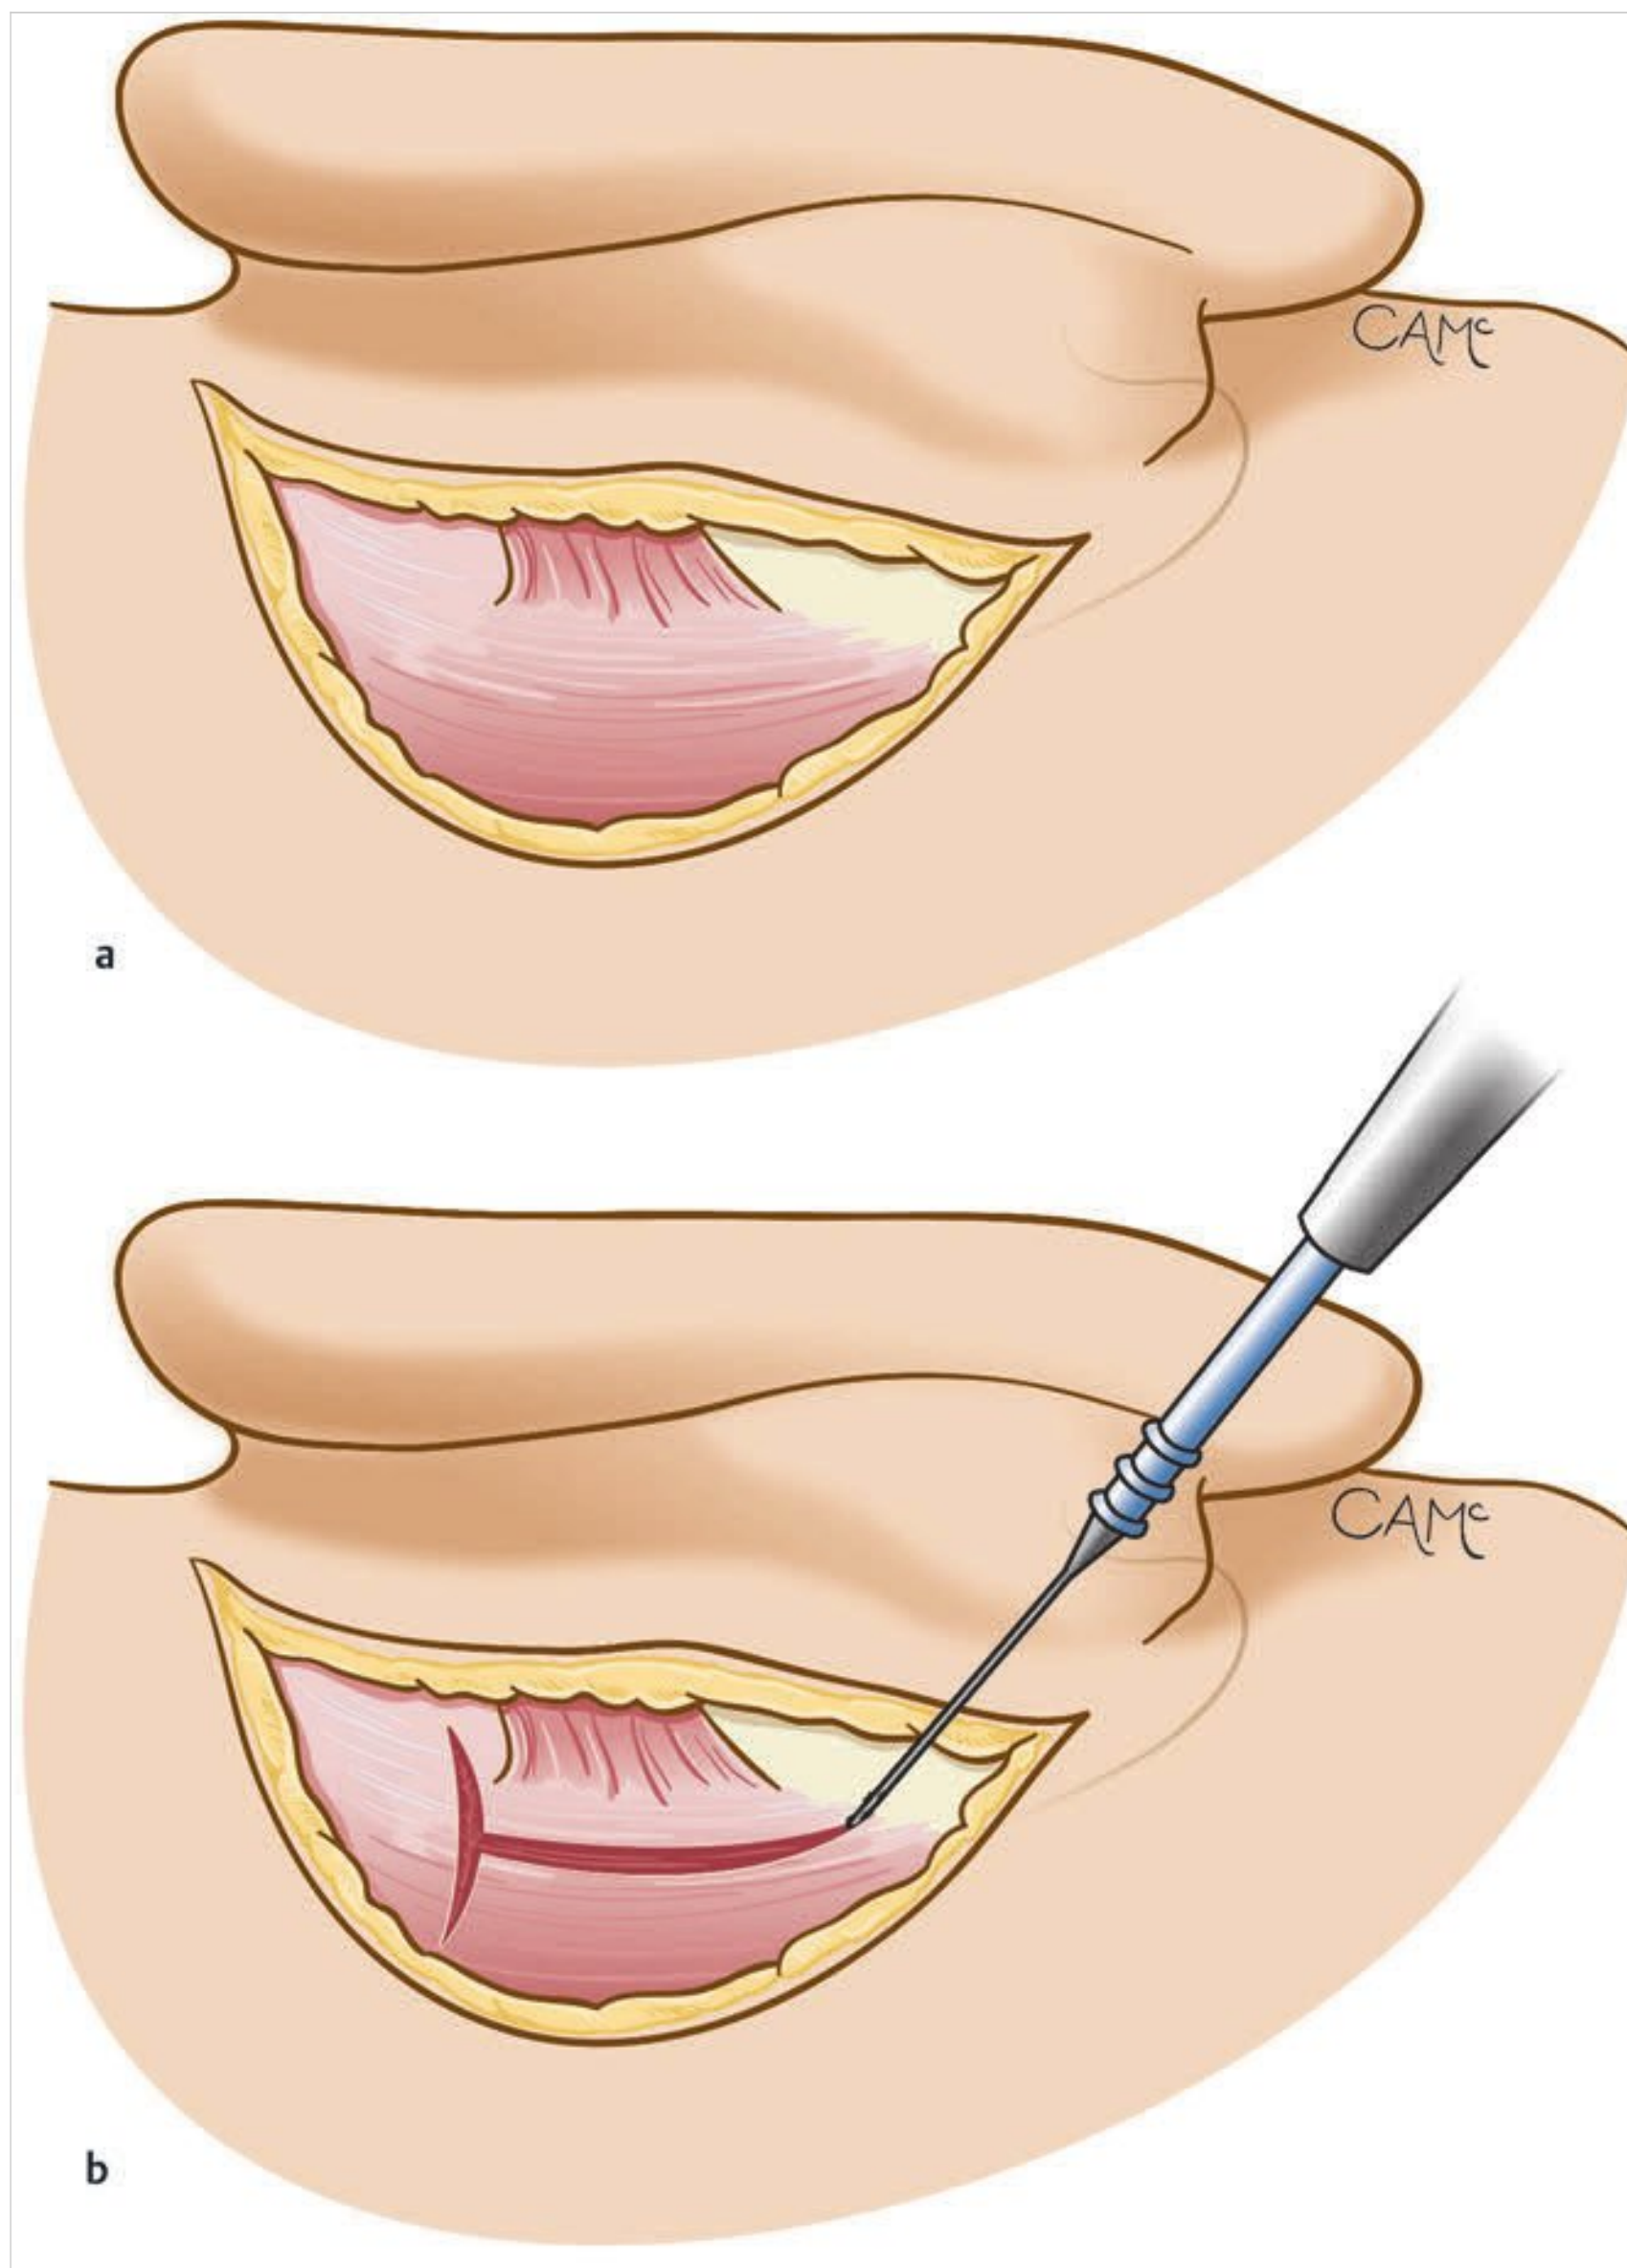

Fig. 66.13 Mastoidectomy. (a) The dissection proceeds down to temporalis fascia, which is (b) split and elevated until the bone is exposed.

11. Early intervention services for infants with confirmed hearing loss should be provided in home and center-based environments by professionals who have expertise in hearing loss.
12. For all infants, regular surveillance of developmental milestones, auditory skills, and middle ear status, as well as parental concerns, should be performed, consistent with the American Academy of Pediatrics (AAP) Periodicity Schedule (well-child care visits).
13. Families should be made aware of all communication options and available hearing technologies (presented in an unbiased manner).

Universal newborn hearing screening has allowed the early identification and treatment of children with impaired hearing. Early intervention programs vary from state to state but are instrumental in providing ongoing audiologic and speech therapy services for participating children and their families.

66.3.1 Speech Delay

Children who pass the newborn hearing screening (NBHS) evaluation at birth and in whom the onset of speech development is delayed are considered to be “speech-delayed.” Regular and routine well-child visits should determine whether babies and children are reaching the recognized developmental milestones for their age (□ Table 66.1). Normal hearing is essential for the normal development of speech and language.

Children with significant delays in speech acquisition and language development require careful evaluation of their ears and hearing. When a child presents with delayed speech acquisition, a careful history should assess for possible risk factors for speech delay. The history should include information about the pregnancy, with attention to prenatal infections associated with hearing loss. Other important considerations are the birth history and perinatal course, including hyperbilirubinemia, the use of mechanical ventilation and NCPAP (nasal continuous

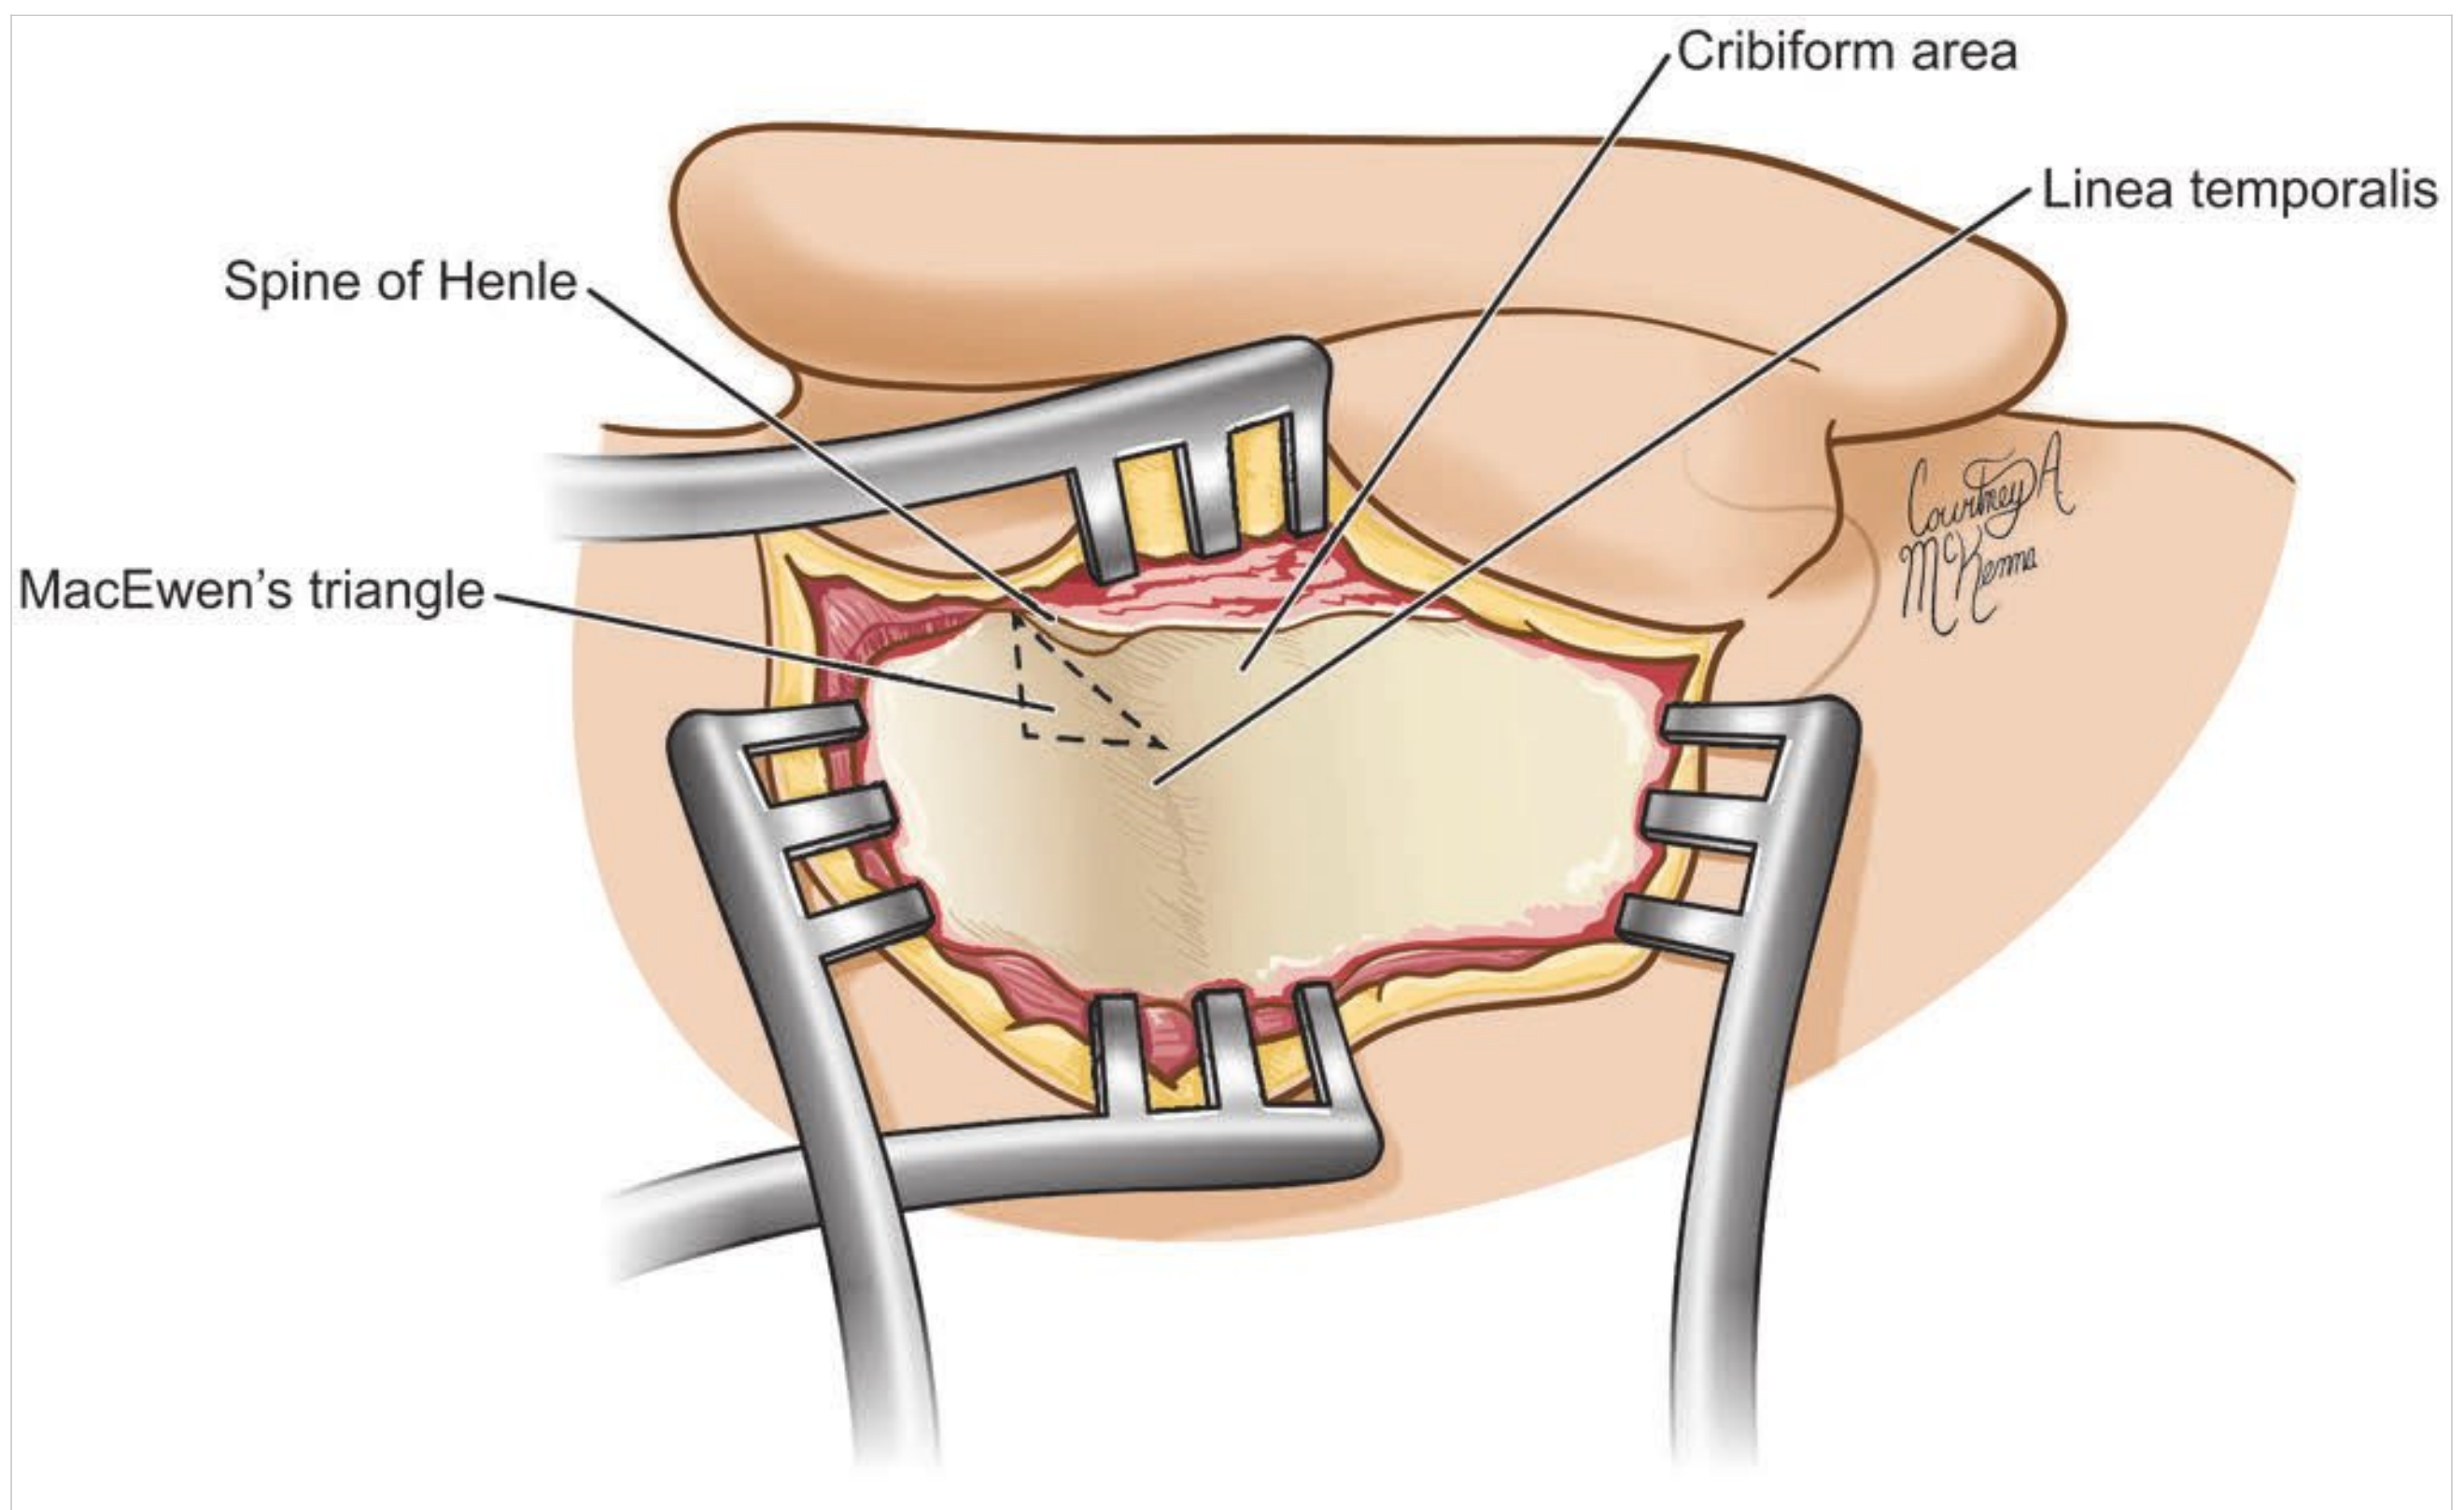

Fig. 66.14 The MacEwen triangle serves as a landmark for identifying the mastoid antrum, which lies approximately 15 mm medial to it.

Fig. 66.15 The mastoid bowl is progressively opened. The pink gleam of the tegmen through a thin layer of bone forms the superior boundary of the dissection. Posteriorly, the bluish tone of the sigmoid sinus forms another boundary of dissection. Identification of the antrum aids in gauging the depth of dissection.

Fig. 66.16 At the completion of the mastoidectomy, the aditus ad antrum is inspected, and the lateral semicircular canal, fallopian canal, chorda tympani, and short process of the incus are all visualized.

positive airway pressure), ototoxic drug exposure, and birth weight. Questions should evaluate for the presence of frequent ear infections and any other otologic history. A family history of hearing loss should be included.

The evaluation includes a complete head and neck examination, with particular attention to the ears and a search for middle ear effusions, and a complete audiologic examination, with audiography, OAE (otoacoustic emissions) or ABR tests, and tympanometry.

When hearing loss is identified by audiometric testing or a positive clinical finding is noted during the physical examination, such as a middle ear effusion, treatment is directed toward correction of the abnormality. For example, middle ear effusions would be treated with the placement of tympanostomy tubes and the hearing retested following the procedure to determine if it has been satisfactorily improved to normal.

In the case of a child with normal hearing test results and physical examination findings, a referral to speech therapy is made. The speech therapist will provide a variety of exercises for the patient to improve speech production and language development. Parents can participate in the child's therapy by continuing specific exercises with the child between the therapy sessions to reinforce the therapy goals. In most cases, speech therapy is able to help the child to "catch up" with speech development and production.

Table 66.1 Milestones for speech and language development

Age	Milestones
Birth–3 mo	Reacts to loud sounds Recognizes caregiver's voice Coos in response to pleasure
4–6 mo	Looks toward sounds and follows Babbles and makes different sounds Laughs, listens to music Knows when toys make sounds
7–12 mo	Turns head to listen to sounds Knows simple words like "milk," "juice" Makes long strings of sounds while babbling Has a few words by 12 mo ("mama," "dada")
12–24 mo	Acquires 50 or more words Puts two words together ("want milk") Points to body parts, pictures in books Uses a variety of consonants at the beginning of words
2–3 y	Makes short sentences Has a large variety of words Can be understood by caregivers and friends
3–4 y	Is able to tell a short story and relate activities Uses sentences with four or more words Hears and responds when called from another room

66.4 Roundsmanship

- The increased incidence of otitis media in children may be attributed to anatomical differences in the eustachian tube that resolve as the child develops. The eustachian tube generally reaches maturity by age 7, and this is the age at which otitis media decreases.
- Acute otitis media is defined as the presence of fluid in the middle ear accompanied by acute symptoms of otalgia, fever, and irritability of 0 to 3 weeks' duration. Recurrent acute otitis media is defined as three or more episodes within 6 months, or four episodes within 12 months. Otitis media with effusion is the presence of fluid in the middle ear space without signs or symptoms of an acute ear infection. Chronic suppurative otitis media is the persistence of purulent fluid behind the tympanic membrane that is unresponsive to medical therapy.
- The most common pathogens responsible for pediatric otitis media are *Streptococcus pneumoniae*, *Haemophilus influenzae*, *Moraxella catarrhalis*, and group A streptococci. One-third of *H. influenzae* and 100% of *M. catarrhalis* bacteria are β -lactamase-positive.
- Common signs of acute otitis media include otalgia, fever, irritability, and otorrhea. More concerning symptoms, such as facial paralysis, vertigo, and swelling behind the ear, may be indicative of a complicated acute otitis media and may require additional imaging.
- Management options for acute otitis media include observation for children between the ages of 2 months and 2 years with mild or moderate symptoms, an uncomplicated acute otitis media, and dependable follow-up. Medical treatment can be administered with amoxicillin as the first-line medication. For patients who are allergic to penicillin, a cephalosporin, trimethoprim/sulfamethoxazole, or a macrolide is recommended. Penicillin-allergic patients show 10 to 15% cross reactivity when treated with cephalosporins. Azithromycin or clarithromycin may also be used.
- Candidates for tympanostomy tube placement include children who have persistent otitis media with effusion for longer than 4 months with hearing loss, children who have otitis media with effusion and structural damage to the tympanic membrane or middle ear, and children who are at risk, defined as developmentally delayed children more likely to have a baseline speech or language delay.
- Complications of tympanostomy tube placement include persistent tympanic membrane perforation and tube retention.
- Complications of otitis media include facial paralysis, acute mastoiditis, acute mastoiditis with periosteitis, and acute coalescent mastoiditis.
- Acute coalescent mastoiditis can be identified on a CT scan by bony destruction and loss of septa between the mastoid cells. An early coalescent mastoiditis may be addressed with tympanostomy tube placement and IV antibiotics, but a simple mastoidectomy may be required. In the setting of a coalescent mastoiditis with facial nerve paralysis, an urgent mastoidectomy is required in addition to 3 to 6 weeks of IV antibiotics.

67 Pediatric Nasal Disorders

Robin A Dyleski

67.1 Introduction

Nasal and sinus complaints are among the most common reasons why children are brought to the primary care physician and to the otolaryngologist for medical attention. Because the etiology of the presenting problem may range from a simple upper respiratory infection to a life-threatening illness, it is important to be able to distinguish these illnesses by using the history, physical examination, and confirmatory testing to make an accurate diagnosis.

67.2 Embryology of the Midface

67.2.1 Nasal Development

Development of the nose and paranasal sinuses is a multifactorial process that begins early in embryonic development and continues until the face has reached maturity in the teenage years. The nose and sinuses originate in the fetus around the third to fourth week of life. A swelling on the lateral aspect of the head, the nasal placode, develops from a thickening of the ectoderm. Just above the oral stoma in the anterior portion of the developing head is a midline structure, the nasofrontal process. Simultaneous development of the nasofrontal process and the nasal placodes shape and form the midface, nose, and sinus portions of the face and head within the first months of life.

At the fifth week, the nasal placode extends into the underlying mesenchyme, transforming into the medial and lateral nasal processes, which results in the development of the nasal pit. As this occurs, the maxillary process of the first branchial arch enlarges and the nasal pit and orbit move anteriorly, with the nasal processes between and below the future orbits. As the nasal processes migrate medially and anteriorly, they ultimately fuse in the midline, creating the precursor of the nose. At this early period of nasal development, the nasal pit intrudes into the future nasal cavity minimally; the deep end of the nasal pit, called the nasobuccal membrane, separates the nasal opening from the oral cavity. The nasobuccal membrane usually canal-

izes between the fifth and sixth weeks of life, creating an opening at the depth of the nasal pit. Choanal atresia is seen when the nasobuccal membrane fails to perforate.

The medial nasal processes ultimately form the nasal septum, the philtrum of the upper lip, and the premaxilla (upper maxillary ridge containing the four central incisors). The lateral nasal processes form the nasal alae, most of the nostrils, and the nasal floor (□ Fig. 67.1).

Within the seventh week of embryogenesis, the medial nasal process, lateral nasal processes, and maxillary processes modulate and transform, with the development of the upper lip and upper alveolar ridge. The two lateral maxillary processes develop into the lateral palatal shelves (becoming the future hard and soft palates). These lateral palatal shelves fuse with the septum and premaxilla at the alveolar ridge bilaterally by the seventh week of development. Aberrations at this time in the development of the lip and palate result in the formation of cleft lip and cleft palate.

The two lateral palatal shelves then fuse in the midline between weeks 7 and 10, beginning anteriorly and extending posteriorly toward the future uvula. This process results in the separation of the oral cavity from the nasal cavity.

Simultaneously, the intranasal tissues are developing into the future lateral nasal structures and sinuses. Around day 40 of embryogenesis, a swelling develops in the anterolateral portion of the nasal wall, called the maxilloturbinate, and soon afterward another swelling, the ethmoturbinate, develops just superior to it; these will become the inferior and middle turbinates, respectively, with the middle meatus forming between them. The superior and supreme turbinates develop from ridges on the superior aspect of the ethmoturbinate around the fourth month of fetal development.

67.2.2 Sinus Development

At approximately 60 days of life, the initial differentiation of the sinuses begins with thickening and intrusion into the mesenchyme laterally from the lateral nasal wall. The maxillary sinus begins to be identifiable around 70 days as a dilatation in

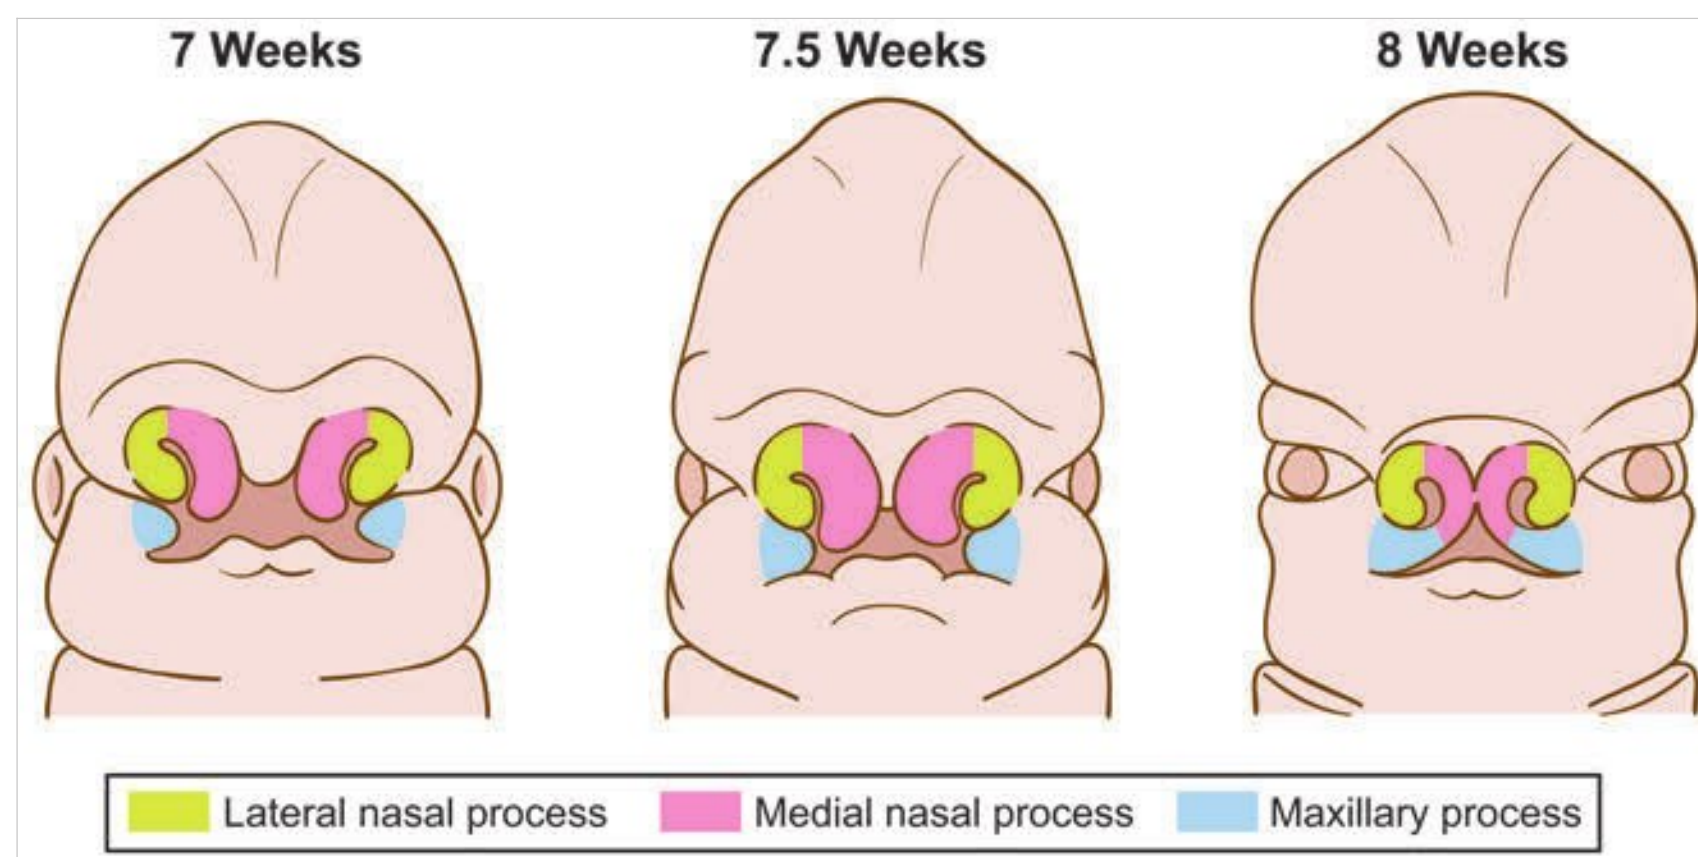

Fig. 67.1 Nasal embryology.

the infundibular groove of the middle meatus region. This dilatation deepens and enlarges into the rudimentary maxillary sinus.

Around the middle of the fourth month, the frontal recess develops just posterior to the anterior attachment of the middle turbinate, and the process of development of the frontal sinus begins. The ethmoidal bulla begins to develop around this time and is recognizable by the day 120, with continued development of the ethmoidal air cell lattice proceeding from that point.

The sphenoid sinus develops within the sphenoid bone, in contrast to the other paranasal sinuses. It is directly invaded by an outpouching from the posterior nasal cavity into the bone. This is noted to have occurred in most fetuses by the fourth month. The development of the sphenoid sinus is variable, and in some individuals, a sphenoid sinus does not develop at all.

The maxillary, ethmoid, and frontal recess buds and sphenoid paranasal sinuses are present at birth but continue to develop and mature well into the teenage years. It is important to consider the relative size and position of the sinuses of the child at various ages (□ Fig. 67.2 and □ Table 67.1).

67.3 Congenital Nasal Anomalies

Derangements of embryologic development result in various congenital nasal anomalies. These congenital anomalies include choanal atresia, nasal dermoids and gliomas, proboscis lateralis, and various types of cleft lip and palate. The majority of these conditions are noted at birth, either by direct observation or because of symptoms directly related to the anomaly.

67.3.1 Choanal Atresia

Presenting Symptoms

Choanal atresia is a congenital malformation of the nasal region that can present as either a unilateral or bilateral condition. It is caused by failure of the nasobuccal membrane to perforate on one or both sides, preventing normal formation of the choanae. Choanal atresia occurs in approximately 1 in 35,000 live births. Children with bilateral choanal atresia usually present at or soon after birth with cyanosis relieved by crying. The atretic plate causes total nasal obstruction and prevents nasal respiration in newborns, who are obligate nasal breathers and in whom apnea and cyanosis develop if they are unable to breathe via the nose. (Oral breathing is a learned behavior that occurs within the first year of life.) The degree of respiratory distress varies among babies; however, bilateral choanal atresia is considered an urgent situation because of the repeated episodes of apnea and cyanosis in affected individuals.

Unilateral choanal atresia is more difficult to diagnose and may be missed in the infant because affected children are able to breathe through the unaffected side. These patients typically

Table 67.1 Sinus size at various ages

Age	Maxillary	Frontal	Sphenoid
Birth	5 mm	4 mm	3 mm
4 y	11 mm	5 mm	5 mm
10 y	18 mm	9 mm	10 mm
Adult	30 mm	25 mm	20 mm

present as toddlers with chronic unilateral nasal discharge that does not respond to medical therapy; they rarely complain of nasal obstruction.

Examination and Diagnosis

The diagnosis is usually suspected by the neonatologist in a newborn child with repeated episodes of cyanosis and apnea. Physical examination and anterior rhinoscopic examination of the newborn will often reveal normal external nasal features. A fiber-optic intranasal examination will often reveal a small intranasal cavity, and the examiner will encounter difficulty in passing the endoscope into the nasopharynx. Inability to pass a 5F feeding tube through the nasal cavity into the oropharynx strongly suggests the diagnosis of choanal atresia. Nasal airflow can be evaluated by simply holding a strip of tissue paper in front of the nares and observing movement of the paper during breathing.

Patients suspected of having choanal atresia should undergo axial computed tomography (CT) of the midface so that the diagnosis can be made definitively. In a patient with choanal atresia, the CT scan will distinguish between complete atresia of the choanal opening (□ Fig. 67.3) and stenosis (narrowing) and determine the extent of the bony plate causing the obstruction.

The majority of patients with choanal atresia have a complete bony plate or a combination of bony and membranous obstruction. CT is instrumental in treatment planning and should not be supplanted with other studies.

Evaluation and Testing

Choanal atresia, when bilateral, is associated with other anomalies in about 50% of cases. The most common associated condition is the CHARGE syndrome (coloboma, congenital heart malformations, choanal atresia, retardation of growth, genitourinary tract malformations, and ear malformations and hearing loss). Before they undergo general anesthesia and correction of the choanal atresia, babies with bilateral choanal atresia should undergo genetic, cardiac, and renal evaluations to assess for the CHARGE association because of the significant possibility that they will have a congenital heart malformation.

Treatment

Bilateral choanal atresia is a life-threatening condition in the newborn until recognized because of the risk for apnea leading to cyanosis. An affected infant may initially be treated with an oral airway (bypassing the nasal obstruction) or intubation

Fig. 67.4 Nasopharyngeal view of unilateral choanal atresia.

when an oral airway is not tolerated. Choanal atresia is definitively corrected by the creation of choanae. The procedure can be carried out via a transnasal endoscopic approach with drilling out of the bony atretic plate and posterior bony vomer plate, or via a transpalatal approach with drilling out of the posterior hard palate and atretic plate.

Stenting with transnasal tubes may be necessary. The procedure is carried out in infants as soon as they are stable and have been evaluated for cardiac malformations.

In the case of unilateral choanal atresia (□ Fig. 67.4), treatment is deferred until the child is at least 2 years of age, even if the condition has been diagnosed in infancy. Correction at an older age is associated with improved success rates and a decreased need for revision surgery. Most cases of unilateral choanal atresia are corrected via the transnasal endoscopic approach. This approach incorporates drilling out of both the lateral wall bone and a portion of the posterior septum/vomer. In this procedure, stenting is not usually necessary. Transpalatal correction is reserved for patients with restenosis.

Complications

Bilateral choanal atresia, if unrecognized, can be a life-threatening condition in the newborn because of the development of hypoxemia and apnea in a baby who is unable to breathe nasally. After the diagnosis, the child should be assessed for the presence of associated medical syndromes. Unilateral choanal atresia is not typically a serious problem and rarely presents with complications before correction. Surgical complications include risk for injury to the brain and brainstem during initial perforation of the atretic plate. This rare complication can be reduced by using a 120-degree nasopharyngeal endoscope to observe the posterior aspect of the choanae during initial puncture of the atretic plate. The most common complication of choanal atresia correction is stenosis at the repair site. This may be caused by the inadequate removal of bone from the choana or septal edge, or the development of excess scar tissue in the posterior nasal cavity. Revision surgery may be per-

formed either transnasally or transpalatally. Transnasal endoscopic surgery has higher rates of stenosis and the need for revision surgery.

Prognosis

Children with choanal atresia have an excellent prognosis for satisfactory nasal breathing with adequate repair, particularly if they have unilateral choanal atresia and do not have the CHARGE association. Most children, even those who require revision surgery, are able to breathe well through the nose once they have healed from reconstruction of the choana.

When the CHARGE association is present, there is an increased risk for restenosis and the need for secondary procedures, yet these children usually fare well after correction of their choanal atresia.

67.3.2 Piriform Aperture Stenosis

Etiology, Pathophysiology, and Pathogenesis

Piriform aperture stenosis is a rare bony congenital malformation characterized by narrowing at the entry of the piriform aperture of the nose. It develops during embryologic formation of the nose and nasal cavity and often is associated with other craniofacial conditions, such as holoprosencephaly, congenital central maxillary incisor, and malformations of the sinuses. There is no known etiologic agent that causes nasal piriform aperture stenosis.

Presenting Symptoms

The most common symptom of piriform aperture stenosis is nasal obstruction in the neonatal period. Children with piriform stenosis may experience significant respiratory distress because they are obligate nasal breathers, and they usually demonstrate loud, stertorous breathing with snorting, chest retractions, and poor nasal airflow.

Medical Evaluation and Testing

Piriform aperture stenosis will have a congested nasal appearance on anterior rhinoscopy. In many cases, the nose will be so narrow that even a flexible fiber-optic nasopharyngoscope cannot be passed into the nasal cavity through the nostril. Choanal atresia can be excluded by visualizing air bubbling from the nostril at times; however, choanal stenosis is not excluded. The exterior of the nose usually appears normal.

The diagnosis is made when typical piriform aperture narrowing is seen on axial CT (□ Fig. 67.5). An aperture width of less than 8 mm confirms the diagnosis. When piriform stenosis is present, other neurologic malformations should be excluded with imaging of the brain.

Treatment
