One of the challenges for computer-based suicide risk detection is that despite the known association with suicide of epidemiologic risk factors such as depression, social isolation, substance abuse, and impulsivity, only rarely do individuals with these risk factors end their lives. Reliance upon these risk factors alone would generate too many false positives unless considered together with a current clinical assessment, and in that way a computer-based interview may be assistive. Depression screening was recommended by the US Preventive Services Task Force, *as long as there are systems in place to enable appropriate treatment*. The expected increase in routine depression screening will therefore require improved methods to follow up patients who report suicidal ideation during self-administered screening (McDowell, Lineberry, & Bostwick, 2011). Computer-based methods have the potential to improve the efficiency and dissemination of this process. The trend toward using computer-assisted screening will lead to the opportunity to study this issue on a population health basis and lead to greater understanding of the role of computer-based or computer-assisted interviewing in the assessment of suicide risk.

As early as 1973, John Greist and his colleagues at the University of Wisconsin developed a computer program that queried patients about their history and psychiatric symptoms and used a predictive model to estimate the risk of a suicide attempt. Not only did they report that the patients preferred the computer interview to talking to a physician, but also, using a retrospective design in a subsequent study, they found that the computer performed better than clinicians in predicting suicide attempts in their small sample of 22 patients. A subsequent larger prospective study (Erdman, Greist, Gustafson, Taves, & Klein, 1987) found that the computer was better at detecting suicide attempters, although clinicians were better at identifying non-attempters. The computer was more sensitive at detecting those at risk, but there were more false positives than the clinicians observed in their assessments. Thus the inference is that computers could be used for screening but would require a follow-up assessment by a clinician. However, wide-scale implementation would depend upon improving the ability of such a screening approach to have both great sensitivity AND specificity for it to be practical. Since then, computer-based screening for suicidal ideation and risk has been used to assess patients with HIV, adolescents with depression, and people with substance abuse. However, ethical considerations and the low frequency of suicide in primary care have limited the practical utility of routine suicide risk screening in general medical settings. Instead, the approach that we recommend is a two-stage screening solution using the PHQ-9 for all patients and a computer-administered approach (i.e., tablet, IVR telephony, or via the Internet using a secure patient web portal), followed by the administration of the P4 Screener, a brief structured interview to assess suicide risk, administered in an office setting where clinical evaluation is available (Dube, Kurt, Bair, Theobald, & Williams, 2010).

Substance Abuse

Computers and the Internet have been used for the identification and treatment of alcohol and substance abuse. Self-administered paper-and-pencil questionnaires have been used for several decades to collect information about substance use from patients, and the National Institute on Drug Abuse and the National Institute on Alcohol Abuse and Alcoholism provide on their websites standardized questionnaires that can be used both to screen for substance abuse behavior and monitor its course (Maisto, Connors, & Allen, 1995). During the past decade, several of these questionnaires have been evaluated for use in computer-based self-assessment by comparing the results of administration of computer-administered versions with the previously validated paper-and-pencil versions. Examples include the Michigan Alcohol Screening Test (MAST; Selzer, 1971) and the Drug Abuse Screening Test (DAST; Gavin, Ross, & Skinner, 1989). These 20-item measures are too long for use in general medical settings for screening, but shorter measures have become widely used: the CAGE four-item screen for alcohol abuse (Gavin, et al., 1989), the Alcohol Use Disorders Identification Test (AUDIT) of 10-items, and the AUDIT-C four-item (Bush, Kivlahan, McDonell, Fihn, & Bradley, 1998) test are excellent screening tools for alcohol misuse. Brief screening for substance abuse other than alcohol is more complex and harder to reduce to ultra-brief screeners, though the two-item Conjoint Screener (TICS) has been validated (Brown, Leonard, Saunders, & Papasouliotis, 2001) and has the sensitivity and specificity suitable for primary care use, if followed up with the AUDIT and the DAST as appropriate. The CRAFFT (Car, Relax, Alone, Forget, Friends, Trouble) is a six-item screener for use with adolescents that screens for both problem drinking as well as drug use. The CRAFFT asks about behaviors that are reliable indicators of consumption and risk; it also can be self-administered and machine scored (Crum, 2007).

Computer-based approaches to primary care screening and intervention for substance abuse offer the possibility of easily accessible, reliable, efficient, and scalable methods of detection. These methods can leverage motivational interviewing methods, leading to brief interventions that engage patients in behavior change and/or referral for specialty care. Computer-assisted interventions offer advantages in that participants are more likely to disclose substance use to computers than to human interviewers, as previously mentioned. Several computer and/or Internet-based interventions are available and have shown promising results in studies of brief computer-based interventions for smoking and for problem drinking. Those screening tools, whether paper-and-pencil or online, merely alert the patient and the clinician to the existence of a problem. It is left to the patient to discuss the results with his or her clinician. Although there are evidence-based brief interventions for smoking cessation and the reduction of risky drinking for use by primary care providers, there are also programs that integrate automated assessment with self-guided treatment.

Boston University researchers and clinicians have developed two websites that enable individuals to complete

anonymous online self-assessments for alcohol and substance abuse problems. The project is based on the Alcohol, Smoking and Substance Involvement Screening Test (ASSIST) developed for the World Health Organization by an international group of substance abuse researchers for the detection and management of substance abuse and related problems in general medical settings. A nonprofit company, Join Together, operates two sibling websites, *DrugScreening.org* and *AlcoholScreening.org*. The latter site provides more intensive assessment and feedback on alcohol consumption and directs users to treatment resources.

Another well-regarded website, *Drinker's Checkup* (www.drinkerscheckup.com), is an evidence-based self-assessment tool and treatment program developed at the University of New Mexico by psychologist Reid Hester with funding from the National Institute of Alcohol Abuse and Alcoholism (NIAAA). A companion program, *Moderate Drinking* (www.moderatedrinking.com) was created to assist individuals who want to reduce their drinking and are interested to learn about moderate drinking or abstaining. Like *Drinker's Checkup* it is also evidence-based, and the modest program fee supports a nonprofit organization that “aims to help people make responsible decisions about their drinking” and to assist those who wish to cut down on their alcohol use.

Advantages of Computer Assessment

Computer-based interviews have been used to assess a wide variety of medical and behavioral factors that are important in the medical care of patients, as summarized in the following chart:

MEDICAL HISTORY/ROS	PSYCHIATRIC HISTORY
Adverse drug reactions	Suicide risk assessment
Compliance monitoring	Symptom monitoring
Sexual abuse/trauma	Eating disorders
HIV risk assessment	Substance abuse
Sexual function	Risky behaviors

Patients have great difficulty disclosing during the medical encounter information related to their behavior or experiences that are private, embarrassing, or shameful, even when the disclosure is vital to their care. The most common examples are matters of sexual behavior, gender identity and orientation, histories of traumatic experiences, substance abuse, and sexually transmitted diseases. Furthermore, the US Preventive Services Task Force is concerned that most clinicians do not do an adequate job collecting this type of information during routine care. In contrast, computers have generally outperformed clinicians in collecting such information when it has been collected using queries delivered by a computer. Despite the widespread bias that machines would not be effective in such sensitive dialogue, it has been shown repeatedly that well-written computer interviews that can establish rapport and provide reasonable assurance about

privacy of the information provided can elicit histories from patients indicating greater levels of disclosure (Locke et al., 1992; Richens et al., 2010).

In addition to minimizing the potential for embarrassment, computer-based interviews offer the opportunity for enhanced privacy, anonymity, and greater reliability. In addition, an interview administered by a computer has potential multilingual capability and can even include comprehension checks along with a built-in glossary to increase the likelihood that the information is tailored for the individual patient.

COMPUTER-BASED PATIENT EDUCATION

When Dr. Slack arrived in Boston in 1970, he and his colleagues undertook a series of studies designed to assess the ability of computers not only to take a history but also to assist patients in making informed medical decisions about treatment. In one study, 46 women with symptoms of a urinary tract infection (UTI) were offered interactive computer-based education about the routine treatment for a UTI, including the option of initiating immediate treatment with oral sulfisoxazole while awaiting the results of the urine culture. Provided by the computer with balanced, easy-to-understand information about the options, 35 women decided to take the sulfisoxazole without waiting for the culture results; one decided to wait for the culture (which was negative), and 10 were referred for further evaluation. Of the 35 who elected to take the medication, 30 thought that a program that enabled them to make the decision was “a good thing” and only one thought it “better if left up to someone else.”

In the ensuing years the field of informed medical decisionmaking grew, and the role of tailored patient educational materials has expanded into a billion-dollar industry. Early in the dot-com boom, former Surgeon General C. Everett Koop helped to found *DrKoop.com*, which became famous for the tagline “information is the best medicine,” which was coined for a patient education media venture. The first consumer education website for mental health was launched in January 1995 as *Psych Central: John Grohol's Mental Health Page*; it got its start by indexing online support groups in the summer of 1991. Psych Central is currently the Internet's oldest independent mental health and psychology network, as well as the largest; it reports having 1.5 million users every month.

Another leading site for consumer and patient health education is Healthwise.org. Founded by Don Kemper in 1975 as a print media producer, Healthwise.org is a nonprofit educational resource dedicated to “helping people make better health decisions [by providing] content that's easy to understand, engaging, and motivating.” Healthwise is now a major online provider of both interactive health content and decision support tools; its content is tested with consumers and clinicians for quality, accuracy, and usability, and requires that information provided is evidence-based and reviewed by experts.

WebMD is another major force in online consumer health education, a major provider of health information services for consumers, physicians, healthcare professionals, employers,

and health plan providers. Like Healthwise, WebMD has an editorial board and process to ensure the quality of its content. There are other commercial health information websites, of varying quality, too numerous to mention. However, there are also educational websites created and maintained by academic institutions that leverage their faculty and their brand to build consumer confidence in the quality of their information.

Several companies that provide patient and consumer education grew out of the laboratories of academic researchers that leveraged the ability to increase dissemination through the advantages of commercialization. One such example is HealthMedia. Founded in 1998 by Dr. Victor Strecher, HealthMedia focuses on the development of tailored patient education materials. Initially, computers were used to produce tailored print media for patient education; later, technology was developed to assemble tailored videos assembled on the fly for individual patients and shipped to their homes from massive video servers. HealthMedia has developed a technological methodology that effectively emulates a health coaching session without the coach, using interactive media (now delivered over the Internet) that offers the advantages of scalability and economy. The company conducts and publishes outcomes research on their programs to determine the impact on compliance, medical utilization, and productivity. The research is conducted through an exclusive relationship with the Health Media Research Laboratory (HMRL) at the University of Michigan, which provides ongoing research for HealthMedia. In turn, the for-profit company builds commercial digital health coaching programs that are science-based and designed to deliver measurable outcomes. This partnership between a private company and academic institution has been successful and offers a model for other, similar ventures in behavioral medicine.

In addition to HealthMedia, several for-profit companies focus on population health management, and contract with large employers and integrated delivery systems. The degree of customization, personalization, tailoring, and interactivity varies a great deal among the various vendors and providers, with a general trend to move toward greater interactivity and mobile applications (“apps”) for smartphones and tablet computing. Behavioral health is increasingly being integrated into population health programs, as its relevance to overall health outcomes is more widely recognized.

In 1959, Ledley and Lusted published in *Science* a rules-based probability model that could be adapted for use in clinical reasoning. During the next decade, Morris Collen at Kaiser Permanente Health Plan instituted a computer-assisted system to aid medical diagnosis, using questions and symptoms on computer punch cards that were sorted by patients into yes and no piles and then tabulated by machine processing. However, the first use of a computer to assist a clinician in diagnosis and to guide management of a patient’s condition was the acid-base decision support program developed by Howard Bleich at Beth Israel Hospital in 1969. Since that time computers have become widely used to guide treatment, but only recently have they been introduced into clinical psychiatry.

During the 1970s, the field of artificial intelligence and expert systems provided the tools for the growing integration of decision support tools into general medical care. This was largely driven by the economic incentives of managed care in an effort to control costs. During the 1980s, this wave swept through mental health; managed behavioral healthcare companies (“carve-outs”) developed computer-based decision support tools to guide their utilization reviewers and care managers in allocating only that level of treatment that was deemed medically necessary. Thus, for most clinicians, the first introduction to decision support in mental health was more focused on benefit to the payer rather than to the patient or the clinician.

In the same era, however, clinical researchers began to evaluate the usefulness of computers as tools to guide clinicians in the care of their patients. Tools were developed to assist not only in diagnosis but also to suggest treatment strategies using evidence-based algorithms developed by clinical experts (Oquendo et al., 2003; Osser, 1993; Trivedi et al., 1998; Trivedi, Fava, Marangell, Osser, & Shelton, 2006). Patients with major depression treated in the Texas Algorithm Medication Project using a computer-assisted decision support system showed greater improvement in their depression than those who received treatment as usual (Trivedi et al., 2004). However, the real challenge is less likely to be the issue of efficacy or even of cost-efficiency than the need to overcome the barriers to adoption of decision support tools in systems of care (Trivedi et al., 2009). Perhaps the most successful of all the innovations in computer-based decision support for both clinicians and patients has been the widespread availability of online drug–drug and drug–food interaction checkers. Finally, the free online resource from the National Library of Medicine, PubMed, makes it easy for clinicians, patients, and family members to search the Medline database.

PATIENT-CENTERED CARE AND SHARED DECISION MAKING

Reflecting a paradigm shift in healthcare, the concept of “shared decisionmaking” emerged during the 1990s and had a marked impact on the doctor–patient relationship. The revolutionary societal changes in the 1960s caused a mistrust of authority and yearning for autonomy that served as a catalyst in fostering the emergence of a new model, “patient-centered care” (Gerteis & Commonwealth Program for Patient-Centered Care, 1993). As the new paradigm arose, the centuries-old traditional authoritarian or paternalistic model yielded to social pressure, as melodramatically depicted in the film *Patch Adams*. Patient-centered care leveled the playing field for patients and doctors and laid the foundation for the development of decision support tools not only for use by clinicians but also by patients and families. This sea change in healthcare took on the qualities of a social movement, spearheaded by Dartmouth’s John Wennberg who coined the term *informed shared medical decisionmaking*, and its tenets became embodied in the influential report of the Institute of Medicine, *Crossing the Quality Chasm* (Institute of Medicine, 2001). The wide dissemination and influence of the IOM

report helped to accelerate the development and adoption of new information technologies by legitimizing and endorsing the paradigm shift. Thus emerged patient-centric clinical computing, tailored Internet-based consumer health education, and online tools to assist with personal healthcare decisions (Drake, Cimpean, & Torrey, 2009). Medical information websites for patients as consumers have changed the physician–patient relationship. No longer are physicians the sole providers of guidance to patients. Rather, their role has been to help patients evaluate information, and the emerging paradigm in information age medicine is that of “shared decisionmaking.”

Use of technology in Shared Decision Making

The forerunner of modern shared decision-making tools was the *Problem Knowledge Coupler* (PKC) developed in the early 1980s by Lawrence Weed, creator of the problem-oriented medical record. Weed and his followers used computers to assemble structured information about patients from their histories, physical findings, and lab results, and used combinatorial rather than probabilistic or algorithmic logic to discern patterns that guided diagnostic and care management decisions. What was especially revolutionary was that the clinicians who used the PKCs showed the computer screens to the patients and invited them to participate in the clinical reasoning and treatment planning.

Weed’s pioneering work on decision aids influenced a generation of health services researchers including John Wennberg, Albert Mulley, and Michael Barry, who created the Foundation for Informed Medical Decision Making (FIMDM) as a joint venture between Dartmouth Medical School and Massachusetts General Hospital. FIMDM was founded to study the role of informed shared medical decision making in helping patients and their doctors to manage important medical conditions, including coronary artery disease, prostate cancer, breast cancer, back pain, osteoarthritis, benign uterine conditions, depression, diabetes, and benign prostatic hyperplasia.

They define shared decisionmaking as “a style of counseling in which the healthcare provider communicates to the patient personalized information about the options, outcomes, probabilities, and scientific uncertainties of available treatment options, and the patient communicates his or her values and the relative importance he or she places on benefits and harms . . . True shared decisionmaking requires three key elements: a patient who is fully informed about the risks and benefits of all viable options, an involved patient (and family members, if appropriate), and a shared process that involves both healthcare provider and patient.”

The Foundation has been a leader in using technology to provide high-quality, unbiased, easily understood information to patients about their condition and its treatment so that they can make an informed decision about their treatment options with confidence. In research using interactive media and linear videotapes, FIMDM researchers have studied how creating a caring and compassionate learning environment, in which shared decisions can be made by patients in partnership

with their doctors, affects the choices that patients make and their satisfaction with the outcomes.

The Foundation’s decision aids can be accessed on their website at http://www.informedmedicaldecisions.org/patient_decision_aids.html.

Decision Aid titles that pertain to psychiatry in the general medical setting include the following:

- Acute Lower Back Pain: Managing Your Pain Through Self Care
- Chronic Low Back Pain: Managing Your Pain and Your Life
- Living with Metastatic Breast Cancer: Making the Journey Your Own
- Living Better with Chronic Pain
- Living with Diabetes: Making Lifestyle Changes to Last a Lifetime
- Looking Ahead: Choices for Medical Care When You’re Seriously Ill
- Coping with Symptoms of Depression
- Growing Older, Staying Well
- Sleeping Better: Help for Long-Term Insomnia

In the future, there will be cloud-based interactive multimedia platforms that patients can access via the Internet that will deliver informed medical decision-making aids to patients and families that can be “prescribed” by their clinical team to assist them in making medical decisions about treatment. Successful implementation of the shared decisionmaking model requires that the clinician assess the patient’s capacity to exercise adequate judgment in clinical decision making.

COMPUTER-GUIDED AND COMPUTER-ADMINISTERED PSYCHOTHERAPIES

Despite the availability of evidence-based behavioral treatments for mental disorders, there are barriers that have prevented them from reaching the majority of the people suffering from mental illness who might benefit from them. These barriers include cost, availability, logistics, stigma, and training. Computer-assisted or online self-guided treatment, under appropriate clinical supervision, has the potential to vastly increase affordability and access to effective treatments. Computer delivery of behavioral therapies represents the possibility for models of care that can be used for population health management and lead to affordable and effective improvements in public health.

The first reported use of computers in psychotherapy was that of Kenneth Colby and his colleagues at Stanford University in 1966. Colby, a maverick psychoanalyst working in the Department of Computer Science at Stanford, created “Overcoming Depression,” a program that used an early version of natural language processing to lead a patient through a

course of cognitive behavioral therapy for depression (Colby, Watt, & Gilbert, 1966). In 1977, Slack developed a form of computer-guided therapy that he called “soliloquy therapy.” Based on the premise that talking about one’s problems can be salutary, Slack programmed a computer to ask people in simple language if they felt sad or blue. If a volunteer answered using the keyboard that he did, the program then asked, “Tell me about your sadness.” Other prompts were used to engage the patient and reinforce speaking freely. In those days very few computers understood speech, so Slack’s program simply “listened” as the subjects spoke into a microphone and when the patient stopped speaking, it encouraged the person to continue. At the conclusion of the preliminary study, Slack noted that the subjects reported that they felt better, and although the design did not permit conclusions about the effectiveness of soliloquy therapy he tucked it away until two decades later, when he and his colleagues conducted a randomized clinical trial that showed that soliloquy therapy reduced anxiety (Slack, Porter, Balkin, Kowaloff, & Slack, 1990).

During the 1980s, computer-based self-help programs made their appearance. A self-help sweepstakes held in 1985 included among its entrants several behavioral programs: Managing Stress, Problem Solving, Stress and Conflict, and Coping with Stress (Turkle, 1995). Roger Gould, a psychiatrist at UCLA, created a stress management program called the *Therapeutic Learning Program*, a problem-solving therapy that used natural language processing to help people identify and solve personal problems. The program was used at Harvard Community Health Plan and at Kaiser Permanente Medical Group in California (Colby, Gould, & Aronson, 1989).

A series of computer-delivered behavior therapy programs were developed in the 1990s by Lee Baer, John Greist, Isaac Marks, and their colleagues in the United States and Great Britain. These international collaborators developed cognitive behavioral therapy (CBT) programs for depression, anxiety, and obsessive compulsive disorder. The programs were tested in clinical trials, and the behavioral program for depression, COPE, was tested in an open trial of patients with mild to moderate depression. COPE consisted of an introductory videotape and 9 booklets, accompanied by 11 telephone calls to an IVR system that made self-help recommendations to patients based on information they entered. The study team reported clinical improvement in the patients that was on the scale of that seen in studies of antidepressant medication. In a randomized clinical trial of patients with obsessive compulsive disorder, these investigators found that computer-guided CBT was more effective than self-guided therapy delivered by IVR, but that both were more effective than a relaxation control (Greist et al., 2002).

Currently, self-guided treatment programs are mostly based upon forms of CBT (Baer, Greist, & Marks, 2007). Most of these programs focus on depression, but some have also focused on anxiety, eating disorders, and substance abuse. Some of these programs are standalone programs that run on a computer; others are available via the Internet. Some programs are merely text on a screen, while others use interactive multimedia. In addition, programs at the intersection of wellness and mental health have addressed smoking cessation,

weight loss, risky drinking, and medication adherence. These programs have been used more widely in Great Britain, New Zealand, and Australia, where the health systems make it easier to deploy the programs and the governments support their development. Meta-analyses have shown the field of self-guided, computer-based treatments is still in its infancy. In a recent review of computer-assisted psychotherapy, Cartreine, Locke, and Ahern concluded that some treatments work better than others and that although they are sometimes as effective as face-to-face therapy, they do not appear to be better. They also believed that because of their scalability, and the observation that dropout rates in computer-based CBT is similar to that of face to face treatment, computer-delivered self-guided therapy may have a role in population health management for selected patients or for use in conjunction with clinical care (Cartreine, Ahern, & Locke, 2010).

Another use of computers in psychotherapy is as a therapist-assist technology for in-session use. Programs have been developed for use by a clinician that guides the therapist through the delivery of a structured care program, such as CBT or exposure therapy. Such programs enable nonspecialist clinicians to deliver specialized behavioral healthcare in the office, by telephone, or over the Internet (with appropriate security). This technology can be very advantageous in rural or other resource-poor settings. It also facilitates the development of highly specialized treatments that can be delivered using evidence-based treatments that have been manualized and adapted for delivery by a clinician guided by a computer. These treatments can be delivered either in a supervised clinical setting or in a behavioral health medical home to a select subset of patients screened to ensure that their complexity, symptom severity, and comorbidities do not preclude remote care. Psychotherapy assistive technologies are being studied for use with veterans with PTSD, adolescents with depression, and patients with phobias. As the evidence accrues for their efficacy, safety, and efficiency, it may be possible to have behavioral healthcare managers assigned to clusters of primary care practices and delivering care to some patients remotely.

APPLICATIONS OF ADVANCED BEHAVIORAL TECHNOLOGIES IN HEALTHCARE

Some of psychiatry’s most sophisticated technologies leap right off the pages of science fiction comic books and out of futuristic television shows. Virtual reality, in which a user sits inside a simulator or dons a helmet with a small computer screen inside, is routinely used to treat PTSD in veterans. Building on the basic principles of script therapy, virtual reality exposure therapy (Rothbaum, 2010) places the patient back into the warzone environment in which they suffered a trauma. Therapists have the ability to control environmental variables to recreate the precise amount of daylight, smells, background noises, and general setting in which the event occurred. Relaxation coaching and traditional habituation techniques are then practiced within these environments. Similar simulators have been constructed for a number of specific phobias (heights, airplanes, animals), and, more poignantly, for victims of the World Trade Center attacks.

Virtual worlds, such as Linden Labs' *Second Life* (Linden Lab, 2009), offer novel ways for psychiatric engagement and education. In *Second Life*, users operate avatars to negotiate interactions with other individuals—shopping, hanging out at cafes, conducting research at virtual libraries, and attending virtual seminars. The MGH Benson-Henry institute has offered courses in relaxation within this virtual world; the UC Davis department of psychiatry replicated their clinic within *Second Life* and developed a psychosis simulator, in which users can walk through a virtual clinic and experience what it must be like to have schizophrenia. Some practitioners are also conducting group and individual therapy sessions within private practice offices (Gorrindo & Groves, 2009).

The “Games for Health” movement largely focuses on the use of video games as a means of engaging and educating patients about disease, compliance, and treatment. Successful games have been used for improving diet, motivating physical activity, increasing asthma regimen compliance, pediatric cancer education, substance abuse education, and facilitating diabetes regimen compliance and understanding (<http://www.gamesforhealth.org/>). This burgeoning field has gained increasing momentum over the last few years, with annual conferences and a peer-review journal.

BEHAVIORAL TELEMEDICINE

Telemedicine holds the great promise of being able to connect patient and provider over great distance. Using two-way interactive videoconferencing, telepsychiatry (a branch of telemedicine) allows those who have difficulty accessing traditional office-based care to obtain mental health services. Applications of telepsychiatry include prehospitalization assessment and post-hospital follow-up care, scheduled and urgent outpatient visits, medication management, psychotherapy, and consultation. While psychiatric specialists are often located at some distance from the patients they are evaluating, best practice guidelines required that appropriate staff be available to meet patient needs before, during, and after mental health telemedicine encounters (Yellowlees, Shore, & Roberts, 2010). Numerous studies have suggested that clinical outcomes and patient satisfaction are similar when comparing telepsychiatry and in-person based interventions (Sharp, Kobak, & Osman, 2011).

Recent studies have examined the feasibility, utility, and cost-effectiveness of asynchronous telepsychiatry. This novel “store-and-forward” methodology allows clinical data, including video, to be collected by nurse practitioners or other medical specialists using structured or semistructured interviews. The compiled data and video are then forwarded to a psychiatrist for diagnostic review and treatment planning (Butler & Yellowlees, 2011). Recommendations are often returned to primary care providers via letter or email for implementation.

LEGAL, REGULATORY, AND LIABILITY ISSUES

Computer software delivered via desktop computers, the Internet, or mobile platforms will transform healthcare. The programs, services, and devices have the potential for causing

both advantageous and harmful effects. Although the federal government's role in protecting the public through the regulation of medical devices has been a subject for political discourse including legislation offered in both the House and Senate, in 2011 the Food and Drug Administration (FDA) announced plans to publish a new guidance document that will define the types of clinical decision support (CDS) software it will regulate. With the growing trend to offer decision support on mobile platforms (smartphones and tablets), the FDA's guidance will shape the future of behavioral telehealth. Even though a few years have passed since the initial announcement, FDA has recently reaffirmed its intention to draft this guidance.

In September 2011, the FDA gave its clearest explanation to date regarding what it expects to include in the CDS category. The agency identified three sources of information as helping to define CDS: (1) that entered into the database either manually or automatically, gathered from any source (including data from a medical device, environmental data, or demographic data); (2) that converted by any means including algorithms, formulae, database look-ups or comparisons, or rules or associations; (3) that which produces actionable information, presumably intended for use in the diagnosis of disease or other conditions, or in the cure, mitigation, treatment, or prevention of disease.

In assessing software for regulatory purposes, it is important to distinguish between software that merely provides support and analysis, and software that actually performs a measurement. FDA sent a warning letter on March 15, 2012, to NeuroTax regarding its product MindStreams. FDA declared the software to be a medical device because the software allowed a physician or psychologist to assess cognitive deficits in patients by having the patient respond to prompts. Software that actually measures cognitive function is not CDS.

UNREGULATED PRODUCTS

As explained in a 2013 guidance that FDA issued on mobile medical applications, FDA does not regulate those manual office functions that are simply automated for the ease of the user (e.g., office automation). But if software is intended to help with any part of cure, mitigation, treatment, or prevention of disease or a medical condition, the FDA may consider it a *device*. For example, a program or website that queries patients about behavioral symptoms and tallies them up and presents the score to a clinician is an unregulated application. If, however, the tallied score is provided to the patient, along with a diagnosis and treatment recommendations, the FDA is likely to regulate it. What is less clear is the use of technology to support self-care, especially in the context of wellness and health promotion.

PREMARKET REVIEWED PRODUCTS

The answer to the question of whether the FDA will require premarket review is a moving target. Experts anticipate that the FDA will provide greater clarity in their forthcoming guidance document. Software functions likely to require

review might include real-time or online patient monitoring, alarms and alerts capability, seriousness of the disease intended to be monitored, the device's contribution to the decision-making process, innovation in data output, individualized patient care recommendations, and the transparency of decision mechanisms. Programs that assess suicide or homicide risk raise obvious regulatory as well as liability concerns.

CURRENTLY REGULATED PRODUCTS

In April 2014 the FDA, with guidance from the Office of the National Coordinator (ONC) and the FCC, explained that it does not intend to focus its regulatory oversight on the following products/functionalities, even if they meet the statutory definition of a medical device:

- Evidence-based clinician order sets tailored for a particular condition, disease, or clinician preference
- Drug-drug interaction and drug-allergy contraindication alerts to avert adverse drug events
- Most drug dosing calculations
- Drug formulary guidelines
- Reminders for preventative care (e.g., depression screening, mammography, colonoscopy, immunizations, etc.)
- Facilitation of access to treatment guidelines and other reference material that can provide information relevant to particular patients
- Calculation of prediction rules and severity of illness assessments (e.g., PHQ-9, AUDIT, Montreal Cognitive Assessment, Young Mania Rating Scale, APACHE score, Charlson Index)
- Duplicate testing alerts
- Suggestions for possible diagnoses based on patient-specific information retrieved from a patient's EHR

In that same report, FDA offered examples of CDS it *does* plan to regulate, including:

- Computer-aided detection/diagnostic software
- Remote display or notification of real-time alarms (physiological, technical, advisory) from bedside monitors
- Radiation treatment planning
- Robotic surgical planning and control
- Electrocardiography analytical software (and, by implication, electroencephalographic or fMRI analytic software)

The cost of an FDA premarket review for a small company attempting to develop clinical innovations is considerable and can be an obstacle for healthcare improvement. Consequently, the need to protect the public must be balanced against the need for a business climate that supports innovation. The challenge is to exploit the potential benefits of behavioral

telehealth when integrated into general medical care so as to maximize benefit and minimize risk of harm.

TECHNOLOGY IN THE RELATIONSHIP

Psychiatry has often distinguished itself from many other fields within medicine through explicit attention to the rules under which the physician and patient interact, often referred to as *the frame*. It has long been held that psychiatrists should withhold details about their personal lives and avoid interacting with patients outside of the office to protect the treatment relationship. The goal has been to preserve a *tabula rasa* so that traditional psychotherapeutic dynamics (e.g., transference and projections) could be understood and leveraged within treatment. Physicians are taught to avoid revealing too many personal details about their lives and to confine their relationship with the patient to clinical space. Through the eyes of the patient, the modern physician lives and dies within the confines of the exam room, never to leave and encounter the real world pressures of kids, friendships, and hobbies. For most psychiatrists in nonrural settings, this was a pretty straightforward task prior to the Internet age but has become almost impossible in modern times.

It is estimated that that two-thirds of US households have broadband connections to the Internet and that nearly 80% of broadband users have searched for health information online (Fox, 2011). While it is not surprising that most of these Internet searches center on disease and treatment, most providers are surprised to learn that 44% of Internet users look for information about doctors or other health professionals (Fox, 2011). Most patients are likely looking for information pertinent to their care, such as where the doctor went to school or contact information, rather than personal details. However, modern search engines coningle the personal and professional spheres; patients are bound to stumble upon one while looking for the other.

Many physicians have taken an abstinence approach to this problem, electing not to post or publish any personal information on the Internet; almost all physicians, however, now have some digital footprint (Gorrindo & Groves, 2008). Mortgage records, campaign donations, state medical board profiles, and neighborhood newsletters are just a few of the many channels through which easily discoverable information is published to the Internet without explicit approval. The *modern physician* recognizes this fact and chooses not to shy away from the digital world, but rather to embrace it as a way of promoting his public self, managing this tricky negotiation carefully and intentionally.

EMAIL

For physicians who are facile with computers and the Internet, email affords quick communication with patients and it offers the benefit of instant documentation of a conversation. In 2008, it was estimated that approximately 30% of physicians emailed with their patients (Menachemi, Prickett, & Brooks, 2011). Modern search engines have facilitated the

ascertainment of physician email addresses for patients; consequently, physicians who have been reluctant to engage in email exchanges with patients may find themselves receiving emails regardless.

The major pitfalls associated with patient–physician emails fall into several categories. First, there are regulatory guidelines surrounding the encryption and integrity of email communication, which is much higher than the regular email systems most physicians use for their personal email accounts. The second regards the mechanics of which types of requests are appropriate for email. Most would argue that medical emergencies should not be conveyed via email, but even mundane tasks such as scheduling may not be appropriate for practices where outside email communication runs the risk of disrupting practice flow. Finally, there is the risk that email communications might be misunderstood or misinterpreted, resulting in an experience where the patient might feel ashamed, confused, or disregarded.

The Federation of State Medical Boards and the AMA have some specific guidelines when it comes to email with patients. Both organizations suggest that:

1. Medical professionals should have written policies that describe the appropriate use of email, the types of transactions that are appropriate for email, and the limitations to privacy that may come with email communication. This process should be treated with the same attention to detail as one might use in obtaining informed consent from a patient for a medication.
2. Medical professionals should use email systems that are encrypted and HIPAA compliant.
3. Medical professionals should establish an appropriate system for inserting email communications into a patient's medical record.
4. Email communications with patients must be secure; ordinary email does not afford this required protection. Most private EHR systems include this functionality. Additionally, there are commercial vendors of secure email and messaging (e.g., Zixcorp and McKesson). Practitioners should avoid anger, sarcasm, harsh criticism, and libelous references to third parties in messages.
5. Practitioners should consider using commercially available encryption software for laptops, smartphones, and tablets. This is especially important for external hard drives and memory sticks (or thumb drives) that may contain protected health information and are easily lost or stolen.

SOCIAL MEDIA

Websites such as Facebook, LinkedIn, and Google Plus are among some of the most common social network sites. A recent trend has been the evolution of support groups for patients with chronic illness from face-to-face meetings to the creation of online communities, leveraging the power of social media to create ways for patients living with chronic conditions to learn from and support each other. One of the

best-known examples is PatientsLikeMe (PatientsLikeMe.com), co-founded in 2004 by three MIT engineers. The team created a consumer-oriented online health data-sharing platform intended to transform the way patients manage their own conditions, as well as to change the way industry conducts research and improves patient care. The power of social networking, though, lies in the connections “between the pages”; Facebook contains powerful search tools that allow a user to find friends or acquaintances and then view their pages. Social networks allow a user to build a virtual web connecting millions of people, where ideas and personal information flow freely. These sites are built to encourage the sharing of personal information including hobbies, favorite music, personal photos, and even birthdays. Privacy settings, when used appropriately, can limit a user's personal information to just friends or acquaintances, but such settings often are left at their default values by users, thus permitting the sites to potentially reveal personal information to anyone on the Internet.

When medical professionals use social networking websites, they need to be mindful of posting personal and unprofessional material. A study in 2008 estimated that 64% of medical students and 13% of residents used Facebook (Thompson et al., 2008). Since that time, use of Facebook and social network technology has grown throughout the general population and has likely grown within medical community as well. Strikingly, in this study only a third of these Facebook profiles were made private, and most accounts shared at least one personal detail.

Medical professionals must always be mindful of how information might be perceived by others, especially if it runs the risk of portraying them as unprofessional. For example, posting pictures from a Halloween party that shows the physician clearly intoxicated while dressed in scrubs might be misconstrued as drinking on the job by a patient who stumbled across the photo.

There are several guidelines for using social networking websites:

1. Physicians should use built-in privacy settings to limit the amount of personal information that is available to the general public and patients. What items are available to the public should support the physician's professional “brand” or identity.
2. Physicians should always ask themselves, “What would a potential patient think about what I'm about to post? Is there a way in which I might be misunderstood?”
3. Physicians should not “friend” patients on their social networking websites, because it implies that it is within their scope of practice to spend time socially with a patient.

BLOGS AND WEBSITES

It has become increasingly common for hospital and clinics to create webpages for their physicians containing basic demographic and clinic-related information. It is not

uncommon that a physician might have a personal webpage or a blog, as well. A physician can easily post thoughts or musings on a blog without the technical know-how necessary for building or running an entire website. While only a small number of medical professionals currently use blogs, in a study of blogs written by self-identified medical professionals it was estimated the 40% of blogs described individual patients, sometimes with enough detail that the patient might actually be identifiable (Lagu, Kaufman, Asch, & Armstrong, 2008). And, given the self-reflective nature of what most people post on blogs, it's not uncommon for physicians with blogs to want to write about medicine. But what happens when one also wants to write about events in one's personal life, or even one's political interpretation of current events? As patients search for information on their physicians, they will be pleased to find the medical information posted by their physicians on webpages and blogs—but what will they think of the personal information, and how will that information change their perception of their physicians? Physicians who wish to have webpages or blogs should consider having separate personal and professional web personas as a way of mitigating any conflation that might occur from having medical information intermixed with personal information.

As a corollary, physicians should also have a constant awareness of what is posted about them on the Internet. Physicians should be searching for their own names on a regular basis. In this exercise, the physician should be asking, what would a patient think of me? What if this was the only information they had about me? Physicians should act promptly to remove incorrect, inappropriate, or deceptive information. Online reputation management services may be helpful should physicians have names that could be confused with web content that would lessen a physician's public image.

TWITTER

Twitter is a social networking and microblogging service that allows users to "tweet" by posting short messages (up to 140 characters in length) to followers. Typically, the content of these tweets focuses on whatever is on the user's mind, and often the content of tweets direct people to websites and news stories. The strict limit on the lengths of tweets forces messages to be concise and to the point. However, the brevity of these messages creates the potential for messages to be misunderstood. For example, "What a day today has been," could convey elation, disgust, defeat, or even shame.

Twitter does, however, have utility to medical professionals; when used to promote one's brand or professional identity it can be a particularly engaging way to patient to follow their physician. Appropriate uses of tweets in the context might be, "This month is depression awareness month. Be sure to call us if you would like to learn more," or, "We are pleased to announce the addition of Dr. Smith to our practice," or, "Interesting new study published today reminding us about the importance of Vitamin D," with a link attached. These uses promote professional identity as well as the health of the

patient. They also boost patient engagement in a physician's practice, with little in the way of additional financial or personnel cost to the practice.

GENERAL GUIDANCE

In recent years hospitals, medical schools, and medical societies have created general guidelines for physicians around appropriate online use. The American Medical Association (Shore, Halsey, Shah, Crigger, & Douglas, 2011) provides a few guiding principles for physicians to consider when engaging patients on the Internet and in managing their digital presence:

1. Physicians should maintain an awareness of patient privacy and confidentiality consideration at all times.
2. Physicians should use privacy settings.
3. Physicians should routinely monitor their own Internet presence.
4. Physicians must maintain appropriate boundaries of the patient–physician relationship.
5. Physicians should consider separating personal and professional content online.
6. Physicians should notify colleagues if they see unprofessional material online.
7. Physicians must recognize that actions online and content posted may negatively affect their reputations and can undermine public trust in the medical profession.

It should also be noted that different generations of physicians may require different types of guidance (Gorrindo & Groves, 2011). For those physicians who feel uncomfortable with technology and who simply need enough knowledge to "stay out of trouble," starting with a basic primer about social media may be useful and sufficient. The CDC has published a social media kit (http://www.cdc.gov/healthcommunication/ToolsTemplates/SocialMediaToolkit_BM.pdf) that provides nuts-and-bolts level information about social media technology along with concrete advice for practitioners to embrace social media as a way of building an online presence that supports and enhances an appropriate professional identity. In contrast, physicians who grew up with technology and feel facile within Web 2.0 tools may need guidance that focuses on online professionalism, maintaining boundaries, and balancing the personal and professional when online.

CLINICAL PEARLS

- Patients' preferences to make disclosures during a computerized interview have been shown regarding questions about substance abuse, sexual behavior, and sexually transmitted diseases such as HIV (Locke et al., 1992; Richens et al., 2010), suggesting that computers are experienced as less judgmental.

- One website, PsychCentral (www.psychcentral.com) is a frequently updated source of self-assessment tools that can be used with patients.
- A search at www.nimh.gov, nida.gov, or va.gov will lead to other useful validated tools, available online and downloadable for use in clinical practice.
- Technology Linked Care (TLC) has screened for depression, dysthymia, bipolar disorder, PTSD, acute stress disorder, generalized anxiety disorder, panic disorder, somatization, social phobia, alcohol and drug abuse, stress, and violence. Usually, after screening, the automated IVR system encourages the person to seek help, provides resources, and monitors adherence using follow-up calls to ensure help has been sought (Farzanfar, Stevens, Vachon, Friedman, & Locke, 2007).
- Medical information websites for patients as consumers have changed the physician–patient relationship. No longer are physicians the sole providers of guidance to patients. Rather, their role has been to help patients evaluate information, and the emerging paradigm in information-age medicine is that of “shared decisionmaking.”
- Successful implementation of the shared decisionmaking model requires that the clinician assess the patient’s capacity to exercise adequate judgment in clinical decision making.
- In a recent review of computer-assisted psychotherapy, Cartreine, Locke, and Ahern concluded that some treatments work better than others, and that though they are sometimes as effective as face-to-face therapy, they do not appear to be better.
- When medical professionals use social networking websites, they need to be mindful of posting personal and unprofessional material.
- The *modern physician* chooses not to shy away from the digital world, but rather to embrace it as a way of promoting his public self, managing this tricky negotiation carefully and intentionally.
- Medical professionals should have written policies that describe the appropriate use of email, the types of transactions that are appropriate for email, and the limitations to privacy that may come with email communication. This process should be treated with the same attention to detail as one might use in obtaining informed consent from a patient for a medication.
- Practitioners should avoid anger, sarcasm, harsh criticism, and libelous references to third parties in messages.
- Physicians should always ask themselves, “What would a potential patient think about what I’m about to post? Is there a way in which I might be misunderstood?”
- Physicians should not “friend” patients on their social networking websites, because it implies that it is within their scope of practice to spend time socially with a patient.
- For those physicians who feel uncomfortable with technology and who simply need enough knowledge to “stay out of trouble,” starting with a basic primer about social media may be useful and sufficient. The CDC has published a social media kit (http://www.cdc.gov/health-communication/ToolsTemplates/SocialMediaToolkit_BM.pdf) that provides nuts-and-bolts level information about social media technology.

DISCLOSURE STATEMENTS

Dr. Locke

Dr. Locke is the Chief Medical Officer of iHope Network, Inc. He is also a shareholder. Dr. Locke is also the Chief Medical Officer of Frame Health, Inc. and is also a shareholder. He is also a consulting psychiatrist at Beth Israel Deaconess Medical Center where he is assisting in the development of a telepsychiatry consulting service to primary care practices.

Dr. Gorrindo

Dr. Gorrindo is the Director of Postgraduate Medical Education at Massachusetts General Hospital and has no commercial disclosures to report.

PSYCHIATRY AND PHYSICAL MEDICINE AND REHABILITATION

Nasser Karamouz, Richard T. Goldberg, Lucienne A. Cahen, and Seth D. Herman

INTRODUCTION

Almost all rehabilitation patients have a reactive emotional response to their injuries, and some patients going through rehabilitation may have other chronic psychiatric symptoms as well. The role of the psychiatric team in a rehabilitation hospital is to help the patient and staff to optimally carry on the rehabilitation tasks. This can be accomplished more effectively if the members of the psychiatric team are familiar with the field of physical medicine and rehabilitation (PM&R) and the role of the physiatrist as the leader of the multidisciplinary team.

Physiatrists are physicians who specialize in physical medicine and rehabilitation. Physical medicine and rehabilitation is a subspecialty of medicine that focuses on three major areas of patient care: diagnosis and treatment of musculoskeletal injury and pain, neuromuscular disorders through study of nerve conduction studies and electromyography, and rehabilitation of patients with severe impairments resulting from traumatic brain injury, spinal cord injury, stroke, and other disabling events (www.physiatry.org). Physical medicine and rehabilitation does not adopt one organ system but treats the “whole” person with a focus on enhancing the function and quality of life of the individual. Not only the biological needs but the emotional, social, and even spiritual needs are addressed to ensure optimal recovery and function of the patient.

HISTORICAL BACKGROUND

Howard Rusk is one of the founding fathers of physical medicine and rehabilitation (Rusk, 1972). In 1942 he created a program in an Air Force hospital to promote the recovery of injured soldiers, which he initially named the Army Air Force Reconditioning and Recreation Program; it was later renamed the Army Air Force Convalescent Committee. The program demonstrated that rehabilitation programs enabled injured soldiers to return to active duty and restored disabled soldiers back to a functional level when they returned home (Gritzer & Arluke, 1985). The formal training of doctors of

physical medicine and rehabilitation was initiated by Dr. John Stanley Coulter, who eventually promoted physical medicine and rehabilitation to be part of formal medical education. Dr. Frank Krusen is credited as well with contributing to the establishment of physical medicine and rehabilitation in the 1930s and ultimately established the first 3-year residency program in Physical Medicine and Rehabilitation at Mayo Clinic in 1936. He created the term *physiatrist* to identify the physician who treats patients via physical medicine and rehabilitation modalities. Both Drs. Coulter and Krusen were leaders in organizing the American Academy of Physical Medicine in 1938. Further promotion of the specialty occurred when, in 1945, a section on PM&R was established in the American Medical Association. Ultimately, in 1947, Physical Medicine and Rehabilitation was declared a specialty of medicine by the Advisory Board of Medical Specialties. Since that time, the field of physical medicine and rehabilitation has continued to grow and expand, especially with an increased demand for services with the aged population, the disabling effects of war, trauma, and other medical conditions such as neurological disorders like Parkinson's disease and cancer.

THE PHYSIATRIST ROLE

The physiatrist is typically the lead physician who directs the medical and rehabilitation treatment program among a team of healthcare providers such as physical therapists, occupational therapists, speech language pathologists, psychologists, nurses, social workers, and other consulting physicians including psychiatrists and other medical specialties. The aim is to provide an interdisciplinary approach for optimal recovery of the patient. The patient is monitored with regular team meetings that enable all members of the team to discuss the recovery of the patient and to ensure optimal progress. The team establishes functional goals and determines the most appropriate discharge plan, such as to home versus another facility. Ultimately, communication among all members of the rehabilitation team is key to ensuring continued recovery and restoration of the patient with the ultimate goals of independence and quality of life.

Table 20.1 WORLD HEALTH ORGANIZATION (WHO) DEFINITIONS

TERM	DEFINITION
Impairment	Any loss or abnormality of body structure or of physiologic or psychologic function
Disability	Any restriction or lack resulting from an impairment of the ability to perform an activity in the manner or within range considered normal for the human being
Handicap	A disadvantage for a given individual, resulting from an impairment or a disability, that limits or prevents the fulfillment of a role that is normal for that individual
Activity	The nature and extent of functioning at the level of the person
Participation	The nature and extent of a person's involvement in life situations in relationship to impairments, activities, health conditions, and contextual factors

REHABILITATION TERMINOLOGY

The physiatrist's specialized training enables identification of a patient's physical, emotional, and cognitive deficits to develop a treatment plan. Functional assessments rely on an understanding of the distinctions among impairment, disability, and handicap, and, more recently, the new philosophic framework of activity and participation as defined by the World Health Organization (World Health Organization, 1980, 1997). Examples include difficulty with community reintegration, earning a wage, navigating architectural barriers (Author, 1998). The identification of these components of function drives the development of the treatment plan to promote quality of life and independent functioning (see Table 20.1).

EMOTIONAL ASPECTS OF REHABILITATION

PREMORBID FUNCTIONING

Although most injuries or illnesses requiring rehabilitation may cause emotional distress, many of the patient's emotional responses may be secondary to the patient's pre-morbid psychiatric disorders. Occasionally the psychiatric disorders actually are the *cause* of the initial injury (suicide attempts, drunk driving, violence, psychotic behaviors resulting in injuries). This is an important distinction to consider, especially when the injury is expected to cause emotional or behavioral changes. For instance, in patients with traumatic brain injury we cannot simply *assume* that all the post-injury psychiatric symptoms are secondary to the brain injury.

EMOTIONAL IMPACT OF ILLNESS OR INJURY

Most of the rehabilitation programs provide help for the following conditions:

- Amputations
- Stroke and other Neurological Disorders
- Burn Injuries
- Traumatic Brain Injury
- Spinal Cord Injuries
- Pediatric Rehabilitation

When we look at the above programs, it seems that most frequently the injuries or illnesses for these patients may have happened suddenly. Usually the patient has not had the time for any adequate preparation or development of coping strategies. Frequently the changes are not just an episodic event but will affect the patients for a long time, maybe for the rest of their lives. It may change them personally, financially, vocationally, and in many other ways. The patient is not the only one affected by the injury. In most cases it affects the patient's family members and significant others.

ACUTE STAGE OF INJURY OR ILLNESS

Because of the severity of their condition, patients usually require urgent medical or surgical interventions. During this acute stage, the patient and family do not have the ability or willingness to perceive the long-term effect of such injuries. This is partially due to a defense mechanism of denial and partially because at this stage they are not certain if the patient will survive. They can focus on the bigger picture only after survival is secured. Usually, the emotional issues related to a patient's survival are experienced by patient and his or her family while the patient is in the intensive care unit. To continue to secure such survival, the patient is usually transferred to the medical-surgical units for further stabilization. When the patient and family are no longer worried about the patient's survival, then the patient is usually stable enough to be transferred to a rehabilitation setting. At this point the patient and the family can begin to evaluate the patient's overall impairment. The stage of comparison begins. Patients begin to compare themselves to others as well to their previously healthy selves. The patient and family begin to see the possible problems in the future. This stage of awareness is usually a difficult stage of emotional coping, and mostly occurs at the time that patients are being admitted to the rehabilitation hospital.

PREADMISSION PROCESS

Before the admission to the rehabilitation hospital, the patient and family need to understand what is expected to be accomplished in the rehabilitation setting. If one expects the need for rehabilitation after a planned medical or surgical

intervention, it would be beneficial to prepare the patient for the expected rehabilitation process as soon as practically possible. Such preparation can be done in an acute hospital or, if possible, even before the patient is admitted to the acute hospital for such a procedure. Increasing the patient's physical strength via exercise, and adequately treating any underlying possible psychiatric or cognitive disturbances, will better prepare them for the upcoming rehabilitation. Some patients arrive in the rehabilitation setting having unrealistic ideas and expectations about their prognosis or disposition, as well as the length of stay in the rehabilitation facility. These misperceptions are partially due to wishful thinking and partly due to wrong rehabilitation information given to the patient by those who are not fully familiar with the strengths and limitations in the field of PM&R. These misperceptions can cause significant stress for the patient after arrival to the rehab hospital. We can minimize such problems by requesting a consultation from a competent PM&R specialist to evaluate the patient in the acute hospital prior to admission to a rehabilitation facility. Such a consultant has the knowledge to initiate the conversation about the goal of the patient's admission to a rehabilitation hospital. Such consultation and liaison work is extremely helpful to patients and their families and to the staff in the rehabilitation setting. The medical psychiatrist in the acute hospital is able to play a significant role in such patients' emotional preparation. The psychiatrists who do PM&R consultations in acute hospitals are best suited to advise the medical and surgical staff about the need for a psychiatric evaluation for emotionally vulnerable patients whom they are asked to see prior to transfer to a rehabilitation hospital. Some patients cannot tolerate the high level of physical, cognitive, and emotional intensity of active rehabilitation. They may respond better if their rehabilitation plan is designed to respect their limitations. We should recommend the "dosage" of rehabilitation in the same manner that we determine the "dosage" of medications for our patients. Some patients may optimally need a higher dosage of a given medication but may not be able to tolerate it, and we need to give them a lower amount to minimize adverse effects. The same is true in the rehabilitation setting, as some patients are unable or unwilling to accept the intensity of their rehabilitation and their treatment plan needs to be modified accordingly. In such cases more rehabilitation does not necessarily result in a better outcome, and may have an "adverse effect."

At the time of transferring patients from the acute hospital to a rehabilitation facility the medical team, including the medical psychiatrist, needs to work with patients to evaluate their physical and emotional status in order to guide them to an appropriate rehabilitation facility. For example, patients who are admitted to an acute rehabilitation hospital should meet the criteria for the need of 3 hours of active rehabilitation therapy per day, while the requirement for admission to a skilled nursing facility is approximately 1.5 hours per day. Some patients who need frequent or daily visits by their physician (PM&R) need to be referred to an active rehabilitation facility, because most skilled nursing facilities allow only for weekly or monthly physician visits. However, going to a skilled nursing facility does not necessarily indicate insufficient rehabilitation—as,

for example, patients with joint replacement from both skilled nursing facilities and inpatient rehabilitation facilities receive considerable amounts of follow-up rehabilitation care (Dejong et al., 2009). Psychiatric services for patients who are in need of active psychiatric care may not be adequate in most skilled nursing facilities, and such patients are better served in an inpatient rehabilitation facility. A long-term acute care hospital is another option for some patients, and their criteria for admission and the extent of their services falls in between that of active rehabilitation and skilled nursing facilities. Patients who are actively suicidal and are under one-to-one supervision are not appropriate for admission to a rehabilitation hospital. Patients who are taking intramuscular or intravenous neuroleptics should be further stabilized before they are admitted to a rehabilitation facility. Patients should also be relatively stable medically and should not be significantly violent, although some agitation and aggressiveness can be expected from some neurologically impaired patients who are confused but in need of rehabilitation.

If there are any significant psychiatric issues, then the discussion between the psychiatry staff at the referring and admitting hospitals can be clinically helpful. Physical and cognitive rehabilitation care should not be denied to the patients who suffer from severe psychiatric illnesses; however, one can reasonably question the clinical appropriateness of such rehabilitation admission if the degree of the psychiatric symptoms is so severe that they would significantly interfere with the rehabilitation process.

ADMISSION TO THE REHABILITATION HOSPITAL

When we consider the admission process, we should be aware that there are two aspects of admission that need to be distinguished—one administrative, the other clinical. This distinction is not usually recognized institutionally. Administratively, we need to determine whether the patients are signing in directly to admit themselves or, alternatively, patients have a legal representative who signs in for the patient so that he or she can be admitted to the rehabilitation hospital. Occasionally, patients who seem incompetent, but are nonetheless competent in the eyes of the law because they do not have a legal representative, arrive in the admissions office at the rehabilitation hospital and are unwilling to be admitted and wish to go home. It would be challenging for a psychiatrist working in the rehabilitation hospital to be called to the admissions office to evaluate such a patient for a safe disposition. In most cases the patient can be encouraged to accept admission for a brief evaluation to see that a safe discharge plan can be designed. Rarely the patient refuses to be admitted and the question of the patient's competency is raised, which is difficult to assess at the time of admission. Patients who are confused should have a healthcare proxy, and patients who are unwilling to be admitted for inpatient rehabilitation should have a legal guardian available or, at a minimum, the process of obtaining guardianship should be initiated prior to their arrival at a rehabilitation hospital.

Once the patient is administratively admitted to the hospital, the all-important process of clinical admission begins. Patients must be evaluated to determine both the nature and severity of their impairments as well as the degree of their understanding of deficits. Patients should be encouraged to think reasonably about the fears, hopes, and expectations that come with rehabilitation. Some patients may minimize their problems while others may be vigilant and unnecessarily focus too much on the possibilities for poor outcomes. The rehabilitation team needs to conduct a full evaluation and come up with a complete rehabilitation care plan. After the primary evaluation and clarification of the expectations of staff and patient (or the patient's formal representatives), a therapeutic contract is designed. When the patient and family agree with such a rehabilitation care plan, then the patient finally can be clinically admitted to the program and the rehabilitation process can begin. Reaching this therapeutic agreement is essential. During the active phase of the rehabilitation process, patients should be reminded of the therapeutic contract if they forget or otherwise undermine the therapeutic care plan and refuse to participate in rehabilitation.

ACTIVE PHASE OF THE REHABILITATION PROCESS

As the rehabilitation process evolves, patients continue to compare themselves to others as well to the previously healthy self. At times the patient may have no adequate cognitive or emotional readiness to make this comparison, but the family begins to compare the patient with who she or he was before the injury. At times, the emotional pain arising from this comparison is so significant and difficult to accept that denial can become the main defense mechanism for the patient and/or the family. If such denial occurs, the patient and family may encounter significant difficulty with the rehabilitation treatment plan—especially since rehabilitation, by its very nature, confronts the patient with the impairment and related deficits. For instance, if a patient uses denial in order to cope with reduced walking ability, it will be impossible for the patient to continue denial while the physical therapist is encouraging the patient to walk. Similarly, if a patient uses denial to overcome the emotional pain arising from expressive aphasia, the patient will be directly confronted while working with the speech therapist. If some patients cannot accept the fact that they are so compromised that they cannot even dress themselves, during their work with their occupational therapist they will be constantly confronted with their deficits. In short, a patient who is in denial will find it difficult to continue to use denial as a defense mechanism when confronted repeatedly while working with the rehabilitation team. As one cannot simultaneously deny and repeatedly be confronted at the same time, a patient may deal with this dilemma by refusing rehabilitation. If such denial continues, the patient will begin to break the previously agreed therapeutic contract. Psychiatry consultation and psychological treatment are usually considered for such patients. If the patient's denial cannot be challenged supportively, then the patient may express wishes to leave

prematurely and against medical advice. Some patients are at higher risk for leaving against medical advice—for example, patients with traumatic brain injury who are 24–35 years old, have a history of intentional injury, alcohol, and substance abuse. These patients need to be identified and evaluated by the psychiatric team soon after admission to the rehabilitation hospital to prevent such risks and also to implement a treatment response in case such patients try to leave prematurely (Kim, Colantino, Bayley, & Dawson, 2011). Although these patients may not be considered a danger to themselves from a purely psychiatric point of view, nonetheless at times they can be clearly unsafe for discharge and meet the criteria for involuntary commitment to an appropriate facility. One example would be a patient who has symptoms of left neglect, who can be in immediate and substantial danger if he leaves the hospital and tries to cross a busy road. Patients for whom a psychiatric consult is requested will, at times, refuse psychiatric services. In most cases this is related to the patient's anxiety or lack of understanding of psychiatric services. They may accept help if we initially back off, supportively reassure them about our role, and give them enough time and space to reconsider their initial refusal. If there is any evidence to suggest those patients can be a danger to themselves or others, it is necessary to supportively establish the fact that they are required to talk with us in order to rule out such safety risks.

THE MULTIDISCIPLINARY REHABILITATION TEAM

The treatment plan for most patients and their disposition after discharge is usually a complicated process and based on the recommendations made and approved by the multidisciplinary team members rather than by any individual member of the team. It is crucial that the psychiatrist and psychologist working in a rehabilitation setting become closely familiar with the short-term and long-term goals and disposition for patients and try to resolve any suspected psychiatric symptoms that may interfere with accomplishing the plan of care. Rehabilitation care plans are based on professional standards, evidenced-based practices, and research, as well as the individual needs of patients. The team includes various staff from different specialized clinical backgrounds.

- **Rehabilitation Nurses** are familiar with the profound impact of disability upon patients' lives and try to prevent further complications while educating them in how they should prepare themselves for the next stage of their care. Nurses have significant information about the overall emotional status of their patients, how they are usually coping, and how patients are reacting to their families and friends during their visits. Nurses are in the forefront of the direct patient care at all times and have significant clinical information that can help the psychiatrist in proper psychiatric management of patients.
- **Case Managers** assist patients in setting appropriate goals and begin the challenging task of obtaining the necessary services for patients during their treatment

and after discharge. Coordinating the psychiatric care and post-discharge follow-up for patients becomes easier with ongoing communication between the case manager and the psychiatric team. In recent years the work of case managers has become increasingly challenging, primarily because of the limitations on resources available to them while they try to provide the best discharge planning for their patients. These challenges are becoming more intense in light of additional pressure from various sources to discharge patients as soon as possible. Although such pressures are felt by all the team members, case managers are on the front lines in such battles. These opposing forces and resulting challenges should be a focal point for PM&R practitioners in the hospital setting.

- **Physical Therapists** evaluate and treat problems related to mobility, strength, coordination, and endurance. They are helpful in reporting any adverse effect of psychotropic medications on patients, and the psychiatrist is fortunate to have their input while modifying patient's medications.
- **Occupational Therapists** assist patients to further improve their ability to perform everyday tasks such as eating, dressing, personal hygiene, meal preparation, housekeeping, and skills required to rejoin the community. If there is any concern about the functional ability of patients, occupational therapists can evaluate them in the community. With such information in addition to other data and the report by the therapeutic recreation specialist, the psychiatrist can better advise the team in terms of a plan to increase the safety of the patient after discharge.
- **Speech-Language Pathologists** try to improve the patient's ability to speak, swallow, understand, read, write, focus, remember, and solve problems. This can be done individually or in a group setting and with or without computer-assisted techniques. They can recommend the best way to communicate with the patient and review the cognitive ability of patients with the psychiatrist, which is important in patients who cannot be fully examined during the psychiatric interview. They also monitor food intake by patients, which makes them a reliable source for the psychiatrist to get information about the possibility of any swallowing problems secondary to psychotropic medications.
- **Respiratory Therapists** assist with 24-hour coverage for evaluating and treating conditions related to respiratory problems.
- **Therapeutic Recreation (TR) Specialists** evaluate a patient's premorbid leisure interests and lifestyle. Once identified, these interests are combined with basic therapy goals that focus on education, skills teaching, and community reentry. Treatment programs are designed to give patients an opportunity to enjoy activities of choice such as adaptive sports, games, crafts, horticulture, pet therapy, community outings, and, when available, music therapy. The focus of many sessions may be improving specific physical and/or cognitive therapy goals and social skills. Sessions may be conducted individually or in groups. The TR specialist may also provide assistive recreational devices to improve independence with leisure activities. Educating the patient and family about ways to have an active leisure lifestyle after discharge, through home and community resources, is another important component of the TR program. Most patients have significant free time while they are in the hospital, and the TR can be very helpful in designing projects based on the interests of patients to keep their minds off an emotionally painful preoccupation with their condition. Such help from TR has allowed some patients to avoid the use of psychiatric medications and to use nonpharmacological approaches to cope with their emotional conditions. TR specialists may also help coordinating the process for patients to become voluntary visitors to help other patients with similar problems; for some patients, being able to relate to others with the same challenges can provide significant assistance in their own coping. The staff from therapeutic recreation is usually the key element in organizing periodic gatherings for patients who have been discharged from the inpatient rehabilitation programs. During these events, patients can meet with staff members who took care of them during their hospitalizations. Such reunions have had many benefits for patients and their families, while educating staff about the long-term effect of their rehabilitation work. Because of such follow-ups, we can periodically obtain firsthand information and direct knowledge from patients and their families that is useful in rehabilitation and discharge planning for other patients.
- **Dietitians** recommend therapeutic diets, supplements, and special feeding programs, and educate patients and families about guidelines to follow after discharge. Depression, especially when combined with a lack of adequate activity, can cause significant weight gain. Also, some patients who have depression may experience weight loss, and the dietician is helpful to the psychiatrist in monitoring such symptoms of depression and the efficacy of the use of antidepressants. Depending on a patient's individualized needs, other professionals, consulting physicians, neuropsychologists, social workers and counselors, and hospital chaplains may also join the rehabilitation team.

WHO SHOULD DO THE COUNSELING?

During the active phase of rehabilitation, the patient usually receives different levels of counseling from various members of the rehabilitation team. As mentioned earlier, some patients minimize their problems and some have a tendency to exaggerate them. The consultant who is trying to help the patient to deal with deficits should have a good understanding of the actual degree of the patient's impairment and possible prognosis. For instance, if the patient has emotional struggles regarding lack of mobility the physical therapist is the most appropriate counselor to help the patient to express

fears and concerns. If the patient is unreasonably concerned about impairment and is not able to be objective about potential outcomes, the physical therapist will have the appropriate knowledge about the patient's condition to offer reassurance. If counseling is to be provided by the psychiatrist or the psychologist, he or she needs to be informed by the rehabilitation team about the details of patient's deficits, rehabilitation needs, and possible prognosis. If the consultant psychiatrist lacks such critical knowledge, the patient's minimization or exaggeration of the problem may cause the counseling to go in the wrong direction.

PATIENT-STAFF INTERACTIONS

As the rehabilitation process continues, the patient and the rehabilitation therapist gradually establish a close therapeutic relationship. For some patients such a supportive relationship is at least as important as the therapist's knowledge and skill. During the rehabilitation process, by definition many emotional and physical boundaries become fragile. Frequently some physical boundaries need to be broken in order to provide effective rehabilitation. For instance, during physical therapy there is a great deal of touching and holding in order to address the patient's ability to sit up and sit down, walk, and maintain balance. Most patients feel comfortable with such approaches, but others may show increased anxiety and discomfort during these kinds of therapeutic interactions. When patients have difficulty with such interactions with rehabilitation staff, the discomfort can negatively impact their participation in physical therapy. In particular, patients diagnosed with schizophrenia need to be cautiously observed for their apprehensive reaction and avoidance behavior during such therapeutic contacts. It is common to observe patients with such diagnoses becoming increasingly anxious when the usual and expected social and physical "boundaries" are broken. Staff respect patients' need for such personal space, but it is not usually possible to keep these boundaries intact when, for example, a physical therapist needs to frequently touch or hold a patient therapeutically or a nurse has to provide personal care. There are also occasions in which other patients may feel "too comfortable" or "too pleased" with such broken boundaries and react personally rather than therapeutically. Patients with a history of affective disorders—for example, those with hypomania—are in this category. Fortunately such patients are usually able to respond to supportive limit-setting when needed. Psychiatrists and counselors working in rehabilitation facilities can use the opportunity to observe some of their patients during rehabilitation sessions to become more familiar with the patient/staff interactions.

SOURCES OF STRESS FOR THE STAFF

The staff working in a rehabilitation hospital may, with or without being fully aware of it, experience a range of emotional disappointments. The psychiatrist and the psychologist working with the team need to be aware of these professional challenges and also monitor their own responses to such stresses. The process of physical rehabilitation can be very

slow. At times it is complicated, with no simple solution available to *eliminate* the patient's problem. Rehabilitation may be defined as the optimal outcome for a patient's physical, cognitive, and emotional problems. Although patients who receive rehabilitation can get better, they usually cannot be cured. This outcome is in contrast with a patient who is admitted to a hospital for surgery and at the time of discharge expects to be, and often is, completely cured and on the road to a full recovery. Being "cured" should not typically be expected at the time of discharge from the rehabilitation hospital. The rehabilitation team may have provided exceptionally competent therapeutic services, and the patient may have improved significantly; however, the patient will likely experience some difficulties with thinking, walking, or talking at the time of discharge. This reality can be disappointing to patients and their families as well as to their caregivers who had wishes, consciously or unconsciously, for a complete cure. The rehabilitation staff gradually recognizes that they cannot help everybody no matter how hard they try. During the process of rehabilitation, patients and staff have many close physical and emotional interactions and occasionally, depending on patients' emotional status and possible underlying psychopathology (i.e., borderline personality), some undesirable emotions may be created among the caregivers. The psychiatrist and psychologist working with the team should be aware of these stresses on staff, including themselves, and monitor the possible effect of such emotional perceptions on the patient's care. If such stresses, for various reasons, are felt by the majority of the team members it is beneficial to have a team meeting to discuss the patient-staff emotional interactions and review the plan of care.

Another source of stress is that staff are trained to believe that all patients have a desire to get better. Sometimes the staff are confronted by patients who do not wish to improve and may resist any fair treatment plan or discharge dispositions. At times the patients are not participating in their plan of care because they have limited cognition, and they do not comprehend the need for any rehabilitation. At other times there are patients that are clearly benefitting from their condition due to a primary (unconscious) or a secondary (conscious) gain, which clearly minimizes their interest to actively try to get better. Also, patients who have conversion disorder may become too anxious about getting better because their symptoms are protecting them from an intrapsychic conflict that needs to be addressed before they become ready to give up their symptoms. At times, patients are not interested in getting better simply because they like to be hospitalized. For instance, some patients who live alone and feel lonely and apprehensive at home may report feeling good in the hospital, where they have fair security, are taken care of by dedicated staff, and usually have more frequent visits by family and friends. We cannot motivate such patients by informing them that if they do not work hard in their rehabilitation they cannot get better to go home. Such statements actually indicate to the patients that if they would like to stay longer they should slow down their participation in their rehabilitation activities; however, when such patients are educated that they will become disqualified to stay in the hospital if they do not participate 3 hours a day

in their rehabilitation, they may try to qualify and prolong their stay by increasing their participation.

The slow pace of the rehabilitation process can be another source of stress. Frequently, rehabilitation staff cannot find a simple solution to their patients' problems, and there is rarely any immediate success. For patients who have had recent surgical interventions, participation in rehabilitation activities can cause some degree of pain and discomfort. Frequently those patients blame their therapists for causing such pain, and become angry or simply minimize participation in their rehabilitation. Some difficulties may also arise when the rehabilitation team is unable to decide if a patient's lack of optimal participation in rehabilitation is due to the patient's *unwillingness* to participate or by the patient's *inability* to do the task. The rehabilitation team expects the psychiatrist and the psychologist to use his/her expertise to clarify whether the patient cannot or will not fully cooperate, and why.

COPING MECHANISMS

A patient with physical disability arrives at a rehabilitation hospital after initial diagnosis and treatment have been accomplished in an acute care setting. The patient has an expectation of being restored to the baseline that came before acute hospitalization. Every patient comes into rehabilitation with previous strengths and weaknesses. Age, gender, previous illnesses, and socioeconomic background are predictors for outcome.

Culture and social class must be understood by the psychiatrist and psychologist who are undertaking psychotherapy with the patient (Goldberg, 2003). Cultural attitudes toward illness affect the reactions of patients toward disability. For example, patients whose families came from traditional countries where the entire family makes decisions about medical treatment may require more intensive family communication and support in the rehabilitation process. Patient whose families were born and raised in the United States may have more freedom in making individual choices about treatment. Age and gender are important predictors of outcome with specific disabilities. For example, spinal cord injury has a ratio of 8 or 9 to 1 in favor of male to female. Within the male population, there is a bimodal distribution in which there is a large group of young men who have been involved in motor vehicle accidents and sports injuries, and an older population who have been injured at work. Psychological treatment focuses on the specific needs of each age group. Young men may not have completed their educational and vocational training. Older men may have established themselves in an occupation, but they may not be capable of returning to a former job.

A psychiatric assessment, along with psychological screening, the report by the rehabilitation team, and direct observation of patients in their rehabilitation program determines the motivational and cognitive strengths of each patient. For motivational assessment one needs to differentiate between abulia and depression, as well as patient's inability versus unwillingness to participate in their rehabilitation care. Screening for alcohol and drug addiction is necessary in the overall evaluation for success. Family history is important not

only for assessment of psychiatric disorders and previous psychiatric hospitalizations, but also to determine familial attitudes toward disability. Illness affects the whole family, and in turn the family's attitude toward illness contributes to a patient's willingness to work toward rehabilitation.

Functional impairments that limit a person's ability to carry out activities of daily living such as managing a house, caring for children, cooking, cleaning, managing personal finances, completing an education, or earning a living are common elements to consider in all disabilities. Disabilities have a profound effect on a person's psychological outlook and psychiatric stability. Persons with previous psychiatric disorders have the additional task of coping with their physical disabilities.

How does one cope with loss? A person with physical disability feels humiliated by a decline in function. An initial strategy may be denial. One pretends that life can proceed as usual until one is faced with insuperable barriers of rejection in the community. In a rehabilitation hospital, a patient is confronted with the tasks of transfer from bed to chair, of using a commode, of standing, balancing, ambulating, ascending and descending stairs. At admission a patient may have a high expectation that he or she will walk out of the hospital at the end of 4 or 5 weeks. When the expectation level is not fulfilled, then comes the hard task of adapting—not just adjusting—to disability.

Adaptation to disability requires a patient to develop the functional skills and cognitive capacity to prepare for return to living independently in the community or semi-independently in an assisted living home. The older term, *adjustment*, meant that a patient had to accept the limitations associated with disability without denial. Although this coping strategy worked for some patients, it did not work for others. Some patients with disability used denial as a healthy mechanism for overcoming disability. A famous example of this strategy was Franklin D. Roosevelt, who became paralyzed from poliomyelitis at the age of 39 (Goldberg, 1981; Oshinsky, 2005). He never accepted the prognosis that he would never walk again, and until his death at age 63 he was planning to return to Warm Springs, Georgia, to complete his rehabilitation. As clinicians we encourage patients to maintain hope that they will improve function with the advent of new technologies while at the same time preparing them to face the realistic challenges of adapting to disability.

Adaptation requires a patient to separate his concept of disability from his concept of himself. Being paraplegic or brain injured or hemiplegic is not the same as being oneself. The person's idea of self as physically disabled may spread to other aspects of self-image. The person with amputation becomes the amputee; the person with blindness becomes the blind man. The phenomenon of spread reaches out to intellectual, emotional, and even spiritual aspects of oneself. By recognizing and learning how to separate the disability from the person, one can adapt to the realistic limitations of disability.

Language is the lattice through which we perceive reality. How we label our patients determines in part how we treat them. When we understand our patients as persons rather than as categorical diseases, then we bring a humane attitude

to our work. Before the term *political correctness* came into vogue, the philosophy and principles of rehabilitation distinguished between impairments and persons. Similarly, the term *handicapped* was assigned to specific restrictions imposed by disability at home, school, and work. "The handicapped" should not be used as a general term referring to persons with disability.

Rehabilitation helps a person with disability to appreciate remaining assets rather than dwelling on liabilities. Focusing on loss of physical function to the detriment of preserving remaining assets leads to a patient's negative expectations. Psychiatrists and psychologists help patients to focus on their remaining assets rather than on their limitations. Patients with a stroke or spinal cord injury may find ways to perform their jobs by adapting to their work environment. For example, an architect with left hemiplegia from an embolic stroke who can no longer do architectural drawings may find work inspecting building sites, since his visual perception remains intact. He may walk around construction sites with the use of a cane.

In a culture that idealizes persons with physical wholeness and attractiveness, physical disability is perceived as a disadvantage in school, work, and marriage. Physical disfigurement as a consequence of burns, amputation, or hemiplegia from stroke further complicates the rehabilitation process. Body image affects a person's self-image, which makes social integration into the community more difficult. The task of psychiatry and psychology is to help a person with physical disability to incorporate a change in body image with a patient's former picture of himself or herself.

COPING STRATEGIES

Although coping strategies may vary among different disabilities, there are specific common elements that guide the care of patients coping with all disabilities. First, care of the patient coping with loss and grief requires the utmost sensitivity by psychiatrists and psychologists. Second, clinicians must focus on the positive assets of the person rather than functional limitations imposed by disability (Wright, 1960). Third, a clinician helps to combat the phenomenon of spread—that is, the idea that because a person has a physical, cognitive, or affective disorder, he or she cannot function normally and compete with able-bodied persons. Disability causes physical, cognitive, and emotional limitations that produce specific handicaps at home, school, and work. Rehabilitation services help persons to cope with limitations in order to become less handicapped in activities of daily living.

Fourth, the clinician helps the patient to cope with the inferior social status of persons with disability, which may exist in some societies. Fifth, the clinician helps the patient to cope with the devaluation of a significant segment of persons with disability due to physical disfigurement such as burns, stroke, and amputation. Devaluation of a person with disability is counteracted by focus on a patient's abilities, moral values, and contributions to community. Inferior social status is perceived when a community focuses only on the disability to the exclusion of other assets of the patient.

In the following sections, specific disabilities will be explored as examples in the setting of psychological and psychiatric treatment to cope with limitations and deficits.

COPING WITH AMPUTATION

Amputation is the classic example of loss. The loss of any body part is symbolic of loss of health and ultimately loss of life. Mourning for loss is the first requirement of adaptation to amputation. Mourning for a lost limb is a normal process of grieving. This period may proceed while the patient is in a rehabilitation program, but if untreated it may persist for several years. Mourning may also be a reaction to cumulative losses that occurred prior to amputation. The person who has an amputation may feel victimized by previous life events. A clinician will treat feelings of isolation, guilt, and vulnerability that have existed antecedent to amputation. When a patient feels targeted to suffer, then intervention is required to prevent suicide. Grief may also be prolonged by concurrent events, such as separation, divorce, and loss of income. For men, amputation may mean loss of power, sexuality, physical prowess, and livelihood. For women, in addition to the prior losses, amputation may mean loss of sexual attractiveness, youth, and body integrity. Amputation is a visible disability and thus is an object of curiosity, staring, and stigma.

Coping with amputation requires understanding of loss. An amputee needs time to mourn the loss of a body part while beginning a structured program of physical and occupational therapy. Rehabilitation is structured around 3 hours of therapy daily. A patient needs to be prepared to tolerate long periods of work in therapy. Psychiatry may follow a patient from the admission to the rehabilitation hospital to discharge. Psychology works with a patient in reasserting body image and self-image. A person with amputation may feel that bodily integrity is completely altered. Coping with amputation requires a therapist to help a patient reconstruct a new body image and self-image. In most instances, over 50% of former activities can be engaged. A psychologist draws two circles to represent the patient's values, interests, and family interaction before and after amputation. The patient describes which values, interests, and family activities can still be accomplished after amputation. The two circles are overlapping, and the areas of agreement are shaded in to represent activities that the patient can still perform. Self-image is improved when the patient perceives that former activities can still be performed. Values, interests, family, and religion remain the same. As a patient becomes aware that he or she can still do many activities at home, school, or work, he or she regains hope for the future. (Dembo, 1956).

Disfigurement in amputation may be modified by the early fitting of a prosthesis. The degree of cosmetic disfigurement in women is related to symptoms of avoidance and emotional numbing characterized by posttraumatic stress disorder (Fukunishi, 1999).

Anxiety and depression are common sequelae of amputation (Horgan & MacLachlan, 2004). Anxiety is associated with depression, poorly perceived quality of life, less self-esteem, and previous level of anxiety before amputation. O'Toole,

Goldberg, and Ryan (1985) concluded that below-knee amputees were more likely than above-knee amputees to be depressed due to sensitivity to their difference from able-bodied persons. Whereas patients with above-knee amputation were glad they survived their surgery, those with below-knee amputation were disturbed by the physical and aesthetic changes in their appearance. Prostheses can help reduce anxiety about altered body image.

The presence of phantom pain can further contribute to patient's difficulty with rehabilitation. Phantom limb pain (PLP) is the pain experienced in the limbs that no longer exist. Distortion of body image is associated with phantom pain (Lindesay, 1985). The onset of phantom limb pain in 50% of cases occurs immediately after or within 24 hours following amputations. An additional 25% of patients experience such pain within a week of their surgeries (Weeks, Anderson-Barnes, & Tsao, 2010). Various medications including antidepressants, anticonvulsants, clonidine and nonsteroidal antiinflammatory drugs, calcitonin (Wall & Heyneman, 1999), and opioids or other agents have been used to treat PLP. In the rehabilitation setting it is desirable to use some medication that does not cause so much sedation or fatigue that it can interfere with the rehabilitation process. The use of antidepressants or anticonvulsants (e.g., carbamazepine, gabapentin) used alone or in combinations can be helpful. Morphine, gabapentin, and ketamine have short-term analgesic efficacy in patients with phantom limb pain (Alviar, Hale, & Dunoca, 2011). In a patient with PLP who also experienced restless legs syndrome, the use of dopamine agonist agents was reported to be beneficial (Skidmore, Drago, Foster, & Helman, 2009). Nonpharmacological approaches such as mirror therapy (Rothgangel, Braun, Beurskens, Setz, & Wade, 2011), transcutaneous electrical nerve stimulation, and nerve block (Ilfeld, 2010) have been helpful in some cases.

COPING WITH STROKE

Stroke is an abrupt, sudden, often unexpected calamity that results in multiple losses of sensation, movement, language, cognition, vision, swallowing, touch, and loss of position. A person who had formerly been able to carry on normal tasks of daily living and other roles such as earning a living, attending school, or being a parent or grandparent, suddenly finds that he or she is limited in one or several of these aspects of life. When a simple skill is learned as a child, we forget about these simple tasks and use our bodies to attain higher goals such as education, work, or homemaking. The sick body requires mental planning and organizational skills. The sick body is felt as strange, alienated, unsafe and insecure. A person with stroke perceives the body as both subject and object. The sick body is also an object of investigation from the outside and is continually being examined by experts who guide the person back to health (Kvigney & Kirkevold, 2003).

The body as viewed from the outside may be beautiful, misshapen, sexual, or ugly. For example, the female body may be viewed as an object of attraction, reproduction, awe, or envy. After stroke, a person is aware that the appearance of the

body is changed by paralysis, facial droop, ataxia, or position of the limbs. The loss of an attractive body may lead not only to the uncomfortable gaze of others but also to the experience of suffering from within. Visible contracture of an arm or leg, drooling from the paralyzed side of the mouth, weight gain resulting from inactivity, benign neglect of one side to appear as being inattentive or not caring to engage in direct eye contact, failing to dress appropriately or to maintain an attractive appearance with cosmetics or hair grooming—all of these deficits contribute to the emotional suffering and depression of a person with stroke.

Coping strategies with stroke begin by recognition of the overwhelming devastation and loss of function *within a blink of an eye*. Initially the focus is on survival and medical treatment. When medical and neurological stability is achieved, the patient will be ready for rehabilitation. After a patient has entered a rehabilitation program, physical and cognitive limitations become more apparent. A patient wants to know how much function will return. Some patients begin with an optimistic attitude toward completion of a rehabilitation program. "I'm always going to keep it in my head that someday I'll walk again." However, they usually are informed that the outcome is in doubt and will depend on the degree of physical and mental restoration as well as possible future medical complications. Some patients have to be sent back to the referring hospital for acute care. Following their stay, they return to rehabilitation. The patient is encouraged to optimally participate in rehabilitation despite some physical and emotional barriers. Rehabilitation has its ups and downs, but in the long run there is usually an upward trend. When patients meet an obstacle in the program, they may become depressed and wish to give up. Here is where the effort of psychiatry and psychology is crucial in contributing to a positive outcome. Both psychotherapy and psychopharmacology help to keep patients in the program.

Toward the end of the rehabilitation program, a patient may express optimism of outcome but may have an unrealistic assessment of functional capacities after discharge. A patient with hemianopsia may not be able to drive a car. A patient with hemiplegia or hemiparesis may not be able to return to skilled labor such as plumbing or carpentry or roofing. A patient with professional training in computer science, engineering, medicine, or scientific research may not be able to continue fulltime work. Neuropsychological testing may be helpful in delineating the areas of strength and weakness in a patient's recovery. A realistic assessment of mental capacities and limitations caused by stroke will help to inform a patient and family about future potential for work. Since professional workers are often primarily identified with their vocation, the loss of work may be traumatic. Professionals, small business owners, and self-employed persons may be able to restructure their work rather than give it up entirely. For example, we have treated physicians who could not return to lecturing or to private practice but who could teach and supervise others in a case study. The length and amount of recovery depends on the location of the stroke and the age of the person. Persons who cannot return to work may develop a hobby or perform volunteer work in the community.

Most patients experience some psychological consequences after stroke. Anxiety is seen in almost 20% of stroke patients. There is insufficient evidence to provide a clear pharmacological recommendation to treat such symptoms; however, paroxetine and buspirone have been found to be effective in reducing anxiety symptoms in stroke patients (Campbell Burton et al., 2011). Depression is the most common psychiatric disorder that adversely affects stroke outcome and is often underdiagnosed or inadequately treated (Ramasubbu, 2011). Its reported prevalence varies from 20% to 80% (Tharwani, Yerramsetty, Mannelli, Patkar, & Masand, 2007). At times, the symptoms that family and staff are observing in “depressed” patients may only be related to the stroke symptoms. Those symptoms may be simply due to poststroke fatigue, pseudodepressive manifestations of ischemic stroke, state of indifference, lack of concerns, or suppression of excitement and passion (apathy). Some patients may appear depressed due to lack of variations in normal speech characteristics such as speed and tone (aprosody), or disorders of motivation, loss or reduction of desire and interest, loss of drive or preferences, and may have flat affect without subjective feelings of depression (athymhormia), or fluctuation of emotions and periodic emotional outbursts (pseudobulbar palsy). Selective serotonin reuptake inhibitors (SSRIs) are considered to be the first choice treatment of poststroke depression (Arseniou, Arvaniti, & Samakouri, 2011). There has been no association of SSRIs and the risk of hemorrhagic stroke, regardless of prior history of cerebrovascular events (Douglas I, et al., 2011). After a stroke, initiation or resumption of treatment with SSRIs should be considered, especially if the patient has a history of depression or was taking SSRIs before the stroke (Reid et al., 2011). A patient’s history of prestroke depression is a significant predictor of poststroke depression (Reid et al., 2010). The medical psychiatrist who usually sees patients soon after a stroke is in a good position to offer SSRIs. Use of SSRIs such as fluoxetine 5–10 days after an acute ischemic stroke has resulted in an improvement of poststroke motor recovery and overall improvement (Cramer, 2011). The same result has been achieved by treating patients with escitalopram (Jorge, Acion, Moser, Adams, & Robinson, 2010). Stroke patients with depression who started antidepressants while in an inpatient rehabilitation hospital had longer length of stay compared to patients in the same impairment condition who had initiated antidepressants in the acute hospitals or sooner (Weeks et al., 2011). Stroke patients treated with antidepressants had a better recovery from disability even 9 months after stopping their antidepressants, indicating that antidepressants may facilitate the neural mechanism of recovery in patients with stroke (Mikami et al., 2011). Modulation of spontaneous brain plasticity by medications is an encouraging factor in treatment of patients with ischemic stroke who suffer from moderate to severe motor deficit (Chollet et al., 2011).

COPING WITH BURNS

Burns rank as the third leading cause of accidental deaths among adults and children in the United States and as the eighth leading cause of nonfatal injuries in children from age 1–4 years. Children living in circumstances of abuse and

neglect are especially vulnerable to burns from a boiling pot on a stove or from touching a faulty electric wire. Adults with drug addiction, mental illness or retardation, dementia, alcoholism, or chronic cigarette smokers are vulnerable to burns either through neglect or through self-inflicted attempts of suicide. In addition, there are adults who practice immolation for a religious or political cause. Burns are a common cause of facial disfigurement, especially among children where the head represents a disproportionate portion of the human body. Among children the head, the neck, and the armpits are the most frequent locations of burns. Posttraumatic stress disorder is one of the common psychiatric disorders following burn injury (Difede, 2002). Although many burn survivors are able to surmount the initial period of acute stress by drawing upon their own psychological and spiritual resources, a significant number of survivors need psychiatric and psychological help during their rehabilitation (Patterson, 2000).

In the acute phase of survival after burns, the survivor is mourning losses of health, physical function, beauty, productivity, and sometimes the loss of a loved one who was victimized by an accident that caused the burns. In the initial stage, the burn survivor is completely devastated and overwhelmed by loss and can think only of survival. When a loved one has died in the fire or explosion, the survivor needs to be monitored for suicidality. A psychiatrist provides empathy, trauma counseling, and expert care. Many survivors respond well to antidepressant medications. After the acute phase has passed, the survivor may be ready to be visited by a SOAR (Survivors Offering Assistance in Recovery) volunteer. The volunteer is not a substitute for good medical, nursing, and psychological care. Reactive depression and grief may respond to a combination of medications, psychological care, and emotional support. Emotional support may be given both to the patient who is the burn survivor and to the patient’s family members, who may be undergoing an extraordinary experience of survivor guilt, anger, and helplessness. A wide variety of factors are predictive of psychological adjustment after burn injury. These factors can be summarized under these categories: (1) burn size, site, inhalation injury, pulmonary complications, catabolic state (Herndon & Tomkins, 2004), temperature regulation (Esselman et al., 2007); patient characteristics: age, gender, education, unemployment, loss of occupational status (Klein et al., 2011; Browne et al., 1985); (3) premorbid psychiatric history that may include alcohol and drug use, anxiety, depression, suicidal ideation and attempts, behavioral problems (Schneider, 2010); acute stress disorder during the first 4 weeks after burn injury and posttraumatic stress disorder that may persist for a month or more after burn injury (Ehde et al., 2000; Van Loey et al., 2003; Fauerbach et al., 2009); depression as a common psychiatric disorder after burn injury (Orr, 1989; Fauerbach et al., 2000; Wiechman et al., 2001; Edwards et al., 2007); sleep disturbances (Schneider, 2010); body image and disfigurement (Fukunishi, 1999; Fauerbach et al., 2000).

Treatment interventions for burn patients have included cognitive behavioral therapy, supportive psychotherapy, pharmacologic treatment for anxiety, depression sleep, and pain

management, and social support from family, friends, and burn survivors. When patients are admitted to a rehabilitation hospital they have been transferred from an intensive care setting in an acute care hospital. In the acute care setting, the patient may have been sedated in order to increase wound healing, stabilize temperature, prevent and treat wound infections, adjust diet to high carbohydrate and protein intake, and stabilize mental status. For the first month after burn injury the patient is physically devastated and overwhelmed by illness. When the patient enters a rehabilitation hospital, he or she often expresses gladness to be alive.

After the first 1 or 2 weeks the patient becomes aware of contractures of arms and legs, neck and armpits, and pain and difficulty in movement. Superimposed upon the physical disabilities resulting from burns, there is disfigurement. Many patients are afraid to look at their faces in the mirror. They need to be gradually desensitized to their disfigurement by cognitive behavioral therapy and relaxation therapy that emphasizes the positive assets that remain. Pharmacologic treatment is helpful in addressing the anxiety and depression engendered by pain, discomfort, and disfigurement.

The transition point between discharge from the rehabilitation hospital to the community provokes anxiety. Patients with burns are fearful of facing friends, fellow workers, and family who have not seen them in hospital. Psychological counseling addresses the issue of stigma in the community. A preparatory visit home may be helpful. The Phoenix Society provides support through visits by burn survivors.

Special problems arise in the context of patients who have become burned while attempting to immolate themselves or others. Patients who have burned themselves in the setting of uncontrolled rage turned inward or in protest against a societal injustice require close psychiatric monitoring. We have treated suicidal patients in rehabilitation by providing one-to-one supervision and appropriate restraints. A small group of patients may be both suicidal and homicidal. While the patient is under our care, he/she is protected from invasion of privacy. However, the patient is ultimately answerable to the court after discharge.

COPING WITH TRAUMATIC BRAIN INJURY

Traumatic brain injury (TBI) is a brain injury acquired after birth from physical trauma to the brain by events like motor vehicle accidents, falls, gunshot wounds, and other injuries. TBI is the leading cause of death in the United States and in other developed nations among individuals under age 45 years. TBI is also the leading cause of disability among this group (Bruns & Hauser, 2003). TBI is a cause of higher rates of hospitalization among individuals over age 65 than among those in any other age group (Coronado et al., 2005). TBI may vary in severity. Generally, those with moderate and severe TBI are initially seen in an acute care setting and later transferred to an inpatient rehabilitation hospital. Treatment by an interdisciplinary team continues for many weeks and is followed by outpatient treatment in clinics and residential settings. Those with mild TBI are generally treated in an outpatient setting by specialists in neurology, physiatry, psychiatry, psychology,

and other rehabilitation specialists. A further distinction may be made between persons who experience a mild concussion with only transient confusion, brief loss of consciousness, and resolution of clinical symptoms within 15 minutes (Glenn et al., 2008). Cognitive impairment does not usually persist beyond 3 to 6 months after concussion (Mittenberg, 2000; Glenn, 2008).

There are multiple and varied effects of TBI on physical function, cognition, communication, affect, social and community integration, work, and financial stability. Individuals with an acquired brain injury are more vulnerable to psychiatric disorders for many years after injury (Bradbury et al., 2008). Social integration is a long-term problem that persists for 10 years or more after onset of injury (Lefebvre et al., 2008). Quality of life includes acceptance by family and friends of the individual's impairments, integration in a community's social and work life that may include volunteer and part-time paid work, a safe environment tailored to the individual's optimal level of independence, and adaptation of the individual to the impairments.

Damage to specific locations of the brain may cause specific alterations of mood, cognition, attention, concentration, sensation, perception, language, and psychosocial adjustment. Neuropsychology is helpful in discriminating the multiple impairments caused by TBI. Neuropsychology may also make specific recommendations to psychiatry and physical medicine specialists in how to treat the individual with brain injury. Cognitive behavioral therapy (CBT) is the most commonly used psychological technique for addressing the changes in self-image and body image caused by TBI (Whitehouse, 1994; Nochi, 1998; Cantor et al., 2005; Dewar & Gracey, 2007). The threat to an individual's identity is based on changes in thoughts, feelings, social roles, and functions. The individual must integrate the former self with the self that now exists post-TBI. The patient needs to understand that only some aspects of self may have changed but not all aspects. This is a challenging but important task for the psychiatric team in rehabilitation hospitals.

Although CBT is most commonly used, individual supportive as well as insight-oriented psychotherapy may also have a place in treatment of TBI patients (Judd & Wilson, 2005). There has been a presumption that individuals with brain injury are unable to process the conceptual changes necessary for growth and adjustment. Therefore, treatment has focused on concrete and specific changes in behavior. A similar argument has been made with individuals with mental retardation, learning disabilities, and schizophrenia. This line of reasoning infantilizes persons with mental disabilities and restricts them from expression of their innermost feelings of rejection, anger, depression, and estrangement from family and friends. A therapeutic alliance between a therapist and individual with TBI may be more difficult because of the countertransference of feelings of anger and contempt (Lewis, 1991). A therapist has to be aware of her or his own feelings toward brain injury and to be capable of setting realistic goals.

The psychiatric assessment and psychological assistance needs to continue beyond the discharge from a rehabilitation hospital. The vast majority of individuals with mild traumatic

brain injury and postconcussive symptoms recover within a period of 6 months from onset of their accident or trauma. However, 10%–20% of patients have persistent symptoms of headache, dizziness, fatigue, loss of memory, loss of concentration, noise intolerance, anxiety, confusion, and depression (Glenn, 2008). Mittenberg (2000) suggests, however, that cognitive impairment does not usually persist beyond 3 months in patients who have sustained a mild head injury. There may also be premorbid cognitive and affective symptoms that might have been ignored prior to injury. Traumatic head injury may activate normal psychological symptoms such as irritability, anxiety, and depression that occur in the range of the general population.

Persistent postconcussive symptoms may have a psychological basis and may be seen in outpatient clinics where patients with mild head injury appear for many months following trauma. Most patients recover in a period of a few months, after which their symptoms resolve. Only a small group of patients recover more slowly and may not return to former activities such as school, work, or homemaking. Previous studies have noted an association between persistent postconcussive symptoms and depression (Glenn et al., 2001), psychiatric disorder including depression, anxiety, and conversion disorder (Mooney & Speed, 2001), mild traumatic brain injury (Rapoport, 2003), child sexual abuse (Raskin, 1997), ongoing litigation (Larrabee, 1997), and polysubstance use (Shahin, Gopinath, & Robertson, 2010).

Coping with mild traumatic brain injury and persistent postconcussive symptoms requires the identification of premorbid experiences that existed before the brain injury. These experiences include history of concussions, child abuse, alcoholism, or drug addiction in the individual's family; chaotic family environment; frequent moves in the family; illness or disease in the individual or in the individual's family; marital stress; bereavement; attitude toward illness and disability; and any other trauma that would have impact on the individual's belief structure. Recent study of two nationwide samples indicates that the scope of TBI as a health concern in young patients is greater than previously documented, and females are more sensitive than males to the effects of mild traumatic brain injuries (Halldorsson et al., 2012). A psychiatrist may enlist the help of a clinical psychologist and social worker to identify family members, friends, and community resources that might support a person's reintegration in the community (McCarthy, 2011).

Recently research has been conducted on the relationship between posttraumatic stress disorder (PTSD) and traumatic brain injury. Jones, Harvey, and Brewin (2005) investigated the relationship between dissociation and PTSD in road traffic accidents. They found that there was no significant difference in the incidence or severity of either Acute Stress Disorder or PTSD between the non-TBI and TBI groups 6 weeks and 3 months post-trauma. Mild TBI patients have significantly more symptoms of PTSD compared with patients who suffered moderate to severe degrees of injury (Jamora et al., 2012).

Stress may result from the effort of coping with the physical and cognitive limitations of TBI. TBI is an overwhelming,

devastating experience for individuals who previously have never experienced a severe illness. The stress experienced during the traumatic event and its aftermath may be sufficient to trigger PTSD even though the individual may not remember the details of the trauma. PTSD may also occur when a patient reacts emotionally to the description of the traumatic event as told to him by a witness. This reaction may be due in part to the pain, impairment, unexpected medical procedures, and unfamiliar surroundings associated with the treatment of TBI. Some recent research being conducted by the Veterans Administration on survivors from the Iraq and Afghanistan wars may be helpful in differentiating between the overlapping clinical symptoms of TBI and PTSD.

The family and friends of patients who sustain TBI and are in a coma are specially stressed due to the lack of clear criteria for the prognosis. *Disorders of consciousness* (DoC) are a challenging clinical condition that has not been adequately addressed in the past. Such patients require unique integrated medical and rehabilitation approaches, cyclical assessments, outcome-linked therapeutic interventions, and interdisciplinary monitoring in order to ensure the optimal outcome (McNamee, Howe, Nakase-Richardson, & Peterson, 2012). There has been a perception among most clinicians that if the patient is "unresponsive," he or she is not a candidate for full and ongoing clinical evaluation and possible rehabilitation or other interventions. There has been no standard of care for such patients, although up to 15% of them can show significant recovery up to 3–5 years post-injury. The improvement of responsiveness and regaining consciousness should not be considered as an exception in patients who have remained in vegetative state (VS) for more than 6 months. However, such patients still remain severely disabled and this may have important ethical implications (Estraneo et al., 2010). In contrast to patients in VS, patients in a minimally conscious state (MCS) may have a better prognosis even one year after coma onset. Determining the boundaries between diagnosis of VS and MCS is becoming more possible using repeated clinical evaluation as well as imaging and neurophysiological tools available today (Luauté et al., 2010). With our enhanced knowledge in the pathobiology of TBI, the progress in neurodiagnostic technologies, and increased clinical interest among experts, we are achieving better results in evaluating and providing rehabilitation to assist such patients (Seel et al., 2010). There are also better scales to assist the clinician in improving the assessment of patients with DoC (Løvstad et al., 2010). Amantadine is reported to promote functional recovery of patients who are experiencing prolonged disorders of consciousness after traumatic brain injury (Giacino et al., 2012). A few studies address the course of recovery from prolonged DoC in patients with TBI. In one particular study, which examined the acute and long-term outcome of persons with DoC, 21% of patients improved sufficiently to be capable of living without in-house supervision. Such findings indicate the need for further studies and revisiting the current criteria for authorization of rehabilitation services for patients with DoC (Nakase-Richardson et al., 2012).

Diagnosis of brain injuries from blasts resulting from various improvised explosive devices in recent wars in Iraq and

Afghanistan can be challenging for some clinicians. These injuries can be caused by initial shock followed by supersonic blast wind and prolonged front of underpressure. Many symptoms, including cognitive impairment and diffuse axonal injuries, can be caused by blast injuries. However, the result of a standard neuroimaging of the brain may not easily reveal structural change (Ropper, 2011). This should be an important factor to consider when the rehabilitation team is comparing the neuroimaging findings to symptomatology of their patients. Some of these patients may be wrongly considered to be only suffering from simple cases of PTSD, or they may be thought to be maximizing their symptomatology for various reasons.

Psychopharmacology and TBI Patients

TBI can cause variety of neuropsychiatric symptomatology such as cognitive impairment, affective disorders, significant anxiety, and sleep disturbances. Agitation, verbal and physical aggressiveness, restlessness, fluctuation of mood, and psychosis as well as other neurobehavioral symptoms can be frequently observed in patients who sustain TBI. The agitation and aggression in TBI patients may seem more frequent or severe in a male population. However, others have found no significant sex differences among these patients in terms of frequency, duration, presentation, or extent of posttraumatic agitation (Kadyan et al., 2004). Some patients may have underlying psychiatric disorders unrelated to their injuries. These illnesses should be treated with appropriate psychotropic medications. Clinicians working with TBI patients have been cautious in using certain psychotropic medications in such populations. The main problem is that most agents that can help psychosis or agitation can probably cause further cognitive impairment and possibly impair neurorehabilitation progress in these already cognitively vulnerable patients. Chronic use of haloperidol and risperidone, for example, could hinder the recovery of TBI patients. This adverse effect cannot simply be attributed to the sedative effect of such agents (Hoffman, Cheng, Zafonte, & Kline, 2008). Despite convincing evidence of adverse effects of some psychotropic medications in the TBI population, however, one cannot simply avoid psychotropic medications in TBI patients altogether. The agitation and severe emotional disturbances in TBI patients, if not treated properly, can clearly interfere with their rehabilitation care plan as well as the safety of the patient and others. A significantly agitated and aggressive patient can cause disruptions in the therapeutic environment which can easily interfere with the care plan of other patients in the rehabilitation program. Such agitation can cause significant emotional pain. Clinicians may also consider the negative impact of untreated emotional and behavioral symptomatology on patients, as well as on family and caregivers. For example, usually a patient's neurological deficits would create sympathy, but the patient's inappropriate or aggressive behaviors may cause discomfort and anger in family members and friends, and possibly in some caregivers. At times, such *behavioral* complications, rather than neurological deficits, have become the main cause of disability in TBI patients, indicating the

need for behavioral and/or cautious psychopharmacological interventions.

Dopamine-enhancing medications (such as amantadine) have been the most consistent agents in helping the cognitive impairment in TBI patients, although acetylcholinesterase inhibitors and antidepressants can also be beneficial for some (Writer & Schillerstrom, 2009). Animal study has indicated that administration of D-amphetamine combined with sensorimotor exercise can produce a steady acceleration of motor recovery, but an alpha 1-NA receptor antagonist drug, such as clonidine or haloperidol, produces negative effect on neurological recovery (Lombardi, 2008). The first-generation or so-called *typical antipsychotics* (haloperidol, thioridazine, fluphenazine, thioxanthenes) can cause adverse effects due to their blockade of D₂ dopamine receptors (Elovic, Lansang, Li, & Ricker, 2003). Patients suffering from TBI may be more vulnerable to the side effects of such psychotropic medications. TBI patients treated with haloperidol reportedly are at greater risk for neuroleptic malignant syndrome compared with the general population (Bellamy, Kane-Gill, Falcione, & Seybert, 2009). Some of the adverse effect, such as extrapyramidal symptoms and Parkinsonism, can further interfere with the patient's optimal progress during the active phase of their physical rehabilitation. At times, even a single administration of haloperidol to a TBI patient in the acute hospital has resulted in progressive disabling motor restlessness, torticollis, urinary symptoms, and confusion for the patient that continued in the rehabilitation hospital (Desai Nierenberg, & Duhaime, 2010).

Atypical antipsychotic medications (AAPs) such as quetiapine, aripiprazole, and olanzapine will not cause as much blockade of D₂ dopamine receptors compared with the first generation of antipsychotics, and are usually tolerated better by these patients. Some AAPs may even have a selected neuroprotective effect, as reported in an animals (Kurosawa et al., 2007). We can consider AAPs as primary agents for the management of psychosis or severe agitation and aggressive behavior that are *not responding to other more "benign" agents*. The AAPs have different mechanisms of actions and a diverse side-effects profile (Elovic et al., 2003). Occasionally they may cause some of the same adverse effects that are usually seen with the use of the typical antipsychotic agents. For example, there is a concern that the use of haloperidol and/or risperidone not only delays behavioral recovery after TBI but also can cause functional impairment in uninjured controls (Kline, Hoffman, Cheng, Zafonte, & Massucci, 2008). The amount of the agents and the length of their use may also contribute to the degree of their adverse effects. Some data suggest that a chronic high dosage of the haloperidol or risperidone can be detrimental in TBI patients, but multiple low dosages of such agents may not cause significant adverse effects (Kline et al., 2007). Overall, the atypical antipsychotics are clinically more appropriate in TBI patients, but side effects need to be monitored closely. The oldest atypical antipsychotic, clozapine, is not usually used in TBI populations due to its significant adverse effects including seizures and agranulocytosis (Michals et al., 1993). Ziprasidone may

cause QT prolongation and patients on risperidone need to be watched for orthostatic hypotension which can interfere with rehabilitation.

Clinicians need to be aware of increased risk of sudden cardiac death and stroke in individuals who are recovering from TBI (Glenn, 2010). Experts using antipsychotics are consistently aware of the importance of monitoring their patients for akathisia, neuroleptic malignant syndrome, and tardive dyskinesia. The use of metrics such as the 14-item Agitated Behavioral Scale is useful to reliably monitor the patient's clinical response to the therapeutic interventions (Corrigan, 1989).

In addition to antipsychotic medications, other agents have also been beneficial in helping TBI patients and *should be tried first*. The antidepressant trazodone, which is most frequently used, can help patients' agitation and sleep disturbances, usually without interfering with their rehabilitation process. Trazodone can help underlying depression that the patient with TBI is unable to verbalize. Reportedly almost half of the patients who suffered TBI have depression at one month post injury, and almost one-third of such patients still are experiencing severe depression 3–5 years after their TBI (Dikman, Bombardier, Machamer, Fann, & Tamkin, 2004). The risk of suicide attempts following TBI and during the first 5 years may reach 15% (Silver, Hales, & Yudofsky, 2002). While treating depression in this population, one should remember that patients who had TBI may be more prone to having seizures and more sensitive to the sedative and to the anticholinergic side effects of antidepressants.

Trazodone is also beneficial in treating patients' anxiety, which frequently interferes with their optimal participation in rehabilitation. To reduce patient's anxiety, beta blockers have been used with some success. Propranolol has been used for a long time and is reported to be a good option for the treatment of agitation, especially during the acute stage of recovery (Brook et al., 1992). Use of benzodiazepines and other sedatives are usually avoided, as they may cause further decreases in patients' cognitive ability as well as possibly causing periodic paradoxical reaction.

At times, patients' lack of interest or interaction rather than their agitation or hyperactivity can become a matter of concern for the caregivers. Apathy is mostly related to frontal/subcortical circuitry abnormality, but is also seen in patients experiencing diffuse axonal injury (Paus, 2001). Although the presence of apathy in TBI patients is usually a neurological symptom, other physiological and psychosocial factors need to be considered as possible contributors. Many different medications are used, but agents that potentiate dopamine release and/or delay dopamine reuptake appear to be more effective in helping patients who exhibit apathy (Roth, Flashman, & McAllister, 2007). While using amantadine, modafinil, methylphenidate, or any other agents in this category, one should watch for increased confusion and aggressiveness, sleep disturbances, vivid hallucinations, or psychotic symptoms. To help patients who have a moderate degree of apathy and memory impairment, some have suggested use of electronics such as pagers (Wilson et al., 2001) or mobile phones (Wade & Troy, 2001) to automatically remind the

patient to recall and initiate various tasks. Such approaches are *always preferable* to using medications if they can be successfully implemented in reducing the undesirable symptoms in patients.

Despite significant progress already made in our understanding the role of psychotropic medications and other agents in TBI population, there is still some scientific uncertainty and clinical disagreement among the experts. No single psychopharmacological agent will become accepted by all experts (Chew & Zafonte, 2009). What is usually agreed is that it is crucial to address the psychopharmacological issues. Of course, the rehabilitation team should consider non-pharmacological approaches, environmental changes, and interdisciplinary training programs such as nonviolent crisis intervention, neuropsychological testing, and behavioral modification for the behavioral management of TBI patients. However, there are times when such efforts alone may not be sufficient.

COPING WITH SPINAL CORD INJURY

Spinal cord injury (SCI) results in a sudden, abrupt, devastating loss of multiple body functions. The incidence of SCI in the United States is 12,000 new cases per year, and the prevalence is 273,000 persons with a range of 238,000 to 332,000 persons in the United States (National Spinal Cord Injury Statistical Center, 2013). Although SCI often results from direct trauma to the spinal cord, it may also result from degenerative or congenital disease. Predictors of adjustment to SCI include premorbid personality, premorbid employment, ability to drive a car, previous interests, work values, and age. SCI tends to fall in a bimodal distribution, with individuals in the younger age group involved in sports injuries, motor vehicle accidents, gunshot wounds, and war injuries, whereas individuals in an older group over 40 years of age are involved in work accidents, construction accidents, home accidents, and motor vehicle accidents. Both groups require psychiatric treatment to address the unique psychological problems of their age group. Younger persons may not have completed their education or prepared for an occupation. Some of them may have an impulsive personality that correlates with involvement in risky behaviors such as diving in unprotected waters, motorcycle accidents, drag racing, trampoline use, or gang warfare. Younger persons may feel cheated out of entering a sexual experience, marriage, and children. The mourning period for SCI is acute within the first 6 months after onset, but it may last for a lifetime. The severity of disability is not the only or even the most significant predictor of adjustment.

The use of hope in treating persons with SCI has been found to be more effective than an appraisal of threat to well-being (Kennedy, Evans, & Sandhu, 2009). Hope has to be tempered by a realistic appraisal of a person's functional capacities and chance of physical restoration. Kennedy et al. (2003) and King and Kennedy (1999) demonstrated that changing a person's negative appraisals of SCI led to a reduction of depression and anxiety. A meta-analysis of 10 studies with 424 subjects concluded that cognitive behavior therapy (CBT) has a significant short-term effect on adjustment of

adults with SCI (Dorstyn, Mathias, & Denson, 2011). The effectiveness of CBT was also evaluated in nine studies using both randomized controls and nonrandomized control studies (Mehta, Orenczuk, & Hanssen, 2011). CBT was found to be a useful approach for reducing depression, anxiety, and coping problems.

Other treatment approaches include group therapy (Duchnick, Letsch, & Curtiss, 2009), individual psychotherapy, and social supports. Hospital ecology is very important in helping patients to use wheelchairs and other assistive devices. Community reintegration, especially among persons who are aging and require more social services, should begin in a rehabilitation hospital where psychologists and psychiatrists prepare a person for the inevitable hardship of adaptation to living in the community (Charlifue & Gerhart, 2004; Scelza et al., 2007).

DISCHARGE PHASE

As the active phase of rehabilitation continues, the rehabilitation team begins to consider various disposition choices. What was expected to be the original discharge plan does not seem possible at times, and the alternative disposition options may be disappointing to the patient and/or family. This moment may become another occasion when the patient's emotional ability to cope can be significantly challenged. It is not unusual to see patients or their family blame staff or others for a less than desirable outcome. In some cases, the discussion of the appropriate length of stay in a rehabilitation hospital can become heated on the part of all involved. Making the patient "eligible" to receive inpatient rehabilitation is becoming more challenging. Patients and their families, as well as staff, may feel disappointed when there is any perception that a patient had to be discharged prior to optimal accomplishment of active rehabilitation. This disappointment can frequently arise when a patient needs to go to a skilled nursing facility rather than to extend participation in active inpatient rehabilitation. Most patients are not aware of the recent progress being made in some skilled nursing facilities in terms of what they can offer by way of rehabilitation programs. Most patients and their families need to be educated that transferring patients to a skilled nursing facility is primarily a way to continue the rehabilitation process, and they should not necessarily see such disposition as a failure, poor outcome, or being "punished" for not working hard. Experienced staff can appreciate the reality of such situations and do their best to provide optimal post-discharge support for patients and their families.

Prior to discharge, the issues related to the cause of the injury need to be revisited and a plan devised to prevent the recurrence of such events. For example, the patient should be advised to avoid alcohol and other substances that can increase the risk of reinjury. If the patient's injury resulted from being assaulted, one should make sure the patient is no longer at risk for assault during rehabilitation or after discharge. The changing roles for family members and significant others need to be clearly discussed to ease the

adjustment after discharge. We should support the family during the rehabilitation but at the same time, if needed, the families should be referred for their own outpatient counseling in the community. If all the support for the patients and their family is coming from the inpatient rehabilitation team, it is disruptive to have this support abruptly discontinued after the patient is discharged from the program. It is a certainty that the injury will have caused many changes for the patient and family. While patients may understand such changes, they should be reminded that some of the definitions of who they are remain the same. For example, if patients have had a stroke or an amputation, regardless of loss of ability or limb they are still sons, daughters, sisters, brothers, or parents, as before. They should be reminded that they have *not* lost their position and identity as such. In fact, some patients and their families experience that their relationships have become even more meaningful. When patients return to the community, additional adaptations may be required. The most frequent and disturbing challenges for these patients are feelings of hopelessness and humiliation. Persons around the patient should be aware of such emotional struggles and reassure the patient. Knowing of such vulnerabilities in patients may help family and friends to adjust their interactions accordingly. We should address any improper conduct by patients—specifically, hostile or inappropriate sexually oriented comments and/or behavior. Although their neurological impairments can usually create sympathy for patients, hostility or sexual inappropriateness can cause significant anger and discomfort among families and friends. Patients with moderate cognitive or other neurological deficits have less trouble getting back to the community compared with patients who mainly tend to exhibit behavioral problems. The psychiatric team also monitors the interaction between patients and their relatives, and, if needed, will address any possible expected "role-changes." Needless to say, issues related to abuse of alcohol or other substances including smoking, lack of activity, improper feeding, and weight gain should be addressed along with post-discharge psychiatric care and advice regarding the safety of the patient (i.e., driving, operating heavy machinery, etc.). Finally, since patients and their families have received support from the staff at the time that they were emotionally most vulnerable, they may have established strong close therapeutic relationships with team members. Ideally, one should plan for sufficient time for them to be able to say goodbye prior to discharge.

PEDIATRIC REHABILITATION—SPECIAL CONSIDERATIONS

While most infants, young children, and adolescents require rehabilitation for conditions similar to those of adults, there are special considerations relevant to a pediatric population. Central nervous system disorders, physical injuries, and infections are the most frequent. Other diagnoses include chromosomal abnormalities, prematurity, cerebral palsy, congenital or genetic disorders, neonatal abstinence syndrome, muscular

dystrophy, sickle cell anemia, and juvenile arthritis. Children are expected to acquire new abilities as they age; when that evolution is interrupted or prevented by a medical condition, the injustice is experienced with particular difficulty. Because parents are responsible for their child's care, it is essential that they receive education and be active participants in their child's rehabilitation. Within the context of family-centered care (Lucas, 2010), the child's development, school, and peers are a focus of attention for assessment and treatment planning. The pediatric psychiatrist functions in complex roles as a consultant in addressing both medical and psychosocial factors that affect the patient, as well as in a liaison capacity collaborating with the rehabilitation team (Shaw & Demaso, 2006; American Academy of Child and Adolescent Psychiatry Work Group on Quality Issues, 2009).

ADMISSION TO THE REHABILITATION HOSPITAL

Ideally, the pediatric psychiatrist should be involved in deciding if a patient is appropriate for admission to an inpatient rehabilitation hospital. Considerations include if the patient is judged to be suitable for a pediatric unit where infants, young children, and their families may be at physical risk or significantly uncomfortable (e.g., a brain injured patient who is dangerously aggressive and/or manifesting disinhibited sexual behaviors). If an older adolescent is deemed to be more appropriate for an adult unit because of such concerns—or because the patient is a parent himself/herself or because of the family's preference—pediatric consultation and resources to support adult unit staff should be available. The pediatric contribution may be, for example, education about adolescent development, involvement of the patient in child life activities with pediatric patients, tutoring, and planning for reintegration to school. Professional caregivers in acute hospitals do not always recognize the limitations of rehabilitation hospitals' resources to provide complex medical evaluation, treatment with potential risks, and/or behavioral control. Psychiatric inpatient units may be unable to offer necessary medical or rehabilitation care. Therefore, it is preferable to stabilize the patient in an acute care hospital until he or she can safely and appropriately begin rehabilitation.

DEVELOPMENT

The pediatric psychiatrist incorporates a developmentally based perspective into a biopsychosocial approach when evaluating and caring for both children and their families. A child's capacity to have insight into his deficits is determined by the developmental abilities attained prior to the medical condition, as well as the condition and its treatments. Young children and many adolescents are unable to imagine the impact of their medical condition on their lives. Visible or invisible abnormalities can affect adolescents' body image and self esteem (Orr, et al., 1989). Dependence on others is particularly difficult for adolescents and their parents, who are already struggling with the challenges of individuation and separation.

In addition to the regression commonly seen in hospitalized patients of all ages, children with central nervous system disorders manifest particularly frequent developmental changes that can reflect either recovery or a contrast to premorbid skills (e.g., as the child's ability to communicate progresses, the severity of his cognitive deficits becomes increasingly apparent). Improvements in physical, cognitive, and emotional acquisitions often have different trajectories (e.g., gait becomes normal, long-term memory is regained while short-term memory deficits persist, immature behaviors increase). Such discrepancies can lead patients and their families to be confused about the child's recovery, and create difficulty in establishing appropriate expectations and goals.

CONSULTATION

The pediatric psychiatrist plays an essential role in the very frequent need to differentiate whether a patient's medical condition, behaviors, or mood are of organic and/or psychological etiology(ies) (e.g., whether an irritable toddler is hypoglycemic or experiencing separation anxiety from an absent parent). Comprehensive evaluation of the precipitating medical event and past history often reveals problems and strengths that affect strategy for rehabilitation; for instance, it helps to know that the child with traumatic brain injury has a history of attention deficit disorder so that the threshold is lower to treat with a stimulant, or that the patient is an athlete familiar with rigorous rehabilitation. The psychiatrist's contributions may include differing degrees of involvement in individual psychotherapy, family psychotherapy, psychotropic medication management, and behavioral management. The choice of which type of participation is appropriate depends on the patient's abilities and needs as he/she improves or does not improve over time. Although every patient and his/her family might theoretically benefit from a psychiatrist's involvement, priorities need be established because of time constraints, the patient's and family's availability on the unit, and their receptiveness to contact with a psychiatrist. An appropriate member of the medical or rehabilitation staff should discuss the reason(s) for the psychiatry consult with the patient and parents, as would occur if other consultations were considered indicated (e.g., by a cardiologist or neurologist). It may be helpful to review the team's belief in the value of support to a child and family when medical conditions are so significant that they require inpatient hospitalization, describe the psychiatrist as an active member of the rehabilitation team, and explain how the psychiatrist's role includes recommending strategies to minimize or avoid the need for medication. When resistance is encountered, the psychiatrist still has opportunities to develop an alliance with the child and parents through informal encounters, as well as to continue to work with the team members.

There is often pressure for the psychiatrist to "fix" a behavior, anxiety, or depression, particularly if those symptoms interfere with compliance (e.g., in rehabilitation therapy, taking medication, eating, or drinking). The question, "Can't he or won't he?" is key, and may focus the need for additional

medical evaluation, medication, psychotherapy, and/or behavioral interventions. Patients with traumatic brain injuries are especially challenging (Warschawsky, Kewman, D., & Kay, 1999). When staff describe that the patient is “behavioral,” the psychiatrist can help them to explore the reasons for the behavior(s) that warrant being addressed.

The psychiatrist’s medical and psychiatric background enables him or her to observe and educate patients and their families. Decisions regarding the content, amount of detail, and timing of discussions should be titrated to their cognitive abilities, tolerance, preference, and needs. Staff and families should take care to avoid talking about certain content in the patient’s presence, even if that patient is considered to be incapable of understanding.

PSYCHOTROPIC MEDICATION

Psychotropic medication should be initiated judiciously, particularly in patients with central nervous system disorders and in young children, employing the adage of “go low, go slow” and considering potential drug–drug interactions. Although many medications have not been approved by the Food and Drug Administration for children under 18 years old, clinical experience may justify their use—particularly in an inpatient setting where the patient can be closely monitored. Patients transferred from acute hospital settings frequently have disrupted sleep, and the success of sleep hygiene and behavioral strategies in any hospital setting is limited. Given the importance of sleep, the threshold to treat with sleep aid medication(s) should be low. Depending on the sleep pattern, medical condition, other medications, and the patient’s age, options may include diphenhydramine, melatonin, trazodone, a short-acting benzodiazepine, zolpidem, and gabapentin. Side effects of daytime sedation or cognitive impairment are rare, and usually can be resolved by adjusting the timing and/or dosage of the medication(s). A short-acting benzodiazepine may be indicated when anxiety is significant or related to a rehabilitation therapy, with the hope of treating for a brief period and later transitioning to a long-acting preparation if necessary. What appears to be “depression” often resolves as the medical condition improves, endurance increases, and the patient’s abilities improve (e.g., to walk, feed himself/herself, be more independent). It is important to observe the patient’s interactions in various settings (e.g., with parents, siblings, peers, in rehabilitation therapies), which may heighten or diminish concerns regarding “depression” and guide appropriate treatment(s). Symptoms of inattention, impulsivity, and overactivity in patients with CNS disorders are very similar to those of ADD and ADHD, and often respond to stimulants. A stimulant may also be efficacious to target apathy and fatigue. A mood stabilizer may benefit patients with aggression or mood lability. Neuroleptics in children/adolescents should be reserved for significant, already observed or potentially dangerous behavior and alarming psychotic symptoms. Prescription of a chemical restraint is preferable to physical restraints; such an approach is particularly relevant in a rehabilitation hospital population because of the frequency of physical injuries and central nervous system disorders.

THE PATIENT’S FAMILY

The patient’s family is an invaluable resource and should be included as an active member of the rehabilitation team. Parents have unique expertise in their child’s personality, strengths, and weaknesses. They may be the only individuals who provide continuity from the onset of the patient’s medical problems, and spend more time with the child than staff can. Their instincts and interpretations are frequently insightful. Patients often manifest progress sooner or more readily with family than with staff (e.g., begin to talk, are more willing to eat). It is important to educate parents about their child’s medical and rehabilitation issues, remind them of their past competence dealing with behavior problems, and help them to set appropriate limits even though their child is ill.

Regardless of the cause of a child’s medical condition, parents often feel a sense of guilt for not having protected their child and/or project blame onto others, including professional caregivers. In addition to attending to their child’s rehabilitation and medical needs, some parents are obliged to learn complicated medical care, which may inflict discomfort or pain (e.g., when their child has a tracheotomy or requires injections). Parents may feel that their ability to nurture or be “in charge” has been lost (e.g., when an infant is unable to feed, or an adolescent “won’t listen”). Many parents have stayed with their child for up to 24 hours per day at the acute care hospital, may continue to do so at the rehabilitation hospital, and are exhausted. They have little time and energy to attend to the patient’s siblings, a spouse, work, financial concerns, or themselves. Because there is a paucity of inpatient rehabilitation facilities for children, the distance from home may be an additional stressor. Although parents are grateful for aid from the community (e.g., providing meals, raising money through benefits), such offerings usually disappear over time. Parents’ coping abilities are significantly challenged and are affected by their past experiences and emotional stability (Beresin, 1990). While providing support, it is important for professionals to respect boundaries and to facilitate referring parents to a primary care physician, individual psychotherapist, and/or couples therapist when indicated. Separated, divorced, or foster parents may present additional challenges. Ideally, information regarding custody should be obtained by the time the patient is admitted to the hospital. When tensions arise between parents, they should be helped to move to an environment where the child is not present and be reminded to focus on what is in the child’s best interest.

Siblings are almost invariably affected by the patient’s medical crisis, the loss of the patient as a companion, parents’ absence and tensions, and/or being cared for by a variety of different people. They are often overwhelmed by questions or rumors about the patient. Even older siblings can experience jealousy because of the attention the hospitalized child is receiving. Manifestations of siblings’ frequently unaddressed distress can include sleep disturbance, anxiety, depression, somatic symptoms, “acting out,” altered relationships with peers, and/or deterioration in academic performance.

LIAISON

The pediatric psychiatrist's interactions with staff, the patient, and the patient's family can be mutually beneficial to all involved and enhance understanding from each individual's perspective. Observing the patient during rehabilitation therapies is a rich source of information about the patient and helps staff to feel respected and supported. In an inpatient rehabilitation facility, the rehabilitation team functions as an essential entity in which multidisciplinary expertise and communication enhance care. Recommendations to the patient and family may be more readily accepted when they come from the team rather than from individual professionals. When preparing the patient for reentry into the community, it is helpful to discuss potential responses the patient and family may encounter from others (e.g., to the patient's being in a wheelchair, or if the patient's face is disfigured by burns). Behavior plans to improve motivation and/or compliance are most successful when developed with the patient, family, and staff, followed by ongoing adjustments and education. In comparison to staff who work with adults, pediatric staff are less experienced and often uncomfortable dealing with sexual issues (e.g., managing a brain injured patient who has sexualized behaviors, discussing sexuality and reproduction with a spinal cord injured patient). Fortunately, deaths on a pediatric rehabilitation unit are uncommon, but when they happen they evoke complex feelings among the staff, including profound sadness, guilt, anger, and identification with the patient's parent(s). Ethical concerns are not infrequent and evoke both professional and personal responses (Deaton, 1996).

A psychologist may function as a psychotherapist, be involved in behavioral management, and/or perform formal neuropsychological or psychological evaluations. Although most patients' cognition is evaluated by a speech therapist, patients who have brain injuries or other brain disorders also benefit from neuropsychological testing (Crowley & White-Waters, 2010). Elucidation of the patient's cognitive strengths and weaknesses provides a more precise understanding of his needs during hospitalization, as well as when he returns to school. Once such a baseline is established, serial evaluations over time may help to differentiate between premorbid versus acquired abnormalities and to document changes.

The child life specialist provides activities and fun to patients and siblings, while assessing their play and responses. The role may include helping patients deal with medical or surgical procedures or preparing them for surgery or radiation. Ongoing communication with the pediatric psychiatrist enriches both professionals' understandings of a patient's emotional state, social abilities, and behavior.

The social worker's role typically includes working primarily with parents, exploring and facilitating resources in the community, and communicating with social services agencies or courts. When the medical condition (e.g., failure to thrive without a medical cause, nonaccidental trauma, a gunshot injury) or parents' behavior during the hospitalization raise concerns, a decision to file a report for suspected abuse or

neglect needs to be considered. Since social service agencies may lack extensive experience with children who have medical conditions, offering education and guidance is beneficial.

The case manager and the team are confronted with pressures from insurance companies to discharge the patient when he or she is not meeting the insurance's criteria of making functional gains in rehabilitation. Insurance benefits for care in the home are precise and limited; therefore, a parent may be obliged to stop working, which sometimes results in losing the family's medical insurance. Parents have difficulty dealing with an adolescent's insistence on going home. Young children may cope better at home, but outpatient rehabilitation resources that have experience with young children are often limited. The pediatric psychiatrist can offer a more global perspective, establish appropriate priorities, and support staff and families as they contend with systems limitations.

SCHOOL

As the team is assessing the patient's physical and/or cognitive needs, the pediatric psychiatrist provides input regarding the child's ability to cope with the psychosocial challenges he/she is likely to encounter. Considerations include when tutoring should begin in the hospital, if the school system is able to provide adequate resources, whether a day program or residential school should be pursued, and how soon the child may be ready to return to school.

If speech, educational, and/or neuropsychological testing reveals that a patient with previously high intellectual abilities has become "average" since a central nervous system injury, the child is at risk for not meeting the school system's criteria for services, being considered "lazy," and developing psychological as well as academic problems. Under such and all circumstances, parents should be educated to identify and advocate for their children's needs (Savage, Pearson, McDonald, Potoczny-Gray, & Marchese, 2001).

CHALLENGES AFTER DISCHARGE FROM THE HOSPITAL

Most pediatric patients who require inpatient rehabilitation have not had major health problems that affect their functioning prior to acquiring the medical condition for which they were admitted to an acute care hospital. Many children are capable of remarkable resilience and make rapid gains in rehabilitation. However, as patients improve, they and their families are confronted with the contrast between their previous lives and current limitations, uncertain prognoses for eventual recovery, and the many challenges they face in the near and distant future (Augutis, Levi, Asplund, & Berg-Kelly, 2007). Interactions with peers are often very difficult; past relationships may be lost. The medical condition may prohibit the patient's ability to engage in activities or be in certain settings (e.g., because of a contraindication to play contact sports after a brain injury, the inability to access a friend's home in a wheelchair). The frequent need that the patient be supervised by a parent can be a "mixed message" that complicates regaining age-appropriate independence. Parents' time, energy, and

finances are stressed by responsibilities to care for the child at home, be involved in rehabilitation and medical appointments, and maintain employment (Brooke, Kahn, Osberg, & Rowe, 1996). Siblings may have difficulties adjusting to the changes in their interactions and relationship with the patient as well as their parents having less time and emotional availability.

Discussions during hospitalization to identify concerns, needs, strategies, and resources may alleviate some of these burdens and stressors. Outpatient psychotherapy to include the patient and family provides a forum in which to process their experiences, identify preexisting and current family strife, address psychodynamics, offer support at a critical time, and facilitate the patient's and family's coping. The recommendation to begin with family psychotherapy may help reduce the stigma for the hospitalized patient and allow time to assess each family member's needs, including if the patient is unable or unwilling to participate in individual psychotherapy. The inpatient pediatric psychiatrist has had the opportunity and privilege to "live" with the patient and his family for an unusually long time and during a period of crisis. Especially when outpatient mental health caregivers do not have extensive experience with medically ill children, the pediatric psychiatrist's communication at the time of discharge and availability for future conversations are greatly valued and, most importantly, enhance the patient's and family's care.

SUMMARY

Almost all rehabilitation patients have an emotional response to their injuries. Some patients going through the rehabilitation process may also have pre-existing and chronic psychiatric symptoms, such that their emotional responses to their injuries may be secondary to their premorbid psychiatric disorders. Occasionally, pre-existing psychiatric disorders are actually a *cause* of the physical injury that will inevitably further change them emotionally, socially, financially, vocationally, and in many other ways. In most cases, these changes are not just episodic but will affect the patient and the family for a long time, often for the rest of their lives. The role of the psychiatric team in a rehabilitation hospital is to help patients and staff to optimize the rehabilitation process while trying to assist with reactive and underlying emotional distresses.

The psychiatrist leads the rehabilitation team, which consists of professionals who have different skills in helping patients who are in need of physical, cognitive, emotional, recreational, and social rehabilitation. Psychiatrists are physicians who specialize in physical medicine and rehabilitation, a subspecialty of medicine that focuses on the diagnosis and treatment of musculoskeletal injury and pain, and neuromuscular disorders, and the rehabilitation of patients with severe impairments resulting from traumatic brain injury, spinal cord injury, stroke, and other disabling events.

Many patients and their families are not well acquainted with the rehabilitation process and with what to expect as an outcome. Some patients may minimize their problems while others may be overly vigilant and unnecessarily focus

too much on the possibility of a poor outcome. While most infants, young children, and adolescents require rehabilitation for conditions similar to those of adults, there are special considerations relevant to the pediatric population. It is crucial that the psychiatric team working in a rehabilitation setting becomes intimately familiar with each patient's short-term and long-term goals and resolves the patient's emotional responses that may interfere with accomplishing the team's plan of care. The rehabilitation team expects the psychiatrist and the psychologist to use their expertise to clarify whether a patient cannot or will not fully cooperate, and why.

Each patient's coping process begins by recognizing the overwhelming devastation and loss of function, which in most instances happens within a blink of an eye. Initially the focus is on survival and acute medical treatments, but once the patient is admitted to a rehabilitation facility the significance of the injury or illness may begin to be more apparent to the patient and the family. The psychiatric team will try to assist the patient to adapt and try to achieve the best possible outcome by considering cognitive, behavioral, social, spiritual, environmental, recreational, psychotherapeutic, and psychopharmacological approaches, as appropriate.

As the active phase of rehabilitation continues, the rehabilitation team begins to anticipate a patient's upcoming discharge and various disposition choices. What was expected to be the original discharge plan may not seem possible at times, and the alternative disposition options may be disappointing to the patient and/or the family. This disappointment can frequently arise when a patient needs to go to a skilled nursing facility. Patients and/or their families are often not aware of the recent progress being made in such facilities, in terms of what they can offer by way of their rehabilitation programs. Community reintegration, especially among patients who are aging and require social services, should begin in a rehabilitation hospital to prepare the patient for the inevitable hardship of adapting to daily life in the community.

Prior to discharge, issues related to abuse of alcohol or other substances, as well as post-discharge psychiatric care, need to be addressed and advice given about the safety of the patient to self and others. Also, the cause of the injury needs to be revisited and a plan devised to prevent the recurrence of such events. The changing roles for family members and significant others need to be clearly discussed to ease the adjustment after discharge. Finally, since patients and their families have received support from the staff at a time that they were emotionally vulnerable, they may have established strong and close therapeutic relationships with the team members. Ideally, one should plan sufficient time for them to be able to say goodbye prior to discharge.

CLINICAL PEARLS

- When the patient and the family are no longer worried about the survival of the patient and begin to evaluate the patient's overall impairment, the stage of comparison with their previous lives begins.

- Misperceptions, partially due to wishful thinking and partly due to the wrong rehabilitation information given, can be minimized by requesting a consultation from a competent PM&R specialist to evaluate the patient in the acute hospital prior to the admission to a rehabilitation facility.
- Some patients are unable or unwilling to accept the intensity of their rehabilitation and we need to modify their treatment plan accordingly. In such cases more rehabilitation does not necessarily result in a better outcome and may have an “adverse effect.”
- A patient who is in denial will find it difficult to continue to use denial as a defense mechanism when confronted repeatedly while working with the rehabilitation team; this may lead to refusal of the rehabilitation program, a problem that can be evaluated by a psychiatric consultant.
- Adaptation requires a patient to separate his concept of disability from his concept of himself.
- Clinicians must focus on the positive assets of the person rather than functional limitations imposed by disability (Wright, 1960).
- One task of psychiatry and psychology is to help a person with physical disability to incorporate a change in body image with a patient’s former picture of him or herself.
- Devaluation of a person with disability is counteracted by focus on a patient’s abilities, moral values, and contributions to community.
- Risk factors for patients who may leave against medical advice include those with traumatic brain injury who are 24–35 years old, and/or a history of intentional injury, alcohol abuse, or substance abuse.
- Patients with schizophrenia need to be cautiously observed for apprehensive reactions and avoidance behaviors during therapeutic contacts that encroach on what has been personal space.
- The staff working in a rehabilitation hospital may, with or without being fully aware of it, experience a range of emotional responses, including disappointment, sadness, frustration, and anger.
- At times the staff is confronted by patients who do not wish to improve and who resist any fair treatment plan or discharge dispositions.
- The rehabilitation team expects the psychiatrist and the psychologist to use their expertise to clarify whether the patient cannot or will not fully cooperate and why.
- Burn survivors may be visited by a SOAR volunteer.
- Quality of life includes acceptance by family and friends of the individual’s impairments, integration in a community’s social and work life that may include volunteer and part-time paid work, a safe environment tailored to the individual’s optimal level of independence, and adaptation of the individual to the impairments.
- Individuals with an acquired brain injury are more vulnerable to psychiatric disorders for many years after injury (Bradbury et al., 2008).
- The individual must integrate the former self with the self that now exists post-TBI. The patient needs to understand that only some aspects of self may have changed, not all aspects.
- There is often a fallacious presumption that individuals with brain injury are unable to process the conceptual changes necessary for growth and adjustment. Therefore, treatment has focused on concrete and specific changes in behavior.
- Most individuals with mild traumatic brain injury and postconcussive symptoms recover within six months; however, 10%–20% of patients have persistent symptoms of headache, dizziness, fatigue, loss of memory, loss of concentration, noise intolerance, anxiety, confusion, and depression (Glenn, 2008).
- Most patients and their families need to be educated that transferring patients to a skilled nursing facility is mainly to continue the rehabilitation process.

DISCLOSURE STATEMENTS

Dr. Cahen, Dr. Goldberg, Dr. Herman, and Dr. Karamouz have no conflicts to disclose with respect to their contributions to this chapter.

PART III

PHARMACOLOGIC AND OTHER SOMATIC TREATMENTS

PSYCHOPHARMACOLOGY IN THE MEDICAL PATIENT

Thomas Markham Brown, Alan Stoudemire, Barry S. Fogel, and Michael G. Moran

INTRODUCTION

The decision to use psychotropic agents in patients with combined medical and psychiatric illness requires careful risk/benefit assessment for a number of reasons. Psychotropic drugs can interact with underlying medical illness causing serious complications, as when tricyclic antidepressants exacerbate heart block in patients with cardiovascular disease. Metabolic abnormalities associated with physical illness can increase the chances of drug toxicity because of altered pharmacokinetics, as when lithium is used in patients with renal insufficiency. Since medical patients are likely to be taking other nonpsychotropic medications, the chance of a clinically significant drug interaction is increased. Finally, elderly medically ill patients are at higher risk for adverse central nervous system (CNS) effects because they have greater sensitivity to psychotropic agents. This chapter gives an overview of the basic psychopharmacologic principles that should be considered in selecting and using psychotropic agents in the medically ill. Individual specialty chapters in this volume discuss psychopharmacologic considerations in greater detail for specific patient populations.

CYCLIC ANTIDEPRESSANTS

CARDIOVASCULAR COMPLICATIONS

In this chapter, the abbreviation “CyADs” refers to unicyclic, bicyclic, tricyclic, tetracyclic, SSRIs, and new antidepressants, except the monoamine oxidase inhibitors. TCAs refer to tricyclic antidepressants only. The use of tricyclic antidepressants (TCAs) by psychiatrists has declined substantially in the past two decades (Luca et al., 2013). This decline is due in part to the improved safety profile of the newer psychotropics. The prescription of TCAs by nonpsychiatrists, however, remains robust. As many as 20% or more of geriatric patients may receive a TCA over the course of a year in some settings (Martinsson et al., 2012). Often the use of a TCA is in low dosage and for nonpsychiatric problems such as neuropathic pain. But even while the target population of TCA prescription evolves, basic issues of safety and management remain. Table 21.1 summarizes the side effect profiles of currently available CyADs.

Table 21.2 summarizes the more common drug interactions for TCAs (Billup, Delate, & Dugan, 2009; Dasgupta, 2008; Forget, Polain de Waroux, Wallemacq, & Gala, 2008).

Conduction Effects

TCAs such as imipramine and amitriptyline have quinidine-like effects on the electrocardiogram (ECG); they can increase the P-R interval, QRS duration, and QTc time, and can cause T wave flattening. Clinically significant lengthening of the P-R, QRS, and QT intervals may imply excessive plasma levels. Direct relationships have been demonstrated between TCA serum concentrations and slowing of intracardiac conduction under steady state conditions. The clinical implication of this relationship is that monitoring of TCA serum levels may be helpful in preventing clinically significant cardiac conduction delays in vulnerable patients.

Because of their quinidine-like effects, the TCAs have antiarrhythmic properties by inhibiting fast sodium channels and thus prolonging the refractory period of the action potential of the cardiac conduction system. When TCAs were used in depressed patients with cardiovascular disease, they were noted to suppress PVCs (Bigger, Giardina, Perel, Kantor, & Glassman, 1977). More recent data, however, suggest that chronic use of TCAs might increase cardiac morbidity and mortality, since when antiarrhythmic drugs (including those with quinidine-like properties) were used prophylactically to prevent post-MI arrhythmias, patients receiving prophylactic antiarrhythmic therapy actually had more cardiovascular complications than did control groups (Hamer et al., 2011).

Clinically relevant deleterious effects on conduction time at therapeutic dosage levels of TCAs are observed almost exclusively in patients with preexisting, usually advanced, conduction problems such as atrioventricular (AV) nodal block. Even in patients with first-degree block, quinidine-like actions of tricyclics at therapeutic doses usually are minor and need not necessarily impede treatment if this is the only evidence of cardiac disease. For example, Roose and colleagues compared 150 depressed patients with normal ECGs and 41 depressed patients with first-degree AV and/or bundle-branch block treated for depression with imipramine or nortriptyline. The likelihood of second-degree AV block developing during treatment was greater in patients who had preexisting bundle-branch block (defined as a QRS interval greater than

0.11 seconds) than it was in patients with normal pretreatment ECGs (9% versus 0.7%). However, more than 90% of patients with preexisting conduction disease did not develop second-degree heart block (Roose et al., 1987a).

Certain types of heart block present particularly high risks with TCAs. In patients with preexisting bundle-branch block (especially those with second-degree heart block), dissociative (third-degree) AV heart block may develop. If type 1 antiarrhythmic medications (quinidine, disopyramide, procainamide) are concurrently administered with tricyclics, additive prolongation on cardiac conduction are possible (Levenson, 1985). It is now suspected, but not proven, that TCAs might increase cardiac morbidity and mortality in depressed post-MI patients (Roose & Miyazaki, 2005). Certain calcium channel blockers may prolong AV conduction and could, at least theoretically, interact with TCAs in this regard. Diltiazem and verapamil both may slow AV conduction; nifedipine, in contrast, generally does not affect AV conduction, and this calcium channel blocker may be preferred if TCA/calcium

channel blocker combination therapy was being considered in a patient with cardiac conduction disease.

Right and left bundle-branch blocks may be seen as a part of underlying cardiovascular disease but are not in themselves a contraindication for TCA treatment. When treating patients with these cardiac conduction defects, the psychiatrist and cardiologist should jointly establish a schedule for monitoring cardiac effects when TCA treatment is pursued. In almost all cases, the SSRIs and newer antidepressants now represent the drugs of choice in patients with cardiovascular disease.

Prolonged QT Syndromes and TCAs

One of the quinidine-like effects of TCAs on the electrocardiogram can be prolongation of the QT interval. This involves inhibition of the human ether-a-go-go (hERG) channel by TCAs. The hERG channel is a potassium channel critical in repolarizing cardiac myocytes. Inhibition of

**Table 21.2 SELECTED DRUG INTERACTIONS
WITH TRICYCLIC ANTIDEPRESSANTS**

MEDICATIONS	INTERACTIVE EFFECT
Type 1A Antiarrhythmics (quinidine, procainamide)	May prolong cardiac conduction time
Phenothiazines	May prolong QT interval and raise TCA levels
Reserpine Guanethidine Clonidine	May decrease antihypertensive effect
Prazosin and other α -adrenergic blocking agents	Potentiate hypotensive effect
Parenteral Sympathomimetic pressor amines (e.g., epinephrine)	May cause slight increases in blood pressure
Disulfiram Methylphenidate Cimetidine Valproate Duloxetine Fluoxetine Paroxetine	Raise TCA levels
Oral contraceptives Ethanol Barbiturates Phenytoin St John's wort	May lower TCA levels
Dextromethorphan	Intoxication may occur with 2D6 inhibitors such as amitriptyline
Anticholinergic agents Cyclobenzaprine	TCA may potentiate side effects
Carbamazepine	Additive cardiotoxicity possible Lowers tricyclic levels
Propafenone (Type 1C antiarrhythmic)	May elevate tricyclic levels
SSRI	May precipitate serotonin syndrome when combined with TCA
Duloxetine Methylene blue St John's wort	

this channel prolongs the QT interval (Dennis, Nassal, Deschenes, Thomas, & Ficker, 2011). Significant prolongation may be associated with an increased risk of ventricular tachycardia and ventricular fibrillation, particularly in patients with congenital or acquired heart disease. Some patients have prolonged QT intervals that are genetic in origin. The QT interval ordinarily varies with heart rate, so that guidelines for TCAs used are best based on the corrected QT interval (QT_c), which is defined as the actual QT interval divided by the square root of the R-R interval. The upper limit of normal for the QT_c is usually quoted as 0.42 seconds for men and 0.43 seconds for women. The TCAs (and, in our opinion, the SSRI citalopram) should now be avoided in such high-risk patients.

Despite the safety of TCAs in the vast majority of patients without preexisting cardiac disease, malignant ventricular arrhythmias rarely have been reported as a complication of TCA treatment. Two groups of patients at risk are patients with the congenital long QT syndrome and patients who develop undue QT interval prolongation during antidepressant treatment (Flugelman, Tal, & Pollack, 1985).

The first group is identified by a pretreatment ECG. The second group is identified by a follow-up ECG on TCA treatment. While follow-up ECGs clearly are indicated in patients with significant baseline abnormalities, it is not clear which patients with normal baseline ECGs and no cardiac history need follow-up ECGs to screen for drug-induced QT prolongation. At present, we advise follow-up ECGs in patients with borderline elevated QT_c intervals at baseline and in patients with a family history of sudden cardiac death, as well as those with definite cardiac histories. A QT_c of 0.44 seconds is regarded by some cardiologists as an acceptable upper limit of QT prolongation (Schwartz & Wolf, 1978; Kallergis, Goudis, Simantirakis, Kochiadakis, & Vardas, 2012). We would recommend, however, the setting of a criterion for each individual case in consultation with a cardiologist.

Therefore, in evaluating cardiac patients with depression, particularly patients with a history of cardiac arrhythmias, special attention should be given to considering whether or not a quinidine-like effect would aggravate heart block or increase vulnerability to ventricular tachycardia/ventricular fibrillation. However, the cardiotoxic effects of tricyclics in inducing life-threatening arrhythmias have been documented primarily in overdose situations. Fortunately, the availability of new generation antidepressants without quinidine-like properties has made treatment of depression in cardiovascular patients much less problematic.

Wolff-Parkinson-White Syndrome and TCAs

Depressed patients with the Wolff-Parkinson-White (WPW) syndrome require special consideration if a clinician is considering the use of TCA antidepressants. WPW syndrome is characterized by the presence of a short P-R interval and widened QRS complex, associated with paroxysmal tachycardia. The condition is caused by an accessory pathway between

the atrium and ventricle that allows atrial impulses to activate the ventricular tissue prematurely, short-circuiting the normal AV conduction system. Arrhythmias associated with WPW syndrome have been described as deriving from “circus movement”—that is, a reentrant tachycardia usually based on ventriculoatrial retrograde conduction over the accessory pathway and anterograde conduction through the AV node. Electrocardiographic findings reveal a prolonged QRS duration, a shortened P-R interval, and a delta wave (slowing of the upstroke component of the QRS complex).

In some patients with WPW syndrome, atrial flutter-fibrillation may occur. If quinidine-like drugs such as the TCAs are administered, the atrial rate may slow during atrial fibrillation-flutter to the extent that anterograde conduction via the anomalous accessory pathway will predominate, sometimes leading to ventricular tachycardia or ventricular fibrillation (O’Connell & Bernard, 2012; Sellers et al., 1977).

Patients with WPW syndrome who have a short (less than 0.27 second) refractory period are at higher risk for life-threatening ventricular tachycardia if they develop atrial fibrillation (O’Connell & Bernard, 2012; Wellens & Durrer, 1974). Patients with a short refractory period have been identified by a special cardiology procedure known as the *procainamide infusion test* in which patients with WPW are monitored with an ECG during an intravenous infusion of procainamide (a type 1A quinidine-like antiarrhythmic; see Schreibman, McPherson, Rosenfeld, Batsford, & Lampert, 2004). If the delta wave does not dissipate and the QRS duration shortens during this infusion, this indicates the presence of a short refractory period and vulnerability to atrial fibrillation (Vieweg et al., 1988; Wellens et al., 1982). All patients with WPW syndrome should be evaluated by a cardiologist prior to treatment with a TCA to assess if a quinidine effect would put them at high risk for arrhythmias. SSRIs and drugs free of quinidine-like properties would clearly be drugs of choice in these patients.

Congestive Heart Failure and TCAs

TCAs are relatively safe in the majority of patients with adequately treated cardiac heart failure unless the patient has symptomatic orthostatic hypotension or markedly impaired cardiac ejection fraction. In elderly patients (mean age 70) with evidence of preexisting left ventricular dysfunction, imipramine (mean daily dose 223 mg/day, mean plasma level 338 ng/ml) had little to no effect on cardiac ejection fraction as measured by first-pass radionuclide angiography (Glassman, Johnson, & Giardina, 1983). Nortriptyline also does not significantly affect ejection fraction in patients with stable congestive heart failure and may be less likely than imipramine to induce orthostatic hypotension (Roose, Glassman, & Giardina, 1986). Nortriptyline would thus be a reasonable first-choice TCA in a patient with stable congestive heart failure. The use of bupropion, fluoxetine, sertraline, venlafaxine, and other relatively new antidepressants in patients with cardiovascular disease is discussed later, since

these newer drugs are almost always preferred in patients with heart disease.

Orthostatic Hypotension and TCAs

The cardiovascular effect of TCAs most often leading to discontinuation of treatment is orthostatic hypotension. Orthostatic hypotension is defined as a fall in systolic blood pressure of 20 mmHg or more, and in diastolic blood pressure of 10 mmHg or more, measured 3 minutes after a person stands up from a supine position. Because many patients with orthostatic hypotension lack subjective symptoms of orthostasis, the clinician should assess for this when there exists a risk, such as with prescription of a TCA (Lanier, Mote, & Clay, 2011).

Antidepressant use travels with an increased risk of having a hip fracture among elderly patients (Oderda, Young, Asche, & Pepper, 2012). Orthostatic hypotension is an important factor in this increased risk. Elderly patients treated with TCAs have a 60% increase in the risk of hip fracture as compared to matched controls, with the highest risk period for falls being the first 90 days in treatment (Ray, Griffin, & Malcolm, 1991). In a study by Glassman and associates, almost half of the study patients had to discontinue the drug because of orthostatic hypotension (Glassman, Bigger, & Giardina, 1979). Impairment of left ventricular function with or without hypotension is a significant risk factor for the development of tricyclic-induced orthostatic hypotension (Glassman, Johnson, & Giardina, 1986). Bundle-branch block may be another risk factor for orthostatic hypotension during treatment (Roose, Glassman, & Giardina, 1986). Glassman, Bigger, and Giardina (1979) reported no consistent relationship between the daily dose of plasma level of imipramine and subsequent development of orthostatic hypotension. A similar lack of predictive correlation between plasma levels and subsequent orthostatic hypotension has also been observed with nortriptyline (Smith, Chojnacki, & Hu, 1980). One reason for the difficulty in correlating plasma levels with orthostatic hypotension may be the activity of P-glycoprotein (Pgp). Pgp is a cellular protein found lining the brain, heart, and intestines that regulates the flux of various compounds across the plasma membrane. TCAs, including amitriptyline and nortriptyline, are substrates of Pgp. Pgp would tend to extrude TCAs from its target organs. However, innate variations in Pgp activity, as well as inhibitors of Pgp, can cause TCAs to accumulate. This may enhance fall risk without being strictly linked to plasma level (Roberts, Joyce, Mulder, & Begg, 2002).

A recent report compared falls in depressed nursing home patients treated with TCAs versus SSRIs. While depressed patients had a higher rate of falls than nondepressed patients, there was no significant difference in falls between patients treated with SSRIs and TCAs. The risk of having a hip fracture among TCAs as a class is essentially the same as for the SSRIs as a class (Oderda et al., 2012). Thus, it appears that depression itself confers a risk of falling, possibly because of psychomotor retardation or dehydration causing syncope. In

patients with preexisting CHF, TCAs still cause dramatically more hypotension than SSRIs do, SSRIs having almost no effect on blood pressure (Thapa et al., 1998).

Bupropion has minimal effect on the cardiovascular system and does not cause orthostatic hypotension (Roose et al., 1987b; Thase et al., 2008); it may even raise blood pressure. Fluoxetine, sertraline, paroxetine, and other SSRIs appear to have little to no clinically significant effect on blood pressure. Venlafaxine, at higher dose ranges (i.e., >225 milligrams per day) can raise blood pressure. Duloxetine and reboxetine can also elevate blood pressure (D. Taylor, 2008). No consistent trend on blood pressure has as yet been observed with mirtazapine, although in some patients it does cause a small decrease in supine blood pressure.

ANTICHOLINERGIC EFFECTS AND TCAS

Particularly in elderly patients, highly anticholinergic drugs are relatively poorly tolerated with common complications being constipation and delirium. In men with benign prostatic hypertrophy, urinary retention may be a major problem, sometimes even necessitating surgical correction before TCAs could be tolerated. In patients with diabetic gastroparesis, the anticholinergic side effects of TCAs exacerbate problems with delayed gastric motility. Precipitation of narrow-angle glaucoma “crises” may occur, although patients with narrow-angle glaucoma can be safely treated with TCAs if they have first been treated ophthalmologically. Open-angle glaucoma, which is much more common than the narrow-angle type, is not exacerbated by the anticholinergic effects of TCAs. And for those patients with narrow-angle glaucoma who have had laser iridotomy, anticholinergic agents are also relatively safe (Kato, Yoshida, Suzuki, Murase, & Gotoh, 2005; Lieberman & Stoudemire, 1987).

In patients prone to the anticholinergic side effects, drugs with lesser anticholinergic effects should be chosen. Drugs of choice among the older TCA agents are desipramine or nortriptyline. The newer agents—bupropion, sertraline, fluoxetine, and venlafaxine—have almost no anticholinergic effects. Paroxetine has distinct anticholinergic properties that can become clinically significant. Citalopram and escitalopram have almost no anticholinergic effects (Chew et al., 2008). While the use of trazodone does not appear to produce anticholinergic effects, it may rarely cause priapism or bladder outlet obstruction, and it frequently is excessively sedating in therapeutic doses (300–600 mg/day). Trazodone at therapeutic dose ranges also tends to cause orthostatic hypotension in elderly patients (Poon & Braun, 2005).

TCA EFFECTS IN PATIENTS WITH RENAL FAILURE

Psychiatric illness is seen in perhaps 5% to 20% of patients undergoing hemodialysis. Many of these patients are being treated for psychiatric disease. In the case of the tricyclic antidepressants, some of these patients may be receiving treatment

for conditions related to their renal problem, such as diabetic neuropathy (Fraile et al., 2009). Clinicians have long noted that patients with renal failure and those on dialysis appear to be more sensitive to the side effects of TCAs, although the reasons for this phenomenon are not entirely clear (Levy, 1987). Hemodialysis does remove TCAs (Unterecker et al., 2012). However, hydroxylated tricyclic metabolites, which have been found to be markedly elevated in renal failure and dialysis patients, may be involved in producing side-effects (Dawling et al., 1982; Lieberman et al., 1985). Although the hydroxylated metabolites of tricyclics are higher in patients with renal disease as compared to normal control patients, serum levels of the parent tricyclic compounds (amitriptyline and nortriptyline) are generally only slightly higher in dialysis patients compared to control subjects after oral doses (Lieberman et al., 1985). Hence, although there are no data suggesting the need for routine measurement of the hydroxylated metabolites of TCAs in patients with chronic renal failure or those on dialysis, the likelihood that these metabolites contribute to side effect hypersensitivity argues for more conservative titration of doses in this patient population. Levels of fluoxetine have been studied in dialysis and renal failure patients and seem to be stable at the usual doses. The SSRIs have supplanted TCAs in renal failure patients for the management of depression.

DOSAGE AND PLASMA LEVELS OF TCAS

An essential principle for the safe use of any TCA in elderly and medically ill patients is careful titration of dosage. Starting doses of traditional tricyclic drugs such as imipramine, desipramine, and nortriptyline should be low (10 mg or 25 mg) in patients with proneness to or preexisting orthostatic hypotension or with other predictable vulnerabilities to side effects of TCAs. Doses may be increased every 2 to 4 days as tolerated. Assessment for expected side effects (e.g., hypotension or cardiac arrhythmia) should be carried out after each dosage increase. Peak plasma levels for most tricyclic antidepressants are reached 2 to 4 hours after oral ingestion. Because of the long half-life of most of the standard antidepressants, the dose may be given once daily in the evening, which can facilitate both sleep induction and compliance.

Obtaining a baseline electrocardiogram is strongly recommended. The serum tricyclic level has often been used to help determine whether or not a patient is on a therapeutic dose. Functional measures of effect, such as the QTc, can help to determine whether or not the same dose is potentially toxic. Just as the dose of a drug does not always translate into a predictable serum level, the serum level is in turn only a rough gauge of the drug's concentration within important target tissues, such as the heart. In other words, TCA dose is not as significant a measure of risk as serum TCA level, and the serum TCA level is not always as accurate an indicator of risk as a functional measure (Rodriguez de la Torre et al., 2001). Because widening of the QTc may be asymptomatic until it is frankly dangerous, a baseline ECG is needed.

PREDOMINATELY "SEROTONERGIC"
ANTIDEPRESSANTS (SSRIS)

Fluoxetine

Fluoxetine, the classic serotonin reuptake blocker, has very little affinity for muscarinic, histaminic, dopaminergic, serotonergic (5-HT₁ or 5-HT₂), and α_1 - or α_2 -noradrenergic receptors *in vitro* (Stark, Fuller, & Wong, 1985). Its low affinity for other neurotransmitter systems probably accounts for its very low incidence of anticholinergic, antihistaminic, sedative, and hypotensive effects. In most of the early studies, the side effects that have been most frequently reported are anxiety, insomnia, anorexia, and nausea (Feighner et al., 1988). Anxiety, nervousness, and insomnia, which may affect 10%–15% of fluoxetine-treated patients, may represent a form of akathisia, a side effect that can limit treatment even if benzodiazepines or beta blockers are coadministered to attenuate it (Koliscak et al., 2009). Panic disorder patients are extremely sensitive to SSRIs and usually tolerate starting doses 50%–70% lower than starting doses for depression (e.g., 5 mg liquid fluoxetine).

Although fluoxetine causes insomnia in some patients, a substantial number of patients (10%–20%) experience drowsiness or sedation, especially in the early phases of treatment, which usually will decrease over time (Feighner & Cohn, 1985). The same observation is true for other SSRIs. The sedation may be continuous, or most pronounced in the late afternoon, a pattern also seen with monoamine oxidase inhibitors (MAOIs).

Fluoxetine is benign in respect to the heart. In a comprehensive study of the effects of fluoxetine on cardiac conduction, Fisch (1985) examined a total of 1506 ECGs from 753 patients treated with amitriptyline (54), doxepin (56), imipramine (165), fluoxetine (312), and placebo (166). No appreciable changes in the ECG were seen with the use of fluoxetine. This observation is confirmed by fluoxetine's lack of cardiotoxicity in overdose.

Accumulating sporadic case reports, however, reveal some cardiac side effects of fluoxetine although cause-and-effect relationships are difficult to assess because of the anecdotal nature of these observations. Case reports of bradycardia (with syncope) and of atrial fibrillation associated with fluoxetine have been published (Buff et al., 1991; Ellison, Milofsky, & Ely, 1990; Feder, 1991). The SSRIs in general are relatively benign, even in patients with significant degrees of cardiovascular illness. Exceptions do exist.

Two important exceptions to the idea that fluoxetine is benign with respect to the heart are the serotonin syndrome and drug–drug interactions. The serotonin syndrome is a catastrophic drug side effect discussed elsewhere. Fluoxetine can contribute to the development of the serotonin syndrome, including its occasionally fatal cardiovascular consequences. The potential pharmacokinetic drug–drug interactions of risk to the heart include some deliberate combinations with fluoxetine. For example, fluoxetine inhibits Pgp, a pump located in the plasma membrane the function of which is to move compounds from within the cell

to the outside. Many drugs are substrates of Pgp and some drugs, such as fluoxetine, inhibit it (Argov, Kashi, Peer, & Margalit, 2009).

Fluoxetine has been reported to prolong the half-life of diazepam and reduce its clearance, resulting in higher plasma concentrations of diazepam and a reduction in the rate of formation of the active metabolite N-desmethyldiazepam. However, there is no evidence that this effect has any major clinical significance as judged by performance on tests of psychomotor abilities (Lemberger et al., 1988). A few other agents have been studied specifically for pharmacokinetic interactions with fluoxetine; no effect on plasma half-life has been observed for chlorothiazide or tolbutamide (Lemberger et al., 1985).

When fluoxetine is coadministered with other drugs that are highly protein-bound, displacement effects may occur that result in more unbound bioactive drug being available. Such effects are possible with warfarin and digitoxin (but much less so with digoxin). There is no strong evidence that such effects are large enough to require dosage adjustment of either warfarin, digitoxin, or fluoxetine in such situations when they are coadministered with each other. However, rechecking prothrombin times or drug levels after instituting fluoxetine is a reasonable precaution. Table 21.3 summarizes clinically significant drug interactions with the SSRIs including fluoxetine (Andrade, Sandarsh, Chethan, & Nagesh, 2010; Binkhorst et al., 2013; Gex-Fabry, Balant-Gorgia, & Balant, 2003; Go, Golightly, Barber, & Barron, 2010; Henderson, Yue, Bergquist, Gerden, & Arlett, 2002; Hersh, Pinto, & Moore, 2007; Hill & Lee, 2013; Mir et al., 2012; Nelson & Philbrick, 2012; Ng & Cameron, 2010; Rolan, 2012; Saruwatari et al., 2012; Spina et al., 2002; Teles, Fukuda, & Feder, 2012).

Fluoxetine's metabolism does appear to be affected by cirrhosis, since, in relatively stable alcoholic cirrhosis, the elimination of fluoxetine is substantially reduced. The mean half-life of fluoxetine was 6.6 days in middle-aged patients with cirrhosis compared to 2.2 days in age-matched volunteer controls. Formation of fluoxetine's principal metabolite, norfluoxetine, was delayed (Schenker et al., 1988). These data are compatible with previous studies in which other low-clearance drugs metabolized predominantly by demethylation have shown impaired elimination in liver disease (Secor & Schenker, 1987; Williams & Mamelok, 1980). It has been recommended that the doses of fluoxetine be reduced by as much as 50% in patients with liver disease, which can be accomplished practically by giving the drug on an every-other-day (or Monday-Wednesday-Friday) schedule. Because the half-life may be even more prolonged in patients with unstable or decompensating liver disease, even lower doses may need to be given. Even under normal circumstances in healthy patients, the elimination half-life of fluoxetine is 2 to 3 days, and that of norfluoxetine is 7 to 9 days. However, there is a great deal of individual variation. Furthermore, chronic high-dose therapy of 80 mg/day has been associated with half-lives of 8 days for fluoxetine and 19 days for norfluoxetine (Pato & Murphy, 1991). Thus, less-than-daily dosage is rational, and frequently necessary, particularly in

**Table 21.3 SELECTED DRUG INTERACTIONS
WITH SELECTIVE SEROTONIN REUPTAKE
INHIBITORS**

DRUG	INTERACTIVE EFFECT
<i>FLUVOXAMINE</i>	
Propranolol	Five-time increase in propranolol levels
Warfarin	Increase in warfarin concentrations by 60%; increased prothrombin time
Theophylline	Increase in theophylline levels by factor of three
Carbamazepine	Conflicting reports: increase in carbamazepine levels as well as stable carbamazepine levels reported when fluvoxamine added
Amitriptyline	Increase in tricyclic antidepressant serum levels
Clomipramine	No increase in demethylated metabolites of clomipramine
Atenolol	Some decrease in clinical effect of atenolol
Bromazepam	Increase in bromazepam levels
Imipramine	Increase in imipramine levels
Desipramine	Slight increase in desipramine levels when fluvoxamine added to patients with stable serum levels of desipramine
Lorazepam	No effect
Clozapine	Increase in clozapine levels
<i>FLUOXETINE</i>	
Imipramine	Increase in imipramine levels
Desipramine	Increase in desipramine levels
Nortriptyline	Increase in nortriptyline levels
Haloperidol	Increase in haloperidol levels
Olanzapine	Increase in olanzapine levels
Risperidone	Increase in risperidone levels
Perphenazine	Increase in perphenazine levels
Diazepam	Increase in diazepam levels
Alprazolam	Increase in alprazolam levels
Carbamazepine	Increase in both carbamazepine and carbamazepine 10,11-epoxide levels
Warfarin	No effect on half-life of warfarin or the prothrombin time
Pimozide	Bradycardia when fluoxetine was added; delirium also reported, probably caused by increased pimozide levels
Cyclosporine	No effect of fluoxetine on cyclosporine levels (variable)
Valproic acid	Increase in valproic acid serum levels

DRUG	INTERACTIVE EFFECT
Clozapine	Increase in clozapine levels
Phenytoin	Possible increase in phenytoin levels
Metoprolol	Bradycardia when fluoxetine was added
Digitoxin	Fluoxetine may displace digitoxin from binding sites
Protease inhibitors	Tend to increase serum fluoxetine levels
<i>PAROXETINE</i>	
Cimetidine	Increase in paroxetine levels by 50%
Phenobarbital	Decrease in paroxetine levels by 25%
Carbamazepine,	No effect on carbamazepine serum levels when paroxetine
valproate, and phenytoin	coadministered with these anticonvulsants
Phenytoin and carbamazepine	Possible decrease in paroxetine levels
Molindone	Increase in extrapyramidal side effects
Olanzapine	Increase in olanzapine levels
Risperidone	Increase in risperidone levels
Drugs metabolized via	Increase in serum levels of almost all
CyP450-2D6 (includes tricyclics)	CyP450-2D6 metabolized drugs
Fosamprenavir/ritonavir	May lower serum paroxetine levels by more than 50%
Warfarin	May significantly increase bleeding tendency
Fexofenadine	Paroxetine delays fexofenadine elimination by 50%
<i>SERTRALINE</i>	
Tolbutamide	Decrease in tolbutamide levels
Warfarin	Increased prothrombin time
Atenolol	No effect on atenolol level
Drugs metabolized by CyP450-2D6	Slight increase in serum levels
Olanzapine	Increase in olanzapine levels
Risperidone	Increase in risperidone levels
Tricyclics (including desipramine)	Slight elevation of tricyclic antidepressant levels
Ritonavir	May raise serum sertraline levels
Efavirenz, nevirapine,	Each may lower serum sertraline levels ritonavir

(continued)

Table 21.3 CONTINUED

DRUG	INTERACTIVE EFFECT
CITALOPRAM & ESCITALOPRAM	
Metoprolol	Doubled levels of metoprolol
Cimetidine	Elevated levels of citalopram
Imipramine	50% increase in desipramine metabolite levels
Omeprazole*	Possible increase in citalopram levels
OTHER	
Tramadol	Can lose analgesic activity when 2D6 inhibition by SSRI prevents formation of analgesic metabolite. Parent compound can still precipitate serotonin syndrome when combined with an SSRI.
Codeine	Can lose analgesic activity when 2D6 inhibition by SSRI prevents formation of analgesic metabolite.
Tamoxifen	Inhibition of 2D6 by SSRIs can reduce formation of active metabolite endoxifen, and reduce efficacy of tamoxifen
NSAIDS,	In patients at risk of gastrointestinal bleeding, the ability of SSRIs
Aspirin, other Anti-platelet agents	to promote bleeding may heighten the risk of bleeding with other agents
St John's wort	Risks serotonin syndrome when combined with an SSRI
Triptans	
Methylene blue	
Linezolid	
Ondansetron	SSRIs can reduce antiemetic effect of ondansetron in some cancer patients receiving highly emetogenic therapy

* Omeprazole is a potent inhibitor of Cy450-C19

elderly patients. The availability of fluoxetine in liquid form has rendered more dosing flexibility for patients needing lower daily doses.

It is now well established that fluoxetine, as well as SSRIs—particularly paroxetine—may increase the serum levels of tricyclics and trazodone, and if fluoxetine or paroxetine is added to the drug regimen of a patient with an established tricyclic level, abrupt elevation in tricyclic levels may result and cause tricyclic toxicity. Tricyclic overdoses in patients taking fluoxetine can lead to very prolonged elevation of tricyclic levels (Rosenstein, Takeshita, & Nelson, 1991). Fluoxetine primarily inhibits the CyP450-2D6 and CyP450-3A4 systems (Cavanaugh,

1990) and may elevate plasma levels of any medication that is demethylated, hydroxylated, dealkylated, or sulfoxidated—which would include most psychotropics, but not lithium (Fabre, Scharf, & Itil, 1991). Carbamazepine levels are known to rise significantly with coadministration of fluoxetine, with a 27% increase in the area under the concentration-time curve when 20 mg of fluoxetine was added to stable carbamazepine doses in a volunteer sample (Grimsley et al., 1991).

The syndrome of inappropriate secretion of antidiuretic hormone (SIADH) has been reported as a side effect of fluoxetine, particularly in the elderly (Cohen, Mahelsky, & Adler, 1990; Hwang & Magraw, 1989; Vishwanath et al., 1991). SIADH has also been observed occasionally and unpredictably with tricyclics, neuroleptics, and with essentially every SSRI.

Sertraline

Sertraline is an SSRI antidepressant with marked similarities to fluoxetine. As compared to fluoxetine, however, pharmacokinetic differences exist in that its elimination half-life is approximately 24 hours and steady state levels are reached more rapidly than with fluoxetine. The drug has selective effects on serotonin reuptake similar to those of fluoxetine, and thus has minimal effects on pulse rate and blood pressure and minimal or no anticholinergic effects. There do not appear to be clinically significant effects on cardiac conduction, at least in patients with normal pretreatment ECGs. There is some evidence that sertraline can cause sinus bradycardia in some patients (Fisch, 1991). Its cardiovascular side effect profile is as benign as that of fluoxetine, and data from its use in medically healthy adults suggest a very safe cardiac profile, although the risks of such events as the serotonin syndrome and unintended cardiac toxicity mediated through such pharmacokinetic mechanisms as P-glycoprotein inhibition also apply to sertraline (Kapoor et al., 2013).

Sertraline, like fluoxetine, theoretically may increase the prothrombin time by competing with warfarin for protein binding sites, leaving more unbound bioactive warfarin available; such effects are believed to be of minor clinical significance (Wilner et al., 1991). The modest increase seen in the prothrombin time with sertraline is likely not clinically significant (Apseloff et al., 1997). Sertraline also has been shown to have no clinically significant effect on the plasma concentration or renal clearance of digoxin (Forster et al., 1991). Sertraline has been reported to very rarely cause reversible elevations in aspartate aminotransferase (AST), alanine aminotransferase (ALT), and alkaline phosphatase levels (Cohn et al., 1991). Sertraline interacts minimally with the cytochrome P450-2D6 system in the liver and is less likely than fluoxetine and paroxetine to affect serum levels of the other medications. Its major route of metabolism is likely CyP450-3A.

Paroxetine

Paroxetine is another potent and selective inhibitor of neuronal reuptake of serotonin. It has a mean terminal elimination half-life of 24 hours. Like fluoxetine and sertraline, it does not appear to have clinically significant effects on the ECG. In doses of 30 mg to 40 mg/day, it also does not appear to alter heart rate or blood pressure. Paroxetine, of all the SSRIs, is the most potent inhibitor of CyP450-2D6.

Maximal plasma concentrations of paroxetine tend to increase with deteriorating renal function, but elimination half-life is prolonged only for patients with severe renal impairment. In patients with hepatic disease there is some evidence of reduced clearance, and patients in this population should be started on doses in the lower end of the therapeutic range. In vitro, paroxetine has more anticholinergic properties than other SSRIs, but this effect is usually of minimal clinical importance other than the side effect of dry mouth. This anticholinergic effect is likely to be detrimental to patients with Alzheimer's disease.

Fluvoxamine

The potent SSRI primarily marketed for obsessive compulsive disorder, fluvoxamine, is complicated most often by nausea, insomnia, sedation, anorexia, and agitation. The agitation leads to discontinuation of fluvoxamine therapy in as many as 6% of patients (Brown & Stoudemire, 1998). Hepatic impairment reduces the clearance of fluvoxamine, and renal impairment may do the same (DeVane & Gill, 1997). The risk of toxicity in special populations, such as patients with cardiovascular disease, is essentially the same for fluvoxamine as for other serotonergic antidepressants.

Fluvoxamine is metabolized in part through the P450-3A4 system, making it unsafe to combine this agent with astemizole. Fluvoxamine raises serum levels of alprazolam, carbamazepine, clozapine, diazepam, methadone, propranolol, theophylline, tricyclic antidepressants, and warfarin. The unanticipated rise in serum warfarin levels could theoretically result in hemorrhagic stroke. Benfield and Ward have reported that the introduction of fluvoxamine to a standing warfarin regimen can increase total serum warfarin levels by 60% with subsequent elevation of prothrombin time (PT) (Benfield & Ward, 1986). The same problem has been encountered with fluoxetine (Sansone & Sansone, 2009). In both cases, displacement of warfarin from binding sites on albumin may have contributed to the elevation in total serum warfarin levels (Stoudemire & Moran, 1998). When initiating fluvoxamine therapy in a patient who takes warfarin, the PT should be monitored until fluvoxamine is established and the patient stabilizes. Serum levels of atenolol and digoxin are unaffected (Brown & Stoudemire, 1998).

Citalopram

The SSRI citalopram was introduced in the United States in late 1998 (Medical Letter, 1998). Its average half-life is

35 hours, which is prolonged in patients with liver disease and in the elderly. It has minimal effects on cholinergic, histaminic, gamma-aminobutyric acid (GABA), dopamine, or norepinephrine receptors—thus a very low side effect profile. Usual dose ranges are 20–40 mg once daily. It has minimal binding to serum proteins and is very unlikely to displace other drugs from their binding sites. Citalopram is metabolized primarily by CyP450 isoenzymes 3A4 and 2C19. Drug interactions of clinical significance are summarized in Table 21.3 (Andrade, Sandarsh, Chethan, & Nagesh, 2010; Binkhorst et al., 2013; Gex-Fabry, Balant-Gorgia, & Balant, 2003; Go, Golightly, Barber, & Barron, 2010; Henderson, Yue, Bergquist, Gerden, & Arlett, 2002; Hersh, Pinto, & Moore, 2007; Hill & Lee, 2013; Mir et al., 2012; Nelson & Philbrick, 2012; Ng & Cameron, 2010; Rolan, 2012; Saruwatari et al., 2012; Spina et al., 2002; Teles, Fukuda, & Feder, 2012). CyP450-3A4 inhibitors such as ketoconazole and erythromycin will likely elevate this SSRI's serum levels, since CyP450-3A4 is involved in the initial step of citalopram's metabolism. Cimetidine will elevate citalopram levels. Citalopram will raise the level of the beta-blocker metoprolol and possibly other beta blockers as well. Citalopram can raise the levels of desipramine by 50%. Its effect on CyP450-2D6 is minimal. No clinically significant interactions have been noted with digoxin, lithium, warfarin, or carbamazepine. Omeprazole, which inhibits CyP450-2C19, might elevate citalopram levels.

The United States Food and Drug Administration (FDA) has determined that citalopram in doses greater than 40 milligrams daily may prolong the QT interval (Castro et al., 2013). Certainly one would want to obtain a baseline electrocardiogram prior to starting citalopram. Identifying patients at risk for symptomatic QT prolongation is also possible.

Escitalopram

The bioavailability of oral escitalopram is about 80%. The drug is 50%–60% bound by serum proteins. It is metabolized through CyP450-3A4 and 2C9. Its elimination half-life ranges from about 27–32 hours. This is roughly doubled in the elderly. Significant liver disease slows the metabolism of escitalopram, and the dosage should be halved.

Escitalopram may be more likely than citalopram to prolong the QT interval (Castro et al., 2013).

SSRIS AND SEROVASCULAR FUNCTION

A rare but important issue with SSRI therapy in general is the potential effect of altering the manner in which platelets handle serotonin, with alterations in their tendency to form clots. Concern about this has led some blood banks to decline blood donated by persons taking SSRIs (Reikvam et al., 2012). The SSRIs all block the

serotonin-reuptake pump of platelets. Platelets release serotonin to dilate intact blood vessels, while causing vessels with damaged endothelium to contract and form platelet plugs that lodge in the damaged and contracting vessel. Basic science and large epidemiologic studies have found no consistent clinical impact of SSRIs on serovascular function (Maschino et al., 2012; Reikvam et al., 2012). Yet in some cases, it appears that SSRIs may significantly impair the ability of platelets to aggregate. This may rarely result in abnormal bleeding manifested by petechia or ecchymosis. Upper gastrointestinal bleeding is the likeliest injury in such cases (Hreinsson, Kalaitzakis, Gudmundsson, & Björnsson, 2013). More severe examples of platelet dysfunction, such as melena, are quite rare. Fluoxetine-induced abnormalities of platelet function are among the best described. These appear to be dose-dependent abnormalities, occurring most often when the dose of fluoxetine exceeds 20 mg per day (Alderman, Moritz, & Ben-Tovim, 1992). Interestingly, bleeding times return to normal 3–4 days after fluoxetine is discontinued, indicating that the primary effect on platelets is fluoxetine itself, since its principal metabolite, norfluoxetine, has a half-life of 10–14 days.

A final serovascular issue of great physiological importance, but of unmeasured epidemiologic significance, is the effect of blocking serotonin reuptake in the vasculature among patients with endothelial disease or abnormal responses to serotonin. Early reports of unexpected deaths among medically ill patients receiving fluoxetine sparked interest in the mechanisms by which cardiac disease might be aggravated by SSRI therapy (Spier & Frontera, 1991). It has been found that patients with angina, both typical and atypical, experience not the normal vasodilatory response to serotonin but rather vasoconstriction (Fricchione et al., 1993; McFadden et al., 1991). Patients with endothelial disease, including that induced by atherosclerosis, diabetes, and hyperlipidemia, have a similarly abnormal response to serotonin (Golino et al., 1991; Sikorski et al., 1993; Luscher et al., 1993). Again, in the aggregate there is no contraindication to the use of SSRIs among patients with cardiovascular disease. Overall, the SSRIs appear to benefit such patients (Paraskevaïdis, Palios, Parissis, Filippatos, & Anastasiou-Nana, 2012).

One way to understand the potential risks of SSRIs and yet their overall safety for patients with a variety of cardiovascular diseases is to include the serovascular effects of depression in the discussion. The platelet of the depressed patient is hyperaggregable. The endothelial function of the depressed patient is also abnormal, and promotes vascular events ranging from atherosclerosis to myocardial ischemia (Pizzi et al., 2012). The initial and primarily pharmacologic effects of SSRIs, such as a transient elevation of serum serotonin, may aggravate the pathophysiology of the depressed platelet and endothelium. But with recovery from depression, platelet and endothelial physiology become more normal and the risk of a cardiovascular side effect declines.

SEROTONIN-NORADRENALINE REUPTAKE INHIBITORS (SNRIS)

Duloxetine

Duloxetine inhibits the reuptake of both serotonin and noradrenaline. This is sometimes referred to as a “balanced” reuptake inhibition. Duloxetine has good oral bioavailability, although with a slight reduction in uptake with food. The elimination half-life ranges from 8 to 17 hours. The drug is over 90% bound to serum proteins. Elimination is mainly via the kidneys (70%), but also in part through the gut (20%). Use of duloxetine is contraindicated in patients with liver or kidney impairment. Duloxetine is a substrate of CyP450-1A2 and 2D6, and tends to inhibit 2D6. Duloxetine tends to inhibit the metabolism of warfarin but less so than paroxetine, venlafaxine, or fluoxetine (Teles, Fukuda, & Feder, 2012).

Side effects with duloxetine tend to be mild and include primarily gastrointestinal complaints and sleep disturbances. More serious side effects, ranging from extrapyramidal side effects to the serotonin syndrome, may rarely occur (Karakaş Uğurlu, Onen, Bayındırlı, & Cayköylü, 2013). Cardiovascular side effects with duloxetine are also rare (Xue, Strombom, Turnbull, Zhu, & Seeger, 2012). Overdose with duloxetine is rarely life-threatening (Darracq, Clark, Qian, & Cantrell, 2013).

Venlafaxine

Venlafaxine inhibits the reuptake of both serotonin and norepinephrine in a manner similar to that of most TCAs. It is five times as active at blocking the reuptake of serotonin as it is at blocking the reuptake of norepinephrine. Side effects are largely dose dependent, and the most commonly reported include sedation (up to 14%), dizziness (12%), initial anxiety (up to 12%), and increased blood pressure (Brown & Stoudemire, 1998).

Cardiovascular side effects attributable to venlafaxine alone are rare (McElroy, Keck, & Friedman, 1995). However, venlafaxine does have a dose-dependent effect on blood pressure. A sustained elevation of diastolic blood pressure greater than 10 mmHg, which is greater than the pretreatment baseline and exceeds 90 mmHg, is seen in 5% of patients taking over 200 mg/day of venlafaxine. This percentage rises to 13% when the total daily dosage exceeds 300 mg. Pharmacodynamic interactions may heighten the risk of cardiovascular side effects. An extreme example of this is the serotonin syndrome precipitated by venlafaxine (Gitlin, 1997). Overdosage of venlafaxine can lead to the serotonin syndrome complicated by left heart failure. The mechanism of the left heart failure is unclear (Batista et al., 2013).

Neither venlafaxine nor its active major metabolite, O-desmethylvenlafaxine, has significant activity at α -adrenergic, D-dopaminergic, histaminergic, muscarinic, or m-opioid receptors (Beliles & Stoudemire, 1998). Venlafaxine is bound minimally at approximately 25% to serum proteins. It has a balanced metabolism through both cytochromes P450-2D6 and 3A4. Its elimination half-life is considerably

extended in both hepatic and renal impairment. Severe hepatic impairment may increase the elimination half-life by almost 200% (Stoudemire, 1996). Doses of venlafaxine in patients with hepatic or renal failure should be adjusted conservatively, as the half-life of the drug is prolonged in both categories of patients. Cimetidine raises the levels of venlafaxine but not its psychoactive primary metabolite *O*-desmethylvenlafaxine. This occurs because venlafaxine's "first pass" metabolism is inhibited by cimetidine, but *O*-desmethylvenlafaxine serum levels do not appear affected to any clinically significant degree. A long-acting controlled-release capsule form of this drug is now available.

Desvenlafaxine

Desvenlafaxine, or *O*-desmethylvenlafaxine, is a synthetic formulation of the major metabolite of venlafaxine. Because the majority of the actions of venlafaxine come from the activity of its major metabolite, desvenlafaxine, the benefits and risks of the two agents is very similar. The oral bioavailability of desvenlafaxine is about 80%. The drug is roughly 30% bound to serum proteins. It is metabolized mainly through hepatic conjugation, with a lesser role played by oxidation via CyP450-3A4. The elimination half-life is 10–11 hours, although this may be markedly prolonged in hepatic or renal failure. Almost half of the drug is excreted in the urine unchanged, while another 25% is renally excreted as metabolites.

Milnacipran

The bioavailability of oral milnacipran approaches 90%. The elimination half-life is 6–8 hours. Milnacipran is 13% bound to serum proteins. The drug undergoes hepatic metabolism. Milnacipran is a comparatively weak inhibitor of cytochromes P450 when compared to other antidepressants (Miguel & Albuquerque, 2011). Over 90% is excreted in the urine, and just over 50% is excreted as unchanged milnacipran (Li, Chin, Wangsa, & Ho, 2012). In moderate to severe renal failure, the dosage must be reduced (Nagler, Webster, Vanholder, & Zoccali, 2012).

A case exists of hypertension, tachycardia, and cardiomyopathy associated with milnacipran use. It was thought that the cardiomyopathy resulted from a hyperadrenergic state due to milnacipran use (Forman, Sutej, & Jackson, 2011). While this may be a uniquely bad outcome, it underscores the potential of milnacipran and agents like it to cause overstimulation of catecholamine and indoleamine systems. The serotonin syndrome, an example of indoleamine overactivity, has also been reported for milnacipran (Levine, Truitt, & O'Connor, 2011). Milnacipran is not available in the United States.

BUPROPION

Bupropion, active through dopaminergic neurotransmission, possibly by blockade of presynaptic dopamine reuptake, is a unique antidepressant different from the SSRIs and TCAs. Bupropion has a half-life of approximately 10 hours. A longer-acting form of bupropion is available, and

its usefulness as part of smoking cessation programs is now well established. The drug has some structural similarities to amphetamine and to diethylpropion, a sympathomimetic agent. Although bupropion has an activating effect that can be beneficial in some patients, it can induce agitation or provoke psychosis (Kumar et al., 2011). The properties of bupropion of greatest interest to psychiatrists working with medical patients are its lack of cardiovascular toxicity and its association with seizures. Bupropion is metabolized primarily through CyP450-2B6.

Cardiovascular Disease and Bupropion

As noted briefly earlier, bupropion has an excellent side effect profile (Roose et al., 1991b). It has minimal anticholinergic properties and minimal effects on histamine and α_1 - and α_2 -adrenergic receptors. Its relative lack of sedative, anticholinergic, antihistaminic, and anti- α -adrenergic effects would make it particularly attractive for medically ill patients if its efficacy were conclusively demonstrated to be equal to that of more established agents.

Bupropion can prolong the QRS and QT intervals. This is the result of inhibition of inwardly-rectifying potassium currents, a relatively frequent source of drug-induced QT prolongation (Caillier et al., 2012). Yet, early studies demonstrated that bupropion had little clinically significant effect on blood pressure, heart rate, or the ECG, and that it was not associated with orthostatic hypotension. Bupropion-treated patients have nevertheless rarely reported symptoms of syncope, dizziness, and fainting. Occasional patients develop hypertension on bupropion.

Few studies have specifically focused on patients with concurrent advanced cardiovascular disease. Large epidemiologic studies report a relatively low rate of sudden cardiac death or arrhythmias among patients taking bupropion, even when compared to other safe antidepressants (Leonard, Bilker, Newcomb, Kimmel, & Hennessy, 2011). Roose and associates (1987b) compared the cardiovascular effects of bupropion to imipramine in a small series of depressed patients with congestive heart failure. In a randomized, double-blind, crossover trial, 10 depressed patients with left ventricular failure received bupropion (mean dose 445 mg/day) versus imipramine (mean dose 197 mg/day). Neither bupropion nor imipramine adversely affected ejection fraction or other indices of left ventricular function. Half of the patients treated with imipramine, however, developed severe orthostatic hypotension. Bupropion, in contrast, was well tolerated and did not cause orthostatic hypotension. Bupropion had no effect on the ECG.

A report (Roose et al., 1991b) on 36 depressed patients with cardiac disease confirmed bupropion's general safety in cardiac patients, indicating that (1) pulse rate was not changed; (2) supine blood pressure sometimes was elevated; (3) orthostatic hypotension was observed in only 1 of 36 study patients; (4) no significant effects were observed on cardiac conduction, nor were higher degrees of AV block induced in patients with preexisting bundle-branch block; (5) preexisting ventricular arrhythmias were not exacerbated; and (6) no

effect was observed on ejection fraction in patients with impaired left ventricular function. In two patients, however, the drug had to be discontinued because of exacerbation of baseline hypertension.

Seizures and Bupropion

Seizures may occur in 0.35% to 0.44% of patients taking bupropion. This risk rises with the dose used, but the association with serum levels is weak enough that obtaining a bupropion serum level does not help stratify the risk. It may be that recreational abuse of bupropion by intranasal insufflation ("snorting") may increase the risk of having a seizure (Kim & Steinhart, 2010). This well-known concern with bupropion and seizures has decreased in general populations with the availability of its longer-acting form due to smoother serum levels and less "peaking" effect in the CNS. The drug should still not be used without anticonvulsant prophylaxis in patients with known risk factors for seizures.

Theoretically, bupropion might be relatively contraindicated in the treatment of depression in alcoholics because of their increased risk of seizures (as a result of head trauma, withdrawal, etc.). Furthermore, bupropion undergoes a first-pass effect influenced by alcoholic liver disease that can alter both pharmacokinetics and dose-response relationships. Although prolongation in the half-life of bupropion metabolites in patients with a history of alcoholism may be only minimal, the drug should be used with lower initial doses and carefully titrated, if it is used at all, in alcoholic patients (DeVane et al., 1990). Similar concerns exist for other high-risk patients in psychiatry, including patients with anorexia nervosa and malnourished patients.

NEFAZODONE

Nefazodone is unique among antidepressants in that its therapeutic action appears to involve both inhibition of serotonin reuptake and antagonism of 5HT₂ receptors. Clinically significant fatigue, dizziness, blurred vision, and lightheadedness are attributed to nefazodone. These may be related to the tendency of nefazodone to lower systolic blood pressure slightly (Beliles & Stoudemire, 1998). As a single agent, nefazodone appears to have little effect on the EKG (Beliles & Stoudemire, 1998).

Nefazodone is metabolized primarily through CyP450 3A4, however, and may inhibit the metabolism of astemizole and interact with other drugs metabolized by this isoenzyme.

One of the major metabolites of nefazodone is the serotonin agonist and anxiogenic compound metachlorophenylpiperazine (mCPP), which is metabolized by CyP450-2D6. If an inhibitor of P450-2D6, like paroxetine, is discontinued and nefazodone added (before CyP450-2D6 activity recovers), high levels of mCPP will continue to circulate and cause severe anxiety. When switching from a long-acting SSRI (like fluoxetine) to nefazodone, a washout period should be allowed for the SSRI consistent with the SSRI's half-life. Activation of 5HT_{2c} receptors by mCPP may cause anxiety and akathisia (Brown & Stoudemire, 1998).

Hepatotoxicity is the most worrisome side effect usually attributed to nefazodone. By 2005, the FDA had received 55 reports of hepatic failure due to nefazodone, 20 of which resulted in death. This is a rate of about 1 case of hepatic failure per 250,000 to 300,000 patients. A reactive metabolite is thought to be responsible for the liver injury (Kalgutkar et al., 2005). Because of the infrequency of this catastrophic side-effect, predicting who is at risk is difficult. The product carries a black box warning for hepatic failure.

MIRTAZAPINE

While usually not formally classified as an SSRI, mirtazapine appears to have limited effects on the cardiovascular system and is relatively safe in overdose. However, over 50% of patients taking mirtazapine experience significant dose-dependent sedation. Increased appetite and weight gain also complicate mirtazapine therapy (Nelson, 1997; Watanabe et al., 2010). Although catastrophic side effects such as the serotonin syndrome can occur with mirtazapine, in general the drug is safe even in overdose (Waring, Good, & Bateman, 2007).

Mirtazapine has a unique mechanism of action. Mirtazapine antagonizes presynaptic α_2 -adrenoreceptors, which "disinhibits" (facilitates) the release of central norepinephrine. Norepinephrine stimulates α_1 -adrenoreceptors located on central serotonin neurons, which then causes the release of serotonin. Mirtazapine also blocks central 5HT₂ and 5HT₃ serotonin receptors, as well as central histamine H₁ receptors (deBoer, 1996). Blockade of central histamine receptors likely accounts for the sedating effect of mirtazapine. The net effect of mirtazapine's complex pharmacologic profile on the cardiovascular system is more difficult to predict. However, at this time mirtazapine alone appears to have little effect on the EKG.

Mirtazapine is 85% bound to plasma proteins. It undergoes extensive metabolism involving cytochromes P450-1A2, 2D6, and 3A4. It is not a potent inhibitor of any of these three isoenzymes (Delbressine & Vos, 1997). The manufacturer notes that hepatic impairment may reduce the clearance of mirtazapine by 30%, while renal impairment may reduce the clearance of mirtazapine by 30% to 50%.

NEUROLEPTICS

The major classes of "standard," or "traditional," or "typical" neuroleptics include phenothiazines (such as chlorpromazine, trifluoperazine, perphenazine, fluphenazine, and thioridazine), butyrophenones (such as haloperidol), thioxanthenes (such as thiothixene), dihydroindolones (such as molidone), and dibenzoxazepines (such as loxapine).

All neuroleptics are well absorbed from the gastrointestinal tract. Hypoacidity (as in antacid therapy) and increased gastric emptying may result in increased absorption, whereas increased gastric acidity and delayed gastric emptying will result in decreased absorption, although such effects are of doubtful clinical significance. Neuroleptics are highly lipophilic and highly protein-bound. Thus, as with

cyclic antidepressants, dialysis is not useful in overdose. Neuroleptics are metabolized primarily via hepatic oxidation pathways. Portal hypertension or congestive failure can decrease first-pass metabolism and increase the activity of these drugs.

Common drug interactions with neuroleptics are listed in Table 21.4 (Laplane et al., 1992).

Neuroleptics may be broadly classified into three major categories: traditional “low-potency” agents such as chlorpromazine and thioridazine, traditional “high-potency” agents such as haloperidol and fluphenazine, and “atypical” agents such as clozapine, olanzapine, risperidone, and quetiapine. Differences among these agents are outlined below (Nordstrom et al., 1998).

Despite the vast improvement in side effects that the atypical agents have brought, the risks of the major neuropsychiatric side effects of antipsychotic medications, such as the neuroleptic malignant syndrome (NMS), likely remains with all available agents including the atypicals (Trayer & Fidler, 1998). For example, NMS has been reported with clozapine and with olanzapine (Apple & Haur, 1999). Both caution and optimism are warranted in this regard with the atypical agents.

The appropriate use of neuroleptics in the medically ill and geriatric populations requires considerable knowledge and care on the part of the physician. In addition to their use in psychiatric patients who have concurrent medical illnesses and in medically ill patients with secondary psychiatric symptoms, neuroleptics are widely used in geriatric patients to control such symptoms as agitation, wandering, behavioral dyscontrol, and confusion. In fact, neuroleptics at one time were the third most utilized class of drugs in nursing homes in the United States (Phillipson et al., 1990). The rate of use of these agents among the elderly in nursing homes remains high. A study of over 1.4 million nursing home residents across the country revealed that 22% were prescribed an antipsychotic. The most commonly prescribed were the atypical agents risperidone, quetiapine and olanzapine (Briesacher et al., 2013). In a similar though smaller study of residents in veterans’ nursing homes, 26% of residents were prescribed an antipsychotic agent. However, only 60% had an evidence-based reason for receiving such medication (Gellad et al., 2012). The extensive use of these drugs in a group of patients who are especially susceptible to their untoward side effects calls for careful attention to treatment strategies and risk/benefit assessments. The availability of antipsychotics with minimal extrapyramidal side effects such as olanzapine, and especially quetiapine, has significantly changed the risk/benefit profile of using neuroleptics in the medically ill.

Other serious medical events have been linked to initiation of an antipsychotic. A worrisome pronouncement was made by the FDA in 2005 that the use of atypical antipsychotics among elderly patients was associated with a 1.6-fold to 1.7-fold increase in all-cause mortality (US Food and Drug Administration, 2005). Across 17 placebo-controlled studies, with a modal duration of 10 weeks, 4.5% of patients with psychosis attributed to dementia died versus 2.6% of

Table 21.4 REPORTED DRUG INTERACTIONS WITH NEUROLEPTICS

MEDICATION	INTERACTIVE EFFECT
Type 1A Antiarrhythmics	Chlorpromazine/thioridazine may prolong cardiac conduction
Tricyclics	Disulfiram can cause extrapyramidal symptoms and increases risk of EPS with neuroleptics
Beta blockers	
Chloramphenicol	
Disulfiram	
Fluoxetine	May increase neuroleptic levels
Paroxetine	
MAOIs	
Other SSRIs	
Acetaminophen	
Valproic acid/valproate	Lower neuroleptic levels through induction of hepatic enzymes
Buspirone	
Barbiturates / Rifampin	
Griseofulvin	
Phenylbutazone	
Carbamazepine	Raises clozapine levels
Fluvoxamine	
Rifampin	Lowers clozapine levels
Gel-type antacids	May interfere with neuroleptic absorption
Enflurane	Potentiate hypotensive effects of neuroleptics
Isoflurane	
Prazosin	Increase hypotensive effect
ACE inhibitors (captopril, enalapril)	
Narcotics	May increase sedative effects of neuroleptics
Tricyclics	
Barbiturates	
Iproniazid	May cause encephalopathy and hepatotoxicity when used with neuroleptics
Guanethidine	Neuroleptics may decrease blood pressure control
Clonidine	

such patients receiving a placebo. Cause of death varied, but tended to be the result of a cardiac event or pneumonia. These findings inspired a host of further studies intended to clarify these risks.

In a review of randomized trials and meta-analyses, Pratt and colleagues found that there was a 20%–30% increased

rate of death among elderly patients prescribed an atypical antipsychotic, or 1 additional death per 100 patients. This compared favorably with the use of typical antipsychotics, which yielded between 2 and 7 additional deaths per 100 patients when compared to the use of atypical agents (Pratt, Roughead, Salter, & Ryan, 2012). Subsequent analysis of the FDA data revealed that for patients over 65 years old, whether demented or not, taking an antipsychotic was associated with a roughly twofold increase in the risk of pneumonia. The risk appeared greatest within the first week of starting antipsychotic therapy. Agents associated with pneumonia also seem to prolong the course of pneumonia, strengthening a causal link. Among typical antipsychotics, phenothiazines such as chlorpromazine may carry a greater risk of being followed by pneumonia than do butyrophenones such as haloperidol, although haloperidol does elevate the risk of pneumonia. Among atypical antipsychotics, clozapine, olanzapine, and risperidone carry a distinct risk. Yang and colleagues found among patients treated for bipolar disorder that certain combinations of agents carried a markedly increased risk of pneumonia. The combination of olanzapine with carbamazepine carried an adjusted risk ratio of 11.88 in their study. Clozapine combined with valproic acid carried an adjusted risk ratio for pneumonia of 4.80. Of note, Yang and colleagues found that carbamazepine and valproic acid, when used alone, did not increase the risk of developing pneumonia (Trifirò, 2011; Yang et al., 2013). Why antipsychotic agents may increase the risk of pneumonia is unclear. Sedation due to antihistaminic effects, inhibition of secretions through anticholinergic effects, and impairments of swallowing due to extrapyramidal side effects may all contribute to an increased risk of pneumonia. It is possible that immunomodulatory effects of psychotropics may be involved. For example, lithium appears frankly protective against pneumonia (Yang et al., 2013). Lithium has been found to inhibit the activities of several DNA viruses (Ren et al., 2011). Perhaps an as yet unrecognized property of antipsychotic agents undermines the pulmonary immune response.

Use of antipsychotic agents by elderly patients is also associated with an increased risk of having a cerebrovascular event. This risk is elevated within the first 30 days of taking such a medication, and may persist for as long as 2 years. Atypical antipsychotics, when compared to no use of an antipsychotic agent, may increase the risk of having a cerebrovascular event 2 to 3 times. However, the risk of having an event serious enough to warrant hospitalization is not increased (Pratt et al., 2012). This concern was raised initially by data generated by trials of risperidone and olanzapine among elderly demented patients with behavioral problems. There appeared to be an increased rate of cerebrovascular events with these agents, mainly risperidone. However, subsequent analysis of this data did not confirm a clear association between the use of either agent and having a cerebrovascular accident. Furthermore, the relative risk with risperidone compared with olanzapine may have been due to the greater inclusion of patients with histories of cerebrovascular events in the risperidone group (Herrmann et al., 2005). Subsequent studies have at times found an

increased risk of having a cerebrovascular event, including stroke, among elderly patients receiving atypical antipsychotics, and sometimes not (Mittal, Kurup, Williamson, Muralee, & Tampi, 2011). The risk of having a cerebrovascular event when taking an atypical versus a typical is at times regarded as equal (Kales et al., 2007). However, in a large retrospective study of elderly patients with dementia prescribed psychotropics, Finkel and colleagues found that the risk of having a cerebrovascular event was roughly twice that with haloperidol compared to that with risperidone, olanzapine, or quetiapine. Furthermore, benzodiazepines conferred a risk of having a cerebrovascular event equal to that of haloperidol, or twice that of the atypical antipsychotics (Finkel et al., 2005). Why elderly demented patients may have an enhanced risk of having cerebrovascular events after initiating treatment with an antipsychotic is not clear. Alpha-adrenergic blockade leading to hypotension and subsequent cerebrovascular events is often cited. However, this is just one pharmacologic mechanism that may be responsible. In some cases, remote effects on the heart such as arrhythmia may be responsible. An interaction between the physiology of the agitated, demented patient and the pharmacology of the medication also cannot be excluded. The clinician should of course consider the use of an antipsychotic only when clearly indicated, begin at a low dose, and monitor closely for side effects.

There is some debate about the risk of having a myocardial infarction while taking an antipsychotic (Brauer et al., 2011). Patients receiving atypical antipsychotics may have a 50% greater risk of nonfatal myocardial infarction than patients taking typical antipsychotics. On the other hand, those patients taking a typical antipsychotic are at greater risk of death overall compared to those receiving an atypical antipsychotic (Vasilyeva et al., 2013). There may be distinct groups at relatively greater risk of a myocardial infarction or a related event. For example, initiation of an antipsychotic among demented patients taking cholinesterase inhibitors may carry a time-limited increase in the risk of having a myocardial infarction. Pariente and colleagues found that among thousands of such patients, the risk of having a myocardial infarction was increased 1.78-fold over the first 30 days, 1.67-fold from day 31 to day 60, and 1.37-fold from day 61 to day 90 (Pariente et al., 2012). Patients receiving an antipsychotic with a propensity to cause significant arrhythmias, such as thioridazine or droperidol, have a secondary increased risk of myocardial infarction (Pacher et al., 2004). Those at risk for orthostatic hypotension may experience greater hypotension with an antipsychotic, and a myocardial infarction may result (Gugger, 2011). Among patients with a recent acute coronary event, use of a phenothiazine antipsychotic increased the adjusted odds ratio of sudden cardiac death 10.9-fold compared to those not receiving a psychotropic. Use of a butyrophenone was associated with an adjusted odds ratio of 6.74 for having sudden cardiac death. Use of any antipsychotic in the setting of an acute coronary event led to an adjusted odds ratio of suffering sudden cardiac death of 3.44, while the odds ratio fell to 1.30 if the antipsychotic was an atypical agent (Honkola et al., 2012). The dose of antipsychotic is also, in general, linearly associated with the

risk of sudden cardiac death (Ray et al., 2001). While interest in this issue increases, the clinician should cautiously consider the individual patient's risk of having a vascular event and weigh the potential risks of starting any antipsychotic against its potential benefits.

Antipsychotic agents also elevate the risk of having a hip fracture among the elderly. Leipzig and colleagues found that the use of a typical antipsychotic increased the risk of having a fall among the elderly 1.4-fold to 1.7-fold (Leipzig et al., 1999). This is significant, as 20%–30% of falls among the elderly result in a hip fracture. Furthermore, the typical agents may carry a 50% greater risk of hip fracture than the atypical antipsychotics (Ordera et al., 2012; Pratt et al., 2012). A variety of factors may affect the risk of having a hip fracture while taking an antipsychotic. These include falls due to hypotension, sedation, or Parkinsonism, low vitamin D levels, and the possibility of hyperprolactinemia causing bone loss (Kishimoto, De Hert, Carlson, Manu, & Correll, 2012). Besides medication, psychosis itself appears to convey an increased risk of increased bone loss (Partti et al., 2010). Weaving antipsychotic therapy into an elderly patient's medication regimen necessitates identifying risk factors for falls and then anticipating and managing these with the patient. A serum vitamin D level helps determine the need for replacement. Proper footwear should be encouraged. Exercise is essential as well. A baseline measure of blood pressure to assess for orthostasis is important, and minimization of psychotropics when possible can help (Moncada, 2011).

We recommend adhering to the following principles in the use of neuroleptics in the medically ill:

1. Whenever possible, identify and treat the underlying illness rather than treating superficial symptoms. For example, treat the etiology of a patient's delirium or cognitive impairment instead of merely controlling secondary symptoms of agitation or hallucinations. This is especially important, since, in the medically ill, neuroleptics can produce improvement in overt psychiatric symptoms while the underlying medical etiology of the symptoms progresses.
2. Avoid polypharmacy that is not scientifically based on the results of randomized, controlled, clinical trials and be cognizant of the potential for drug interactions and of pharmacokinetic and pharmacodynamic reasons for increased risks of adverse effects. For example, decreased albumin in malnourished patients implies the increased bioavailability of free fractions of protein-bound drugs and therefore more potent effects per milligram dosage (more unbound drug is available to act on receptor sites).
3. Identify specific target symptoms and carefully evaluate the treatment response objectively. Whereas agitation and behavioral symptoms may respond promptly, symptoms such as hallucinations and delusions may require weeks to respond.
4. Use the minimum effective dosage. High neuroleptic dosages are associated with increased side effects and do not necessarily increase antipsychotic efficacy (Kane, 1990). Even when higher doses give somewhat better control of positive psychotic symptoms, the patient's overall function may be worse because of extrapyramidal side effects of typical neuroleptics such as bradykinesia, apathy, akathisia, or rigidity. When treating geriatric patients, starting doses as low as 0.5 to 1 mg of risperidone, for example, are often quite sufficient.

LOW-POTENCY "TYPICAL" OR TRADITIONAL NEUROLEPTICS

Low-potency typical neuroleptics such as chlorpromazine and thioridazine have a side effect profile that includes α -adrenergic receptor blockage resulting in a risk of orthostatic hypotension, histaminic blockage resulting in sedation, and anticholinergic effects that can cause dry mouth, constipation, blurred vision, urinary retention, and sinus tachycardia.

In the elderly, the central anticholinergic actions of these medications are especially prone to cause memory deficits and place the patient at increased risk for central anticholinergic toxicity and delirium. In particular, patients with Alzheimer's disease are more susceptible to these deleterious side effects.

In addition, the low-potency typical neuroleptics are more likely to be associated with miscellaneous dermatologic and systemic side effects such as photosensitivity and cholestatic jaundice. Neuroleptic-induced cholestatic jaundice is almost always benign and is thought to be an allergic response, since it is frequently accompanied by rash, fever, and eosinophilia (Lader, 1989).

At higher doses (600–800 mg/day), thioridazine carries a small risk of pigmentary retinopathy; doses over 800 mg/day are contraindicated because of an unacceptable risk of this side effect. It is also the neuroleptic most likely to be associated with male sexual dysfunction (e.g., retrograde ejaculation, erectile dysfunction).

Low-potency phenothiazines such as chlorpromazine are also more likely to have quinidine-like side effects on myocardial conduction. This may result in P-R and QT interval prolongation and in flattening of the T wave on the ECG. These effects rarely are clinically significant unless the patient is also receiving a type I antiarrhythmic or has a preexisting heart block or prolonged QT syndrome (Stoudemire, Moran, & Fogel, 1991). Thioridazine appears to have the most pronounced quinidine-like effects of the neuroleptics and should not be used in patients with heart block (Wenzel-Seifert, Wittmann, M., & Haen, 2011).

Although all neuroleptics can lower the seizure threshold, the low-potency phenothiazine chlorpromazine is more strongly associated with seizures and should be avoided in epileptics and patients at high risk for seizures. Hematologic side effects such as agranulocytosis, transient leukopenia, and thrombocytopenia can occur with any neuroleptic but

seem to have a higher incidence with the low-potency typical neuroleptics as compared to the high-potency typical agents (Balon & Berchou, 1986).

Reversible endocrinologic side effects of all typical neuroleptics include gynecomastia, amenorrhea, and galactorrhea due to stimulation of prolactin secretion.

In general, because of their propensity to cause orthostatic hypotension and sedation, low-potency typical neuroleptics should be avoided in patients with acute medical illness. This is especially true in delirious patients, in whom monitoring the sensorium is of critical importance, and in patients with cardiovascular or cerebrovascular disease, in whom an episode of hypotension could have catastrophic effects.

The use of low-potency agents in patients with chronic and stable medical illness is reasonable in the special situation in which a very small dose of a low-potency agent (e.g., 10–25 mg of thioridazine) gives dramatic relief of target symptoms. At very low dosages, the hypotensive, sedative, and anticholinergic effects of low-potency agents may be minimal or easily tolerated. If low doses of low-potency agents do not control symptoms, switching to a high-potency agent may be safer than raising the dose of the low-potency agent. New drugs like quetiapine and olanzapine will likely supplant the use of the older low-potency and higher potency “typical” neuroleptics in the geriatric population, especially if parenteral forms of these drugs become available.

HIGH-POTENCY TYPICAL NEUROLEPTICS

High-potency typical neuroleptics, with haloperidol as the prototypic agent, are less likely to induce orthostatic hypotension and sedation but are more likely to be associated with extrapyramidal side effects (EPS). Acute EPS syndromes include acute dystonias, parkinsonian symptoms, bradykinesia, akathisia, and the “rabbit syndrome”—an unusual rhythmic perioral tremor. In addition, high-potency typical neuroleptics are more commonly associated with neuroleptic-induced catatonia and neuroleptic malignant syndrome.

Acute Dystonias

The risk for acute dystonia is greatest in young men. Children constitute another high-risk group for dystonia and for EPS in general (Pringsheim et al., 2011). Dystonia may be manifested by torticollis, retrocollis, tongue protrusion, opisthotonos, facial grimacing, or an oculogyric crisis, which occurs in approximately 2.5% of patients receiving typical neuroleptics (Lader, 1989). Laryngospasm is a rarer form of acute dystonia, but may also result from antipsychotics or other agents, such as antiemetics, that work by blocking the dopamine D2 receptor (Derinöz & Caglar, 2013). The symptoms usually respond to 25–50 mg of diphenhydramine or 1–2 mg of benztropine intramuscularly or intravenously, followed by oral doses of diphenhydramine 25–50 mg three times daily or benztropine 1–2 mg three times daily. Trihexyphenidyl also is effective. If patients are unable to tolerate anticholinergic agents, amantadine, a weak dopamine agonist with very mild anticholinergic effects, can be used instead; 50–100 mg orally twice a

day is the usual dose (Pringsheim et al., 2011; Stoudemire & Fogel, 1995).

Parkinsonian Symptoms

Parkinsonian side effects are particularly prevalent and problematic in elderly patients and can limit the use of typical high-potency neuroleptics in this population. Neuroleptic-induced parkinsonism can be clinically indistinguishable from idiopathic Parkinson’s disease with masked facies, bradykinesia, rigidity, pill-rolling tremor that is greater at rest, and festinating gait.

However, parkinsonian side effects from typical neuroleptics comprise a continuum and functionally significant bradykinesia, rigidity, or gait disturbance can occur without a prominent tremor or the typical “cogwheeling” on examination of the limbs. The finding of rigidity in the neck and cogwheeling in the forearm and wrist muscles are useful confirmatory signs on physical examination when a partial parkinsonian syndrome is suspected. The occurrence of an incomplete parkinsonian syndrome should trigger the same management approach as a full syndrome, if the symptoms and signs are associated with either subjective distress or impairment in daily activities. Management strategies include reducing the dosage of neuroleptic, switching to a lower potency neuroleptic, prescribing concurrent antiparkinsonian agents, or switching to an atypical antipsychotic such as quetiapine.

The choice of antiparkinsonian drugs should depend on the specific EPS as well as medical risk factors. Anticholinergic drugs, such as trihexyphenidyl and benztropine, are rapidly effective for tremor and dystonia and can be given preventively but cause a full range of peripheral and central anticholinergic side effects. Patients with constipation, urinary retention, or vulnerability to confusion may tolerate them poorly. Amantadine, a dopamine agonist with mild anticholinergic effects, has fewer physical side effects although it can occasionally cause hallucinations, confusion, and other mental symptoms. It may be more effective for rigidity and akinesia than the anticholinergics. It is not available parenterally. Finally, severe and disabling drug-induced parkinsonism can be treated with major dopamine agonist drugs such as levodopa-carbidopa or bromocriptine. Because of the risk of mental side effects of these drugs, they would generally be used only if motor disability outweighed mental disability. Neuroleptics can also unmask subclinical idiopathic Parkinson’s disease, and, even if antipsychotics are discontinued, up to 11% of patients may show persistent symptoms (Sakauye, 1990). Symptoms that persist after 6 months to a year after withdrawal of the antipsychotic likely represent idiopathic Parkinson’s disease (Lim et al., 2013). With the atypical antipsychotics, the frequency of EPS is much lower—especially with quetiapine. Among elderly patients with dementia, the risk of EPS with quetiapine rivals that of risperidone and olanzapine when equivalent doses are used. Being male in the population carries a twofold greater risk of EPS with these atypical antipsychotics (Marras et al., 2012).

Akathisia

Akathisia (literally, “unable to remain seated”) is an intense, unpleasant, subjective sense of inner restlessness and associated motor restlessness. The most common estimates of the prevalence in patients treated with typical neuroleptics range from about 5% to 20% (Bakker, de Groot, van Os, & van Harten, 2011). Unlike neuroleptic-induced parkinsonian symptoms, akathisia typically does not respond well to anti-parkinsonian therapy but may respond to beta-adrenergic blockade. Beyond neuroleptic dose reduction, when feasible, propranolol 30–120 mg/day in divided doses may be effective in most patients, although concerns regarding hypotension and bradycardia in the medically ill may limit this option (Prigshie et al., 2011). It is important to exclude other organic etiologies of the anxiety states such as hypoxia, drug withdrawal states, and metabolic abnormalities.

ATYPICAL NEUROLEPTICS

Aripiprazole

Aripiprazole’s oral bioavailability is nearly 90%. There also exists an intramuscular version. Serum protein binding is 99%. The elimination half-life of aripiprazole is about 75 hours, and that of its active metabolite dehydroaripiprazole is 94 hours. Among slow metabolizers through CyP450-2D6, the elimination half-life of aripiprazole may double. About 55% of a dose of aripiprazole is eliminated in the feces and 25% in the urine. Aripiprazole appears to be well tolerated among those with renal or hepatic impairment (Mallikaarjun et al., 2008).

Among the main advantages claimed for aripiprazole when compared to other atypical antipsychotics is a reduced tendency to weight gain and an associated reduction in the risk of developing the metabolic syndrome (Khanna et al., 2013). The main limitation of aripiprazole is usually dose-related EPS, which is more common among children and adolescents than adults. The rate of EPS with aripiprazole appears to be more than that of most other atypical antipsychotics, but less than that of risperidone and of haloperidol (De Fazio et al., 2010; Rummel-Kluge et al., 2012).

Asenapine

Asenapine is among the newest of the atypical antipsychotics. The bioavailability of asenapine is less than 2% if swallowed, but rises to 35% when given sublingually. It is 95% bound to serum proteins. Its elimination half-life is about 24 hours. About 50% of a dose is excreted in the urine and 40% in the feces. Inducers of CyP1A2 may speed the elimination of asenapine (Minassian & Young, 2010). Side effects include somnolence in 24%, significant weight gain in nearly 20%, akathisia in 2%, and other EPS in 5% (McIntyre, 2011).

Iloperidone

Iloperidone is another of the newest atypical antipsychotics. It appears to be well absorbed. Iloperidone is metabolized through CyP450-2D6 and 3A4 and has two active

metabolites. The elimination half-life of iloperidone ranges from 18 hours among rapid 2D6 metabolizers to 33 hours among slow 2D6 metabolizers. Protein binding is about 95%. Metabolism occurs through CyP450-2D6 and 3A4. The drug is mainly excreted in the urine. However, it can be safely used in patients with impaired renal function. Patients with impaired hepatic function may require a dose adjustment or discontinuation (Citrome, 2011). Dose-dependent orthostatic hypotension obligates the clinician to a slow upward titration. Other important side effects are weight gain, tachycardia, somnolence, and QT prolongation similar to that of ziprasidone (Arif & Mitchell, 2011). Extrapyramidal symptoms, including akathisia, occur in about 2% of patients. In registration trial studies, use of iloperidone when CyP450-2D6 and 3A4 were simultaneously inhibited prolonged the QTc by an average of 19 milliseconds (Novartis 2013).

Lurasidone

Lurasidone is among the newest of the atypical antipsychotics. It has a low oral bioavailability of about 10% to 20%. Serum protein binding is 99%. Lurasidone is metabolized mainly through CyP450-3A4, and produces an active metabolite. The elimination half-life of lurasidone is 18 hours, while that of its active metabolite is 8 to 10 hours. No dosage adjustment is needed in either renal or hepatic impairment. Lurasidone is complicated by dose-dependent EPS that may be seen in as many as 10% of patients, and akathisia in as many as 20% (Yasui-Furukori, 2012). There appears to be no significant effects on weight, lipids or the QTc with lurasidone (Kantrowitz et al., 2012).

Risperidone

Table 21.5 contrasts the differences between typical and atypical neuroleptics. Risperidone in low doses embraces many of the benefits of the atypical antipsychotics. It is effective against negative symptoms of chronic psychosis and has a

Table 21.5 DIFFERENCES BETWEEN TRADITIONAL (TYPICAL) AND ATYPICAL NEUROLEPTICS

Traditional Neuroleptics	Atypical neuroleptics
Are associated with a high incidence of EPS (extrapyramidal symptoms)	Are associated with a low incidence of EPS
May cause tardive dyskinesia	May not cause tardive dyskinesia
Increase serum prolactin levels	Show minimal or no increase in serum prolactin levels
Treat mainly positive symptoms of psychosis (such as hallucinations), but not negative ones (such as social withdrawal)	Treat both positive and negative symptoms of psychosis
Cause catalepsy in animals	Do not cause catalepsy in animals

low rate of development of tardive dyskinesia. Quality of life during risperidone therapy appears demonstrably better than with typical antipsychotics such as haloperidol, and comparable to that of the other atypical agents. Quality of life is generally defined to incorporate measures of benefit, tolerability, and patient satisfaction (Bobes et al., 2007; Chouinard & Albright, 1997).

Neuropsychiatric side effects of risperidone include dose-dependent sedation (20% to over 40%), sleep disturbances (15%–30%), and impairments of memory and concentration (15% to over 20%) (Peuskens, 1995). Rarely, mania has been reported with risperidone (Diaz, 1996). In one suicide attempt, 240 mg of risperidone was ingested, with minimal side effects; the most significant abnormalities were cardiovascular with QRS and QT_c prolongation (K Brown et al., 1993). The risk of cardiovascular complications during therapy with usual doses of risperidone, however, appears to be low (Casey, 1997a).

With a daily dosage of under 4 mg/day of risperidone, the incidence of extrapyramidal side effects (EPS) is relatively low. However, when the daily dosage of risperidone is increased to between 4 mg/day and 8 mg/day, then the rate at which EPS emerge begins to resemble that of traditional neuroleptics, especially in elderly patients (Miller et al 2008; Owens, 1994). Reports of risperidone-induced neuroleptic malignant syndrome also exist (Arslankoylu et al., 2011; Dave, 1995; Singer, Richards, & Boland, 1995; Tarsy, 1996). The elderly and patients with renal and hepatic disease are at risk for reduced clearance of risperidone, as well as of its active metabolite 9-hydroxy-risperidone. Accumulation of these agents is associated with increased problems with EPS (Heykants et al., 1994).

Risperidone appears to exert its antipsychotic action through the potent blockade of both central serotonin 5HT₂ and dopamine D₂ receptors (Kapur, Zipursky, & Remington, 1999). The 5HT₂ antagonism is more potent than the D₂ antagonism, but after the daily dosage reaches 4 mg to 8 mg, the clinical effect of the greater potency for 5HT₂ receptors is lost. Also of importance is the disinhibition of dopamine release from central dopamine neurons by risperidone. Presynaptic 5HT₂ receptors located on central dopamine neurons inhibit the release of dopamine; blockage of these receptors by risperidone probably leads to increased release of dopamine. This may be a mechanism through which risperidone in low doses limits the emergence of EPS (Kapur & Remington, 1996). Blockade of 5HT₂ receptors does not appear to be directly antipsychotic.

Risperidone is 90% bound to serum proteins. 9-Hydroxy-risperidone is 77% bound to serum proteins. The metabolism of risperidone is accomplished largely through cytochrome P450-2D6 (DeVane, 1996). Patients who are genetically poor metabolizers through this isoenzyme and patients receiving other medications that inhibit the activity of this isoenzyme may increase serum risperidone levels. Such effects may have reduced clinical consequences because the active metabolite of risperidone, 9-hydroxy-risperidone, has a pharmacologic and therapeutic profile very similar to that of the parent compound (Grant & Fitton, 1994; Keegan, 1994). Risperidone is associated with EPS, even in low doses, in children and in the elderly (Prigsheim et al., 2011).

Paliperidone

The bioavailability of oral paliperidone is 28%. Only about 30% of paliperidone is metabolized. This occurs mainly through CyP4502D6, and to a lesser extent through 3A4. The elimination half-life is 23 hours. The drug is 74% bound to serum proteins. Mild to moderate liver disease does not significantly affect the elimination of paliperidone. 59% of a dose of paliperidone is excreted as unchanged drug in the urine. However, because paliperidone is excreted in part by active transport in the renal tubules, impairment of renal function does slow the elimination of paliperidone (Marino, English, Caballero, & Harrington, 2012; Vermeir et al., 2008). For patients whose creatinine clearance (CrCl) is between 50 and 80 mL/min, the clearance of paliperidone falls by 32%. When the CrCl is between 30 and 50 mL/min, the clearance falls by 64%, and for those patients whose CrCl is below 30 mL/min the clearance of paliperidone falls by 71% (Janssen, 2012). The elimination half-life among elderly patients is 25 hours (Snoeck et al., 1995). For the elderly and those with renal disease, a reduction in dose is reasonable. Because Invega is prepared as a time-released product stored within a rigid capsule, patients with intestinal strictures should not take Invega.

Paliperidone treatment is limited by many of the same side-effects that limit treatment with risperidone. Extrapyramidal symptoms (EPS) that occur more often than with placebo include hypertonia, dystonia and akathisia. In a study comparing the safety and efficacy of paliperidone and quetiapine, EPS rates were higher with paliperidone, including akathisia (10% versus 3%), hypertonia (5% versus 1%), and drooling (6% versus 0%) (Vieta et al., 2010). Several cases of NMS have been attributed to paliperidone (Özdemir et al., 2012).

The usually modest QT-prolonging effects of risperidone are mainly due to paliperidone (Suzuki et al., 2012). Rodent and in vitro human data reveal that paliperidone prolongs the QT interval by inhibiting the hERG channel (Vigneault et al., 2011). Fortunately, the QT_c prolongation of paliperidone is 4 milliseconds or less. Rarely is *torsades de pointes* a risk with paliperidone (Wenzel-Seifert et al., 2011). On the other hand, mild tachycardia is seen among 10% to 20% of patients receiving paliperidone. This does not usually have a significant effect on overall cardiac function (Marino et al., 2012).

Olanzapine

Olanzapine is an atypical neuroleptic both in terms of its pharmacologic activity as well as its efficacy for both positive and negative symptoms of chronic psychoses. Olanzapine is metabolized by the CyP450-1A2 isoenzyme and multiple others. Its use as an antipsychotic for the medically ill and delirious patients appears promising. This is because of the relatively mild side effect profile, as well as olanzapine's potential for use in patients with Parkinson's disease who become psychotic on otherwise therapeutic doses of dopaminergic agents. Especially promising is the very low rate of tardive dyskinesia with olanzapine. It has been estimated that the risk of developing tardive dyskinesia during olanzapine therapy may

be about 1% per year, which is essentially the rate at which never-medicated psychotic patients develop tardive dyskinesia (Tollefson et al., 1997a, 1997b).

The side effect profile of olanzapine is characterized by a reduced risk of extrapyramidal side effects (EPS), although sedation and dizziness occur in 10%–20% of patients (Beasley et al., 1996; Lilly Research Laboratories, 1996). Olanzapine shares risperidone's relative freedom from direct cardiovascular toxicity and has significantly fewer EPS than risperidone (Casey, 1997a). In first-episode schizophrenia, olanzapine is associated with akathisia in about 10%, Parkinsonism in 6%, and very rarely dyskinesias and dystonia (Haddad et al., 2012). This is due to the slightly different pharmacodynamic activity of olanzapine (Kapur, Zipursky, & Remington, 1999).

As with other atypical neuroleptics, olanzapine potentially antagonizes both the central 5HT₂ serotonin receptor as well as the central D₂ dopamine receptor, with much greater affinity for the 5HT₂ receptor than the D₂ receptor. However, olanzapine also binds to muscarinic cholinergic receptors, histamine H₁ receptors, and α₁-adrenergic receptors with a predictable but mild side effect profile.

Alcohol can increase olanzapine uptake from the gut. Cimetidine may increase serum olanzapine levels, probably through effects on multiple enzyme systems.

Olanzapine has been associated with significant weight gain (average about 2.3 kg) after 4–6 months of treatment and sometimes marked increases in serum triglycerides (Osser et al., 1998). Olanzapine has also been associated with the onset of diabetes (possibly type II due to weight gain) as well as exacerbation of preexisting diabetes. Like clozapine, olanzapine can cause sialorrhea (Perkins & McClure, 1998). At least one case of priapism has been reported with olanzapine (Deirmenjian et al., 1998).

Quetiapine

Quetiapine, a dibenzothiazepine, is another of the new atypical neuroleptics. It is characterized by having only rare EPS, although two anecdotal cases of the neuroleptic malignant syndrome have been ascribed to quetiapine. Dizziness, somnolence, and agitation each affect about 10% of patients (Small et al., 1997; Zeneca, 2013). Because of the development of cataracts in dogs ingesting doses of quetiapine, the manufacturer now recommends slit lamp examinations before initiating therapy with quetiapine and every 6 months thereafter (Zeneca, 2013).

Quetiapine is like the other typical antipsychotics in that it is a more potent antagonist of serotonin 5HT₂ receptors than of dopamine D₂ receptors; however, quetiapine also potentially antagonizes, in descending order of potency, histamine H₁ receptors, α₁-adrenergic receptors, and α₂-adrenergic receptors (Casey, 1997b). H₁ antagonism accounts for quetiapine's tendency to cause somnolence, while α₁-adrenergic blockade can produce some orthostatic hypotension.

The elimination half-life of quetiapine is about 6 hours. This drug is 83% bound to serum proteins but does not appear to alter warfarin pharmacokinetics. Quetiapine is metabolized to inactive metabolites through cytochrome P450-3A4.

Inhibitors of this isoenzyme, which include erythromycin, itraconazole, fluconazole, and ketoconazole, will slow the elimination of quetiapine and subsequently raise its serum levels. Phenytoin and thioridazine both reduce the serum quetiapine level. Quetiapine slightly raises serum lorazepam levels. Cimetidine, fluoxetine, haloperidol, imipramine, lithium, risperidone, and warfarin appear not to have pharmacokinetic interactions with quetiapine. Alcohol, antihistamines, and benzodiazepines are among the many drugs that have synergistic sedative effects with quetiapine.

Quetiapine may antagonize the action of dopamine agonists used in the treatment of Parkinson's disease (Zeneca, 2013), although reports suggest that it causes the least EPS in Parkinson's disease patients with the exception of clozapine. Early reports from some neurologists hail quetiapine as the new "drug of choice" for Parkinson's disease psychosis, with claims that quetiapine has minimal EPS in therapeutic doses even in Parkinson's disease. More research is needed to confirm this initial enthusiasm for quetiapine in Parkinson's disease patients.

Clozapine

Because of the risk of agranulocytosis, if clozapine is used the physician must access the distribution system for clozapine through the Sandoz Pharmaceuticals Corporation to ensure that weekly monitoring of serum white blood cell (WBC) levels occurs. Parameters for use of clozapine are outlined in Box 21.1 (Novartis, 1997) but may change.

Box 21.1 PARAMETERS FOR CLOZAPINE USE

Check white blood cell (WBC) and automated neutrophil count (ANC) prior to initiating treatment. If WBC >3500/mm³ and ANC >2000/mm³, and there is no prior history of a myeloproliferative disorder, including due to clozapine use, then treatment may begin.

During treatment, if cell counts remain as above then:

- (a) for the first six months, check cell counts weekly;
- (b) for the second six months, check cell counts every two weeks;
- (c) after the first year, check cell counts monthly; and,
- (d) after cessation of treatment, check white cell count after one month.

During treatment, clozapine use and monitoring changes as follows:

- (a) for WBC counts between 3000 and 3500, or ANC between 1500 and 2000, check cell counts twice weekly;
- (b) for WBC counts between 2000 and 3000, or ANC between 1000 and 1500, clozapine treatment is stopped until the abnormal finding has resolved; and,
- (c) for WBC count <2000, or ANC <1000, clozapine treatment is permanently suspended.

Many of clozapine's side effects are predictable and result from its antihistaminic, anticholinergic, and antiadrenergic activity. In one multicenter study, the most frequent adverse side effects were sedation (21%), tachycardia (17%), constipation (16%), dizziness (14%), hypotension (13%), and hypersalivation (13%) (Kane et al., 1988). Although tremor, akathisia, and rigidity have been reported with clozapine treatment, these are uncommon (approximately 5%) and generally mild. Moreover, the drug does not appear to be associated with masked facies, acute dystonic reactions, and parkinsonian gait abnormalities.

Clozapine lowers the seizure threshold, with the incidence of seizures increasing with dosage: 1% at dosages below 300 mg/day, 2.7% at dosages of 300–599 mg/day, and 4.4% at higher dosages of 600–900 mg/day. The risk of seizures with clozapine is cumulative over time, reaching 10% at 3.8 years of treatment (DeVinsky, Honigfeld, & Patin, 1991). Clozapine is contraindicated in patients with myeloproliferative disorders or granulocytopenia and should not be used with other medications known to have myelosuppressive effects (e.g., carbamazepine).

If clozapine is needed in a patient with epilepsy, the patient should be switched to an anticonvulsant other than carbamazepine. To minimize the risk of seizures, anticonvulsant levels should be monitored frequently during initiation of clozapine and kept at the higher end of the therapeutic range. Some authors favor concurrent use of an anticonvulsant such as phenytoin or valproate if clozapine doses in excess of 500 mg are utilized, even in nonepileptic patients (Baldessarini & Frankenberg, 1991).

It is recommended that clozapine treatment be instituted at low dosages (12.5 mg–25 mg) in elderly patients because of its potential to induce marked sedation and hypotension. In elderly patients a starting dose of 12.5 mg twice daily is recommended. The typical therapeutic range for schizophrenia in physically healthy patients is 300–500 mg/day, with a maximum of 900 mg/day. Dosing should be on a twice or three times daily schedule (Lieberman, Kane, & Johns, 1989).

Fever up to 103°F may occur when starting clozapine and may persist with fluctuation for 4–6 weeks. Fever should be managed supportively with acetaminophen and is not in itself a reason to discontinue the drug. However, care should be taken to ensure that patients are adequately hydrated and to reassess patients frequently for symptoms suggesting an infectious cause for the fever or the possible emergence of NMS.

Friedman and Lannon reported on the successful treatment with clozapine of psychotic symptoms in six patients with Parkinson's disease. In patients who exhibited psychotic symptoms such as auditory hallucinations and paranoia, and who ranged in age from 52 to 78 years, they found that clozapine improved psychiatric symptoms without worsening motor manifestations of Parkinson's disease such as rigidity and gait disturbance. In two patients, parkinsonian symptoms actually improved. They noted that the likely explanation is that clozapine has relatively low affinity for striatal dopamine receptors. Its affinity for the D₂ receptor in the caudate nucleus is only 1/50 that of haloperidol and 1/10 that of chlorpromazine. The patients in this case series did not

develop agranulocytosis, and the major side effect encountered was hypersalivation, which can be treated with clonidine. Psychotic symptoms were controlled with relatively low doses ranging from 25 or 50 mg/day up to 275 mg/day (Friedman & Lannon, 1989). Another original case report (Roberts, Dean, & Stoudemire, 1989) showed similar symptomatic improvement in hallucinosis and paranoia in a 64-year-old woman with Parkinson's disease. When treated with clozapine 25 mg by mouth every 4 hours, not only did mental symptoms improve but the patient's parkinsonian symptoms improved to the point at which specific parkinsonian pharmacotherapy (carbidopa, levodopa, and trihexyphenidyl) could be discontinued. These reports have been confirmed by several other papers (Bernardi & DelZampa, 1990; Kahn et al., 1991; Pfeiffer et al., 1990).

Due to clozapine's orthostatic effects, psychotic PD patients may need as little as 12.5 mg clozapine a day, and blood pressure should be monitored as the dose is raised.

Granulocyte colony-stimulating factor (G-CSF) has proven effective in reversing many cases of clozapine-induced neutropenia. In one case in which clozapine was the only effective and available antipsychotic for a young man with severe clozapine-induced neutropenia, coadministration of clozapine with G-CSF led to a prompt normalization of the patient's white blood cell count (Sperner-Unterweger et al., 1998).

Clozapine can have a profound effect on gut motility. The anticholinergic and antiserotonergic effects of clozapine are likely involved. Effects can range from constipation to severe ileus leading to necrosis and bowel perforation, and even death. When colonic dilatation develops in the absence of mechanical obstruction, the condition is called *Ogilvie's syndrome*. The triad of colonic dilatation of greater than 6 centimeters, inflammation of the colon, and septic shock is referred to as *toxic megacolon* (Alam, Fricchione, Guimaraes, & Zuckerberg, 2009). Palmer and colleagues found that among 102 patients who developed life-threatening gastrointestinal hypomotility with clozapine, 28 died. Risk factors included recent initiation of clozapine, higher doses and serum levels of clozapine, concomitant use of other anticholinergic agents, and intercurrent illness (Palmer, McLean, Ellis, & Harrison-Woolrych, 2008). There is no specific medication used to manage clozapine's effects on the gut (Chukhin et al., 2013). Instead, management of clozapine's effects on the gut begin with the preparations to begin treatment. Patients with preexisting bowel problems, including those caused by other medications, would ideally have good control of these problems prior to starting treatment with clozapine. Since patients may not report bowel complaints spontaneously, especially those patients with prominent negative symptoms of psychosis, regular inquiries into bowel function must be made. When problems with bowel function do arise, they should be managed aggressively and monitored closely.

Ziprasidone

The bioavailability of oral ziprasidone is 60% or less; this is greatly enhanced by taking the medication with food. In some patients the bioavailability nearly doubles with food. The type

of food appears to have little impact on the improvement in bioavailability (Miceli, Glue, Alderman, & Wilner, 2007). Its elimination half-life is 2–7 hours. Serum protein binding is 99%. Ziprasidone is extensively metabolized by the liver, although less than a third of this metabolism is through cytochromes P450, specifically 3A4 and to a lesser extent 1A2. The bulk of hepatic metabolism of ziprasidone is accomplished by aldehyde oxidase.

Compared to agents such as risperidone and perphenazine, patients on ziprasidone discontinue the medication because of EPS relatively infrequently (Miller et al., 2008). But ziprasidone is also generally considered less effective an antipsychotic than olanzapine or risperidone (Stip et al., 2011). Ziprasidone also has the greatest QT prolongation among available atypical antipsychotics (Wenzel-Seifert et al., 2011). The significance of this QT prolongation is debated, with some authors claiming that the nature and extent of ziprasidone's QT prolongation is clinically insignificant (Correll et al., 2011).

INJECTABLE DEPOT ATYPICAL ANTIPSYCHOTIC AGENTS

Injectable, long-acting, or depot forms of atypical antipsychotics exist for aripiprazole, olanzapine, paliperidone, and risperidone. These agents have the potential to improve the consistency of medication use. One of the main limitations of the agents is the persistence in the systemic circulation after side effects develop. For example, the offending agent in neuroleptic malignant syndrome or an allergic reaction is much easier to stop when given orally than when given as a depot agent, due to the protracted action of the depot agent.

Depot aripiprazole is marketed as Abilify Maintena. This agent is given as a monthly injection of 300 or 400 mg of long-acting aripiprazole. Side effects of depot aripiprazole include insomnia that may develop in 8% to 10% of patients, anxiety in 6% to 8%, akathisia in 6%, tremor in 2% to 6%, and weight gain in 7% to 10%. An important aspect of the large, 52-week registration study performed by Kane and colleagues was the initial 4-week to 12-week period of stabilization on oral aripiprazole. This period allowed an assessment of whether a patient would have a hypersensitivity reaction to aripiprazole (Kane et al., 2012).

A depot form of risperidone was the first atypical antipsychotic made available as a depot agent. It is marketed as Risperdal Consta. It is recommended that patients who may receive this agent begin with oral risperidone for 2 weeks prior to initiating depot risperidone, and for 3 weeks after beginning depot risperidone. This agent is given every 2 weeks in doses of 12.5 mg, 25 mg, 37.5 mg, or 50 mg. The formulation of Risperdal Consta causes less than 1% of the drug to be released immediately into the systemic circulation. The bulk of the release occurs around week 3, and is maintained between weeks 4 and 6. After four such injections, a steady state is achieved that lasts for 4–6 weeks after the last injection. The main reason for discontinuing depot risperidone is the emergence or worsening of movement disorders. Insomnia and anxiety are the most common side effects of treatment. Perhaps 15% of patients will develop or experience

worsening of parkinsonism, and 15% of patients will have the same concern with regard to another form of EPS (Singh & O'Connor, 2009).

Depot paliperidone, currently marketed as Invega Sustenna, is a monthly injection that utilizes an induction protocol. Peak plasma levels are usually achieved on day 13, and the elimination half-life ranges from 25 to 50 days. The initial injection is a 234mg injection given on day 1. The next injection is a 156mg dose given on day 8. Injections thereafter are monthly. The monthly dose typically ranges from 39–234 milligrams based on such factors as weight, benefit, and side effects. Weight gain and elevations of prolactin are the most common concerns (Bishara, 2010). In general, side effects are the same as for oral paliperidone.

Olanzapine has been formulated for depot injection. It was introduced in 2010 as Zyprexa Relprevv. Recommended doses for acute schizophrenia are 210 or 300 mg every 2 weeks, or 405 mg monthly. For maintenance treatment of schizophrenia, the recommended doses are 150 or 300 mg every 2 weeks, or 405 mg monthly (Lindenmayer, 2010). The elimination half-life of this agent is 30 days. Steady state is achieved in 12 weeks. Typically, supplementation with oral olanzapine is not needed. An important complication of depot olanzapine treatment is a postinjection delirium sedation syndrome (PDSS). PDSS occurs in 0.07% of injections, and typically within 1 to 3 hours of receiving the injection. It resembles an overdose of olanzapine, and is characterized by sedation grading into somnolence, dizziness, confusion, and dysarthria. Cardiovascular function normally is preserved (Di Lorenzo & Brogli, 2010). PDSS is thought to result when there is a partial injection of the agent directly into the vascular space. Serum levels then may quickly rise above the expected range of 5 to 73 ng/ml. Levels approaching 600 ng/ml have been observed. The serum level usually resolves without a specific intervention within 24 to 72 hours (McDonnell et al., 2010). PDSS is thus generally a self-limiting side effect for which support but no specific intervention is needed (Duran-Sindreu et al., 2013). Experience with oral olanzapine overdoses indicates that severe central nervous system depression with tachycardia, orthostatic hypotension, hyperthermia, miosis, and respiratory depression requiring ventilation is possible (Tse, Warner, & Waring, 2008). Patients should wait in their injection clinic for 3 hours after each injection.

BENZODIAZEPINES

Benzodiazepines are commonly used in medically ill patients as anxiolytics, muscle relaxants, anticonvulsants, and hypnotics, and for sedation for procedures. The medically ill and elderly, however, are at increased risk for adverse side effects from these medications. There is also evidence that, in addition to pharmacokinetic changes related to aging, the elderly may be intrinsically more sensitive to both positive and negative clinical effects of the benzodiazepines (Greenblatt, Harmatz, & Shader, 1991). Benzodiazepine use may increase the risk of delirium among medically ill patients (Pisani, Murphy, Araujo, & Van Ness, 2010). Along with anticholinergic agents,

benzodiazepines are among the agents most likely to impair cognitive functions such as short-term memory (Chavant, Favrelière, Lafay-Chebassier, Plazanet, & Pérault-Pochat, 2011). However, it is unclear as yet to what degree benzodiazepine use is a marker for patients at risk of developing delirium and to what degree their use actually precipitates delirium (Tse et al., 2012). A further potential complication of benzodiazepine use is their tendency to lower extracellular levels of neurotrophic factors (Tamaji et al., 2012). Reduction in the brain levels of brain-derived neurotrophic factor (BDNF) is a marker for neurodegeneration across disease states (Diniz & Teixeira, 2011). This may be one mechanism, besides sedation, by which benzodiazepines increase the risk of cognitive disorders such as delirium. Despite these risks, benzodiazepines, along with anticholinergic agents, are among the agents most commonly prescribed to elderly patients with mild cognitive impairment. Over 30% of such patients in the community are prescribed a benzodiazepine (Weston, Weinstein, Barton, & Yaffe, 2010).

Hypnotics, both the benzodiazepine and the nonbenzodiazepine, are associated with an increased risk of various types of morbidity as well as mortality. One controversial but persistent finding is an association between hypnotic use and an increased risk of cancer (Kao et al., 2012; Kripke, 2008). The risk of developing cancer is increased an average of 1.35-fold (95% CI: 1.18 to 1.55). This effect appears to be dose dependent and occurs across a surprising array of agents (Kripke, Langer, & Kline, 2012). Zopiclone, zolpidem, and ramelteon were found to be clastogenic in rodents during preliminary studies. These agents are associated with an increased risk of nonmelanoma skin cancers (Stebbing et al., 2005). Some authors caution that controlling carefully for other health risk factors can reduce the apparent size of the effect of hypnotics on overall mortality and some cancers, although it does not eliminate it (Hartz & Ross, 2012). The link between GABA-A-active agents and cancer may be related to GABA's role in modifying the behavior of stem cells (Young & Bordey, 2009). Other authors caution that the epidemiological association between the use of certain hypnotics and cancer does not prove causality (Phillips, 2012). Nonetheless, the association between hypnotic use and increased morbidity and mortality may be an argument for the use of behavior and lifestyle-modifying techniques for some patients with insomnia.

As a class, benzodiazepines share more similarities than differences in their intrinsic pharmacologic activity, which is mediated via the benzodiazepine receptor (increasing GABA-ergic tone), and side effect profile. There are, however, considerable differences in the pharmacokinetics of the various benzodiazepines. Thus, the knowledge of an individual benzodiazepine's pharmacokinetic profile may be more important, especially in the medically ill and the elderly, than the somewhat arbitrary distinctions between anxiolytic and hypnotic indications. Pharmacokinetic distinctions are especially significant because there is no convincing evidence that one benzodiazepine is clinically more effective than any other, and no evidence that benzodiazepines marketed as hypnotics for the treatment of insomnia are more effective for sleep than those marked as anxiolytics, and vice versa.

METABOLIC ROUTE AND ELIMINATION HALF-LIFE

Pharmacokinetic considerations in the use of benzodiazepines include the route of metabolism and biotransformation, elimination half-life, and relative lipophilicity. Most benzodiazepines, including diazepam, chlordiazepoxide, alprazolam, flurazepam, triazolam, and midazolam, undergo primary biotransformation in the liver via microsomal oxidative pathways. Thus, for these medications, drugs that inhibit hepatic microsomal enzymes, such as alcohol, isoniazid, and cimetidine, will increase plasma concentrations and elimination half-lives. Conversely, drugs that induce microsomal enzymes, such as estrogen, methylxanthines, rifampin, and cigarette smoking, will decrease the concentrations of these benzodiazepines. An example of the clinical significance of this latter observation is the fact that theophylline preparations and benzodiazepines are frequently used together in intensive care settings. If the theophylline were discontinued in a patient who was concurrently receiving a benzodiazepine, the patient would theoretically be at risk for a rise in the plasma concentration of the benzodiazepine that could result in a diminished level of consciousness and a degree of respiratory depression (Bonfiglio & Dasta, 1991). Since hepatic biotransformation is impaired by advanced age and hepatic disease, such as hepatitis and cirrhosis, benzodiazepines that are eliminated by hepatic oxidation should either be avoided or be given at reduced dosages and at increased time intervals. Drug interactions with benzodiazepines are listed in Table 21.6 (Barnes, Gerst, Smith, Terrell, & Mullins, 2006; Leach, Mohanraj, & Borland, 2012; Oliver, Keen, Rowse, & Mathers, 2001; Park & Jung, 2010; Stoudemire, Moran, & Fogel, 1991).

The parent compounds of benzodiazepines that are eliminated via oxidative metabolism typically are transformed into active metabolites that may be long-lived. For example, diazepam, chlordiazepoxide, clorazepate, and prazepam are metabolized to their common active metabolite, desmethyldiazepam, which has a half-life in excess of 50 hours in young, healthy patients and up to 175 hours in elderly or medically ill patients (Barbee & McLaulin, 1990). Similarly, the benzodiazepine hypnotics flurazepam and quazepam share the active metabolite desalkylflurazepam, which has an elimination half-life of 48 to 120 hours (Greenblatt, 1991). Two triazolobenzodiazepines that are metabolized by oxidative pathways but do not have significantly active metabolites are triazolam and alprazolam, with elimination half-lives of 3–5 hours and 12–15 hours, respectively.

Three available benzodiazepines are metabolized primarily in conjugation with glucuronic acid: lorazepam, oxazepam, and temazepam. These drugs, therefore, are less likely to accumulate in the elderly and in patients who have hepatic disease. For example, for a patient who presented with symptoms of alcohol withdrawal and had an unknown liver function status, lorazepam or oxazepam would be preferable to chlordiazepoxide. Lorazepam is also one of the only

**Table 21.6 DRUG INTERACTIONS WITH
BENZODIAZEPINES AND PSYCHOSTIMULANTS**

MEDICATION	INTERACTIVE EFFECT
<i>Benzodiazepines</i>	
Cimetidine	May elevate serum levels of benzodiazepines
Disulfiram	Metabolized predominantly by oxidation
Ethanol	
Isoniazid	
Estrogens	
Cigarettes	Tend to lower benzodiazepine levels
Methylxanthine derivatives	
Rifampin	
<i>Opiates</i>	
Propylene glycol	Vehicle used for some intravenous preparations; can accumulate and cause toxicity; monitor osmolar gap
Olanzapine	May synergistically cause hypotension
Opiates	Synergistic sedation; may cause respiratory sedation
<i>Psychostimulants</i>	
Guanethidine	Decreased antihypertensive effect
Vasopressors	Increased pressor effect
Oral anticoagulants	Increased prothrombin time
Anticonvulsants	Increased levels of phenobarbital, primidone, phenytoin
	Stimulants may undermine efficacy of anticonvulsants
Tricyclics	Increased blood levels of TCA
	May precipitate mania, hyperadrenergic state, or hyperserotonergic state
MAOIs	Hypertension
	May precipitate mania, hyperadrenergic state, or hyperserotonergic state
SSRIs	Increased risk of serotonin syndrome
P-glycoprotein inhibitors	May increase brain concentrations of methylphenidate, but not of amphetamine or modafinil

two benzodiazepines (along with midazolam) that is reliably absorbed intramuscularly, should the patient be unable to take oral medications.

When drugs that inhibit the CyP450-3A enzyme are used (e.g., nefazodone), many benzodiazepines such as alprazolam will have increased serum levels.

Clonazepam, technically marketed as an anticonvulsant, has an elimination half-life of 30–40 hours. Its biotransformation is primarily by reduction of the 7-nitro group to the 4-amino derivative. This metabolite is acetylated, hydroxylated, and glucuronidated. Cy450-3A may play some role in the drug's reduction and oxidation. Clonazepam will be discussed in more detail in several other parts of this chapter.

TRIAZOLAM

Triazolam, an ultra-short-acting triazolobenzodiazepine marketed as a hypnotic, has been associated with reports of confusion, delirium, anterograde amnesia, and rebound insomnia and rebound anxiety. Bixler et al. (1991) examined 18 poor sleepers placed in three parallel groups treated with 0.5 mg of triazolam, 30 mg of temazepam, or placebo. Immediate recall was similar in all three groups; however, delayed recall was more impaired in the triazolam-treated patients. In addition, five of the six triazolam-treated subjects reported episodes of next-day memory impairment. Greenblatt et al. (1991) evaluated the sensitivity to triazolam in the elderly via a double-blind crossover study of 26 healthy, young (mean age 30 years) and 21 healthy, elderly (mean age 69 years) patients. Impaired psychomotor performance and memory, and increased psychomotor sedation were found in the elderly subjects. The authors recommend reducing the average dose of triazolam in the elderly by 50%, suggesting that clinical efficacy of 0.125 mg in the elderly is equivalent to 0.25 mg in healthy, young patients. We do not recommend the use of triazolam in the elderly or any other population.

It has also been suggested that triazolam may have a lower therapeutic index than other benzodiazepines, which, as a class, have a relatively high therapeutic index. A case report of coma with an overdose of only 0.5 mg has been described, whereas other benzodiazepines require approximately 100 times the clinical dose for serious overdose (Kales, 1990). Inhibition of Cyp450 3A4 or pf P-glycoprotein can increase serum levels of triazolam. Because many drugs and some foods, such as grapefruit juice, are potent inhibitors of both of these proteins, the risk of unintended increases in serum triazolam levels is significant (Bailey, Malcolm, Arnold, & Spence, 1998).

If a short-acting soporific drug is needed, the nonbenzodiazepine soporific zolpidem is likely somewhat more preferable, but it has been reported to have some of the side effects of triazolam with less frequency. We still tend to prefer the intermediate-acting benzodiazepine temazepam, which is metabolized by glucuronide conjugation and has an elimination half-life of about 12 hours.

Clonazepam

As noted, clonazepam has a half-life of 30–40 hours. Since it may take longer than 1 week to achieve steady state, elderly patients may be at increased risk for progressive oversedation, ataxia, and psychomotor slowing (Stoudemire, Fogel, & Gulley, 1991). The pharmacodynamic profile of clonazepam may provide a gradual physiologic “self-taper.” For example, Patterson (1988) described successful detoxification in ten alprazolam-dependent patients, substituting clonazepam for alprazolam on a milligram-for-milligram equivalent basis and then discontinuing the clonazepam. Clinical experience indicates that clonazepam is one of the least sedating benzodiazepines. It is an excellent benzodiazepine for the treatment of panic disorder (Nardi et al., 2013).

Quazepam

Quazepam is a highly lipophilic benzodiazepine approved by the FDA for use as a sedative-hypnotic agent. It is rapidly absorbed and reaches peak plasma concentration 1.5 hours after ingestion of an oral dose. Quazepam is extensively metabolized in the liver, with an elimination half-life of 41 hours, although, as noted above, it is metabolized to the same long half-life metabolite as flurazepam, desalkylflurazepam (Kales, 1990). Recommended dosage is 15 mg orally for young adults and 7.5 mg orally for elderly patients. Its long elimination half-life diminishes the risk of rebound insomnia and withdrawal symptoms, at the expense of increased risk of accumulation and daytime sedation. Since it is more slowly absorbed and may cost slightly more than flurazepam, it seems to offer no particular advantages over already established hypnotics for regular use (Medical Letter, 1990). For occasional use, the relative selectivity of the parent compound and its 2-oxo metabolite for BZ1 benzodiazepine receptors may be relevant. Specifically, it may cause relatively less cognitive and motor side effects than flurazepam after a single dose. However, even this potential advantage is not well established. Inducers of Pgp and of Cyp450 3A4, such as St. John’s wort, can lower serum quazepam levels (Izzo & Ernst, 2009).

Estazolam

Estazolam, like triazolam, is a triazolobenzodiazepine derivative with sedative-hypnotic efficacy. It is rapidly absorbed, with a mean time to maximum plasma concentration of less than 2 hours, and its half-life is approximately 14 hours (Gustavson & Carrigan, 1990), which is similar to that of temazepam. Estazolam is metabolized via microsomal oxidation and has no significant active metabolites. Cyp450 3A4 is the primary responsible hepatic enzyme (Miura, Otani, & Ohkubo, 2005). The usual daily dose is 1–2 mg (clinical trials have found 2 mg of estazolam comparable to 30 mg of flurazepam; see Cohn et al., 1991; Scharf et al., 1990). Although it is clinically efficacious, there have been concerns that estazolam may share the increased toxicity and increased risk of withdrawal-rebound syndromes with the other triazolobenzodiazepines, triazolam and alprazolam.

Midazolam

Midazolam is primarily used as a parenteral preanesthetic in induction of general anesthesia and for sedation before short diagnostic procedures such as endoscopy. It can be administered intramuscularly or intravenously. However, its sedating and anxiolytic action, its remarkably short onset and duration of action, and the option of parenteral use suggest potential usefulness for psychiatric patients. This notion has been bolstered by case reports in the psychiatric literature of its efficacy in the management of acutely agitated and psychotic patients (Bond, Mandos, & Kurtz, 1989; Mendoza et al., 1987).

Midazolam is highly lipophilic at physiologic pH and, unlike most benzodiazepines, is rapidly and well absorbed intramuscularly (Matson & Thurlow, 1988). It has a very rapid onset of CNS effects, with sedation occurring within 5–15 minutes after intramuscular injection (3–5 minutes after intravenous administration) and reaching its peak within 30–60 minutes. Midazolam is rapidly displaced from benzodiazepine receptors and has a short duration of action of approximately 2 hours, with a range of 1–6 hours (Bond, Mandos, & Kurtz, 1989). Its biologic half-life is only 1.3 to 2.2 hours (Beck, Salom, & Holzer, 1983). Midazolam undergoes extensive biotransformation to its major pharmacologically active metabolite, 1-hydroxy-methylmidazolam, by way of microsomal oxidation. Critically ill patients, including infants and children, may experience a higher serum level of midazolam for any given dose due to illness-related decreases in Cyp450 3A4 activity (Ince et al., 2012). Drug–drug interactions mediated through Cyp450 3A4 and related 3A isoenzymes can have a profound effect on midazolam serum levels (Lichtenbelt et al., 2010). The problem of illness and drug–drug interactions can be an acutely important issue for midazolam use, since it is often given to very ill patients receiving multiple medications (see Box 21.2).

There is also evidence that there are significant age-related differences in the clearance of midazolam with decreased clearance in elderly patients, especially elderly men (Holazo, Winkler, & Patel, 1988). Lower initial doses are therefore recommended in patients older than 60 years. Although the drug is generally well tolerated, like other benzodiazepines, respiratory depression (including apnea) has been associated with its intravenous use. In addition, there have been case reports of hypotension (Matson & Thurlow, 1988), disinhibition of aggressive behavior (Bobo & Miwa, 1988), transient paranoia and agitation (Burnakis & Berman, 1989), and delirium, especially in the elderly. Advancing age and use of an opiate are each associated with an increased risk of acute confusion in the presence of midazolam (Colombo et al., 2012). This may be due in part to midazolam’s well-described respiratory sedation, which may be greater among the elderly (Fredman et al., 1999; Huang, Chen, Yang, & Liu, 2012).

Midazolam may induce anterograde amnesic episodes, primarily when it is used intravenously during medical procedures. Retrograde amnesia is not usually achieved. But essentially all patients given midazolam will have anterograde

amnesia if sufficient midazolam is given. In one study, 5 mg given intravenously appeared sufficient to produce anterograde amnesia in all patients (Bulach et al., 2005).

Midazolam is approximately three to four times as potent per milligram as diazepam, and initial intramuscular dosage is 0.07–0.08 mg/kg, with the average dosage in a healthy adult being 5 mg and lower dosages recommended in elderly or debilitated patients. Dosage guidelines in the psychiatric setting are not established. On occasion, midazolam may assist in the management of aggressive behavior. Bond, Mandos, and Kurtz (1989) reported three cases of use of midazolam in the treatment of mentally retarded patients with acute and refractory aggressivity and violence, using 5–10 mg of midazolam administered intramuscularly. The patients (a 14-year-old girl, a 17-year-old boy, and a 26-year-old man) showed rapid improvement in aggressive behavior. Mendoza et al. (1987) reported three patients with acute psychotic states with hyperarousal who responded favorably when treated with lower dosages of midazolam in a psychiatric emergency room setting. The patients included a 17-year-old boy, a 38-year-old man, and a 34-year-old woman. The authors noted the onset of sedation in these patients to occur within 6 to 8 minutes, with sedation lasting approximately 90 minutes after an intramuscular dose of 2.5–3 mg. More recent and larger studies paint a less optimistic picture. One randomized study of 301 patients compared midazolam 15 mg intramuscular injection for agitation in psychotic patients against an intramuscular combination of haloperidol 10 mg and promethazine 50 mg. Being asleep or tranquil at 20 minutes was the primary outcome measure. The two regimens were equally effective in achieving this. However, 6% more of the midazolam group had a second episode of aggression. There was one episode of respiratory

depression in the midazolam group, and none in the other (TREC Collaborative Group, 2003). A large, randomized, double-blind study involving 150 patients compared olanzapine, ziprasidone, haloperidol plus midazolam, haloperidol plus promethazine, or haloperidol alone in the management of acute agitation. After 12 hours, only the group randomized to receive haloperidol plus midazolam had high levels of agitation. They also had the most side effects (Baldaçara, Sanches, Cordeiro, & Jackowski, 2011).

RELATIVE LIPOPHILICITY

In addition to metabolic fate and elimination half-life, the relative lipid solubility of a benzodiazepine is also important to consider. More highly lipophilic drugs, such as diazepam and midazolam, cross the blood–brain barrier quickly but also may be distributed more widely in the peripheral tissues. Diazepam is highly lipophilic and has a rapid onset of action when given intravenously, whereas lorazepam is relatively less lipophilic with less rapid onset of clinical activity when given intravenously (Greenblatt, 1991). When single doses of highly lipophilic drugs are given, redistribution rather than elimination determines the duration of clinical effect.

Elimination half-lives vary widely among individual benzodiazepines. Short half-life benzodiazepines are less likely to accumulate with repetitive dosing, since they reach steady state more rapidly (steady state is more than 90% achieved after approximately four times the elimination half-life; see Greenblatt, 1991). The ultra-short-acting benzodiazepines such as triazolam carry the risk of interdose anxiety, rebound anxiety, and insomnia.

One aspect of the clinical importance of the distinction between long and short half-life benzodiazepines is the propensity of long half-life medications to accumulate in the elderly and increase the risk of falling. In a large retrospective epidemiologic study, Ray, Griffin, and Downey (1989) examined the relative risk for hip fracture in patients age 65 and older who had suffered a hip fracture and had filled a prescription for benzodiazepines within the past 30 days, utilizing computerized pharmacy records available via the Saskatchewan, Canada, universal healthcare plan. These investigators found that current users of long half-life benzodiazepines (diazepam, chlordiazepoxide, flurazepam, clorazepate) had a 70% greater risk of hip fracture than did patients on no psychotropic medications. There was no increased risk in current users of short half-life benzodiazepines (alprazolam, lorazepam, oxazepam, triazolam, bromazepam) (Ray, Griffin, & Downey, 1989). Mortality rises significantly within the first few months after a hip fracture and gradually declines over several years (Yoon, Park, et al., 2011). In one 12-month study of over 500 elderly patients, the withdrawal of psychotropics, including benzodiazepines, led to an 8-fold reduction in the number of falls. In light of the significant and well established morbidity and mortality associated with hip fracture in the elderly (Kelsey & Hoffman, 1987), the clinician should minimize or avoid the use of long half-life benzodiazepines in elderly fragile patients because the prolonged elimination of these benzodiazepines leads to accumulation with daytime drowsiness or ataxia.

FINAL CONSIDERATIONS IN BENZODIAZEPINE USE

All benzodiazepines can lead to tolerance and psychological and physiological dependence. Risk factors for dependency include increased duration of treatment, utilization of higher doses, and a previous history of alcoholism. Physical dependence can occur within as short a time as 2–3 weeks, and often does occur within 4 months at two to five times the therapeutic dose. In addition, benzodiazepine discontinuation syndromes can include reemergence of symptoms that were targeted by treatment. Withdrawal symptoms in tolerant patients include rebound anxiety or insomnia, and major symptoms such as psychosis and seizures (Salzman, 1991).

Despite the high therapeutic index of benzodiazepines in healthy patients, their use should be considered carefully in medically ill patients. In addition to pharmacodynamic alterations and increased drug interactions, the medically ill may be particularly at risk for sedation, especially if benzodiazepines are used concurrently with other CNS depressants such as barbiturate anticonvulsants or narcotics. In addition, it is well established that benzodiazepines reduce the ventilatory response to hypoxia. In chronically hypercapnic patients who have lost their hypercapnic respiratory drive, the suppression of hypoxic drive may result in respiratory suppression. Therefore, baseline arterial blood gases should be obtained in patients with pulmonary disease, and the use of benzodiazepines should be avoided if $p\text{CO}_2$ is elevated (Stoudemire & Fogel, 1995). In addition, benzodiazepines are contraindicated in sleep apnea and may exacerbate symptoms in patients with undiagnosed sleep apnea syndromes (Mendelson, 1987). Agents such as zolpidem and triazolam may be used in sleep apnea cautiously, and only when the risk of respiratory depression is judged to be low (Aurora et al., 2012).

A final caveat regarding the use of benzodiazepines in the elderly and medically ill is that the clinician should give a high priority to the exclusion of underlying treatable pathophysiology before symptomatic treatment of anxiety and insomnia is undertaken. Insomnia, the most common reason for benzodiazepine prescriptions, can be due to underlying medical problems such as restless legs syndrome, the disturbed sleep/wake cycle of delirium or dementia, paroxysmal nocturnal dyspnea, or due to primary psychiatric syndromes such as major depression (Buysse, 2013; Moran & Stoudemire, 1992).

NONBENZODIAZEPINE ANXIOLYTICS AND HYPNOTICS

BUSPIRONE

Buspirone is a nonbenzodiazepine anxiolytic that is free from the side effect of respiratory depression and also lacks withdrawal symptoms on discontinuation (Apter & Allen, 1999). Buspirone's mean elimination half-life is 2 to 3 hours, although its metabolites may have elimination half-lives of 6 to 8 hours (Jann, 1988). While buspirone has significant

anxiolytic activity, it is devoid of anticonvulsant, muscle relaxant, and sedative-hypnotic activity. There are no synergistic or additive effects between buspirone and alcohol or other sedative-hypnotics.

The pharmacokinetics of the drug have been studied in patients with impaired liver and kidney function. In patients with hepatic cirrhosis, after a single 20mg dose, the elimination half-life was 6.21 versus 1.79 hours in patients with cirrhosis compared to 4.19 versus 0.53 hours in healthy subjects (Dalhoff et al., 1987; Goa & Ward, 1986). In patients with impaired renal function, including some who were completely anuric, buspirone clearance decreased between 33% and 50%, with no correlation between the severity of renal impairment and buspirone clearance (Gammans, Mayol, & Labudde, 1986). Hence, small reductions in buspirone dosage are likely to be needed in patients with hepatic and renal disease, although the reported prolongation of elimination half-lives by liver or kidney failure is likely to represent an effect of smaller magnitude than normal interindividual differences in optimal dosage. Side effects are not generally more frequent or severe among patients with renal or hepatic impairment (Barbhaiya et al., 1994). No clinically significant prolongation of buspirone pharmacokinetics in elderly patients has been observed (Gammans et al., 1989). However, the pharmacokinetics are highly variable in the general population, implying a need to individualize dosage.

Drug Interactions

Buspirone does not induce or inhibit hepatic mixed oxidase enzymatic functions (Molitor et al., 1985). Buspirone is metabolized through Cyp450 3A4. Inhibitors of Cyp450 3A4 can increase serum buspirone levels. Grapefruit juice, a potent inhibitor of Cyp450 3A4, can elevate serum buspirone levels fourfold (Lilja, Kivistö, Backman, Lamberg, & Neuvonen, 1998). Similarly, inducers of Cyp450 3A4 such as rifampin can lower serum buspirone levels (Finch, Chrisman, Baciewicz, & Self, 2002). The ability of buspirone to displace phenytoin, warfarin, propranolol, and digoxin from protein binding has been studied in vitro (Gammans et al., 1985), and interaction with these drugs does not appear to be clinically significant. Buspirone also appears free from interaction with antihistamines, bronchodilators, H_2 histamine receptor blockers, oral contraceptives, nonsteroidal antiinflammatory drugs, benzodiazepine hypnotics, digitalis preparations, and oral hypoglycemics (Domantay & Napoliello, 1989; Levine & Napoliello, 1988). Pharmacokinetic interactions between buspirone and TCAs have not been found (Gammans, Mayol, & Labudde, 1986). However, buspirone has been observed to increase serum haloperidol concentrations (Sussman, 1987). Elevations in blood pressure have been observed in patients taking buspirone and MAOIs (Knapp, 1987), leading to the manufacturer's recommendations against this combination. There may be some slight prolongation in the metabolism of diazepam when it is used concurrently with buspirone, although this is of doubtful clinical significance (Meltzer & Fleming, 1982).

Some slight increase in sedation may occur if buspirone is used concurrently with diazepam (Gershon, 1982). Some anecdotal reports claim verapamil and diltiazem (calcium channel blockers) may elevate buspirone serum levels.

Buspirone is generally regarded as an agent with only mild side effects. Yet, buspirone may contribute to development of the serotonin syndrome. This may sometimes occur unexpectedly, as when buspirone is combined with linezolid (Morrison & Rowe, 2012). Linezolid is an antibiotic that reversibly inhibits monoamine oxidase, which creates the potential to amplify the serotonergic effects of medications such as buspirone (Taylor, Wilson, & Estes, 2006). Buspirone is sometimes used to induce therapeutic hypothermia. Its combination with meperidone is considered an effective regimen for induction of hypothermia (Sessler, 2009). However, meperidone combined with serotonergic agents is also capable of precipitating the serotonin syndrome (Gillman, 2005).

Buspirone and Pulmonary Disease

Buspirone is of value in patients with pulmonary disease. Animal studies suggest that buspirone may serve either as a partial respiratory stimulant or as an agent that improves alveolar oxygen diffusion (Garner et al., 1989; Meyer, Hetem, Fick, Mitchell, & Fuller, 2010). In an open study of 82 patients, buspirone was used safely for reduction of anxiety in patients with chronic lung disease. No problems developed from using buspirone together with bronchodilators such as theophylline and terbutaline (Brenes, 2003; Kiev & Domantay, 1988).

Buspirone and Other Conditions

Many case reports and studies indicate clinical efficacy for buspirone in a variety of conditions other than anxiety disorders. Buspirone has been used to treat autism (Brahm, Fast, & Brown, 2008; Realmuto, August, & Garfinkel, 1989), for the suppression of neuroleptic-induced akathisia (D'Mello, McNeil, & Harris, 1989), as an augmenting agent in antidepressant treatment (Robinson et al., 1989), and for ADHD in children. Antidepressant-induced bruxism is often effectively treated with buspirone (Albayrak & Ekinici, 2011). Buspirone can counteract SSRI-induced sexual dysfunction in some patients. It does not, however, appear to increase libido (Moll & Brown, 2011). Buspirone can help reduce anxiety and agitation in brain-injured patients and in patients with dementia (Colenda, 1988; Levine, 1988; Loane & Politis, 2012; Tiller, Dakis, & Shaw, 1988). Typically, relatively low doses are needed for this antiagitation effect (5–10 mg tid). Buspirone also may be helpful in smoking cessation (Carrão, Moreira, & Fuchs, 2007; Gawin, Compton, & Byck, 1989) and in luteal phase dysphoric disorder (Rickels, Freeman, & Sondheim, 1989; Yatham, Barr, & Dinan, 1989). Current studies are investigating high doses of buspirone for the treatment of tardive dyskinesia. In this role, buspirone may help both by stimulating normal dopamine activity in the brain

and by offering neuroprotection (Lauterbach et al., 2010). Buspirone may also help treat functional dyspepsia, as it relaxes the fundus (Tack, Janssen, Masaoka, Farré R, & Van Oudenhove, 2012).

Stimulant Effect of Buspirone

Although buspirone has an anxiolytic effect that is maximal in 4 to 6 weeks, some patients experience early stimulation or agitation from the drug. The authors have seen several of these reactions in patients with diagnoses ranging from panic disorder to depression to mental retardation. The reaction is dose dependent and can be treated by discontinuing buspirone until the agitation or insomnia resolves, then restarting the drug at a lower dose. A reasonable approach to starting buspirone in “panicky” or neurologically impaired patients is to start no higher than 2.5 mg three times daily and warn the patient or caretaker about possible early and transient agitation. Since buspirone has a weak antidepressant effect at higher doses (30–90 mg/day), it may precipitate hypomania or mania. In some cases, the agitation represents akathisia caused by buspirone (Patterson, 1988). Akathisia related to serotonergic agents appears to be a separate entity from the anxiety or “jitteriness” that agents such as buspirone sometimes cause (Sinclair et al., 2009). However, drug-induced akathisia also tends to be dose dependent. Many patients who might develop these side effects with buspirone may tolerate the drug with a gradual upward taper. In some cases, however, it may be necessary to abandon treatment with buspirone.

MELATONIN

Melatonin spares psychomotor performance, unlike agents such as zaleplon, zopiclone and temazepam (Paul, Gray, Kenny, & Pigeau, 2003). Melatonin easily crosses the blood–brain barrier and stimulates endogenous receptors, promoting sleep. Melatonin indirectly also promotes the release of GABA and inhibits the release of glutamate (Banach, Gurdziel, Jędrych, & Borowicz, 2011). Melatonin lacks known toxicity in acute settings. It is not a mutagen in the Ames test (Anisimov, 2003). Endogenous melatonin is metabolized through CyP450 1A (Rifkind, 2006). Oral melatonin doses of 0.1–0.3 mg achieve serum levels that are similar to those normally seen at night. Sleep latency is reduced, and sleep duration is prolonged (Dollins, Zhdanova, Wurtman, Lynch, & Deng, 1994). Because of its relative benignity, as well as its potent antioxidant effects, melatonin use has been recommended for a variety of disorders including Alzheimer's disease, myocardial infarction, and diabetes (Korkmaz et al., 2012; Sánchez-Barceló et al., 2010). Doses of melatonin higher than 0.3 mg can cause protracted elevations of serum melatonin, and hence persistent daytime sedation. In some cases, while melatonin reduces the time it takes to fall asleep it does not prolong sleep, and patients wind up sleeping the same total amount of time and waking up earlier (Gringras et al., 2012).

RAMELTEON

The bioavailability of oral ramelteon is about 2%. Its elimination half-life is 1–3 hours, and that of its active metabolite is 2–5 hours. Over 80% of the drug is excreted as metabolites in the urine. Metabolism is primarily through CyP450s 1A2 and 2C19, with a small contribution from 3A4 (Obach & Ryder, 2010). Ramelteon is an agonist at melatonin MT1 and MT2 receptors. Although its active metabolite has some affinity for the serotonin 5HT2b receptor, there is no significant activity at other receptors including the GABA-A receptor. Significantly less impairment of cognition and of psychomotor performance is expected with ramelteon compared to those agents active through the GABA-A receptor (Mets et al., 2011). Ramelteon does not have significant withdrawal effects or lead to rebound insomnia on discontinuation. There are no significant effects on respiration among patients with pulmonary problems placed on ramelteon (Greenberg & Goss, 2009). Somnolence is the most common side effect with ramelteon and may affect 5% of patients (Kohsaka et al., 2011).

ESZOPICLONE

Eszopiclone is the *s*-enantiomer of zopiclone, a nonbenzodiazepine agent that is an allosteric modulator of the GABA-A channel. Its elimination half-life is 6 hours. The drug is 50% to 60% protein-bound. Over 75% is eliminated in the urine as metabolites; less than 10% is recovered in the urine as the parent compound. Eszopiclone is metabolized through CyP450 3A4. Inhibitors of CyP450 3A4, as well as advancing age and liver disease prolongs the elimination half-life (Greenblatt & Zammit, 2012). While sedation and dizziness do occur in a minority of patients, dose-dependent dysgeusia is the most common adverse event. Between 20% and 60% of patients prescribed eszopiclone will experience dysgeusia (Uchimura, Kamijo, & Takase, 2012). There is an elevated risk ratio of 1.4 for developing an infection during treatment with zopiclone or eszopiclone. These are usually mild. The reasons for this association are unclear (Joya, Kripke, Loving, Dawson, & Kline, 2009).

ZALEPLON

The bioavailability of oral zaleplon is about 30% (Drover, 2004). The elimination half-life of zaleplon is an hour. About 70% of the drug is excreted in the urine as metabolites and 17% in the feces as metabolites. Almost no unchanged drug is found in the urine. Zaleplon has a weaker association with mortality and cancer than do zolpidem and temazepam, based on the available data (Kripke et al., 2012). Overdose with zaleplon may cause ataxia, confusion, hallucinations, tachycardia, and vomiting, but these are not typically life threatening (Forrester, 2006). An advantage of zaleplon is that its very short elimination half-life helps minimize cognitive impairment the next day (Lieberman, 2007).

ZOLPIDEM

Among the agents used for insomnia, zolpidem has a relatively strong association with falls and fractures. Among 1,508 patients with fractures and insomnia, Kang and colleagues noted a relative risk of 1.72 (95% CI: 1.37 to 2.16) of having a fracture among patients taking zolpidem. The relative risk among patients taking a benzodiazepine was 1.00 (Kang et al., 2012). Zolpidem overdose has the same general presentation as overdose with zaleplon, although zolpidem is more likely to cause side effects requiring medical attention (Forrester, 2006). Zolpidem appears to be safe for patients with stable mild to moderate chronic obstructive pulmonary disease and for patients with treated sleep apnea (Estivill et al., 2003). Zolpidem is available both as an immediate-release agent and as an extended-release agent. The extended-release formulation permits 60% of the active agent to be taken up immediately, while the remaining 40% is released slowly. This reduces peak serum concentrations and extends the duration of action by 3 hours. Two important differences between the indications of immediate-release and sustained-release zolpidem are that the latter is indicated for sleep maintenance, not just sleep promotion, and also can be used chronically (Lieberman, 2007).

Zolpidem use has also been linked to cancer. The hazard ratio for oral cancer among patients taking more than 300 mg of zolpidem in a year was reported by Kao and colleagues (2012) to be 2.36 (95% CI: 1.57 to 3.56).

ZOPICLONE

The bioavailability of oral zopiclone is generally 70%–80%. The elimination half-life normally ranges from 3.5–6.5 hours. Plasma protein binding ranges from 45%–80% (Drover, 2004; Fernandez, Martin, Gimenez, & Farinotti, 1995). Potent inducers of CyP450 3A4, such as carbamazepine, phenytoin and rifampicin, speed the elimination and reduce the effects of zopiclone (Villikka, Kivistö Lamberg, Kantola, & Neuvonen, 1997). Zopiclone resembles zolpidem in being relatively safe for patients with pulmonary disease. Neither agent significantly impairs respiratory drive when used in recommended dosages (Estivill et al., 2003).

As discussed for eszopiclone, there is an increased risk of infection with zopiclone (Joya et al., 2009).

LITHIUM CARBONATE

EFFECT ON RENAL FUNCTION

Lithium is one of the older psychotropic agents still in use. Its benefits in managing mania remain the gold standard of treatment for bipolar disorder. And the robust neurotrophic effects of lithium continue to inspire research into its potential for other diseases, such as Alzheimer's disease (Diniz, Machado-Vieira, & Forlenza, 2013). Lithium has been used clinically for centuries. Moving into the 1900s, lithium was

often used as a sedative or a treatment for gout. In the 1940s it was recommended as a “salt substitute” for patients with cardiovascular disease. This use of lithium led to marked toxicity in a vulnerable population, and by 1949 the drug was banned as too toxic for clinical use (Maletzky & Shore, 1978). That very year, however, Cade began publishing his studies of lithium in mania. Cade’s thoughtful assessment of lithium’s potential in the management of “psychotic excitement,” including comments about the toxicity of lithium, inspired its reintroduction for clinical use (Cade, 1949). With the introduction of anticonvulsants for use in bipolar disorder, and more recently the atypical antipsychotics, use of lithium has been replaced or deferred in many patients. But lithium, with all of its potential benefits and side effects, remains an important therapeutic tool and frequent source of medical concern.

The primary metabolic consideration in the use of lithium in medically ill patients is renal function. Lithium is excreted by the kidney, and rates of excretion are affected by age and creatinine clearance. Before starting lithium, all patients require a routine assessment of renal function via measurement of serum electrolytes, blood urea nitrogen (BUN), and creatinine, along with a standard urinalysis. In patients with known or suspected kidney disease, a 24-hour urine collection to determine baseline creatinine clearance should also be obtained. Lithium excretion is primarily determined by glomerular filtration rate (GFR) and proximal reabsorption. Lithium is filtered freely at the glomerulus; then, approximately 55% of filtered lithium is reabsorbed in the proximal tubule (DePaulo, 1984) and a further 15% is reabsorbed in the descending loop. Sodium depletion increases the reabsorbed fraction of both sodium and lithium ions up to 95%, therefore decreasing clearance of lithium. Thiazide diuretics that act primarily at the distal tubule enhance proximal reabsorption of lithium because they deplete sodium, leading to enhanced proximal reabsorption of sodium and lithium. Loop diuretics such as furosemide appear to have less effect on lithium clearance, although they can deplete sodium as well. Potassium-sparing diuretics such as spironolactone and triamterene also may reduce lithium clearance, although they have been less well studied than other diuretics. Lithium toxicity has been reported with nonthiazide diuretics, however, such as indapamide (Hanna, Lobao, & Stewart, 1990).

Medications such as acetazolamide, theophylline, and aminophylline, which act as diuretics by inhibiting proximal tubular reabsorption, increase lithium excretion moderately and may therefore decrease serum levels. Nonsteroidal antiinflammatory drugs including indomethacin, ibuprofen, phenylbutazone, and piroxicam decrease renal lithium clearance and increase lithium levels (Ragheb, 1990; Rogers, 1985). Aspirin and sulindac, however, apparently have no effect on lithium clearance.

Patients on thiazide diuretics usually need approximately 50% less lithium to attain therapeutic levels, but there is considerable interindividual variation. Patients on diuretics should be dosed slowly, and lithium levels should be monitored at least twice a week during the initiation of therapy. Frequent monitoring of levels should be resumed for a few weeks after any change in diuretic dosage or in diet. Patients on diuretics

and their families deserve especially detailed warnings about the early signs of lithium intoxication; commercially available bracelets with imprinted medical warnings are appropriate for some patients. A report showed that furosemide (a loop diuretic) does not increase serum lithium as much as the distal tubular diuretic hydrochlorothiazide (Crabtree et al., 1991).

Lithium is dialyzable. Therefore, lithium should be given to patients after dialysis, with the usual dose being 300–600 mg by mouth. The dose need not be repeated until after the next dialysis. Serum levels of lithium should be taken several hours after dialysis, since plasma levels may actually rise in the postdialysis period when reequilibration with tissue stores occurs (Bennett, Muther, & Parker, 1980). The dialyzability of lithium can be exploited to rapidly reduce lithium levels in life-threatening cases of lithium toxicity. In cases of lithium intoxication, intermittent hemodialysis can also quickly reduce serum lithium levels. Once again, the problem of rebound in serum levels of lithium after discontinuation of hemodialysis requires ongoing monitoring for days, as lithium moves from intracellular compartments to the extracellular space (Sood & Richardson, 2007).

In virtually all patients on lithium there is some loss of the kidney’s ability to concentrate the urine. This develops within 4 to 8 weeks of starting treatment with lithium. Occasionally, this leads to symptomatic polyuria and a diagnosis of nephrogenic diabetes insipidus (NDI). Even when these do not occur, a careful history reveals more frequent urination and larger urine volumes in most patients on lithium. The mechanism of these changes is a direct toxic effect of lithium on the loop of Henle and the distal tubule mediated by interference with the translocation and function of aquaporin-2. The effect is dose related. Usually, stopping lithium allows the renal defect to resolve. However, full recovery can take months or years. In 20% of patients with lithium-induced NDI the condition is permanent and resistant to arginine vasopressin (Bedford et al., 2008). Polyuria may disrupt work or sleep routines and can aggravate incontinence in patients with impaired bladder control. This problem can be partially mitigated by once-daily dosing of lithium.

Because of its potential acute toxicity, as well as its relentless effects on renal function, routine monitoring of renal function during lithium treatment is recommended. During the first 6 months of lithium therapy, renal function should be checked every 2–3 months. In a stable patient receiving chronic lithium therapy, renal function can be checked every 6 months to a year (Jefferson, 2010). Elevations in serum creatinine and reductions in the GFR are indications of possible lithium-induced renal injury. The GFR can be estimated from the serum creatinine. If the GFR falls below 60 mL/minute, as may occur in as many as 1 of 4 patients on lithium therapy for a year, consultation with a nephrologist is advised (Severus & Bauer, 2013). On average, it takes 20 years of lithium treatment to produce end-stage renal disease (Presne et al., 2003). Thyroid function tests should also be obtained. The TSH level, measured at quarterly intervals, is an excellent screen for lithium-induced hypothyroidism in its early asymptomatic stages. Serum electrolyte levels, calcium levels, and thyroid function studies should also be obtained. A baseline ECG is

recommended prior to starting lithium treatment. When to repeat the ECG is largely a clinical decision. Finally, a pregnancy test should be obtained prior to starting lithium, since lithium is a teratogen. When to repeat this test is also a clinical decision.

When lithium-induced polyuria threatens to limit lithium treatment, there are several options open. One option is to shift lithium's contact with the kidney away from the collecting ducts. The treatment of choice in this case is the potassium-sparing diuretic amiloride (Oliveira et al., 2010). Amiloride binds to the epithelial sodium channel in the renal collecting duct and diverts lithium and its effects away from this portion of the kidney. Amiloride may help with this side effect in doses ranging from 5–20 mg per day (Bedford et al., 2008; Kosten & Forrest, 1986). In refractory cases, 50 mg/day of hydrochlorothiazide could be added. With or without adjunctive thiazide therapy, amiloride can increase lithium levels, potentially leading to lithium toxicity if levels are not monitored and dosage adjusted. If amiloride is used alone, hyperkalemia is a risk; electrolytes should be rechecked a few times after starting the drug. If amiloride is used with hydrochlorothiazide, lithium dosage must be reduced.

Thiazide diuretics may also be employed, with suitable precautions, to enhance lithium reabsorption at the proximal tubule, thereby protecting the more distal nephron from high lithium concentrations (Forrest, Cohen, & Torretti, 1974; Lippman, Wagemaker, & Tucker, 1981; MacNeil, Hanson-Nortey, & Paschalis, 1975; Mukhopadhyay, Gokulkrishnan, & Mohanaruban, 2001). The total lithium dose is reduced by as much as 50% if this strategy is used.

Angiotensin converting enzyme (ACE) inhibitors used in the treatment of hypertension have been reported to have a pharmacokinetic interaction with lithium. This may be due to ACE inhibitors–induced lithium retention (Baldwin & Safferman, 1990; Roughead, Kalisch, Barratt, & Gilbert, 2010). If the two classes of drugs are used together, lithium levels must be monitored closely (Doust-Blazy et al., 1986) for elevations of lithium levels. Similar problems have been reported with most ACE inhibitors, including enalapril, captopril, and lisinopril.

As a cation, lithium competes with other cations at various sites, including calcium, magnesium, potassium, and sodium. A host of ECG changes and cardiac effects can occur during lithium treatment. Among the changes that occur are QT prolongation and changes in the ST segment and T wave. These changes may result from a cumulative effect of lithium on cardiac tissues, and in intoxication (Kayrak et al., 2010). A normal serum lithium level does not mean that there is no potential for cardiotoxicity. Sinus node dysfunction and sinoatrial node block have been described, as well as rare episodes of ventricular irritability, even at therapeutic levels (Mitchell & MacKenzie, 1982). The most common cardiac abnormality associated with lithium in therapeutic doses is sinoatrial node dysfunction; aggravation of ventricular arrhythmias and heart block have been very rarely reported (Horgan et al., 1973; Jaffe, 1977; Tangedahl & Gau, 1972; Tilkian et al., 1976). In contrast, antiarrhythmic effects of lithium have also been described (Leonard et al., 2011; Levenson et al., 1986;

Polumbo et al., 1973). Clinically significant cardiovascular side effects of lithium, however, are sufficiently rare that they are seldom relevant to drug choice even in patients with cardiovascular disease. Electrocardiograms made before and after initiation of lithium therapy are an appropriate precaution for patients with asymptomatic abnormalities of cardiac conduction or repolarization. In patients with symptomatic arrhythmias, appropriate monitoring during initiation of lithium therapy should be worked out in collaboration with a cardiologist. Rarely, lithium may cause hypercalcemia by inducing parathyroid adenomas and elevated PTH levels, which can lead to EKG abnormalities and arrhythmias (Wolf et al., 1998). Lithium-induced thyroid dysfunction is another potential cause of arrhythmias.

Hypothyroidism and goiter are two common complications of lithium therapy. Although as many as 50% of patients may develop one or both of these abnormalities, clinically significant thyroid disease likely occurs much less frequently. Hypothyroidism may occur within the first few months of lithium treatment, but on average it takes about 18 months to develop. At-risk groups include women, those over 50 years old, patients who are positive for thyroid autoantibodies, and those with a family history of thyroid disease (Kibirige, Luzinda, & Ssekitoileko, 2013). Hyperthyroidism may also result from lithium therapy, but it is rare. Perhaps 1%–2% of patients chronically receiving lithium will develop hyperthyroidism (Bocchetta et al., 2007). In patients with known hypothyroidism, lithium is safe provided adequate thyroid replacement is given. Patients with Hashimoto's disease may have fluctuating thyroid levels; when they are treated with lithium, fluctuations may increase because lithium can cause increases or decreases in thyroid antibody levels. Obtaining TSH and free thyroxine levels is advisable whenever there is an unexplained change in physical or mental status in a patient with Hashimoto's disease who is taking lithium (Lazarus, 1986).

Both elderly patients and patients with brain disease are particularly susceptible to developing mild cognitive dysfunction, delirium, and tremor, even at therapeutic lithium levels (Babinsky & Levene, 2012; Stoudemire & Moran, 1998). Dosage aiming for the lower end of the therapeutic range is therefore recommended for elderly individuals and others susceptible to the neurologic side effects of lithium (Delva & Hawken, 2001). Maintenance doses of lithium for elderly patients usually are about 50% of the maintenance doses required in younger individuals. When lithium is used to potentiate tricyclics in elderly patients with unipolar depression, doses may be even smaller. At times, doses as small as 150 mg/day may yield therapeutic effects, with much less likelihood of CNS toxicity than with full antimanic dosage (Kushnir, 1986). If cognitive problems develop with lithium in elderly patients, valproate or an atypical antipsychotic such as risperidone may be considered as alternative agents. A syndrome of irreversible lithium-effectuated neurotoxicity, referred to as "SILENT," may develop. SILENT is characterized by persistent evidence of neurologic injury 2 months after discontinuation of lithium. SILENT may develop at any age. A characteristic feature of SILENT is the presence

of cerebellar or brainstem findings. It is thought that injury to myelin may be involved in the pathophysiology of this side effect (Adityanjee, Munshi, & Thampy, 2005; Khanna & Sethi, 1993).

Lithium can be a risk factor for complications during electroconvulsive therapy (ECT). Lithium can prolong neuromuscular blockade induced by succinylcholine or pancuronium (Blackwell & Schmidt, 1984). Inhibition of acetylcholinesterases by lithium may explain this drug–drug interaction (Petraglio et al., 2008). If possible, lithium therapy should be discontinued during ECT treatment and prior to elective surgery. The aggravation of post-ECT confusion and amnesia by lithium in some patients is another reason to discontinue lithium during ECT (Naguib & Koorn, 2002). If lithium must be given during a course of ECT, the serum lithium level should be maintained at the lower end of therapeutic (Thirthalli, Harish, & Gangadhar, 2011).

LITHIUM IN CHRONIC RENAL FAILURE

Although lithium is not recommended in the presence of acute renal failure, there is no evidence that it is necessarily contraindicated in chronic renal failure (CRF) (DasGupta & Jefferson, 1990). In one study of patients with CRF continued on lithium, there is a trend toward a gradual decline in estimated GFR over 60 months compared to no decline in estimated GFR among patients with CRF whose lithium treatment was discontinued (Rej, Abitbol, Looper, & Segal, 2013). Thus, CRF is not an absolute contraindication to lithium therapy but must be weighed against the possible therapeutic advantages of continuing lithium versus stopping lithium. Lithium doses should be adjusted downward to accommodate decreases in creatinine clearance (Chiu, Shen, Chen, & Lu, 2007; Csernansky & Hollister, 1985). Since it is not known if lithium accelerates the progression of certain types of renal disease, close monitoring is indicated in patients with chronic renal disease (such as semiannual creatinine clearance determination or quarterly BUN/creatinine levels). Alternative mood-stabilizing agents such as carbamazepine, valproate, and atypical antipsychotics should be considered if not contraindicated for other reasons. The use of lithium in hemodialysis appears to be both safe and effective if lithium doses are reduced to the range of 300–600 mg and if lithium doses are given after hemodialysis (Bjarnason et al., 2006; Lippman, Manshadi, & Gultekin, 1984; Port, Kroll, & Rosenzweig, 1979; Stoudemire & Fogel, 1995).

Since renal transplantation has become a relatively common procedure, clinicians increasingly will encounter renal transplant patients requiring lithium therapy for bipolar disorder or for mood disorders secondary to corticosteroids. Experience with the use of lithium in transplant recipients remains quite limited, but there are a few reports of its successful implementation (Blazer, Petric, & Wilson, 1976; Koecheler et al., 1986). Koecheler et al. recommended more conservative use of lithium in patients receiving cadaveric transplants, because their renal function is more unstable than in those with living related donor transplants. Cyclosporine can elevate lithium levels by decreasing

lithium excretion, so lithium doses may need to be adjusted downward in patients receiving this drug (DasGupta & Jefferson, 1990; Dieperink et al., 1987; Vareesangthip et al., 2004; Vincent, Weimar, & Schalekamp, 1987). Close monitoring of lithium levels is essential given that the transplant's function may be unstable for weeks following transplantation. In animal models and in patients, the combination of lithium with cyclosporine can be synergistically nephrotoxic (Tariq, Morais, Sobki, Al Sulaiman, & Al Khader, 2000).

DRUG INTERACTIONS

Table 21.7 summarizes clinically significant drug interactions with lithium (Adan-Manes, Novalbos, López-Rodríguez, Ayuso-Mateos, & Abad-Santos, 2006; Beijnen, Bais, & tenBokkelHuink, 1994; Dick, Towler, Whiting, & Forrester, 1992; Gardner & Lynd, 1998; Ma, Shiah, Chang, Kao, & Lee, 2012; Preskorn, 2007; Shirley, Walter, & Noormohamed, 2002; Su, Chang, & Hwang, 2007; Torre, Menon, & Power, 2009; Türck, Heinzel, & Luik, 2000.). Concurrent use of a tetracycline for lithium-induced acne may slightly lower lithium levels, but the effect is of no real clinical significance (Frankhauser et al., 1988).

Movement disorders, including cerebellar and extrapyramidal, may develop during lithium treatment (Lloyd, Perkins, & Schwartz, 2010). When this occurs, the clinician should suspect lithium toxicity (Reed, Wise, & Timmerman, 1989). At other times, a pharmacodynamic drug–drug interaction may be responsible (Bondon-Guitton et al., 2011). Choreoathetosis is a striking example of such a drug interaction with lithium. Choreoathetosis has been observed in one case when lithium was combined with verapamil (Helmuth et al., 1989). Other involuntary movements have been reported with the combined use of verapamil and lithium (Price & Giannini, 1986).

LITHIUM, DIABETES, AND THE METABOLIC SYNDROME.

The role of lithium in producing the metabolic syndrome or diabetes is unclear. Some studies suggest a greater risk of having the metabolic syndrome among bipolar patients treated with lithium versus those treated with carbamazepine, valproic acid, or antipsychotics (Ezzaher et al., 2011). There is evidence to suggest that, at least in some patients, lithium can decrease glucose tolerance (DasGupta & Jefferson, 1990). However, increased glucose tolerance also has been reported as a lithium effect (Vendsborg, 1979). Confounding these studies is the fact that mania and psychosis both impair pancreatic beta-cell function, which in turn promotes insulin resistance (Shiloah et al., 2003). Although glucose tolerance curves may be affected by lithium in some patients, there is no strong evidence that this is a clinically significant effect in the vast majority of patients nor is there evidence to suggest the need for routine glucose monitoring in patients treated with lithium other than diabetic patients with unstable control of

Table 21.7 DRUG INTERACTIONS WITH LITHIUM

MEDICATION	INTERACTIVE EFFECT
Thiazide diuretics	Raise lithium levels
Spirolactone	
Triamterene	
Enalapril	
Nonsteroidal antiinflammatory drugs (e.g., indomethacin, ibuprofen, meloxicam, phenylbutazone, piroxicam)	
Telmisartan	
Valsartan	
Cyclosporin	
Acetazolamide	
Theophylline	
Aminophylline	Lower lithium levels
Caffeine	
Theophylline	
Cisplatin	
Calcium channel blockers	
	May either raise or lower lithium levels, effects not clear; verapamil may cause bradycardia when used with lithium
Metronidazole	May increase lithium levels; may increase chances of nephrotoxicity
Tetracycline	Minor elevation of lithium levels
Antipsychotics	Pharmacodynamically increase the risk of neuroleptic malignant syndrome during lithium treatment
Serotonergic agents (e.g., SSRIs, MAOIs, venlafaxine, triptans)	Pharmacodynamically increases risk of serotonin syndrome during lithium treatment

blood glucose, who would undoubtedly be monitored closely anyway (DasGupta & Jefferson, 1990). Weight gain caused by lithium may be a factor to consider. As many as 30% of patients on chronic lithium therapy will gain 4 to 10 kilograms (Grandjean & Aubry, 2009).

LITHIUM AND EPILEPSY

Lithium administration is associated with EEG changes. Especially in overdose, lithium may induce seizures. Since nonconvulsive status epilepticus (NCSE) is one type of seizure that can occur in lithium intoxication, monitoring of the serum lithium level and making use of the EEG when patients on lithium develop altered mentation are very important (Yip & Yeung, 2007). Note that NCSE may be caused by lithium even when the serum lithium level is therapeutic

(Bellesi, Passamonti, Silvestrini, Bartolini, & Provinciali, 2006). However, lithium is not contraindicated for patients with epilepsy. A series of bipolar patients treated with lithium suggested that lithium may be benign in patients with epilepsy (Shukla, Mukherjee, & Decina, 1988). In an open study of eight patients, lithium levels were maintained in the 0.6 to 1.1 mEq/liter range, and concurrent anticonvulsants were limited to phenytoin and phenobarbital (no patients were on carbamazepine, sodium valproate, or clonazepam). Lithium prevented the recurrence of affective episodes without increasing seizure frequency in patients with incompletely controlled seizures and did not induce any seizures in well-controlled patients.

Although lithium should not be dismissed because of an undue concern about aggravation of seizures, the mood-stabilizing anticonvulsants carbamazepine and sodium valproate are natural alternatives for patients with concurrent bipolar disorder and epilepsy. When lithium and anticonvulsants are given simultaneously, pharmacodynamic interactions may lead to CNS side effects at lithium levels within the therapeutic range (Fogel, 1988), so the upper end of the therapeutic range of lithium levels usually should be avoided. A classic example of this would be cerebellar ataxias at therapeutic doses of phenytoin combined with lithium (Manto, 2012).

While lithium is problematic in many medically ill and elderly patients, the availability of valproate and of some atypical antipsychotics as antimanic agents has provided excellent alternative drugs for this patient population.

ANTICONVULSANTS AS PSYCHOTROPICS

As noted, in the last several years anticonvulsants have entered the mainstream of psychopharmacologic practice. Carbamazepine (Tegretol), valproate (Depakote, Depakene), and lamotrigine (Lamictal) and topiramate (Topamax) all have been widely employed for psychiatric indications. Anticonvulsants have found a particularly important place as alternatives or adjuncts to lithium in the treatment of bipolar disorder (Goodwin & Jamison, 1990; Pope et al., 1991; Prien & Gelenberg, 1989).

CARBAMAZEPINE

Issues to be considered when prescribing carbamazepine to medically ill patients include hematologic toxicity, hepatic toxicity, quinidine-like effects on cardiac conduction, antidiuretic actions, enzyme induction leading to drug interactions, clinical interpretation of carbamazepine blood levels, and management of carbamazepine overdose. Drug interactions are summarized in Table 21.8 (Bauler et al., 2012; Brzaković et al., 2012; Chrościńska-Krawczyk et al., 2011; Contin et al., 2002; Glue et al., 1997; May et al., 2007; Sockalingam et al., 2013; Spina, Pisani, & Perucca, 1996; Strack, Leckband, & Meyer, 2009; Yamamoto et al., 2012).

**Table 21.8 SELECTED DRUG INTERACTIONS
WITH CARBAMAZEPINE**

MEDICATION	INTERACTIVE EFFECT
Erythromycin	May raise carbamazepine to toxic levels and precipitate heart block
Antiarrhythmics	May have additive effects on cardiac conduction time
Fluoxetine	May raise carbamazepine levels to toxic levels
Cimetidine	
Diltiazem	
Verapamil	
Acetazolamide	
Grapefruit juice	
Danazol	
Metronidazole	
Propoxyphene	
Nefazodone	
Quinidine	
Carbamazepine	
Felbamate	
Lamotrigine	
Phenytoin	
Pregabalin	Serum levels lowered by carbamazepine
Topiramate	
Valproate	
Warfarin	
Fluindione	
Tricyclic antidepressants	
Neuroleptics	
Propranolol	
Cyclosporine	
Boceprevir	
Telaprevir	
Theophylline	
Phenobarbital	
Phenytoin	
Warfarin	Decreases serum levels of carbamazepine and increases concentrations of carbamazepine's epoxide metabolite
Oral contraceptives	
Caffeine	Decreases levels of carbamazepine; phenytoin levels decrease when used with carbamazepine
	Carbamazepine causes increased metabolism of anticoagulants due to hepatic enzyme induction
	Carbamazepine reduces efficacy; loss of contraceptive effect possible
	Reduces anticonvulsant efficacy of carbamazepine and other anticonvulsants

One of the more important pharmacokinetic actions of carbamazepine is the induction of its own metabolism, as well as many other drugs metabolized through hepatic cytochromes P450. This effect typically takes 10 to 14 days to become maximal. At this time the serum level of carbamazepine should be checked, as it may become subtherapeutic. The same is true for many other medications coadministered with carbamazepine. P-glycoprotein does not appear to be affected by carbamazepine (Magnusson, Dahl, Cederberg, Karlsson, & Sandström, 2008). See also below.

A particularly common and relevant interaction for medical-psychiatric practices is the interaction of carbamazepine with the calcium channel blockers diltiazem and verapamil. These two drugs, but not nifedipine, raise carbamazepine levels substantially, frequently producing toxicity such as ataxia if carbamazepine dosage is not lowered (Bahls, Ozuna, & Ritchie, 1991; Wijdicks, Arendt, & Bazzell, 2004). Carbamazepine is now available in long-acting preparations.

HEMATOLOGIC TOXICITY

When carbamazepine was first introduced in the United States, the manufacturer recommended frequent blood counts because of concerns about the development of agranulocytosis. However, as evidence accumulated that these potentially fatal side effects were rare and idiosyncratic, this recommendation has been modified by major national clinical neurological associations. Present practice regarding monitoring for hematologic interactions is based on the idea that there are two different hematologic reactions to carbamazepine.

One reaction is a predictable and often transient drop in both red and white blood cell counts; the other is a rare and idiosyncratic failure of the bone marrow that can occur at any unpredictable time after initiation of therapy. Leukopenia occurs in 7% to 12% of treated patients. Leukopenia apparently is unrelated to aplastic anemia, which occurs in approximately 1 in 575,000 treated patients per year (Seetharam & Pellock, 1991). Among psychotropics, carbamazepine is second only to clozapine in causing severe blood dyscrasias (Stübner et al., 2004).

When patients have preexisting anemia or neutropenia, the predictable drop in red and white blood cell counts induced by carbamazepine occurs at a lower baseline. However, there is no evidence that patients with preexisting blood disorders are at greater risk in general for the life-threatening complications of aplastic anemia and agranulocytosis. Therefore, preexisting cytopenias are relative but not necessarily absolute contraindications to carbamazepine. The authors recommend that hematologic consultation be obtained prior to initiating carbamazepine in any patient with a baseline hemoglobin below 12 g/dl or a white blood cell count below 4000/mm³. The consultant should be asked both for an individualized assessment of risk and for specific guidelines for monitoring and drug discontinuation if carbamazepine is begun.

Caution should be used when combining carbamazepine with other drugs known to cause severe blood dyscrasias, such as agranulocytosis. Ticlopidine, spironolactone, and antithyroid drugs are among the many agents that can affect blood cell production (Ibáñez, Vidal, Ballarín, & Laporte, 2005). It is tempting to consider combining carbamazepine with agents that increase blood cell counts. For example, lithium is known to increase serum white cell counts, in part through enhanced release and action of granulocyte colony-stimulating factor (G-CSF) (Focosi, Azzarà, Kast, Carulli, & Petrini, 2009). Patients receiving combined therapy with lithium and carbamazepine may be at somewhat less risk for a lowering of the white cell count because of lithium's mild stimulatory effects on white cell production (Brewerton, 1986; Vieweg et al., 1986–87). However, leukopenia has been reported with combined therapy (Sheehan & Shelley, 1990).

HEPATIC TOXICITY

In general, carbamazepine should be avoided, or only cautiously introduced, to children and to patients with preexisting liver disease, alcohol abuse or dependence, or patients with chronic acetaminophen use (Ferrajolo et al., 2010; Sedky, Nazir, Joshi, Kaur, & Lippmann, 2012). This is because, as in the case of hematologic toxicity, hepatic toxicity from carbamazepine comes in two kinds: frequent, predictable, and benign; and rare, idiosyncratic, and life threatening (Dreifuss & Langer, 1987). The relatively benign form of toxicity, seen in no more than 5% of patients (Jeavons, 1983), consists of mild asymptomatic elevations of AST and ALT, usually to less than twice the upper limit of their normal values. The life-threatening toxicity is acute hepatic necrosis with liver failure, occurring in less than 1 in 10,000 treated patients. Only 21 cases of this severe hepatic toxicity were reported in the first 20 years of carbamazepine's clinical use (Jeavons, 1983). Severe hepatic toxicity occurs unpredictably, usually within the first month of therapy but occasionally after several months of uneventful treatment. All patients should be advised to report for an examination and tests of liver enzymes should they develop anorexia, nausea, vomiting, or upper abdominal pain. Elevations of AST and ALT to less than twice the upper limit of normal would not necessitate discontinuation of the drug. Greater elevations would trigger either drug discontinuation or consultation with a gastroenterologist or a specialist in liver diseases.

In regard to monitoring liver enzymes, it should be noted that the gamma-glutamyl transpeptidase (GGT) level can be markedly elevated by carbamazepine, as well as by other anticonvulsants, in the absence of clinical symptoms of liver disease (Jeavons, 1983). An isolated elevation of GGT, even to high levels, would indicate consultation with a gastroenterologist but not necessarily discontinuation of the drug. A full panel of liver function tests, including a prothrombin time, should be taken into account when evaluating the significance of an elevated GGT level.

Prescription of carbamazepine to patients with preexisting liver disease has two risks (Sedky et al., 2012). The first is that any hepatic reaction to carbamazepine will occur on a lower baseline of liver function, so that a mild reaction could become symptomatic. The second is that carbamazepine will be metabolized more slowly, since its primary route of metabolism is hepatic. For this reason, significant liver disease is a relative contraindication to carbamazepine. Consultation with an internist should be obtained before prescribing carbamazepine to a patient with significant liver disease. In patients such as alcoholics who are at risk for liver disease that is not necessarily apparent on routine screening liver function tests, carbamazepine should be started more slowly than usual, with frequent determinations of liver enzymes, prothrombin time, and carbamazepine levels during the initiation of therapy.

EFFECTS ON CARDIAC CONDUCTION

Carbamazepine is similar in chemical structure to the TCAs and has similar effects on the heart, with the potential for slowing conduction through the AV node and suppressing ventricular automaticity (Benassi et al., 1987). It does not, however, apparently affect the QRS complex or QT interval at normal heart rates (Kenneback et al., 1991). Symptomatic heart block has been reported when carbamazepine has been given to patients with known or suspected preexisting cardiac disease (Beerman & Edhag, 1978), and cardiac rhythm disturbances are a feature of severe carbamazepine overdose. Therefore, pretreatment ECGs are warranted prior to carbamazepine therapy. If the ECG shows more severe block than first-degree AV block, right bundle-branch block, left anterior hemiblock, or asymptomatic Mobitz type I (Wenckebach-type) block, carbamazepine should not be prescribed on an outpatient basis unless the patient has been cleared first by a cardiologist (Jankovic & Dostik, 2012). In patients with benign, asymptomatic forms of heart block, a posttreatment ECG should be obtained to rule out aggravation of the heart block by carbamazepine. Valproate would be an excellent alternative drug for bipolar patients with cardiac disease.

ANTIDIURETIC ACTIONS OF CARBAMAZEPINE

Carbamazepine has an antidiuretic action and is associated both with clinically significant hyponatremia and with mild, asymptomatic reductions in serum sodium (Letmaier et al., 2012). The effect is thought to be via a direct action on the renal tubules. Patients with other factors predisposing to hyponatremia, including advanced age, diuretic use, and congestive heart failure, are especially at risk. They should have electrolyte determinations weekly during the first month of carbamazepine therapy, with additional determinations done if there is any change in mental or physical status or if there are significant changes in carbamazepine dosage or in their other medications.

As suggestions for practical management of carbamazepine-induced hyponatremia, the authors offer the following recommendations.

1. If the sodium level drops below 125 mEq/liter on carbamazepine, the drug should be discontinued.
2. If the sodium level drops to between 125 and 130 mEq/liter, and carbamazepine appears clinically useful, other drugs that may aggravate hyponatremia (such as thiazide diuretics) should be discontinued if possible. If the sodium level still remains below 130 mEq/liter, carbamazepine should be discontinued.
3. If the sodium level is between 130 and 135 mEq/liter, discontinuation of carbamazepine is not necessary but electrolytes should be followed weekly for 1 month to assure stability of the level. Serum sodium should be rechecked immediately if mental status changes.
4. An evaluation for SIADH should be carried out if the sodium level remains below 130 mEq/liter after carbamazepine discontinuation and is not otherwise explained (e.g., by congestive heart failure).
5. Discontinuation of long-term carbamazepine, when indicated by a low sodium level, should be gradual to avoid withdrawal phenomena such as cholinergic rebound or seizures.
6. When carbamazepine is being used for the indication of seizures, an alternate anticonvulsant less likely to cause hyponatremia should be initiated prior to tapering carbamazepine (e.g., phenytoin or valproate).

ENZYME INDUCTION LEADING TO DRUG-DRUG INTERACTIONS

Carbamazepine is known to be a potent inducer of the cytochrome P450 system. As such, it influences the metabolism of all drugs that rely on this system for their metabolism. One well-known consequence of enzyme induction is that it decreases its own serum level with increased dosages and induces its own metabolism; hence the need to gradually build up carbamazepine dosage over the first few weeks of treatment to maintain a steady blood level. Two other consequences are clinically significant. The first is that the blood levels of some drugs may drop if carbamazepine is added to the patient's medication regimen. This has been reported for benzodiazepines, with potentially clinically significant withdrawal when carbamazepine is added to a steady dosage of alprazolam, midazolam, triazolam, and other benzodiazepines (Arana et al., 1988; Yuan, Flockhart, & Balian, 1999). A similar concern exists for antipsychotics combined with carbamazepine, including aripiprazole, clozapine, haloperidol, quetiapine, risperidone, ziprasidone, and other agents metabolized through such cytochromes P450 as 3A4 (Arana et al., 1986; Besag & Berry, 2006; Strack, Leckband, & Meyer, 2009). Valproate levels for a given dose decrease when carbamazepine is given concurrently (Ieiri

et al., 1990); a similar effect has been reported on imipramine levels in children (Brown et al., 1990). Concurrent use of valproate with carbamazepine also increases the levels of the toxic epoxide metabolite of carbamazepine. Serum moclobemide levels are similarly reduced by carbamazepine (Rakic, Miljkovic, Todorovic, Timotijevic, & Pokrajac, 2009).

Carbamazepine may induce the metabolism and undermine the efficacy of agents used to treat HIV and AIDS. Serum levels of agents such as efavirenz and nevirapine may be lowered by coadministration of carbamazepine (Birbeck et al., 2012). Data on such interactions is limited, which means the clinician must proceed with caution when combining carbamazepine with antiviral agents.

The second effect is that drug metabolites not ordinarily clinically significant might be present in larger quantities as a result of carbamazepine-induced induction of metabolic enzymes. Hydroxymetabolites of desipramine have been reported to cause EKG changes in a patient concurrently treated with carbamazepine and desipramine, despite a desipramine level in the therapeutic range (Baldessarini et al., 1988; see discussion in TCA section of this chapter).

A practical implication of these observations with carbamazepine is that blood levels of drugs metabolized by the liver should be determined promptly if unexpected toxicity or lack of therapeutic effect occurs in the context of concurrent carbamazepine therapy. Furthermore, toxicity in the presence of apparently therapeutic blood levels is possible on the basis of unusually great concentrations of unmeasured metabolites. Specifically, medically ill patients on combined carbamazepine and tricyclic therapy should have posttreatment ECGs even if tricyclic blood levels appear normal.

CLINICAL INTERPRETATION OF CARBAMAZEPINE BLOOD LEVELS

Carbamazepine blood levels are published for the use of carbamazepine in the treatment of epilepsy. Typical normal ranges are 8–12 ng/ml for single-drug therapy and 4–8 ng/ml for combined therapy with other anticonvulsants. However, when carbamazepine is used as a psychotropic, or when it is used together with other medications in medically ill patients, the interpretation of levels is subject to several caveats. First, since carbamazepine is heavily protein-bound, free carbamazepine levels, on which both therapeutic and toxic effects depend, can vary if other drugs displace carbamazepine from its protein binding sites. This has been reported for agents as ubiquitous as aspirin. Second, pharmacodynamic interactions can induce neurotoxicity of carbamazepine at therapeutic blood levels when the drug is given in conjunction with other psychotropics (Fogel, 1988). This has been reported for coadministration with haloperidol and with lithium, although such reports have all but disappeared from the literature. The neurotoxicity of combined carbamazepine–lithium therapy has been shown to be additive rather than synergistic (McGinness, Kishimoto, & Hollister, 1990). Third,

the level of carbamazepine needed for maximum psychotropic effect may be greater than the level optimal for seizure control.

Finally, usually unmeasured metabolites, such as carbamazepine 10,11-epoxide, can contribute to both therapeutic and toxic effects. While the ratio of the parent compound to the epoxide is fairly predictable among medically well persons, it may vary in the medically ill, particularly in the setting of liver disease or polypharmacy. As noted earlier, the combination of carbamazepine with valproate can produce toxic levels of carbamazepine 10,11-epoxide (Rambeck et al., 1990). A similar effect is seen when probenecid or a barbiturate is combined with carbamazepine (Kim, Oh, Park, & Park, 2005). In general, coadministered medications, younger age, larger doses of carbamazepine, and timing of carbamazepine doses may all influence the extent to which the epoxide is formed (Lanchote et al., 1995). For all these reasons, scrupulous and frequent clinical monitoring clinical reassessments must supplement blood levels in evaluating carbamazepine effect. Serum free carbamazepine and 10,11-epoxide levels can be obtained to supplement clinical observations.

MANAGEMENT OF CARBAMAZEPINE OVERDOSE

Because carbamazepine has been increasingly prescribed both as an anticonvulsant and psychotropic, the incidence of carbamazepine overdose has been increasing. The problems of carbamazepine overdose include coma, seizures, hypotension, and cardiac arrhythmia. The general approach to supportive management is similar to that used for TCA overdose. In treating carbamazepine overdose, vigorous use of activated charcoal and laxatives is helpful because the absorption of carbamazepine is quite slow, and much may remain in the intestine at the time the patient presents for emergency treatment. In cases of severe carbamazepine intoxication, hemodialysis can reduce serum carbamazepine levels (Ozhasenekler, Gökhan, Güloğlu, Orak, & Ustündağ, 2012). Hemodialysis can remove both carbamazepine and its 10,11-epoxide metabolite (Harder, Heung, Vilay, Mueller, & Segal, 2011). The phenomenon of prolonged absorption can lead to a recurrence of coma following apparent recovery as a result of the eventual absorption of drug remaining in the intestine (Fisher & Cysyk, 1988; Sethna et al., 1989). For this reason, patients with serious carbamazepine overdose should be observed in the hospital for a full 24 hours following the return of consciousness.

VALPROATE

Depakene is valproic acid, and Depakote is divalproex sodium, which is a stable compound of sodium valproate and valproic acid formed by the neutralizing effects of sodium hydroxide. Hence, sodium valproate causes fewer gastrointestinal side effects and is much better tolerated than valproic acid.

Issues to be considered when prescribing valproate to medically ill patients include (1) gastrointestinal side effects, (2) hepatic toxicity, (3) effects on coagulation, (4) drug interactions, (5) clinical interpretation of blood levels, and (6) management of overdose.

GASTROINTESTINAL TOXICITY

In comparative studies of anticonvulsant side effects, the most prominent and troublesome side effect of valproate has been nausea, often accompanied by vomiting. Medically ill patients, particularly those with diseases predisposing to nausea, may be at increased risk. Since valproate is much less likely to cause gastrointestinal upset than valproic acid, more frequent dosing, preferably after meals, is almost always better tolerated than larger doses taken fewer times per day. Occasional patients will be better on valproic acid syrup or Depakote "sprinkles," a pediatric preparation designed to be sprinkled on food. However, regardless of the preparation used, some patients simply will be unable to tolerate the drug. As noted earlier, we rarely have gastrointestinal problems with Depakote if it is taken on a full stomach. Elevated amylase levels may occur with valproic acid.

HEPATIC TOXICITY

Shortly after valproic acid was first introduced, there were several deaths from acute hepatic necrosis, and, as of 1988, approximately 100 fatalities had been reported from valproate-induced liver failure (Scheffner et al., 1988). These and subsequent cases inspired much research into the link between valproic acid use and liver injury (Neyns, Hoorens, & Stupp, 2008). These deaths also led to considerable caution in the use of the drug. As experiences have accumulated, however, it appears that hepatic necrosis is a major risk only for children under 2 years, particularly those given multiple-drug therapy for epilepsy.

Overall, the risk of severe liver injury with valproic acid is low (Gerstner et al., 2008). The incidence of hepatic necrosis in adults receiving valproate is well under 1 in 10,000 (Eadie, Hooper, & Dickinson, 1988) and may be as low as 1 in 50,000, with 95% of reported cases developing symptoms within the first 6 months of therapy (Scheffner et al., 1988). Given this very infrequent occurrence of life-threatening hepatic toxicity, routine long-term monitoring of liver function tests does not seem necessary unless patients have some form of liver disease or a history of liver disease. Periodic liver function tests for the first 6 months are a reasonable precaution but, as noted above, are not recommended as routine for all patients. All patients should be warned of the early signs of liver disease and be told to report immediately for repeat testing of liver function should those signs develop during valproate therapy. L-carnitine has been used successfully to manage some cases of hepatotoxicity due to valproic acid (Chan, Tse, & Lau, 2007). Hemodialysis is also effective in removing ammonia in hepatic encephalopathy (Thanacoody, 2009).

A much more common (although benign) hepatic effect of valproate is an increase in the serum ammonia level. A twofold increase in serum ammonia levels may be seen in the majority of patients starting treatment with valproic acid. In the vast majority of cases this is an asymptomatic change in liver function (Chicharro, de Marinis, & Kanner, 2007). This elevation in serum ammonia may, however, be of concern in individuals with preexisting liver disease, especially those in whom there is a history of hepatic encephalopathy. Significant liver disease is a relative contraindication to valproate therapy, and close monitoring of both liver enzymes and serum ammonia would be an appropriate precaution with alcoholic patients suspected to have subclinical cirrhosis of the liver. Other risk factors for clinically significant hyperammonemia during valproic acid therapy include doses of greater than 20 mg/kg/day and coadministration of either carbamazepine or topiramate (Yamamoto, Inoue, Matsuda, Takahashi, & Kagawa, 2012). Consultation with a gastroenterologist would be advisable before starting valproate in a patient with known liver or pancreatic disease.

Valproic acid may also cause pancreatitis. Pancreatitis is not dependent on the dose of valproic acid and often occurs when serum valproic acid levels are in the normal range. This is also not a toxicity that tends to develop upon initiation of treatment. Many patients have been tolerating valproic acid for years before they develop pancreatitis (Werlin & Fish, 2006). Fortunately this is an infrequent side effect of valproic acid therapy (Barreto, Tiong, & Williams, 2011).

EFFECTS ON COAGULATION

Valproate therapy can increase the prothrombin time, decrease fibrinogen levels, and reduce the platelet count. These findings, one or more of which may occur in as many as one-third of patients receiving valproate (Rochel & Ehrental, 1983), rarely lead to clinically significant bleeding. Children may be particularly susceptible to valproate-induced coagulopathy (Koenig et al., 2008). Among children, the risk of having a clinically significant valproate-induced coagulopathy is estimated to be 4% for those on chronic valproic acid therapy (Gerstner et al., 2006). Valproate-treated patients should have a full coagulation panel including a platelet count, bleeding time, prothrombin time, and partial thromboplastin time prior to undergoing surgery or dental work, and patients with preexisting anticoagulant therapy or bleeding diatheses require especially close monitoring during initiation of valproate therapy.

Valproic acid may also displace warfarin from serum protein binding sites. When valproic acid is initiated after a therapeutic dose of warfarin has been established, it is possible that a rise in free serum warfarin levels may lead to significant bleeding (Yoon, Giraldo, & Wijdicks, 2011).

DRUG INTERACTIONS

In contrast to carbamazepine, which is an enzyme inducer, valproate inhibits liver enzymes that metabolize other drugs

(Perucca, 2006). Therefore, it can prolong the half-life of other drugs with mainly hepatic metabolism. This effect has been documented for diazepam and the tricyclics, which have a prolonged half-life in the presence of valproate. In general, the coadministration of long-acting benzodiazepines with valproate may be problematic, both because of the prolongation of benzodiazepine metabolism and because of additive sedation and ataxia. If a benzodiazepine must be given to a patient on valproate, lorazepam is a good choice since it is not likely to interact significantly. The full range of drugs that might have altered metabolism in the presence of valproate is not known, so the possibility of drug accumulation should be considered with other drugs that rely primarily on hepatic metabolism.

Interactions of valproate with other anticonvulsants have been studied extensively and are well established (Bourgeois, 1988). Carbamazepine, phenytoin, and phenobarbital all can lower valproate levels (May & Rambeck, 1985; Perucca, 2006). In contrast, valproate increases levels of phenobarbital by inhibiting its metabolism (Redenbaugh et al., 1980) and raises the free fraction of phenytoin by displacing the drug from protein binding sites. This phenomenon can lead to phenytoin toxicity at apparently "therapeutic" phenytoin levels (Bruno et al., 1980).

Of even greater interest to psychiatrists who might be using valproate together with carbamazepine for treatment-refractory mania is the observation that valproate raises the concentration of the carbamazepine 10,11-epoxide metabolite (Pisani et al., 1986). This metabolite, not usually measured, has additive toxicity with its parent drug carbamazepine (Bourgeois & Wad, 1984). Thus, when valproate is given concurrently, carbamazepine can produce toxicity at apparently therapeutic levels because of an increased level of the 10,11-epoxide carbamazepine metabolite.

Aspirin in usual antipyretic doses can raise both total and free valproate levels because of both metabolic enzyme inhibition and displacement of valproate from protein binding sites. Significant toxicity can result (Goulden et al., 1987). Therefore, alternate agents such as acetaminophen would be preferable for treating fever or minor pain in patients on valproate. A opiate-induced fatality has been reported when a child was given hydrocodone in addition to clarithromycin and valproic acid (Madadi et al., 2010). While clarithromycin likely was responsible for the majority of the opiate's accumulation, valproic acid may have contributed.

Pharmacodynamic interactions have been reported between valproate and neuroleptics, with the development of an encephalopathic syndrome with diffuse EEG slowing (Van Sweden & Van Moffaert, 1985) or increased parkinsonism (Puzynski & Klosiewicz, 1984). Valproate toxicity also has been reported to develop when erythromycin was given to a patient on valproate, leading to abrupt elevations in valproate levels (Redington, Wells, & Petito, 1992). A summary of established drug interactions with valproate is listed in Tables 21.9 and 21.10 (Blackford, Enlow, & Reed, 2013; Cervera et al., 2012; Coulter et al., 2013; De Dios, Fudio, & Lorenzo, 2011; de Jong et al., 2007; Diaz et al., 2008; Gu & Huang, 2009; Haslemo, Olsen, Lunde, & Molden, 2012; Lee, Lee, & Heo, 2002; Lin et al.,

Table 21.9 SELECTED DRUG INTERACTIONS WITH VALPROIC ACID/VALPROATE

MEDICATION	INTERACTIVE EFFECT
Benzodiazepines	Sedative effects and serum levels of benzodiazepines increased by valproate (except lorazepam)
Carbamazepine	Lower levels of valproate
Phenytoin	
Phenobarbital	
Phenobarbital	Phenobarbital levels increased by valproate
Phenytoin	Bioavailable phenytoin and carbamazepine increased
Carbamazepine	by valproate by displacing these drugs from their serum protein binding sites
10,11-epoxide metabolite	This metabolite's levels of CBZ increased by valproate of carbamazepine
Tricyclic antidepressants (TCAs)	TCA levels increased by valproate
Chlorpromazine	Increased levels of valproate
Cimetidine	
Salicylates	
Guanfacine	
Anticoagulants (warfarin)	Increased prothrombin times (valproate also inhibits secondary phase of platelet aggregation)

2008; Luszczki, Sawicka, Kozinska, Borowicz, & Czuczwar, 2007; Kim, Hwang, Jeon, & Do, 2012; Michaelis, Ha, Doerr, & Cinatl, 2008; Perucca, 2006; Pisani, 1992; Sandson, Marcucci, Bourke, & Smith-Lamacchia, 2006; Stewart, Nesmith, & Mattox, 2012; Taha, Hammond, & Sheth, 2013; Unterecker, Burger, Hohage, Deckert, & Pfuhmann, 2013; Unterecker, Reif, et al., 2013; Yoon & Kim, 2013).

More recently, the effect of valproic acid on medications intended for HIV and other infections have been explored. Valproic acid may raise serum levels of agents such as lopinavir and zidovudine but not atazanavir, ritonavir, or efavirenz (Birbeck et al., 2012). On the other hand, meropenem lowers serum valproic acid levels and can result in therapeutic failure of the anticonvulsant. Seizures may result (Coves-Orts et al., 2005). This appears to be a class effect of the carbapenems on valproic acid (Mancl & Gidal, 2009). This pharmacokinetic interaction may be exacerbated by the tendency of penicillins to antagonize the GABA-A receptor. Valproic acid also appears to potentiate the replication of human cytomegalovirus, while undermining the antiviral effects of cidofovir, foscarnet, and ganciclovir (Michaelis, Ha, Doerr, & Cinatl, 2008).

While adverse drug interactions abound with valproic acid, there is also evidence that it may be helpful in settings

Table 21.10 EFFECTS OF VALPROATE ON ANTICONVULSANTS AND OTHER DRUGS: POTENTIALLY IMPORTANT INTERACTIONS

DRUG ADMINISTERED WITH DIVALPROEX SODIUM	INTERACTION
Amitriptyline	Adding valproate to amitriptyline can lead to a marked elevation of serum amitriptyline and nortriptyline levels
Antiviral agents	In vitro valproate inhibits the activity of cidofovir, foscarnet, and ganciclovir against human cytomegalovirus
Aspirin	Can displace valproate from protein binding sites and increase serum free valproate levels several-fold
Carbapenem	Serum levels of valproic acid decreased by 90%
Carbamazepine and 10,11-epoxide of CBZ	Serum levels of carbamazepine decreased by 17%. Levels of carbamazepine-10,11-epoxide increased by 45% in patients with epilepsy taking valproate and carbamazepine
Cimetidine	Slows the elimination of valproate, and increases serum valproate levels
Cisplatin	Valproate may enhance sensitivity of tumor cells to cisplatin
Clonazepam	Concomitant use with valproic acid may induce absence status in patients with a history of absence-type seizures.
Clozapine	Valproate significantly lowers serum clozapine levels.
Diazepam	Valproate displaced diazepam from plasma albumin-binding sites and inhibited its metabolism. Coadministration of valproate 1500 mg/day to healthy volunteers increased the free fraction of diazepam (10 mg) by 90%; diazepam plasma clearance decreased by 25% and volume of distribution by 20%. Elimination half-life of diazepam did not change.
Doxepin	Valproate can double serum levels of doxepin plus N-doxepin
Ethosuximide	Valproate inhibited ethosuximide metabolism. Administration of a single 500 mg dose of ethosuximide with valproate (800-1600 mg/day) to healthy volunteers increased ethosuximide elimination half-life by 25% and decreased its total clearance by 15%. Serum levels of both drugs should be monitored in patients receiving valproate and ethosuximide, especially with other anticonvulsants.
Ertapenem	May decrease serum valproate concentrations

(continued)

Table 21.10 CONTINUED

DRUG ADMINISTERED WITH DIVALPROEX SODIUM		DRUG ADMINISTERED WITH DIVALPROEX SODIUM		INTERACTION
Felbamate	Can increase serum valproate levels	Quetiapine	Valproate may occasionally increase serum quetiapine levels significantly	
Furosemide	Appears pharmacodynamically to enhance the anticonvulsant activity of valproate; significance uncertain	Rocuronium	Valproate reduces efficacy of rocuronium, possibly through enhanced elimination of rocuronium	
Imatinib	Valproate may restore sensitivity to imatinib in patients with certain tumors	Rufinamide	Serum rufinamide levels may rise significantly as the serum level of valproate rises	
Irinotecan	Serum levels of the active irinotecan metabolite SN-38 may be significantly lowered in the presence of valproate	Temsirolimus	Valproate reduces the maximum tolerated dose of temsirolimus, with mucositis being the dose-limiting toxicity	
Isoniazid	Can elevate serum valproate concentrations to toxic levels; valproate may also slow elimination of isoniazid	Tolbutamide	In vitro, the unbound fraction of tolbutamide was increased from 20% to 50% when added to plasma samples from patients treated with valproate. The clinical relevance of this displacement is unknown.	
Lamotrigine	Coadministration of valproate to healthy volunteers increased lamotrigine elimination half-life from 26 to 70 hours. The dose of lamotrigine should be reduced when coadministered with valproate	Topiramate	Topiramate may increase risk of hyperammonemia with valproic acid.	
Lorazepam	Valproate can slow elimination of lorazepam and cause stupor or coma	Warfarin	The potential exists for valproate to displace warfarin from its plasma albumin-binding sites. The therapeutic relevance of this displacement is unknown; coagulation tests should be monitored if divalproex sodium is initiated in patients taking anticoagulants.	
Meropenem	As is true for other carbapenems, may rapidly lower serum valproate concentrations	Venlafaxine	Combining valproate with venlafaxine does not affect serum venlafaxine levels, but can significantly elevate serum levels of O-desmethylvenlafaxine	
Olanzapine	Valproate can significantly lower serum olanzapine levels	Zidovudine	In HIV-positive patients, the clearance of zidovudine 100 mg every 8 hours decreased by 38% after administration of valproate 250 or 500 mg every 8 hours; zidovudine half-life was unaffected.	
Phenobarbital	Valproate inhibited phenobarbital metabolism, resulting in a 50% increase in phenobarbital half-life and a 30% decrease in plasma clearance. The fraction of phenobarbital dose excreted unchanged increased by 50%. There is evidence for severe central nervous system depression, with or without significant elevations of barbiturate or valproate serum concentrations. All patients receiving concomitant barbiturate therapy should be monitored closely for neurologic toxicity.	Reprinted from Stoudemire & Moran, 1998. Used with permission.		
Primidone	Primidone is metabolized to a barbiturate and may be involved in a similar interaction with valproate.	other than the neurologic and psychiatric. For example, valproic acid may offer synergistic pharmacodynamic effects when combined with cytarabine for the treatment of pediatric acute myeloid leukemia. In this case, the ability of valproic acid to inhibit histone deacetylase may be of value (Xie et al., 2010). Similar benefits have been reported for the same disease when valproic acid is added to clofarabine or to gemtuzumab (ten Cate et al., 2007; Xie et al., 2012). Such off-label potential benefits require caution when being considered for use, as valproic acid continues to have its usual toxicities. However, if obliged to choose between one anticonvulsant and another in the management of a child with acute myeloid leukemia, this data may provide an argument for choosing valproic acid.		
Phenytoin	Valproate displaced phenytoin from its plasma albumin-binding sites and inhibited its hepatic metabolism. Coadministration of valproate 400 mg twice a day with phenytoin 250 mg to healthy volunteers increased the free fraction of phenytoin by 60%; total plasma clearance and apparent volume of distribution increased by 30%. Both the clearance and the apparent volume of distribution of free phenytoin were reduced by 25%. In patients with epilepsy, breakthrough seizures have occurred with the combination of valproate and phenytoin.			

CLINICAL INTERPRETATION OF BLOOD LEVELS

Therapeutic blood levels for valproate in the treatment of epilepsy usually are reported as 50–125 ng/ml. The work of Bowden, McElroy, Keck, and others suggests that effective blood levels for bipolar disorder are similar and that little clinical effect is seen with blood levels less than 50 ng/ml (Gyulai et al., 2003). Toxic effects begin to occur with levels greater than 100 ng/ml, so the therapeutic index is quite low. Because of individual variations in metabolism of valproate, blood levels should be obtained routinely during upward titration of valproate dosage to assure that the blood level is indeed adequate and to avoid toxicity. Considering the relationship between blood levels and toxicity, it should be noted that toxicity may develop at apparently therapeutic levels when the patient is on multiple drugs, whereas levels above the usual therapeutic range may be tolerated in the context of single-drug therapy.

MANAGEMENT OF VALPROATE OVERDOSE

Because valproate is not toxic to the heart, patients receiving aggressive support have tolerated massive valproate overdoses, including ingestions of greater than 50 gm (Grynnerup et al., 2012). Current recommendations for managing valproate overdose focuses on supportive therapy; although gastric lavage might be considered early in an overdose, it is unlikely to be of much help later in an overdose because absorption of valproate is fairly rapid. Similar arguments hold for activated charcoal (Vannaprasaht, Tiamkao, Sirivongs, & Piyavhatkul, 2009). Hemodialysis is effective in clearing ammonia in cases of hyperammonemic encephalopathy. Coma caused by valproate overdose might be reversible by naloxone because of the latter's effects on GABA receptors (Alberto et al., 1989). Given the low toxicity of naloxone and its empiric use in overdoses of unknown agents, it is an appropriate consideration as adjunctive therapy even when a patient is known to have taken valproate rather than a narcotic (Manoguerra et al., 2008).

LAMOTRIGINE

Lamotrigine at one time inspired great interest for use in bipolar disorder, but in recent years its limitations have become more apparent. Though the drug clearly has value in the management of depression in bipolar disorder, it is not regarded as an effective first-line agent for mania. It is often used, however, as maintenance therapy in bipolar disorder (Tränkner, Sander, & Schönknecht, 2013). Lamotrigine is not recommended as monotherapy in bipolar disorder (Bowden & Singh, 2012).

Lamotrigine causes dizziness in 25% of patients, diplopia (21%), ataxia (16%), blurred vision (11%), somnolence (7%), exacerbation of seizures (3%–4%), and depression or psychosis (in less than 1% of patients). Lamotrigine can cause dose-dependent myoclonic jerks. These have been observed primarily in patients with idiopathic generalized epilepsy

(Crespel et al., 2005). Abrupt withdrawal of lamotrigine may cause a rebound increase in seizure frequency. In the extreme, status epilepticus may occur with secondary rhabdomyolysis and multisystem organ failure (Pellock, 1994; Schmidt & Kramer, 1994; Wang-Tilz et al., 2005). Perhaps the best known of lamotrigine's side effects is the risk of developing a rash. Perhaps 8% of adults receiving lamotrigine will develop a rash. This is usually a benign maculopapular rash that develops within the first 4 months of treatment. About 0.1% of patients develop a serious rash, such as Stevens-Johnson syndrome. Among children and adolescents, the risk of rashes appears to be higher. In one study of 102 such patients, 23 developed a rash within the first 7 weeks of treatment with lamotrigine. One of these cases was of the Stevens-Johnson syndrome (Tak et al., 2012). A black box warning for lamotrigine exists for rashes in children. Other risk factors for a lamotrigine-induced rash include coadministration of valproic acid, rapid upward titration of the medication, and higher doses of the medication.

The metabolism of lamotrigine is induced by acetaminophen, carbamazepine, and phenytoin. Valproic acid raises the serum lamotrigine level. Lamotrigine may pharmacodynamically increase the activity of L-dopa in the treatment of parkinsonism (Meldrum, 1994; Patsalos & Duncan, 1993). Lamotrigine appears to be a substrate of Pgp (Lovrić et al., 2012), and its distribution may be affected by other drugs acting on or through Pgp. Lamotrigine is also a substrate for organic cation transporter 1 (OCT1), which, like Pgp, lines the blood–brain barrier. Inhibitors of OCT1, such as quetiapine, may concentrate lamotrigine in target organs (Dickens et al., 2012).

EPILEPSY AND MENTAL ILLNESS

Diseases of the central nervous system are not only a reason to prescribe psychotropics, but issues that may confound their safe use, as well as side effects in some cases of psychotropic medications. Perhaps nowhere else in psychopharmacology is a side effect more striking—and often less obvious in its etiology—than a seizure. This is problematic for psychiatrists, because anticonvulsants are very often used as mood stabilizers, and various psychotropics may alter the seizure threshold. Excellent reviews exist that detail individual agents and their side effects (Cavanna, Ali, Rickards, & McCorry, 2010; Mula & Monaco, 2009). However, it is useful to have a general concept of the potential problems. There may be three ways in which anticonvulsants alter affect, behavior or cognition, and movement. First, an anticonvulsant's pharmacologic actions may affect some aspect of mentation. An obvious example would be sedation and subsequently impaired cognition, with agents that stimulate the GABA-A receptor. Second, anticonvulsants may interact with seizure disorders in complex ways that secondarily affect mood, behavior, or thought. Finally, if the brain has underlying structural or functional abnormalities manifesting as a seizure disorder, anticonvulsants may generate side effects or further impairments of brain function that present as disturbances of mood, behavior, or cognition.

Depression is intimately linked to epilepsy. The rate of major depressive disorder among patients with epilepsy may approach 20% (Jones et al., 2005). Having depression is a risk factor for more severe or treatment-refractory epilepsy (Kanner, 2011). Patients with epilepsy are five times more likely than the general population to commit suicide. Among patients with complex partial seizures or temporal lobe epilepsy, this rate may soar to as high as 25 times that of the general population (Kalinin, 2007). Reasons for this may include frontal lobe hypometabolism, folate deficiency, and abnormalities of hippocampal structure and function (Beydoun, Shroff, Beydoun, & Zonderman, 2010; Bromfield et al., 1992; Pineda, Shin, Sankar, & Mazarati, 2010). Decreased levels of neurotrophins such as brain-derived neurotrophic factor may also foster the evolution of both epilepsy and mood disorders (LaFrance, Leaver, Stopa, Papandonatos, & Blum, 2010). Anticonvulsants may affect these rates both positively and negatively. Being seizure-free over a year, for example, is associated with a reduced risk of suicide (Ridsdale, Charlton, Ashworth, Richardson, & Gulliford, 2011). And, of course, anticonvulsants are routinely used in the management of bipolar disorder.

In 1999, Ketter and colleagues proposed the existence of two mechanisms by which anticonvulsants may affect mood, psychomotor activity, and cognition. The first mechanism was stimulation of GABA receptors, which would tend to be “sedating.” The second mechanism was interference with glutamatergic activity at NMDA receptors, which would be “activating.” Sedating agents were hypothesized to have anti-manic potential, while the activating agents would potentially have an antidepressant effect (Ketter, Post, & Theodore, 1999). Some authors rightly argue that the simplicity of Ketter’s hypothesis risks failing to explain the actions of complex agents (Roberts et al., 2005). Yet, research supports the idea that NMDA receptor antagonists such as ketamine may exert an antidepressant action (Autry et al., 2011). The role of GABA activity in the modulation of mood is also increasingly appreciated (Möhler, 2012). Interestingly, rapid cessation of anticonvulsants, and the mood and anxiety symptoms that may accompany their withdrawal, are also suggestive of a pharmacological basis of mood effects for anticonvulsants (Ketter et al., 1994).

The FDA issued a warning in 2008 that anticonvulsants may increase the risk of suicide (US Food and Drug Administration, 2008). This finding was based on registration trial studies of 11 anticonvulsants. Paterno and coauthors found that patients taking gabapentin, lamotrigine, oxcarbazepine, and tiagabine, when compared to those taking topiramate, had an increased risk of suicide or related behaviors (Paterno et al., 2010). Limiting these studies is the short duration and the fact that the time shortly after the diagnosis of epilepsy is known to be a time of increased risk for suicide. Arana and colleagues used a database of over 5 million patients, followed on average for 6 years, and found that the use of an anticonvulsant prescribed for epilepsy did not increase the risk of suicide (Arana, Wentworth, Ayuso-Mateos, & Arellano, 2010). Gibbons and colleagues

found that the anticonvulsants assessed by the FDA also did not increase the risk of suicide among patients receiving anticonvulsants for bipolar disorder (Gibbons, Hur, Brown, & Mann, 2009). In a study of veterans over the age of 66 years old, VanCott and coauthors (2010) also noted no increase in the risk of suicide. This does not mean that compelling cases of apparent anticonvulsant-induced suicidality do not exist, and that attention to the mental health of persons prescribed anticonvulsants should not be monitored (Mago, Huege, Ahuja, & Kunkel, 2006). In general, though, it does appear that while having a mood disorder, whether as a consequence of epilepsy or independent of epilepsy, increases the risk of suicide, while being prescribed an anticonvulsant does not (Machado et al., 2011).

In treating the patient with epilepsy and depressed mood, several principles should be considered. First, the goal of anticonvulsant therapy should be freedom from seizures. In pursuing this goal, the gradual upward titration of the fewest possible agents appears to be the safest from the standpoint of avoiding psychiatric side effects. The time after initial diagnosis of epilepsy and in the initiation of treatment appears to be the period of greatest risk for suicidal thoughts and behaviors, so attention to the patient’s mood and functioning is important. Anticonvulsant side effects that may increase the risk of depression or a change in mentation, such as a drop in serum folate or hyponatremia, should be considered. Finally, if depression does emerge, treating the patient with an antidepressant should be considered. Emerging data suggest that treating depressive states may actually improve the management of epilepsy. There may be many reasons for this. For example, a depressed patient may not comply as reliably with anticonvulsant therapy as a euthymic patient. Also, selective serotonin reuptake inhibitors (SSRIs) may increase the seizure threshold in epilepsy (Kondziella & Asztely, 2009). However, SSRIs may also occasionally cause hyponatremia, as may carbamazepine. Caution is warranted when combining these agents (Jackson & Turkington, 2005). Some agents may lower the seizure threshold, such as bupropion, and may not be suitable as first-line therapies.

DISTURBANCES OF THOUGHT

Anticonvulsants may occasionally provoke psychosis. This may occur in 1%–2% of patients with epilepsy. Gibbs was among the first to connect the treatment of epilepsy with the appearance of psychosis. He reported on the occasional development of psychosis among patients treated for temporal lobe epilepsy (Gibbs, 1951). Ethosuximide is an example of an established agent that continues to be recognized as a cause of psychiatric disturbances (Chien, 2011). For example, in a study of 105 patients taking ethosuximide, psychosis was seen in 3 subjects (Fischer, Korsjaer, & Pedersen, 1965). Landolt observed that psychosis may develop when seizure control is achieved through medication, and in 1953 called this “forced normalization” (Mula & Monaco et al., 2009). Trimble and Reynolds suspected that this resulted from pharmacologic actions associated with over-rapid normalization of the electroencephalogram (Trimble & Reynolds, 1976). Tellenbach

broadened the relationship between epilepsy and psychosis—with seizures alternating with psychosis during seizure-free periods—by introducing the concept of “alternative psychosis” (Tellenbach, 1965). Tellenbach’s formulation eliminated the need for a normalized EEG as part of the etiology of the psychosis, and hinted at the underlying seizure disorder as participating in what appeared to be a drug side effect. The concept of forced normalization is no longer widely accepted. The rate at which seizures are suppressed is simply not related to the risk of psychosis (Youroukos, Lazopoulou, Michelakou, & Karagianni, 2003). Inhibition of glutamatergic NMDA receptors, either directly or indirectly, as through inhibition of voltage-gated sodium channels, is a more current and useful way of conceptualizing the ability of some anticonvulsants to cause psychosis (Farber, Jiang, X. P., Heinkel, C., & Nemmers, 2002). However, despite decades of research the mechanism of ethosuximide’s action—and thus its method of inducing psychosis, mania, and depression—are not known (Greenhill, Morgan, Massey, Woodhall, & Jones, 2012). It should be noted that psychosis with ethosuximide is not common, nor are changes in mentation necessarily more or less common with other anticonvulsants (Glauser et al., 2010).

In general, psychosis with anticonvulsants is rare. It appears to occur most often with temporal lobe epilepsy (Nadkarni et al., 2007). Starting with monotherapy and gradually increasing the dose of an anticonvulsant to the lowest effective dose may help avoid the development of drug-induced psychosis (Mula & Monaco et al., 2009). Difficulty with one anticonvulsant does not necessarily mean that another agent will also cause disturbances of thought, mood, or behavior. If psychosis develops, the clinician must determine whether another disorder such as depression or schizophrenia is also present. Among the disorders that must be considered is postictal confusion, which may result from medication ineffectiveness or noncompliance. At times an antipsychotic may be needed to manage anticonvulsant-induced psychosis. In such cases, agents known to lower the seizure threshold—such as clozapine, haloperidol, and chlorpromazine—should be avoided.

MOVEMENT DISORDERS

A postural tremor is one of the more common findings among patients receiving treatment for epilepsy. Valproic acid and carbamazepine, followed by phenytoin, are the most common offending agents (Zadikoff et al., 2007). When cerebellar dysfunction is the cause, phenytoin is among the most serious offenders. Phenytoin intoxication typically presents with cerebellar findings, including the pancerebellar syndrome (Luef, Chemelli, Birbamer, Aichner, & Bauer, 1994). In their seminal studies of phenytoin for epilepsy, Merritt and Putnam (1938) noted that about 15% of their patients developed cerebellar findings. These findings generally resolve as the free serum concentration of phenytoin falls to normal therapeutic limits. However, as many as 30% of patients receiving chronic phenytoin develop cerebellar atrophy. Duration of treatment appears to be the most important variable (De Marcos, Ghizoni, Kobayashi, Li, &

Cendes, 2003; Ney, Lantos, Barr, & Schaul, 1994). Typically patients present with the pancerebellar syndrome, including hypotonia, ataxia, nystagmus, and dysarthria. Radiography often reveals diffuse cerebellar atrophy. It does appear that acute phenytoin intoxication may also rarely cause cerebellar atrophy and the pancerebellar syndrome (Alioğlu, Sari, Velioglu, & Oumlzmenoğlu, 2000). In the acute case, immediate discontinuation of phenytoin usually permits complete resolution of symptoms. This is more likely in the absence of cerebellar atrophy. The latter does not always respond to drug cessation, in which case symptoms may persist. The cause of this atrophy remains unknown.

Benzodiazepines may also cause cerebellar findings, including the pancerebellar syndrome. As is true for phenytoin, this occurs in intoxication. Though no longer routinely employed in the treatment of epilepsy, benzodiazepines are still often used to manage seizures, including those of alcohol withdrawal and status epilepticus (Nair, Kalita, & Misra, 2011). When a benzodiazepine is used for alcohol withdrawal, it is crucial to distinguish between the cerebellar findings of Wernicke’s encephalopathy and the cerebellar findings that may be caused by the benzodiazepine. This distinction requires a good physical and mental status examination prior to starting treatment with the benzodiazepine. The role of thiamine in preventing the emergence or worsening of Wernicke’s encephalopathy has been reviewed elsewhere and should be familiar to all clinicians (Thomson et al., 2002). Benzodiazepines do not cause cerebellar atrophy to the extent seen with phenytoin. But concern about neurodegeneration with benzodiazepines is not new (Poser, Poser, Roscher, & Argyrakakis, 1983). Benzodiazepines may inhibit neurogenesis through stimulation of GABA-A receptors and may promote apoptosis through activation of peripheral benzodiazepine receptors (Jordà et al., 2005; Yamaguchi & Mori, 2005). This may be another set of reasons to use caution when considering chronic use of benzodiazepines.

SSRIs are also recognized as an important potential cause of EPS due to antidopaminergic effects. SSRI-induced EPS may consist of parkinsonism, akathisia, dyskinesias, or dystonias. Although EPS may be seen in less than 5% of patients, it must be anticipated as a potential source of worsening among susceptible patients (Stoudemire & Moran, 1998). Such patients include the elderly with subclinical Parkinson’s disease. Paroxetine (because of its anticholinergic properties), and sertraline (because it potentiates brain dopaminergic transmission) may be relatively less likely to cause this side effect. Duloxetine frequently has been implicated in cases of SSRI-related EPS. However, EPS may develop with any of the currently available antidepressants. This is not a dose-dependent side effect and can develop at any time during antidepressant treatment (Madhusoodanan, Alexeenko, Sanders, & Brenner, 2010).

Anticonvulsants may at times cause or worsen EPS. This is an important problem, as anticonvulsants are often combined with antipsychotics in the management of bipolar disorder and because after cerebellar dysfunction, EPS may be the most common movement disorder caused by anticonvulsants. In a study of 201 patients with epilepsy receiving a

wide variety of agents, Zadikoff and colleagues found that 9, or 4.5%, had EPS (Zadikoff et al., 2007). Valproic acid is likely the worst offender. Jamora and colleagues (2007) found 6 patients among 266 treated with valproic acid who developed parkinsonism. Valproic acid is also implicated in the development of parkinsonism coupled with cognitive decline. In a series of 364 patients, Ristić and colleagues (2006) observed reversible Parkinsonism with cognitive decline in 5. Fortunately this drug-induced syndrome, as well as simple EPS, reverses when valproic acid is stopped. Striking features of this syndrome include cerebrocortical atrophy that reverses upon discontinuation of valproic acid, a normal electroencephalogram, and a normal ammonia level (Evans, Shinar, & Yaari, 2011; Guerrini, Belmonte, Canapicchi, Casalini, & Perucca, 1998). Although EPS and EPS with cognitive impairment may arise shortly after initiation of treatment with valproic acid, in some cases patients tolerate the medication with good result for years and then develop these reversible side effects (Masmoudi, Gras-Champel, Masson, & Andréjak, 2006).

Ethosuximide may worsen the resting tremor of patients with Parkinson's disease and patients with neuroleptic-induced Parkinsonism (Pourcher, Gomez-Mancilla, & Bédard, 1992). A similar result can be seen with levetiracetam (Lyons et al., 2006). Other agents reported to cause or worsen extrapyramidal symptoms include carbamazepine, gabapentin, lamotrigine, phenytoin, vigabatrin, and zonisamide (Ertan et al., 2006; Raju, Walker, & Lee, 2007; Santens, Claeys, Vonck, & Boon, 2007; Zadikoff et al., 2007). Dystonias and tics are reported as rare side effects of a variety of anticonvulsants. These rarer examples of anticonvulsant-induced extrapyramidal dysfunction remind the clinician of the need to be vigilant when prescribing psychoactive medications, especially to patients whose brain structure or function may not be normal. In such cases a cautious reduction in the dose of the suspected offending agent is important. Another anticonvulsant can be substituted with equal benefit and less side effects in many cases.

Gabapentin may occasionally cause reversible myoclonus (Ege et al., 2008). This is more likely when toxic levels are reached, as may occur in renal disease (Zhang, Glenn, Bell, & O'Donovan, 2005). Other agents, including pregabalin and topiramate, may also rarely cause myoclonus (Healy, Ingle, G. T., & Brown, 2009; Miller, Prost, Bookstaver, & Gaines, 2010).

ACUTE CONFUSIONAL STATES

There are many ways in which anticonvulsants can provoke acute confusion. Valproic acid for example, commonly elevates serum ammonia levels. Serum ammonia levels may on average double after starting valproic acid. In most cases the rise in serum ammonia is not accompanied by changes in mentation (Chicharro et al., 2007). Yet, on occasion valproic acid causes hyperammonemic encephalopathy. This can be an acute and devastating example of an anticonvulsant-induced alteration in mentation. Treatments include lactulose, carnitine, and hemodialysis, and stopping valproic acid (Lheureux & Hanson, 2009; Thanacoody, 2009).

When a patient with a psychiatric disorder that may be treated with an anticonvulsant, (such as bipolar disorder) also has a seizure disorder, the anticonvulsant may worsen the seizure disorder. Table 21.11 lists the reported adverse effects of anticonvulsants on seizure disorders (Chiron & Dulac, 2011; Genton & McMenamin, 1998; Mantoan & Walker, 2011; Sazgar & Bourgeois, 2005). If a patient appears to be at risk for worsening of a seizure disorder, consultation with a neurologist should precede institution of the anticonvulsant if possible. Note that the cause of seizure worsening by anticonvulsants may be the result of either anticonvulsant withdrawal when tolerance has developed, anticonvulsant intoxication, or an adverse effect of an anticonvulsant on particular neurons at therapeutic drug levels (Perucca et al., 1998; Perucca, 2006). When any of these causes can be managed, then the patient may be able to remain on the anticonvulsant without harm.

MONOAMINE OXIDASE INHIBITORS

Despite the introduction of many new psychotropics, MAOIs remain an important alternative for several conditions, including atypical or tricyclic-refractory depression, panic disorder/agoraphobia, social phobia, and for some patients with obsessive compulsive disorder and posttraumatic stress disorder. Some patients have strikingly positive therapeutic responses to MAOIs with poor response to all other available medications. When such patients have a significant concurrent medical illness, situations arise in which risks and benefits must be balanced, and clinical strategies must be employed to contain risks that are not completely avoidable. This section deals with several such issues, including (1) general anesthesia for patients on MAOIs, (2) drug interactions, (3) dietary precautions, and (4) management of medically important side effects.

Before discussing these issues, we review some important differences among the MAOIs most commonly prescribed in the United States: phenelzine (Nardil), tranylcypromine (Parnate), and selegiline (Eldepryl) and selegiline transdermal system (Emsam). Phenelzine, tranylcypromine, and transdermal selegiline are FDA approved for psychiatric indications. Oral selegiline is approved for the treatment of Parkinson's disease but can be an effective antidepressant when used at higher doses sufficient to produce nonselective (MAO_A plus MAO_B isoenzyme) MAO inhibition (Mann et al., 1989). Moclobemide, a selective reversible MAO_A inhibitor with less chance of tyramine reactions, is not currently available in the United States (available in Canada). It is also important to note the MAOI isocarboxazide is also available in the US market. Linezolid (Zyvox) is marketed as an antibiotic, but it too is an MAOI. Linezolid reversibly and competitively inhibits MAO_A.

The first main difference among the three drugs is that phenelzine and tranylcypromine are nonselective MAOIs (inhibiting both MAO_A and MAO_B), whereas selegiline is a selective inhibitor of MAO_B at doses up to approximately 20 mg/day. When selegiline is used at this lower,

Table 21.11 SEIZURE DISORDERS AND POTENTIAL WORSENING BY ANTICONVULSANTS

DRUG	SEIZURE DISORDER	EFFECT OF ADDING DRUG
Barbiturates	Absence	Aggravation Worsen Dravet syndrome
Benzodiazepines	Lennox-Gastaut syndrome	Serial tonic seizures
Carbamazepine	Benign "Rolandic" epilepsy	Drop attacks
	Childhood absence	Increases in absences
	Juvenile myoclonus epilepsy	Increases episodes of myoclonus
	Progressive myoclonus epilepsy	Increases episodes of myoclonus
Gabapentin	Absence	Worsens Dravet syndrome
	Absence (any type)	Aggravation
Lamotrigine	Absence (any type)	Increases in absences
	Severe myoclonic epilepsy	Aggravation Worsens Dravet syndrome
Oxcarbazepine	Juvenile myoclonus epilepsy	Increases episodes of myoclonus
Idiopathic generalized epilepsy		Increase in absences and myoclonus
Phenobarbital (large doses)	Childhood absence	Increases in absence
Phenytoin	Childhood absence	No efficacy; aggravation
	Other generalized epilepsies	No efficacy; aggravation
	Progressive myoclonus epilepsy	Long-term aggravation
	Juvenile myoclonus epilepsy	Increases episodes of myoclonus
Pregabalin	Juvenile myoclonus epilepsy	Increases episodes of myoclonus
Tiagabine	Nonconvulsive status epilepticus	Aggravation
	Juvenile myoclonus epilepsy	Increases episodes of myoclonus
Vigabatrin	Childhood absence	Increases in absences
	Juvenile myoclonus epilepsy	Increases episodes of myoclonus
	Myoclonic epilepsy	Increases in episodes of myoclonus

antiparkinson dose, no dietary restrictions or drug interaction precautions are necessary. At higher doses, although precautions may be necessary, tyramine sensitivity may be less than with tranylcypromine at a comparable dose (Bieck & Antonin, 1989; Wimbiscus, Kostenko, & Malone, 2010). When used as a transdermal patch, 6 mg per day is effective for the treatment of depression. Note that the bioavailability of transdermal selegiline is about 75%, versus 4% to 5% for oral selegiline (Wimbiscus et al., 2010). While some authors suggest that no dosage adjustment is required for selegiline in the presence of hepatic or renal impairment, or other factors routinely considered such as age, others note that this may not be true for all patients. For example, Nagler and colleagues (2012) argue for a dosage reduction if selegiline is given to patients with stage 3–5 chronic kidney disease.

Moclobemide is the reversible inhibitor of MAO_A. Its main potential advantage in the medically ill is that it typically does not cause weight gain like the classic MAO_{A/B} inhibitors. It is also much less likely to cause tyramine reactions at normal dose levels than nonselective MAO_{A/B} inhibitors such as phenelzine. Since MAO_A is responsible for the degradation of both serotonin and noradrenaline, it is at least of theoretical concern when a patient with severe endothelial disease such as hypertension is started on an inhibitor of MAO_A. Such patients may be at risk for the development of catecholaminergic or serotonergic toxicity if the MAO_A inhibitor is coadministered with a noradrenergic or serotonergic agent, such as a stimulating decongestant or an SSRI.

Moclobemide causes some dose-related excessive stimulation in roughly 3% of patients leading to agitation or insomnia; more severe side effects are rare. Seizures may occur in about 1.5% of patients; these are primarily patients who have preexisting seizure disorders. Severe hypertensive reactions have been noted, usually in conjunction with tyramine ingestion, in about 0.2% of patients, but tyramine reactions are much less likely than those from combined MAO_{A/B} inhibitors. Hepatotoxicity is rare but may first manifest as an encephalopathy (Brown & Stoudemire, 1998). Cardiovascular side effects are rare and consist primarily of tachycardia. Occasional reports appear of ECG abnormalities, without a consistent pattern (Chen & Ruch, 1993).

The possibility of inducing the serotonin syndrome during treatment with moclobemide is important to consider for two reasons. First, it underscores a predictable pathophysiologic reaction to moclobemide for some patients. Second, although rare, the serotonin syndrome is occasionally fatal.

Drug interactions are potentially an important cause of toxicity with moclobemide. The most obvious are noted above, such as the ingestion of a stimulant, (e.g., phenylpropanolamine) with moclobemide; other important pharmacodynamic interactions include the coingestion of opiates such as morphine or dextropropoxyphene with moclobemide. In such cases, excessive stimulation of the central nervous system may occur. Cimetidine may prolong the normal 1-hour to 3-hour half-life of moclobemide by 100% (Callingham, 1993).

GENERAL GUIDELINES FOR ANESTHETIC MANAGEMENT OF PATIENTS ON MAO INHIBITORS

Patients taking MAOIs may safely have surgery, with some medication-specific cautions. Isocarboxazide, phenelzine, and tranylcypromine irreversibly inhibit monoamine oxidases. Because of this, normal monoamine oxidase activity typically takes weeks to regenerate, well after these MAOIs have been eliminated from the body. If an MAOI must be stopped prior to an operation or any other major procedure, or even a medication change, the clinician should assume the presence of residual monoamine oxidase inhibition for 2 weeks after discontinuation of the MAOI (Fiedorowicz & Swartz, 2004). Since untreated depression warrants as much caution as most potential drug side effects and interactions, discontinuation of an MAOI is not a routine recommendation prior to surgery.

1. Meperidine is absolutely contraindicated for postoperative analgesia in patients on MAOIs. Its use in such patients can produce hypertension, hyperthermia, and death. The problem is relatively specific to meperidine. Dextromethorphan, tramadol, and possibly fentanyl have been associated with deaths in combination with MAOIs. This is likely due to a hyperserotonergic state, such as the serotonin syndrome. Morphine and its analogues, such as codeine, have long been given without complications to patients on MAOIs (Gillman, 2005). Nonetheless, because of potential interactions, initial dosage of narcotic analgesics should be conservative. The availability of potent NSAIDs such as ketorolac, with analgesic potencies approaching that of narcotics, is an option for patients on MAO inhibitors.
2. Because it has an indirect sympathomimetic effect, curare should be avoided in MAOI-treated patients (Anonymous, 2003; Stack, Rogers, & Linter, 1988). If succinylcholine is given to a patient on phenelzine, monitoring of neuromuscular function and adequacy of respiration must be particularly careful because phenelzine can reduce pseudocholinesterase levels in some patients (Bodley, Halwax, & Potts, 1969).
3. If hypotension develops intraoperatively, initial correction should be attempted through volume expansion. If this is inadequate, then direct sympathomimetics such as norepinephrine are the preferred therapy. The clinician should bear in mind that the pressor response to the sympathomimetic may be amplified by residual MAOI activity (Dawson, Earnshaw, & Graham, 1995). Indirect-acting sympathomimetics such as metaraminol should be avoided, because they can produce hypertensive crises (Janowsky & Janowsky, 1985).
4. Previously, because of concerns about blood pressure stability, it was recommended that patients receiving prolonged anesthesia for major surgery should be monitored with an indwelling arterial catheter (Sides, 1987; Wong, 1986). While drug–drug interactions do require careful

monitoring, it appears that use of either moclobemide or tranylcypromine is safe before surgery, that patients taking these agents have fewer episodes of intraoperative hypotension than patients not taking MAOIs, and that they have the same rate of bradycardia, tachycardia, and hypertension as do patients not taking MAOIs (van Haelst et al., 2012).

5. If significant hypertension develops during surgery, it can be managed with intravenous phentolamine or nitropruside (Tuncel & Ram, 2003).
6. Because of the potential for various drug interactions, particular care must be taken to assure that all staff caring for surgical patients are aware of the patient's MAOI therapy and its implications. Prescribing or drug administration errors sometimes take place in the course of a patient's journey from operating room to recovery room to intensive care to surgical floor. At each point along the way, MAOI-related safety issues should be reinforced. As a practical precaution, a sticker stating that the patient is "allergic to Demerol (meperidine)" can be placed on the patient's chart.

DRUG INTERACTIONS WITH MAO INHIBITORS

The MAOIs are associated with a wide range of drug interactions, many of which are displayed in Table 21.12 (Barkhuizen, Petzer, & Petzer, 2013; Brown & Stoudemire, 1998; Huang & Gortney, 2006). These can be grouped into three general classes: interactions with indirect-acting sympathomimetics; interactions with serotonin drugs; and pharmacodynamic potentiation of other drugs' CNS side effects.

Selegiline is metabolized to its metabolites by CyP4502B6, 2A6, and 3A4 (Benetton et al., 2007). However, it does not appear to alter the disposition of drugs metabolized through cytochromes P450, including alprazolam, olanzapine, and risperidone (Azzaro, Ziemniak, Kemper, Campbell, & VanDenBerg, 2007). Moclobemide is a substrate of CyP450 2C19, and inhibits the activity of this enzyme and of 1A2 and 2D6. Little is known about the influence of tranylcypromine, phenelzine, or isocarboxizide on hepatic drug metabolism. Some data suggest that (like moclobemide) phenelzine and tranylcypromine may inhibit their own metabolism (Polasek et al., 2006).

When an indirect-acting sympathomimetic agent is given, excessive amounts of catecholamines can be released, leading to a hypertensive crisis. Indirect-acting sympathomimetics include cocaine, amphetamines, methylphenidate, ephedrine, pseudo-ephedrine, and phenylpropanolamine. As a practical point, the most frequent occasion for such reactions is patients' use of over-the-counter (OTC) cold remedies that include a sympathomimetic decongestant. The problem is complicated by the fact that many OTC drugs have multiple formulations with similar sounding names, some of which are safe and others of which are not.

Although not strictly sympathomimetics, L-dopa and carbidopa-levodopa (Sinemet) can also produce hypertensive reactions in combination with MAOIs. Direct-acting

antiparkinson drugs such as bromocriptine would presumably be safer if a patient with Parkinson’s disease required MAOI therapy at antidepressant doses. The use of selegiline in antiparkinson doses of 10 mg/day is, of course, compatible with L-dopa or carbidopa-levodopa.

Direct-acting sympathomimetics can be used if necessary—for example, as bronchodilators for the treatment of asthma. Inhalers are safer than systemic drugs. Furthermore, a challenge with the inhaled drug, with blood pressure determination before and after, provides even greater security that a particular drug is safe in the face of MAOI therapy.

The second major type of drug interaction with MAOIs concerns their combination with serotonin drugs such as the SSRIs or buspirone. The interaction with meperidine may have a similar mechanism, since meperidine blocks serotonin reuptake (Guo et al., 2009).

Clinical symptoms of the “serotonin syndrome” include myoclonus, ataxia, fever, and confusion. Neuromuscular symptoms range from tremor to lead-pipe rigidity. Neurologic examination shows hyperreflexia, sometimes with clonus; nystagmus; altered mental status; and,

frequently, rigidity. Blood pressure may be either normal or elevated, but hypertension, when it occurs, usually is not extreme. Fever usually is present, and at times there is hyperthermia. However, profuse sweating, so common in neuroleptic malignant syndrome, is not part of the serotonin syndrome. The syndrome is best prevented by avoiding the addition of serotonin drugs when patients are on MAO inhibitors. Furthermore, MAO inhibitors should be avoided for at least 5 weeks following discontinuation of fluoxetine because of the very long half-life of the latter drug and its active metabolite, norfluoxetine. If the safety of an MAOI is in question in a patient who has recently taken fluoxetine, a fluoxetine blood level should be obtained. Detectable levels of fluoxetine or norfluoxetine are a contraindication to starting MAO inhibitors. It is not known, but very unlikely, that a shorter SSRI “washout” period would be safe for short-acting SSRIs like sertraline.

Treatment begins with instituting supportive measures and discontinuing the drugs that promote the syndrome. Specific therapy has been reported anecdotally with a number of drugs with serotonin-blocking effects, including chlorpromazine and cyproheptadine (Gillman, 2005, see also Chapter 23).

The third type of drug interaction concerns pharmacodynamic potentiation of other drugs’ CNS effects. For example, MAOIs potentiate the anticholinergic effects of atropine (Janowsky & Janowsky, 1985). Central nervous system depressant effects of narcotics, benzodiazepines, and barbiturates can be greater in patients taking MAOIs, as can sedative side effects of nonsteroidal antiinflammatory drugs. The mechanism of these pharmacodynamic interactions is not well understood, but their prevalence argues for particular conservatism in dosage of anticholinergics and CNS depressant drugs in MAOI-treated patients.

MAO INHIBITORS AND FOOD INTERACTIONS

The interaction of MAO inhibitors with tyramine-containing foods remains the primary deterrent to their wider use by psychiatrists, and may be a major reason for their nonuse by nonpsychiatric physicians. Moreover, burdensome dietary restrictions often are a reason that patients are reluctant to take MAOIs even when they are clinically helpful. Patients with concurrent medical diseases such as diabetes or renal failure that impose additional dietary restrictions may be particularly reluctant to restrict their diets further. For the otherwise healthy patient, the MAOIs impose only modest dietary restrictions. Box 21.3 outlines the amount of cheese—in particular cheddar cheese, which is typically rich in tyramine—that would be too much. Note that the amount of tyramine required to precipitate a pressor response, defined as a rise in the systolic blood pressure by 30 mmHg, is 2–3 times greater in the fed state compared to the fasting state (EMSAM, 2005; Wimbiscus et al., 2010).

Box 21.3 THE CHEESE REACTION: HOW MUCH IS TOO MUCH?

To Raise the Systolic Blood Pressure by 30 mmHg:

- (1) a person not taking an MAOI would need to consume, when fasting, 500 mg of tyramine, or 2 pounds of cheddar cheese consumed in 30 minutes;
- (2) for a patient on a 6 mg selegiline patch, again, 2 pounds of cheddar cheese;
- (3) for a patient on tranylcypromine, 10 mg of tyramine if fasting, or 25 mg if taken with food, or about an ounce of cheddar cheese.

However, many patients’ and physicians’ problems with MAOI diets are both unnecessary and avoidable. Cheese, the food most often implicated in hypertensive reactions, varies enormously in its tyramine content. Cream cheese and cottage cheese are free from tyramine. The tyramine content of cheddar cheeses in a large sample varied from 0 to 1.4 mg/g of cheese—an astonishing number when one considers that the average threshold for 30 mmHg blood pressure elevation with tranylcypromine is only 10 mg of tyramine (EMSAM, 2005). Patients therefore should be told that the lack of a hypertensive reaction on one occasion does not imply that a particular aged cheese is safe. And, in general, one should assume that a cheese is aged if there is any uncertainty.

In the past, psychiatrists frequently confronted hospital diets or published recommendations that advocated stringent food restrictions for MAO inhibitors that are not supported by a critical review of the literature. Since spontaneous hypertensive reactions do occur with MAOIs, multiple reports of a particular food–drug interaction, along with chemical analyses or challenge studies, are needed to establish conclusively that a particular food is risky. We recommend explaining these issues to patients, encouraging them to be extremely scrupulous about high-risk foods, and less concerned about foods less definitely associated with hypertensive reactions. The list of foods that should absolutely be avoided is fairly short. Box 21.4 lists these (Gardner et al., 1996).

MANAGEMENT OF SIDE EFFECTS

Side effects of traditional A and B enzyme MAOIs that are particularly problematic in medically ill patients include orthostatic hypotension, hypertensive episodes, weight gain, and insomnia. An additional but infrequent side effect is potentiation of insulin-induced hypoglycemia by MAOIs in diabetic patients (Bodnar, Starr, & Halter, 2011; Cooper & Ashcroft, 1966; McIntyre, Soczynska, Konarski, & Kennedy, 2006). Active management of these side effects can enable

Aged cheeses
Aged or spoiled meat
Banana peels
Draft beer
Fava beans
Marmite
Sauerkraut
Soybeans and soybean products

patients who benefit from MAOI therapy to continue the treatment.

Orthostatic hypotension may occur with any of the MAOIs. Its initial management involves making sure the patient is safe and, for example, knows to stand slowly and be cautious of falling, and also clarifying whether the MAOI is indeed responsible. Orthostatic hypotension is approached initially by reducing or eliminating diuretics, vasodilators, and other medications that may lower blood pressure. Adequate hydration is assured, and salt intake is liberalized if it has been restricted. If these measures are insufficient, administration of fludrocortisone (Florinef) 0.1 mg/day may be helpful, at least for the short term (Simonson, 1964). Fludrocortisone should be used with caution in patients with congestive heart failure (Stumpf & Mitrzyk, 1994). In some cases it may be necessary to discontinue the MAOI.

Episodes of hypertension, whether spontaneous or attributable to food–drug or drug–drug interactions, pose particular risks in patients with cerebral vascular disease and cardiovascular disease, and in patients on anticoagulants. In these patients especially we recommend training patients to recognize the early signs of a hypertensive reaction, such as headache and flushing, and to carry with them an oral hypotensive medication. Patients are asked to seek medical attention urgently should they develop an episode, but immediate use of an oral hypotensive agent relieves some of the risk and discomfort they would otherwise face before getting medical attention. Among the first-line agents is oral nifedipine. The initial recommended dose is 20 mg. The medication should be swallowed, not bitten or otherwise taken sublingually, in order to avoid uncontrolled hypotension (van den Born et al., 2011). If symptoms do not resolve within 15 minutes for nifedipine, a second dose can be taken while the patient is in transit to an emergency room.

Insomnia is a common side effect of MAOIs that can be particularly problematic for patients with other medical conditions, such as arthritic pain, that keep them awake at night. In such patients the first step in managing insomnia is to identify and optimally treat medical problems that can interfere with sleep. If this is insufficient, options include a short-acting benzodiazepine at bedtime or trazodone 25–50 mg every four hours (Jacobsen, 1990). At times the atypical antipsychotics in low dose, such as quetiapine 50 mg at bedtime, can help

if standard options fail to treat MAOI-related insomnia (Sokolski & Brown, 2006).

Weight gain in patients on MAOIs is particularly a problem for those with diabetes or hyperlipidemia. In such patients, tranylcypromine usually is the MAOI of choice because it is less likely to cause weight gain than phenelzine. If available, moclobemide might be the best choice in such a situation. If a patient must be switched to tranylcypromine from another MAOI, there must be a 2-week drug-free interval to avoid a hypertensive reaction. If weight gain persists on tranylcypromine, caloric restriction and exercise can be advised, but these prescriptions often are not successful.

Autonomic side effects such as urinary retention and impotence may be more likely in patients with preexisting autonomic problems, such as those with diabetes. It is rational to attempt management of these side effects with bethanechol, a cholinergic agonist drug that does not cross the blood–brain barrier. Initial dosage should be conservative—5 mg three or four times daily; the dose can be increased if tolerated and helpful. The main side effect is nausea.

Finally, the possibility that MAOIs may influence patients' response to insulin leads us to recommend that when insulin-dependent diabetics are started on MAOIs, blood sugar should be checked with a glucometer four times a day over the first 72 hours of treatment and for a similar period after each dosage increase.

PSYCHOSTIMULANTS

Psychostimulants offer some patients distinct advantages over traditional antidepressants. Unlike CyADs, psychostimulants produce an improvement in mood that, if it occurs, is rapid, usually within the first 24 to 48 hours of treatment. In addition, the psychostimulants are relatively well tolerated even in most older, medically ill patients. Patients with recent myocardial infarctions, congestive heart failure, or ventricular arrhythmias, and patients who were taking an MAOI within the last 2 weeks, are at risk for complications with psychostimulants (Berlim & Turecki, 2007). However, the possibilities of rebound depression after cessation of the drugs, habituation, abuse, and precipitation of paranoid reactions argue against routine usage of psychostimulants to treat major depression except in patients whose medical illness contraindicates use of standard antidepressants. Drug interactions with psychostimulants are listed in Table 21.9. Commonly used psychostimulants and their usual daily doses include methylphenidate (10–60 mg/day, usually divided in twice-daily doses), dextroamphetamine (10–40 mg/day divided in twice-daily doses), atomoxetine (40–120 mg/day divided in twice-daily doses), and pramipexole (0.25 to 1 mg three times daily).

Bupropion, with its CNS stimulant properties, might be considered as a long-term antidepressant for patients who respond well to dextroamphetamine or methylphenidate. Psychostimulants, however, remain valuable and essential treatment modalities for psychiatrists working with the medically ill.

Although little debate continues as to the short-term efficacy of psychostimulants in the treatment of depression among the medically ill, the use of methylphenidate among patients with a variety of neurological injuries has helped to clarify how methylphenidate and dextroamphetamine work and how they may be most effectively employed. Galynker et al. (1997) studied the effects of methylphenidate on negative symptoms (typically including social withdrawal, flattened affect, anhedonia), other measures of depression, and cognition. Negative symptoms and cognition both improved, whereas other measures of depression did not. This is consistent with many other studies in which methylphenidate and dextroamphetamine have been shown to improve psychomotor performance. In the severely ill patient, such as poststroke patients, linking the use of psychostimulants to rehabilitation such as physical therapy can have a synergistically beneficial effect (Delbari, Salman-Roghani, & Lolk, 2011; Max, Richards, & Hamdan-Allen, 1995; Van Dyck et al., 1997; Walker-Batson et al., 1995; Whyte et al., 1997). Psychostimulants can both hasten stroke therapy and improve the outcome (Grade et al., 1998).

Masand, Pickett, and Murray (1991) performed a retrospective, uncontrolled review of 4740 consecutive hospital consultations in patients with secondary depression (i.e., the onset of the depression coincided with or came after their medical illness). Of the 198 patients treated with psychostimulants (primarily dextroamphetamine), 82% experienced some improvement and 70% were retrospectively rated as markedly improved. Side effects encountered included confusion and agitation (4 patients), hypomania (3 patients), paranoid delusions (3 patients), elevated blood pressure and sinus tachycardia (3 patients each), and 1 case of atrial fibrillation. In another retrospective chart review study of 29 patients by Rosenberg, Ahmed, and Hurwitz (1991), although moderate or marked improvement was seen in 55% of the patients, significant side effects were noted in 28%, including agitation, tachycardia, and visual hallucinations. The presence of delirium predicted nonresponse.

Masand, Murray, and Pickett (1991) noted improvement in 82% of 17 poststroke patients studied retrospectively with equal efficacy with dextroamphetamine and methylphenidate. Improvement typically was rapid, usually within the first 2 days of treatment. Lingam and associates (1988) retrospectively studied the records of 25 patients with poststroke depression who were treated with methylphenidate at dosages of at least 20 mg/day for 5 consecutive days. These authors found “complete” recovery from depression in 52% of the patients. In a prospective study of another medically ill population, depressed cancer patients, Fernandez et al. (1987) treated 30 patients (7 men and 23 women) at an initial dose of 10 mg of methylphenidate three times daily, with 23 showing marked or moderate improvement. This study included 11 patients who were treated for 1 year at low doses of 5–10 mg/day without evidence of tolerance or abuse. One patient with dementia became more agitated and confused on the psychostimulant.

A subgroup of medically ill patients who may not fare well under psychostimulant treatment includes those infected

with HIV or with hepatitis C virus. Studies with methamphetamine indicate that this particular amphetamine may both undermine the immune response to these viruses and enhance the neurotoxicity of HIV (Cadet & Krasnova, 2007; Ferris, Mactutus, & Booze, 2008; Ye et al., 2008). This finding may not apply to all viruses nor even to all psychostimulants. For example, methamphetamine appears to inhibit the replication of the influenza A virus (Chen, Wu, & Chen, 2012).

Although use of psychostimulants in the treatment of primary depression in physically healthy patients remains controversial, their use in medically ill patients—at least for short periods—is well accepted. It is important to remember, however, that there is no formal FDA approval for using these medicines as antidepressants.

The two most commonly used psychostimulants are methylphenidate and dextroamphetamine.

Dextroamphetamine is approximately twice as potent as methylphenidate, with typical therapeutic dosages of 10–20 mg/day for dextroamphetamine versus 20–40 mg/day for methylphenidate (Jenike, 1985). Higher doses may safely be used as need indicates (Berlim & Turecki, 2007). Dextroamphetamine excretion is influenced by urinary pH, and when urine is acidic, dextroamphetamine is excreted more rapidly and largely unchanged in the urine (Thus, ascorbic acid or cranberry juice could be used in the ambulatory treatment of mild dextroamphetamine toxicity.). Its plasma half-life is approximately 12 hours (Chiarello & Cole, 1987) as opposed to the 2-hour average half-life of methylphenidate, which is quickly metabolized by the liver to ritalinic acid, a metabolite with little CNS activity (Goff, 1986). Long-acting forms of dextroamphetamine and methylphenidate are available.

Adderall is a new stimulant approved for the treatment of attention deficit disorder with hyperactivity and for narcolepsy. It is a combination of mixed salts of amphetamine product consisting of dextroamphetamine sulfate, dextroamphetamine saccharate, amphetamine sulfate, and amphetamine aspartate. To our knowledge, it has not yet been used for depression in the medically ill.

In general, the psychostimulants are safe for short-term use. Occasional reports of important side effects encourage vigilance in monitoring patients’ responses. Rarely, a switch into mania may be provoked by a psychostimulant (Parker & Brotchie, 2010). Among children taking psychostimulants for attention deficit hyperactivity disorder, over 90% of cases of psychostimulant-induced mania or psychosis occur in children with no history of either. Hallucinations are often visual or tactile (Mosholder, Gelperin, Hammad, Phelan, & Johann-Liang, 2009). Pramipexole has been associated with hypersexuality and impulse-control disorders such as pathological gambling among patients taking the medication for Parkinson’s disease (Weintraub et al., 2010). For those patients with psychostimulant intoxication as the cause of their altered mentation, discontinuation of the offending agent and supportive care are usually sufficient. In those few patients in whom a diathesis has been activated—for example, those patients whose latent bipolar disorder is unmasked by a psychostimulant—more prolonged management may

be required. In some cases, despite significant side effects it is not possible to eliminate some form of stimulant altogether. An example is Parkinson's disease, in which dopamine agonist therapy is often complicated by psychiatric side effects. In these cases, cautious selection of another agent to control side effects may be needed. Dose reductions of the psychostimulant, as well as lower potency antipsychotics such as clozapine and quetiapine, have been used with success in such cases (Georgiev et al., 2010; Rotondo, Bosco, Plastino, Consoli, & Bosco, 2010).

CLINICAL PEARLS

- Because many patients with orthostatic hypotension lack subjective symptoms of orthostasis, the clinician should assess postural signs when the mechanism of a drug predicts risk, such as with prescription of a TCA (Lanier et al., 2011).
- Antidepressant use travels with an increased risk of having a hip fracture among elderly patients, both for TCAs and SSRIs (Oderda et al., 2012).
- Citalopram will raise the level of the beta blocker metoprolol and possibly other beta blockers as well. No clinically significant interactions have been noted with digoxin, lithium, warfarin, or carbamazepine. Omeprazole, which inhibits CyP450-2C19, might elevate citalopram levels.
- The half-life of escitalopram is roughly doubled in the elderly. Significant liver disease slows the metabolism of escitalopram, and the dosage should be halved.
- Both citalopram and escitalopram can prolong the QT interval.
- We recommend adhering to the following principles in the use of neuroleptics in the medically ill:
 - Whenever possible, identify and treat the underlying illness rather than treating superficial symptoms. For example, treat the etiology of a patient's delirium or cognitive impairment instead of merely controlling secondary symptoms of agitation or hallucinations.
 - Avoid polypharmacy that is not scientifically based on the results of randomized, controlled, clinical trials and be cognizant of the potential for drug interactions and of pharmacokinetic and pharmacodynamic reasons for increased risks of adverse effects. For example, decreased albumin in malnourished patients implies the increased bioavailability of free fractions of protein-bound drugs and therefore more potent effects per milligram dosage (more unbound drug is available to act on receptor sites).
 - Identify specific target symptoms and carefully evaluate the treatment response objectively. Whereas agitation and behavioral symptoms may respond promptly,

symptoms such as hallucinations and delusions may require weeks to respond.

- Use the minimum effective dosage.
- Lurasidone is complicated by dose-dependent EPS that may be seen in as many as 10% of patients, and akathisia in as many as 20% (Yasui-Furukori, 2012).
- Because Invega paliperidone is prepared as a time-released product stored within a rigid capsule, patients with intestinal strictures should not take it.
- Physical dependence to benzodiazepines can occur within as short a time as 2–3 weeks, and often does occur within 4 months, at 2–5 times the therapeutic dose.
- Buspirone may also help treat functional dyspepsia, as it relaxes the fundus (Tack et al., 2012).
- Pharmacokinetic distinctions are especially significant because there is no convincing evidence that one benzodiazepine is clinically more effective than any other, and no evidence that benzodiazepines marketed as hypnotics for the treatment of insomnia are more effective for sleep than those marked as anxiolytics, and vice versa.
- An important complication of depot olanzapine treatment is a postinjection delirium sedation syndrome (PDSS). PDSS occurs in 0.07% of injections and typically within 1 to 3 hours of receiving the injection. It resembles an overdose of olanzapine and is characterized by sedation grading into somnolence, dizziness, confusion, and dysarthria.
- At each point along the way, MAOI-related safety issues should be reinforced. As a practical precaution, a sticker stating that the patient is “allergic to Demerol (meperidine)” can be placed on the patient's chart.

DISCLOSURES

Dr. Brown has no potential conflicts to disclose.

Dr. Fogel is Chief Scientific Officer of Synchronuron Inc., Managing Director of Anal-Gesic LLC, and Executive Vice President of PointRight Inc. He is the sole inventor or lead inventor on several pharmaceutical patents. In his opinion these affiliations do not entail any conflict of interest with regard to the editing of this book or his personal contributions to it. He has no other potential conflicts, direct or indirect, financial or otherwise, to disclose in connection with the editing of this book or his personal contributions to it.

PHARMACOKINETICS OF PSYCHOTROPIC DRUGS IN THE CONTEXT OF GENERAL MEDICAL ILLNESS

Cynthia A. Gutierrez and Barry S. Fogel

INTRODUCTION

Pharmacokinetics provides details of the relationship between the dose of drug administered and the alterations in drug concentration in the body over time (Varghese, Roberts, & Lipman, 2010). In patients with general medical illness, the pharmacokinetic parameters of many psychotropic agents can be altered, at times drastically. Chronic disease states, acute medical problems, surgery and other procedures, and concomitant nonpsychotropic medications all play a role. In addition to the influence of impaired hepatic or renal function, other factors relevant to pharmacokinetics include changes in protein binding and altered gastrointestinal function such as delayed gastric emptying or altered gastrointestinal transit time. Alternate nonenteral routes of administration and specialized oral formulations can have special relevance in the context of diseases that interfere with swallowing or gastrointestinal function. Changes in drug levels due to pharmacokinetic factors can lead to toxicity or to lack of efficacy, and the influence of psychotropic drugs on the pharmacokinetics of general medical drugs can cause toxicity or lack of efficacy of those medications. Therapeutic drug monitoring—and sometimes pharmacogenetic testing—can reduce risk in many cases, while in others the best risk mitigation strategy is to use a different drug or different dose. General advice such as “start low and go slow” is naïve and in some cases actually is counterproductive; when mental and behavioral symptoms are the greatest and most immediate threat to patients’ function and well-being, it is far better to make the right choice of psychotropic drug and dosage as soon as possible.

Pharmacokinetics specifically deals with all of the steps between the administration of a dosage form and the elimination of the drug from the body (Shargel, Wu-Pong, & Yu, 2005). This includes the delivery of the drug to its ultimate site of action—the brain in the case of psychotropic drugs. Pharmacodynamics characterizes the relationship between the drug concentration at the site of action and the drug’s clinical effects, both therapeutic and adverse. In other words, pharmacokinetics is what the body does to the drug, and pharmacodynamics is what the drug does to the body. The relevant steps in pharmacokinetics are summarized by the acronym ADME: Absorption, Distribution, Metabolism, and Excretion. These processes are sequential at the molecular

level, but at the gross level they are simultaneous; one process can influence another, as when the action of a drug on the intestine influences the absorption of drugs still present there.

PHARMACOKINETICS VERSUS PHARMACODYNAMICS

Brain effects do not correspond directly to the blood concentrations of a drug for several reasons. First, the level of the drug in the blood can differ greatly from the level of the drug in the central nervous system (CNS) because of the blood–brain barrier. The difference in concentrations can be as great as two orders of magnitude; it is related to the lipophilicity of the drug, whether its entry into the brain is facilitated by its interaction with a transporter, and whether the drug is actively transported into or out of the cerebrospinal fluid (CSF). Second, the drug’s mechanism of action may not require that the drug be continuously present; it may, for example, induce RNA transcription leading to the synthesis of a protein that will persist for hours or days. And third, the changes in neuronal function initially produced by the drug can cause secondary changes in the same neurons or connected neurons that produce clinically relevant effects. For example, if a drug blocks a neuron’s dopamine receptors that neuron will synthesize additional receptors; also, activity in related glutamatergic neurons will increase. This in turn may have effects on the targets of those neurons’ axons.

THE PHARMACOKINETIC CURVE

The pharmacokinetic (PK) curve, or time-concentration curve, is a plot showing time since drug administration on the x-axis and the drug’s blood concentration (typically its plasma level) on the y-axis. It is illustrated in Figure 22.1. Three essential parameters of the PK curve, which do not totally define it but are critical to the drug’s clinical effects, are the *maximum concentration attained* (C_{max}), the *time needed to reach the maximum concentration* (T_{max}), and the *total area under the PK curve* (AUC) (Shargel, Wu-Pong, & Yu, 2005). The AUC is based on extrapolation of the PK curve to infinity from the last actual measurement of concentration (Shargel,

Figure 22.1 The Pharmacokinetic Curve.

Wu-Pong, & Yu, 2005). The definitions of some common PK terms including the parameters of the PK curve are shown in Table 22.1.

PHARMACOKINETICS AND GENERIC SUBSTITUTION

When generic equivalents of previously approved drugs receive regulatory approval they are required to be *bioequivalent*. This is defined as having a Cmax and an AUC whose 95% confidence limits in a clinical population lie between 80% and 125% of the (mean) Cmax and AUC of the originally approved

drug (Center for Drug Evaluation and Research, 2003). Note that formulations that are bioequivalent are not necessarily identical in their pharmacokinetic properties, because (1) the Tmax and exact shape of the PK curve are not required to be equivalent; (2) the confidence limits of the new formulation's PK parameters can vary with the subject population tested; and (3) the excipients in the new formulation need not be the same as in the original one, and in some patients the excipients could have a biological effect—for example, if the patient was allergic to one of them. Of the noted reasons, the population-specificity of the PK curve is most relevant to medical psychiatrists. The similarity of two formulations of the same drug might be less in patients with abnormal gastrointestinal function, or in patients who are taking several other drugs with physiological actions that influence the absorption of the drug of interest. In addition, any specific patient can be an outlier in whom the ratios of Cmax and AUC lie outside the 80%–125% range.

These considerations do not rule out the substitution of generic for brand name drugs or of one generic drug for another; they only imply that the optimal dosage of two different formulations might not be the same for a specific patient, and that a specific patient might experience a different response—either therapeutic benefits, adverse effects, or both—with one formulation of a drug versus another. It is thus useful to know when a pharmacy substitutes one maker's formulation for another, particularly for drugs in which precise dosage is clinically important. If clinicians are aware of

Table 22.1 TERMINOLOGY IN PHARMACOKINETICS

PARAMETER (SYMBOL)	DESCRIPTION	TYPICAL UNITS
Dose (D)	Amount of drug administered	mg
Dosing interval (τ)	Time between drug dose administrations	hours
Maximum concentration (Cmax)	Peak plasma concentration of a drug after administration	mg/L, μ g/ml
Tmax	Time to reach Cmax	hours
Minimum concentration (Cmin)	Lowest (trough) concentration that a drug reaches before the next dose is administered.	mg/L, μ g/ml
Volume of distribution (Vd)	Apparent volume in which a drug is distributed (i.e., the parameter relating drug concentration to drug amount in the body)	liters
Concentration (C)	Amount of drug in a given volume of fluid, usually plasma	mg/L, ng/ml, μ g/ml
Elimination half-life ($T_{1/2}$)	Time required for the concentration of the drug to reach half of its original value	hours
Elimination rate constant (k_e)	Rate at which a drug is removed from the body	hours ⁻¹
Infusion rate (k_i)	Rate of infusion required to balance elimination	mg/hour, ml/hour
Area under the curve (AUC)	Integral of the concentration-time curve (after a single dose or in steady state)	(mg/L) * hours
Clearance (CL)	Volume of plasma cleared of the drug per unit time	L/hour
Bioavailability (F)	Systemically available fraction of a drug	percentage \leq 100%

DeVane, 1990.

the potential for a difference in effects or tolerability, they will be quick to recognize it and respond accordingly. This is especially important for drugs with a narrow therapeutic index or a small range between concentrations required for therapeutic effect and those that cause toxicity.

There have been instances where change to generic formulations initially deemed bioequivalent by the FDA have resulted in decreased efficacy and/or increased toxicity. Phenytoin, carbamazepine, clozapine, and bupropion have each had reports of these issues with generic formulations (Hartley, Aleksandrowicz, Ng, McLain, Bowmer, et al., 1990; Jumao-as, Bella, Craig, Lowe, & Dasheiff, 1989; Chen, Allen Oxley, & Richens, 1982; Oles, Penry, Smith, Anderson, Dean, et al., 1992; Lam, Ereshefsky, Toney, & Gonzales, 2001; Kluznik, Walbek, Farnsworth, & Melstrom, 2001; Woodcock, Khan, & Yu, 2012). In the instance of the bupropion product, specifically the 300mg tablet, reports of decreased effectiveness led to further pharmacokinetic studies and subsequent withdrawal from the market (Woodcock, Khan, & Yu, 2012).

ABSORPTION

Absorption is both the rate and extent to which a drug leaves its administration site, passes through biological barriers, and reaches the systemic circulation (Buxton & Benet, 2011; Bauer, 2011). Absorption of a medication is dependent on many factors, including the surface area of the site(s) of absorption, blood flow to the site(s), the dissolution of the drug in body fluids (which often is pH-dependent), and the presence and functioning of active or passive transporters. Clinical focus typically is on *bioavailability*, the fraction of the dose administered that eventually reaches the circulation. (Note, however, that equal bioavailability of two versions of the same drug does not imply therapeutic equivalence, as the two versions can differ in the peak blood level they produce—C_{max}—and in how rapidly a therapeutic threshold is reached—both factors of obvious therapeutic relevance.) Bioavailability is conventionally abbreviated by an upper case F.

For medications administered intravenously, F equals 1. For intramuscular medications, absorption can be erratic as the drug must pass one or more biological membranes to enter the systemic circulation. For patients with poor peripheral perfusion, as with shock, absorption after intramuscular administration may be delayed or incomplete. For enterally administered medications, bioavailability usually is less than 1 because absorption is often incomplete, and because drugs absorbed in the intestine are subject to metabolism prior to reaching the systemic circulation—the “first pass” effect. Most first-pass metabolism takes place in the liver, but for some drugs there is a significant contribution from metabolic enzymes in the intestinal mucosa. In addition to the absolute value of F, the *variability of F between patients* is a potentially important distinction between drugs. For example, when metabolism of a drug by CYP3A4 in the intestinal mucosa lowers a drug’s bioavailability, patients with low activity of

this enzyme will absorb more drug. It is known that CYP3A4 activity is highly variable in the general population, and hence that F for that drug will be highly variable as well. A few points related to drug absorption are useful in choosing drug oral drug formulations:

1. Solutions and suspensions are most rapidly absorbed; enteric-coated tablets are least rapidly absorbed; capsules are more rapidly absorbed than standard tablets. When a rapid onset of action is sought from a single oral dose of a medication, a solution or suspension is the ideal form when it is available and the patient will accept it.
2. Prodrugs—agents that become therapeutically active only after they are metabolized—usually are lipophilic compounds with high bioavailability; many have rapid absorption. Many prodrugs offer the additional benefit of avoiding a high C_{max} of the active metabolite(s); this mitigates C_{max}-related side effects and in some cases reduces the liability of the drug for abuse via intravenous injection. Slowly activated prodrugs can make once-a-day administration feasible for drugs that in their active form would require dosing several times a day for optimal effectiveness. Prodrugs usually are not suitable when a rapid onset of action is required because their activation rather than their absorption controls the rate of onset of therapeutic action, making rapid onset of action dependent upon rapid metabolism.
3. Extended-release or enteric-coated formulations should be avoided when a patient has diarrhea or another condition involving increased intestinal motility. In the latter situation, the pill may have passed into the colon or even have been eliminated before it is fully absorbed.
4. Delayed gastric emptying and/or decreased intestinal motility, caused either by disease or by anticholinergic drugs or opiates, can have variable and in some cases unpredictable effects on the absorption of psychotropic drugs. For most psychotropic drugs the bulk of absorption takes place in the proximal ileum (DeVane, 1990), and changes in gastrointestinal motility will alter the time after ingestion at which the drug reaches the absorptive site. Overall bioavailability can change, and in virtually all cases the PK curve will have different parameters with consequences for therapeutic efficacy or side effects.
5. For many psychotropic drugs, absorption will differ when the drug is taken with food versus in the fasting state. Food effects are measurable more often than they are clinically relevant, but they do matter for some drugs, as noted below. Effects can go in either direction. Because food slows gastric emptying and intestinal transit time, it can increase the absorption of drugs when the latter depends on time in contact with a particular area of the small intestine. For the same reason it can increase the time to peak concentration of the drug. On the other hand, if there are saturable transporters involved in intestinal absorption of the drug, substances in the food eaten can compete with the drug for spots on those

transporters and thereby reduce absorption. The bioavailability of ziprasidone *doubles* when it is taken with or just after a high-calorie meal as opposed to in the fasting state (Lincoln, Stewart, & Preskorn, 2010). Similarly, the antipsychotic lurasidone's AUC doubles, and C_{max} increases threefold, when administered in the fed state and should be given with at least 350 calories for maximal absorption (Lurasidone Product Information, 2013). On the other hand, acamprosate, a drug used to suppress craving in recovering alcoholics, is 20%–30% less well absorbed if taken with food (Saivin, Hulot, Chabac, Potgieter, Durbin, et al., 1998), probably because of competition for amino acid Saivin transporters in the small intestine. Complicating matters further, the peak concentration nonetheless can be higher when acamprosate is taken with food. Medical conditions and their treatments often influence food intake, but there is little literature on food effects on psychotropic drug pharmacokinetics.

Patients receiving *intermittent* tube feedings can be dosed with drugs in either the fed or the fasting state. Those receiving *continuous* tube feedings are always in the fed state and therefore may require adjustment of dosage of drugs for which there is a significant food effect. Phenytoin pharmacokinetics especially are altered in the presence of tube feedings, with serum concentrations three to four times lower when given during continuous tube feedings, and should be administered at least 2 hours before and 2 hours after tube feedings (Bauer, 1982).

6. In addition to hepatic metabolism, the first-pass effect also includes active transport of drug from the portal circulation back into the intestinal lumen and metabolism of the drug by enzymes in the intestinal wall. Of these, CYP3A4 (see the discussion of the cytochrome p450 enzymes below) is particularly important because (1) it is the CYP enzyme most prevalent in intestinal cells, (2) it is involved in the metabolism of several commonly prescribed psychotropic drugs, and (3) it can be induced or inhibited by several common general medical drugs. Active transport of drugs from intestinal mucosal cells back to the intestinal lumen is mediated by P-glycoprotein (Pgp). This mechanism has clinically relevant magnitude for the antipsychotic drugs risperidone and paliperidone; when Pgp is inhibited by the calcium channel blocker verapamil, absorption of the drugs increases significantly (Nakagami, Yasui-Furukori, Saito, Tateishi, & Kaneo, 2005). The pharmacodynamic consequences are even greater than the pharmacokinetic effects, because Pgp is also present at the blood–brain barrier, and its inhibition increases the proportion of drug in the plasma that reaches the brain. Likewise, when Pgp activity is increased in the presence of a Pgp inducer, less substrate is able to reach the CNS. Other psychotropic drugs for which Pgp is important in controlling absorption (and distribution to the CNS) are the antidepressants amitriptyline, nortriptyline, doxepin, citalopram, paroxetine, sertraline, and venlafaxine; the anticonvulsants carbamazepine and topiramate; and

the antipsychotics chlorpromazine, quetiapine, and olanzapine (Levine, 2012). Other common inhibitors of Pgp are cardiovascular drugs amiodarone, captopril, carvedilol, diltiazem, felodipine, and ranolazine, and the anti-infectives azithromycin, clarithromycin, erythromycin, itraconazole, and ketoconazole (U.S. Food and Drug Administration, 2011). Certain psychotropics including venlafaxine (though not desvenlafaxine) (Bachmeier, Beaulieu-Abdelahad, Ganey, Mullan, & Levin, 2011), and, to a lesser extent, nefazodone and trazodone, can induce Pgp, leading to a decrease in bioavailability and clinical efficacy of substrates such as protease inhibitors (Levine, 2012). Table 22.2 summarizes drugs that have been involved in clinically significant interactions through Pgp, are associated with strong warnings, or have recommendations for specific interventions, including several other drugs of medical-psychiatric interest.

7. When the first-pass effect leads to very low bioavailability or highly variable bioavailability (which can be a worse problem clinically), nonenteral options should be considered if they are available. These include intravenous, intramuscular, or subcutaneous injections; transdermal delivery systems; sublingual tablets; intranasal and inhaled preparations; and rectal suppositories—the latter effective because the lower rectal veins drain in to the systemic rather than the portal circulation.

DISTRIBUTION

Drug distribution refers to the disposition of drug from the plasma to various tissues of the body, including body fat, internal organs, and the brain. Once a drug has entered the systemic circulation, it is distributed to the interstitial and intracellular fluids (Buxton & Benet, 2011). Distribution immediately after drug administration is dependent on cardiac output, regional blood flow, and tissue volume. Initially, the drug is rapidly distributed to well-perfused organs including the heart, brain, kidneys, and liver. During the second phase, drug is distributed to and reaches equilibrium with other tissues such as muscle, skin, and adipose tissue, at a much slower rate (minutes to hours). Tissue distribution is dependent on lipophilicity and pH, but most significantly on the compound's ability to bind with plasma proteins and macromolecules (Buxton & Benet, 2011).

PROTEIN BINDING

In the context of pharmacokinetics, protein binding refers to the binding of drugs to *plasma* proteins, rather than to cellular proteins in the tissues that are the targets of drug action. Protein binding impacts the ability of drug to reach the desired target, as only unbound drug may cross tissue to the site of action, and only free, unbound drug is in equilibrium across membranes. Bound drug cannot cross the blood–brain barrier, nor can it be metabolized by the liver or excreted by a normal kidney. In general, acidic drugs bind to

Table 22.2 POTENTIALLY SIGNIFICANT INTERACTIONS WITH PSYCHOTROPIC AGENTS VIA ALTERATIONS IN Pgp ACTIVITY

Pgp SUBSTRATES	Pgp INHIBITORS (POTENTIALLY INCREASE CNS LEVEL OF SUBSTRATE)	Pgp INDUCERS (POTENTIALLY DECREASE CNS LEVEL OF SUBSTRATE)
<i>Antidepressants</i>	<i>Cardiovascular drugs</i>	<i>Antiepileptic agents</i>

albumin while basic molecules bind to alpha-1 glycoprotein (also known as alpha 1 acid glycoprotein, AAG, or orosomucoid, OSM). There is clinically relevant genetic variation in the binding properties of AAG in the general population. The extent of binding to other plasma proteins is much less, and not likely clinically relevant. Protein binding is a saturable, nonlinear process, with the amount bound dependent on drug concentration, affinity for protein binding sites, and the number of binding sites present. With most drugs within their usual therapeutic ranges the extent of protein binding as indicated by the free fraction is relatively constant (Buxton & Benet, 2011).

The degree of protein binding exhibited by a drug is expressed quantitatively as the free fraction—the concentration of free drug divided by the total concentration (free + bound). Binding of drugs to albumin or AAG is nonspecific, and, because the number of binding sites is limited, it is possible for the free fraction of a drug to increase if the patient is taking other drugs that bind to the same protein. At equilibrium the percentage of binding will not affect the free concentration of the drug. Nonetheless, there can be a transient change in the free concentration following the addition of a second drug that competes for the first for binding on the same protein. This can be relevant in drugs with slow elimination and a low therapeutic index. In malnourished patients with low serum protein concentrations, the binding sites for drugs will be saturated at lower concentrations, and clinical effects related to competition of drugs at protein binding sites may be greater.

Disease processes can alter the concentrations of albumin and AAG and thereby increase or decrease protein binding. Hypoalbuminemia, typically due to malnutrition, hepatic dysfunction, or proteinuria, can increase the free fraction of acidic drugs. The free fraction of basic drugs such as chlorpromazine can be decreased under conditions that increase AAG levels; these include inflammatory states due to infection, autoimmune disease, cancer, or myocardial infarction. Animal models suggest that even physiological stress without disease can elevate AAG levels. Cigarette smoking can elevate AAG levels; the clinical significance of this fact is uncertain. The basal concentration of AAG is much lower than that of albumin; however, in inflammatory states it can increase to a multiple of baseline (Dasgupta, 2007). In patients receiving the antipsychotic clozapine, plasma concentrations can be significantly elevated to toxic levels in the presence of severe inflammation and infection although signs of toxicity may not be present. This may be attributed to elevations of AAG, as the drug is highly bound to AAG (Espnes, Heimdal, & Spigset, 2012).

Changes in the free fraction (as opposed to the level of free drug) typically do not affect drug efficacy or toxicity at equilibrium, because the concentration of free drug is unchanged. Note, however, that, laboratory assays of drug levels typically measure total drug concentration. When therapeutic drug monitoring is utilized and dosing targets a particular range of blood levels, a change in free fraction can be problematic because published therapeutic ranges presume a typical free fraction (Schmidt, Gonzalez, & Derendorf, 2010; Dasgupta, 2007). Within an individual patient, a change in measured blood levels between two points in time can be due to a change

in protein binding rather than a change in free concentration; such a change should not be misinterpreted as a reason to change dosage or to suspect the drug is not being taken as prescribed. The free drug level should be monitored in this situation if therapeutic drug monitoring is clinically required. When highly protein-bound drugs are initiated in situations where decreased protein binding is likely to occur, as with hepatic cirrhosis or the nephrotic syndrome, the starting dose should be lower than usual. If lack of efficacy suggests the dose should be increased, monitoring of free drug levels—if available—will reduce the risk of toxicity (Israili & Dayton, 2001).

The above issues of protein binding and drug levels are clinically significant only for drugs that are highly protein bound, namely, with a free fraction <20% (Table 22.3). The mood-stabilizing antiepileptic drugs carbamazepine and valproate both are in this category. For these drugs, measurement of free drug levels is preferable when it is available—especially when a patient has risk factors for decreased protein binding such as low serum albumin and/or concomitant drugs that compete for albumin binding sites.

The total volume of distribution of a drug is a function of both body mass and body composition; obese patients can, for lipophilic compounds, have a significantly higher volume of distribution than those of normal weight, especially with highly lipophilic drugs (Hanley, Abernethy, & Greenblatt, 2010). They therefore can require higher doses for efficacy than patients with normal body weight. The need for a dosage adjustment, and how much dosage should be changed, is specific to the drug and its indication. Linear adjustment via mg/kg dosing is not generally appropriate because body *composition* is different in severely obese patients. In morbid obesity, 20%–40% of weight increase is attributable to an increase in lean body mass (De Baerdemaeker, Mortier, & Struys, 2004). The clinical relevance of obesity to pharmacokinetics is complex because obesity can affect drug metabolism as well as drug distribution, and it is often associated with inflammatory states that increase AAG levels, thereby increasing the protein binding of basic drugs. Appropriate adjustments for dosing for obesity will depend on the distribution and metabolism of the specific drug and whether the drug is intended for short-term or longer-term use. Before equilibrium is reached, a patient with a large volume of distribution can require larger than usual doses for an adequate therapeutic effect; after equilibrium is reached, the need for a dosage adjustment will depend more on whether the drug's metabolism was affected by a medical complication of obesity.

Finally, distribution of a drug across the blood–brain barrier is obviously relevant to its therapeutic effect; however, differences in such distribution rarely manifest as differences in blood concentrations because the brain contributes relatively little to the overall volume of distribution. Pgp, mentioned above in connection with its role in drug absorption, has special relevance to distribution across the blood–brain barrier; some drugs are actively transported from brain endothelial cells back into the bloodstream. Inhibitors of Pgp, therefore, will therefore increase the relative brain concentration of a drug that it actively transports. Inducers of Pgp will reduce the relative brain concentration of such a drug. The effect of Pgp at

Most of the listed drugs are primarily bound to albumin. Those with significant binding to AAG are indicated with an asterisk. PK issues related to protein binding of albumin-bound drugs usually arise because of low serum albumin, typically due to liver disease, malnutrition or proteinuria. PK issues related to protein binding of AAG-bound drugs usually arise because of an increase in AAG with infection and with inflammatory or autoimmune disease.

the blood–brain barrier can be large and clinically important (Lin & Yamazaki, 2003). Drugs with clinically significant Pgp transport at the blood–brain barrier include the antidepressants fluvoxamine, citalopram and escitalopram, venlafaxine and desvenlafaxine; and the antipsychotic drugs haloperidol, risperidone, and paliperidone. The pharmacokinetic and pharmacodynamic effects of Pgp will go in the same direction; when induction of Pgp decreases a drug's blood level by decreasing its net intestinal absorption, it will also decrease the drug's brain

level by increasing the drug's transport across the blood–brain barrier from brain to blood. For some drugs, the difference in the brain: blood ratio can be more clinically important than the difference in blood level. Four general medical drugs known to be potent inhibitors of Pgp are erythromycin, ketoconazole, quinidine, and verapamil (Wang, Ruan, Taylor, Donovan, Markowitz, et al., 2004; Linnet & Ejlsing, 2007). A frequently updated source of data on PK properties of drugs, including their interactions with transporters like Pgp, can be found on the Internet at www.drugbank.ca. The website provides PK information as well as supportive references.

ELIMINATION

METABOLISM

Most psychotropic drugs are lipophilic; this property facilitates their crossing the blood–brain barrier. Psychotropic drugs that are not lipophilic either are effective despite relatively low brain levels or have their access to the brain facilitated by transporters. In their unaltered form, lipophilic compounds are poorly excreted by the kidneys because they will be reabsorbed into the systemic circulation in the renal tubules. To terminate drug action and to allow for elimination from the body, drugs are transformed by metabolism to more polar, hydrophilic compounds. Hydrophilic metabolites usually are inactive, but some have useful therapeutic activity and have even been developed as drugs in their own right—for example, 9-hydroxyrisperidone (paliperidone).

Prodrugs are pharmaceuticals that are biologically inactive until they are metabolized; one or more of the metabolites has the desired therapeutic effect. Prodrugs are developed to address poor bioavailability and/or other pharmacokinetic challenges. Medical psychiatrists should be aware when a patient has a medical condition that can interfere with the metabolism of a prodrug into its active metabolite(s).

Biotransformation reactions can be classified as Phase I (oxidative) or Phase II (conjugative). Phase I oxidative reactions usually involve an enzyme of CYP (aka cytochrome P450) system. Phase II conjugation reactions, which bind the drug to be eliminated with a polar moiety such as glucuronic acid, a sulfate group, or glutathione, often involve the uridine 5-diphosphate glucuronosyltransferase (UGT) enzymatic system. The liver is the most important site of action of both the CYP and the UGT enzymes, though both classes of enzymes are found in the gut wall and to a lesser extent in other tissues.

Typically, drugs undergo Phase I metabolism followed by Phase II metabolism (Sandson, Armstrong, & Cozza, 2005). For most psychotropic drugs, Phase I metabolism is most important for terminating the drug's action; even for prodrugs that initially are activated by Phase I metabolism, subsequent Phase I metabolism of the active metabolite yields an inactive molecule. Changes in Phase II metabolism have particular clinical significance when the drug or active metabolite does not undergo Phase I metabolism (or when its Phase I metabolism is impaired). In this situation, an active molecule can accumulate to potentially toxic levels.

Cytochrome P450 enzymes, a family of heme-containing proteins, are so named because when they are in the reduced state and complexed with carbon monoxide, they are a red pigment with maximum absorption of light at a wavelength of 450 nm. The enzymes are officially designated by the initials CYP followed by an Arabic numeral, a capital letter, and another numeral to indicate the family, subfamily, and specific isoform of the enzyme. Their function is catalysis of oxidative reactions, most often the insertion of an oxygen atom into an organic compound, such as replacing a hydrogen atom with a hydroxyl group. Standard nomenclature is to refer to a CYP enzyme in a standard font and its associated gene in italics; for example, *CYP3A4* denotes the gene encoding the enzyme CYP3A4. Six enzymes are most important in the oxidation of CNS drugs: CYP1A2, 2C9, 2C19, 2D6, 2E1 and 3A4. Among these, 2D6 and 3A4 have the highest concentration in the human body. CYP2B6 and CYP2C8, while less important overall, still have a role in clinically significant interactions with common drugs.

Exogenous substances including foods, drugs, and environmental toxins can induce or inhibit the CYP enzymes. CYP *induction* usually entails increased synthesis of the enzyme beginning with increased mRNA transcription, although some CYP inducers raise CYP enzyme levels by inhibiting degradation of the enzyme. These mechanisms imply that the induction of a CYP enzyme will take hours, and maximal induction can take several days to weeks. In contrast to induction, *activation* of a CYP enzyme entails a direct interaction between a substance and the enzyme that increases the enzyme's catalytic activity with its intended substrate. Activation is an immediate process rather than a delayed one. Though it is frequently observed in vitro, activation is an uncommon cause of clinical drug interactions. CYP *inhibition* usually involves interaction of the substance with the enzyme rather than the substance influencing the synthesis and degradation of the enzyme. An inhibitor of a CYP enzyme can be a substrate, but not necessarily. Inhibitors can be reversible or irreversible, competitive or noncompetitive. Clinically relevant drug interactions involving CYP enzymes can be understood better if the specific mechanisms of the involved drugs' effect on the CYP enzymes in question are known (Hollenberg, 2002).

Most of the well-recognized, clinically significant drug interactions involving psychotropic drugs are related to Phase I oxidative metabolism of the drugs by the CYP system. Clinically significant interactions related to Phase II metabolism or to the action of membrane transporters like Pgp are less common. Because of the wider occurrence of clinically significant interactions related to Phase I metabolism, most studies of genetic variation in psychotropic drug metabolism have focused on genetic variability in the CYP system.

PHARMACOGENETICS

With respect to a particular CYP enzyme, individuals can be classified as *extensive metabolizers* (EM)—the usual or “wild-type” situation—or as poor (PM), intermediate (IM),

or ultrarapid (UM) metabolizers. For some enzymes and substrates, UM status requires induction by exposure to the substrate. Patients with PM status have two defective copies of the gene for the CYP enzyme of interest, and therefore will metabolize the drug through an alternate pathway. Patients with IM status usually have one normal gene and one defective gene, so that the pathway using that CYP enzyme continues to be used but others become more relevant. Inhibition of a CYP enzyme can have a more profound clinical effect in IM patients, while having no effect at all in PM patients who don't use the enzyme in metabolizing the drug in question.

Particular ethnic groups are known to have a relatively high prevalence of non-wild type CYPs. Variability is especially well known and clinically important for CYP2D6, where 5%–10% of Caucasians are PM, 50% of Asians are IM, many Africans are IM, and UM status is common among those of Middle Eastern or North African descent (Cavallari & Lam, 2011).

The impact on the metabolism of a specific drug of a specific CYP variation will depend on whether the drug is primarily, substantially, or secondarily metabolized by that CYP enzyme. When a drug is primarily metabolized by a CYP enzyme—call it CYPx—no other CYP enzyme is involved in metabolizing the drug under usual conditions. In this situation of absent or diminished enzyme activity, CYPx will significantly raise the drug concentration because alternative metabolic pathways will be substantially less efficient. When the drug is substantially metabolized by CYPx, that enzyme will account for the metabolism of more than 50% of the drug under usual conditions. If another CYP enzyme, CYPy, accounts for the rest, diminished activity of enzyme CYPx will lead to a larger role for CYPy. The level of activity of CYPy will then determine whether the blood level of the drug is elevated. In that situation, diminished activity of enzyme B will become clinically relevant. When a drug is partially metabolized by CYPx—namely, when CYPx accounts for less than 50% of its metabolism under usual conditions—an *isolated* decrease in the activity of CYPx will not increase the drug level significantly, but a decrease in the activity of CYPx can be clinically important if there also is decreased activity of the CYPs that usually dominate the drug's metabolism. If the activity of CYPx is markedly *increased*, it doesn't matter whether that CYP is primarily, substantially, or partially involved. It will take over most of the metabolism of the drug, and the blood level will be lower than usual for a given dose. For this reason the ultrarapid phenotype for a CYP enzyme has broad clinical implications, because it can affect blood levels of drugs for which that enzyme is not usually the main metabolic route.

The following discussion of the CYP enzymes and drug interactions is introductory and heuristic; the reader is encouraged to consult standard references on potential drug interactions before starting any new drug. We will focus especially on situations where a single CYP enzyme is primary for a particular drug, as those situations offer good examples of the underlying principles.

INDICATIONS FOR PHARMACOGENETIC TESTING

The indications for pharmacogenetic testing are evolving with the increasing availability and decreasing cost of profiling patients' genetics of drug metabolism. Patients interested in gaining maximal control of their pharmacologic fate can already get pharmacogenetic profiles without a physician's order from several consumer-oriented clinical laboratories. Testing should be considered when patients have a strong personal or family history of unusual reactions to drugs that suggest PM or UM status, or when the patient belongs to an ethnic group known to have a high frequency of non-EM status for a CYP enzyme important in metabolizing a drug under consideration for use in treatment. An increased likelihood of PM status is especially relevant in when a drug to be prescribed has a low therapeutic index and/or when the patient will be on other drugs that can cause severe interactions in patients with PM or IM status.

From the practical viewpoint, CYP genotyping is widely available and the sample for analysis can be obtained by swabbing the patient's cheek—no blood draw is required. Laboratories will test for individual CYP enzymes or perform a panel of four, where the enzymes are known to affect the metabolism of many psychotropic drugs and to have a significant frequency of PM and/or UM alleles in the general population, and where genotype and phenotype have an established association. These enzymes are CYP1A2, 2C9, 2C19, and 2D6. CYP3A4 has very wide variability in enzyme activity in the general population, and it has many single nucleotide polymorphisms. However, the genotype–phenotype associations are not sufficiently well established to infer the enzyme's metabolic activity from the genotype. For this reason, CYP3A4 is not included in pharmacogenetic testing even though interactions involving CYP3A4 are very common.

For many psychotropic drugs, the rate of metabolism is linear over a broad range of dosing (first order kinetics). For these drugs, clearance of the drug at therapeutic dosage can be inferred from clearance of the drug at a “microdose”—a dose small enough that significant adverse effects would be unlikely even in a patient with unusual sensitivity to the drug. The feasibility of assessing patients' profiles of CYP activity through assaying blood levels after microdosing of typical substrates for each of the CYP isozymes has been demonstrated in research contexts, but for both practical and regulatory reasons it is not clinically used. However, measuring the blood level of one specific drug of interest after a small test dose could be a rational clinical strategy when one plans to use a drug with widely variable pharmacokinetics and many potential interactions in a vulnerable patient with clinical conditions or on other drugs that could alter the activity of the relevant CYP enzyme(s) (Madakasira & Khazanie, 1985).

CYP ENZYMES ESPECIALLY RELEVANT TO PSYCHOTROPIC DRUG METABOLISM

Several CYP enzymes are especially relevant to the metabolism of commonly prescribed psychotropic drugs; there are some facts about each that are well established and of particular interest to medical psychiatrists.

CYP1A2

CYP1A2 is the primary route of metabolism for the antipsychotic drugs clozapine and olanzapine, for the SSRI fluvoxamine, for the stimulants caffeine and theophylline, for the adrenergic agents propranolol and tizanidine, and for the analgesic (and potentially hepatotoxic) drug acetaminophen. It has a substantial role in the metabolism of the antidepressants duloxetine, clomipramine, and imipramine, and the antipsychotic drug chlorpromazine. It is induced by cigarette smoking and by insulin, modafinil, and omeprazole among other drugs, and (at least in theory) by eating large quantities of cruciferous vegetables such as broccoli and cauliflower. It is strongly inhibited by fluvoxamine, ciprofloxacin, and several other fluoroquinolones, and potentially by herbal teas made from chamomile, dandelions, peppermint, or cannabis. It is worth noting that smoked cannabis, like smoked tobacco, *induces* CYP1A2 (Grant, Atkinson, Gouaux, & Wilsey, 2012).

Of particular concern to medical psychiatrists is the effect of alterations in CYP1A2 activity on concentrations of drugs such as clozapine and olanzapine, and of *discontinuing* agents that induce CYP1A2. General medical illness, and especially hospitalization, frequently is associated with smoking cessation, dietary changes, and/or discontinuation of drugs because they are deemed undesirable or unnecessary in the current medical context. When smoking cessation is initiated, drugs like clozapine and olanzapine can require dosage reductions of 30%–40% to maintain the prior blood level of the drug (Haslemo, Eikeseth, & Tanum, 2006). The effect of smoking to induce CYP1A2 can be maximal on as few as seven cigarettes a day, so even light smokers are vulnerable to the interaction (Lowe & Ackman, 2010).

There is substantial variability of CYP1A2 activity in the general population on a genetic basis; patients can be PM, IM, EM, or inducible UM, who develop ultra-rapid metabolism when exposed to a CYP1A2 inducer. The majority of patients of pure Japanese descent will have the UM phenotype; it is also very common in patients of sub-Saharan African background. While UM status is less common among patients of northern European background, it is common enough that it should be considered when a patient with such background fails to respond as expected to a conventional dose of a drug primarily metabolized by CYP1A2 (Mrazek, 2010).

CYP2C9

CYP2C9 is the primary metabolic enzyme for the SSRI fluoxetine and for the anesthetic (and potential antidepressant) ketamine. It is also the predominant metabolic enzyme for most of the nonsteroidal antiinflammatory drugs (NSAIDs), for the antiepileptic drug (AED) phenytoin, for several commonly prescribed oral hypoglycemic drugs, for the PDE5 inhibitor sildenafil and for the anticoagulant warfarin. It is strongly inhibited by valproate (Gunes, Bilir, Zengil, Babaoglu, Bozkurt, et al., 2007), by the antifungal drugs miconazole and fluconazole, by amentoflavone, a constituent of *Ginkgo biloba* and of St. John's wort (Kimura, Ito, Ohnishi, & Hatano, 2010), and by cannabis (Yamaori,

Koeda, Kushiara, Hada, Yamamoto, et al., 2012). The effect of valproate, one of the most common treatments for bipolar disorder, is of special interest to medical psychiatrists since it implies that patients treated for bipolar disorder with valproate can develop severe hypoglycemia on typical doses of oral hypoglycemic drugs, and can develop unexpectedly severe side effects from typical doses of NSAIDs or sildenafil. Whether the effect of *Ginkgo biloba* or St. John's wort on CYP2C9 will be clinically significant will depend on the dosage and on the amentoflavone content of the specific preparation consumed. Commercial preparations of these herbal remedies are standardized for their concentrations of ginkgosides and of hypericin, respectively, and not for their concentrations of amentoflavones; this introduces another element of uncertainty. Cannabis use should be taken into account when considering CYP2C9 substrates, especially in light of increasing legalization for both medical and recreational use. There are relatively few inducers of CYP2C9; the anti-TB drug rifampicin is the best known.

There is significant genetically based variability of the CYP2C9 phenotype in the general population. Of patients of European descent approximately 10% will be poor metabolizers. However, some ethnic groups have a particularly high prevalence of non-EM phenotypes. For example, over one-third of patients with Ashkenazi Jewish background have either an IM or PM phenotype (Scott, Edelman, Kornreich, Erazo, & Desnick, 2007). Patients of Asian or African descent are unlikely to have non-EM phenotypes.

CYP 2C19

CYP2C19 is the predominant enzyme in the metabolism of the SSRIs citalopram and escitalopram, of the TCAs amitriptyline and clomipramine, and of the benzodiazepine diazepam and its active metabolite nordiazepam (Andersson, Cederberg, Edvardsson, Heggelund, & Lundborg, 1990). It has a substantial role in the metabolism of the TCAs doxepin, imipramine, and nortriptyline (Morinobu, Tanaka, Kawakatsu, Totsuka, Koyama, et al., 1997); the SSRI sertraline; and the MAO-A inhibitor moclobemide, as well as in the metabolism of the older AEDs phenytoin, primidone, and phenobarbital. It is induced by the AED carbamazepine, by the oral contraceptive norethisterone, by the corticosteroid prednisone, and by the anti-TB drug rifampicin, among others. It is strongly inhibited by fluvoxamine and fluoxetine (Jeppesen, Gram, Vistisen, Loft, Poulsen, et al., 1996).

Approximately 2% of patients of Northern European descent are PM for 2C19; 26% have the IM phenotype for 2C19. Among Chinese patients, however, only 25% of patients will have EM phenotypes, while 50% will have the IM phenotype and 25% will have the PM phenotype. Over 25% of patients of African descent will have PM phenotypes for 2C19. Four percent of the Northern European population have UM phenotypes and another 9% have a lesser degree of increased 2C19 activity. The UM phenotype is rare in Chinese patients. (Desta, Zhao, Shin, & Flockhart, 2002).

CYP2C19 is of special medical-psychiatric interest for several reasons. Prednisone is widely prescribed for a range of

inflammatory and autoimmune conditions, many of which have depression as a psychiatric complication or comorbidity. If such patients are treated for their depression with citalopram or escitalopram, the drug may have less efficacy than expected because it will be more rapidly metabolized. Initiation of prednisone in a patient on long-term treatment with diazepam may reduce levels of diazepam and its active metabolite nordiazepam, leading to a rebound of anxiety. Citalopram is very widely prescribed as an antidepressant and is generally viewed as having low toxicity, but it can cause dose-dependent QT prolongation. QT prolongation could be clinically significant in patients with the PM phenotype treated with typical doses of this drug. Many oral contraceptive drugs contain norethisterone. Such contraceptives can make citalopram or escitalopram less efficacious at their usual doses by accelerating their metabolism.

CYP2D6

CYP2D6, the second most prevalent drug-metabolizing enzyme in the human body, is involved in the metabolism of hundreds of drugs. It is the primary enzyme involved in the metabolism of the SSRI antidepressants fluoxetine and paroxetine; the SNRI venlafaxine; the TCAs desipramine, doxepin, and nortriptyline; the first-generation antipsychotic drugs chlorpromazine, haloperidol, perphenazine, and thioridazine (von Bahr, Movin, Nordin, Lidén, Hammarlund-Udenaes, et al., 1991); and the second-generation antipsychotic drug risperidone (Spina, Avenoso, & Facciola, 2001). It is substantial in the metabolism of several other antidepressants and of the second-generation antipsychotic drugs aripiprazole and olanzapine. It is important (primary or substantial) in the metabolism of the opioids codeine, hydrocodone, oxycodone, and tramadol. Both codeine and tramadol are prodrugs requiring metabolism for activation; thus, patients with the PM phenotype for 2D6 may get poor pain relief from codeine or tramadol, while those with the UM phenotype may get a more rapid onset of effect, with greater abuse liability. CYP2D6 has a substantial role in the metabolism of most of the beta blockers, the amphetamines and atomoxetine, and the cholinesterase inhibitor donepezil.

CYP2D6 is induced by dexamethasone and by rifampin. It is strongly inhibited by the antidepressants fluoxetine, paroxetine, and bupropion; by quinidine; and by the antiretroviral agent ritonavir. The effect of quinidine to inhibit CYP2D6 is exploited to increase dextromethorphan concentrations in the fixed-dose combination of quinidine and dextromethorphan, which is indicated for treating pseudobulbar affect.

CYP2D6 shows clinically important genetic variability. Five to ten percent of Caucasian patients and more than 10% of those with sub-Saharan African background have the PM phenotype. About half of the Asian population have the IM phenotype. And, a significant number of patients of North African or Middle Eastern background have the UM phenotype.

The involvement of CYP2D6 in the metabolism of opiate analgesics is of particular medical-psychiatric interest because pain and depression are associated, and it is common

for patients to receive both an opiate and an antidepressant. Fluoxetine, paroxetine, and bupropion can each prolong the effect of the commonly prescribed opiates oxycodone and hydrocodone, while interfering with the efficacy of codeine or tramadol.

CYP3A4

CYP3A4 is the most prevalent of all of the CYP enzymes. It is found in large quantities in the intestine as well as in the liver, and it is involved in the metabolism of hundreds of drugs. For psychotropic drugs, CYP3A4 typically is not the exclusive route of metabolism. When CYP3A4 is not the exclusive route of Phase I metabolism, the lack of CYP3A4 activity or its inhibition becomes clinically significant when the other CYP enzyme(s) involved also have diminished or absent activity.

Psychotropic drugs that are substrates for CYP3A4 include the tertiary amine TCAs; the SSRIs citalopram and escitalopram, norfluoxetine, and sertraline; the SNRI venlafaxine; trazodone and nefazodone; buspirone; several of the antipsychotic drugs including risperidone, iloperidone, haloperidol, aripiprazole, and ziprasidone; opiates including buprenorphine, codeine, fentanyl, and methadone; several of the benzodiazepines including alprazolam (Greenblatt, Wright, von Moltke, Harmatz, Ehrenberg, et al., 1998); the hypnotic “Z” drugs zolpidem, zaleplon, and eszopiclone; and the PDE5 inhibitors sildenafil and tadalafil. CYP3A4 is also involved in androgen and estrogen metabolism. Inducers of particular medical-psychiatric interest include the AEDs carbamazepine, oxcarbazepine, phenytoin, and phenobarbital; modafinil; glucocorticoids including prednisone; and the herbal remedy St. John’s wort. Strong inhibitors include the antidepressant drug nefazodone, several of the antiretroviral drugs, the macrolide antibiotics clarithromycin and telithromycin, and the antifungal drugs ketoconazole and itraconazole. Several other agents of medical-psychiatric interest are inhibitors of lesser or unknown strength. These include grapefruit juice, the SSRIs fluoxetine (and its metabolite norfluoxetine) and fluvoxamine, and the herbal remedies valerian, milk thistle, and *Ginkgo biloba*.

CYP3A4 activity varies widely in the general population, but the phenotypic variability is not readily assessed by pharmacogenetic testing.

Of particular interest to medical psychiatrists is the role of CYP3A4 in the metabolism of commonly prescribed hypnotic drugs, antianxiety drugs, and opiate analgesics, as medical patients often receive these in conjunction with drugs that can induce or inhibit its activity. Inhibition of CYP3A4 by grapefruit juice (Lilja, Kivisto, Backman, Lamberg, & Neuvonen, 1998) and induction of CYP3A4 by St. John’s wort have caused serious adverse events in well-documented cases.

CYP2E1

CYP2E1 metabolizes ethyl alcohol and several of the anesthetic drugs. While it typically has less of a role in ethanol

metabolism compared to alcohol dehydrogenase, it is induced by chronic alcohol use, thereby making alcoholics more rapid metabolizers of alcohol.

DRUG METABOLISM AND SELECTION OF PSYCHOTROPIC DRUGS

The medical psychiatrist has an opportunity to prevent adverse drug interactions related to drug metabolism in three general clinical situations:

1. The patient is taking one or more psychotropic drugs chronically, then develops an acute medical illness—or an exacerbation or relapse of a chronic medical condition—that necessitates starting a general medical drug that interacts with one of the continuing psychotropic drugs. In this case, preventive strategies include prospective adjustment of the psychotropic drug dose and/or the general medical drug dose, monitoring clinical presentation, therapeutic drug monitoring, and/or switching to a noninteracting alternative within the same therapeutic class.
2. The patient is being treated for one or more general medical conditions and then develops a mental disorder or other condition requiring treatment with a psychotropic drug. In addition to the strategies for the first case, here the medical psychiatrist may have the option of prescribing or recommending a psychotropic drug within the relevant therapeutic class that is less likely to cause a clinically significant drug interaction. For example, it is generally wise to avoid initiating fluoxetine in patients with multiple general medical conditions because of its strongly inhibitory effect on CYP2D6 and other inhibitory actions on CYP2C19 and CYP3A4.
3. Hospitalization or other consequences of acute general medical illness implies cessation of smoking or discontinuation of nonprescribed drugs or supplements that have affected drug metabolism. Discontinuation of agents that induce or inhibit the metabolism of the patient’s general medical or psychotropic drugs will alter the levels of those drugs, often with clinically significant consequences. Prevention is based on anticipating the effects and estimating their magnitude. If the expected effect is large, doses should be adjusted. If it is relatively small, closer clinical monitoring, potentially with checking drug levels, may suffice.

EXCRETION

Drugs and metabolites are removed from the body through excretion. The kidney is the primary organ for excretion of psychotropic medications, although there may be unabsorbed drug or metabolites secreted into the bile or directly into the intestinal tract that are excreted in the feces. Less clinically relevant, drugs may be excreted in sweat, saliva, tears, and breast milk. Renal excretion involves glomerular filtration, active tubular secretion, and passive tubular reabsorption.

Table 22.4 RELEVANT CYTOCHROME P450 DRUG INTERACTIONS

ENZYME	SUBSTRATE	INDUCER	INHIBITOR
CYP1A2	<i>Antidepressants</i>	<i>Smoking</i>	<i>Fluvoxamine Ciprofloxacin</i>
	Fluvoxamine	Cruciferous vegetables	Cimetidine
	Clomipramine	Insulin	Amiodarone
	Duloxetine	Modafinil	Interferon
	Imipramine	Omeprazole	
	<i>Antipsychotics</i>		
	Clozapine		
	Haloperidol

*activation required for clinical activity.

Glomerular filtration controls the amount of drug entering the tubular lumen. As noted above, only unbound drug is filtered except in cases of proteinuria. Active tubular secretion occurs via transporters in the proximal renal tubule and can add drug to the tubular fluid. Reabsorption occurs mainly in the distal tubule via nonionic passive diffusion, though some active reabsorption by transporters also occurs.

Pgp transporters, discussed above in connection with intestinal absorption and in affecting relative brain concentrations, are also located in the proximal tubules of the kidney, where they actively excrete certain drugs. Inhibition of Pgp at the proximal tubule can also lead to reduced clearance of those drugs. Thus induction of Pgp transporters in the kidney can reduce a drug's effect, while Pgp inhibition can increase it—but this will be the case only if the form of drug excreted by the kidney is active. Paliperidone, for example, is excreted in active form. Note that Pgp activity always reduces the effect of a CNS drug, if it matters at all, by reducing the drug's absorption from the intestine, by increasing its elimination via the kidney, and by removing drug from the CSF and thereby reducing the ratio of brain concentration to plasma concentration.

CLEARANCE

Clearance (Cl) describes the body's ability to remove drug from the plasma; it is often used as a synonym for renal clearance, although other organs are often involved. It is expressed in units of ml/minute. It is affected by body weight and surface area, protein binding, blood flow to the liver and kidneys, extraction ratio, renal function, hepatic function, and cardiac output. Clearance is useful in determining the dosing rate to maintain a steady-state concentration within a therapeutic window. When a drug has first-order kinetics, the elimination of it is proportional to its concentration. This is the case for most drugs for which renal excretion is the primary route of elimination. When it has zero-order kinetics, there is a fixed amount of drug that can be eliminated per unit time. Zero-order kinetics are most often encountered when the drug is eliminated via a metabolic process that is saturated (i.e., maximal) at usual concentrations of the drug. The antiepileptic phenytoin, while following first-order kinetics at low doses, changes to zero-order when the dose is increased and maximum velocity of metabolism (V_{max}) is reached (Richens, 1979). Of great importance to safe driving, the clearance via hepatic metabolism of ethyl alcohol has zero-order kinetics.

VOLUME OF DISTRIBUTION

Volume of distribution (Vd) relates the total amount of drug in the body at steady state to its plasma concentration. It is the volume of plasma that would be needed to yield the steady-state plasma concentration actually observed, if the entire body consisted only of plasma rather than an assortment of tissues with different affinities for the drug. A highly lipophilic drug can have a relatively large Vd because much of the drug will be absorbed by body fat. High protein binding is another factor that can raise the Vd. Loading doses often are employed when

initiating treatment with drugs that have a high Vd. Once the body is loaded with the drug, a steady-state concentration can be obtained with a lower daily dose of the drug, since only the drug that is free in the plasma can be eliminated.

ELIMINATION HALF-LIFE

Elimination half-life describes the rate of drug removal from the body. Specifically, $T_{1/2}$ is the time required for the plasma concentration (C_p) to decrease by 50%. Half-life is dependent on both clearance and volume of distribution:

$$T_{1/2} = 0.693 \times V_D / CL$$

Elimination half-life is useful in predicting the time to achieve steady state with regular dosing. *Steady state* describes the point where daily drug elimination equals the bioavailable daily dose of the drug. Conventionally, the time to steady state is estimated as 5 times $T_{1/2}$. Three half-lives after a drug is initiated or a dosage is changed its plasma concentration, C_p is at nearly 88% of the predicted steady-state concentration (C_{ss}); after 5 half-lives, C_p is at nearly 97% of C_{ss} . The value of $T_{1/2}$ can be used to determine a maximum interval between doses of a drug compatible with maintaining C_p above a therapeutic threshold. For example, if a drug has a minimum plasma concentration of 100 ng/ml for therapeutic efficacy, its $T_{1/2}$ is 12 hours and its C_{max} after an oral dose is 300 ng/ml the drug must be given twice daily, as the elimination half-life of 12 hours implies that C_p would be subtherapeutic 24 hours after a single dose.

THERAPEUTIC DRUG MONITORING

Therapeutic drug monitoring (TDM) is defined as the management of a patient's medication regimen based on the measured concentration of the drug in blood, plasma, serum, or another body fluid (Dasgupta, 2007). For drugs with a wide range between the concentration required for pharmacologic activity and toxicity—that is, drugs with a high *therapeutic index*—TDM is not routinely performed. For drugs with a low therapeutic index and a well-established therapeutic range—for example, lithium—the use of TDM is a standard of practice.

The measurement of drug levels in plasma, serum, or other body fluids has clinical utility in several situations where TDM is not the standard of practice. These situations arise often in medical psychiatry. They comprise the following:

1. A patient fails to respond to a prescription for a typical therapeutic dosage of a medication and does not have side effects typical for that medication. In this situation a low level of the drug in the blood can suggest an individual difference in ADME, implying that the typical dosage will be inadequate for that particular patient. Alternatively, the patient might not be taking the medication as prescribed.
2. A patient develops typical adverse effects of an excessive dose of a medication while under a prescription for a typical therapeutic dosage of a medication. In this situation a

high level of the drug in the blood can suggest an individual difference in ADME, implying that the typical dosage will be excessive for that particular patient. Alternatively, the patient might be taking more of the medication than is prescribed.

3. A patient has a history of poor adherence to prescriptions, or there is some other reason to believe that adherence to a prescription will be an issue. Checking a blood level after several scheduled doses can establish whether the patient is taking the medication. A patient's knowledge that the blood level will be checked can, in some cases, motivate the patient to be more adherent.
4. A patient has a known reason for having PK for a given drug differing from the general population. This could be having a genotype associated with poor metabolism or ultrarapid metabolism of the drug, having liver or kidney disease, being morbidly obese, or taking other medications that induce or inhibit the metabolism of the drug in question. In this situation a prospective dosage adjustment typically will be made based on an estimate of the patient's PK profile for the drug. Checking the blood level after one or several doses of the drug can inform a more accurate and patient-specific dosage adjustment.
5. A patient is taking a drug that does not have first-order kinetics and its therapeutic index is sufficiently low that there is a danger of toxicity during initial dosing adjustments.

Most psychotropic drugs follow first-order kinetics, in which the steady-state concentration of the drug is proportional to the total dose (Bauer, 2011). Exceptions are important, because when drugs do not have first-order kinetics small increments of dosage can produce large increases in blood levels, or, alternatively, large increments in dosage produce small increases in blood levels. Two antiepileptic drugs offer classic examples. In the case of phenytoin there is a maximum amount of drug that can be metabolized per day. If, for example, a dosage of 300 mg per day saturated the metabolic enzymes, a dosage of 350 mg per day might double the blood level of the drug. In the case of carbamazepine, the drug induces CYP3A4—the enzyme that is the principal enzyme in its own metabolism. When a patient is initiating therapy with carbamazepine, increases in dosage can be necessary just to maintain a constant blood level. Non-first-order kinetics are an especially relevant concern when a standard dosage increment (e.g., one pill per day) can alter a patient's blood level from a subtherapeutic to a toxic one, or when autoinduction of metabolism can lead to a loss of the drug's therapeutic effect.

PLASMA OR SERUM, TOTAL OR FREE CONCENTRATIONS

When physicians order “blood levels” of a drug, the clinical laboratory typically makes the decision about whether serum or plasma will be assayed for the drug. The difference between serum and plasma is the presence of clotting factors (proteins) in the latter

and the presence of substances released by clotting in the former. For drugs that are highly protein bound, the total concentration of drug can be greater in plasma than serum although the free drug concentration is the same in both. Therapeutic ranges for total drug concentration, therefore, can differ between serum and plasma. When feasible, measurement of the free drug concentration is the most reliable basis for TDM. When free drug levels are not available, protein binding effects should be considered in the interpretation of serum or plasma levels.

PK CONSIDERATIONS FOR SPECIFIC PSYCHOTROPIC DRUGS

For each psychotropic drug there are several PK considerations that together can help the medical psychiatrist anticipate issues that might necessitate dosage adjustments or even contraindicate the drug in particular patients. They are:

1. Hepatic metabolism
 - a. Is it necessary to activate the drug?
 - b. Is it necessary to inactivate the drug?
 - c. Are there active metabolites, and, if so, do they require further hepatic metabolism to inactivate them?
 - d. Are there active metabolites that can accumulate and cause toxicity?
 - e. What enzymes are involved, and which are primary?
 - f. Does the drug induce or inhibit its own metabolism?
 - g. Is the drug's metabolism affected by drugs commonly prescribed together with it?
2. Renal elimination
 - a. Is elimination by the kidney necessary to terminate action of the drug?
 - b. Are there toxic metabolites that must be eliminated by the kidney?
 - c. Is elimination of the drug and its metabolites dependent only on glomerular filtration, or is there a significant role for renal tubular function?
 - d. To what extent is the drug eliminated by hemodialysis?
3. Protein binding
 - a. Is the drug highly protein bound?
 - b. Is the drug bound to albumin, AAG, or both?
 - c. Is there significant binding to any other proteins?
 - d. Is the difference between serum and plasma levels big enough to impact TDM?
4. Interindividual variability
 - a. Is there large variability in the PK of the drug in the general population?
 - b. Are there known associations with age, gender, race, or ethnicity of the patient?
 - c. Are there well-established genetic issues affecting the drug's PK?
5. Nonlinear kinetics
 - a. Does the drug have nonlinear kinetics over some part of its usual dosage range?
 - b. Is the effect to increase or decrease the increase in blood concentration for a given dosage increase?

6. Nutritional issues
 - a. Is there a measurable food effect on drug absorption?
 - b. Is it clinically relevant?
 - c. How does malnutrition affect the drug's PK?
 - d. How does obesity affect the drug's PK?
 - e. How does obesity surgery affect the drug's PK?
7. Clinical significance of blood levels
 - a. Is there a well-defined therapeutic range ("therapeutic window")?
 - b. Is there a minimum threshold level for therapeutic effect?
 - c. Is there a maximum threshold above which significant toxicity is common?
 - d. Is TDM the standard of practice for utilizing the drug?
8. Dosing-related issues
 - a. How long does it take for the drug to reach steady state?
 - b. What is the elimination half-life?

ALTERNATE ORAL FORMULATIONS AND ALTERNATE ROUTES OF ADMINISTRATION

Alternate oral formulations comprise alternatives to standard tablets and capsules. Each alternative is associated with specific properties of interest to medical psychiatrists.

1. *Liquids—solutions and suspensions.* Liquids are more suitable for patients who have difficulty swallowing solids but not liquids, or who are unwilling to swallow pills for emotional reasons. These may be preferred after gastric bypass surgery, as absorption of liquid preparations is more predictable postprocedure than tablets or capsules. They also can be administered via a nasogastric tube or gastrostomy.
2. *Orally disintegrating tablets (ODTs)*—tablets that disintegrate while still in the mouth, with the active ingredient dissolving in the patient's saliva. Though there may be some absorption in the buccal and pharyngeal regions, their absorption takes place primarily in the gastrointestinal tract. Their primary benefit is ease of administration. Typically there is no difference in Tmax or Cmax between ODTs and standard tablets, and the quantitative effect on bioavailability is not clinically significant.
3. *Sublingual tablets.* These have rapid onset of action and high bioavailability, since first-pass metabolism is bypassed as the buccal and pharyngeal regions drain to the superior vena cava rather than to the portal vein. They require a measure of patient cooperation to keep the tablet under the tongue rather than swallow it. For this reason they are unsuitable for cognitively impaired patients.
4. *Controlled-release or extended-release (ER) tablets or capsules.* One specific form is the gastric retentive (GR) tablet. GR tablets, when taken with food, remain in the

stomach for several hours and slowly release the active ingredient into the gastric fluid. GR tablets must be taken with food to have optimal pharmacokinetics. Thus they work best with cooperative patients who eat regular meals. CR and ER tablets are helpful to individuals who are susceptible to adverse effects when the drug is at Cmax, as these tend to produce lower peak concentrations compared to standard formulations. CR and ER formulations can be suitable for less frequent dosing, which can improve treatment adherence. A special situation of note is the patient with cognitive impairment living in the community who can receive one supervised medication dose per day.

5. *Enteric-coated tablets*—tablets coated with a material impervious to stomach acid but soluble in the less acidic environment of the intestine. These are more tolerable to patients prone to dyspepsia, but their absorption can be adversely impacted by shortened intestine or a gastrointestinal hypermotility.

Non-oral routes of administration for psychotropic drugs similarly have properties with special medical-psychiatric interest. They have the common feature of increased bioavailability because they do not require intestinal absorption and they do not undergo first-pass metabolism.

1. *Injections*—intravenous (IV), intramuscular (IM), or subcutaneous (SC). Injections avoid treatment adherence issues—although not compliance issues in patients who are resistant to care in general or injections in particular.
 - a. IV administration allows for 100% bioavailability, and when given as a bolus Tmax is instantaneous with a corresponding relatively high Cmax. This can be desirable in patients in severe distress, but can also produce severe adverse effects. Administering medications as an intravenous push runs the risk of the patient experiencing an anaphylactic reaction. Additionally, if an adverse event occurs, administration is already complete and cannot be terminated early. Intravenous infusion likewise results in 100% availability but allows for greater control of absorption rate by adjusting rate of the drip. The issue of respiratory depression is particularly salient with IV antianxiety drugs, antiepileptic drugs, and analgesics; these can interact with other CNS depressants and cause a life-threatening situation. In general, IV psychotropic drugs with respiratory depressant effects should not be given without anesthesiology backup. IV access can be difficult in patients who have scarred veins because of frequent prior IV access (e.g., patients receiving cancer chemotherapy) or IV drug abusers.
 - b. IM injections have a slower onset of action and lower Cmax than IV injections. The onset of action can be especially slow in patients with poorly perfused muscle because of peripheral vascular disease, heart failure, or shock. They are also associated with an increase in serum CPK levels. While serum CPK is no longer used to diagnose myocardial infarction, it is used in the

diagnosis of neuroleptic malignant syndrome. A moderate elevation of CPK should be interpreted with caution when a patient with suspected neuroleptic malignant syndrome has recently received an IM injection of an antipsychotic drug—or any other drug. IM injections can be problematic in severely malnourished or cachectic patients with markedly decreased muscle bulk. In these patients the trauma to muscle can be clinically significant, while blood levels can rise more rapidly than in patients with normal muscle bulk.

- c. SC injections are seldom used to administer psychotropic drugs.
 - d. Although not approved for intravenous use, haloperidol given IV for delirium can be effective. However, there is a higher risk of QTc prolongation and *torsades de pointes* with IV administration compared with oral. The FDA issued a safety alert in September 2007 detailing this information. The alert recommends ECG monitoring, should haloperidol be given IV (Food and Drug Administration, 2007). The antiemetic droperidol is sometimes provided in lieu of haloperidol, but it also carries the risk of QTc prolongation and *torsades de pointes*, with the FDA issuing a black box warning for the risk of sudden cardiac death in 2001 (Gan, 2004). Other parenteral antipsychotics are designed to be given as intramuscular injections and should not be given IV.
 - e. Benzodiazepines—specifically lorazepam, diazepam, and midazolam—may be administered IV. Because of increased lipophilicity compared to lorazepam, diazepam and midazolam more easily cross the blood–brain barrier and thus have a much more rapid onset of action.
2. *Depot intramuscular injections*, also known as long-acting injectable (LAI) formulations, mitigate problems of medication nonadherence in outpatients. However, once a depot injection has been given it is not feasible to remove it, so if a patient has an adverse reaction to the medication it may last a long time. When depot injections of antipsychotic drugs cause adverse neurological effects, these can persist for weeks or months. Depot injections of narcotic antagonists can complicate analgesic therapy if the patient develops a painful medical condition, has severe trauma, or requires major surgery while the drug is still on board. In general, depot injections are not a good choice for patients with multiple medical comorbidities.

The pharmacokinetics of LAI antipsychotic drugs exhibit the “flip-flop” phenomenon, where the drug’s half-life is determined by its absorption rate rather than by its elimination (Ereshefsky et al., 1983). Flip-flop kinetics occur when a drug’s elimination rate is substantially shorter than the rate of absorption. The PK curve of haloperidol, a typical LAI antipsychotic drug, is shown in Figure 22.2. When a change in metabolism occurs, the plasma concentration changes but the terminal elimination half-life does not.

Figure 22.2 Pharmacokinetic Curve of Haloperidol Decanoate.

While medical psychiatrists would be unlikely to start an LAI antipsychotic drug in a person with an unstable medical condition, they are likely to encounter patients already receiving LAI antipsychotic drug therapy who need to start a general medical drug that might interact with the antipsychotic drug already on board. While the new drug likely won’t affect absorption, it can effect distribution, metabolism, and excretion of the antipsychotic agent. For example, a patient on an LAI formulation of paliperidone might develop sedation or dystonia if started on cyclosporine, a potent inhibitor of Pgp. Or, a patient with schizoaffective disorder in remission on LAI olanzapine might experience an exacerbation of symptoms after the initiation of insulin for new-onset Type II diabetes, because insulin can induce CYP1A2.

3. *Rectal gels and suppositories*. Rectal administration may be considered if oral or parenteral routes are not viable options. However, absorption following rectal administration is erratic and often incomplete. Bioavailability is affected by drug placement: absorption in the lower rectal region bypasses first pass metabolism, while medication absorbed in the upper region passes through the portal vein. In general, 50% of drug absorbed rectally will bypass first-pass metabolism. These formulations have a limited role in the administration of psychotropic drugs. One exception is the use of rectal diazepam for the treatment of status epilepticus or delirium tremens in patients in which IV access is difficult to establish. In fact, diazepam is more rapidly absorbed as a rectal solution than either oral or IM administration, although rectal suppository results in decreased bioavailability and slower rate of absorption (Moolenaar, Bakker, Visser, & Huizinga, 1980). Diazepam is also commercially available as a rectal gel, which has 90% bioavailability with Tmax at 1.5 hours (Diastat Product Information).
4. *Transdermal patches*. Transdermal administration allows for a drug to be delivered into the systemic circulation via the skin. Transdermal patches are the most common formulation. Depending on the product, drug may be released immediately or over a prolonged period of time. Most formulations deliver drug at a constant rate

(zero-order process), providing a stable plateau plasma concentration. Transdermal administration bypasses first-pass metabolism and thereby increases bioavailability. Transdermal patches are more convenient than taking oral medication several times a day, when the pharmacokinetic properties of oral formulations would require it. Transdermal patches obviously avoid direct gastrointestinal irritation, and in some cases the lack of direct gastrointestinal effect reduces systemic toxicity. This is the case with the transdermal MAO inhibitor selegiline, which does not cause the food–drug interactions (“cheese effect”) that limit the use of oral MAO inhibitors in treating depression. Finally, transdermal preparations do not produce high peak concentrations of drug that can be associated with adverse effects.

Transdermal delivery systems are available for an increasing number of psychotropic drugs. At this time there are transdermal delivery systems available for (1) selegiline, an MAO-B inhibitor antidepressant; (2) clonidine, an alpha-2 agonist used in treating tics and ADHD; (3) methylphenidate, a stimulant used in treating ADHD; (4) the opiate analgesics buprenorphine and fentanyl; (5) the cholinesterase inhibitors donepezil and rivastigmine; (6) nicotine, used for aid in smoking cessation; and (7) the sex hormones estradiol and testosterone. At this time there is no transdermal antipsychotic drug available.

Medical psychiatric patients for various reasons require individualization of drug dosage, and in some cases the optimal dose of a transdermally delivered drug can be less than the dose in the smallest marketed skin patch. In this situation, cutting of the patch often is considered—but this approach is not appropriate for transdermal systems based on a reservoir of drug rather than drug homogeneously embedded within a matrix. If a reservoir-based patch is cut, the entire dose of the drug can leak out at once. Successful transdermal therapy requires adequate blood flow to the skin and adequate adhesion of the patch to the skin. Patches should be applied to dry, hairless, and well-perfused skin for this reason. Absorption is variable in cachectic patients.

5. *Nasal sprays.* Because the nasal mucosa is highly vascularized, drugs administered by the intranasal route are rapidly absorbed into the systemic circulation; thus the nasal route is an alternative to injections when a rapid onset of action is required. These preparations have the same advantages as sublingual preparations; the nasal mucosa is well-perfused. Nasal disease is the primary limitation to their use. Nasal sprays can be problematic when the drug has a low therapeutic index and the patient is cognitively impaired or has a drug abuse liability. “Puffs” of a nasal spray can be large or small, and when a patient takes multiple puffs the resulting drug level may be toxic.
6. *Intranasal solutions.* While no solution of a psychotropic drug has been FDA approved for intranasal administration, it is feasible to administer solutions by the intranasal route if the volume of drug required is 1–2 ml or less.

When a solution is given this way the PK curve is similar to that produced by IV injection. Intranasal administration has been of particular interest in the treatment of narcotic overdose with naloxone and in the treatment of benzodiazepine overdose with flumazenil.

Off-label intranasal administration of solutions designed for injection might be contemplated if rapid onset of action is important and venous access is difficult. However, the very rapid onset of action with intranasal administration makes necessary the same precautions regarding cardiac, respiratory, and neurological side effects that are taken with intravenous administration.

Psychotropic drug administration by the intranasal route is entirely off-label. Notwithstanding, there is a community of interest in intranasal drug therapy including family members of opiate addicts and of children with intractable seizures. Intranasal benzodiazepines can abort status epilepticus as well as intravenous or rectal benzodiazepines (Holsti, Dudley, Schunk, Adelgais, Greenberg, et al., 2010), and intranasal naloxone can be life-saving in cases of opiate overdose (Robertson, Hendey, Stroh, & Shalit, 2009). Flumazenil, the benzodiazepine antagonist, might also be given by this route for emergency treatment of benzodiazepine overdose (Heard, Creighton, & Lerman, 2009).

7. *Aerosols for inhalation.* These offer a virtually instantaneous onset of action without requiring intravenous access. They lead to a high C_{max}, which can be either helpful or harmful according to the circumstances. Inhaled products are rapidly absorbed if they reach the lower airways, which have a larger total surface area than the small intestine. This requires optimization of particle size to 1–4 microns in diameter; larger particles can be deposited in the large airways, and smaller ones can be exhaled prior to absorption (Rabinowitz, Lloyd, Munzar, Myers, Cross, et al., 2006).

The first-generation, mid-potency drug loxapine is available in an inhaled formulation (Lesem, Tran-Johnson, Riesenberger, Feifel, Allen, et al., 2011). The drug is rapidly absorbed into the systemic circulation with a T_{max} of 2 minutes, unlike oral and intramuscular, which offers an average T_{max} of 2 hours and 1 hour respectively (Spyker, Munzar, & Cassella, 2010).

AVAILABILITY OF ALTERNATE FORMULATIONS

Many psychotropic drugs come in alternate formulations that are FDA-approved. Others are at times administered off-label by routes other than the ones for which they are marketed. For example, capsules are emptied and dissolved in water to make a solution, or a drug designed for IM injection is given intravenously. These improvised approaches to drug delivery can have unwanted consequences when their implications for pharmacokinetics are not appreciated. When a solution intended for IM use is given IV, the C_{max} will be higher and the T_{max} will be shorter. This can potentially increase side effects dependent on C_{max} such as cardiac arrhythmias or

respiratory depression. On the other hand, the short T_{max} makes intensive monitoring and emergency backup more practical. A CR tablet can be turned into an immediate-release product; doing the same for a GR tablet will destroy the physical properties that enable its retention in the stomach.

Availability (in the United States) of alternate formulations of psychotropic drugs is shown in Table 22.5. Drugs not ordinarily classed as psychiatric drugs are included if they are widely prescribed for psychiatric conditions; propranolol for symptoms of anxiety disorders is an example. The table includes only those alternate formulations that are FDA approved for some indication. Formulations made by compounding pharmacies or available in the United States only via personal importation are not included.

IMPACT OF ORGAN SYSTEM DISEASES ON PHARMACOKINETICS

KIDNEY DISEASE

Compounds with a high fraction of drug excreted unchanged remain active until they are eliminated by the kidney, so decreased renal function will affect their therapeutic action and their toxicity more than it will for drugs that are inactivated by hepatic metabolism or by conjugation with a hydrophilic moiety. Relevant examples are lithium, gabapentin, topiramate, and paliperidone.

Of drugs dependent on renal excretion for termination of their activity, lithium is considered the most problematic

Table 22.5 AVAILABLE FORMULATIONS OF PSYCHOTROPIC MEDICATIONS

MEDICATION	FORMULATION
<i>Antidepressants</i>	
<i>Selective Serotonin Reuptake Inhibitors</i>	
Citalopram	Tablet, oral solution
Escitalopram	Tablet, oral solution
Fluoxetine	Tablet, capsule, oral solution, weekly tablet
Fluvoxamine	Tablet, extended release capsule
Paroxetine	Tablet, controlled release tablet, oral suspension
Sertraline	Tablet, oral solution
<i>Dual Reuptake Inhibitors</i>	
Bupropion	Immediate release tablet, sustained release tablet, extended release tablet
Duloxetine	Delayed release capsule
Venlafaxine	Tablet, extended release tablet, extended release capsule
Desvenlafaxine	Extended release tablet
Levomilnacipran	Extended release capsule
<i>Novel Mechanism Agents</i>	
Mirtazapine	Tablet, oral disintegrating tablet
Nefazodone	Tablet
Trazodone	Tablet
Vilazodone	Tablet
<i>Tricyclic Antidepressants</i>	
Amitriptyline	Tablet
Clomipramine	Capsule
Desipramine	Tablet
Doxepin	Capsule, oral solution
Imipramine	Tablet, capsule
Nortriptyline	Capsule, oral solution
<i>Monoamine Oxidase Inhibitors</i>	
Isocarboxazide	Tablet
Phenelzine	Tablet
Selegiline	Transdermal patch

MEDICATION	FORMULATION
<i>Antipsychotics</i>	
<i>First Generation Agents</i>	
Haloperidol	Tablet, oral solution, long-acting decanoate, short-acting IM solution
Fluphenazine	Tablet, oral elixir, long-acting decanoate, short-acting IM solution
Chlorpromazine	Oral tablet, injectable solution
Perphenazine	Tablet
Loxapine	Capsule, oral inhaler
<i>Second Generation Agents</i>	
Risperidone	Tablet, oral disintegrating tablet, oral solution, long-acting injectable suspension
Quetiapine	Tablet, extended release tablet
Olanzapine	Tablet, oral disintegrating tablet, long-acting injectable suspension, short-acting IM solution
Ziprasidone	Capsule, short-acting IM solution
Aripiprazole	Tablet, oral disintegrating tablet, oral solution, short-acting IM solution, long-acting injectable suspension
Paliperidone	Extended release tablet, long-acting injectable suspension
Iloperidone	Tablet
Asenapine	Sublingual tablet
Lurasidone	Tablet
Clozapine	Tablet, oral disintegrating tablet
<i>Anxiolytics</i>	
Buspirone	Tablet
Alprazolam	Tablet, oral disintegrating tablet, extended release tablet, oral solution
Chlordiazepoxide	Capsule
Clonazepam	Tablet, oral disintegrating tablet
Diazepam	Tablet, oral solution, injection solution, rectal gel
Lorazepam	Tablet, oral solution, injection solution
Oxazepam	Capsule
Clorazepate	Tablet, extended release tablet
Midazolam	Oral solution, oral syrup, injection solution
<i>Sedative Hypnotics</i>	
Estazolam	Tablet
Flurazepam	Capsule
Quazepam	Tablet
Temazepam	Capsule
Triazolam	Tablet
Eszopiclone	Tablet
Zaleplon	Capsule
Zolpidem	Tablet, extended release tablet, sublingual tablet, oral spray
Ramelteon	Tablet
<i>Autonomic Agents</i>	
Propranolol	Tablet, extended release capsule, oral solution, intravenous solution
Clonidine	Tablet, extended release tablet, transdermal patch
Guanfacine	Tablet, extended release tablet
Dexmedetomidine	Intravenous solution

Table 22.5 (CONTINUED)

MEDICATION	FORMULATION
<i>Antiepileptics and Lithium</i>	
Valproic acid and derivatives	Capsule, delayed release capsule, delayed release tablet, extended release tablet, oral liquid, intravenous solution
Carbamazepine	Tablet, chewable tablet, extended release tablet, extended release capsule, oral suspension
Oxcarbazepine	Tablet, extended release tablet, oral suspension
Lamotrigine	Tablet, extended release tablet, chewable tablet, oral disintegrating tablet
Levetiracetam	Tablet, extended release tablet, oral solution, intravenous solution
Tiagabine	Tablet
Gabapentin	Tablet, capsule, oral solution
Topiramate	Tablet, capsule, extended release capsule
Lithium	Tablet, extended release tablet, capsule, oral solution, oral syrup
<i>Stimulants</i>	
Dexedrine	Tablet, extended release capsule, oral solution
Dextroamphetamine/Amphetamine	Tablet, extended release capsule
Methylphenidate	Tablet, extended release tablet, chewable tablet, extended release capsule, oral solution, oral suspension, transdermal patch
Lisdexamfetamine	Capsule
Atomoxetine	Capsule
Modafinil	Tablet
Armodafinil	Tablet
<i>Cognition Enhancing Drugs</i>	
Donepezil	Tablet, oral disintegrating tablet, transdermal patch
Rivastigmine	Capsule, oral solution, transdermal patch
Galantamine	Tablet, extended release capsule, oral solution
Memantine	Tablet, extended release capsule, oral solution
<i>Drugs Used to Treat Addiction</i>	
Naltrexone	Tablet, long-acting injection
Acamprosate	Delayed release tablet, enteric coated tablet
Buprenorphine/Naltrexone	Sublingual tablet, sublingual film
Varenicline	Tablet
Nicotine Replacement	Gum, lozenge, transdermal patch, oral inhaler, nasal spray

due to its narrow therapeutic index and significant risk of severe toxicity. The renal clearance of lithium is proportional to creatinine clearance down to a creatinine clearance of 30 ml/minute. Below this point, tubular reabsorption of lithium has a larger role, so the clearance of lithium decreases more rapidly than creatinine clearance. An essential point is that lithium is reabsorbed in the proximal tubules in proportion to sodium reabsorption, so lithium reabsorption is increased when aldosterone is increased, when patients are on thiazide diuretics, or when the patient has another clinical condition (e.g., heart failure) or is taking another drug associated with sodium retention. Hypokalemia can be an indicator of such conditions and should be a trigger for closer monitoring of lithium levels, slower titration of

lithium dosage, and usually a lower ultimate dose of the drug. The complexity of giving lithium to patients with medical comorbidities has led many psychiatrists to avoid lithium in favor of other mood stabilizing agents, but this is not necessarily wise. Many patients with bipolar disorder attain a full remission on lithium but have only partial remissions on alternative agents. Furthermore, a full response to lithium makes neuroleptic drugs unnecessary; patients thus avoid the significant metabolic side effects of the latter drugs. Finally, there is some suggestion from recent research that consistent use of lithium can have a neuroprotective effect, preventing the loss of executive cognitive function that frequently complicates the long-term course of bipolar disorder (Diniz, Machado-Vieira, & Forlenza, 2013).

HEMODIALYSIS

Factors that affect drug removal by hemodialysis include water solubility, volume of distribution, molecule size, and degree of protein binding. Lipophilic or otherwise poorly soluble molecules are not dialyzed. When a drug has a high Vd, its concentration will change less with dialysis than one with a small Vd. Additionally, only free, unbound molecules can cross the dialysis membrane, so drugs with extensive protein binding will be less completely removed during the procedure. Information regarding psychotropic medications, renal impairment, and dialysis can be found in Table 22.6.

LIVER DISEASE

The liver is the primary site of drug metabolism, and thus the primary site of drug inactivation. The usual routes of inactivation of psychotropic drugs are oxidative reactions and conjugation with hydrophilic moieties; often the former are followed by the latter. Liver disease can alter any combination of pharmacokinetic parameters including bioavailability, the ratio of drug to metabolites, and conjugation of drug and/or metabolites as a prerequisite for renal excretion. For drugs metabolized by the liver, the typical effect of liver disease is an increase in drug level for a given oral dose—due to diminished

Table 22.6 DOSAGE ADJUSTMENTS OF SELECT PSYCHOTROPIC MEDICATIONS IN RENAL IMPAIRMENT

MEDICATION	RECOMMENDED DOSAGE ADJUSTMENT IN MILD TO MODERATE RENAL IMPAIRMENT (CRCL 30–50 ML/MIN)	RECOMMENDED DOSAGE ADJUSTMENT IN SIGNIFICANT RENAL IMPAIRMENT (CRCL 10–30 ML/MIN)	REMOVAL BY DIALYSIS

hepatic inactivation, and potentially also to portal-systemic shunting that reduces first-pass metabolism. However, the relationship of liver disease to drug action has potential complexities. Impaired venous drainage of the intestines due to portal hypertension can reduce the intestinal absorption of drugs. Laxatives given to mitigate hepatic encephalopathy can decrease intestinal transit time and reduce drug absorption. Ascites and edema associated with advanced liver disease increase volume of distribution, which can initially reduce drug levels for a given oral dose but that will slow the elimination of the drug from the body. Decreased levels of serum proteins can increase the biologically active free fraction of drugs that are extensively protein bound. Furthermore, when the compound administered is a prodrug that requires metabolism for activation, liver disease can be associated with decreased levels of active metabolites and thus a decrease in therapeutic effect (Verbeck, 2008).

Another concern is that the *metabolic* activity of the liver is not directly measured by typical laboratory tests. “Liver enzymes” such as ALT and AST measure leakage of enzymes from damaged hepatocytes, and increased bilirubin levels reflect impaired biliary excretion (in the absence of hemolysis). Decreased albumin levels or increased clotting times typically reflect decreased hepatic protein synthesis. None of these phenomena have a consistent proportionality to changes in drug metabolism.

Because of these complexities, specific precautions in drug administration related to hepatic dysfunction have been arrived at largely through clinical experience and are based on Child Pugh scores. Child Pugh is based on factors including international normalized ratio, albumin levels, and bilirubin, as well as degree of ascites and encephalopathy (Child & Turcotte, 1964; Pugh, Murray-Lyon, Dawson, Pietroni, & Williams, 1973). Scores are used to assess prognosis in those with liver disease. Therapeutic drug monitoring may be required—especially with narrow therapeutic index medications such as tricyclic antidepressants—to minimize risk of significant toxicity. Psychotropic drugs that require significant dosage adjustment in patients with hepatic dysfunction can be found in Table 22.7.

HEART DISEASE

Medical psychiatrists’ concerns about cardiovascular disease often have focused on cardiac rhythm; many psychotropic drugs affect the QT interval or potentially exacerbate conduction blocks; this issue is discussed in depth on cardiology chapter. However, both acute and chronic heart disease can have *pharmacokinetic* effects as well. Acute myocardial infarction or myocarditis can lead to increased levels of AAG, which will increase protein binding of basic drugs and lead to overestimation of the free drug concentration when the laboratory measures total concentration. The increase in protein binding can also slow the rate of renal clearance of the drug by increasing the volume of distribution. Heart failure can influence all four pharmacokinetic processes. Slowing of gastric motility can increase drug absorption, while decreased splanchnic blood flow can decrease it. Edema can increase volume of distribution. Hepatic congestion can lead to decreased drug metabolism. Decreased renal blood flow can imply decreased renal clearance, and clearance can be reduced further by sodium retention for drugs like lithium that are reabsorbed in the proximal tubules. The net effect will be greater with more severe heart failure, but the direction of effect, its magnitude, and its clinical relevance will depend on the drug—with, as always, drugs with a low therapeutic index being of greatest concern (Rodighiero, 1989). The drugs of greatest concern in patients with heart disease include tricyclic antidepressants and lithium, which not only have pharmacokinetic changes in patients with heart disease for the aforementioned reasons but also are known to have cardiotoxic effects (Roose, 1983; Roose, Glassman, & Dalack, 1989; Tilkian, Schroeder, Kao, & Hultgren, 1976).

RESPIRATORY DISEASE

Respiratory failure can influence the elimination of some drugs via metabolic acidosis. Decreased free fraction of basic drugs can occur (du Suich, McLean, Lalka, Erill, & Gibaldi, 1978), likely related to changes in alpha 1 glycoprotein concentrations. Further, decreased renal perfusion can impact elimination of drugs cleared by the kidney. Theoretically,

Table 22.7 DOSAGE ADJUSTMENTS OF PSYCHOTROPIC MEDICATIONS IN HEPATIC IMPAIRMENT

DRUG	RECOMMENDED DOSAGE ADJUSTMENT IN MILD HEPATIC IMPAIRMENT (CHILD-PUGH SCORE A)	RECOMMENDED DOSAGE ADJUSTMENT IN MODERATE HEPATIC IMPAIRMENT (CHILD-PUGH SCORE B)	RECOMMENDED DOSAGE ADJUSTMENT IN SEVERE HEPATIC IMPAIRMENT (CHILD-PUGH SCORE C)

hypoxia can lead to decreased biotransformation of drugs with decreased hepatic extraction ratios, thus decreasing rates of elimination (Taburet, Toller, & Richard, 1990). In mild to moderate hypercapnia, an initial stress response leads to increased cardiac output and pulmonary pressure; however, as severity increases, cardiac output and vascular resistance decreases (Devlin, 2014). Mechanical ventilation and subsequent decreases in both cardiac output and hepatic blood flow can lead to increased plasma concentrations of drugs with high hepatic extraction ratios (Taburet, Toller, & Richard, 1990), including certain antidepressants and antipsychotics such as amitriptyline and chlorpromazine, as well as propranolol. The benzodiazepine midazolam displays an extended elimination half-life when administered to those on mechanical ventilation (Byatt, Lewis, Dawling, & Cochrane, 1984).

INFECTIOUS AND INFLAMMATORY DISEASES

Infection and inflammatory processes can significantly impact both drug distribution to site of action as well as drug metabolism (Aitken, Richardson, & Morgan, 2006). Inflammation—as seen with acute infection, cancer, or chronic inflammatory disease such as rheumatoid arthritis—can lead to decreased expression of metabolic enzymes, including CYP enzymes, and drug transporters via proinflammatory cytokines including IL-6. Decreased metabolic enzyme activity is seen in both the liver and the gut (Xu, Wang, Sun, Chen, & Wei, 2006).

Increased plasma concentrations of drug can occur, along with toxicity. Decreased Pgp expression leads to greater penetration into the CNS for psychoactive drugs, increasing the risk for serious toxicity. Alternatively, use of targeted therapeutic proteins such as antitumor necrosis factor alpha or monoclonal antibody targeting IL-6 to treat chronic inflammatory diseases can cause an upregulation in metabolic enzymes and transporters, leading to increased clearance and decreased exposure to therapeutic medications and, ultimately, decreased therapeutic effect (Morgan, 2009). Alterations in pharmacokinetics of existing medications should be taken into account when therapy is initiated.

Infectious and inflammatory diseases can cause an increase in synthesis and release of acute phase proteins, including C-reactive protein and AAG (Morgan, 2009). Increased concentrations of AAG protein can lead to decreased free fractions of highly bound medications, including clozapine (as described above), and the synthetic opioid methadone (Kapur, Hutson, Chibber, Luk, & Selby, 2011).

MORBID OBESITY AND GASTRIC BYPASS SURGERY

As noted above, morbid obesity has complex effects on the pharmacokinetics of many medications, and predictions for dosing adjustments can be difficult to make. Alterations in Vd

are dependent on protein binding, tissue blood flow, and physicochemical properties of the drug itself (Hanley, Abernethy, & Greenblatt, 2010). Obesity has little impact on albumin concentrations, but data, though mixed, suggest AAG concentrations can be elevated in obese persons and result in a lower free fraction of drug (Ghobadi, Johnson, Aarabi, Almond, Allabi, et al., 2011; Hanley, Abernethy, & Greenblatt, 2010). Tissue perfusion may be reduced in individuals who are obese, and cardiac output can be altered (Hanley, Abernethy, & Greenblatt, 2010). Stroke volume may be increased as well as heart rate, leading to greater cardiac output (Ghobadi, Johnson, Aarabi, Almond, Allabi, et al., 2011). Drugs that are highly lipophilic, such as diazepam or trazodone, have a much larger Vd in obese individuals and can accumulate in adipose tissue. Alterations in efficiency of drug metabolism have also been noted in obesity. Certain enzymes of the cytochrome P450 system display altered metabolic activity in obesity; activity of CYP3A4 can be decreased 10%–40%, while activity at CYP2E1 can be substantially increased, ranging from 10%–140% (Ghobadi, Johnson, Aarabi, Almond, Allabi, et al., 2011; Kotlyar & Carson, 1999). Alterations in other CYP enzymes have not been fully elucidated. (Kotlyar & Carson, 1999). Hepatic clearance can be increased, as seen with diazepam; likewise, GFR may be increased in obesity. Because obese individuals can have an increase in lean muscle mass as well as increased adipose tissue, estimating GFR can be complicated; using an adjusted body weight that falls between ideal body weight and actual body weight may be more accurate. If significant changes in Vd occur, while clearance remains constant or is altered less dramatically, $T_{1/2}$ can be greatly increased, as is seen with carbamazepine (Emery, Fisher, Chien, Kharasch, Dellinger, et al., 2003).

As the obesity epidemic in the United States has progressed, surgical treatment for obesity—typically with gastric bypass—has become much more common. Gastric bypass surgery reduces the absorptive surface of the intestine, usually decreasing drug absorption. Beneficial effects of weight loss on cardiac, hepatic, and/or renal function usually will decrease steady-state drug levels. Weight loss reduces volume of distribution. Initially postprocedure, absorption of oral tablets and capsules, either immediate release or extended release products, can be unpredictable and lead to exacerbation of illness. Use of oral liquids, crushed immediate release tablets, or alternate routes of administration may be preferred when available. (Hamad, Helsel, Perel, Kozak, McShea, et al., 2012). Delayed-release and extended-release products may be not absorbed completely, which can lead to clinical decompensation as seen with the antidepressant duloxetine, which is available as only a delayed-release capsule (Roerig, Steffen, Zimmerman, Mitchell, Crosby, et al., 2013). Whenever possible, immediate-release preparations should be provided. Drugs that require food for absorption, such as the antipsychotics ziprasidone and lurasidone, will have absorption rates of one-third to one-half of that when provided with a large calorie meal (Lincoln, Stewart, & Preskorn, 2010; Lurasidone Product Information, 2013), and alternate agents should be considered. Patients should be monitored carefully for worsening of symptoms postprocedure because of changes

in drug absorption. Those who undergo gastric bypass may also experience changes in absorption of alcohol, with higher Cmax and shorter Tmax, leading to increased clinical effects (Maluenda, Cendes, De Aretxabala, Ponichik, Salvo, et al., 2010; Klockhoff, Naslund, & Jones, 2002).

Nutritional deficiencies are frequently seen after gastric bypass, with some of the most common being decreased levels of thiamine, folate, B₁, zinc, iron, copper, calcium, and fat-soluble vitamins A, D, E, and K. Problems such as Wernicke's encephalopathy and peripheral neuropathy can develop if deficiencies are not corrected (Bloomberg, Fleishman, Nalle, Herron, & Kini, 2005). Further, B₁₂ and folate deficiencies are associated with depression (Tiemeier, van Tuijl, Hofman, Meijer, Kiliaan, et al., 2002; Alpert & Fava, 1997). Nearly 50% of those who have undergone gastric bypass develop unrecognized nutritional deficits (John & Hoegrel, 2009), and it is imperative that these be considered when evaluating patients.

CLINICAL PEARLS

- Brain effects do not correspond directly to the blood concentrations of a drug because:
 - The level of the drug in the blood can differ greatly from the level of the drug in the CNS because of the blood–brain barrier due to the lipophilicity of the drug; whether there is interaction with a transporter; and whether the drug is actively transported into or out of the CSF.
 - The drug's mechanism of action may not require that the drug be continuously present; it may, for example, induce RNA transcription, leading to the synthesis of a protein that will persist for hours or days.
 - The changes in neuronal function initially produced by the drug can cause secondary changes in the same neurons or connected neurons that produce clinically relevant effects. For example, if a drug blocks a neuron's dopamine receptors, that neuron will synthesize additional receptors; also, activity in related glutamatergic neurons will increase.
- Clinical focus typically is on *bioavailability*, the fraction of the dose administered that eventually reaches the circulation. (Note, however, that equal bioavailability of two versions of the same drug does not imply therapeutic equivalence, as the two versions can differ in the peak blood level they produce—Cmax—and in how rapidly a therapeutic threshold is reached.)
- Elimination half-life is useful in predicting the time to achieve steady state with regular dosing.
- CYP3A4 has very wide variability in enzyme activity in the general population, and it has many single nucleotide polymorphisms. However, the genotype–phenotype associations are not sufficiently well established to infer the enzyme's metabolic activity from the genotype. For this reason, CYP3A4 is not included in pharmacogenetic testing even though interactions involving CYP3A4 are very common.

- Sublingual tablets have rapid onset of action and high bioavailability, since first-pass metabolism is bypassed as the buccal and pharyngeal regions drain to the superior vena cava rather than to the portal vein. They require a measure of patient cooperation to keep the tablet under the tongue rather than swallow it. For this reason they are unsuitable for cognitively impaired patients.
- For many psychotropic drugs, absorption will differ when the drug is taken with food versus in the fasting state. Food effects are measurable more often than they are clinically relevant, but they do matter for some drugs, as has been noted. Effects can go in either direction.
- Nearly 50% of those who have undergone gastric bypass develop unrecognized nutritional deficits (John & Hoegrel, 2009), and it is imperative that these be considered when evaluating patients who have undergone this procedure.

DISCLOSURE STATEMENTS

Dr. Gutierrez has no conflicts of interest, direct or indirect, to disclose.

Dr. Fogel is Chief Scientific Officer of Synchroneuron Inc., Managing Director of Anal-Gesic LLC, and Executive Vice President of PointRight Inc. He is the sole inventor or lead inventor on several pharmaceutical patents. MEDICALLY SIGNIFICANT SIDE EFFECTS OF PSYCHOTROPIC DRUGS

Thomas Markham Brown

INTRODUCTION

Among the side effects associated with the drug treatment of mental disorders are some that threaten life, impair function, or exacerbate the symptoms of one or more of the patient's illnesses. Such side effects represent legal as well as clinical risks. While some clinicians fail to recognize or respond to them, others deny their patients optimal psychopharmacological treatment because of excessive concern about them. This chapter reviews the clinical features, epidemiology, course, and treatment of the most important medical side effects of commonly prescribed psychiatric drug treatments. All but one of them are related to individuals' responses to the intrinsic pharmacodynamic actions of the drug prescribed; the one exception is Stevens-Johnson syndrome, which is an idiosyncratic allergic reaction.

The side effects described all can occur at dosages of the drugs within the usual therapeutic range, but all are more frequent and more severe at excessive doses. In many general psychiatric settings, intentional overdoses due to drug abuse or self-destructive intent are salient concerns. By contrast, in general medical settings overdoses are most likely to occur because of drug interactions or genetic variations in drug metabolism, or because of medication errors by patients or caregivers. Mitigating risk of severe adverse events involves systematic consideration of drug interactions, pharmacodynamics, potential medication errors, and barriers to treatment adherence such as cognitive impairment.

The side effects discussed in this chapter are (1) serotonin syndrome, (2) neuroleptic malignant syndrome and neuroleptic-induced catatonia, (3) central anticholinergic syndrome, (4) Stevens-Johnson syndrome and related skin rashes, (5) blood pressure changes (hypertension and orthostatic hypotension), (6) cardiac arrhythmias including heart block and ventricular tachycardia, and (7) metabolic syndrome.

SEROTONIN SYNDROME

CLINICAL FEATURES

The serotonin syndrome (SS) is an infrequent but potentially life-threatening side effect of serotonergic medications. The incidence is estimated by some to be less than one in 10,000 among patients taking serotonergic antidepressants (Mackay, Dunn, & Mann, 1999). However, in a retrospective study of fluoxetine overdoses, Borys and colleagues (1992) found that 5 of 67 adults who ingested fluoxetine alone developed tremor. This suggests the possibility that some cases of SS are overlooked. SS itself is a constellation of symptoms and signs involving the gut, the cardiovascular system, and the central nervous system. The symptom profile is similar to that associated with paroxysmal release of excessive serotonin in the carcinoid syndrome. Gastric distress, autonomic instability that may include hypertension and cardiac ischemia, delirium, and hyperreflexia with clonus are typical features. In contrast to the situation in the carcinoid syndrome, systemic levels of serotonin and its metabolites usually are normal—thus laboratory measures of serotonin or of its metabolites are of little use in making the diagnosis, which remains a clinical one.

Serotonin was first isolated and characterized in 1948 (Rapport, Green, & Page, 1948). The earliest descriptions of what may have been the SS appeared in the literature several years later when the mental, gastric, and autonomic changes of the carcinoid syndrome were linked to excessive serotonin (Bean & Funk, 1956–1957). In 1991, Sternbach proposed an operationalized pathophysiology of SS, as well as criteria for its diagnosis (Sternbach, 1991). This work inspired greater interest in and recognition of the disorder. Sternbach's criteria are still often cited in making the diagnosis, although other methods such as Hunter's criteria are increasingly used because of their improved sensitivity and specificity (Isbister, Buckley, & Whyte, 2007). Box 23.1 outlines one version of the Hunter criteria for SS (Altman & Jahangiri, 2010).

**Box 23.1 CRITERIA FOR DIAGNOSIS OF THE
SEROTONIN SYNDROME**

Treatment with a serotonergic agent and one or more of the following:

- clonus (preferred finding)
- agitation
- autonomic disturbance
- tremor
- hyperreflexia

Obviously, these criteria are sensitive but nonspecific; many patients with delirium have one or more of these signs, and many may be on selective serotonin reuptake inhibitors (SSRIs) for treatment of depression or anxiety comorbid with or secondary to their primary medical problems. Many patients with delirium may have hyperreflexia and a few beats of clonus; what is distinctive about SS is the prominent and sustained clonus disproportionate to other signs of encephalopathy. The concurrence of gastrointestinal symptoms helps with the diagnosis, but the most useful point is a history of simultaneous onset of the CNS, autonomic, and GI symptoms in relation to a change in medications with serotonergic effects, or a change in medications that interact with a serotonergic medication to increase its level or its effect.

WHO IS AT RISK?

SS is caused by increased activity of neurons stimulated by serotonin. Thus drugs or medical conditions that increase serotonin release, drugs that impair the neuronal reuptake or systemic clearance of serotonin, and drugs that directly stimulate serotonin receptors all can contribute. Moreover, the neuromodulator nitric oxide shuts off serotonin release, so agents that reduce nitric oxide levels may indirectly increase serotonergic activity. The onset of SS usually is provoked by a change in one or more of these three factors.

Circumstances and substances that increase serotonin release include the following: acute stress, trauma, surgery, hypoxia, hypoglycemia, alcohol, opiates, cocaine, MDMA, amphetamines and other sympathomimetic agents, lithium, and the nutritional supplement 5-hydroxytryptophan (5-HTP), which is the immediate precursor of serotonin.

Drugs directly stimulating serotonin receptors include: triptans, buspirone, lithium, and LSD.

Drugs inhibiting neuronal reuptake of serotonin include SSRIs, selective noradrenaline reuptake inhibitors (SNRIs), tricyclic antidepressants (TCAs), monoamine oxidase inhibitors (MAOIs) and linezolid.

Drugs that inhibit nitric oxide (NO) synthesis include paroxetine, fluoxetine, and methylene blue (Ng & Cameron, 2010). It is thought that the former two SSRIs may carry increased risk of SS because of their dual effect on NO synthase and on serotonin reuptake.

SS is more common in smokers. Diabetes and hypertension are both associated with increased risk of the condition.

Patients undergoing acute medical illness, surgery, or trauma are overall at increased risk of SS because acute stress causes serotonin release.

TREATMENT

Treatment of SS involves removing potentially offending agents (to the extent medically feasible) and providing supportive care. More specific treatment options involve either augmenting endogenous serotonergic regulatory processes or blocking serotonin receptors with a drug. The magnitude of treatment response will depend on syndrome severity. Mild cases of SS will resolve within 72 hours of discontinuing the offending drug. Severe cases of SS may involve dehydration, hyperthermia, and rhabdomyolysis similar to that seen in neuroleptic malignant syndrome (see below). In such cases intensive care is needed, which may include neuromuscular paralysis and assisted ventilation (Brubacher, Hoffman, & Lurin, 1996; Zand, Hoffman, & Nyman, 2010; Ables & Nagubilli, 2010).

Endogenous regulation of serotonin release can be enhanced by administering nitroglycerin. This will stimulate the synthesis and release of nitric oxide and thus shut off serotonin release. Case series report its rapid effectiveness in severe and refractory cases of SS; the theoretical argument for its use is solid, but evidence from controlled trials is lacking (Brown, 2004). The authors suggest that nitroglycerin be considered in severe SS where the symptoms are a threat to the patient's life and health, and in cases of SS that show no improvement in the first 24 hours after discontinuation of offending medications and provision of symptomatic treatment with benzodiazepines and/or cyproheptadine. A necessary caution is to avoid nitroglycerin in a patient who has recently taken a PDE5 inhibitor, particularly the long-acting PDE5 inhibitor tadalafil (Cialis). Because of the frequent occurrence of sexual dysfunction as an SSRI side effect, it is not uncommon to find patients on a combination of SSRIs and PDE5 inhibitors.

Other drug treatments of SS include drugs that block serotonin receptors. Cyproheptadine, an antihistamine that blocks all types of serotonin receptors, has a relatively benign side-effect profile, with sedation being the most common reaction; however, it also has anticholinergic effects that can be problematic in some medically fragile patients. It is formulated as 4mg tablets; treatment can start with one or two tablets, and this dose of 4 mg or 8 mg of cyproheptadine may be repeated every 1 to 4 hours until symptoms of SS are resolved. Other reported treatments include benzodiazepines, ondansetron (a 5HT3 blocker), chlorpromazine, and olanzapine (which blocks 5HT2 receptors). Benzodiazepines are most helpful for agitation and hyperreflexia but may not be effective for the full syndrome. Chlorpromazine can be helpful for agitation and the GI symptoms but may exacerbate tremors and autonomic disturbances, and it has substantial anticholinergic effects. Ondansetron is highly effective for nausea and vomiting, but its relatively selective inhibition of 5HT3 receptors may actually disinhibit serotonin release in some brain regions. Similar considerations apply to olanzapine, with its relatively selective 5HT2 blocking action. Benzodiazepines, often the first choice for managing

SS, help with GI symptoms and agitation but can exacerbate neuromuscular symptoms and may disinhibit serotonin release by some neuronal populations (TM Brown, Skop, & Mareth, 1996; Brown, 2004; Brubacher et al., 1996; Jones & Story, 2005; Ables & Nagubilli, 2010; Zand et al., 2010). Because of these considerations, the authors recommend the use of benzodiazepines for mild cases with predominant agitation and hyperreflexia, cyproheptadine for mild to moderate cases with a combination of GI and CNS symptoms, and consideration of nitrates for severe cases. Ondansetron would be a good alternative when nausea and vomiting are the predominant symptoms. Hypotension, hypertension, and hyperthermia, when they occur, should be treated symptomatically. The authors do not recommend the use of neuroleptics to treat SS.

Restarting a serotonergic medication in a patient who has experienced SS can be safe. This is particularly true when one or more of the additional causal factors is no longer present. For example, if a patient developed SS while on the combination of an SSRI and an opiate, it might be safe to restart the SSRI if the patient no longer requires opiate analgesics. In this case, a note would be made to discontinue the SSRI if in the future the patient faced surgery or developed a painful condition for which opiates would be needed. If the patient was taking fluoxetine or citalopram when he or she developed SS, switching to citalopram, escitalopram, or sertraline would be reasonable because these agents do not inhibit nitric oxide synthase, thereby removing a factor that can contribute to the syndrome (Brown, 2004). In cases in which no manageable precipitating factor or drug can be identified as contributing to development of SS other than a serotonergic agent apart from fluoxetine or paroxetine, it would be prudent to avoid SSRIs and SNRIs for treating the patient's depression in the future. Several treatment options would remain, including bupropion, the TCA desipramine (which has the least serotonergic effect of the TCAs), and the nonpharmacologic somatic treatments ECT and rTMS.

NEUROLEPTIC MALIGNANT SYNDROME

The neuroleptic malignant syndrome, or NMS, may have been first described in 1959 by Walker, who reported a case of what appeared to be tetanus in a 19-year-old man given trifluoperazine—fever and profound parkinsonian rigidity that was partially relieved by trihexyphenidyl (Walker, 1959). Credit for identifying the disorder is usually, however, given to Delay and colleagues for their description in 1960 of “akinetic hypertonic syndrome,” renamed *neuroleptic malignant syndrome* in 1968 by Delay and Deniker (Delay, Pichot Lempiere, Blissalde, & Peigne, 1960; Delay & Deniker, 1968). In 1986, the first case of NMS due to an atypical antipsychotic—in this case clozapine—was reported. This dashed hope that clozapine, with its greatly reduced propensity to cause extrapyramidal symptoms (EPS), would not cause NMS (Pope, Cole, Choras, & Fulwiler, 1986).

Levenson in 1985 proposed a set of major and minor criteria for diagnosing NMS (see Box 23.2). The condition would

Box 23.2 LEVENSON'S CRITERIA FOR NMS

Major Criteria

- fever
- rigidity
- elevated serum creatinine kinase

Minor Criteria

- tachycardia
- hypertension *or* hypotension
- altered mentation
- diaphoresis
- leukocytosis

be diagnosed if a patient had three or more major criteria, or two of the major criteria and four of the minor criteria (Levenson, 1985). Other criterion sets, including one proposed by the American Psychiatric Association, see fever and rigidity as essential to the diagnosis and add dysphagia, incontinence, mutism, and tremor to the minor criteria. The APA criteria require both severe rigidity and fever (rather than accepting just one of the two if there is an elevated creatine kinase); only two minor criteria must be present (American Psychiatric Association, 2000).

NMS occurs in approximately one in 500 patients treated with neuroleptics, though the incidence may be higher in particular vulnerable populations. In a retrospective study of 224,372 patients with psychiatric disorders, Nielsen and colleagues (2012) identified 83, or 0.04%, as having had NMS. Among 672 acutely manic men given antipsychotics, three (0.45%) who received haloperidol developed NMS (Sarkar, Natarajan, & Gode, 2009). Its importance is related to its mortality, which may exceed 10%, making it one of the most life-threatening adverse effects encountered in psychiatric drug therapy.

There is little disagreement about the clinical diagnosis of NMS when all of the characteristic features are present; diagnostic confusion arises when one of the typical features is obscured. For example, muscular rigidity is less severe if the offending drug is clozapine and may be absent if the patient suffered damage to the cerebellum as a consequence of severe and prolonged hyperthermia (Trollor, Chen, & Sachdev, 2009; Brown, 1999; Lee et al., 1989).

The combination of fever, rigidity, and altered mental status can be seen in several other conditions as described in Table 23.1. These include tetanus, (Walker, 1959) serotonin syndrome, malignant hyperthermia, neuroleptic-induced catatonia, and the central anticholinergic syndrome (Fink, 2011; O'Brien & Young, 1989). Differentiation of NMS from these conditions is based on the differences in the constellation of symptoms, association of the disorder with the initiation of neuroleptic therapy, a change in dosage, or initiation of a drug that interacts with a preexisting neuroleptic to raise its level or enhance its dopamine-blocking effects. As with serotonin syndrome, clinicians who have seen several cases of NMS often can recognize a distinctive overall pattern of history, symptoms, and signs.

Table 23.1 CLINICAL FEATURES OF NEUROLEPTIC MALIGNANT SYNDROME AND RELATED CONDITIONS

CONDITION	HYPERTHERMIA	NEUROMUSCULAR	MENTAL STATUS	LABORATORY
NMS	Usual; often >104° F	Rigidity is usual; typically severe and tremulous	Cognition usually impaired; mutism common	Creatine kinase (CK) usually high, often extremely; myoglobinuria in severe cases
Tetanus	Fever in most cases but not usually over 104° F	Muscle spasms but not tremulous rigidity typical of neuroleptic-induced EPS	Confusion is sometimes present	Positive culture for <i>Clostridium tetani</i>
Serotonin syndrome	Inconsistently present	Hyperreflexia and clonus but not rigidity; sometimes tremor	Confusion is sometimes present	No specific finding; mild but not severe elevation of CK in some cases
Malignant catatonia	Often present but not essential	Catatonia (“waxy flexibility”); not severe rigidity; no tremor	Usually confused, often mute	No specific finding; CK may be mildly elevated
Malignant hyperthermia	Fever over 104° F	Rigidity usual but not necessarily extreme; not tremulous	Often confused but not necessarily	CK elevated, sometimes extremely; myoglobinuria in severe cases
Heat stroke	Fever is usual	Not rigid	Sometimes confused	No specific findings

WHO IS AT RISK?

NMS occurs in patients who have impaired dopamine transmission but not in all such patients, so other factors are involved. It can be precipitated not only by neuroleptics but also by other drugs that block dopamine receptors—for example, metoclopramide (Supariwala, Kant, & Jean, 2011)—or by drugs that deplete dopamine, such as tetrabenazine or reserpine (Guay, 2010). NMS may also be precipitated by the abrupt withdrawal of levodopa in a patient with Parkinson’s disease (Gibb & Griffith, 1986).

Cautious use of other agents (such as statins) that can cause muscle injury is important, since such agents can markedly worsen the course of NMS even though there is no evidence that they cause it (Cooper & Jones, 2009). Some agents of abuse, such as ecstasy and methamphetamine, may also increase the risk of muscle injury and organ failure and of subsequent NMS (Matsusue et al., 2011; Russell, Riazi, Kraeva, Steel, & Hawryluck, 2012). Tantalizing associations between NMS and anesthetic agent–induced malignant hyperthermia have been identified, but after decades of research these entities appear pathophysiologically distinct (Matsusue et al., 2009; Wagner, Fink, & Stephenson, 2004).

NMS develops shortly after initiating a neuroleptic (or other dopamine blocking drug) or increasing its dose. Almost all cases begin within a month of starting neuroleptic therapy, increasing the dose, or adding a second drug that interacts with the first either to raise its blood level or to augment its effect on CNS dopamine receptors. Symptoms tend to evolve over 24–72 hours (Adnet, Lestavel, & Krivosic-Horber, 2000). Young men are the highest risk demographic. Clinical conditions associated with increased risk include agitation, dehydration, alcoholism, alcohol withdrawal, fever, structural brain injury, hyponatremia, iron deficiency, infection, and

concomitant lithium therapy. Increased dopamine blockade increases risk: higher neuroleptic dosage, higher potency drugs, and intramuscular administration all carry a higher risk of NMS (O’Brien & Young, 1989). Atypical (second generation) neuroleptics carry less risk than typical (first generation) neuroleptics. Notwithstanding, numerous cases of NMS due to atypical neuroleptics have been reported. Among 20 patients between the ages of 11 and 18 years treated with atypical antipsychotic agents who suffered a total of 23 episodes of NMS, Nehut and colleagues found that the average time to onset of symptoms was 8.7 + 16.2 days (Nehut, Lindenmayer, & Silva, 2009). Another risk factor for developing NMS is rechallenge with a neuroleptic drug in a patient who has had NMS in the past.

The symptoms of NMS are due to the combination of direct effects of dopamine blockade (or dopamine deficiency) and compensatory increases in the activity of other neurotransmitters due to the dopamine blockade. Activity of both monoamine neurotransmitters and glutamate is increased. It is worth noting that several of the conditions that increase the risk of NMS involve increased activity in sympathetic and glutamatergic systems. The pathophysiology of NMS is outlined in Figure 23.1 (Brown, 2001).

TREATMENT

NMS is always an emergency requiring hospitalization and in most cases intensive care. Treatment of NMS begins with discontinuing all potentially offending agents, including both antipsychotic drugs and other antidopamine agents such as metoclopramide. Supportive therapy is begun to manage fever, autonomic instability, and dehydration, as well as electrolyte abnormalities if these are present. Specific therapy for NMS is

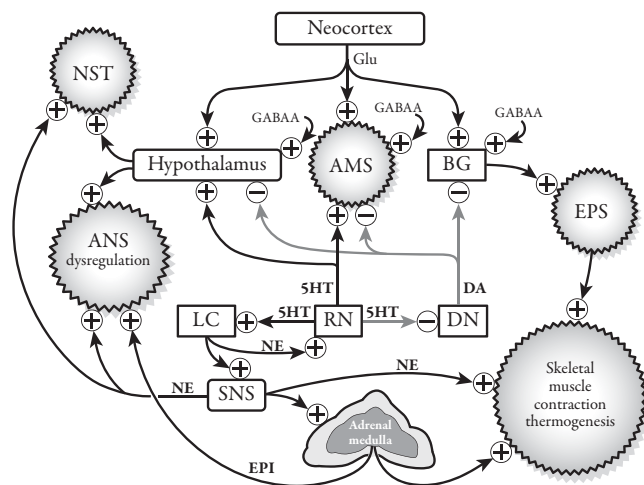

Figure 23.1 Actions of various neurotransmitters on brain structures and functions and their relationship to neuroleptic malignant syndrome (NMS). Abbreviations: + = stimulates release of neurotransmitter; - = inhibits release of neurotransmitter; AMS = altered mental status; ANS = autonomic nervous system; BG = basal ganglia; DA = dopamine; EPI = epinephrine; EPS = extrapyramidal side effects; GABA = gamma-aminobutyric acid; GABAA = GABAA receptor; GLU = glutamate; 5HT = serotonin; LC = locus coeruleus; NE = norepinephrine; NST = nonshivering thermogenesis; RN = raphe nuclei; SN = substantia nigra; SNS = sympathetic nervous system.

initiated with a dopamine agonist and a neuromuscular blocking agent that treats rigidity. The dopamine agonist most often utilized is bromocriptine; the dose is 5 mg by mouth or nasogastric tube every 6–8 hours. The usual neuromuscular blocking agent is dantrolene 50 mg IV every 6 hours. Rosenberg and Green (1989) observed that five patients with NMS who received only supportive treatments began to improve after an average of 6.8 days, while 15 patients who received bromocriptine began improving after an average of one day. Ten patients who received dantrolene began improving after an average of 1.7 days. Full resolution of symptoms took on average 15 days with supportive care only, compared with 9 days for bromocriptine and 10 days for dantrolene (Rosenberg & Green, 1989). Clinical experience over the subsequent two decades has corroborated their initial study. The authors recommend treating NMS with a dopamine agonist and dantrolene, maintaining the patient on dantrolene until muscular rigidity is completely resolved and the creatine kinase is normal, and continuing the dopamine agonist for 10 days beyond that point. Acceptable alternatives to bromocriptine are pramipexole, amantadine, and levodopa; the authors prefer bromocriptine because of the more extensive reported experience with that agent.

Patients in whom the distinction between NMS and catatonia is unclear can be challenged with intravenous lorazepam. This agent will often reverse catatonia but will not reverse the symptoms of NMS (Casamassima et al., 2010).

Laboratory tests that should be done as soon as NMS is seriously suspected include serum CK, a complete blood count, serum electrolytes, calcium, magnesium, iron, liver enzymes, and urine myoglobin. Liver enzymes should be retested after the patient has been on dantrolene for several days, as a small percentage of patients receiving dantrolene develop drug-induced hepatitis. Significant myoglobinuria implies a need for nephrology consultation and, potentially, hemodialysis. Shalev and colleagues reported that myoglobinuria and

renal failure were strongly predictive of mortality in NMS, with 50% of patients dying who had these findings (Shalev, Hermesh & Munitz, 1989). Early and aggressive treatment of acute renal failure, for example with hemodialysis or hemofiltration, can restore renal function and prevent death in NMS (Sanai et al., 2006). As noted above, all but the mildest case of NMS warrants intensive care until hyperthermia and rigidity are resolved.

PREVENTION OF RECURRENCE

Many patients who develop NMS may subsequently need drug treatment for psychotic disorders. To minimize the risk of recurrence, high-potency neuroleptics should be avoided; most clinicians would opt for a second-generation neuroleptic or clozapine.

The patient who requires maintenance treatment for psychosis, but who has had an episode of NMS, requires some thought in order to manage the risk of recurrence of NMS. Authors who have studied this problem suggest that going from a high-potency antipsychotic to a different high-potency antipsychotic yields a much higher risk of recurrence than moving to an agent of lower potency with respect to dopamine D2 blockade (Mendhekar, Jiloha, Mehndiratta, & War, 2002; Shalev et al., 1989). Atypical antipsychotics may have a lower risk of causing severe NMS. The atypical antipsychotics as a class have a lower mortality (perhaps 3%) than the typical antipsychotics, estimated at 16% by Trollor and colleagues (2012). Among atypical antipsychotics, aripiprazole—despite its status as a partial agonist at the dopamine D2 receptor—does not appear to have a reduced risk of causing NMS (Patel & Brunetti, 2010).

Prophylaxis against NMS, as might theoretically be achieved by combining a dopamine agonist with an antipsychotic, is not an established intervention. Because withdrawal of dopamine agonists has caused NMS, their routine use is not necessarily benign (Man, 2011).

Certainly, addressing predisposing factors is crucial and may include reassessing the need for an antipsychotic. A patient with psychotic depression may do as well, for example, with electroconvulsive therapy. A non-antipsychotic mood stabilizer may help a patient with bipolar disorder.

Hospitalization of a patient with a history of NMS who requires resumption of an antipsychotic is also reasonable, to ensure that if NMS recurs it can be managed quickly.

CENTRAL ANTICHOLINERGIC SYNDROME

CLINICAL FEATURES

The central anticholinergic syndrome (CAS) is well described. This is due partly to the large number of agents that interfere with the central and peripheral actions of acetylcholine, acting primarily at muscarinic receptors. Atropine and hyoscine are classic offenders (Frampton & Spinks, 2005). In CAS, patients typically present with a combination of central and

peripheral findings. In addition to confusion and agitation, the patient may have weakness, ataxia, dilated and poorly-reactive pupils with blurred vision, tachycardia, dry mucous membranes, hyperthermia, a flushed appearance, urinary retention, and constipation (Hall, Feinsilver, & Holt, 1981; Mintzer & Burns, 2000). Stupor, seizures, and coma may develop in severe cases. CAS may be fatal. A brief saying that describes the anticholinergic state is “hot as a hare, red as a beet, dry as a bone, blind as a bat, and mad as a hatter” (Ramjan, Williams, Isbister, & Elliott, 2007). Table 23.2 outlines some central and peripheral features of atropine intoxication (Brown, 1998).

The electroencephalogram (EEG) in CAS is essentially the same as that in delirium. Serum anticholinergic activity is one measure of the total serum anticholinergic medication burden but does not correlate well with the EEG (Thomas et al., 2008). While serum anticholinergic activity does identify agents that pose a risk of anticholinergic toxicity, it does not correlate reliably with clinically significant adverse events (Nishtala et al., 2009). There is no specific laboratory study that identifies CAS. However, in cases of hyperthermia and confusion some consideration should be given to infection and other processes that may also have these findings. See under Neuroleptic Malignant Syndrome, Table 23.1, for a selection of differential diagnoses.

WHO IS AT RISK?

Many drugs have anticholinergic activity. These include agents well known for such activity as well as agents that one might not expect to have any anticholinergic activity. Table 23.3 lists a few of these agents. Of note, some agents reported as having detectable serum anticholinergic activity

may have such activity only at doses beyond those normally used. These include diazepam, digoxin, furosemide, metformin, and phenytoin (Chew et al., 2008; Gjerden, Bramness, & Slørdal, 2009; Mintzer & Burns, 2000). Cimetidine is a drug sometimes implicated in cases of CAS, but it is unclear if this is due to innate muscarinic anticholinergic activity, pharmacokinetic effects on more potent anticholinergic drugs, or a combination of these (Nishtala et al., 2009). Sometimes the causal agent in CAS is a surprise: Speich and Haller (1994) reported a clear case of CAS due to mefloquine. And in many cases, no one drug may be the cause of CAS; rather, a combination of drugs may be responsible.

The risk of CAS is often a matter of age complicated by the degree of muscarinic anticholinergic activity to which the patient is exposed. The very young and the very old are especially sensitive to anticholinergic agents (Garza, Osterhoudt, & Rutstein, 2000). Slow metabolizers—whether due to genotype, pharmacokinetic drug–drug interactions, or renal or liver disease—are also at risk. General anesthesia is another setting in which CAS may develop (Link, Papadopoulos, Dopjans, Guggenmoos-Holzmann, & Eylich, 1997). Because many of these risks are common, including polypharmacy and being elderly, several groups have approached the task of identifying agents that pose significant central and peripheral anticholinergic risk. These include the American Geriatric Society’s (AGS) Beers Criteria, as well as the Anticholinergic Risk Scale.

The Beers Criteria comprise a set of drugs that the AGS recommends be avoided among elderly patients (American Geriatrics Society, 2012). The AGS refers to the medications on the Beers list as “potentially inappropriate” for geriatric patients, although the medications pose risks as well for the very young, and for any age group when given in larger doses

Table 23.2 CENTRAL AND PERIPHERAL FEATURES OF ATROPINE INTOXICATION

ATROPINE DOSE (MILLIGRAMS)	CENTRAL EFFECTS	PERIPHERAL EFFECTS
0.5	Mild effects on arousal.	<i>Cardiac:</i> mild slowing <i>Pupillary:</i> minimal <i>Gut:</i> slight dryness of mouth
1.0	Increased effects on arousal. Some short-term memory impairment.	<i>Cardiac:</i> slight tachycardia <i>Pupillary:</i> dilatation <i>Gut:</i> increased oral dryness
2.0	Worsening of above effects.	<i>Cardiac:</i> marked tachycardia <i>Pupillary:</i> dilatation now complicated by impaired accommodation (blurred vision) <i>Gut:</i> marked oral dryness
5.0	Restlessness and fatigue. Onset of confusion and agitation. Visual hallucinations may occur.	<i>Cardiac:</i> marked tachycardia <i>Pupillary:</i> worsening of above <i>Gut:</i> swallowing difficult; constipation <i>Other:</i> urinary retention, skin dry
10	Delirium may progress to seizures, coma and death.	<i>Cardiac:</i> tachycardia may be complicated by reduced cardiac output <i>Pupillary:</i> pupils maximally dilated; paralysis of accommodation <i>Gut:</i> skin red, hot, dry

Table 23.3 ANTICHOLINERGIC RATING SCALE: SELECTED AGENTS

1 POINT	2 POINTS	3 POINTS
carbidopa-levodopa	amantadine	amitriptyline
haloperidol	baclofen	atropine
paroxetine	cimetidine	benztropine
quetiapine	clozapine	cyproheptadine
ranitidine	cyclobenzaprine	diphenhydramine
risperidone	olanzapine	fluphenazine
trazodone	pseudoephedrine	hydroxyzine
ziprasidone		hyoscyamine
		imipramine
		perphenazine
		promethazine
		thioridazine
		tizanidine

or in combination. The AGS posts their list of potentially inappropriate medications on the Internet (see <http://www.dcri.org/trial-participation/the-beers-list/>). While the medications on the Beers list are regarded as risky based on their anticholinergic activity, it is possible for a medication to be potentially anticholinergic and yet have poor central penetration. Glycopyrrolate is a valuable medication precisely when such effects are needed, as in managing bradycardia during electroconvulsive therapy. Such medications have reduced risk of causing CAS. This fact has led other groups to establish rating systems for anticholinergic activity based upon their combined peripheral and central risks. The Anticholinergic Risk Scale (ARS) is the product of one such effort.

The ARS rates a drug's risk of causing such central effects as cognitive impairment and delirium on a 0- to 3-point rating scale. A score of 0 would indicate no such risk. A score of 3 indicates marked risk of central anticholinergic side effects. A drug rated as a 3 would have a 70% chance of causing two or more anticholinergic side effects in a geriatric patient. The sum of each individual medication's score can be added to create a number that reflects the total anticholinergic burden for a given medication regimen. Table 23.3 lists some of the agents studied for inclusion in the ARS (Rudolph, Salow, Angelini, & McGlinchey, 2008).

The serum anticholinergic activity (SAA) assay is referenced in studies of anticholinergic drug effects. Tune and Coyle developed this laboratory assay in 1980 using competitive inhibition of the potent muscarinic agonist, tritiated quinuclidinyl benzilate (Tune & Coyle, 1980). When nonstandard solutions are assessed, such as the serum of patients taking multiple anticholinergic agents, confounding pharmacokinetic actions and patient-specific variables can undermine the utility of the assay (Carnahan, Lund, Perry, &

Pollock, 2002). Further limitations of this assay in clinical work include its inconsistent association with anticholinergic side effects, including central (Kersten et al., 2013). Some authors have, however, found the SAA assay useful in describing the risk of anticholinergic agents for large cohorts of patients (Pasina et al., 2013). This may represent a combination of endogenous and medication-specific effects, which may be valuable in itself even if it does not specifically reflect the anticholinergic risk of medications alone.

TREATMENT

Stopping offending agents as tolerated is the first step in managing CAS. As mentioned above, serum anticholinergic assays are not routinely helpful, nor are they usually immediately available. An EEG can be helpful in the hospital setting, but in an emergency the diagnosis is more likely to be made by clinical examination and history (Frampton & Spinks, 2005). Because CAS can be a lethal process, urgent attention to management of symptoms is crucial. Cooling blankets, antipyretics, and intravenous fluids can limit the effects of hyperthermia. Diazepam has been used to treat agitation and, on occasion, seizures. However, since the mid-19th century and the work of Thomas Fraser, the antidote to atropinism has been physostigmine (Proudfoot, 2006). Table 23.4 outlines an algorithm for management of CAS.

Physostigmine is a reversible anticholinesterase that crosses the blood-brain barrier. It has been used to treat CAS as well as to treat sedation after anesthesia, in which significant anticholinergic activity may occur (Frampton & Spinks, 2005; Panagopoulou, Tzimas, Arampatzis, Aroni, & Papadopoulos, 2011). The elimination $t_{1/2}$ of physostigmine appears to be under 20 minutes, although its anticholinesterase activity may average 80–90 minutes (Asthana et al., 1995). In a 6-week-old child with CAS, Kulka and colleagues (2004) used physostigmine 0.04 milligrams per kilogram intravenously. These authors administered two doses of physostigmine and noted full recovery within 24 hours. In adults, 2 mg may be pushed intravenously (Speich & Haller, 1994). The amount given should be titrated to effect, although caution is required to avoid overshooting the mark. Atropine can be used in cases of physostigmine intoxication. Nausea and vomiting are the most common side effects of physostigmine. These can be avoided by pushing the drug at a rate of 1 mg per minute or slower (Jastak, 1985). Some clinicians hesitate to use physostigmine because of concerns about seizures and arrhythmias. However, these side effects are more common when physostigmine is used in the absence of anticholinergic toxicity (Fracogna, 2007; Suchard, 2003).

Similarly, pyridostigmine, a reversible anticholinesterase that crosses the blood-brain barrier, has also been used to treat CAS. Its relatively long elimination $t_{1/2}$ of 1–2 hours, prolonged duration of action (roughly 6 hours), and availability for intravenous administration can make it more useful than other anticholinesterases in managing CAS (Aquilonius & Hartvig, 1986). It should be noted that the central penetration of pyridostigmine is limited, even in overdose (Almog et al., 1991). This means that confusion and hallucinations

Table 23.4 ALGORITHM FOR MANAGEMENT OF CAS

PRESENTATION	INTERVENTION
(1) CAS identified	(1) Patient should be transported to a hospital if not already in one, given the possibility that mild CAS may be the first evidence of more severe impending deterioration.
(2) Check ABCs	(2) <i>Place in darkened, quiet room.</i> This reduces agitation. <i>Gather data.</i> Measure oxygen saturation, and consider obtaining an arterial blood gas. Also obtain serum glucose level, electrolytes, and complete blood count. Consider serum CK level if patient is agitated. Obtain urine drug screen. Electrocardiogram for arrhythmias and ischemia. Chest x-ray. Consider neuroimaging, especially if evidence of trauma is present.
(3) Initiate treatment	(3) Establish intravenous access. Thiamine 200 mg IV every eight hours. Activated charcoal for gut decontamination. Cooling blankets or antipyretics for hyperthermia. Benzodiazepines for agitation. Consider physostigmine for severe intoxication. Urinary catheter for urinary retention.

in some patients may not respond significantly to pyridostigmine. Furthermore, contraindications to pyridostigmine tend to reflect its peripheral benefits. Contraindications to pyridostigmine are related to its parasympathetic effects: enhanced insulin secretion among diabetics, patients with functional or structural bowel dysfunction, patients with cardiac arrhythmias or conduction disturbances who may not tolerate parasympathetic effects, and so on (Hall et al., 1981). However, when used cautiously and as an antidote to CAS, pyridostigmine is generally safe. Pyridostigmine is given orally in doses of 0.1 milligram per kilogram.

REBOUND PSYCHOSIS

CLINICAL FEATURES

While antipsychotics treat psychosis, their abrupt discontinuation can provoke psychosis. This is called *rebound psychosis* or *supersensitivity psychosis*. Many examples exist of patients whose antipsychotic therapy was stopped, only to be followed by the swift emergence of psychosis, agitation, confusion, and movement disorders (Jacob, Ash, & Craighead, 2012). The

issue is, in large part, one of central adaptation to dopamine D2 receptor blockade. This fact is strikingly demonstrated when a potent D2 antagonist not given for mental illness, such as metoclopramide or domperidone, is abruptly stopped and frank psychosis ensues (Lu, Pan, Teng, Su, & Shen, 2002; Roy-Desruisseaux et al., 2011). The unexpected emergence of psychosis or confusion, or of an extrapyramidal movement disorder (or both) upon discontinuation of a D2 antagonist should lead the clinician to consider a withdrawal encephalopathy. In cases in which the patient has a history of mental illness for which a neuroleptic was prescribed, the clinician may need to distinguish between a drug side effect and the underlying mental illness.

Rebound psychosis differs from relapse into the initial psychotic state in being a relatively swift development after medication discontinuation. Rebound psychosis must be distinguished from frank withdrawal effects that may also occur with some antipsychotics. Shiovitz and colleagues (1996) studied this during a study of 28 patients with schizophrenia placed on clozapine for a month. The medication was abruptly discontinued after the single study month. Within 1 week after discontinuation of clozapine, one patient had developed frank psychosis requiring urgent hospitalization. Four patients experienced moderately severe withdrawal characterized by agitation, nausea, and vomiting. Only 11 patients had no evidence of withdrawal (Shiovitz et al., 1996). This study nicely illustrated key points in differentiating rebound psychosis from withdrawal. In withdrawal, one often sees the triad of a constellation of systemic findings, accompanied by a nonspecific change in mental status described generally as “agitation,” and dyskinesias (Lambert, 2007). In the case of rebound psychosis, distinct symptoms of psychosis developed in the absence of systemic findings and dyskinesias. Table 23.5 outlines some distinguishing features of rebound psychosis (Miller, 2009).

WHO IS AT RISK?

As is true for drugs in general, individual antipsychotics have their own propensities for causing rebound psychosis. For example, some authors speculate that aripiprazole may be less likely to cause rebound psychosis (Tadokoro et al., 2011). Furthermore, the more anticholinergic an agent the less likely rebound psychosis may happen with abrupt discontinuation of that agent. Interestingly, patients who do not respond to antipsychotics may be less likely to suffer rebound psychosis when the medications are discontinued (Miller, 2009). Time on medication appears to be a reliably important risk factor for rebound psychosis: the longer the duration of treatment, the greater the potential risk. Older age, longer duration of illness, more psychotic symptoms, and a tendency not to tolerate minor life stressors may each increase the likelihood of rebound psychosis (Fallon & Dursun, 2011). Treatment-emergent movement disorders may also signal a risk of rebound psychosis. In the CATIE study, the presence of antipsychotic-induced movement disorders appeared to herald susceptibility both to rebound psychosis and to tardive dyskinesia. Both of these side effects are thought to be due to a “supersensitive” dopamine D2 receptor (Chouinard & Chouinard, 2008).

Table 23.5 DISTINGUISHING FEATURES OF REBOUND PSYCHOSIS

	REBOUND	WITHDRAWAL	RELAPSE
Time to occurrence after medication discontinuation	Typically days	Typically days	Gradual accumulation of cases over 1–2 years
Systemic findings	May or may not be seen	Usually present, and often accompanied by dyskinesias	Usually absent
Mental status changes	Typical psychosis	Non-specific with agitation or confusion	Typical psychosis
Effect of resuming discontinued medication	Gradual improvement	Swift resolution of systemic and mental status findings	Gradual improvement
Effect of not resuming medication	Gradual improvement may occur over weeks, but is not assured, and may be less likely with less anticholinergic agents	Gradual improvement occurs over weeks	No improvement without intervention

TREATMENT

Management of rebound psychosis begins with its anticipation. If a medication must be stopped, a gradual tapering and simultaneous initiation of another antipsychotic can help. Occasionally patients may experience rebound psychosis despite the clinician's best effort to make slow, tolerable changes. Hospitalization may, in such cases, be inevitable. For patients whose rebound psychosis is linked to noncompliance with treatment, depot antipsychotics may be helpful.

GABA-A ANTAGONISTS

CLINICAL FEATURES

A worrisome feature of some drugs is their antagonism of GABA-A receptors. This is most often recognized with antibiotics. Reuling and Cramer (1947) reported that intrathecal penicillin causes convulsions. The neurotoxicity of the beta-lactams, including the penicillins and cephalosporins, has subsequently become well established. Perhaps 1% or more of patients prescribed a beta-lactam will have a seizure. Sicker patients are at greater, and sometimes substantial, risk (Miller, Ball, Bookstaver, & Dornblaser, 2011). Among beta-lactam antibiotics, imipenem-cilastatin has the most worrisome record. In a study of 82 children with systemic cancer who received 143 courses of imipenem-cilastatin, 3 children suffered convulsions (Karadeniz, Oğuz, Canter, & Serdaroglu, 2000). Among 200 patients with severe pneumonia who received imipenem-cilastatin, 11 had seizures. In the same study, in a separate group of 202 patients who received ciprofloxacin, only 3 had seizures (Fink et al., 1994). Benzylpenicillin and cefazolin are other beta-lactam antibiotics with a relatively high risk of neurotoxicity (Schliamser, Cars, & Norrby, 1991). This contrasts with other beta-lactams. For example, in a study of 4,872 patients who received meropenem and who represented a variety of ages and illnesses, the incidence of seizures due to meropenem was estimated to be 0.08% (Norrby & Gildon, 1999).

The central role of GABA-A receptor antagonism in producing the observed side effects helps the clinician to

recognize the symptoms. Patients may experience a host of findings ranging from anxiety and hallucinations to myoclonus and disorientation, and even seizures. New-onset generalized status epilepticus has been reported with penicillins (Fernández-Torre, Santos-Sánchez, & Pelayo, 2010).

WHO IS AT RISK?

Patients who may be at increased risk of seizures with GABA-A antagonists include those with impairments of the blood–brain barrier—as can be caused for example by meningitis or structural brain lesions—as well as the elderly, those with lower body weight, and patients with renal impairment (Hoffman, Trimble, & Brophy, 2009). Renal function looms large as a risk factor. In a study of 1,951 patients who received doses of imipenem-cilastatin adjusted for renal function, only 4 developed seizures. Interestingly, even in this study the four who had seizures received inappropriately high doses of imipenem-cilastatin for their renal function (Pestotnik, Classen, Evans, Stevens, & Burke, 1993).

Other agents may facilitate the development of seizures among patients taking beta-lactams. For example, furosemide may cause hyponatremia, which increases the risk of seizures and antagonize GABA-A receptors (Korpi & Luddens, 1997). Withdrawal from alcohol, barbiturates, or benzodiazepines may also increase the risk of seizures with a GABA-A receptor antagonist.

TREATMENT

If GABA-A antagonism is thought to be present and symptomatic, an electroencephalogram can help to document the problem. A benzodiazepine can also provide insight into the pathophysiology of the process, as well as provide relief (Grill & Maganti, 2008).

While benzodiazepines are effective in managing beta-lactam-induced neurotoxicity, other anticonvulsants may not be. Serum valproic acid levels may be lowered by some beta-lactams, making this approach difficult and potentially confusing (Miller et al., 2011). Simply being

on an anticonvulsant does not ensure protection against beta-lactam-induced neurotoxicity (Anzellotti et al., 2011). However, phenytoin has proved helpful in cases of beta-lactam-induced convulsions (Job & Dreter, 1990).

THE METABOLIC SYNDROME

CLINICAL FEATURES

Perhaps one in three or four persons worldwide meets criteria for the metabolic syndrome (MS) (Nieman, Brock, Butterworth, Utter, & Nieman, 2002). The MS is a constellation of findings that stems in large part from peripheral insulin resistance and that indicate an increased risk of cardiovascular disease (Reaven, 2006). In addition to peripheral insulin resistance, visceral adiposity appears to be another essential component, while atherogenic dyslipidemia and endothelial dysfunction round out the usual constellation of findings (Huang, 2009). The MS is of great concern to psychiatrists; it travels with many of the more worrisome features of mental illness, such as obesity and excess mortality, largely associated with cardiovascular disease and increasingly cancer. The MS is also a concern to psychiatrists because mental illness, and even chronic stress, is strongly associated with the development of insulin resistance and its consequences. Police officers who become depressed, for example, have a risk of developing the MS that increases with the degree of job stress and of depression (Hartley et al., 2012). While many medications provoke weight gain and thereby lead to insulin resistance, it is thought that atypical antipsychotics as a class may directly cause insulin resistance and thus contribute to the development of the MS (de Hert, Schreurs, Vancampfort, & Van Winkel, 2009). Why this may be so is as yet unclear (Stahl, Mignon, & Meyer, 2009). What is clear is that attention to the essential features of the MS, and some sense of what factors may affect their appearance and resolution, is an important element in the practice of modern psychopharmacology.

Several organizations have established criteria for the diagnosis of the MS. The American Heart Association with the National Heart, Lung, and Blood Institute (AHA/NHLBI) is among these, and their criteria are outlined in Box 23.3 below (Grundey et al., 2005). Using the AHA/NHLBI criteria, any three of the five findings is sufficient to make the diagnosis. Patients with chronic and severe mental illness develop the metabolic syndrome roughly two to three times more often than the general population (Toalson, Ahmed, Hardy, & Kabinoff, 2004). Frank diabetes is significantly more common among drug-naïve patients with schizophrenia than among healthy controls (Verma, Subramaniam, Liew, & Poon, 2009). Excess mortality among patients with severe mental illness is two to three times that of the general population. This translates into 13–30 years less life for the patient with severe mental illness, with the majority of the mortality stemming from cardiovascular events (de Hert et al., 2011). Recognizing and managing the MS is thus an urgent priority for the mentally ill.

With these criteria in mind, the clinician is able to look for evidence of the MS. The next step is identifying who may be

Box 23.3 AHA/NHLBI GUIDELINES FOR THE CLINICAL DIAGNOSIS OF THE METABOLIC SYNDROME

Measure Cut-off Values

Waist circumference > 102 cm (>40 inches) in men

or

> 88 cm (>35 inches) in women

Elevated > 150 mg/dL (1.7 mmol/L) triglycerides

or

On drug treatment for elevated triglycerides

Reduced HDL-C < 40 mg/dL (1.03 mmol/L) in men

or

< 50 mg/dL (1.3 mmol/L) in women

or

On drug treatment for reduced HDL-C

Elevated blood pressure >130 mmHg systolic blood pressure

or

> 85 mmHg diastolic blood pressure

or

On antihypertensive drug treatment in a patient with a history of hypertension

Elevated fasting >100 mg/dL glucose

or

On drug treatment for elevated glucose

at risk. Intriguingly, mental illness itself appears to be a risk factor for development of the MS.

WHO IS AT RISK?

The relationship between mental illness and insulin resistance is complex. Walter Cannon and colleagues described “emotional glycosuria,” in which distressed patients transiently excreted glucose in their urine (Cannon, Shohl, & Wright, 1911). Kooy in 1919 reviewed the impact of emotions on the urinary excretion of glucose. He noted that while this “emotional” or “nervous” glycosuria sometimes deteriorated into frank diabetes, it did not always do so (Kooy, 1919). Kasanin noted in 1926 that “It seems safe to conclude that in psychogenic stupors one frequently encounters a decreased carbohydrate tolerance” (Kasanin, 1926). Depression, mania, and psychosis may each provoke an acute decline in insulin sensitivity. This may be seen in roughly a third or more of patients with severe mental illness (Freeman, 1946). More recent studies have found similarly large numbers of untreated mentally ill patients expressing insulin resistance, even in such disorders as posttraumatic stress disorder (de Hert et al., 2009; Weiss et al., 2011). Insulin resistance in mental illness clearly predates both modern psychopharmacology and the obesity epidemic. This raises the question: why might there be insulin resistance in mental illness?

One link between insulin resistance and mental illness may be neuroprotection (Wada, Yokoo, Yanagita, & Kobayashi, 2005). The brain operates on the brink of energetic failure. A constant supply of the substrates of aerobic

metabolism, including glucose and oxygen, is required by the brain and helps to explain why brain activity accounts for 20% of the body's resting caloric expenses (Heiss, 2011). During periods of starvation or stress, a state sometimes called "fasting diabetes" develops: this is a state of adaptive insulin resistance in which glucose is diverted away from the periphery and toward the brain and a few other obligate consumers of glucose (Stannard & Johnson, 2004). Neel (1962) formulated the "thrifty gene hypothesis"—the idea that under stress, an inducible state of insulin resistance might be adaptive. Since then, the neuroprotective and neurotrophic roles of insulin have become clearer, indicating that the value of "fasting diabetes" or adaptive peripheral insulin resistance rests not solely in the diversion of glucose to the brain, but in the delivery of additional insulin to the brain as well (Jolivald et al., 2008). Insulin coma therapy crudely but effectively capitalized on the potential benefits of enhancing insulin delivery to the brain (Sakel, 1938). And yet, as Neel and others have emphasized, a tendency to peripheral insulin resistance, no matter what the basis, may produce disease (Neel, 1962; Stannard & Johnson, 2004). The metabolic syndrome is one such disease state.

As a syndrome, there are several pathways to the MS and to insulin resistance in particular. Severe stress or mental illness are just two such pathways. Box 23.4 outlines some factors and conditions known to be associated with the MS. Many of these risk factors are commonly seen among patients with major mental illness (Chatterjee et al., 2010; Cornier et al., 2008; Hruz, 2011; Saad, 2009; Smith, Ju, Saha, Racette, & Fisher, 2004; Vardeny et al., 2011).

**Box 23.4 FACTORS AND ASSOCIATED CONDITIONS
THAT INCREASE THE RISK OF HAVING
THE METABOLIC SYNDROME**

Diseases

hyperlipidemia
hypotestosteronemia
mental illness
nonalcoholic fatty liver disease
non–insulin-dependent diabetes mellitus
obstructive sleep apnea
polycystic ovarian disease

Medications

antiretrovirals (mainly protease inhibitors, some nucleoside reverse transcriptase inhibitors)
beta-blockers
corticosteroids
potassium-wasting diuretics
agents that promote weight gain
levodopa-carbidopa

Behavioral

diets rich in refined carbohydrates, sugar, or fat
physical inactivity
obesity
tobacco smoking

TREATMENT

Management of the MS begins with recognition of its antecedents. This may include making dietary changes, increasing physical activity, and assessing the potential roles on insulin sensitivity of coexisting diseases and their treatments. Baseline and regularly repeated measures of weight, waist circumference, blood pressure, fasting glucose, and fasting lipid profiles are recommended (Newcomer, 2007). The American Diabetes Association and the American Psychiatric Association jointly developed recommendations for patients starting on treatment with atypical antipsychotics. The recommendations included baseline assessments of personal and family history, weight or body mass index (BMI), waist circumference, blood pressure, fasting plasma glucose, and a fasting lipid profile. The greatest emphasis was placed on tracking weight or BMI, with less frequent reassessment of the other items of interest. (American Diabetes Association et al., 2004) Of note, these consensus recommendations included checking weight or BMI every 4 weeks for the first 3 months. This underscores the fact that one's risk of having the MS may evolve quickly. Table 23.6 further outlines measures that may be useful in deciding whether a patient is at risk for the MS (Hadaegh et al., 2009; Kaur, Adams-Huet, Smith, & Jialal, 2013; Reaven, 2006).

The World Health Organization recommends intervening when BMI exceeds 27 in a person with evidence of obesity-related disease such as diabetes, or 30 in a person without acute evidence of obesity-related illness (McIntyre et al., 2012). If a medication is promoting weight gain or some other aspect of the MS, consideration should be given to a trial of an agent less likely to cause such side effects. Medication may also offer some relief from weight gain and its metabolic consequences. Among the agents added to atypical antipsychotics for management of weight gain, metformin is the best studied and most promising. Several large studies have concluded that this agent is beneficial as add-on treatment for antipsychotic-induced weight gain (Fiedorowicz et al., 2012). Metformin appears to be most effective when given early in the treatment of drug-naïve or first-episode adult patients. It is less effective for children and adolescents. Metformin's benefits include not just a reduction in weight gain but also improvement in insulin sensitivity (Smith, 2012). Doses of metformin tend to range from 1000 to 1500 milligrams a day. However, metformin is not the only option nor is it the most effective for every patient (Baptista et al., 2007).

Among the other options for antipsychotic-induced weight gain are orlistat, histamine H₂ receptor antagonists, topiramate, amantadine, and various other agents with less substantiated utility. Orlistat is indicated for the management of obesity. It is a gastrointestinal lipase inhibitor. Orlistat 120 mg three times a day is generally safe and effective for weight loss and improves insulin sensitivity. Mild gastrointestinal distress, and very rarely severe liver injury, are important side effects (Ioannides-Demos, Piccenna, & McNeil, 2011).

It is not clear why H₂ receptor antagonists such as nizatidine or famotidine may be helpful, but it is possible that peripheral suppression of cholecystokinin activity is helpful.

Table 23.6 IDENTIFYING INSULIN RESISTANCE: CLINICAL MEASURES AND THEIR LIMITATIONS

FACTOR	MEASURE	LIMITATIONS
Fasting insulin level	An elevated serum level suggests insulin resistance	Not every clinic has this study available.
Fasting glucose	A normal level is <100 mg/dL	Elevations may reflect a late stage of insulin resistance
HgbA1C	Normal values are 4% to 5.6%	Elevations may reflect a late stage of insulin resistance.
Triglyceride/HDL (fasting)	A ratio <3 suggests low risk for the MS, while a ratio >6 indicates a >50% risk of having the MS.	The “poor man’s” insulin sensitivity assay. Lipoprotein lipase is under the control of insulin, and affected by insulin resistance. An independent disorder of lipid metabolism, or treatment for a lipid disorder, may skew results and reduce the value of this ratio as a measure of insulin sensitivity.
Waist circumference	Men: > 40 inches Women: > 35 inches	Increases the likelihood of metabolic syndrome, but overall contribution is only about 25%.
Body mass index	> 25: overweight > 30: obese > 40: morbid obesity	Highly correlated with waist circumference and obesity, with same limitation as for waist circumference
White cell count	Elevations are a well-established feature of the MS.	An elevated white cell count is very nonspecific.

Benefits with these agents are not as consistent as with metformin (Fiedorowicz et al., 2012). Topiramate 250 mg daily has been effective for some patients (Ko, Joe, Jung, & Kim, 2005). The FDA has approved Qysmia for weight reduction. This is a combination of low-dose phentermine and controlled-release topiramate (Garvey et al., 2012). Concerns about cardiovascular and pulmonary toxicity with phentermine are somewhat assuaged by the low-dose use in Qysmia as well as toxicity studies for the combination agent. Topiramate has well described unwanted cognitive effects. These are dose-dependent. However, because the serum levels achieved by a single dose of topiramate may vary by a factor of over 50 times among individuals, it is difficult to predict the impact of a single dose (Cirulli et al., 2012). Amantadine 200 mg daily when added to olanzapine separates from placebo in reducing weight gain (Hoffmann, Case, & Jacobson, 2012).

An inquiry should also be made into sleep quality and characteristics. If obstructive sleep apnea suggests itself in the patient’s history, a sleep study should be considered to make a definitive diagnosis (Rajagopalan, 2011). For some patients, bariatric surgery may be significantly helpful in treating obesity and, as a result, the MS (Giugliano, Ceriello, & Esposito, 2008; Madan, Orth, Ternovits, & Tichansky, 2006).

DERMATOLOGICAL REACTIONS

CLINICAL FEATURES

The skin holds a special distinction among drug side effects as being the site of some of the drug reactions that are the most visible, violent, and difficult to diagnose. Among these reactions are the Stevens Johnson syndrome (SJS), drug rash with eosinophilia and systemic symptoms (DRESS) syndrome,

and toxic epidermal necrolysis (TEN). Acute hypersensitivity reactions may be difficult to anticipate. The clinician should, however, be aware of a few important points.

Many drugs can cause rashes: among the most common offenders are aromatic anticonvulsants; other psychotropics are less frequent offenders. The aromatic anticonvulsants include carbamazepine, lamotrigine, phenobarbital, phenytoin, and trileptal. Their metabolism rarely yields arene oxides, which are often implicated in the anticonvulsant hypersensitivity syndrome (AHS). AHS may also be an immune-mediated (or allergic) response. As many as 8% of all persons exposed to medications will develop some form of cutaneous side effect. Perhaps 3% of all patients prescribed carbamazepine will develop a drug eruption (Elias, Madhusoodanan, Pudukkadan, & Antony, 2006). In one retrospective study of patients started in lamotrigine, 13% developed a nonserious rash of some kind (Ginsberg, 2006). Most of these rashes are benign. A rash that spreads widely, is intensely pruritic, involves the mucous membranes of the eye or mouth, or has other systemic findings such as fever or lymphadenopathy, should raise alarm and lead to treatment of the rash and discontinuation of any medication suspected of causing it. Leukocytosis, especially with eosinophilia, and elevation of hepatic enzymes are also indicative of a more severe systemic reaction. But devastating hypersensitivity reactions to anticonvulsants, or AHS, are rare. First described in 1950 by Chaiken and colleagues, AHS typically occurs with older anticonvulsants such as carbamazepine, phenobarbital, phenytoin—but, as noted, it may occur with lamotrigine. Because of the relatively high incidence of seizures in the first decade of life, children may present relatively frequently with AHS (Chaiken, Goldberg, & Segal, 1950; Scaparrotta et al., 2011). The clinician must be concerned when an extensive rash develops that is complicated by fever, eosinophilia, lymphadenopathy, nephritis, or hepatitis (Cacoub et al., 2011).

WHO IS AT RISK?

As noted, those prescribed anticonvulsants are at relatively higher risk of developing a fulminant drug eruption. These include children, patients with epilepsy, patients receiving radiation therapy for brain tumors, and patients with psychiatric illnesses who are prescribed anticonvulsants mainly as mood stabilizers (Metro, Pino, Pellegrini, Sacerdoti, & Fabi, 2007). Those newly started on anticonvulsants are at higher risk of developing an AHS, which tends to develop within the first few weeks of treatment. Intriguingly, a genetic link exists. Among certain groups of Asians, including Han Chinese, carbamazepine-induced SJS and TENS occur relatively frequently among carriers of the HLA-B*1502 allele (Zhang et al., 2011). Lamotrigine-induced SJS or other adverse cutaneous reactions are currently not associated with the HLA-B*1502 allele among the Han Chinese (Shi et al., 2011). The HLA-B*1502 allele does not predict risk of AHS or maculopapular eruptions among persons of Asian descent. Among patients of European ancestry, the HLA-A*3101 allele is found in 2%–5%. This allele appears to confer some risk of developing SJS or TENS as well as milder adverse cutaneous reactions, such as maculopapular eruptions, when carbamazepine is prescribed (McCormack et al., 2011). It is not yet known how these alleles are associated with the risk of severe drug eruptions. Yet the connections are sufficiently sturdy that the risk of SJS and TENS among carriers of the HLA-B*1502 allele is now advertised in a black box warning in package inserts for carbamazepine (Novartis, 2011).

The involvement of the immune system in severe drug-induced skin reactions such as SJS and TENS is clear. This relationship may be unmasked or underscored when there are other challenges to the immune system. An example of this is the suspected relationship between infection with certain human herpes viruses (HHV) and drug-induced hypersensitivity reactions. It is thought that infection with Epstein Barr virus, cytomegalovirus, HHV-6, and HHV-7 may increase the risk of a drug hypersensitivity reaction (Shiohara, Inaoka, & Kano, 2006). Typically a drug eruption precipitates reactivation of a latent HHV infection (Aihara et al., 2001). However, the reverse has also been observed (Calligaris et al., 2009; Saida et al., 2010). Because post-herpetic neuralgia may be treated with carbamazepine, the potential for a synergistic stimulation of the immune system against autoantigens may be significant in such cases (Garcia, Ferro, Carvalho, da Rocha, & de Souza, 2010).

TREATMENT

When a rash develops and might be caused by a medication, the patient and the clinician are faced with the question of which medication may be the offending agent and whether it should be stopped. The rash is usually exanthemous and starts within a week or so of beginning the causative agent. Certainly when large areas of skin as well as the mouth are involved in a rash, if the skin begins to break down, or in the presence of systemic findings such as fever or lymphadenopathy, it is important to consider stopping the medication. Oral

antihistamines and topical steroids may be helpful in minor cases, whether or not the offending agent is stopped. Usually, the rash subsides over a few weeks after discontinuation of the responsible medication (Rawlin, 2011).

The treatment of a severe dermatologic reaction due to a medication begins with stopping the offending agent. Identifying the offending agent can at times be difficult, and a systematic approach to identifying the likeliest agent, agents, or circumstances is crucial. When an agent must be withdrawn abruptly, issues such as withdrawal and the ongoing need to treat other illnesses must be considered. Corticosteroids are routinely provided. Symptomatic measures may at times include life support but usually include intravenous fluids, pain medications, and ocular care. Improvement in skin manifestations and eosinophilia is often prompt with these interventions. However, in some cases substantial or full resolution may take months (Pereira de Silva, Piquioni, Kochen, & Saidon, 2011). Infection, neoplasia, other immune reactions, and other drugs are typically in the differential for a suspected drug-induced rash. Certainly when one aromatic anticonvulsant has caused an AHS, it is reasonable to avoid treatment with another aromatic anticonvulsant. Seitz and colleagues (2006) warned that TCAs are structurally similar to carbamazepine and may lead to a recurrence of a drug-induced hypersensitivity reaction among sensitive patients. Their rough data suggested that a third of patients with a history of AHS will have a recurrence when administered a structurally similar anticonvulsant or TCA.

In some cases it may be possible to pursue treatment with an agent that has caused a rash. For example, if a patient develops a rash during lamotrigine treatment, and if arene oxides are indeed the cause, it may be possible to limit their production by hepatic cytochromes P450 by increasing the dose slowly and perhaps to a lower final dosage (Naveen et al., 2012). Because a visible, pruritic rash may be a late development in what proves to be a severe systemic drug reaction, the clinician should be cautious in rechallenging a patient (Lonati et al., 2012).

HYPONATREMIA

CLINICAL FEATURES

Hyponatremia is generally defined as a serum sodium concentration less than 134–136 milliequivalents per deciliter (mEq/L). It is the most common electrolyte disturbance among hospitalized patients and may occur in as many as 15%–30%. The brain is particularly susceptible to edema and injury in hyponatremia, but overrapid correction of hyponatremia is also perilous. Hyponatremia may cause acute confusion, obtundation, and seizures. It may also cause more subtle problems. For example, motor and gait disturbances due to hyponatremia can reduce quality of life and increase the risk of falls. When the serum sodium falls below 115 mEq/L, the clinician may observe an altered sensorium in over 50% of patients, seizures in over 20%, nausea and vomiting in 5%, disturbances of gait and falls in 4%, dysarthria in 2%, and coma in another 2% (Douglas, 2006). Once discovered, hyponatremia

Box 23.5 APPROACH TO THE DIAGNOSIS OF HYPONATREMIA

- (1) Check serum osmolality
If serum is hyposmolar, then:
 - (a) Obtain urine osmolality to determine:
if urine is appropriately dilute (<100 mOsm/kg) or inappropriately concentrated (>100 mOsm/kg).
 - (b) Check urine sodium and urea to assess whether these are being retained or inappropriately excreted.
If serum osmolality is normal, consider pseudohyponatremia.
- (2) If possible, determine whether hyponatremia is of acute onset (48 hours or less) or is chronic.
Symptomatic hyponatremia of acute onset should be corrected quickly.
Hyponatremia of prolonged duration should be corrected slowly.
- (3) Next, identify signs and symptoms suggestive of cerebral edema.
- (4) Initiate treatment as indicated.
Determine rate of correction: do not exceed 12 mEq/L per day to avoid demyelination.
Identify any conditions or medications that may promote hyponatremia.

requires clinical action. Box 23.5 outlines a clinical approach to hyponatremia (Chubb, 2009; Esposito, Piotti, Bianzina, Malul, & Dal Canton, 2011; Josiassen et al., 2012; Vaidya, Ho, & Freda, 2010).

A host of medications and conditions can cause, or encourage the development, of hyponatremia. Box 23.6 outlines the general categories of these agents and treatments.

WHO IS AT RISK?

Many factors increase the risk of developing hyponatremia. Being female, advancing age, commonly used medications such as thiazide diuretics and SSRIs, a variety of common medical problems including hypothyroidism, and a history of having hyponatremia are among the risk factors for developing it (Musham, Jarathi, & Pedraza, 2010). The syndrome of inappropriate antidiuretic hormone (SIADH) activity is the most common cause of hyponatremia (Hannon & Thompson, 2010). Patients with SIADH cannot dilute their urine despite hyposmolar serum. Among medications, the SSRIs appear to be a common precipitant of SIADH.

Certainly SSRI-induced SIADH is not common; perhaps a few cases per thousand occur. And yet the SSRIs are prescribed so widely that the problem has become well known. Typically, SSRI-induced SIADH develops within 2 to 4 weeks of initiating treatment. Dosage does not appear to be a risk factor. But hyponatremia may develop 3 months or more after starting treatment with an SSRI (Liu et al., 1996; Madhusoodanan

Box 23.6 AGENTS AND OTHER FACTORS THAT PROMOTE HYPONATREMIA

- (1) Agents and factors that promote sodium loss:
 - Renal:
 - hypoaldosteronemia
 - hypocortisolism
 - cerebral salt-wasting syndrome
 - Medications:
 - thiazide diuretics
 - Gastrointestinal:
 - diarrhea, vomiting
 - Burns
- (2) Agents and factors that promote volume expansion:
 - Intravenous fluids
 - Parenteral nutrition
 - Congestive heart failure
 - Cirrhosis
 - Hypothyroidism
- (3) Agents and factors that enhance the release or activity of antidiuretic hormone:
 - Stimulate ADH release:
 - Cerebral disease*
 - infections, multiple sclerosis, malignancies
 - Medications*
 - SSRIs may be the most common cause of drug-induced SIADH
 - Other*
 - pulmonary diseases, including asthma, bacterial pneumonia, tuberculosis
 - Tumors*
 - small cell lung cancer, less commonly lymphoma, pancreatic cancer
 - Enhance sensitivity to ADH:
 - Medications*
 - SSRIs, carbamazepine, cyclophosphamide
 - ADH analogues*
 - desmopressin, oxytocin, vasopressin

et al., 2002), Fisher and colleagues (2002) found that the vast majority of patients with symptomatic hyponatremia due to citalopram were at least 70 years old and that three in four were women. It appears that the SSRIs increase the expression of aquaporin 2 in the inner medullary collecting duct of the kidney (Moyses, Nakandakari, & Magaldi, 2008). This enhances the renal response to ADH and leads to hyponatremia.

It is sometimes argued that other classes of antidepressant may pose less risk of hyponatremia and studies have found that the risk of hyponatremia with mirtazapine and venlafaxine was significantly less than with SSRIs (Jung, Jun, Kim, & Bahk, 2011). However, case reports of hyponatremia have been linked to essentially every class of antidepressant. Roxanas and colleagues reported in a prospective study that 10 of 58 patients over 65 years old started on venlafaxine developed hyponatremia within weeks (Roxanas, Hibbert, & Field, 2007).

Antipsychotics can also cause hyponatremia, and this is typically due to SIADH (Kohen, Voelker, & Manu, 2008). This risk may be just as great for antipsychotics as for antidepressants, but the risk may be overlooked in the presence of other agents with better known risk, such as SSRIs (Mannesse et al., 2010). Indeed, the combination of typical or atypical antipsychotics with other psychotropics known to cause SIADH, such as SSRIs, may compound the risk of developing hyponatremia (Vucicevic, Degoricija, Alfirevic, & Vukicevic-Badouin, 2007). The profile of the patient at risk for developing hyponatremia during antipsychotic therapy may differ from that of patients receiving antidepressants. Meulendijks and colleagues (2010) found that the majority of patients reported to have antipsychotic-induced hyponatremia were middle-aged men. Among the severely mentally ill, the possibility of psychogenic polydipsia must also be considered, as the incidence of psychogenic polydipsia in that group ranges from 6%–20% (Dudeja, McCormick, & Dudeja, 2010). Distinguishing psychogenic polydipsia from drug-induced SIADH is important. Table 23.7 outlines some important differences (Dundas, Harris, & Narasimhan, 2007).

Anticonvulsants are another well-known cause of hyponatremia. In a prospective study involving oxcarbazepine, 25% of patients developed hyponatremia after starting the drug, and in a third of these patients the serum sodium level fell to less than 128 mEq/L. Higher doses, and use in combination with other drugs capable of causing hyponatremia, increased the risk (Lin et al., 2010). Many other anticonvulsants have been linked to hyponatremia, with reports ranging from the frequent (for carbamazepine, phenytoin, and valproic acid) to the rare for agents such as pregabalin (Beers, van Puijenbroek, Bartelink, van der Linden, & Jansen, 2010; Blum, Simsolo, & Tatour, 2009).

There are several mechanisms by which medications may produce the syndrome of inappropriate antidiuretic hormone (SIADH) or some other form of hyponatremia. These include both central and peripheral actions (Esposito et al., 2011). Centrally, psychotropics may alter the regulation of sodium and water. In humans, hyponatremia may develop rapidly as a result (Karim, Jawairia, Rahman, Balsam, & Rubinstein, 2011). Agents that inhibit serotonin reuptake or promote serotonin release tend to cause rats to retain water and reduce their appetite for sodium. The net result is a centrally-mediated hypoosmolar hyponatremia (de Magalhães-Nunes et al., 2007). A direct effect on renal sodium and water handling

may also be exerted by medications. For example, SSRIs such as fluoxetine may increase water reabsorption specifically within the kidney by increasing the number of aquaporin receptors in the inner medullary collecting duct (Moyses et al., 2008). Given the multitude of central and peripheral effects that medications may have on sodium and water handling, the clinician is obliged to be attentive to the possibility of iatrogenic hyponatremia.

TREATMENT

Correction of hyponatremia involves identifying modifiable risk factors and causes, clarifying the type of hyponatremia, and determining how recently the hyponatremia has developed. It is of course important to exclude pseudohyponatremia, in which the serum sodium concentration is low, but the serum osmolality is normal, as may occur in hypertriglyceridemia or hyperproteinemia. Pseudohyponatremia may develop in conditions such as acute pancreatitis or myelomas (Douglas, 2006). Once pseudohyponatremia is excluded, and reversible causes of hyponatremia have been identified, and their reversal initiated, the clinician should move quickly to correcting the serum sodium level. The pacing of sodium replacement depends heavily upon the duration of the hyponatremia. As noted above, if hyponatremia has persisted beyond 48 hours, its correction should be gradual in order to avoid such injuries as central demyelination. Hyponatremia developing in less than 48 hours has not typically been accompanied by substantial movements of cellular sodium and can be treated more aggressively.

The replacement of serum sodium is designed to take place at a rate that will not produce significant osmotic changes with neurons, and with a goal of minimizing such neurological consequences of hyponatremia as seizures. A hypertonic saline solution of 3%, given at a rate of 1–2 mL/kg/hour, is often combined with a loop diuretic to enhance free water elimination. A fast rate may be used if seizures or other signs of neurologic deterioration are present. The serum sodium level should not rise faster than 2 mEq/L/hour. In the first 24 hours, the total rise should not be more than 12 mEq/L. The goal is a serum sodium level of 118 mEq/L and an asymptomatic patient. Once these are achieved, the rate of correction can be slowed further, with a goal of 125 mEq/L. In euvolemic and hypervolemic hyponatremia, fluid restriction

Table 23.7 DISTINGUISHING FEATURES OF PSYCHOGENIC POLYDIPSIA AND SIADH

FACTOR	PSYCHOGENIC POLYDIPSIA	SIADH
Urine osmolality	Low, and sometimes profoundly low. <100 mOsm/L	Not low given serum osmolality: >100 mOsm/L
Urine sodium levels	Low: <10 meq/L	Not low: >40 meq/L
ADH levels	Low or very low	Elevated
Plasma osmolality	Low	Low
Fluid intake	Increased	May be normal

may be useful (Douglas, 2006). In SIADH, restricting fluid intake to 800–1200 milliliters of water a day is the first-line treatment (Sherlock & Thompson, 2010).

In cases of chronic, asymptomatic hyponatremia, medications may be of use. Demeclocycline is an antagonist of vasopressin that reduces the urine concentration. It works in about 60% of patients by causing diabetes insipidus. Demeclocycline can cause nephrotoxicity, but this is usually reversible with discontinuation of the drug. A newer class of medication is that of the vasopressin type 2 receptor antagonist, or *vaptans* (Sherlock & Thompson, 2010). These relatively new agents are not widely used as yet, in part because of their newness and in part due to cost.

For the patient with medication-induced SIADH who requires treatment of a disorder such as depression, for which the recommended treatments caused SIADH, the clinician must decide with the patient how to manage both the medication-induced SIADH as well as the disorder for which the offending medication was prescribed. In some cases a different medication or treatment may be sufficient. Electroconvulsive therapy may substitute for an SSRI in a depressed patient. A patient with epilepsy may fare better with some anticonvulsant other than carbamazepine. For the patient who is obliged to continue treatment with a medication that lowers his or her serum sodium, options may include careful fluid restriction or a trial of a vaptan or demeclocycline. Careful monitoring of serum sodium is essential in such cases. In addition, the patient must be taught to recognize the signs and symptoms of hyponatremia such as subtle changes in gait, an increase in clumsiness, or worsening memory (van der Lubbe, Thompson, Zietse, & Hoorn, 2009). The patient must also know the consequences of such signs and symptoms and how to respond—for example, no driving if gait or memory worsens and a trip to see the clinician for testing of the serum sodium.

CLINICAL PEARLS

- On serotonin syndrome: Many patients with delirium may have hyperreflexia and a few beats of clonus; what is distinctive about SS is the prominent and sustained clonus disproportionate to other signs of encephalopathy. The concurrence of gastrointestinal symptoms helps with the diagnosis, but the most useful point is a history of simultaneous onset of the CNS, autonomic, and GI symptoms in relation to a change in medications with serotonergic effects or a change in medications that interact with a serotonergic medication to increase its level or its effect.
- Drugs directly stimulating serotonin receptors include triptans, buspirone, lithium, and LSD.
- Drugs inhibiting neuronal reuptake of serotonin include SSRIs, SNRIs, TCAs, MAOIs, and linezolid.
- Drugs that inhibit nitric oxide synthesis include paroxetine, fluoxetine, and methylene blue. It is thought that the former two SSRIs may carry increased risk of SS

because of their dual effect on NO synthase and on serotonin reuptake.

- SS is more common in smokers. Diabetes and hypertension are both associated with increased risk of the condition.
- Young men are the highest risk demographic for neuroleptic malignant syndrome.
- Clinical conditions associated with increased risk for NMS include agitation, dehydration, alcoholism, alcohol withdrawal, fever, structural brain injury, hyponatremia, iron deficiency, infection, and concomitant lithium therapy.
- Increased dopamine blockade increases risk: higher neuroleptic dosage, higher potency drugs, and intramuscular administration all carry a higher risk of NMS.
- Atypical (second generation) neuroleptics carry less risk than typical (first generation) neuroleptics. Notwithstanding, numerous cases of NMS due to atypical neuroleptics have been reported

NEUROSTIMULATION: ECT, VNS, rTMS AND DBS

Lawrence Park

INTRODUCTION

Somatic therapies have played a prominent role in the history of psychiatric therapeutics. The term *somatic therapies* refers to a wide range of treatment modalities that utilize treatment interventions based in biological mechanisms. While it could be argued that pharmacological treatment is a form of somatic therapy, the term is typically used to distinguish biologically based therapies from pharmacological treatments. At the present time, pharmacological treatments serve as the mainstay of psychiatric therapeutics, but somatically based interventions are gaining in prominence and in the future may commonly be utilized in clinical settings.

Somatic treatments proliferated in the late 1800s and early 1900s as the foundations of modern neurology and psychiatry were being developed. During this period of time, the biological substrates of mental phenomena were just beginning to be understood, and a paucity of effective treatments existed (Shorter, 1997). Prior to the advent of modern psychopharmacology (i.e., generally considered to have started with the synthesis of chlorpromazine in 1954), a variety of somatic treatments were developed. Many treatments, such as hydrotherapy—the immersion of patients into hot water—had little scientific evidence to support their safety and effectiveness. Other interventions were based on a rudimentary understanding of the biological basis of psychiatric conditions and demonstrated marginal effectiveness and/or significant adverse events. For instance, Julius Wagner von Jauregg (an Austrian psychiatrist) investigated the use of pyrotherapy, the use of febrile illness to treat psychiatric conditions. Targeting dementia paralytica (dementia related to neurosyphilis), he injected patients with live malaria parasites from infected individuals. While the ensuing fevers from malaria were purported to be quite effective for eradicating *treponema pallidum* and treating tertiary syphilis, the patient was then left with another pernicious, and incurable, condition (malaria). For his work, von Jauregg was awarded the Nobel Prize for medicine in 1927. Another somatic treatment developed in this era was the use of insulin coma therapy. Manfred Sakel (a Polish psychiatrist) developed the technique of administering insulin to psychiatric patients (primarily for psychotic symptoms) in order to induce hypoglycemic coma (Sakel, 1958). Again, while beneficial outcomes were reported, the potential

complications of intentionally induced sustained hypoglycemia were significant. A final example of a somatic treatment during this era is the development of ablative surgical procedures for psychiatric symptoms. Colloquially referred to as “psychosurgery,” anatomical targets of ablation, such as the frontal lobe, were proposed based on empirical experience of an individual who had sustained accidental brain injury (i.e., John Gage) and the resulting effects. As in the previous examples, proponents of ablative procedures, such as frontal lobotomy or lobectomy, reported positive outcomes on psychiatric target symptoms, but rigorous studies have never been conducted and significant and permanent neuropsychiatric complications are known to occur.

Recently, somatic treatments have focused on a number of neurostimulation techniques for the treatment of neurological and psychiatric indications. Neurostimulation techniques currently being investigated or used in clinical practice include electroconvulsive therapy (ECT), vagus nerve stimulation (VNS), repetitive transcranial magnetic stimulation (rTMS) and deep brain stimulation (DBS).

While the development of modern neurostimulation techniques rests on the previous crude somatic techniques described, it is important to recognize important distinctions between the two eras. First, current neurostimulation techniques are based on a more sophisticated understanding of the biological substrates of psychiatric illness (e.g., neurofunctional imaging of anatomical correlates, brain mechanisms of learning through long-term potentiation). As a result, interventions are designed with much more precision and therefore may maximize therapeutic effects and minimize associated side effects. Second, clinical investigations in the current era are conducted with much greater scientific rigor than in the past. As a result, a greater degree of certainty about safety and effectiveness can generally be gained from the current body of scientific data.

Based on greater insights into the biological mechanisms underlying neuropsychiatric disease, there has been a proliferation of modern somatically based technologies, including neurostimulation interventions utilizing various forms of stimulation (Rosa & Lisanby, 2012). In addition to neurostimulation using electrical and/or electromagnetic stimulation, a host of other modalities of intervention are being investigated. These interventions include light box therapy

(for seasonal affective disorder; Terman et al., 1989), focal electrically administered seizure therapy (Spellman, Peterchev, & Lisanby, 2009), magnetic seizure therapy (Lisanby, Schlaepfer, Fisch, & Sackeim, 2001), low intensity pulsed ultrasound (Tyler et al., 2008), near infrared light therapy (Hamblin & Demidova, 2006), low field magnetic stimulation (Rohan et al., 2004) and optogenetic stimulation (in animals; see Yizhar et al., 2011). Each varies in the type of energy utilized and in the methods of application. Moreover, while each of these technologies is at a different stage of development, none have been approved or cleared for use by the FDA. These treatments remain investigational, and in the clinical setting they would only be encountered in patients participating in clinical trials studying their use.

This chapter will focus on neurostimulation treatments that have been approved or cleared for neurological and/or psychiatric indications. These treatments include well-established treatments such as ECT, which has a long history of use, as well as more recently developed interventions such as VNS, rTMS and DBS. These technologies are being used or investigated to treat a growing number of neuropsychiatric conditions such as seizure disorder, Parkinson's disease, essential tremor, dystonia, catatonia, obsessive compulsive disorder, and depression, and are currently being studied for numerous other diseases. We will examine the historical development and theoretical foundation of each treatment, the indications for use, potential associated adverse events, typical clinical management, and settings where these treatments may be encountered in the care of the medical patient.

ECT

Considered by many to be one of the most effective treatments for depression, ECT is also one of the oldest treatments still used for psychiatric conditions. The application of electricity to the scalp with the intention of causing a seizure was first conducted by two Italian physicians, Cerletti and Bini, in 1938 (Bini, 1995). Since that time, ECT has had a varied history with periods of significant use and relative disuse. In the 1940s and 1950s, given the relative lack of effective pharmacotherapy and used in association with psychosurgical techniques, ECT was used quite widely. At this time, ECT was administered without modern medical and anesthetic management. In the 1960s through the 1980s—pharmacotherapy became more effective, while there was increasing public concern about coercive treatment and the stigmatization of mentally ill people. In this context the usage of ECT waned, even for the treatment of patient populations in which it is remarkably effective. From the 1990s through the present, with the development of modern anesthesia (general anesthesia, muscle relaxation, cardiovascular and pulmonary management), modifications in the ECT technique, and increasing concern about treatment-resistant disease, ECT has once again become an important option in the treatment algorithm of severe, treatment-resistant depression.

Currently, ECT is used to treat depression (both unipolar and bipolar) and catatonia, as well as other conditions

Figure 24.1 Electroconvulsive therapy (ECT)

such as psychotic depression, mania, and schizophrenia (U.S. Department of Health and Human Services, 1999). While a significant amount of research has been conducted on ECT for various indications, recent systematic reviews and meta-analyses of the literature support effectiveness only for depression, and only in the acute period within the first month after the course of treatment (Greenhalgh, Knight, Hind, Beverley, & Walters, 2005). For depression, ECT is generally considered after failure of multiple antidepressant trials and/or deterioration of the patient's psychiatric or medical condition creating a need for a rapid, definitive response (i.e., acutely suicidal, medically unstable; American Psychiatric Association, 2001). Because of the lack of other effective treatments, and the high mortality rate associated with treatment-resistant catatonia, in the clinical setting ECT is considered in treatment resistant catatonia (i.e., refractory to adequate trials—at least 2 mg parenteral lorazepam or equivalent—of benzodiazepine; Bush et al., 1996) as an off-label treatment.

Of all the treatment modalities discussed in this chapter, ECT is the most likely treatment intervention to be encountered in clinical practice. Treatment-resistant depression has been a growing concern (Rush et al., 2006) and individuals who have adequately responded to multiple antidepressant medication trials and suffer from severe symptomatology may be encountered in both the outpatient and inpatient setting. The catatonic syndrome, though uncommon, should be anticipated in the general hospital setting, given that the etiology may be medical, neurological, or psychiatric in nature, and the presentation may masquerade as a variety of related conditions. The typical course of ECT consists of 6–12 treatments, administered 2–3 times per week. Catatonic symptoms may be more persistent and may require longer courses of treatment. As previously noted, the effectiveness of ECT has been demonstrated in the acute period; symptom relapse after a successful course of ECT is a clinical concern. Clinical practice strategies that are intended to decrease the relapse rate include continuation pharmacotherapy using post-ECT administration of antidepressants, such as nortriptyline and lithium carbonate (Sackeim et al., 2001), or maintenance ECT (a tapered

course of periodic administration after a full course of ECT, e.g., once/week, once/month, etc.) (Kellner et al., 2006).

ECT is associated with considerable medical and psychiatric risks. Adverse events of ECT are presented in Table 24.1.

Medical risks of ECT include acute cardiovascular adverse events (such as hypertension, hypotension, arrhythmias, ischemia, embolic or hemorrhagic strokes), pulmonary complications (such as aspiration pneumonia or prolonged apnea), prolonged or tardive seizures, physical trauma (including bodily/dental/oral/ocular injury, skin burns), pain/discomfort/nausea, adverse reaction to anesthesia, and death. Psychiatric risks of ECT treatment include induction of mania, post-ECT cognitive disorientation, anterograde memory impairment, and retrograde autobiographical memory impairment.

Developments in medical and anesthetic management have significantly improved the safety profile of the procedure. This includes the use of general anesthesia to render the patient unconscious during the procedure, neuromuscular blocking agents to prevent tonic clonic muscle activity, and cardiovascular/pulmonary management as well as ECG, EEG, and ventilatory monitoring. Of note, depolarizing muscle blockers such as succinylcholine are considered the first-line agents for muscle relaxation. Contraindications to the use of succinylcholine include inherited cholinesterase inhibitor deficiency that may result in prolonged recovery time, or neuromuscular conditions or other states of muscular inactivity that may predispose the patient to excess potassium release from muscle tissue during the procedure. A complete history and physical should be conducted prior to ECT—including past medical and family history for adverse reactions to general anesthesia or neuromuscular blocking agents—in order to assess the occurrence of past adverse events. The information gained in the initial evaluation may aid in the optimal selection of medications to be used during the procedure.

Overall, the use of general anesthesia and neuromuscular blockers have greatly reduced the discomfort and amount of physical trauma (i.e., fractures and soft tissue trauma) associated with ECT. Appropriate cardiovascular and pulmonary monitoring and management have also significantly decreased the medical risks of ECT.

Management of other risks of ECT include EEG monitoring during the procedure to assess for prolonged or tardive seizures. In the event of prolonged seizure activity, ready access to antiepileptic agents should be available. The use of bite blocks during the procedure prevents significant dental/oral trauma. Proper skin preparation, the use of conductivity gel and snug electrode placement minimize the occurrence of skin burns. Pain, discomfort, and nausea are treated symptomatically.

As with any procedure utilizing general anesthesia, a rare but potential adverse event is death. Estimates of the mortality rate associated with ECT are 1 per 10,000 patients or 1 per 80,000 treatments (American Psychiatric Association, 2001). This rate is similar to that of general anesthesia use associated with minor elective surgical procedures.

Psychiatric adverse events associated with ECT include inadvertent induction of mania, post-procedure disorientation and confusion, and anterograde and retrograde memory

impairment. Induction of mania is a rare but documented possibility of ECT treatment. The occurrence of mania may indicate an underlying bipolar diathesis. If hypomania or mania occurs during a treatment course, ECT is often discontinued and, if needed, appropriate mood-stabilizing pharmacotherapy can be initiated. Post-procedure disorientation and confusion are commonly seen and typically resolve in the minutes to hours after treatment administration.

Perhaps the most concerning adverse events associated with ECT deal with memory impairment. It is generally accepted that ECT results in memory deficits in different domains, namely anterograde memory (i.e., recent memory or the creation new memories) and retrograde personal memory (i.e., memory for past autobiographical information). For both types of memory, impairment is greatest just after treatment. Studies suggest that anterograde memory deficits resolve within days to weeks of the cessation of treatment (Semkowska & McLoughlin, 2010). Studies examining retrograde autobiographical memory demonstrate that while there may be improvement over time, complete resolution of memory deficits has not been observed as far out as 6 months posttreatment (Fraser, O'Carroll, & Meier, 2008).

Selection of stimulation parameters may aid in the minimization of memory impairment. Greater memory impairment has been associated with sine wave stimulation, bilateral and unilateral dominant hemisphere electrode placement, increased frequency of treatment (i.e., 3/week vs. 2/week) and increasing doses of energy (for bilateral electrode placement only). In order to optimize the positive effects of ECT and minimize memory adverse events, the current standard for administering ECT is to use unilateral nondominant hemisphere placement, high energy dose (>3 times seizure threshold; seizure threshold determined by stimulus titration at the onset of treatment), and brief pulse (1–1.5 msec) waveform. Recent studies have examined the use of ultrabrief pulse stimulus (0.3 msec), which demonstrates some promise with regard to significantly decreasing memory adverse events (though this may occur at the expense of lost efficacy; see Sienaert, Vansteelandt, Demyttenaere, & Peuskens, 2010).

Because of the possibility of significant adverse events and past reports of coercive or inadequate informed consent procedures, an approved written informed consent process, with complete discussion of all the benefits and risks of treatment, should be undertaken prior to initiating any course of ECT.

A thorough psychiatric and medical evaluation is essential to ensure the safety of ECT. In addition to the treating psychiatrist, the initial workup should be conducted with the involvement of an appropriate anesthesia provider. A routine initial evaluation typically includes complete medical and psychiatric history, physical examination, laboratory tests (CBC, chemistries, UA), chest x-ray, and ECG. Preexisting medical conditions may warrant further consultation and workup (Park, Weiss, & Welch, 2004). While there are no absolute contraindications to ECT, several conditions deserve further attention before considering a course of ECT. Patients with coronary artery disease, recent myocardial ischemia/infarction, hypertension, vascular aneurysms, and cardiac arrhythmias often require cardiac consultation, further pre-ECT

Table 24.1 ADVERSE EVENTS ASSOCIATED WITH ECT AND POTENTIAL MITIGATING FACTORS

SYSTEM	ADVERSE EVENT	POTENTIAL MITIGATING FACTORS
Cardiovascular	Hypertension, hypotension, arrhythmias, ischemia, embolic or hemorrhagic strokes Frequency: BP changes common, CV uncommon, stroke rare. Severity: mild–severe	<ul style="list-style-type: none"> • Pre-ECT assessment (e.g., BP, EKG, echocardiogram, holter, neuroimaging, neurovascular studies) • Appropriate procedure monitoring (e.g., BP and rate control, anticoagulation for patients with atrial fibrillation) • Appropriate clinical management
Pulmonary	Apnea, aspiration Frequency: rare Severity: high	<ul style="list-style-type: none"> • Pre-ECT assessment (e.g., chest x-ray, pulmonary function tests) • Appropriate procedure monitoring • Appropriate clinical management
Neurological	Prolonged or tardive seizures Frequency: uncommon Severity: moderate-severe	<ul style="list-style-type: none"> • Pre-ECT neurological evaluation • EEG monitoring • Availability of seizure treatment during procedure
Physical	Fractures, soft tissue injury, dental fractures, dislocations, oral lacerations, prosthetic damage, corneal abrasions, burns at electrode site Frequency: uncommon Severity: mild–severe	<ul style="list-style-type: none"> • Pre-ECT dental assessment • Removal of prostheses • Use of general anesthetic agents and neuromuscular blocking agents • Use of mouth protection (bite blocks) • Skin preparation and electrode contact • Use of conductivity gel
Anesthesia-related	Adverse reaction or prolonged reaction to anesthetic agents, neuromuscular blocking agents Frequency: rare Severity: severe	<ul style="list-style-type: none"> • Pre-ECT assessment (medical, family history) • Appropriate procedure monitoring • Appropriate clinical management
Death	Resulting from other pathophysiological processes Frequency: rare Severity: severe	<ul style="list-style-type: none"> • Appropriate workup and management of specific medical and psychiatric risks
Pain/ discomfort/ nausea	Frequency: common Severity: mild–moderate	<ul style="list-style-type: none"> • Use of analgesic/antiemetic medications
<i>Psychiatric</i>		
Induction of mania	Frequency: uncommon Severity: moderate–severe	<ul style="list-style-type: none"> • Cessation of treatment • Administration of mood stabilizers
Cognition	Disorientation generally occurs posttreatment, but typically resolves minutes after completion of treatment. Frequency: common Severity: mild	<ul style="list-style-type: none"> • Use of square wave, direct current, brief pulse waveform stimulus (not sine wave) • Use of unilateral nondominant electrode placement • Use of ultra-brief pulse (0.3 msec) stimulus • Frequency of treatment no greater than twice weekly during a course of ECT
Memory	Anterograde memory impairment—appears to resolve within 3 months posttreatment. Retrograde autobiographical memory impairment—data out to 6 months do not demonstrate full resolution of impairment. Frequency: common Severity: mild–severe	<ul style="list-style-type: none"> • Exclusive use of square wave, direct current, brief pulse waveform stimulus • Use of unilateral nondominant electrode placement • Frequency of treatment no greater than twice weekly during a course of ECT • Use of ultra-brief pulse (0.3 msec) stimulus

evaluation, and special observation and management (if ECT is pursued). In particular, individuals with cardiac valve disease (e.g., aortic stenosis) may require cardiac outflow studies and correction of the underlying structural anomaly prior to

initiating ECT. Other conditions that warrant additional evaluation and management include pregnancy, space-occupying intracranial lesions, cerebral aneurysms, neurovascular malformations, and recent TIAs/strokes.

Some medications may have potentially problematic interactions with ECT and should be tapered or discontinued prior to treatment. Tricyclic antidepressant medications and MAO inhibitors may increase the risk of cardiac arrhythmias; therefore, they should be discontinued and/or cardiac status should be closely monitored. Lithium has been associated with increased confusion when used during a course of ECT; theophylline may increase the length of seizures. These medications are usually tapered during a course of treatment. Anticonvulsant agents (including benzodiazepines) increase the seizure threshold and therefore may interfere with seizure induction during the procedure. If adequate seizures are not being achieved, tapering or discontinuation of these agents may be indicated.

VNS

VNS involves the electrical stimulation of the left vagus nerve with the intention of affecting the functioning of limbic and higher cortical structures. VNS was initially explored as a potential treatment modality because of its role in the autonomic nervous system and direct connections to brainstem structures. It was theorized that because fibers from the vagus nerve synapse in the nucleus tractus solitarius (NTS), stimulation of the vagus nerve would affect NTS neurons, and from there could exert an ascending influence on other brain structures related to mood (George et al., 2000). Stimulation is targeted at the left vagus nerve because the majority of nerve fibers (80%) are ascending afferent fibers (in contrast to the largely efferent right vagus nerve). Early investigations noted changes in cortical EEG (McLean, 1990) and anticonvulsant effects of VNS in animals (Zabara, 1992).

Based on these findings, VNS has been studied for seizure disorders and psychiatric disorders. In 1997, VNS was approved for adjunctive therapy in reducing the frequency of refractory partial-onset seizures in individuals 12 years of

age and older. In 2005, VNS was approved for the long-term treatment of chronic or recurrent depression in adults who have not had an adequate response to four or more adequate antidepressant trials. For the one-third of patients who will suffer from medication refractory seizures, and who do not want or are not candidates for surgical resection, VNS may be a viable treatment alternative (Milby, Halpern, & Baltuch, 2008). VNS was also approved for treatment-resistant depression in 2005. The pivotal trial upon which approval was based (Rush et al., 2005) did not demonstrate a significant difference between active and sham groups at 10 weeks, though a post-hoc comparison of treatment-resistant depression patients receiving VNS and treatment as usual showed significant results favoring the VNS group (Rush & Siefert, 2009). Measures of depression improved over several months, with the investigators inferring that the maximal effect of VNS for depression occurs 6-12 months after implantation of the unit. Treatment response can increase over time when VNS is used for epilepsy as well. For example, Kuba et al. (2009), reporting a series of epilepsy patients who received VNS for 5 years or more, noted that one year after implantation of the unit 44.4% of patients were assessed as responders to treatment, while after two years 58.7% of patients were judged as responders. Given the potential delay in symptom improvement, VNS should not be viewed as an appropriate treatment for acute depression. In the treatment of chronic treatment-refractory depression the benefit of VNS *may* justify the expense and risk of adverse events, but it should be kept in mind that only a minority of patients treated will experience a remission of depression with VNS, and some will not improve as well. A retrospective study of Medicare beneficiaries with treatment resistant depression (TRD) (Feldman et al., 2013) suggests that there may be long-term economic benefits of VNS treatment on a population basis even if the benefit is not predictable for individual patients. They found that average medical costs per patient year *post-implantation* for Medicare beneficiaries with TRD receiving TNS were substantially lower than the costs for beneficiaries with TRD receiving other treatments.

The VNS device consists of an implanted pulse generator (IPG) and an electrode that attaches to the left vagus nerve. The IPG is surgically implanted into the left chest wall, either subcutaneously or in a pocket in the pectoral muscle, and the electrode is attached to the left vagus nerve, and then a connection is made with the IPG. In addition, the system also includes an external programming device that links to the IPG with a programming wand and a wristwatch style magnet that can be used to reset the microprocessor. After surgical implantation and an adequate time for healing, the treating physician may activate the device and program the settings. Typical stimulation parameters are presented in Table 24.2. Note that the VNS is active intermittently; the percentage of the time the unit is active is an important determinant both of side effects and of battery life.

Adverse events associated with the implantation and operation of a VNS unit include incisional pain, neck pain, dysphagia, nausea, paresthesias, increased cough, dyspnea, laryngismus, pharyngitis, voice alteration (hoarseness), and

cardiac events (bradycardia, tachycardia, palpitations, postural hypotension, and syncope). Of these, the most common are hoarseness, coughing and dyspnea, neck pain, and dysphagia. These complications occur during the active stimulation phase and are generally uncomfortable but not severe. If patients do not acclimate to these effects over time, the frequency and intensity of the stimulus, or the percentage of time the stimulator is active, may be reduced to decrease their occurrence or severity. Bradycardia, hypotension, and syncope when they occur are typically seen during the active stimulation phase and are thought to be due to increased vagal tone. While quite concerning and potentially severe, cardiac complications are not commonly seen with VNS treatment. If they do occur, they are often successfully managed by decreasing or suspending stimulation.

Appropriate preimplantation workup includes a comprehensive medical and psychiatric evaluation involving psychiatrist, anesthesiologist, and neurosurgeon (Fahy, 2010). VNS placement is contraindicated in patients with a bilateral or left cervical vagotomy, and cardiac arrhythmias are a relative contraindication. VNS can cause or exacerbate bradycardia and rarely can induce asystole requiring resuscitation. It can exacerbate obstructive sleep apnea (OSA), or precipitate the onset of OSA in patients not previously affected. Patients with chronic lung disease may experience a worsening of dyspnea when the vagus nerve is stimulated. Postoperative arrhythmia will not necessarily be detected by a day of Holter monitoring conducted when the patient is asymptomatic; when a patient develops episodic faintness, syncope or palpitations following VNS an effort should be made to obtain an ECG when the patient is symptomatic. Patients with implanted VNS units should not receive diathermy treatments either utilizing short-wave or microwave radiation or therapeutic ultrasound. Magnetic resonance imaging (MRI) of the body, transcutaneous electrical nerve stimulation (TENS), defibrillation, and extracorporeal shockwave lithotripsy all have the potential to damage the VNS unit (Cyberonics, 2007). At the time of writing, VNS has been approved as adjunctive therapy for reducing seizure frequency in patients at least 12 years old with partial seizures refractory to antiepileptic medications, and as adjunctive long-term therapy for chronic or recurrent depression that has not had an adequate response to four or

more adequate antidepressant treatments. Clinicians working in hospital settings are more likely to encounter patients with vagus nerve stimulators for the epilepsy indication than for the depression indication. While depression and epilepsy are the only approved indications for VNS, clinicians have published case series of its use in other conditions of interest to medical psychiatrists, notably fibromyalgia (Lange et al., 2011) and anxiety disorders (George et al., 2008).

Clinical situations that can arise in the management of VNS devices include battery depletion and device malfunction. Depending on the parameters of the VNS – amplitude and frequency of stimulation, and the percentage of the time the unit is activated – expected battery life ranges from less than one year to more than 10 years. In addition to battery depletion, another common device malfunction is lead breakage, which can be due to trauma to the chest or neck, or to growth in the case of adolescents treated for epilepsy with VNS. In both cases, stimulation can terminate abruptly and this can result in a precipitous exacerbation of symptoms. The nature of device malfunction usually can be established by externally querying the device with its remote control. Surgical revision would be required to replace or repair the defective components.

VNS is not compatible with full body MRI. MRI should not be performed with a body coil in transmit mode (this may result in heating of the VNS lead). Compatibility of VNS with brain MRI has been demonstrated with the stimulator in the off mode (i.e., current = 0 mA) with a transmit-and-receive type of head coil and a static magnetic field strength of 2 Tesla or less.¹ Finally, although several case reports have been published recently, the safety of administering ECT in patients with VNS has not been firmly established.

rTMS

Repetitive transcranial magnetic stimulation is a noninvasive brain stimulation technology that utilizes the principle of electromagnetic induction to subject the brain to an alternating electrical current by externally applying an alternating magnetic field. This technology is based on Ampère and Faraday's (Liao, Dourmashkin & Belcher, 2004) finding that passing a wire through a magnetic field generates an electric current—in other words, “a changing magnetic field can generate electrical current in nearby wires, nerves or muscles” (George, 2010). The basic rTMS system consists of an external wire coil through which an alternating electrical current is passed. A fluctuating magnetic field is created around the coil, which induces an alternating electric current in underlying neuronal tissue. This current by altering the electrical environment of neurons influences their firing properties (Wassermann & Zimmermann, 2012). The magnetic fields penetrate tissues and are not subject to the electrical resistance of bone and soft tissues that limits the use of external

1. IPG output = 0 mA, transmit and receive head coil only, static magnetic field strength ≤ 2 T, specific absorption rate (SAR) < 1.3 W/kg for 70 kg patient, time-varying intensity of < 10 T/sec.

Figure 24.3 Repetitive transcranial magnetic stimulation (rTMS)

electrical stimulation (though, however, transcranial direct current stimulation with low current is feasible and is under exploration as a therapy for depression and other conditions). Through the use of shaped coils, the magnetic flux may be focused on specific cortical anatomical targets. While magnetic stimulation utilizing different characteristics has been investigated (i.e., single pulse vs. repetitive, alternating vs. direct current), repetitive stimulation—rTMS, utilizing alternating current—has received the most attention. rTMS devices have been investigated in a number of different conditions. However, they are approved for only one condition, which is major depression. In 2008, an rTMS device was cleared for the treatment of major depressive disorder in adult patients who have failed to achieve satisfactory improvement from one prior antidepressant medication at or above the minimal effective dose and duration in the current episode.² The pivotal randomized controlled trial demonstrated a p-value of 0.057 for the prespecified primary effectiveness endpoint (difference between active and sham baseline to 4-week endpoint change on the Montgomery-Asberg Depression Rating Scale; see O'Reardon et al., 2007). Based on the evidence available, rTMS was cleared by the FDA for use in individuals with major depression who had failed one prior antidepressant trial.

While rTMS has not been cleared or approved for other indications, current investigations are examining its use for various conditions including schizophrenic hallucinations, PTSD, obsessive compulsive disorder, Parkinson's disease, Alzheimer's disease, neurorehabilitation, migraine headache, chronic pain, and tinnitus (Wassermann & Zimmermann, 2012).

The system includes a wrapped wire coil, a console (including energy source), and a patient chair. Coils are of various shapes (a common shape is "figure 8") to create an optimal magnetic field (Marangell, Martinez, Jurdi, & Zboyan, 2007). For depression, stimulation is localized over the left dorsolateral prefrontal cortex. Certain parameters are then set for the treatment, such as frequency of pulses, and intensity (as a percentage of motor threshold-MT, train duration, and total

Table 24.3 MAXIMUM SAFE DURATION (IN SECONDS) OF SINGLE TRAINS OF RTMS

FREQ (HZ)	INTENSITY (% MT)				
	90	100	110	120	130

number of pulses). Maximum safe stimulation criteria have been established, originally published by Wassermann (1998) and later updated by Rossi et al. (2009; see Table 24.3). rTMS is generally conducted in the outpatient setting, with a typical course of treatment comprising one-hour stimulation sessions five days a week for 4 to 6 weeks. Potential adverse events include seizures, induction of mania, pain over the stimulation site, headache, visual changes, dental pain, facial numbness or twitching, temporary or permanent hearing loss, and, in children and adolescents, neurocardiogenic syncope. The risk of a seizure can be minimized by adherence to safe stimulation criteria. EEG monitoring and appropriate antiepileptic management should be available in the event that seizures occur in the course of treatment. Induction of hypomania or mania is also a rare complication of rTMS, and should be managed by cessation of rTMS treatments and/or appropriate mood stabilizing interventions. Given the loudness of the rTMS device and the potential for permanent hearing loss, earplugs should be worn at all times by all patients and treaters. If rTMS is off-label for a child or adolescent the patient's blood pressure and pulse should be monitored because of the risk of neurocardiogenic syncope. Overall, however, the incidence of serious adverse events with rTMS is very low and the treatment should be regarded as relatively safe, as compared with ECT, multi-drug regimens and other treatment options for treatment-refractory depression. Contraindications to rTMS include any metal in the head (except in the oral cavity), increased intracranial pressure, cardiac pacemakers, implanted neurostimulators, medication pumps, and intracardiac lines. Other conditions that may preclude rTMS treatment or require additional monitoring and management include significant cardiac disease, pregnancy, history of bipolar disorder, stroke, brain lesions, suicide attempts, and personal or family history of seizure disorders.

DEEP BRAIN STIMULATION

Deep brain stimulation (DBS) is an invasive brain stimulation technique which involves direct electrical stimulation of cortical and subcortical brain structures through the precisely-localized implantation of an electrode into deep

2. www.accessdata.fda.gov/cdrh_docs/pdf8/K083538.pdf

Figure 24.4 Deep brain stimulation (DBS)

brain structures. Electrodes are connected via a lead wire to neurostimulator pulse generators implanted under the skin in the chest wall. Like the implanted VNS device, the DBS system includes external programming devices for use by the physician and by the patient that control the implanted device via a radio frequency connection. External radio frequency stimulation can induce sufficient current in the implanted device to recharge its battery.

Perhaps more than any of the other neurostimulation techniques, DBS is rooted in a structural theory of brain function, and, while not an ablative procedure, is founded on the experience of past ablative neurosurgical procedures (Goodman & Insel, 2009). DBS was initially attempted by Heath in 1963 (Heath, 1963). Based on the understanding of motor circuitry in the brain involving cortical-thalamo-striatal-cortical circuits, treatments for movement disorders using DBS were developed. Theoretical advances in understanding were paralleled by technological advances in stereotactic neurosurgery, which provided the ability to precisely and accurately localize electrode placement in specific brain structures. While movement disorders were the initial indications of DBS research, DBS targeting limbic structures emerged as a new somatic treatment for severe primary mental disorders. The application of DBS to primary mental disorders has been informed by emerging neuroanatomy-based models of their pathophysiology. DBS is currently approved for several indications, including Parkinson's disease, essential tremor, dystonia, and obsessive compulsive disorder (OCD). Dystonia and OCD were approved by the FDA under a Humanitarian Device Exemption, which allows for a maximum annual number of patients treated of 4,000. In clinical practice, given the increased use and experience of DBS for movement disorders, patients with implanted DBS devices are most likely to be encountered by medical psychiatrists when they consult to neurology services. On occasion medical psychiatrists are asked to do pre-implantation assessments of candidates for DBS. Table 24.4 outlines the indications and anatomical targets.

In addition, DBS is currently being investigated at various locations for a number of other disorders. These disorders include major depression, epilepsy, Tourette

Table 24.4 CURRENTLY APPROVED DBS INDICATIONS

DISEASE	INDICATION	ANATOMICAL TARGET
Parkinson's Disease	Adjunctive therapy in reducing some of the symptoms of advanced, levodopa-responsive Parkinson's disease that are not adequately controlled with medication.	Bilateral stimulation of GPi or STN
Essential Tremor	Suppression of tremor in the upper extremity in patients who are diagnosed with essential tremor or parkinsonian tremor not adequately controlled by medications and where the tremor constitutes a significant functional disability.	Unilateral thalamic stimulation
Dystonia	Chronic, intractable (drug refractory) primary dystonia, hemidystonia, generalized and segmental dystonia, hemidystonia, and cervical dystonia (torticollis), for individuals 7 years of age or older.	Unilateral or bilateral stimulation of the GPi or STN
OCD	Chronic, severe, treatment-resistant OCD in adult patients who have failed at least 3 SSRIs.	Bilateral anterior limb of the internal capsule

syndrome, headache, other chronic pain, eating disorders, and posttraumatic coma, (Perlmutter & Mink, 2006; Pluza, Perazza & Golub, 2011), PTSD, substance abuse, and Alzheimer's disease. Studies examining DBS for major depression have targeted locations such as subgenual cingulate white matter (Brodmann area 25; see Mayberg et al., 2005) and the ventral capsule/ventral striatum (Malone et al., 2009). Typical stimulation parameter ranges are presented in Table 24.5.

Table 24.5 TYPICAL DBS STIMULATION PARAMETERS

PARAMETER	RANGE
Output current	0–2.25 mA
Frequency	<185 Hz
Amplitude	<3.5 V
Pulse width	<210 μ sec
Charge density	30 μ C/cm ² /phase
Duty cycle	
• Stimulation ON	≤60 sec
• Stimulation OFF	0.3–180 min

From Kuncel & Grill, 2004.

The most serious adverse events associated with DBS are related to the surgical implantation of the stimulating apparatus; these include intracranial hemorrhage, stroke, seizures, cerebrospinal fluid (CSF) leaks, infections, allergic reactions, neurological symptoms, cardiovascular/pulmonary complications, incisional pain, and headaches. Intracranial hemorrhage occurs in approximately 2% of patients (Follett et al., 2010). The mortality rate for the procedure has been estimated at approximately 1%. While DBS implantation is relatively benign compared with other neurosurgical procedures, it represents a significant risk in the context of neuropsychiatric disorders and their standard non-surgical treatments.

In order to minimize surgery-related risks, a full preoperative medical evaluation should be conducted prior to DBS implantation. In addition to the usual anesthesia-related risks, bleeding disorders and cerebrovascular disease are especially relevant. Potential neuropsychiatric symptoms associated with deep brain stimulation itself (as opposed to device implantation) include confusion, depression or hypomania, suicidal ideation, agitation/irritability, cognitive/behavioral changes, speech disturbance. Specific symptoms are encountered with specific electrode placement sites. Neuropsychiatric symptoms sometimes can be mitigated or eliminated by adjusting stimulation parameters.

Device malfunction such as electrode migration, lead breakage, battery depletion or other malfunction of the implanted pulse generator usually requires surgical revision and/or replacement of the implanted device components.

As with all permanently implanted metallic devices, diathermy (including shortwave diathermy, microwave diathermy, and therapeutic ultrasound diathermy) is contraindicated with DBS devices because heating of the device components can occur and lead to severe injury or death. Undergoing MRI with an implanted DBS system may pose a safety risk; the possibility of safely performing an MRI procedure in a specific patient depends on the device, the specific image to be obtained, and the details of the MRI machine. There have been reports of serious injury and death in individuals with implanted DBS devices undergoing MRIs due to heating and/or movement of the implanted pulse generator, the electrodes or the leads that connect them (Rezai et al., 2004). The FDA has adopted a classification of “MR Safe”, “MR Unsafe” and “MR Conditional” to describe safety in the MR environment for those with implanted devices.³ Some manufacturers have conducted safety testing and provided this information in the approved labeling of the device. Provided the device-specific conditions set forth in the approved labeling are followed, there is a reasonable assurance that MR imaging can be performed safely. Finally, the safety of administering ECT in patients with DBS has not been established.

After electroconvulsive therapy (ECT), DBS is the second most common neurostimulation modality currently in clinical use. However, because of its invasiveness, and the limited evidence of efficacy for conditions other than movement disorders, it is not the first-line treatment for any condition.

Medical psychiatrists consulting to neurological services will encounter patients receiving DBS for movement disorders (Parkinson’s disease, essential tremor, and dystonia). Often, consultation will be requested regarding management of symptoms that could either be adverse effects of DBS or symptoms of one of the psychiatric conditions commonly associated with the movement disorder (e.g., major depression with Parkinson’s disease). If neuropsychiatric symptoms have arisen or worsened following a recent adjustment of device stimulation parameters, an attempt should be made to readjust stimulation initiating or changing psychopharmacologic treatment of the symptoms. In some cases the adjustment of stimulation parameters will worsen motor symptoms at the same time as it helps neuropsychiatric symptoms – a situation similar to the one that arises when levodopa is reduced in a patient with Parkinson’s disease because of levodopa-induced mental status changes. An appropriate response is to assess and quantify the distress and functional impairment associated with the motor symptoms and the neuropsychiatric symptoms with different choices of stimulation parameters. This will inform a decision, which often involves a dialogue among the neurologist, the medical psychiatrist, and the patient. Finally, when a patient with a DBS device has a sudden exacerbation of primary symptoms, the device should be interrogated via its remote controller to ensure that it is functioning properly. Abrupt device malfunction (or battery depletion) could be responsible for occurrences of sudden and severe rebound symptomatology.

SUMMARY

ECT is a standard treatment for refractory depression and DBS a standard treatment for certain severe movement disorders. With the development of newer technologies various forms of neurostimulation are finding broader application in neurology and psychiatry, and it is likely that some will emerge as standard treatments, competing with or complementing drug therapies. Each neurostimulation procedure and device is associated with specific adverse events with which the medical psychiatrist should be familiar.

CLINICAL PEARLS

Currently available neurostimulation techniques are based on a more sophisticated understanding of the biological substrates of psychiatric illness than ECT, the historical option for treatment of psychiatric disorders with neurostimulation. Recent neurostimulation techniques have been designed with more precise targets and, with the exception of DBS, are safer than ECT. The level of evidence currently required to establish the safety and effectiveness of treatments for particular indications is much higher than what was required in the past.

A host of non-pharmacologic somatic therapies for mental disorders are under investigation or in off-label clinical use, including transcranial direct current stimulation (tDCS), light therapy (for seasonal affective disorder and delayed

3. <http://www.fda.gov/MedicalDevices/DeviceRegulationandGuidance/GuidanceDocuments/ucm107705.htm>

sleep phase, focal electrically administered seizure therapy (FEAST), magnetic seizure therapy (MST), focused ultrasound (FUS), near infrared light therapy (NILT), low field magnetic stimulation (LFMS), and optogenetic stimulation.

Because of the lack of other effective treatments and the high mortality rate associated with treatment-resistant catatonia, ECT is generally considered if catatonia is refractory to adequate trials of benzodiazepines (at least 2 mg parenteral lorazepam or equivalent) or if symptom relapse is experienced despite maximal benzodiazepine treatment.

Catatonic symptoms may be more persistent and may require longer courses of ECT treatment than major depression without catatonia.

With ECT, anterograde memory impairment appears to resolve within 3 months posttreatment. Retrograde autobiographical memory impairment for up to 6 months prior to the date of the first treatment does not fully resolve. Techniques to minimize memory impairment with ECT include exclusive use of square wave, direct current, brief pulse waveform stimulus; use of unilateral nondominant electrode placement; frequency of treatment no greater than twice weekly during a course of ECT; and the use of ultra-brief pulse (0.3 msec) stimulus.

In 2005, VNS was approved for the long-term treatment of chronic or recurrent depression in adults who have not had an adequate response to four or more adequate antidepressant trials. However, the pivotal trial upon which the approval was based showed only a 15% response rate in the active group at 12 weeks, not statistically significant when compared to 10% response rate in a control group receiving sham VNS. The rate of improvement was substantially higher after 6 to 12 months of treatment, implying that when VNS is utilized for treatment-refractory depression the patient and psychiatrist should be slow to decide whether treatment was efficacious. Further, VNS appears more suitable for truly chronic rather than relapsing-remitting depression.

For depression, rTMS is localized over the left dorsolateral prefrontal cortex.

Potential adverse events associated with rTMS include seizures, induction of mania, local pain, headache, visual changes, dental pain, facial numbness or twitching, and temporary or permanent hearing loss due to barotrauma from the very loud noise produced by the device. Neurocardiogenic syncope can occur in children and adolescents. The most concerning risk of rTMS is the rare possibility of seizures, which can be minimized by adherence to the safe stimulation criteria.

DBS is currently approved for Parkinson's disease, essential tremor, dystonia, and OCD. Dystonia and OCD are approved by the FDA as a Humanitarian Device Exemption, which allows for a maximum annual number of patients treated of 4,000.

Patients receiving DBS for movement disorders can develop new or worsened neuropsychiatric symptoms shortly after stimulation parameters have been adjusted. In this situation re-adjustment of stimulation parameters usually should precede new or altered pharmacologic treatment. When optimal treatment of motor symptoms entails an increase in neuropsychiatric symptoms, the distress and functional

impairment from the movement disorder should be weighed against the distress and functional impairment from the neuropsychiatric symptoms, much as is done when adjusting dosage of levodopa in advanced Parkinson's disease with neuropsychiatric comorbidity.

ACUTE PAIN MANAGEMENT AND PSYCHOPHARMACOLOGY IN THE MEDICALLY ILL

Robert J. Boland, Monique V. Yohanan, and Richard J. Goldberg

The greatest evil is physical pain. SAINT AUGUSTINE

INTRODUCTION

Pain is the most common reason a patient presents to a doctor. It is a common symptom in many types of trauma and disease. In a US National Health Survey, it was found that within the 3 months before the survey 29% of adult respondents had experienced lower back pain, 17% had had a severe headache, 15% had experienced neck pain, and 5% had experienced facial or jaw pain (Sondik, Madans, & Gentleman, 2011). The cost of pain in treatment, disability, and lost time at work is immeasurable.

Alleviating pain is one of our most fundamental roles. At times, this can be complex and frustrating. Often, however, through understanding some fundamental principles of pain management, even the inexperienced clinician gives some relief to the suffering patient.

Pain serves an important signaling function in the organism and often leads to recognition of an underlying disease that can be remedied. However, pain remains hard to describe and quantify. Of more concern is that it is often inadequately treated.

BARRIERS TO ADEQUATE PAIN MANAGEMENT

Historically, the undertreatment of pain has been an all too frequent reality. Well into the modern medical era, there have remained many barriers to adequate pain management. These barriers include cultural attitudes about pain as an inevitable part of the human condition, fear of analgesic misuse, fear of disciplinary action against those who prescribe such analgesics, and inadequate medical training in pain management. Some patient groups have been found to be at higher risk for inadequate pain control, including members of minority ethnicities, women, children, older patients, people with cognitive impairments, and those with a psychiatric diagnosis (Moskovitz et al., 2011; Groenewald, Rabbitts, Schroeder, & Harrison, 2012).

Although these problems have continued into the present, there has been a gradual shift in attitudes about a patient's right to adequate treatment. Although fear of legal

prosecution sometimes is cited by physicians as a rationale for not providing prescriptions for opioid medications, it generally is accepted that appropriate pain management is an obligation of the doctor–patient relationship (Hall & Boswell, 2009). This obligation may be gaining some ground socially, ethically, and even legally as a fundamental human right (Brennan, Carr, & Cousins, 2007).

ASSESSMENT OF PAIN

One of the most common reasons for inadequate pain management is a discrepancy between the patient and physician assessment. Adequate assessment of pain usually follows the same basic principles as assessment of other medical problems. A history is taken in an attempt to classify the type and cause of pain. While this categorization has an important role in pain assessment, for most patients pain is not an isolated problem but an experience that may be affected by and impact medical, psychiatric, social, and spiritual concerns. Optimal pain management begins with an assessment that considers all these domains.

Usually we attempt to differentiate whether pain is acute or chronic. Acute pain is not only brief, it is also usually associated with clear injury or disease. Acute pain has biological purpose; it alerts the patient to injury or disease. It is commonly associated with activation of the sympathetic nervous system manifest as tachycardia, tachypnea, and diaphoresis, and, as such, elicits an empathetic response and tends to be easier for healthcare providers to recognize. Acute pain levels may change dramatically over a short period. An example of acute pain is postsurgical pain, in which the pain is reasonably well correlated to the degree of injury. While chronic pain may begin with an acute insult, it persists beyond a temporal association with the factors that initiated it and long past the point of any biological purpose.

In addition to determining the time course of the pain, it is also common in assessment to distinguish between nociceptive and neuropathic pain. Nociceptive pain occurs when the nerves appropriately sense and respond to tissue damage. It is worse with stress or pressure and tends to respond to

treatment with opioids and antiinflammatory agents. Patients may use words such as sharp, dull, aching, or throbbing when asked to describe this type pain. While radiation may be present, it is less common, and when it is noted it often does not follow a distinct nerve distribution.

Neuropathic pain reflects an abnormal functioning of the central or peripheral nervous system, which may be triggered by a direct nerve injury or systemic illness. Severe pain may occur with trivial stimuli, such as a light touch or a breeze on a patient's skin. Opiates are less helpful in alleviating neuropathic pain, and when they are used they tend to require higher doses to provide adequate analgesia. Patients may describe the pain as electric or burning. Radiation is common and tends to follow a typical nerve distribution.

The experience of pain in a particular patient may not always fit neatly into these categories. Patients may have acute surgical pain but a complicated postoperative course that ultimately leads to a chronic pain syndrome. Despite the limitations of the acute/chronic, nociceptive/neuropathic framework, it may be a useful starting point in developing a management approach.

In addition to categorizing pain in terms of its time course and mechanism, a common next step is to rate pain intensity. Since many patients will have more than one area of pain at any given time, rating pain is usually preceded by a determination of the total number of pain problems (and where they are located), and then describing and rating each. Various instruments are available to assess pain, including visual analog and numeric scales. Despite the limitations of numeric scales, they are commonly used and practical for bedside assessment. They are easily administered, require no special forms, and can be used to track changes over time (Hawker, Mian, Kendzerska, & French, 2011). Typically, the person administering the scale asks the patient to rate his/her pain intensity from 1 to 10, 1 being no pain and 10 being the worst pain imaginable. In addition to asking the patient to provide a number to rate his/her current pain level, it also can be helpful to ask, "What number would you like it to be?" Once this assessment has been performed, a common starting dose for patients who are opiate-naïve would be 5–10 mg of oral morphine equivalent every 4 hours. The lower dose range should be considered for patients who are older and who have renal or hepatic insufficiency, which may affect drug metabolism and effective half-life.

In addition to assessing the experience of pain itself, a thorough evaluation also should include an investigation for the presence of other associated non-pain symptoms that may be present. These include but are not limited to physical symptoms, such as dyspnea and nausea, and also an evaluation for psychiatric comorbidities or complications. Determining the degree to which a patient is suffering is essential. Suffering has been described as "a state of severe distress associated with events that threaten the intactness of the person" (Cassel, 1982). While suffering may be difficult to quantify, it has a significant impact on quality of life. If it is not addressed, it is unlikely that even the most thoughtfully chosen pain regimen will provide adequate palliation.

PAIN FROM A PSYCHIATRIC PERSPECTIVE

The various editions of the American Psychiatric Association's *Diagnostic and Statistical Manual* contain diagnoses related to pain; however, these all apply to chronic pain and continue to wrestle with the problem of whether pain can be subdivided into subtypes that are "primarily psychological" and "primarily medical." In the fifth edition of the manual, the work group responsible for this disorder recommended that these distinctions be dropped and the category of *Pain Disorder* be subsumed into a new, more general somatoform disorder (currently referred to as *Somatic Symptom Disorder*). Many individuals currently diagnosed with Pain Disorder would fit into this category, whereas for others, psychological factors affecting other medical conditions or an adjustment disorder would be more appropriate.

In clinical practice, the majority of pain patients—particularly acute pain patients—will not have a somatoform disorder. However, even short-term pain symptoms can predispose a patient to other psychiatric disorders, particularly depressive and anxiety disorders. In addition, even in the absence of a formal psychiatric disorder it should be remembered that all pain is, in part, a psychological phenomenon (Lavand'homme, 2011). The Institute of Medicine underscored this point in its description of the nature of pain: "The experience of pain is more than a simple sensory process. It is a complex perception that involves higher levels of the central nervous system, emotional status, and higher order mental processes" (Osterweis, 1988).

PHARMACOLOGIC TREATMENT FOR PAIN

While nonpharmacologic approaches may have an important role in acute pain management (and are addressed later in this chapter), most patients treated for acute pain will be medicated. The choice of analgesic therapy is based on the type and severity of pain, individual patient concerns and preferences, and knowledge of the clinical pharmacology of the drug prescribed, including its half-life and common drug–drug interactions. Attention to all these factors increases the likelihood of providing successful analgesia at any stage of treatment.

There are some instances of acute pain when correcting the underlying problem will immediately resolve severe pain symptoms. For example, while a patient with an acute hip dislocation may present with excruciating pain that warrants opiate medication prior to definitive therapy, when reduction is performed it may lead to immediate resolution of pain. This speaks to the idea of pattern matching. Appropriate pharmacological treatment of pain provides medication that addresses both the severity and likely time course of the pain condition.

Medication choice also will depend on patient-specific factors. If the patient has a previous history of using pain medication, the response to specific agents may be useful in guiding current therapy. The presence of renal and/or hepatic impairment will impact the choice of agent. If a patient has more than one symptom—for example, back pain and debilitating cough—a regimen that includes an opioid could reasonably be expected to palliate both symptoms.

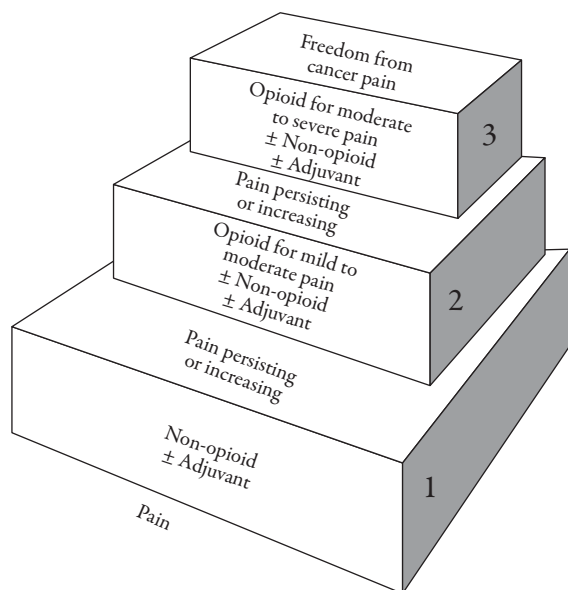

Figure 25.1. WHO Pain Ladder The World Health Organization (WHO) analgesic ladder for the management of cancer pain (reproduced with permission from WHO).

Although regimens should be individualized, general guiding principles are available. The World Health Organization (WHO) ladder (Ventafridda, Saita, Ripamonti, & De Conno, 1985) provides a step-wise approach for the treatment of cancer pain, which also may provide guidance for the management of noncancer pain (Figure 25.1). Step 1 addresses the management of mild to moderate pain and advises the use of non-opioid agents (e.g., nonsteroidal antiinflammatory drugs or paracetamol). Adjuvant agents may be used at any of the steps and include (but are not limited to) antidepressants, anticonvulsants, steroids, muscle relaxants, and behavioral therapy. When pain persists or increases, Step 2 suggests continuing the non-opioid drug and adding a low potency opioid (e.g., codeine). For pain that persists or increases despite this regimen, Step 3 recommends more potent opioids (e.g., morphine) as first-line therapy.

Minimizing polypharmacy is a preferred treatment strategy. This is in part because single agents may be more carefully titrated and have more predictable side effect profiles. In addition, the benefits of adding adjuvant medications, such as antidepressants, should be weighed against the potential for drug–drug interactions. The use of codeine illustrates this concern. The analgesic effect of codeine is dependent on conversion to an active metabolite by the CYP 450 2D6 substrate (Eissing, Lippert, & Willmann, 2012). Approximately 7% of the population lacks the 2D6 enzyme and are not benefited by this medication. The enzyme can also be blocked by many commonly prescribed medications, such as selective serotonin reuptake inhibitors (SSRIs) (Sindrup & Brosen, 1995) like paroxetine and fluoxetine that significantly inhibit the 2D6 enzyme.

EFFECTIVE USE OF OPIOIDS IN ACUTE PAIN

For patients with severe, acute pain, morphine represents the standard opioid against which all others are usually compared.

Unlike some other agents, including the NSAIDs, acetaminophen and the mixed agonist-antagonist analgesics, morphine has no ceiling effect.

Short-acting and long-acting opioid formulations are available, and each class has particular benefits and limitations in the treatment of acute pain. Short-acting opioid formulations with a quick onset of action may be of particular benefit in achieving immediate analgesia, and doses may be easily adjusted to address fluctuating pain levels. Opioids with longer half-lives, such as sustained-release morphine and methadone, may have a role for the patient whose acute pain has been stabilized on short-acting opioids and is likely to remain severe and continuous for several days or longer. The slow-release mechanism may result in fewer peak-and-trough fluctuations and therefore may cause fewer side effects such as nausea and vomiting (Walsh, 1984). Their delayed onset of action and lack of ability to be precisely titrated should be considered if they are used in treating a patient with acute pain.

DOSE AND FREQUENCY

The most common cause of inadequate acute pain management is the underuse of opioid analgesics. In fact, many doctors prescribe less than half the effective analgesic dose for their patients with pain (Marks et al., 2009). In addition to doses that are inadequate, opioids often are prescribed at time intervals that extend beyond the effective half-life of the drug. The use of suboptimal doses and excessive time between dose intervals may result from physician orders, nursing administration, or patient bias. Some patients attempt to endure pain and earn the respect of the nurses and doctors as “good” patients. When patients start to complain of severe pain before their next dose is “due,” they often are thought of as “addicted” or excessively preoccupied with medication. In fact, such patients may only be expressing the fact that their pain has reemerged because their dose time has gone beyond the effective duration of the opioid. Table 25.1 lists usual dose ranges for commonly prescribed opioids and their average duration of action.

The consultant dealing with a pain patient who continues to complain despite “usually adequate treatment” should first look at the dose and frequency of analgesic delivered. Ask patients what level of relief they get within the first hour after their dose. If relief during that time is inadequate, the dose is too low. If pain relief is complete but reemerges before the next dose, the duration between doses is too long. It is essential to look directly at the drug administration record, not at orders or progress notes, to confirm what has actually been given to the patient and on what schedule. Opioids should be given on a schedule corresponding to their analgesic half-life (see Table 25.1).

Pain symptom palliation always should take into account the balance between opioid analgesic benefit and the suffering that common opioid side effects may cause. Many symptoms, such as nausea, constipation, respiratory suppression, and delirium, may be avoided or minimized, and strategies are discussed later in this chapter.

Table 25.1 OPIOIDS AND RELATED COMPOUNDS TYPICALLY USED FOR ANALGESIA

DRUG	USUAL PO DOSE (MG)	USUAL PARENTERAL DOSE (MG)	DOSING INTERVAL (HRS)	APPROXIMATE ORAL EQUIVALENT TO 30 MG ORAL MORPHINE (MG)	APPROXIMATE IV EQUIVALENT TO 10 MG IV MORPHINE (MG)	COMMENTS
<i>Morphine and Related Compounds</i>						
Morphine <i>Sustained release</i>	30 90–120	3–6 –	3–4 8–12	– 60	–	
Hydromorphone	6	1.5	3–4	3–4	1.3–2	
Oxymorphone	10–20	3–5	4–6	0.5–1	1	
<i>Codeine and related compounds</i>						
Codeine	60	3–5	3–4	180–300	100	Little benefit in doses beyond 60 mg, as higher doses may lead to agitation and dysphoria
Dihydrocodeine	16–32	–	3–4	120–150		Only available in combination with aspirin and caffeine
Hydrocodone	5	–	3–4	60		Only available in combination with acetaminophen, aspirin or ibuprofen
Oxycodone <i>Extended release</i>	5–30 10–60	–	3–4 12	12–15	10	Also available in combination with acetaminophen or aspirin. Extended release dose varies depending on tolerance.
<i>Synthetic Opioids and Related Compounds</i>						
Meperidine	Not recommended	100	3–4	250	80	Not recommended. Can be psychotoxic.
Fentanyl transdermal	(transdermal: 25 ug/h)		72	0.2		Immediate release available but primarily used for anesthesia
Methadone	20	4–6	8–12	2–10	2–10	Long half-life.
Levorphanol	4	2	6–8	4–8	2	
Tramadol	50		3–4	300		Is a mu receptor agonist, however is not an opioid.

FIXED VERSUS AS-NEEDED DOSE SCHEDULES

When acute pain has been diagnosed, physicians must consider whether analgesics should be prescribed on an as-needed or fixed-dose schedule. Severe, continuous pain is better treated on a fixed schedule. A routine schedule not only increases the likelihood of effective analgesia, but also will tend to minimize some of the common adverse effects associated with shifting blood levels, including nausea and respiratory depression (Lo Presti, Roscetti, Muriess, & Mammucari, 2010).

A schedule based on the half-life of the opioid prevents reemergence of pain before the next dose, but even well-intentioned efforts to provide as-needed medication based on half-life may provide insufficient analgesia, as drug metabolism and duration of benefit may vary among individual patients. The dose required to treat reemergent pain resulting from an as-needed or PRN (Latin: *pro re nata* literally, “from the thing born”; figuratively, “as the need arises”) schedule often is larger than would be required to prevent it using a fixed schedule. Giving patients medications on a PRN basis places them in a dependent position. The requirement that they must ask staff for each dose of pain medication can be humiliating for the patient and can be negatively interpreted by care providers as an excessive preoccupation with receiving medication. In patients who do have a propensity for drug seeking, this type of regimen may reinforce this negative behavior. Patients who have cognitive impairments or fluctuating levels of alertness may have difficulty being able to ask for medication.

Another challenge to the PRN approach is in the management of nighttime pain. Lack of sleep creates a vicious cycle of increased pain, which causes more lack of sleep, and diminished sleep efficiency tends to lower the pain threshold. Strategies to address this problem include administering opioids before bedtime in patients whose sleep is being interrupted by pain or who awaken in the morning with excessive reemergent pain. Alternatively, the use of long-acting medications may be associated with improved sleep, although these formulations should be used with caution in older patients and those with renal insufficiency. Conversely, if a patient is sleeping well and is not awakening with increased perception of pain and its consequent anxiety, there is no need to schedule analgesic doses during the patient's sleep time.

An alternative opioid scheduling method is known as “reverse PRN.” This method involves offering the medication to the patient on a scheduled basis, allowing the patient to accept, refuse, or delay the dose. This reverse PRN method ensures that the medication is made available and offered, but also helps the patient maintain some autonomy and control over titrating the dose.

Although standing dose regimens may be more appropriate for persistent, acute pain, there are circumstances in which PRN regimens are preferred. Patients with hepatic or renal impairment may not be optimal candidates for fixed dosing. There also are circumstances where pain is not continuous and can be predicted. If a patient is undergoing debridement of a

decubitus ulcer, it is reasonable to provide short-acting premedication in anticipation of this event. When a fixed-dose pain regimen is ordered, it is common practice to write an accompanying order for PRN medication to provide breakthrough pain coverage. Generally, the appropriate PRN dose should be related to the total daily morphine equivalent of the standing dose medication. Frequent reassessments of the amount of PRN medication being accessed may be useful in guiding dose adjustments and optimizing pain management.

CHOICE OF ROUTE OF ADMINISTRATION

There are multiple routes available for opiate administration that may be appropriate in providing acute pain management. These vary in terms of onset, intensity, and duration of analgesic effect; ease of dispensing; availability; and cost. Conversion between forms is discussed later in this chapter.

ORAL

Oral analgesic administration offers simplicity and economy, avoids the discomforts and potential complications of repeated injections, makes the patient less dependent on others for care, and may obviate the need for hospitalization in some cases. Dosage forms include tablets, capsules, and liquids. Pure opiate and combination (opiate/NSAID or paracetamol) forms are available. Oral medications are available in short-acting, immediate-release, and long-acting release formulations. As discussed earlier in this chapter, short-acting opioid formulations with a quick onset of action are more likely to give immediate analgesia and are more easily adjusted than longer acting medications. Opioids with longer-half lives and extended release medications may have a role in acute pain after stabilization has been achieved with short-acting medications, if the pain is likely to remain severe and continuous for several days or longer.

Oral analgesics often are used in patients with dysphagia and/or feeding tubes. In these circumstances, the medications are crushed and mixed with food or liquid to allow for easier swallowing or feeding tube administration. Many long-acting pain formulations (e.g., morphine sulfate controlled release, oxycodone controlled release), should not be crushed, as this results in a bolus dose of the medication. Morphine sulfate extended release capsules, as well as liquid formulations of morphine and methadone, are available and may be used in these circumstances.

SUBLINGUAL

Sublingual administration may be a useful route when swallowing is impaired. Sublingual opioids are directly absorbed into the systemic circulation. The high opioid concentration of commonly available formulations (e.g., morphine sulfate concentrate), allows for immediate analgesia in patients with limited or absent ability to swallow even small amounts of liquid medication.

RECTAL

Substances absorbed by the rectal route provide another option when a patient cannot tolerate oral medication. Suppository forms of many opioids are commercially available. Alternately, many oral tablet formulations can be administered rectally when coated with glycerin gel.

INTRAVENOUS

Intravenous (IV) opioid administration remains the most rapid and effective means of delivering opioids to the systemic circulation (Miner, Moore, Gray, Skinner, & Biros, 2008). Most commonly, an IV dose is given at regular intervals. Proper use of this method requires understanding the pharmacokinetics of a drug to ensure that the blood level does not go below the minimum effective concentration. This can be particularly difficult when the drug is given on an “as needed” basis.

Continuous IV administration can be a very efficient way to provide pain relief for patients whose pain management requirements are anticipated to last for several days or weeks. To provide continuously effective pain relief, the blood level of the drug must always be kept above the minimally effective concentration. Since this can be particularly difficult at the beginning of continuous therapy, as a drug requires four to five half-lives to achieve steady-state concentration, a loading dose is recommended before starting continuous infusion.

PATIENT-CONTROLLED ANALGESIA

Patient-controlled analgesia (PCA) may be administered through the IV or subcutaneous routes. It has gained widespread use in several areas of acute pain management. Computerized programmable pumps allow bolus doses of opioid to be administered by the patient. This may be coupled with a background basal infusion of opioid. Bolus dose limits, “lock-out” intervals, and a maximum total hourly dose all are programmable by medical staff (Karci et al., 2003). Patients who are confused are not good candidates for this method of drug administration. In addition, patients with a drug addiction history may be unable to self-limit their utilization. Despite these limitations, for many patients PCA is a reasonable option that provides immediate pain relief while optimizing autonomy.

SUBCUTANEOUS

We know surprisingly little about the pharmacokinetics of subcutaneous (SC) opioids. For morphine, the blood levels achieved with SC administration are probably comparable to IV administration. Due to local irritant effects, the dose of opiate that may be administered via the SC route tends to be smaller than what is possible through the IV and intramuscular routes. Other limitations to subcutaneous administration include more difficult administration and erratic absorption in patients with severe cachexia.

INTRAMUSCULAR

Intramuscular (IM) administration of opioids, although a popular route, has significant limitations. Opioids given through this route are less predictably absorbed. IM injections are painful, and patients can alternate between toxicity and undertreatment. This method of administration should generally be reserved for unusual cases in which no other method of administration is feasible.

SPINAL ADMINISTRATION

Opioid analgesics may also be given through the spinal route, for example, epidurally (Marret, Remy, Bonnet, & Postoperative Pain Forum Group, 2007). Preoperative and perioperative use of epidural analgesia can significantly reduce the need for postoperative analgesia. Its use should be reserved for patients who have failed good trials of opioid medication by other routes.

TRANSDERMAL

The first transdermal opioid was the fentanyl citrate patch. The route of administration is often preferred by patients, and some side effects (such as nausea and constipation) may be less commonly seen than with oral opioids (Tassinari et al., 2009). Limitations include expense and erratic absorption in patients with severe cachexia.

SPECIFIC OPIOID MEDICATIONS

COMBINATION AGENTS

There are multiple available agents that combine a non-opioid drug (typically acetaminophen or NSAIDs) with an opioid agent (e.g., codeine, hydrocodone, or oxycodone; see Gaskell, Derry, Moore, & McQuay, 2009). These combination agents have many attractive features. They are inexpensive, readily obtainable, and maximize patient autonomy. There are, however, some limitations to their use. Acetaminophen combinations are limited by the drug's toxic effects. NSAID-containing combinations also carry with them the potential for gastrointestinal irritation and hemorrhage. The side effects of NSAIDs and acetaminophen are discussed in further detail later in this chapter.

CODEINE

Codeine is a pro-drug converted to its active metabolite, morphine, by the CYP450 2D6. It is an opioid agonist that produces analgesia, sedation, and antitussive effects. It is usually dispensed in an oral form (tablet or liquid) and is often compounded with other agents (e.g., acetaminophen, guaifenesin) depending on the desired effect. Its half-life generally ranges from 2–4 hours, and dosing may need to be adjusted in the presence of renal impairment. As noted above, approximately 7% of the general population lacks the enzyme necessary to

convert this medication to its active metabolite (Sindrup & Brosen, 1995), and medications that inhibit the P450 2D6 enzyme can inhibit this conversion. In this circumstance the constipating effects of the medication still are present, but the patient may receive little to no analgesic benefit.

PROPOXYPHENE

Propoxyphene exerted its analgesic effect by binding various opioid receptors. It is metabolized in the liver by the CYP 450 3A4 enzyme, and also acts as an inhibitor of the 3A4 and 2D6. It was available in a tablet form both alone and in a combination form (with napsylate/acetaminophen). While the half-life of propoxyphene is 6–12 hours, the half-life of its active metabolite, norpropoxyphene, is 30–36 hours (Inturrisi et al., 1982). Black box warnings have called attention to numerous reports of overdose when this drug is taken alone or in combination with alcohol or other central nervous system depressants and also have cautioned against concomitant use with other CYP3A4 inhibitors (e.g., protease inhibitors, macrolide antibiotics, azole antifungals), as this may increase propoxyphene levels. There are numerous drug–drug interactions and associated side effects, including potential cardiac toxicity (Barkin, Barkin, & Barkin, 2006). As a result of concerns about increasing the risk of arrhythmias, the US Food and Drug Administration (FDA) announced a safety review in July of 2009, and in November of 2010 recommended against further use of the pain reliever (FDA, 2010), and it has been withdrawn from the US market. The European Medicines Agency decided on a phased withdrawal of propoxyphene from the European market in June of 2009.

MORPHINE

Morphine is metabolized by the liver and gastrointestinal tract by the CYP 450 enzyme. It is available in multiple forms include short-acting and long-acting tablets, liquid, a concentrated solution that may be administered sublingually, suppositories, and formulations that may be administered by the SC, IM, or IV routes. It undergoes significant first-pass metabolism (Wiffen & McQuay, 2007). Monitoring may include a baseline creatinine as well as assessment of respiratory function, particularly with epidural or intrathecal use. Black box warnings also stress concerns regarding abuse potential.

OXYCODONE

Oxycodone undergoes extensive liver metabolism by CYP450 3A4, although there is some 2D6 metabolism as well; an active metabolite is formed. It is available in short-acting and long-acting tablet forms, and a concentrated liquid that may be administered sublingually (Gaskell et al., 2009). Oxycodone seems to have a side-effect, safety, and efficacy profile similar to morphine. It may be a reasonable therapeutic option for patients unable to tolerate other opiates or who have special considerations such as renal insufficiency (Risichitelli & Karbowicz, 2002).

HYDROMORPHONE

Hydromorphone is metabolized by the liver (CYP450) and the upper gastrointestinal tract (1A3, 2B7), and some providers prefer it to morphine in patients with renal insufficiency. It is available in oral tablet, liquid, and suppository forms. It also may be administered via the SC, IM, and IV routes (Quigley, 2002). It is a reasonable choice for patients who need a more potent opioid option than morphine, but this same property also is responsible for its primary limitations. Its black box warning emphasizes its high potential for abuse and respiratory depression.

MEPERIDINE

Meperidine is a phenylpiperidine analgesic with CNS effects similar to those of morphine. Hypertension, excitation, delirium, hyperpyrexia, convulsions, respiratory depression, and death have been reported with meperidine monotherapy in relation to the accumulation of the metabolite normeperidine with a longer half-life and renal excretion, particularly in settings of longer use and renal insufficiency.

Meperidine is particularly contraindicated for concomitant administration with monoamine oxidase inhibitors (MAOIs), which may exacerbate this general cerebrototoxic effect. Although the mechanism of this interaction is not clear, it appears to be a central serotonin effect analogous to a “serotonin syndrome” (Latta, Ginsberg, & Barkin, 2002).

METHADONE

Methadone is metabolized by the liver, primarily via CYP 450 2B6, but also with minor effects by the 2C10, 2D6, and 3A4 enzymes. Chronic administration may lead to the drug inducing its own metabolism. It is available in multiple forms, including tablet and liquid, and may also be administered via the SC, IM, and IV routes. It is excreted in both the feces and urine and has a widely variable half-life ranging from 8–60 hours. It tends to accumulate in the liver and other tissues and is slowly released from these sites. Its black box warning suggests that its use should be limited to practitioners who well understand its pharmacokinetics, and then only in patients for whom the potential analgesic benefits outweigh its significant risks. Its risk of inducing respiratory depression may last longer than its peak analgesic effects (Fainsinger, Schoeller, & Bruera, 1993).

FENTANYL

Fentanyl is available in transdermal and transmucosal (film, lozenge, tablet) formulations and also may be administered via the IM and IV routes. It is metabolized by the liver via the CYP450 3A4 substrate. Its half-life varies depending on formulation; the IM half-life is up to 4 hours, lozenge up to 7 hours, and transdermal up to 17 hours (the transdermal half-life may be prolonged due to continued absorption from drug deposition in the skin). Its most common use is for chronic moderate to severe pain. Transmucosal forms may only be prescribed by oncologists and pain specialists (Fine, Narayana, & Passik, 2010).

Conversions Among Opioids

There are several situations where improper opioid conversion leads to psychiatric consultation. These include (1) increasing or decreasing analgesic requirements (e.g., the need to switch from morphine to hydromorphone due to pain severity or renal insufficiency); (2) the need to change the type of medication provided based on the venue of care (e.g., converting IV medications used in the inpatient setting to oral formulations on discharge); or (3) the need for a different medication based on a change in the patient's medical condition (e.g., new inability to swallow).

When calculating conversions between opioid formulations, or to sort out the total opioid dose in situations where many analgesics have been used, it is helpful to convert all analgesics to a standard reference. This conversion among opioids is facilitated by converting all drugs to oral morphine equivalents (see Table 25.1). From a methodological viewpoint, the information for this table comes primarily from pain relief studies in cancer patients, whose acute pain needs and analgesia metabolism may be different from those of non-cancer patients. In addition, the time-effect curves for studying various doses of analgesia generally result from single-dose experiments. Single-dose studies neglect the kinetic changes that take place following repeated dosing, especially with opioids such as methadone that have long half-lives. Finally, the conversion information presented in Table 25.1 does not acknowledge the probable differences in pain relief associated with age, sex, race, or quality of pain (Kaiko, Wallenstein, Rogers, & Houde, 1982).

A commonly used strategy is to calculate the 24-hour equivalent of the old drug (including both the amount of fixed-dose and PRN opiate being dispensed) and then use this calculation to determine the 24-hour equivalent of new drug (or new route of administration). Then the dosing interval of the new drug (based on its half-life) is divided into this 24-hour period to determine the appropriate dose. It is important to keep in mind cross-tolerance when converting a patient from one opioid regimen to another. For some patients, tolerance to one formulation may result in a decreased response to a new, structurally similar formulation. However, for other patients cross-tolerance is incomplete or paradoxical, and it is possible that a 1:1 conversion based on the daily morphine equivalent will deliver too high an effective dose. Predicting what an individual patient's response will be is, at best, an imprecise endeavor. One way to address this concern is to begin with a standing dose that is less than the calculated 24-hour morphine equivalent, and also provide PRN coverage. The dosage of the new opioid may then be titrated up or down based on the patient's response to the standing dose, as well as on PRN usage.

DEVELOPMENT OF TOLERANCE

In addition to complicating opioid conversion, the development of tolerance has other implications in acute pain management. Tolerance must be differentiated from loss of pain

control due to new or advancing disease, inadequate dose, or inadequate duration. The tolerant patient is the one who notices a shortened duration of analgesic effect and an eventual decrease in pain relief. The rate of development of tolerance varies, but any patient who is exposed to continuous doses of opioids may develop tolerance; this may occur in as few as 5–7 days. It is often necessary to increase the dose in order to obtain the same pain relief, and even substantial tolerance can usually be surmounted and adequate analgesia restored by giving a higher dose. Unfortunately, staff may become anxious about continuing opioids for a long period and attempt to decrease the dose just at the time when the patient has developed tolerance and an increase in analgesic medication is called for. The consultant must explain this phenomenon and should anticipate some resistance to the recommendation to increase opioids for a “problem” patient just at the time when the staff expected a solution that included tapering opioids.

Tolerance also may be considered in relation to adverse dose-limiting effects of opioids, including respiratory and CNS depressant effects. While side effects will be discussed at greater length later in this chapter, in general they most commonly have a temporal relationship to shifts in serum opiate levels and tend to resolve once a steady state level is reached. Tolerance to the constipating effects of opioids is a notable exception to this general rule; constipation may persist even when opiate levels are at steady state.

FEAR OF THE ADDICTED PATIENT

A major concern among physicians and other healthcare workers is the fear of creating an addicted patient. There have been only a few studies examining this question, and most of the existing studies examine the use of long-term opioids for chronic pain. The studies are difficult to compare given their different definitions and methodologies, and the reported risks vary widely, ranging from 0% to 7.7% in cancer patients and 0% to as high as 50% in patients with chronic nonmalignant pain; the most rigorous of the studies for nonmalignant pain reported rates around 25% (Hojsted & Sjogren, 2007). In most of these studies, patients with an addiction history were not excluded, and the lengths of treatment were much longer than that seen with acute pain treatment. Taken as a whole, it would appear that iatrogenic addiction is unlikely but not impossible, and patients who are to receive more than a few days of opioid treatment should be evaluated for possible addictive behaviors. Such an evaluation should include an assessment of the patient's initial reaction to opioids; it has been suggested that patients who became addicted to opioid treatment experienced more euphoria when first taking the drug (Bieber et al., 2008).

TREATMENT OF ACUTE PAIN IN OPIOID ADDICTS

In situations involving acute pain treatment in the opioid addict, it is often helpful to keep the management of the addiction separate from the management of the pain. For example,

the patient's underlying opioid addiction can be managed with methadone. Most street addicts can be adequately managed on an oral dose of methadone between 20 and 40 mg/day. With methadone used for maintenance of the underlying addiction, the pain can then be treated as a separate issue, using a different opioid at doses 50% greater than normal.

OPIOID WITHDRAWAL

If opioids are taken on a regular basis, physical dependence develops. It generally occurs in patients taking oral opioids for more than 3 to 4 weeks and, along with tolerance, is a characteristic feature of the opioids. Physical dependence on opioids is best defined as a condition that is associated with withdrawal symptoms after an abrupt discontinuation or significant decrease in dosage. The emergence of withdrawal symptoms occurs more rapidly and more intensely with the use of drugs with shorter half-lives. Withdrawal symptoms are best described as a noradrenergic and cholinergic hyperactivity state and include abdominal pain, diarrhea, muscle aching, yawning, rhinorrhea, and lacrimation. Opioid withdrawal (or abstinence) symptoms may create an acute management problem and occur on a predictable and observable basis. Significant objective symptoms—but not subjective anxiety or drug craving alone—warrant attention with increased opioid coverage.

There are several options available for discontinuing opioids in patients who have become physically dependent on them. One possibility is slow weaning from the specific opioid to minimize the development of withdrawal symptoms. Bedtime doses should be decreased last in order to minimize sleep disruption. For morphine, a 10% to 25% decrease each day is reasonable. The main drawbacks are the need to tolerate some withdrawal symptoms and the extension of drug use over time, especially when the process is initiated on the day the patient is otherwise medically ready to leave the hospital. Clonidine may allow for the rapid withdrawal of opiates.

OPIOID SIDE EFFECTS

PREVENTION AND TREATMENT OF OPIOID-INDUCED RESPIRATORY DEPRESSION

Like many of the side effects of opioids, respiratory depression tends to be associated with fluctuating opiate levels and tends to resolve once levels stabilize. There are important caveats to consider. The risk of respiratory depression may be greater with the concomitant administration of some medications, such as benzodiazepines. In addition, there may be patient-specific factors, such as a history of emphysema, which may limit respiratory reserve. In patients who are older or who have renal or hepatic impairment, the functional half-life may be prolonged. A related concern is the phenomenon of dose stacking. This is most common when a long-acting medication, particularly one with a widely variable half-life, is dosed at an interval shorter than the drug's half-life. This can lead to

an accumulation of opioid and may precipitate acute respiratory depression. Finally, the respiratory depressant effects of opiates may persist beyond their analgesic effects, even in the absence of dose stacking (Dahan et al., 2004).

PREVENTION AND TREATMENT OF OPIOID-INDUCED GASTROINTESTINAL SIDE EFFECTS

Nausea and vomiting are among the most common side effects associated with opiate administration. There are a variety of mechanisms that may be at play, including anticipatory nausea prior to medical treatments (especially in cancer patients), medication-related histamine release (e.g., morphine), and shifts in dopamine levels prior to reaching a stable opiate dose. Premedication and/or treatment of frank nausea and vomiting should include careful assessment as to the most likely contributing factors and the choice of an agent whose pharmacology is appropriate to the situation at hand. In contrast to other opioid side effects, constipation tends to persist even when stable opiate doses are achieved. Constipation can be uncomfortable and disturbing to patients and can lead to severe cramping pain or even functional ileus or obstruction (Brock et al., 2012).

PSYCHOTOXICITY

Psychiatric consultation may be requested when the patient develops some behavioral disturbance and the question is raised whether it represents a reaction to opioids. All opioids have some psychotoxic potential, with more specific problems associated with meperidine, pentazocine, and nalbuphine. Opioids produce analgesia, drowsiness, changes in mood, and mental clouding, although analgesia should occur without loss of consciousness. For a given degree of analgesia, the mental clouding produced by therapeutic doses of morphine is considerably less pronounced and of a different character than that produced by alcohol or barbiturates. Morphine and its related analgesics rarely produce the garrulous, jocular, and emotionally labile behavior seen with alcohol or barbiturate intoxication. As the dose is increased, the subjective effects, including pain relief, become more pronounced. Moreover, in some individuals the euphoric effects become greater (Lawlor, 2002). For many patients these side effects are most pronounced during dose adjustments, which often abate or resolve once steady state levels are achieved.

OPIOID ALLERGIES

Idiosyncratic reactions to morphine and related opioids, such as nausea, vomiting, and dizziness, often are described by patients as an "allergy" to opioids. Actually, true allergic phenomena to opioids are uncommon and usually are manifested by urticaria, skin rashes, and dermatitis. More severe anaphylactoid reactions are rare. When severe pain requires opioids in an opioid-allergic patient, there are several options available. Obviously, a non-opioid analgesic should be considered, recognizing the hematologic and gastric risks associated with

high-dose aspirin and nonsteroidal agents. No research data are available describing the degree of cross-reactivity of allergic responses within the family of opioid opioids. If one needs to use an opioid analgesic, an allergic reaction to one opioid does not necessarily imply an allergy to a chemically related congener. As there are other families of opioid analgesics, an alternative would be to use an opioid from a different family.

Non-Opioid Analgesics and Augmenting Agents

Non-opioid analgesics as potentiators of opioid analgesics, both alone and in combination, have been used for more than two decades. Despite this common practice there have been relatively few controlled studies of their effectiveness. They may have a particular role in situations where it is important for the patient to have a lower opioid dose (or to avoid opioids altogether) because of respiratory suppression, nausea, constipation, sedation, or other side effects.

NSAIDS

Nonsteroidal antiinflammatory drugs (NSAIDs), of which aspirin in the salicylate family is best known (see Table 25.2), control pain via the inhibition of prostaglandin synthetase function and thus prevent the formation of prostaglandin E₂. Most painful conditions are associated with some inflammation, which will at least in part be remediated by NSAIDs. These drugs have a role in treating a variety of painful conditions including arthritic pain, postoperative pain, dysmenorrhea, headaches, and metastatic bone pain. Ketorolac tromethamine is available in IM and oral forms and may be a useful alternative to opioids in postoperative patients for whom opioids are contraindicated. NSAIDs are not associated with the development of dependence, although discontinuation syndromes such as rebound headache may occur (Rapoport et al., 1996).

Table 25.2 ANALGESIC DURATION (WITH ORAL DOSING)

ANALGESIC	DURATION OF ACTION (hr)
Morphine	2.5–7
Meperidine	2–4
Methadone	4–7 (longer with chronic use)
Hydromorphone	4–6
Pentazocine	3–4
Codeine	4–7
Propoxyphene	4–7
Oxycodone	3–5
Tramadol	4–6

NSAIDs include the following drug families with the following representative members: salicylates (aspirin), pyrroles (indomethacin and sulindac), propionic acids (ibuprofen and naproxen), and oxicams (piroxicam). The pyrroles, propionic acids, and oxicams differ from aspirin primarily with respect to their higher analgesic potential and better patient tolerance (see Table 25.2) The non-aspirin salicylates differ primarily in their pharmacokinetics and duration of analgesic action, with their side effects and toxicities being essentially the same. Adverse effects that need to be taken into account and that may influence dosing include diminished platelet function, renal and hepatic insufficiency, and fluid retention (Dieppe, Bartlett, Davey, Doyal, & Ebrahim, 2004). Although CNS side effects including nervousness, anxiety, insomnia, and drowsiness are possible, these are less commonly reported. The gastrointestinal side effects, especially hemorrhage, are of particular concern. Although it is common practice to prescribe proton pump inhibitors in an attempt to limit this risk, the protective effect may be limited in some patients (Stillman & Stillman, 2007).

The risk of gastrointestinal hemorrhage with NSAIDs was one of the factors that drove the development of cyclooxygenase-2 (COX-2) inhibitors. COX2 inhibitors decrease inflammation and pain by selectively inhibition of the cyclooxygenase-2 and reduction of prostaglandin synthesis, and as such it was thought that they would have a decreased risk of peptic ulceration and gastrointestinal hemorrhage as compared with traditional NSAIDs. Although earlier reports did suggest that the drugs had improved side effect profiles, later data suggested that with chronic use the gastrointestinal benefits are not as apparent. In addition, the rates of other NSAID-related side effects, such as renal failure, were no better than with other NSAIDs. Of most concern, however, was the realization that COX-2 inhibitors lack some of the platelet-inhibiting properties of nonspecific NSAIDs and may have an increased risk for heart attack, thrombosis, and stroke (Bunimov & Laneuville, 2008). In 2004, rofecoxib (Vioxx) was voluntarily withdrawn from the market due to an increased risk of cardiovascular and cerebrovascular events. Valdecoxib (Bextra) was withdrawn from the market in 2005. Evidence to date has not suggested the same vascular risks with celecoxib; however, it includes a black box warning regarding the potential of these risks along with its gastrointestinal risks.

ACETAMINOPHEN

Para-aminophenol (acetaminophen) is the most widely used pharmaceutical analgesic and antipyretic agent in the United States and the world. It has similar analgesic potency to the NSAIDs. It is metabolized by the liver via CYP450 1A2 and 2E1 substrates, but its analgesic mechanism of action is not entirely understood. It is commonly used alone for mild pain relief, and in combination with various opiates for moderate pain. It is limited by its toxic effect on the liver, and a maximum dose of 4 grams/day is generally accepted. Its use is cautioned in patients with chronic alcohol use and/or hepatic impairment.

STEROIDS

Steroids are important analgesic adjuncts for acute pain syndromes associated with metastatic bone disease, epidural cord compression, headache due to increased intracranial pressure, and tumor infiltration of brachial and lumbar plexuses or other peripheral nerves. Steroids are thought to provide analgesia via their peripheral antiinflammatory effects and their central effects on neurotransmitters, and may be of particular benefit preceding and during radiation therapy for conditions ranging from epidural cord compression to nerve infiltration. They may also have the additional benefits of producing increased appetite, weight gain, and improved mood. Intra-articular steroid injections are a common treatment for managing degenerative joint disease.

Care must be taken when steroids are administered with NSAIDs because of the increased risk of gastrointestinal side effects (ulcers and gastrointestinal bleeding).

STIMULANTS

Stimulants represent another class of analgesic adjuvant most useful in patients with coexisting sedation, loss of alertness, or depressive symptoms. Dextroamphetamine has been shown to augment morphine analgesia while offsetting its sedative effects, without significantly changing vital signs. Amphetamine coprescribing is not common practice for several reasons—some of which, including suppression of sleep and appetite, may be exaggerated. Keeping these concerns in mind, many prescribers use lower doses of stimulants when treating patients who are older or medically frail, particularly those with coexisting heart disease.

In addition to the amphetamines, caffeine also may have analgesic benefit. Caffeine may act as a sympathomimetic and can potentiate the action of opiates and NSAIDs. It is not clear whether this effect is long-term or short-term (Palmer, Graham, Williams, & Day, 2010).

ANTIDEPRESSANTS

The analgesic effects of tricyclic antidepressants (TCAs) is well known and may represent the most common use of these drugs in the United States. While amitriptyline is the most commonly used antidepressant for pain treatment, other TCAs such as nortriptyline (a metabolite of amitriptyline) and doxepin may have fewer anticholinergic side effects. The analgesic effects of antidepressants possibly are mediated centrally by enhancing the transmission in monoamine pathways, which exert a regulatory effect in the brain. Norepinephrine release and beta receptor affinity varies between TCAs, which may account for some of the differences in analgesic effect among agents in this class (Saarto & Wiffen, 2007).

Although the serotonin transmitter is intimately involved in pain modulation, SSRIs have generally been reported to be less effective as analgesics than the TCAs. There have been some promising studies; however, they are limited and focus on the

treatment of chronic neuropathies. It appears that combined effects on norepinephrine, as well as serotonin, are important for an analgesic effect; hence the increased efficacy of TCAs over SSRIs. With that in mind, investigators have looked at newer dual-acting agents such as the serotonin-norepinephrine reuptake inhibitors (SNRIs), which, theoretically, should have the benefits of the TCAs without the side effect profile. Venlafaxine appears to have an effect on pain similar to that of TCAs; however, there are only limited data to support this (Amr & Yousef, 2010). The SNRI duloxetine has been successfully used for a number of pain disorders, including diabetic peripheral neuropathic pain and fibromyalgia pain (Perahia, Pritchett, Desai, & Raskin, 2006), and is currently approved by the FDA for both conditions. Its effectiveness in more acute forms of pain is not well known.

It should be remembered, however, that anxiety and depression can significantly affect the emotional expression of pain, and both can cause an amplification of existing pain symptoms. In such cases, antidepressant treatment of any class can be dramatically helpful to the patient.

ANTICONVULSANTS

Anticonvulsants are also frequently used for pain; however again, most of the data is for the treatment of painful neuropathies. They may act by suppressing neuronal firing in damaged neurons. The FDA has approved many of these agents for pain management, including carbamazepine for trigeminal neuralgia and gabapentin for postherpetic neuralgia. There is good evidence to support the use of carbamazepine, gabapentin, and pregabalin for pain treatment (although primarily for chronic diabetic neuropathy) and there is preliminary evidence for lamotrigine (Vinik, 2005).

When used for pain, anticonvulsants are generally started slowly and gradually increased in dose to minimize side effects. Common side effects include dizziness, ataxia, drowsiness, blurred vision, and gastrointestinal irritation. Specific organ toxicities can present a problem: carbamazepine can cause bone marrow suppression, sodium valproate can cause liver toxicity, and both drugs require blood monitoring. Valproic acid and topiramate have not shown consistent efficacy for pain treatment, and phenytoin may cause a peripheral neuropathy (Wiffen et al., 2005).

LOCALLY ACTING AGENTS

Locally acting agents, such as lidocaine and 2-chloroprocaine, are used for peripheral neuropathies. These agents are generally used topically (Lin et al., 2008); other routes of administration, including intranasal, have been described. Capsaicin, another locally acting agent, can be applied topically as a cream to painful areas. It is an alkaloid irritant derived from chili peppers, which appears to work by depleting substance P. It has been shown to be useful for a number of syndromes including diabetic neuropathy, osteoarthritis, postherpetic neuralgia, and psoriasis (Zhang & Po, 1994).

NEUROLEPTICS

Although there are occasional analgesic reports of antipsychotics being used as co-analgesics, the primary use of phenothiazines in terminal cancer patients remains antiemetic or anxiolytic in conjunction with morphine (Seidel et al., 2008).

BENZODIAZEPINES

Benzodiazepines do not appear to have a significant role in the treatment of acute pain. They may modify the affective experience of pain and ameliorate some of the affective elements of nonpain symptoms such as nausea. Adjunctive use benzodiazepines with opiates may increase respiratory depressant effects. They may have some utility as muscle relaxants, which can be beneficial in addressing some types of acute musculoskeletal pain such as neck pain (Malanga et al., 2009).

TRAMADOL

Tramadol hydrochloride is a centrally acting analgesic. Tramadol is indicated for moderate to moderately severe pain, in a manner analogous to low-potency opioids. Although marketed as a “non-opioid analgesic” it acts as a weak mu-receptor agonist. It is also a weak norepinephrine and serotonin reuptake inhibitor and may act through this mechanism as well. The most common side effect associated with tramadol is nausea, and while it is generally considered to have fewer respiratory and gastrointestinal effects than traditional opioids, there are multiple adverse effects including lethargy, agitation, respiratory depression, and coma, which are possible with overdose. Patients with a history of seizures and those taking antidepressants, antipsychotics, or MAOIs appear to be at relatively higher risk for seizures with tramadol. Tramadol levels are raised by drugs that inhibit the cytochrome P-450 2D6 isoenzyme, such as paroxetine. Although initially described as “less abusable” than opioids, physical dependence and withdrawal syndromes have been described (Duhmke, Cornblath, & Hollingshead, 2004).

MIXED OPIOID AGONIST-ANTAGONIST DRUGS

The mixed opioid agonist-antagonist drugs have moderate to strong analgesic activity. The group consists of a number of drugs, including pentazocine, buprenorphine, and nalbuphine. All of the members of this group cause respiratory depression and can lead to physical dependence with prolonged use, and to an opioid withdrawal syndrome (Heel, Brogden, Speight, & Avery, 1978); therefore, these drugs should be tapered gradually after chronic use. Overall, the mixed agonist-antagonist group is likely to be used as an analgesic adjunct to anesthesia for relatively short-term pain problems.

CANNABINOIDS

Cannabinoids appear to have some analgesic effect. This effect is probably mediated by non-opioid receptors, which may argue for an adjunctive role in pain management. Some investigators have suggested that the cannabinergic neurotransmitter system serves to modulate pain sensitivity. Whether other cannabinoids such as dronabinol (an oral synthetic cannabinoid) offer similar benefits with fewer ill effects is a matter worthy of investigation. Dronabinol has the obvious advantage of being legally available throughout the United States; it is used for nausea and as an appetite stimulant. There is limited available evidence in the medical literature regarding whether it is effective as an analgesic (Kraft et al., 2008).

ALTERNATIVE AND COMPLEMENTARY TREATMENTS

A number of alternative treatments, such as Therapeutic Touch, Reiki Healing, herbal remedies, dietary changes, or nutritional supplements have all been used for the treatment of pain, and, anecdotally, many individuals have attested to the relief provided by one or another approaches. However, the few studies that have rigorously investigated these treatments have largely been either negative or too flawed to be convincing.

An exception to this may be acupuncture. Most studies investigating acupuncture also suffer from methodological difficulties; however, there is some convincing evidence for the efficacy of acupuncture in the treatment of dental pain, and preliminary data for lower back pain, headache, and fibromyalgia (Sierpina & Frenkel, 2005).

USE OF PLACEBOS

Placebo (Latin: “I shall please”) is a term that evokes emotion in both healthcare givers and recipients. A placebo is an inert substance, given in any form, and without inherent pharmacologic property, which may have a desired effect on a given disorder by virtue of the environment in which it is taken, the psychological state of the recipient, and the specific neurophysiological processes of the recipient. Unfortunately, there remains significant misunderstanding within the medical community regarding placebos and their purpose (Goldberg, Leigh, & Quinlan, 1979). Up to 30%–40% of patients are placebo responders, which may explain why occasionally clinicians will administer placebo pills or injections when they are skeptical of a patient’s report of pain. Attempting to deceive a patient is unethical, and a positive response to placebo does not prove that the pain was merely “in the patient’s head.” It is more likely that the pain is a very real phenomenon, probably mediated by the release of endogenous substances such as endorphins.

When placebo use is encountered or contemplated, the physician should ask, “What is happening in this treatment system?” Typical answers include the following: inadequate

opioid medication is being used; the personality style of the patient has promoted the staff to become unduly suspicious; and/or the patient and staff are caught in ongoing interpersonal conflict. The only appropriate clinical role for placebos is in research protocols conducted with proper informed consent.

BEHAVIORAL TREATMENTS

Behavioral treatments are primarily used for chronic pain, with an emphasis on helping patients cope with the pain and minimize functional impairment. However, some behavioral strategies can be useful in the acute pain setting as well. Psychoeducation is crucial: patients should be instructed in the proper use of pain medication, particularly the importance of attempting to request pain medication (or use their PCA) at the emergence of pain and not wait until the pain has become unbearable. Similarly, patients should be reassured about their fears of becoming an addict should they use opioids.

Other behavioral techniques may be useful as well. Hypnosis has been shown useful in altering patient's perceptions; in a typical treatment a patient will receive the suggestion that his or her pain is another sensation, such as a sense of warmth. One advantage of hypnosis is that, with practice, patients can learn to hypnotize themselves. Relaxation training can be useful for a variety of pain conditions, particularly those in which tension plays a role, such as tension headaches. Biofeedback can reduce muscle contractions, which can also aid tension headaches. Cognitive therapy has been very useful in treating pain behavior and the conscious thoughts that influence such behavior; however, this is mainly used for chronic pain management.

CLINICAL PEARLS

- In addition to asking the patient to provide a number to rate his/her current pain level, it also can be helpful to ask, "What number would you like it to be?"
- In addition to assessing the experience of pain itself, a thorough evaluation also should include an investigation for the presence of other associated nonpain symptoms that may be present.
- If suffering is not addressed, it is unlikely that even the most thoughtfully chosen pain regimen will provide adequate palliation.
- Minimizing polypharmacy is a preferred treatment strategy.
- Opioids often are prescribed at time intervals that extend beyond the effective half-life of the drug.
- A routine schedule not only increases the likelihood of effective analgesia, but also will tend to minimize some of the common adverse effects associated with shifting blood levels, including nausea and respiratory depression (Lo Presti et al., 2010).

- The dose required to treat reemergent pain resulting from an as-needed or PRN schedule often is larger than would be required to prevent it using a fixed schedule.
- An alternative opioid scheduling method, "reverse PRN," involves offering the medication to the patient on a scheduled basis and allowing the patient to accept, refuse, or delay the dose.
- Morphine sulfate controlled release tablets and oxycodone controlled release tablets should not be crushed for use in feeding tubes, as this results in a bolus dose of the medication. Morphine sulfate extended-release capsules or liquid formulations of morphine and methadone are alternatives.
- The tolerant patient notices a shortened duration of analgesic effect and an eventual decrease in pain relief. The rate of development of tolerance varies, but any patient who is exposed to continuous doses of opioids may develop tolerance; this may occur in as few as 5–7 days.
- The emergence of withdrawal symptoms occurs more rapidly and more intensely with the use of drugs with shorter half-lives.
- If one needs to use an opioid analgesic, an allergic reaction to one opioid does not necessarily imply an allergy to chemically related congeners.
- Although CNS side effects from NSAIDs are possible, including nervousness, anxiety, insomnia, and drowsiness, these are less commonly reported.

PHARMACOLOGIC AND OTHER SOMATIC TREATMENTS OF NAUSEA AND VOMITING

Danielle N. Ko and Eva H. Chittenden

INTRODUCTION

Nausea and vomiting are common complaints in the general population. In one study 3% of people had nausea once a week, while 2% reported vomiting more than once a month (Talley, Zinsmeister, Schleck, & Melton, 1992). These symptoms are frequent causes of presentation to outpatient clinics (Britt & Fahridin, 2007; Frese, Klauss, Herrmann, & Sandholzer, 2011) as well as highly prevalent in the inpatient population. In patients with advanced cancer, nausea and vomiting are estimated to affect between 40%–70% of patients (Borison & Wang, 1953). Nausea is a common side effect of many medications.

Systematic and effective treatment of these often very distressing symptoms requires knowledge of the physiological mechanisms and potential treatments for nausea and vomiting. In some patients mental states significantly contribute to or exacerbate the experience of these symptoms. While the relationship between one's emotional state and gastrointestinal (GI) function has been the subject of medical discussion for centuries, (Van Oudenhoove, Vandenberghe, Demyttenaere, & Tack, 2010), the details of these interactions remain an unresolved question. We hope to elucidate known contributions of the central nervous system to nausea and vomiting.

PATHOPHYSIOLOGY

The pathophysiology of nausea and vomiting involves both central nervous system (CNS) and peripheral mechanisms. The brainstem, specifically the medulla, is an important anatomic area for nausea and vomiting with two separate areas involved, the chemoreceptor trigger zone (CTZ) and the vomiting center (VC).

The CTZ is located in the area postrema in the floor of the fourth ventricle, a site with an ineffective or absent blood-brain barrier. The CTZ, despite its location in the CNS, can sample blood for endogenous or exogenous toxins. Electrolyte imbalances such as hypercalcemia and hyponatremia, liver or kidney failure with their associated endogenous toxins, and exogenous toxins such as medications (including chemotherapy agents) and chemicals found in spoiled food

can all activate the CTZ. The CTZ then sends signals to the vomiting center (VC).

The VC is anatomically more diffuse and includes the nucleus of the tractus solitarius and the reticular formation of the medulla. The VC is stimulated via multiple pathways (described below) and, once activated, controls the physical act of vomiting by coordinating parasympathetic and motor efferent activity (Krakauer, et al., 2005; Mannix, 2005; Quigley, Hasler, & Parkman, 2001).

The relationship of nausea to vomiting is unclear but is hypothesized to be a quantitative one: nausea without vomiting occurs when the VC is not sufficiently stimulated to trigger the vomiting reflex. Vomiting without preceding nausea is less common and even less understood.

EMETOGENIC PATHWAYS

The Vomiting Center (VC), the final common pathway in vomiting, is triggered via four pathways:

1. The chemoreceptor trigger zone (CTZ), which is stimulated by various endogenous and exogenous chemicals in the bloodstream.
2. Afferent neural pathways from the GI tract. These include the vagus nerve, the splanchnic nerves, sympathetic ganglia, and the glossopharyngeal nerves. The vagus nerve is stimulated by mechanoreceptors in the GI tract that sense stretch or distension and by chemoreceptors that sense mucosal irritation or damage, usually through the secretion of serotonin by the GI mucosa. Conditions that cause stretch or distension include diabetic gastroparesis, slowed motility from opioids, bowel obstruction, and constipation. Conditions that cause mucosal irritation include infections such as candidiasis or viral/bacterial gastroenteritis, ulcers due to *H. pylori* infection or nonsteroidal antiinflammatory agents, alcoholic gastritis, and mucositis from chemotherapy. The vagus nerve sends signals directly to the VC.
3. Afferent neural pathways from the viscera and serosa of the thorax and abdomen. Signals originate in mechanoreceptors and chemoreceptors in all of

the viscera and serosa of the head and neck, thorax, abdomen, and pelvis. As in the GI tract, the mechanoreceptors and chemoreceptors of the pharynx, heart, liver, and kidneys, communicate primarily through the vagus nerve. The vagus nerve (and to a lesser extent the splanchnic and sympathetic nerves) send nausea-inducing signals to the VC when organ capsules are stretched (e.g., hepatitis, liver metastases, or pyelonephritis) or when hollow organs, ducts or tubes are stretched (e.g., in cholelithiasis, choledocolithiasis, nephrolithiasis, or ectopic pregnancy.) The vagus nerve also sends nausea-inducing signals when serosal linings—the pleura, peritoneum or pericardium—are stretched.

4. Afferent neural pathways from CNS sites outside the medulla, including the vestibular system, the diencephalon, and the cerebral cortex. The vestibular system is activated by motion in susceptible individuals (i.e., motion sickness) and in conditions such as benign positional vertigo, labyrinthitis, and Meniere’s disease. Rarely, the vestibular system may be sensitized by opioids, which can then cause nausea and vomiting through this pathway. Although the mechanism remains unclear, one hypothesis is that nausea is mediated by the mu receptors on the vestibular epithelium (Porreca & Ossipov, 2009). The vestibular system sends signals to the VC and perhaps also to the CTZ.

Increased intracranial pressure and mass effect from traumatic brain injury, hemorrhage, edema, or CNS infection can cause nausea and vomiting. Migraine headaches are often associated with nausea. The pathways involved are not fully understood.

It has been postulated that the relationship between gastrointestinal function and one’s emotional/psychological state can be partially explained by the fact that CNS control of the gut is primarily located in the limbic system (anatomically comprised of the hypothalamus, amygdala, medial thalamus and anterior cingulate cortex), the same area responsible for one’s emotions (Jones, Dilley, Drossman, & Crowell, 2006). In addition, serotonin is an important neurotransmitter in both the GI tract and CNS system.

The cerebral cortex may provide inhibitory input to the VC, much as it provides inhibitory input to nociceptive neurons in the spinal cord and brainstem, although the mechanisms are poorly understood. The rationale behind this thinking is based on the limited data suggesting that nonpharmacological interventions such as cognitive behavioral therapy and hypnosis decrease chemotherapy-related nausea and vomiting (Lotfi-Jam, Carey, Jefford, Schofield, Charleson, & Aranda, 2008).

Nausea is often accompanied by strong emotional as well as cognitive components (Muth, Stern, Thayer, Koch, 1996). The cerebral regions responsible for processing nausea in humans are not well elucidated, but it has been hypothesized that it is likely to include areas that are responsible for conscious awareness of internal body states, including the insular and dorsal anterior cingulate cortices (Napadow et al., 2013).

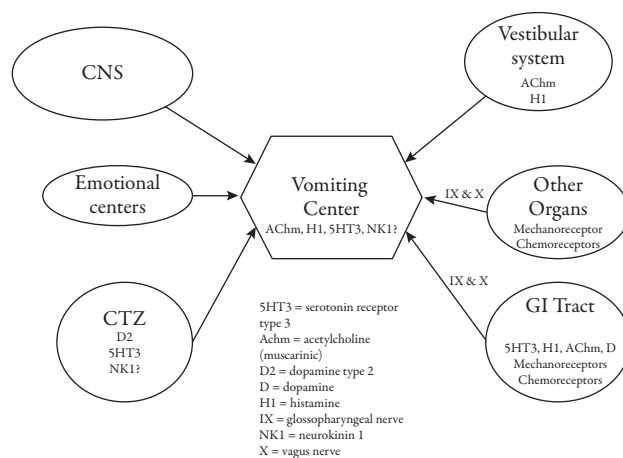

Figure 26.1 Pharmacologically relevant neural pathways and neurotransmitters.

NEUROTRANSMITTERS AND RECEPTORS INVOLVED IN NAUSEA AND VOMITING

Figure 26.1 summarizes the neural pathways and neurotransmitters thought to be important in nausea and vomiting. The most important receptor in the CTZ is the dopamine type 2 (D2) receptor; the primary receptors in the VC are muscarinic cholinergic (AChm) and histamine (H1) receptors. Serotonin type 3 (5HT3) receptors are also present in both sites and serotonin type 2 (5HT2) receptors in the VC. Substance P is found in high concentrations in the CTZ and VC and binds to neurokinin 1 (NK1) receptors; a role for substance P in nausea and vomiting has been postulated. H1 and AChm receptors mediate nausea in the vestibular apparatus.

In the GI tract there are many receptors involved in nausea and vomiting, including serotonin, acetylcholine, histamine, and dopamine. 5HT3 receptors on vagal or glossopharyngeal afferents are stimulated by release of serotonin from enterochromaffin cells in the GI tract. Release of serotonin can occur with mucosal irritation from drugs, radiotherapy, or bacterial endotoxins. Dopamine is also thought to be an important neurotransmitter in the regulation of gastrointestinal function. While there are many subtypes of dopamine receptors throughout the GI tract, the mechanisms through which dopamine acts on the gut remain elusive. Outside the GI tract there are acetylcholine and histamine type 1 receptors on viscera and serosal surfaces (Mannix, 2005; Hernandez et al., 1987; Li, 2009; Krakauer et al., 2005; Mannix, 2005; Naylor & Inall, 1994).

ETIOLOGY

Table 26.1 is a comprehensive list of possible causes of nausea and vomiting. Acute causes usually are infectious, inflammatory or iatrogenic. Chronic nausea and vomiting have a wide differential diagnosis.

Table 26.1 DIFFERENTIAL DIAGNOSES OF NAUSEA AND VOMITING

GASTROINTESTINAL		
<i>General</i>	<i>Obstruction</i>	<i>Functional</i>
Appendicitis Cholecystitis/choolangitis Hepatitis Inflammatory bowel disease Pancreatitis Peritonitis Chronic intestinal pseudo-obstruction Gastroparesis Irritable bowel Peptic ulcer disease Non-ulcer dyspepsia Liver failure	Adhesions Constipation (severe) Esophageal disorders Intussusception Malignancy Pyloric stenosis Strangulated hernia Volvulus	Chronic idiopathic nausea Cyclical vomiting Functional vomiting
<i>Infectious</i>	<i>Metabolic/Endocrine</i>	<i>Medications/Toxins</i>
Acute otitis media (in children) Bacteria (e.g., shigella, salmonella, staphylococcal, cholera) Pneumonia Spontaneous bacterial peritonitis Urinary tract infection/pyelonephritis Viruses (e.g., adenovirus, Norwalk, rotavirus)	Adrenal disorders Diabetic ketoacidosis Electrolyte imbalance e.g., hypercalcemia, hyponatremia Paraneoplastic syndromes Pregnancy	Medications, including Antiarrhythmics including digoxin Antibiotics Anticonvulsants Chemotherapeutics NSAIDS Opiates Radiation therapy

(AGA, 2001; Hall & Driscoll, 2005; Mannix, 2005; Murtagh, 2011; Scorza, Williams, Phillips, & Shaw, 2007; Talley, 2007)

GASTROINTESTINAL CAUSES

Differential diagnosis of nausea and vomiting begins with a full exploration of the patient's history of other gastrointestinal symptoms. Presence or absence of abdominal pain, diarrhea or constipation, passing of flatus, fever, and jaundice should help in differentiating between the general gastrointestinal causes.

The sudden onset of severe abdominal pain radiating to the back associated with nausea and vomiting suggests acute pancreatitis. Conditions such as gastroesophageal reflux disease, irritable bowel syndrome, and peptic ulcer disease all can cause nausea and vomiting, but these rarely are the patient's chief complaint.

Bowel obstructions may present as acute, chronic, or acute on chronic, depending on the underlying cause, and are often associated with severe abdominal pain as well as inability to pass flatus/stool. Feculent vomitus is typical of ileal or colonic obstruction.

INFECTIOUS CAUSES

Infectious causes tend to present acutely and are usually self-limiting. Severe cases can lead to dehydration and electrolyte disturbances that must be corrected.

METABOLIC/ENDOCRINE CAUSES

Pregnancy, with nausea and vomiting occurring in more than 50% of cases, must be considered in any woman of childbearing age. *Hyperemesis gravidarum*, which occurs in less than 1%

of pregnancies, is a severe form of pregnancy-related nausea and vomiting that can cause severe dehydration and electrolyte disturbance. Nausea and vomiting are present in the majority of cases of diabetic ketoacidosis and in Addisonian crisis.

MEDICATIONS/TOXINS

Almost any medication can cause nausea and/or vomiting. Symptoms tend to occur soon after starting a medication. In cases of chemotherapy there can be anticipatory nausea/vomiting. Delayed vomiting after chemotherapy, by definition, will occur at least one day post-chemotherapy. Digoxin toxicity, a medical emergency, often is associated with visual changes, mental status changes, and/or symptoms or signs of cardiac arrhythmia. Ethanol intoxication and withdrawal both are common causes of nausea and vomiting, as are opioid intoxication and withdrawal. Withdrawal of alcohol and opioids are associated with other typical physical and behavioral withdrawal symptoms.

CNS CAUSES

Patients with CNS causes of nausea and vomiting usually present with additional neurological symptoms and signs. Vertigo may be present if the labyrinth is involved. A classic presentation of migraine is one-sided headache, photophobia, nausea, and vomiting. Nausea and vomiting associated with severe gait disturbance points to cerebellar hemorrhage. Nausea and vomiting may also occur in seizure disorders. The rare presence of ictal vomiting usually indicates involvement

of the nondominant insular cortex, but by itself it is not definitive in localizing the hemisphere in which the seizure arises. Nausea and vomiting are also associated with severe pain and with the eye pain of acute glaucoma.

MYOCARDIAL INFARCTION

Nausea is a common presenting symptom of myocardial infarction, occurring in 60%–70% of all infarcts. While nausea and vomiting were previously thought to be more common in inferior myocardial infarctions (Culic, Miric, & Eterovic, 2001), newer data assert that nausea is just as common in anterior MIs (Fuller, Alemu, Harper, & Feldman, 2009). Nausea may be associated with infarct size rather than location (Herlihy, McIvor, Cummings, Siu, & Alikahn, 1987; Quigley et al., 2001).

POSTOPERATIVE NAUSEA

Postoperative nausea and vomiting is estimated to complicate the post-operative period in approximately one third of patients undergoing general anaesthesia (Quinn, Brown, Wallace, & Asbury, 1994). Risk factors include younger age, female sex, use of certain inhalational agents such as nitrous oxide, longer duration of surgery and anaesthesia, and type of surgery (e.g., gynecological and middle ear surgery). Prophylactic treatment with ondansetron has been shown to be only mildly more effective and to cause more side effects when compared to symptomatic treatment. Prophylactic treatment is not considered to be cost efficient (Tramer, Phillips, Reynolds, McQuay, & Moore, 1999; AGA, 2001; Britt & Fahridin, 2007; Hall & Driscoll, 2005; Metz & Hebbard, 2007; Murtagh, 2011).

CHRONIC UNEXPLAINED NAUSEA AND VOMITING DISORDERS

There are patients who have chronic nausea and/or vomiting that remain undiagnosed after extensive diagnostic workup. Previously, patients with unexplained chronic nausea and vomiting were labeled as having “psychogenic” vomiting, namely, vomiting secondary to an emotional disorder (Hill, 1968). In one study 53% of patients met criteria for conversion disorder and 36% met criteria for depression (Muraoka, Mine, Matsumoto, Nakai, & Nakagawa, 1990). In a study that included controls with explained nausea and vomiting (unlike the Muraoka study), there was no difference in rates of psychiatric disease in patients with unexplained versus diagnosed conditions (Olden & Crowell, 2005). While there is clearly an overlap, the relationship between chronic gastrointestinal and psychiatric symptoms remains unclear (Talley, 2007). The pathophysiology of functional disorders is multi-factorial, with biological, psychological, and social factors influencing the presence and severity of disease, as well as presentation for medical care. Three types of functional vomiting disorders have been described as part of the Rome III classification of functional gastroduodenal and

bowel disorder: cyclical vomiting syndrome (CVS), chronic idiopathic nausea (CIN), and functional vomiting (FV) (Tack et al., 2006).

Cyclical vomiting syndrome (CVS), well described in children and more rare in adults, is a disorder in which the patient has stereotypical and severe episodes of nausea and vomiting lasting up to a week that occur three or more times per year. In between episodes, the patient is free of gastrointestinal symptoms. Diffuse abdominal pain is often present. In up to 25% of patients, there is a family or personal history of migraine headaches. A subset of these patients may have accelerated gastric emptying (Pasricha et al., 2011). While it can relieve nausea and vomiting, cannabis can also cause CVS. In such cases, complete cessation of cannabis use can lead to resolution of the cyclical vomiting disorder (Talley, 2007).

Anxiety and depression occur in about 60% of patients with CVS, a subset of which has panic attacks. Tricyclic antidepressants (TCAs), beginning with low-dose amitriptyline, have been used as an effective treatment—a treatment that would be efficacious for migraine as well as anxiety/depression. Clinicians called attention to chronic cannabis or opioid use and undiagnosed more serious psychiatric illness as possible causes of the vomiting syndrome in the 15% of non-responders to TCAs (Hejazi & McCallum, 2011). Use of acute migraine therapies, such as the triptan medications, can be effective during an acute attack. Beta-blockers, and the newer antiepileptic medications, such as levetiracetam, can be effective in preventing or decreasing the severity of vomiting episodes. In women with cyclical vomiting related to menstruation, the oral contraceptive pill can prevent episodes (Talley, 2007).

Chronic idiopathic nausea (CIN) is recurrent and unexplained nausea without vomiting that occurs at least once a week. It must be differentiated from non-ulcer dyspepsia, which usually occurs in relation to meals, and is associated with abdominal discomfort. It must also be differentiated from gastroesophageal reflux disease, which can rarely present as nausea in the absence of heartburn. Although promotility agents such as metoclopramide or antiemetics can be tried, there are no good treatments for chronic idiopathic nausea to date. Long-term use of metoclopramide is not recommended due to the possibility of developing extrapyramidal side effects (Talley, 2007).

Functional vomiting is defined as one or more episodes of vomiting weekly in the absence of an eating disorder, regurgitation, major psychiatric illness, chronic cannabinoid use, or any other organic etiology (Talley, 2007). There are limited treatments for functional vomiting. Tricyclic antidepressants have been anecdotally successful in the absence of depression. Antiemetics are marginally useful (Talley, 2007).

In a six-center study of patients with gastroparesis and more than 12 weeks of symptoms, the 106 (25%) patients with normal gastric emptying and chronic nausea did not differ in gastrointestinal symptoms, demographic characteristics, or depression from those without delayed gastric emptying. Only 12% of these patients were described by the stand alone

criteria of functional vomiting or chronic idiopathic nausea. The majority in both groups qualified for the diagnosis of irritable bowel syndrome or chronic dyspepsia. The physiology remains unclear for these patients who do not differ in symptoms from those with gastroparesis (Pasricha et al., 2011).

PSYCHIATRIC CAUSES

Several psychiatric diagnoses should be considered when investigating unexplained chronic nausea and vomiting. These include not only depression and conversion disorder but also anxiety and panic disorder.

Nausea can be a somatic symptom of depression. In one study examining the relationship between somatic symptoms and depression, 13% of those suffering from major depressive disorder reported at least moderate levels of nausea and vomiting. Nonetheless, nausea was much less prevalent than fatigue, “feeling weak,” headache, and other pain complaints. In fact, nausea was ranked 28th of the 28 somatic symptoms studied (Vaccarino, Sills, Evans, & Kalali, 2008). Morning nausea is seen in melancholia, the form of depression in which symptoms are often worse in the morning.

Patients with panic disorder most commonly present with a constellation of symptoms called the “cardiorespiratory subtype,” in which dyspnea or chest pain are predominant. The next most common symptom cluster, called the “mixed somatic subtype,” includes nausea, sweating, trembling, chills/hot flashes, and dizziness (Meuret et al., 2006). Generalized anxiety disorder can also feature nausea and, less commonly, vomiting. In anorexia nervosa and bulimia nervosa, patients can self-induce vomiting either by taking emetogenic drugs, by gagging themselves, or by gorging on food to the point of distending the stomach sufficiently to trigger vomiting. Some patients with these disorders train themselves to vomit without exogenous stimulation. Other psychiatric diagnoses that the clinician should include in the differential include factitious disorder and malingering, in which patients may self-administer emetogenic drugs like ipecac.

Conditioned or anticipatory nausea and vomiting is seen after multiple treatments of emetic chemotherapy; the patient is triggered by the thought of the chemotherapy, the location of treatment, the smells or sights associated with previous treatment, or the memory of the last food eaten before treatment. Reminders after treatment is over may evoke a similar response. This natural evolution of nausea, as a result of medical treatment, offers evidence of how conditioned nausea and vomiting can evolve in other settings in which the provocation for nausea and vomiting is not as obvious.

ASSESSMENT

The probable cause of nausea and vomiting usually is evident after a thorough history and physical examination, especially in acute cases. When the probable cause is viral gastroenteritis,

laboratory tests are needed only in moderate to severe cases for detecting electrolyte abnormalities and assessing dehydration. When other causes are suspected, imaging studies and laboratory tests are directed to confirm and assess the suspected underlying cause. Nausea and vomiting in immunocompromised or frail elderly patients can be difficult to diagnose from history and examination alone and usually require an extensive diagnostic workup.

HISTORY

Nausea and vomiting are two distinct entities, and therefore each one should be assessed independently. Vomiting should also be distinguished from other symptoms such as retching, regurgitation, and rumination (see Box 26.1). The nature of the vomitus should be elicited. Coffee-ground emesis is indicative of upper GI bleeding, whereas feculent vomiting suggests distal small bowel obstruction. The timeframe of symptoms should be established early as the differential diagnosis for acute (less than one month) and chronic nausea and/or vomiting are very different. Triggers as well as timing in relation to food intake may also provide helpful clues. A systems review must be performed to identify any accompanying symptoms, including neurological symptoms (e.g., vertigo, difficulty walking, and headache) or symptoms suggestive of infection. The patient should also be asked about prescriptions (e.g., digoxin, antibiotics) and any over-the-counter medications/supplements. In acute cases, a history of contact with other ill persons, recent travel, and recent food intake should be elicited. In chronic cases, questions that screen for depression, anxiety, and eating disorders (e.g., self-image, binge eating, and self-induced vomiting) should be used. Symptom diaries can also be kept. Such logs can help patients feel some sense of control and ownership of the problem. They can help healthcare providers by highlighting any patterns to symptoms, as well as helping both patients and clinicians track response to treatments. A number of assessment tools have been developed for nausea and vomiting, especially in the context of chemotherapy related nausea and vomiting,

Box 26.1 DEFINITIONS

- Nausea** is the unpleasant subjective sensation of needing to vomit.
- Vomiting** or emesis is the forceful expulsion of upper gastrointestinal contents through the mouth.
- Retching** involves the same physical act of vomiting but against a closed glottis.
- Regurgitation**, which is the effortless return of contents to the mouth without diaphragmatic contraction, should be distinguished from vomiting.
- Rumination** is the repeated regurgitation of undigested pleasant tasting food from the stomach back up into the mouth. It is likely a learned reflex response, not a conscious action.

which can aid in monitoring the frequency, severity, and duration of symptoms (Wood, Chapman, & Eilers, 2011; Rhodes & McDaniel, 1999).

EXAMINATION

The physical examination should focus on the following:

1. Signs of dehydration including hypotension, orthostatic changes, tachycardia, decreased tissue turgor and dry mucous membranes.
2. Abdominal examination including observing for jaundice (involvement of the liver, bile duct, pancreas), abdominal distention that may indicate obstruction and hernias; palpating for focal or rebound tenderness or guarding, masses, or hepatomegaly; and rectal examination. Auscultation should focus on the presence or absence of bowel sounds (ileus) as well as the quality and frequency of bowel sounds (increased, high-pitched bowel sounds suggest obstruction). Presence of a succussion splash indicates gastric outlet obstruction.
3. Neurological examination. Any cranial nerve abnormality or gait disturbance suggests a brainstem lesion; cognitive mental status abnormalities suggest cortical disease. The optic disc should be examined for papilledema (raised intracranial pressure). Nystagmus indicates dysfunction of the vestibular system.
4. Signs of eating disorders (parotid gland enlargement, loss of tooth enamel, and lanugo), depression, and anxiety.

INVESTIGATIONS

Typical laboratory tests and imaging studies for patients presenting with nausea and vomiting are listed in Table 26.2. In more severe or prolonged episodes of vomiting, elevated hemoglobin level and hematocrit may be seen secondary to volume contraction, while hypochloremia is seen following large losses of HCl with vomiting, often resulting in a hypochloremic metabolic alkalosis.

Further testing will be guided by clinical suspicion and may include serum drug levels (e.g., digoxin toxicity), gastroscopy (proximal lesions), small bowel follow-through (for lesions up to the terminal ileum), abdominal ultrasounds (for liver, gallbladder or pancreatic disease), computed tomography (CT) with oral and IV contrast, and CT or MRI of the brain (intracranial lesions).

(AGA, 2001; Metz & Hebbard, 2007; Murtagh, 2011; Scorza, et al., 2007)

MANAGEMENT

Initially, management should be directed toward stabilizing the patient via methods including rehydration and correction of any electrolyte abnormalities. Empiric treatment should also be instigated early in an attempt to provide some

Table 26.2 INITIAL TESTS

TEST	REASON
<i>Laboratory tests</i>	
Complete blood count	Increased white cell count if infection is suspected. Anemia would warrant further investigation for causes such as malignancy in chronic cases.
Electrolytes	To assess electrolyte abnormalities in more serious cases of nausea and vomiting e.g., hypokalemia, alkalosis
Liver enzymes/ Pancreatic enzymes	When liver or pancreatic disease is suspected
Calcium	Hypercalcemia
Blood glucose, urinary and blood ketones	If suspect diabetic ketoacidosis and in all patients with known diabetes
bHCG	Any woman of childbearing age
TSH	Patients with symptoms and signs of thyroid toxicity
Albumin	Cases of chronic vomiting to assess nutritional status
Urinary microscopy and culture	For suspected cases of UTI, pyelonephritis
Stool microscopy	Where there is associated diarrhea looking for bacterial or parasitic

symptomatic relief. When possible, the underlying cause should be corrected. Cases requiring hospital admission include moderate to severe dehydration (especially in the elderly), possible bowel obstruction, increased intracranial pressure, acute myocardial infarction, and other gastrointestinal and neurological emergencies.

NONPHARMACOLOGIC TREATMENTS

Simple measures such as avoiding noxious stimuli (e.g., strong odors) and eating food frequently and in small amounts can be helpful. For more chronic cases, such as chemotherapy related nausea and vomiting, a number of nonpharmacological techniques can be considered. Relaxation techniques including biofeedback, self-hypnosis, progressive muscle relaxation, cognitive distraction, guided imagery, and systematic desensitization can be helpful particularly for patients with anticipatory nausea and vomiting and for those with prominent anxiety around chemotherapy. While many patients find these techniques effective, there have been few controlled clinical trials. In an uncontrolled study of self-hypnosis for chemotherapy-related nausea and vomiting in 16 cancer patients, all had complete remission of anticipatory symptoms and major decreases in post-chemotherapy nausea and vomiting (Marchioro et al., 2000). However,

there have been no controlled studies reported, and clinicians' experiences have been mixed. Patients' varying hypnotic susceptibility may account for much of the variability in response. There have been positive controlled studies of progressive muscle relaxation, with or without guided imagery, for chemotherapy-induced nausea and vomiting (Lyles, Burish, Krozely, & Oldham, 1982; Molassiotis, Yung, Yam, Chan, & Mok, 2002; Morrow & Morrell, 1982). The reported studies have shown decreases in incidence and duration of anxiety, nausea and vomiting during chemotherapy (Arakawa, 1997; Lyles, et al., 1982). The evidence for guided imagery alone is less effective than guided imagery combined with other techniques such as music therapy or progressive muscle relaxation (Yoo, Ahn, Kim, Kim, & Han, 2005). Both cognitive distraction and systematic desensitization are supported by more robust studies, with both techniques shown to significantly decrease both anticipatory nausea and vomiting as well as decrease post-chemotherapy symptoms (Hoffman, 1982; Vasterling, Jenkins, Tope, & Burish, 1993). Apart from greater relaxation, other potential benefits include decreased feelings of helplessness and an enhanced sense of control. Acupressure and acupuncture increasingly are being accepted by mainstream medicine as potentially useful for controlling nausea and vomiting in pregnancy, postoperative and chemotherapy-related contexts (NIH Consensus Conference, 1998). Studies systematically reviewing the efficacy of the wrist acupuncture point P6 have been generally positive, though virtually all have methodological limitations (Arsenault, et al., 2002; A. Lee & Done, 2004; E. J. Lee & Frazier, 2011).

In conclusion, all of the above treatments have some empirical support but none have become the standard of care. In practice, local availability of practitioners skilled in administering the treatment and patient preference are likely to determine the prescription for nonpharmacologic treatment.

PHARMACOLOGIC TREATMENTS

Over-the-Counter Medications/Supplements

Ginger (*Zingiber officinale*) is often advocated as beneficial for nausea and vomiting. A meta-analysis demonstrated that a fixed dose at least 1 g of ginger is more effective than placebo for the prevention of postoperative nausea and vomiting. Studies also suggest efficacy in pregnancy, but the evidence is inconsistent (Ernst & Pittler, 2000; Dennehy, 2011). Vitamin B₆ is also thought to be helpful, but again, it is not supported by high-level evidence.

Prescription Medications

Antiemetic medications are appropriate when a cause is identified but treatment of the underlying condition is impossible or does not provide adequate or timely relief. There are several steps involved in choosing an effective antiemetic. First, one must decide on the likely cause; then, the relevant emetogenic pathway(s) as well as major relevant neurotransmitters. Table 26.3 is a summary of representative antiemetics from each class of medication, the receptors and sites at which they act, the dosages used, and the main side effects.

D2 ANTAGONISTS

Haloperidol is the most potent antagonist of the D2 receptor at the CTZ. Small doses are often very effective. Prochlorperazine is a less potent D2 antagonist. Olanzapine, an atypical antipsychotic, has been effective for nausea even with highly emetic chemotherapy (Navari, Nagy, & Gray, 2013).

Metoclopramide is a prokinetic with potent activity in the GI tract to antagonize D2 and stimulate 5HT₄ receptors. Acetylcholine is released by the stimulated

Table 26.3 REPRESENTATIVE ANTIEMETICS, THEIR RECEPTORS, AND INDICATIONS

MEDICATION	RECEPTOR ANTAGONIZED/ SITE OF ACTION	PRIMARY INDICATIONS	USUAL DOSAGES AND ROUTES	MAJOR SIDE-EFFECTS/ NOTES
<i>Dopamine Antagonists</i>				
Haloperidol	D2 in CTZ	Medication-induced nausea Chemical/ metabolic causes of N and V	0.5–1 mg oral, subcutaneous, IV every 8 hours	Extrapyramidal reactions Caution re: prolonged QT, especially with IV route
Prochlorperazine	D2 in CTZ	Medication-induced nausea Chemical/ metabolic causes of N and V	5–10 mg oral every 8 hours; 25 mg rectally twice a day	Extrapyramidal reactions
Metoclopramide	D2 in CTZ and GIT 5HT ₄ in GIT	Gastric stasis, ileus	10–20 mg oral, subcutaneous, iv, every 6 hours	Extrapyramidal reactions Caution re: prolonged QTc in higher doses or prolonged use

5HT₄ receptors, which reverses gastroparesis in the upper GI tract. There is also some antidopaminergic action at the CTZ. Metoclopramide can be used in partial bowel obstruction, but should not be given if the patient has colic as this will likely exacerbate abdominal pain in an obstructed patient.

All of the D₂-blocking medications can acutely produce the side effect of akathisia. With chronic use, they can cause tardive dyskinesia. In fact, there is a black box warning specifically concerning tardive dyskinesia risk with long-term use of metoclopramide.

ANTIHISTAMINES/ANTICHOLINERGIC MEDICATIONS

Scopolamine, meclizine, and dramamine are used classically for the nausea of motion sickness or as augmentation for nausea related to the distension of viscera.

SEROTONIN (5HT₃) RECEPTOR ANTAGONISTS

Serotonin receptor antagonists are thought to be most effective through their effects in the GI tract. Emetogenic chemotherapies such as cisplatin induce serotonin release from enterochromaffin cells in the GI mucosa; the serotonin stimulates local vagal afferents that send messages to the VC. Although there are serotonin (5HT₃) receptors in the CTZ and VC, the serotonin receptor antagonists are not thought to be effective at these sites.

CORTICOSTEROIDS

Corticosteroids have antiemetic effects, which can be potent in certain settings. The mechanisms of action are poorly understood but are likely multiple. Through their antiinflammatory effects, they are thought to decrease output from peripheral mechanoreceptors. Examples of nausea caused by swelling would include nausea from intracranial mass or hemorrhage, stretch of the liver capsule from metastases, hepatocellular carcinoma, or acute hepatitis. Corticosteroids can be given either intravenously or orally if the patient is not actively vomiting. The irritant effects of these medications on the stomach tend to occur with chronic use only and can be prevented with H₂-blockers or proton pump inhibitors. These effects on the stomach do not commonly cause symptoms, but rather they can increase the chances of nonsymptomatic gastric bleeding from ulcers. Corticosteroids can help nausea at low or high doses. It is often prudent to start at low doses (e.g., 2 mg of dexamethasone) and increase the doses as needed given the acute side effect profile of insomnia and dysphoria or euphoria. The long-term side effects of hypertension, elevated sugars or diabetes, infection, and decreased bone density are less relevant when using these medications for acute nausea. When using long-term, it is usually in the setting of terminal disease, such as metastatic cancer, where these long-term side effects are no longer relevant.

NEUROKININ-1 ANTAGONISTS

Aprepitant is one neurokinin-1 antagonist used for chemotherapy induced vomiting with highly emetic drugs. It also has an indication for post-operative nausea and vomiting.

BENZODIAZEPINES

While benzodiazepines have no antiemetic properties at any of the nausea pathways described earlier in the chapter, they can be very useful in reducing the anxiety associated with nausea and in treating anticipatory nausea from chemotherapy and other triggers. One must be mindful of their sedating properties, especially in patients who have not used them before and especially when used in conjunction with other sedating antiemetics (e.g., D₂ antagonists) or opioids. Patients with end-stage cancer often have nausea, anxiety, and pain. In this setting it is often more useful to use a dopamine antagonist such as haloperidol with opioids, as haloperidol is less sedating, helps with anxiety, and has more potent antiemetic properties than benzodiazepines (depending on the etiology of the nausea, of course).

CANNABINOIDS

Synthetic cannabinoid analogues may not be as effective as cannabis. Cannabinoids working at a distinct receptor have benefit for chemotherapy induced vomiting resistant to other antiemetics. Common side effects of somnolence, disturbances in thinking, psychotic symptoms, and dizziness may limit benefit (AGA, 2001; Arsenault, et al., 2002; Mannix, 2005; Murtagh, 2011; Naylor & Inall, 1994; Quigley, et al., 2001; Scorza, et al., 2007).

REFRACTORY NAUSEA AND VOMITING

If nausea and vomiting are significant, it is important to schedule medications around the clock, rather than as needed. If nausea and vomiting continue despite targeted antiemetics, reassess for missed diagnoses including contributing psychological factors. If using more than one antiemetic, use medications with different mechanisms of action while bearing in mind the suspected cause of the nausea and vomiting and the medications' side effects. Choosing an appropriate route of administration is important. Avoid the oral route in severely nauseated patients and use other routes such as IV, subcutaneous, rectal, sublingual, or topical.

SUMMARY

Many psychotropic drugs are antiemetic; they may be used to treat psychiatric syndromes at the same time as they act against nausea and vomiting—antipsychotics by virtue of dopamine blockade, benzodiazepines by suppressing conditioning, or antidepressants when depression or chronic anxiety is a major perpetuating cause. The nausea-producing serotonergic side effects of serotonin reuptake inhibitors may be prevented

with the antidote of ondansetron or similar 5HT₃ antagonist. Olanzapine is mood stabilizing and has been shown effective for chemotherapy related emesis. The contributions of substance abuse and withdrawal to nausea—via alcohol, cannabis, and opiates—should be noted. Alleviation of motion-related nausea by antihistamines or benzodiazepines as well as the use of tricyclic antidepressants for the nausea of migraines and functional vomiting can be considered. Alleviation of anxiety by nonpharmacological modes can prevent the cascade of nausea when arousal is an element of conditioned nausea and vomiting.

CLINICAL PEARLS

- Ethanol intoxication and withdrawal both are common causes of nausea and vomiting, as are opioid intoxication and withdrawal
- During an acute attack of the functional disorder of cyclic vomiting, acute migraine therapies, such as the triptan medications, can be effective. In addition to low dose tricyclic antidepressants, beta-blockers, and the newer antiepileptic medications, such as levetiracetam, can be effective in preventing or decreasing the severity of vomiting episodes. In women with cyclical vomiting related to menstruation, the oral contraceptive pill can prevent episodes (Tulley NJ, 2007).
- Olanzapine, an atypical antipsychotic, has been effective for nausea even with highly emetic chemotherapy (Navari, 2013).
- Those patients with chronic nausea and vomiting with gastroparesis are not easily distinguished in their course and characteristics from those that do not have gastroparesis.
- Many psychotropic drugs are antiemetic; they may be used to treat psychiatric syndromes at the same time as they act against nausea and vomiting: antipsychotics by virtue of dopamine blockade, benzodiazepines by suppressing conditioning, antidepressants when depression is a major perpetuating cause.
- The nausea-producing serotonergic side effects of serotonin reuptake inhibitors may be prevented with the antidote of ondansetron or similar 5HT₃ antagonist. Olanzapine has been shown effective for chemotherapy related emesis.
- Alleviation of anxiety by non-pharmacological anti-anxiety techniques can prevent the cascade of nausea when arousal is an element of conditioned nausea and vomiting.

PHARMACOLOGIC AND OTHER SOMATIC TREATMENTS OF DYSPNEA

Pedro E. Pérez-Cruz and Eva H. Chittenden

INTRODUCTION

The American Thoracic Society defines dyspnea as “a subjective experience of breathing discomfort that consists of qualitatively distinct sensations that vary in intensity” (Parshall et al., 2012) and is not necessarily associated with hypoxia or hypercarbia. Patients with dyspnea experience associated distress, functional impairment and decreased quality of life. Dyspnea has been recognized as a strong and independent predictor of mortality (Parshall et al., 2012). Physiologic, psychological, social and cultural factors influence the perception of dyspnea. The *perception* of dyspnea refers to the unique manner in which a particular individual experiences breathlessness and it consists of three distinct dimensions: a sensory dimension (i.e., the intensity of the symptom), an affective dimension (i.e., how unpleasant the symptom is), and a functional dimension (i.e., the impact or burden of the symptom). While the goal of the clinician is to resolve the underlying cause of the derangement, this is often not possible and leads to situations of chronic dyspnea in many patients with cardiopulmonary disease. Understanding the underlying pathophysiologic and emotional factors that impact dyspnea will help the clinician choose targeted interventions for these patients when the underlying cause cannot be cured or further treated. This chapter will review symptomatic treatments of dyspnea that decrease the sense of breathlessness and improve the patient’s quality of life.

The reported prevalence of dyspnea in oncologic patients varies from 21% to 90% depending on the stage of cancer (Thomas & von Gunten, 2002). The prevalence of dyspnea in patients with cancer increases as patients approach death. In the National Hospice study, 70% of cancer patients reported dyspnea at least once during their last 6 weeks of life (Reuben & Mor, 1986). In patients with lung cancer dyspnea is the most distressing symptom, with a prevalence between 55% and 90% (Xue & Abernethy, 2010). Dyspnea is also a frequent symptom in the palliative care population. In a retrospective English study of patients referred to palliative care services, 31% of the patients had dyspnea at the time of referral (Potter, Hami, Bryan, & Quigley, 2003).

With a prevalence between 72.5% and 94%, dyspnea is the most common and distressing symptom in chronic obstructive pulmonary disease (COPD) patients (Pauwels, Buist,

Calverley, Jenkins, & Hurd, 2001). It is also a predictor of all-cause mortality in COPD patients with stable disease (Esteban et al., 2008). Dyspnea is frequent in patients with congestive heart failure (CHF), and its prevalence increases before death. In the SUPPORT study 35% of patients with CHF had dyspnea 3 to 6 months before death, and this increased to over 60% during the last 3 days of life (Stuart, 2007).

PHYSIOLOGY OF THE RESPIRATORY CONTROL SYSTEM

The respiratory control system functions to maintain ventilatory homeostasis. Clusters of neurons in the medulla oblongata of the brainstem (the respiratory complex) send messages to the respiratory muscles to breathe. This structure is responsible for spontaneous breathing and the automatic adjustments to ventilation that maintain oxygenation and acid–base balance. It triggers contraction of the various muscle groups involved in breathing, increasing or decreasing the number and types of muscles activated. Under normal conditions breathing is an automatic phenomenon—patients do not need to think about inspiration or expiring air from the lungs—and functional adjustments are unconsciously regulated. Nevertheless, automatic breathing can be overridden by voluntary action: the motor cortex can stimulate respiratory muscles directly via the pyramidal motor system, bypassing the respiratory complex (American Thoracic Society, 1999).

There are several inputs to the medullary respiratory complex:

Chemoreceptors: Both peripheral and central chemoreceptors sense levels of oxygen and carbon dioxide in blood and send signals to the respiratory complex, which adjusts breathing as necessary to maintain oxygenation and acid–base balance. The peripheral chemoreceptors are located in the carotid and aortic bodies and are responsive to changes in the partial pressure of oxygen and, to a lesser extent, to variations in the partial pressure of carbon dioxide. The carotid bodies are innervated by the glossopharyngeal nerve and the aortic bodies by the vagus nerve; these nerves convey the information

to the respiratory complex. Central chemoreceptors are located in the medulla oblongata and primarily sense carbon dioxide levels in the cerebrospinal fluid. Under normal conditions, the respiratory drive is mainly regulated by the partial pressure of carbon dioxide in the cerebrospinal fluid sensed at the central level. In certain circumstances during central nervous system depression (e.g., under the effect of anesthesia or when a patient has hypercarbia), the central chemoreceptors are inhibited and their ability to trigger normal ventilation is decreased. Unlike central chemoreceptors, peripheral chemoreceptors are not inhibited during central nervous system depression. In these situations, the respiratory drive is maintained by the partial pressure of oxygen sensed in the carotid and aortic bodies.

Vagal receptors: The upper airways have vagal receptors that are stimulated by cold air. There are stretch receptors in the smooth muscle of the larger airways that are activated by CO₂ and inhaled furosemide (which can help the sensation of dyspnea). In the parenchyma of the lungs, there are pulmonary irritant receptors that react to chemical irritants such as cigarette smoke, to inflammatory mediators, and to fluid and inflammation in the lung parenchyma. Finally, there are C-fibre receptors that are in close proximity to either the pulmonary or bronchial circulation. At this point, there is no definitive evidence that stimulation of these receptors causes dyspnea.

Chest wall receptors: Mechanoreceptors in the joints, tendons and muscles of the chest wall send afferent signals to the respiratory complex.

Neural pathways from receptors to the brain: This wealth of information from the chemoreceptors in the medulla and bloodstream, vagal receptors in the airways and lung parenchyma, and mechanoreceptors in the chest wall provides continuous feedback to the respiratory complex in the medulla, which sends signals to the thalamus and up to the cortex. Neuroimaging studies of dyspnea show stimulation of specific areas of the brain cortex, including the anterior right insula, the cerebellar vermis, the amygdala, and the cingulate cortex. In response to these sensory inputs, the medullary respiratory complex (or the motor cortex when breathing is under conscious control) sends efferent commands to the ventilatory muscles.

Corollary motor discharge: When a motor command is sent to the respiratory muscles, a copy of this command, called corollary motor discharge, is relayed to the sensory cortex (with an “expected” response from the respiratory muscles). The motor response of the respiratory muscles will trigger a sensory input that will be also relayed to the sensory cortex, which represents the “actual” motor response. The corollary motor discharge (“expected” response) and the actual motor response received by the sensory cortex will be compared allowing the sensory cortex to detect discrepancy between these two sources of information. This mechanism could

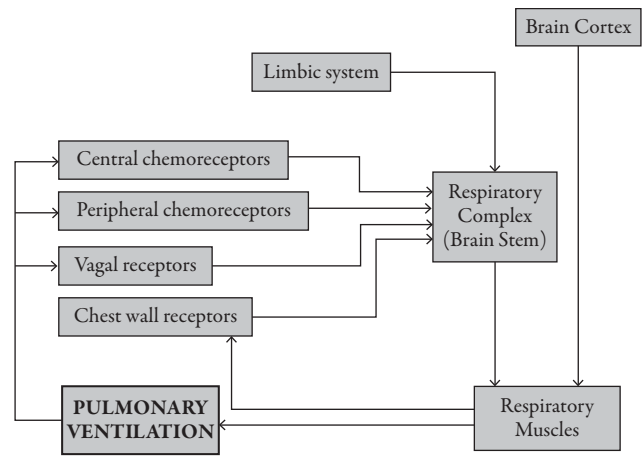

Figure 27.1 A schematic diagram of the structures involved in the control and regulation of breathing. Adapted from Duffin & Phillipson, 2010.

explain the conscious awareness of the effort of breathing that is described by some patients experiencing dyspnea (Nishino, 2011; Schwartzstein & Adams, 2010).

Figure 27.1 describes the pathways involved in the regulation of breathing. The respiratory complex triggers the involuntary activation of different respiratory muscle groups involved in breathing. The brain cortex can voluntarily activate the respiratory muscles. Changes in oxygenation, acid-base balance, lung function, and muscle effort will be communicated to the respiratory complex via a variety of receptors. Emotions, through limbic connections, influence the perception and functioning of the respiratory complex (De Peuter et al., 2004; Duffin & Phillipson, 2010; Evans, Shea, & Saykin, 1999).

PATHOPHYSIOLOGY OF DYSPNEA

Dyspnea is a complex symptom and its mechanisms are not completely understood. Hypercarbia and hypoxia can induce dyspnea in normal subjects, but in individual patients the sensation of breathlessness correlates poorly with the degree of the abnormality (Burki & Lee, 2010). Dyspnea associated with blood gas abnormalities results from increased respiratory motor activity mediated by chemoreceptor activation (American Thoracic Society, 1999), and it could also result from a direct dyspneogenic effect, independent of the ventilatory motor output (Burki & Lee, 2010). This sensation is not due to the resulting increased respiratory muscle activity as quadriplegic people experience dyspnea with hypercarbia. Studies of the hypoxic respiratory drive, in which pCO₂ and ventilation are kept constant, show that PO₂ has to drop below 6.7 kPa before subjects experience a sharp increase in dyspnea. The mechanism by which vagal afferents from the airways and lungs and the mechanoreceptors from the chest wall cause dyspnea is not known.

The corollary motor discharge from the respiratory center is thought to be key to the generation of the sensation of

dyspnea. Others theorize that dyspnea results from a mismatch between respiratory drive and sensory inputs. Dyspnea is experienced when the respiratory complex sends greater than usual stimulus to the respiratory muscles but the sensors convey data implying insufficient ventilation, insufficient muscle contraction, or insufficient movement of air. In other words, there are more signals going out from the respiratory complex but not enough good news coming back from the chest wall mechanoreceptors, central and peripheral chemoreceptors, and vagal airway and pulmonary interoception.

Researchers hypothesize that dyspnea has an affective component in addition to the sensory dimension already discussed. In severe dyspnea, the insular cortex and anterior cingulate gyrus, both part of the limbic system, are activated in functional imaging studies. These areas are postulated to process the distress caused by the sensation of dyspnea, and they may also process the distress caused by physical pain. This evidence correlates well with what we know clinically, that the experience of dyspnea is often accompanied by anxiety and fear. Patients with chronic lung disease who suffer from dyspnea often exhibit anxiety and/or depressive symptoms (Gift & Cahill, 1990).

The association between dyspnea and psychological symptoms is well described in both healthy individuals and in populations with lung disease (Dales, Spitzer, Schechter, & Suissa, 1989; Neuman et al., 2006). Healthy and asthmatic patients with a personality characterized by high negative emotionality (anxiety and highly irritable) report more dyspnea than those with low negative emotionality, regardless of their pulmonary function (Bogaerts et al., 2005). Likewise, dyspnea in patients with stable asthma is explained by both the degree of airway obstruction and patient's emotional status (Martinez-Moragon, Perpina, Belloch, de Diego, & Martinez-Frances, 2003).

The degree of dyspnea experienced in populations of patients and in individuals does not correlate well with airflow limitation or exercise performance. (De Peuter et al., 2004). Emotional and cognitive factors, as well as the ability to use adaptive techniques, such as distraction, influence the perception of dyspnea. For example, individuals experiencing dyspnea who are able to shift their attention to external stimuli have decreased sense of breathlessness (Thornby, Haas, & Axen, 1995). Likewise, patients with COPD who listen to music while on a rehabilitation program improve their performance compared to patients who do not listen to music (Bauldoff, Hoffman, Zullo, & Sciurba, 2002). Studies have also shown that situational or emotional cues associated with a particular symptom can trigger the symptom even in the absence of the physiological trigger (Rietveld, Everaerd, & Vanbeest, 1999). Negative emotions have been shown to be associated with decreased accuracy in dyspnea perception (De Peuter et al., 2004).

Dyspnea appears to involve qualitatively different sensations. Healthy subjects and patients describe three sensations: (1) "air hunger" or an "urge to breathe"; (2) an "increased work" of breathing; and (3) "chest tightness." Dyspnea that is due to acute hypercarbia or acute severe hypoxia and that is mediated by the peripheral and central chemoreceptors

is often described as "air hunger," or an "urge or need to breathe." This description of dyspnea is also observed in the context of exercise-induced dyspnea, especially if ventilatory response is constrained (Parshall et al., 2012). It is related to a conscious awareness of inadequate respiratory motor complex output in relation to the afferent information sensed via corollary discharge (Mahler et al., 1996; Nishino, 2011; Parshall et al., 2012). Dyspnea that is due to either muscle weakness or an increased mechanical load causes an increased sense of respiratory effort, often described as increased work or effort to breathe. Both types of dyspnea, air hunger and increased work of breathing, are associated with increased respiratory drive. A third description of dyspnea is "chest tightness." This phrase is often used by asthmatics and is thought to be associated with bronchoconstriction. It has been suggested that chest tightness arises from stimulation of pulmonary receptors and not from and increased sense of effort (Nishino, 2011; Parshall et al., 2012). Thus, probing about the quality of the dyspnea can guide the clinician in diagnosing the underlying pathophysiologic mechanism, but it is important to keep an open mind because these mechanisms may overlap in complex patients.

ETIOLOGIES

The differential diagnosis of dyspnea is large and includes respiratory, cardiovascular, hematologic, neuromuscular, and psychiatric disorders. Identifying the underlying cause or causes and the likely pathophysiologic mechanisms will help in devising an appropriate treatment plan. Uncommon etiologies, such as chronic pulmonary microemboli and myasthenia gravis, should be ruled out before attributing dyspnea exclusively to a psychiatric cause. Etiologies of dyspnea are listed in Table 27.1.

The clinical history, physical examination, and appropriate testing will aid in determining the most likely system involved and the underlying etiology. There may be more than one process involved especially for patients with chronic dyspnea or for those with an acute exacerbation of chronic dyspnea. Emotional and cognitive factors influence the perception and the functional impact of dyspnea even when there is no primary or secondary mental disorder.

We will flesh out the psychiatric causes of dyspnea a bit more given these causes of dyspnea are less well understood and are often a diagnosis of exclusion after cardiopulmonary and hematologic disorders have been ruled out. Panic disorder, in which panic attacks are associated with concerns about recurrence and often lead to agoraphobia and high use of medical resources, often presents with somatic symptoms, including dyspnea and chest pain, along with a feeling of anxiety and impending doom. In a study of 55 primary care patients presenting with panic disorder, 39% had cardiac symptoms, such as chest pain, dyspnea, and tachycardia (W. Katon, 1984). In fact, a "respiratory subtype" of panic disorder has been described (Abrams, Rassovsky, & Kushner, 2006). Somatic symptoms such as headaches, lightheadedness and epigastric discomfort are often associated with panic disorder as well.

Table 27.1 ETIOLOGIES OF DYSPNEA

SYSTEM	SUBTYPE	MAJOR DISEASES
Respiratory	Airways Disease	Asthma, Chronic obstructive pulmonary diseases, Upper airway obstruction
	Parenchymal lung disease	Pneumonia, Interstitial lung disease, Adult respiratory distress syndrome, Lung cancer
	Pulmonary vascular disease	Pulmonary embolism, primary pulmonary hypertension, chronic pulmonary microemboli
	Pleural Disease	Pleural effusion, Pneumothorax
	Neuromuscular and chest wall diseases	Polymyositis, Myasthenia gravis, Guillain-Barre, kyphoscoliosis
Cardiovascular		Left-sided heart failure, mitral stenosis, pericardial tamponade
Psychiatric		Anxiety, panic attacks, somatization disorder
Other		Anemia

Dyspnea can occur in other mental disorders with a high level of somatization, including somatization disorder, social anxiety disorder, and stimulant abuse (W. Katon, Ries, & Kleinman, 1984; Kroenke & Rosmalen, 2006).

PSYCHIATRIC COMORBIDITIES IN PATIENTS WITH CARDIOPULMONARY DISEASE

Patients with asthma have a higher prevalence of panic disorder and panic attacks than the general population (Hasler et al., 2005). According to one literature review, patients with asthma have a frequency of panic attacks ranging between 6.5% and 24% (W. J. Katon, Richardson, Lozano, & McCauley, 2004). Patients with COPD have a higher prevalence of generalized anxiety disorder (10%–15.8%) and panic disorder (32%–37%) compared to the general population (3.6%–5.1% and 3.4% respectively) (Periyakoil, Skultety, & Sheikh, 2005). Depression is also common in patients with COPD (Chavannes et al., 2005). In patients with CHF dyspnea is associated with fatigue, perception of poor health, and depression. Dyspnea and depression are associated in patients with asthma, cancer, and in mechanically ventilated patients (Ramasamy et al., 2006).

ASSESSMENT

The goal of the clinical assessment is to characterize the magnitude and impact of the symptom and identify possible etiologies. Two major groups of patients must be recognized: those with no prior history of dyspnea, for whom we need to identify the cause of the symptom; and those with a known cardiovascular, respiratory, or muscular disease with worsening dyspnea, for whom we need to distinguish if the cause of the symptom is a new problem or worsening of the underlying disease (Parshall et al., 2012).

We would like to highlight again that as dyspnea is a symptom, it can only be perceived by the person experiencing it. In fact, the correct assessment of dyspnea depends on self report. Therefore, it is important for clinicians to distinguish dyspnea from the clinical signs that health care providers use as evidence of respiratory dysfunction such as increased respiratory rate, use of accessory breathing muscles and intercostal retraction (Parshall et al., 2012).

Dyspnea scales have been developed to standardize the magnitude or impact of the symptom. A large number and variety of tools have been developed to assess dyspnea but each tool measures specific domains. Recent reviews have recognized three different types of measures (Parshall et al., 2012): scales that assess the sensory-perceptual experience of the patient by measuring what breathing feels like to the patient (e.g., modified Borg scale; Borg, 1982); scales that assess the affective stress by measuring associated distress and the impact/burden of the symptom, focusing on the functional ability of the patient (e.g., Medical Research Council—MRC scale; Fletcher, Elmes, Fairbairn, & Wood, 1959).

In patients with dyspnea, the history, past medical history, and physical examination are the most important components of the diagnostic evaluation.

The history should be directed at identifying the quality of dyspnea, associated symptoms, triggers or alleviating factors, and comorbidities.

A thorough past medical and social history will provide us with essential information about risk factors for dyspnea and for particular etiologies. The presence or absence of specific symptoms will orient us to a possible cause. For instance, dyspnea associated with cough, sputum, hemoptysis, or wheezing, may suggest a respiratory cause, although congestive heart failure can also present with cough and wheezing. The presence of stridor will point to central airway obstruction. The combination of dyspnea on exertion, orthopnea, and lower extremity edema suggests heart failure. Dyspnea associated with generalized muscle weakness raises the possibility of neuromuscular disease. If the physical examination is normal and additional workup is negative, one could consider a

primary psychiatric condition, such as anxiety or depression. It is important to keep in mind that a patient may have multiple causes of dyspnea, especially if there is an acute worsening of chronic dyspnea.

A complete physical examination will help confirm or modify the initial hypothesis. Findings such as hyperinflation, dullness to lung percussion, rales, rhonchi, or wheezing will suggest pulmonary etiologies. A severe chest deformity or generalized muscle atrophy will lead us to think of problems with the respiratory pump. The presence of a third heart sound on cardiac auscultation, crackles in the lungs, and bilateral swelling of the lower extremities would point to heart failure. The presence of pale mucosa with tachycardia should make us think of anemia. Commonly used tests in the workup of dyspnea are listed in Table 27.2.

SYMPTOMATIC TREATMENT

The treatment of dyspnea should focus on the underlying cause and its complications. Interventions to treat the etiology will reduce the intensity of the dyspnea and increase the patient’s comfort. Table 27.3 describes common reversible etiologies that cause dyspnea in terminal patients and their main treatments. Interventions should be focused on treating the

Table 27.2 INITIAL STUDIES TO EVALUATE DYSPNEA

TESTS	RATIONALE
<i>Lab Tests</i>	
Arterial and mixed venous blood gases	Assess oxygenation and acid-base status
CBC	Detect anemia and infection
Electrolytes and renal function	Estimate anion gap and assess kidney function
Sputum analysis and culture	Identify infectious etiology
Pleural fluid analysis and cultures	Identify cause of pleural effusion and infection
<i>Pulmonary Function Tests</i>	
Spirometry and lung volumes	Differentiate obstructive from restrictive lung disease
CO Diffusion	Assess alveolar diffusion
Cardiopulmonary exercise testing	Differentiate pulmonary, cardiovascular and musculoskeletal causes of dyspnea.
<i>Imaging Techniques</i>	
Chest X-ray	Assess multiple etiologies
Chest CT scan/ PE CT scan	Assess multiple etiologies and/or detect PE
<i>Cardiac Evaluation</i>	
EKG	Detect arrhythmias or ischemia
Echocardiogram	Assess heart structure and function

Table 27.3 COMMON REVERSIBLE ETIOLOGIES AND TREATMENTS IN PATIENTS WITH DYSPNEA

UNDERLYING CAUSE	INTERVENTIONS
Pleural effusion	Drainage if significant, consider pleural catheter if indicated
Airway obstruction by tumor	Steroids, radiation therapy, stents
Carcinomatous lymphangitis	Steroids
COPD exacerbation	Bronchodilators, steroids, oxygen, antibiotics, non-invasive ventilatory support
Pulmonary embolism	Anticoagulation
Pneumonia	Antibiotics
Ascites	Paracentesis
Congestive Heart Failure	Diuretics, digoxin, betablockers, ACE inhibitors
Anemia	Transfusions of packed RBC

Adapted from Del Fabbro, Dalal, & Bruera, 2006.

breathlessness itself when the underlying disease cannot be effectively treated. Unfortunately, there are no completely satisfactory treatments for the various forms of dyspnea (Lanken et al., 2008). Treatment should focus on both the physical and psychological components of dyspnea. In this section we will describe the available nonpharmacologic and pharmacologic interventions for the symptomatic treatment of dyspnea.

NONPHARMACOLOGIC INTERVENTIONS

Nonpharmacologic interventions tend to be inexpensive and underutilized. A recent review published in the Cochrane database analyzed the effectiveness of these interventions (Bausewein, Booth, Gysels, & Higginson, 2008). In brief, the available and effective interventions include the following:

Fans: Hand-held fans that deliver cool air to the face have been shown to decrease dyspnea both in patients with COPD and in normal volunteers (American Thoracic Society, 1999). This intervention is effective for any severity of dyspnea at any stage of disease (Booth, Moffat, Burkin, Galbraith, & Bausewein, 2011). The mechanism of action may be related to stimulation of trigeminal receptors in the face.

Positioning: Leaning forward while standing or sitting improves the efficiency of accessory muscles. This position improves diaphragmatic function, especially in hyperinflated lungs as seen in emphysema and chronic severe asthma (American Thoracic Society, 1999; Booth et al., 2011). It is useful mainly for patients with dyspnea at rest. Other beneficial positions include lying on one’s side in a semi-recumbent position or leaning forward into a stack of pillows (Booth et al., 2011).

Energy conservation interventions: Slowing one’s gait can reduce physical effort and decrease the sense of breathlessness at any stage of illness. It is important to encourage patients to

pace themselves and use available energy for the most important tasks. Energy conservation techniques can promote a sense of control and well-being.

Walking aids: Walking aids, such as canes or walkers, can reduce exertional breathlessness and increase walking distance (Probst et al., 2004). They may decrease dyspnea by prompting the patient to lean forward while walking.

Exercise training and rehabilitation programs: Pulmonary rehabilitation programs improve exercise capacity, health related quality of life and dyspnea in patients with COPD (Ries et al., 2007). Patients with chronic progressive lung disorders should be encouraged to participate early on in their illness, as these programs are less effective at advanced stages of disease. In fact, they are not indicated in patients with end-stage disease. Further, pulmonary rehabilitation prior to the terminal phase of an illness can be helpful in alleviating anxiety at the end of life (Booth et al., 2011; Lanken et al., 2008). Mechanisms for improvement may include increased aerobic capacity, a smaller increase in lactate levels during exercise, knowledge and use of relaxation techniques, increased mechanical efficiency (longer stride length), improvement of self-esteem (with an associated reduction in anxiety and depression) and desensitization to the sensation of dyspnea during exertion (American Thoracic Society, 1999).

Anxiety reduction interventions: These approaches, which include education and psychotherapeutic interventions, are postulated to work by modifying the central perception of breathlessness. Educating the patient about his or her disease and teaching and encouraging coping strategies can help patients feel a greater sense of control, which in turn, may improve their experience of breathlessness (Ben-Aharon, Gafer-Gvili, Paul, Leibovici, & Stemmer, 2008; Schwartzstein & Adams, 2010). Cognitive-behavioral approaches to modify the affective response have been shown to modify the intensity of the symptom. Sharing experiences with others in support groups and psychotherapy decreases patients' emotional distress and improves dyspnea in chronic lung disease (Ries et al., 2007; Schwartzstein & Adams, 2010). These interventions are more appropriate at earlier stages of disease, as they require motivation and active participation on the part of the patient.

Noninvasive positive pressure ventilation: The use of non-invasive ventilation can allow respiratory muscles to rest in patients with increased ventilatory demand due to increased respiratory muscle use. This intervention might reduce the need for intubation, the length of hospitalization, mortality, and dyspnea in patients with COPD exacerbations (Del Fabbro et al., 2006). It might also have a role in patients with acute CHF decompensation and in patients with amyotrophic lateral sclerosis. Unfortunately, these types of masks, which must fit tightly, can be highly uncomfortable and many patients cannot tolerate them. Clinicians must assess and discuss the burdens and benefits of this intervention, particularly at the end of life.

Other proven interventions include the use of specific breathing techniques such as diaphragmatic or pursed lip breathing, neuromuscular electrical stimulation to improve respiratory muscle weakness, use of music as an attention-diverting strategy, and acupuncture and acupressure.

PHARMACOLOGIC INTERVENTIONS

Oxygen therapy: There are both medical and symptomatic indications for chronic oxygen therapy. Medical indications include oxygen for any patient who is hypoxemic. Chronic hypoxemia can lead to the sequelae of pulmonary hypertension. In COPD patients who are severely hypoxemic, oxygen therapy prolongs survival and improves symptoms. In patients with chronic hypoxemia from other causes (e.g., interstitial lung disease, neuromuscular disease), oxygen therapy is indicated only for symptomatic relief. It does not modify patient survival. Side effects of oxygen therapy that should be taken into consideration when prescribing it include airway damage due to the direct effect of oxygen reactive species on the respiratory mucosa, and carbon dioxide retention, due to decreased lung ventilation induced by the abolition of the hypoxemic respiratory stimulus by increased blood oxygen levels. The role of oxygen therapy in non-hypoxemic patients is less clear. A recent randomized controlled trial compared the effect of oxygen versus room air (administered by nasal cannula) in relieving dyspnea in non-hypoxemic patients with advanced disease. The study demonstrated that oxygen is no better than room air (Abernethy et al., 2010). Both groups of patients had improved dyspnea at the end of the one-week study, supporting the idea that air movement near the face may improve the sensation of breathlessness.

Opioids: This family of drugs is the most effective for the treatment of dyspnea. They stimulate opioid receptors not only in the CNS, but also peripherally and in the lungs in particular. Opioids relieve dyspnea and improve exercise capacity in patients with COPD (Thomas & von Gunten, 2002). A systematic review of the use of opioids in patients with terminal disease from cancer, congestive heart failure, or COPD supports the use of oral and parenteral opioids for palliation of dyspnea (Jennings, Davies, Higgins, Gibbs, & Broadley, 2002). This same review did not show improvement of breathlessness when opioids were administered via inhalation. Side effects from opioids should be continuously assessed. The doses of opioids needed to treat dyspnea tend to be lower than those required for pain and do not affect respiratory rate or oxygen saturation if used appropriately (Thomas & von Gunten, 2002). In general, one should start with the lowest dose and titrate up cautiously. One would start with short-acting oral opioids and add in a long-acting opioid (such as long acting morphine) only if the patient was using more than the equivalent dose of the long-acting opioid in a 24-hour period. When starting a long acting opioid, it is good practice to continue the short acting opioid as needed for breakthrough dyspnea. Opioid starting doses for patients with chronic lung disease are described in Table 27.4. In patients with concurrent pain already on opioids, you can increase the opioids by about 25%. All of the various opioids relieve dyspnea equally. In general, patients quickly develop tolerance to the sedating effects of opioids if started slowly and titrated carefully, and clinicians need not be fearful of causing significant sedation or respiratory depression. On the other hand, patients rarely develop tolerance—or the need for increasing doses to obtain the same anti-dyspnea effect—to

Table 27.4 OPIOID DOSING IN PATIENTS WITH CHRONIC LUNG DISEASE

OPIOID	STARTING ORAL DOSE (SHORT-ACTING)	*STARTING ORAL DOSE (LONG-ACTING)	STARTING IV DOSE
Morphine	5–10 mg po q4 hours prn dyspnea	Long-acting morphine (e.g., MS Contin) 15 mg po q12 hours	1–2 mg IV q4 hours prn dyspnea
Oxycodone	5–10 mg po q4 hours prn dyspnea	Long-acting oxycodone (e.g., OxyContin) 10 mg po q12 hours	No IV formulation
Hydromorphone	1–2 mg po q4 hours prn dyspnea	No long acting formulation on the market currently	0.1–0.2 mg IV q3 hours prn dyspnea

*Only start long-acting if the patient is taking more than the equivalent dose of short-acting in a 24-hour period.

the anti-dyspnea effects of opioids. Most often, the need for increasing doses would signify a worsening of the underlying disease process. All patients on opioids develop physiologic dependence on opioids such that they will experience withdrawal symptoms if the medications are stopped suddenly.

Anxiolytics: In a systematic review of interventions for alleviating cancer-related dyspnea, only one study was identified that assessed the effect of benzodiazepines. In this study, the addition of a benzodiazepine to an opioid eased the sense of breathlessness compared to the opioid alone, without additional adverse effects (Ben-Aharon et al., 2008). However, there is no evidence to support the routine use of benzodiazepines in the management of dyspnea (Del Fabbro et al., 2006). Still, they may have a role in patients with significant anxiety related to their dyspnea. The clinician should monitor side effects closely and start the medications in sequence, not in parallel. One can also consider low-dose neuroleptics (e.g., quetiapine or olanzapine) or an SSRI for the chronic anxiety component related to the dyspnea. Given the high incidence of confusion or delirium in elderly patients or patients with chronic illness receiving benzodiazepines, as well as the potent sedation caused by the combination of opioids and benzodiazepines, many palliative care clinicians choose to use neuroleptics for anxiety related to dyspnea.

SUMMARY

Dyspnea is a common symptom in patients with cancer, cardiopulmonary disease and neuromuscular conditions that affect respiratory muscles. Anxiety often accompanies the dyspnea. While gaps in our knowledge remain, dyspnea is thought to represent a mismatch between the central respiratory motor command and incoming afferent information from sensory receptors. The perception of dyspnea is highly influenced by emotions. The history and physical examination and the judicious use of laboratory and functional tests will help identify the possible etiologies and underlying mechanisms of dyspnea. Treatment should be focused first and whenever possible on the underlying cause of the dyspnea and on the symptom itself when disease-modifying interventions are ineffective or have become burdensome. Opioids and other interventions, pharmacologic and non-pharmacologic, can be implemented effectively for the symptomatic treatment

of dyspnea. The challenge is to combine the tools of medicine and psychiatry to affect the emotional dimension.

CLINICAL PEARLS

- The *perception* of dyspnea refers to the unique manner in which a particular individual experiences breathlessness and it consists of three distinct dimensions: a sensory dimension, i.e., the intensity of the symptom; an affective dimension, i.e., how unpleasant the symptom is; and a functional dimension, i.e., the impact or burden of the symptom.
- Dyspnea in patients with stable asthma is explained by both the degree of airway obstruction and patient's emotional status (Martinez-Moragon, Perpina, Belloch, de Diego, & Martinez-Frances, 2003).
- In severe dyspnea, the insular cortex and anterior cingulate gyrus, both part of the limbic system, are activated in functional imaging studies. This evidence correlates well with what we know clinically, that the experience of dyspnea is often accompanied by anxiety and fear.
- Individuals experiencing dyspnea who are able to shift their attention to external stimuli have decreased sense of breathlessness (Thornby, Haas, & Axen, 1995). Likewise, patients with COPD who listen to music while on a rehabilitation program improve their performance compared to patients who do not listen to music (Bauldoff, Hoffman, Zullo, & Sciruba, 2002).
- Negative emotions have been shown to be associated with decreased accuracy in dyspnea perception (De Peuter et al., 2004).
- Both types of dyspnea, "air hunger" and "increased work of breathing" are associated with increased respiratory drive. A third description of dyspnea is "chest tightness." This phrase is often used by asthmatics and is thought to be associated with bronchoconstriction
- Hand-held fans that deliver cool air to the face have been shown to decrease dyspnea both in patients with COPD and in normal volunteers (American Thoracic Society, 1999). This intervention is effective for any severity of

dyspnea at any stage of disease (Booth, Moffat, Burkin, Galbraith, & Bausewein, 2011).

- For dyspnea at rest, leaning forward while standing or sitting improves the efficiency of accessory muscles.
- Walking aids, such as canes or walkers, can reduce exertional breathlessness and increase walking distance (Probst et al., 2004).
- Cognitive-behavioral approaches to modify the affective response have been shown to modify the intensity of dyspnea. Sharing experiences with others in support groups and psychotherapy decreases patients' emotional distress and improves dyspnea in chronic lung disease (Ries et al., 2007; Schwartzstein & Adams, 2010).
- The role of oxygen therapy in non-hypoxemic patients is less clear. A recent randomized controlled trial compared the effect of oxygen versus room air (administered by nasal cannula) in relieving dyspnea in non-hypoxemic patients with advanced disease. The study demonstrated that oxygen is no better than room air (Abernethy et al., 2010).
- Opioids relieve dyspnea and improve exercise capacity in patients with COPD (Thomas & von Gunten, 2002).

THERAPEUTIC NUTRIENTS, HERBS, AND HORMONES

Patricia L. Gerbarg and Richard P. Brown

Editors' Preface

The editors think that Gerbarg and Brown's chapter on nutrients, herbs, and hormones in medical psychiatry warrants a special preface. In their chapter the authors present a thoughtful assessment of the current status of alternative, integrative, and less conventional nonprescription treatments for mental and behavioral symptoms. They present the scientific evidence related to the efficacy and safety of the most widely used nutrients, herbs, and nonprescription hormones, and describe how they use them in their own specialized integrative psychopharmacologic practice. Many of the treatments in this chapter are not yet considered to be part of standard psychiatric practice. Consequently, many medical psychiatrists are not cognizant of their potential benefits and do not know how to integrate these therapies into their practices. Virtually all psychiatrists treating patients with general medical illness will encounter individuals presenting for consultation who are already using these complementary and alternative treatments, or will have patients or family members asking whether such treatments might be helpful. When a patient presents for consultation already taking a nutrient, herb, or nonprescription hormone that is working well for its target symptoms and not causing adverse effects, if the clinician counsels discontinuation because he or she does not personally favor the treatment it will potentially worsen the clinical outcome. On the other hand, many patients who take such treatments on their own are unaware of potential interactions with prescription drugs and with general medical diseases and, as a result, take risks of which they are not aware.

Most of the treatments described in this chapter are not classified as pharmaceuticals by the US Food and Drug Administration; all are legal nonprescription supplements sold without claims of efficacy for any specific disease; some are prescription medications used by conventional psychiatrists in Europe. For some of the agents discussed here, the evidence from controlled clinical trials is similar in amount and quality to the evidence used to support a prescription drug's marketing approval. For others the evidence is less, and the support for use of the agent is based on a combination of open or pilot studies, personal and anecdotal clinical experience, preclinical data, and

the putative mechanism of action. Inquiring whether patients are using alternative therapies is essential, and, when they are, the medical psychiatrist must check an appropriate database for interactions of the agents being used with the patient's diseases and prescription drugs. It is also recommended, if feasible, to check each agent to determine whether the manufacturer is known to make a product of reliable potency and purity. Recommending alternative treatments is an optional part of medical psychiatric practice.

Medical-psychiatric patients are potentially attracted to nonprescription alternative treatments for several reasons: (1) they may believe that they are safer; (2) they may have a philosophical preference for "natural" treatments; (3) they may have had relevant personal or vicarious experience, either positive with alternative treatments and/or negative with conventional prescribed drug therapies; (4) many patients are unable to tolerate side effects from prescription medications; (5) complementary and alternative treatments may be less expensive and insurance companies often refuse to cover physician recommended prescription medications; (6) taking supplements without a doctor's prescription may give the patient a greater sense of control over his/her treatment in a context of general medical illness that always entails some loss of control over one's life; and (7) taking an agent to treat symptoms, with no psychiatric diagnosis (documentation of the diagnosis is necessary for a prescription medication) avoids potential stigma, keeps psychiatric content out of the medical record, and protects the patient from being identified as having a psychiatric disorder that could jeopardize their career if it became known, for example commercial pilots who are subject to drug testing and active duty military personnel. Medical psychiatrists frequently encounter patients who are open to herbal and nutritional therapies at a time when they would not accept a psychotropic drug prescription. The most common reason for consulting specialists in integrative psychopharmacology is that many, if not all, categories of conventional prescription treatments have been tried and failed. In such cases the physician must decide between telling the patient there is nothing left to offer relief or broadening the treatment options by integrating low risk, less conventional approaches.

In counseling a patient to begin an alternative treatment—or even to continue one the patient has already started—the psychiatrist assumes clinical and legal responsibility. The clinician should share with the patient what is known about the risks and benefits of the agent(s) involved and how they might interact with the patient's diseases and other treatments, and why the patient might do better with the alternative treatment than a conventional prescription psychotropic. This discussion should be documented in the record. Finally, the patient's treatment choice and response to treatment should be documented in the medical record.

INTRODUCTION

Medical patients suffer from the psychological effects of their medical conditions, the direct and indirect stressors of their illnesses, and the medications and procedures used to treat these conditions. Therapeutic nutrients and herbs have an emerging role in ameliorating neuropsychiatric and physical symptoms in medical patients. Synthetic psychotropic medications used to treat anxiety, insomnia, depression, and cognitive impairment can add to the burden of side effects in medical patients who may be more susceptible to adverse reactions and medication interactions. Furthermore, prescription anxiolytics, sedative hypnotics, and analgesics have the potential for habituation, addiction, overdose, and withdrawal symptoms. In general, herbs and nutrients have far fewer side effects and far less addiction potential. Rather than taking an encyclopedic approach, this chapter focuses on clinically useful treatments, their mechanisms of action, and the evidence for safety and efficacy. The safety of most herbs during pregnancy and breastfeeding has not been adequately studied. Herb–drug interactions and the use of herbs to counteract medication side effects are covered in the last sections of this chapter. Summaries of dose ranges, side effects, and drug interactions, are provided in Tables 28.1, 28.2 and 28.3.

Many herbs and nutrients have been considered to be part of complementary and alternative medicine (CAM). Advances in neurophysiology, molecular biology, and genomics have created a deeper understanding of the mechanisms of action and the potential benefits of treatments that were previously considered outside the purview of conventional medicine. Integrative medicine and integrative psychiatry are emerging fields that cultivate integrative approaches using herbs, nutrients, neurohormones, mind–body practices, and mainstream medical treatments.

GENERAL ISSUES IN THE PURSUIT OF QUALITY

STANDARDIZATION OF SUPPLEMENTS

Considerable progress has occurred in the standardization of botanical extracts based on the concentration of marker

compounds believed to be essential for therapeutic activity and/or to be unique to the species. High-pressure liquid chromatography (HPLC) can be employed to measure the presence and concentration of marker compounds, and for most herbs this is sufficient. However, for certain rare and more expensive herbs, adulteration may still occur by “spiking” the product with marker chemicals. Usually the reporting of one or two marker compounds is adequate, but the testing of more marker compounds or comparison of the complete HPLC profiles would be preferable for more complex herbs. The ultimate test of an extract is proven efficacy in a good quality controlled trial, published in a peer-reviewed journal.

Most supplements are stable enough that their quality is not significantly affected by differences in processing. In this chapter, complex products whose quality is more affected by differences in cultivation and extraction procedures—for example, *Ginkgo biloba*, *Hypericum perforatum* (St. John's wort) and *Rhodiola rosea* (Arctic root)—will be identified. The relative amounts of active compounds in herbs are affected by the soil, climate, time of harvest, and age of the plant at the time of harvest. The composition of plant extracts depends upon the method of drying and extraction. Some compounds are soluble in water, others in alcohol. Procedures for extraction of certain herbs, such as *R. rosea*, use either water or alcohol or both. Volatile compounds can be lost if subjected to excessively high temperature during processing. Extracts are sold to companies that encapsulate and market products under various brand names. Companies may change the source of raw product as the cost and availability of plant extracts change. Product labels rarely state the source of extracts. *Ginkgo biloba* is one exception. Many products containing *Ginkgo biloba* identify their content as, for example, EGb 761 or Kira, which are both known to be reliable, potent extracts based on numerous scientific studies in which they were used. For other complex herbs, additional investigation is needed to identify products containing high-quality extracts. For example, the Swedish Herbal Institute has a long history of producing high-quality products with demonstrated efficacy in research studies. In determining the appropriate dosage, it is important to note not only the milligrams of the marker compounds but also the percentage of those marker compounds. For example, 150 mg of an *R. rosea* product containing 4% of marker compounds called *rosavins* is more potent than a brand containing 3% *rosavins*. The authors have provided lists of high-quality products in previous publications (Brown, Gerbarg, & Muskin, 2009; Brown & Gerbarg, 2011). Proprietary preparations do not always reveal the exact amount of each component. Companies may consider secrecy to be a business necessity; however, prescribing a product without knowing its exact contents is problematic for clinicians.

Improved verification of the authenticity and quality of herbal products is evolving with new technologies. Ideally, in the future herbs may be identified by genomic analysis, the concentration of key constituents assessed at each stage of production, and supplement brands systematically tested for purity and efficacy.

REGULATORY ISSUES

Each country has its own regulatory processes. Within the US Food and Drug Administration (FDA) the Center for Food Safety and Applied Nutrition monitors the safety of dietary supplements and the accuracy of labels and inserts. The US Federal Trade Commission requires and oversees truthfulness in product advertising (www.ftc.gov).

RELIABLE SOURCES FOR INFORMATION ABOUT QUALITY AND SAFETY OF SUPPLEMENTS

Information on the safety of specific supplements is available at the FDA website: www.fda.gov/Food/DietarySupplements/Alerts. The “Alerts and Advisories” section of the National Center for Complementary and Alternative medicine (NCCAM) posts information about problematic supplements at www.nccam.nih.gov/news/alerts. The National Institute of Health National Library of Medicine maintains the *Dietary Supplement Labels Database* containing information about the ingredients in over 2,000 brands of supplements on their website, www.dietarysupplements.nlm.nih.gov/dietary.

In Germany, the German *Commission E* closely regulates the quality of phytomedicines and publishes highly respected monographs that are available at <http://cms.herbalgram.org/commissione/index.html>.

The American Herbal Pharmacopoeia (AHP) maintains authentic botanical reference materials to insure the identity and quality of medicinal plants. These are used by academic institutions, researchers, supplement manufacturers, and those who evaluate products, such as ConsumerLab. The AHP publishes scholarly qualitative and therapeutic monographs and books on herb safety (see http://www.herbal-ahp.org/order_online.htm).

The American Botanical Council (ABC) is an independent, nonprofit research and education organization that provides reliable information about herbs for consumers, healthcare practitioners, researchers, industry, and the media. The ABC publications are peer reviewed and include periodicals, books, monographs, safety reviews, continuing education materials, and searchable online databases. *Herbalgram*, the quarterly journal of the ABC, publishes extensive articles on the history of phytomedicines, modern uses, and current issues that affect cultivation and quality. *HerbClips* reviews current research studies and books. The ABC website is accessible at <http://abc.herbalgram.org/site/PageServer>.

The *Natural Medicines Comprehensive Database* (NMCD) covers a great deal of information, even on obscure herbs, with yearly updates. The drawbacks are that it cites articles that mention side effects even if based on weak or nonvalidated evidence. Most of the information is accurate, but some is not. Consequently, the long lists of potential side effects may include nonvalidated items, speculations based on information from in vitro or animal studies, or equivocal cases. The burden is on the reader to check the original citations to determine the degree of validity and clinical relevance of the information (Jellin, 2010).

ConsumerLab.com is one of the best nongovernmental resources for up-to-date, detailed, practical information on most of the supplements encountered in clinical practice. Companies pay a fee to ConsumerLab to analyze and report on the contents and quality of their products. Clinicians and consumers pay a modest annual fee for access to reports that cover thousands of brands. ConsumerLab purchases products from stores, not directly from the manufacturer, and sends them to independent laboratories for HPLC assessment of marker compounds and other constituents that play a role in therapeutic action. Products are tested for lead and other contaminants as appropriate. A passing score is given to products that meet US Pharmacopoeia standards for tablet disintegration, fulfill FDA labeling requirements, contain 100% of the label claims for content, do not exceed legal levels for lead contamination, and meet other product-specific quality indices.

Herbal Contraindications and Drug Interactions by Francis Brinker is an excellent resource providing precise explanations on the sources of information, limitations and contradictions in the literature, and the complexity of the available evidence (Brinker, 2010). The publisher posts free updates at www.eclecticherb.com/emp.

Herbs, Nutrients and Yoga in Mental Health Care by Richard P. Brown, Patricia Gerbarg, and Philip Muskin is a practical clinician's guide that includes sources of quality products, recommended dosages, how to combine standard, complementary, and alternative treatments, and case illustrations (Brown, Gerbarg, & Muskin, 2009).

REPORTING SIDE EFFECTS AND ADVERSE REACTIONS

As with prescription medications, adverse reactions to phytomedicines and nutritional supplements are underreported. Side effects can be reported to MedWatch by phone (1-888-463-6332) or through the FDA website at www.fda.gov/safety/MedWatch/HowToReport/ucm053074.htm. For reporting serious adverse reactions, healthcare providers may call the MedWatch hotline at 1-800-FDA-1088.

LIABILITY ISSUES

Individuals who request CAM treatments are entitled to the same quality of diagnostic evaluation as those who seek conventional treatments. Malpractice experts note that the following categories of malpractice could be applied to CAM: misdiagnosis, failure to treat, failure of informed consent, fraud and misrepresentation, abandonment, vicarious liability, and breach of privacy and confidentiality (Cohen & Schouten, 2007). In general, the approach to liability issues—and to all categories of liability in integrative mental healthcare using nutrients and herbs—are similar to those for standard practices. The issue of failure to treat raises several potential scenarios worth noting:

1. The risk of liability is less if scientific evidence supports the safety and efficacy of a CAM treatment. In cases in

which a patient does not tolerate or respond to conventional treatments and whose condition could be treated effectively with a reasonably safe CAM therapy, one could argue that it would be negligent not to inform the patient of the CAM treatment and offer the option to try it.

2. If scientific evidence indicates that a particular CAM treatment is ineffective or is likely to cause harm, then the practitioner should try to dissuade the patient.
3. If the evidence for safety or efficacy of a CAM treatment is equivocal, then the patient should be informed of all known potential risks as well as the quality of the evidence both in favor and against the treatment. If the patient chooses to try the treatment after this discussion (and the discussion has been documented in the chart), then the practitioner should monitor the patient during the trial for benefits and side effects and should intervene if any adverse reactions occur.
4. If the patient has a condition that could be easily or rapidly cured by standard treatment, and if the use of CAM delays effective treatment such that the patient suffers harm or illness progresses, this could be considered malpractice, negligence, or substandard care.

The same principles that govern informed consent in conventional treatments can be applied to CAM. Each state has specific regulations governing the practice of CAM. The U.S. Federation of State Medical Boards (FSMB) has approved model guidelines for the use of CAM therapies in medical practice (Federation of State Medical Boards, 2007; see http://www.fsmb.org/pdf/2002_grpol_complementary_alternative_therapies.pdf). The FSMB recommends that the physician conduct an appropriate medical history, physical examination, and review of patient medical records before offering any recommendation for treatment. The FSMB Guidelines note that

“The evaluation shall include, but not be limited to, conventional methods of diagnosis and may include other methods of diagnosis as long as the methodology utilized for diagnosis is based upon the same standards of safety and reliability as conventional methods, and shall be documented in the patient’s medical record. The medical record shall also document:

- what medical options have been discussed, offered or tried, and if so, to what effect, or a statement as to whether or not certain options have been refused by the patient or guardian; that proper referral has been offered for appropriate treatment;
- that the risks and benefits of the use of the recommended treatment to the extent known have been appropriately discussed with the patient or guardian;
- that the physician has determined the extent to which the treatment could interfere with any other recommended or ongoing treatment.”

In their discussion of liability issues Brown, Gerbarg, and Muskin include an example of a note for documentation of the decision-making process that leads to the use of a CAM treatment (Brown, Gerbarg, & Muskin, 2009).

ANXIETY DISORDERS AND INSOMNIA

NUTRIENTS FOR ANXIETY DISORDERS AND INSOMNIA

Evaluating the nutritional status of medical patients is part of standard practice. Nutritional deficiencies develop in association with poor diet, chronic illness, loss of appetite, aging, dementia, chemotherapy, malabsorption, gastrointestinal problems, and substance abuse.

Gamma-aminobutyric Acid

Gamma-aminobutyric acid (GABA), the major central nervous system inhibitory neurotransmitter, is involved in cardiovascular regulation, pituitary function, immunity, fertilization, and renal function. Many foods contain small amounts of GABA, and fermented food products may contain high levels. Natural GABA produced by fermentation is widely used as a functional food supplement in Japan.

The effects on EEG of 100 mg of GABA produced by natural fermentation (pharma-GABA) were compared to 200 mg L-theanine and placebo in a double blind placebo controlled (DBPC) crossover study of 13 healthy adults. Alpha waves are associated with relaxed, effortless alertness. Beta waves occur in highly stressful situations and during difficulty with mental concentration. GABA intake resulted in a significantly greater increase in alpha and decrease in beta compared to both L-theanine and placebo control (Abdou et al., 2006). The high alpha/beta ratio indicates a state of arousal with relaxation or relaxed concentration. Low levels of salivary immunoglobulin-A (IgA) found in highly anxious individuals drop further in stressful situations. In a double blind randomized placebo controlled (DBRCT) study, 8 adults with acrophobia (fear of heights) walked across a suspension bridge 300 meters long and 54 meters above the ground. In the placebo group, IgA levels (a marker of stress and immune response) dropped substantially halfway across and at the end of the bridge. In comparison, in subjects given 100 mg GABA (pharma-GABA), IgA levels dropped only slightly midway and rose above baseline by the end of the bridge (Abdou et al., 2006).

Pregabalin is a synthetic structural analogue of GABA approved by the FDA for treatment of neuropathic pain and partial-onset seizures. It is being considered for approval as an adjunctive treatment for generalized anxiety disorder (GAD). Several randomized controlled trials (RCTs) confirm that pregabalin is comparable to lorazepam (Ativan), alprazolam (Xanax), and venlafaxine (Effexor) for moderate to severe GAD. Pregabalin is generally safe and well tolerated. Side effects include dizziness, somnolence, cognitive

interference, incoordination, headache, and some potential for dependence. The onset of anxiolytic effects requires 1 week of daily treatment (Bandelow, Wedekind, & Leon, 2007). In clinical practice, the authors (PLG and RPB) use pregabalin only when first-line treatments have failed. Starting doses of 50 mg three times daily are titrated upward as tolerated.

L-lysine and L-arginine

Lysine is an essential limiting amino acid in wheat-based diets. In a 3-month DBRCT in poor Syrian families whose diet is based on wheat, lysine fortification of wheat resulted in improvements in anxiety and stress response (Smriga, Ghosh, Mounieimne, Pellett, & Scrimshaw, 2004). L-lysine combined with L-arginine may affect neurotransmitters involved in stress and anxiety. Acting as a partial serotonin receptor 4 (5-HT₄) antagonist, L-lysine was found to reduce serum cortisol and brain–gut responses to stress. A study of men with high trait anxiety based on the Stait-Trait Anxiety Inventory found that L-lysine/L-arginine improved the ability to handle induced stress more than placebo (Jezova, Makatsori, Smriga, Morinaga, & Duncko, 2005). A double blind randomized placebo controlled (DBRPC) study found that after one week of L-lysine (2.64 g/day) plus L-arginine (2.64 g/day), healthy Japanese men had lower basal salivary cortisol levels and reduction in state anxiety (Smriga et al., 2007). Lysine supplementation may reduce anxiety in people with lysine-deficient diets. The combination of L-lysine and L-arginine may be useful in treating anxiety.

Magnesium in Combination Products

Although research has not shown magnesium monotherapy to be anxiolytic, a few studies of multivitamins containing magnesium show some positive effects. A multivitamin with calcium, magnesium, and zinc reduced anxiety in healthy young men in a 28-day DBRPC study (Carroll, Ring, Suter, & Willemsen, 2000). Another 1-month study of 200 mg magnesium plus 50 mg vitamin B₆ reduced premenstrual anxiety in a DBR crossover study (De Souza, Walker, Robinson, & Bolland, 2000). Without further study, however, anxiolytic effects in healthy normal subjects should not be extrapolated to those with anxiety disorders. In clinical practice, the authors (PLG and RPB) find 600–800 mg of magnesium to be beneficial for some anxious patients.

Omega-3 Fatty Acids

Although few studies have used omega-3 fatty acids (n-3 FAs) for anxiety disorders, evidence suggests that they may be beneficial, particularly in patients with low levels. Omega-3 FAs were approximately 30% lower in the red cell membranes of untreated patients with social anxiety disorder and showed a significant inverse correlation with social anxiety ratings (Green et al., 2006). In a 3-month DBRPC study of substance

abusers with presumed poor dietary habits, 13 were given 3 gm of omega-3 polyunsaturated fatty acids (n-3 PUFAS; in this case, eicosapentaenoic acid, EPA + docosahexaenoic acid, DHA) versus 11 given placebo. Compared to the placebo group, those given n-3 PUFAS had significant progressive decline in anxiety scores over 6 months (Buydens-Branchey & Branchey, 2006). One DBRPC crossover trial of EPA alone in patients with obsessive compulsive disorder on serotonin reuptake inhibitors (SSRIs) found no effect on anxiety (Fux, Benjamin, & Nemets, 2004). It is possible that a combination of EPA + DHA might have been more effective than EPA alone. The testing of n-3 FA levels is not done routinely, but it is available. In light of the general health benefits and minimal side effects, n-3 FAs are worth trying in patients with anxiety disorders, particularly if nutrition has been compromised.

HERBAL TREATMENTS FOR ANXIETY DISORDERS

Traditional research has focused on isolating single active components from plants—for example, aspirin (salicylic acid) from white willow (*Salix alba*) or digitoxin from foxglove (*Digitalis purpurea*). However, many plant extracts contain tens or hundreds of bioactive compounds that often have synergistic and polyvalent effects (Sarris, Panossian, Schweitzer, Stough, & Scholey, 2011). *Synergy* implies that the sum of multiple compounds exerting one main biological effect is greater than the effect of any one alone. *Polyvalence* indicates that multiple biological actions contribute to an overall effect. This occurs when numerous constituents have varying physiological effects or when one constituent exerts multiple effects. Furthermore, one compound may influence the absorption, distribution, metabolism, or excretion of other components.

The mechanisms of action of phytochemicals include binding to neurotransmitters and receptors, effects on synthesis of neurotransmitters or the enzymes that metabolize them, stimulation or inhibition of CNS activities, modulation of neuroendocrine systems, neuroprotection (for example, against free radicals, oxidative stress, toxins, or hypoxia), enhancement of energy production and cellular repair, and support for neurogenesis. Sarris and colleagues (2011) use the term *herbomics* to mean the use of proteomic, genomic, and other “omic” technologies in herbal research. For example, in an animal model, after 8 weeks of daily doses St. John’s wort extract (*Hypericum perforatum*) showed regulation of 66 genes compared with imipramine regulation of 74 genes. St. John’s wort (SJW) and imipramine had 6 transcripts in common that were related to synaptic and energy metabolism (Wong et al., 2004).

A systematic review of clinical studies found strong evidence for herbal supplements containing passionflower (*Passiflora incarnata*) or kava (*Piper methysticum*) and insufficient evidence for SJW in the treatment of anxiety (Lakhan & Vieira, 2010). A subsequent review of psychopharmacological

and clinical studies (Sarris et al., 2011) used the following defined levels of evidence:

A—meta-analysis or replicated RCTs with positive results;

B—one unreplicated RCT or studies with mixed but mainly positive results; or

C—one or more clinical trials with poor methodology or mixed evidence from clinical trials.

The level of clinical evidence for effects on anxiety was rated A for kava; and B for chamomile (*Matricaria recutita*), passionflower, and Arctic root or roseroot (*Rhodiola rosea*). Preclinical in vitro and animal studies indicate that anxiolytic phytochemicals commonly affect the GABA system by reducing CNS stimulation and quieting the overactivity of the amygdala that occurs in posttraumatic stress disorder (PTSD) and other anxiety disorders. Anxiolytic herbs that inhibit two enzymes known to metabolize GABA were tested in rat brain homogenates. Extracts of lemon balm (*Melissa officinalis*) showed the strongest inhibition of GABA transaminase; extracts of chamomile (*Matricaria recutita*) and hops (*Humulus lupulus*) significantly inhibited glutamate acid decarboxylase (Awad et al., 2007).

Matricaria recutita (Chamomile)

Chamomile grows in Europe, Asia, North America, and Australia. The aromatic flowers are used to make tea. Active constituents include terpine bisabolol, farnesene, chamazulene, flavonoids (including apigenin, quercetin, patuletin, and luteolin) and coumarin. Traditional uses are for stomach ache and irritable bowel syndrome, and as a gentle sleep aid, mild laxative, antiinflammatory, and bactericidal. An 8-week RCT of moderately anxious GAD patients given 220–1100 mg/day of standardized chamomile extract found significant improvement on Hamilton Anxiety scores versus placebo (Amsterdam et al., 2009). Apigenin, a component of chamomile with high affinity for benzodiazepine GABA receptors, modulates monoamine neurotransmission and neuroendocrine activity but exerts minimal sedative or muscle-relaxant effects. Chamomile can trigger allergic reactions in people who have ragweed allergy. In one case a 70-year-old patient on warfarin experienced increased internal bleeding when she drank chamomile tea (Segal & Pilote, 2006).

Ginkgo biloba (Ginkgo)

An extract of ginkgo (EGb 761, Willmar Schwabe Pharmaceutical Co., Germany), distributed in the United States by Nature's Way as Ginkgold, reduced anxiety in two studies. A DBRPC study of 170 adults (aged 18–70 years) with GAD or adjustment disorder with anxious mood were given 480 mg/day EGb761, 240 mg/day EGb761, or placebo for 4 weeks. Hamilton Anxiety Rating scores decreased significantly ($p = .0003$) and ($p = .003$) in the higher and lower doses respectively compared to placebo (Woelk, Arnoldt,

Kieser, & Hoerr, 2007). European studies of ginkgo have tended to show more favorable results than American studies. This may be due to the use of better quality standardized ginkgo extracts in Europe. American researchers are becoming more aware of the importance of testing the best quality products in research studies. Whether the positive effects on anxiety seen with EGb761 would be the same with other ginkgo preparations remains to be proven. Ginkgo will be discussed in greater detail in the section titled Herbs for Treatment of Cognitive Dysfunction.

Piper methysticum (Kava)

Kava (extracted from *Piper methysticum*), a traditional social ceremonial drink in Pacific Islands, contains alpha-pyrone (kavalactones) which have been shown to block sodium and calcium channels, reduce excitatory neurotransmitter release, enhance ligand binding to GABA type A receptors, reversibly inhibit monoamine oxidase B, inhibit cycloxygenase, and reduce reuptake of dopamine and noradrenaline. Kava has shown modest benefits in eight short-term RCTs of mild anxiety. In a 6-week double-blind, randomized, placebo-controlled trial in patients with generalized anxiety disorder ($n = 75$), Sarris and colleagues (2013a, 2013b) studied the effects of neurotransmitter polymorphisms on response to Kava. Subjects given 120/140 mg kavalactones per day had significant reductions in anxiety compared to placebo. GABA transporter polymorphisms rs2601126 and rs2697153 were associated with HAMA reduction in response to kava.

Since 1998, reports of hepatotoxicity, including liver failure requiring transplantation, led the FDA to issue a *Letter to Health Care Professionals* and a consumer advisory warning of potential liver injury (Kraft et al., 2001; US Food and Drug Administration, 2002). Ship's records left by Captain Cook from the 1800s describe kava intoxication in natives and seamen (Singh & Blumenthal, 1996). Among Maori in Australia, long-term kava users have developed facial swelling, scaly rash, increased patellar reflexes, dyspnea, low albumin levels, increased GGTPase, decreased white blood cell and platelet counts, hematuria, and tall P waves on ECGs consistent with pulmonary hypertension (Mathews et al., 1988). Side effects include gastrointestinal symptoms, allergic reactions, headache, and light sensitivity. Less common side effects are restlessness, drowsiness, lack of energy, and tremor. Investigations of adverse reactions implicate the use of incorrect plant parts or species, acetonic or ethanolic extraction, and poor storage resulting in hepatotoxic mold (Teschke, Qiu, & Lebot, 2011). Recent short-term studies using high quality standardized Kava report minimal side effects. Taking kava with alcohol, sedatives, or muscle relaxants can induce coma (Almeida & Grimsley, 1996). Extracts of kava and kava lactones inhibit P450 enzymes (see Herb–Drug Interactions) involved in the metabolism of many pharmaceuticals (Mathews, Etheridge, & Black, 2002; Gurley et al., 2005). Considering the risks of intoxication, abuse, dependency, medication interactions, and, rarely, severe adverse reactions, the authors do not recommend prescribing kava until more compelling data on safety and efficacy become available and until a consistently

high quality of manufacturing and reliable batch testing are established.

Melissa officinalis (Lemon Balm)

In a DBRPC crossover study of *Melissa officinalis* using a 20-minute laboratory-induced psychological stressor, 20 healthy subjects were given single doses of 600 mg, 1000 mg, or 1600 mg of lemon balm or placebo. The 600 mg dose significantly improved self-ratings of calmness (Kennedy et al., 2003). Lemon balm may be helpful for mild anxiety, but in some cases it may work best in combination with other anxiolytic supplements.

Passiflora incarnate (Passionflower)

Passionflower (*Passiflora incarnata*) contains a dihydroflavone, chrysin, which binds to benzodiazepine receptors. Effects mediated via modulation of the GABA system include affinity for GABAA and GABAB receptors and effects on GABA uptake (Appel et al., 2011). In a DBRPC trial, 36 patients with a *DSM-IV* (American Psychiatric Association, 1994) GAD and Hamilton Anxiety Scale scores ≥ 14 were given passionflower extract 45 drops/day plus a placebo tablet, or oxazepam 30 mg/day plus placebo drops for 4 weeks. Although the oxazepam effect was more rapid, passionflower was as effective in reducing anxiety and showed a trend toward less impairment in job performance (Akhondzadeh et al., 2001). A study of presurgical anxiety ($n = 60$) showed that patients given passionflower had significantly greater reductions in anxiety compared with those given placebo (Movafegh, Alizadeh, Hajimohamadi, Esfehani, & Nejatfar, 2008). Larger controlled trials are needed to validate these findings. Side effects are usually mild and may include dizziness, confusion, incoordination, altered consciousness, and inflammation. This herb should not be used during pregnancy because it may cause uterine contractions. In practice, the authors begin with one or two pills 2–4 times a day as needed with gradual increase.

Melissa officinalis (Lemon Balm) and *Valeriana officinalis* (Valerian)

A combination of lemon balm and valerian in three doses (600 mg, 1200 mg, 1800 mg) was given to 24 healthy volunteers in a DBRPC crossover trial using a 20-minute laboratory-induced psychological stressor (Kennedy, Little, & Scholey 2004). Mood and anxiety were evaluated at baseline and at 1, 3, and 6 hours. The 600mg dose significantly reduced anxiety ratings, while the 1800mg dose somewhat increased anxiety ratings. Within a therapeutic window, the combination of *M. officinalis* and *V. officinalis* may reduce anxiety under stress. In a large uncontrolled multicenter study, a valerian/lemon balm product (Euvegal forte) was tested in 918 children under the age of 12 years with restlessness and dysomnia (Muller & Klement, 2006). Substantial improvement occurred in 80.9% of the children with dysomnia and 70.4% of those with restlessness. The tolerability of Euvegal forte was

evaluated as “good” or “very good” by 96.7% of the patients. No herb-related adverse events occurred.

Valeriana officinalis (Valerian) and *Piper methysticum* (Kava)

A DBRPC internet-based study of kava and valerian reported no significant differences between kava and placebo for anxiety or between valerian and placebo for sleep disturbance (Jacobs, Bent, Tice, Blackwell, & Cummings, 2005). Subject selection was based on State-Trait Anxiety Inventory subtest and on self-report of “a problem going to sleep or staying asleep over the past 2 weeks” rather than on standard diagnostic criteria. The negative results may have been due to selection of a heterogeneous population, comorbid conditions, inadequate doses of herbs, or other limitations of Internet surveys.

Butterbur (Ze 185: *Petasites hybridus* or *Petasites officinalis*), Valerian, Passionflower, Lemon Balm

In a 2-week RCT, 182 patients with somatoform disorders were randomized to three groups: (1) Ze 185, a combination of butterbur, valerian, passionflower and lemon balm; (2) valerian, passionflower, and lemon balm; (3) and placebo. Those on the 4-herb combination had greater improvements in anxiety and depression compared to the 3-herb combination. Both the 4-herb and the 3-herb outperformed placebo. Although there were nine complaints including dry mouth, headache, constipation, or drowsiness, no serious side effects occurred (Melzer, Schrader, Brattstrom, Schellenberg, & Saller, 2009).

Another RCT of 60 patients with migraine found that Petadolex—a preparation of butterbur containing 25 mg per capsule, given as two capsules twice a day for 12 weeks—significantly reduced the frequency of migraines compared to placebo (Grossmann & Schmidramsl, 2000). Butterbur extract was well tolerated with no significant side effects.

Rhodiola, Artic Root, Roseroot, Rosewort, Golden Root

Rhodiola rosea and several of its 18 related subspecies, including *R. kirolowi*, *R. crenulata*, *R. imbricata*, and *R. sacra*, have been studied for adaptogenic properties. Plant adaptogens are metabolic regulators that enable organisms to resist many forms of stress (e.g., physical, mental, psychological, chemical, radiological, toxic, oxidative, hypoxic, and carcinogenic). The evidence has been reviewed that *R. rosea* alone and in combination with other adaptogens significantly improves mental and physical performance under stress (Brown, Gerbarg, & Muskin, 2009; Brown, Gerbarg, & Ramazanov, 2002; Panossian, 2013; Panossian & Wagner 2005). Psychoactive constituents of root extracts from *R. rosea*, phenolic compounds, structurally related to catecholamines, are involved in sympathetic nervous system (SNS) activation during stress response. Salidroside extracted from *R. rosea* protected PC 12 cells (derived from rat adrenal medulla pheochromocytoma) from glutamate toxicity—excitatory neurotransmitter

whose damaging effects on emotion regulatory systems have been studied in PTSD (Cao, Du, & Wang, 2006). Studies have shown that *R. rosea* increases the capacity of muscle and nerve cells to maintain production of the high energy molecules adenosine triphosphate (ATP) and creatine phosphate (CP), needed to sustain cellular activities and repair mechanisms (Kurkin & Zapesochneya, 1986b). In a pilot study (Bystritsky, Kerwin, & Feusner, 2008) 10 patients from the UCLA Anxiety Disorders Program between the ages of 34 and 55 with *DSM-IV* diagnosis of GAD, given a total daily dose of 340 mg *R. rosea* (Rhodax) for 10 weeks, showed significant decreases in mean Hamilton Anxiety Rating Scale scores at endpoint ($t = 3.27$, $p = 0.01$). Adverse events were generally mild or moderate, the most common being dizziness and dry mouth. These preliminary findings warrant further exploration. While the authors sometimes find moderate doses of *R. rosea* beneficial in anxiety disorders, its stimulative effects may initially increase agitation in sensitive individuals. Nevertheless, in clinical practices the authors note that over time it can increase stress resiliency and reduce symptoms of PTSD. Panossian and colleagues (Panossian, 2013; Panossian, Hamm, Wikman, & Effert, 2014) continue to explore the molecular and genomic bases for these actions: See Figure 28.1, *Hypothetical Neuroendocrine Mechanism of Stress Protection by Adaptogens* and Figure 28.2, *Hypothetical Molecular Mechanisms by which Adaptogens Activate Stress Response G-protein Coupled Receptors (GPCR) Pathways*. *R. rosea* will be discussed in greater detail under Herbs for Treatment of Cognitive Dysfunction.

Hypericum perforatum (St. John's Wort)

Extracts from the flowers and leaves of St. John's wort (*Hypericum perforatum*) are best known for their antidepressant effects. Case reports and some open-label studies of patients with generalized anxiety disorder suggesting response to SJW have appeared in the literature, but controlled studies have not been supportive (Kobak, Taylor, Warner, et al., 2005; Kobak, Taylor, Bystritsky, et al., 2005). In clinical practice with anxious patients, the authors prefer to use SJW brand Kira rather than Perika (Nature's Way) because it is less stimulating and therefore less likely to exacerbate anxiety and agitation. However, Perika may be more helpful in activating patients who have a sluggish depression (e.g., apathy or psychomotor retardation). Side effects and dosage will be discussed in the section on Herbs for Treatment of Mood Disorders.

Camellia sinensis (Green Tea, Theanine)

Green tea, made from leaves of *Camellia sinensis*, has been used for centuries for its calming and medicinal effects. Three to four cups of green tea contain 60–160 mg of theanine (5-N-ethylglutamine or γ -glutamylethylamide), an amino acid found in green tea that may reduce anxiety under conditions of stress. In animal studies, theanine perfusion into the brain increased dopamine release and possibly inhibited excitatory neurotransmission (Yamada, Terashima, Okubo, Juneja, & Yokogoshi, 2005). Small studies in humans have

shown mixed results. One DBRPC theanine study in 16 healthy volunteers showed some evidence of a mild relaxing effect under resting conditions, but not during experimentally induced anxiety (Lu et al., 2004). Another DBRPC study of 12 healthy subjects given a mental arithmetic task as a stressor found that those given L-theanine had reduced heart rate and attenuation of SNS activation (Kimura, Ozeki, Juneja, & Ohira, 2007). In clinical practice, the authors (RPB and PLG) find that theanine can be helpful in mild to moderate anxiety, particularly in patients who are highly sensitive to side effects of other agents. It has minimal and usually no side effects when given in a starting dose of 200 mg 1–3 times a day up to a maximum of 6 times a day. In brain damaged patients, large doses may cause paradoxical overactivation. Green tea and theanine have numerous health benefits, including antioxidant and antiproliferative activity. Decaffeinated green tea and capsules work well for anxious or agitated patients.

Valeriana officinalis (Valerian)

Studies in mice show that valerenic acid and vulerenos, two of the active constituents of valerian (*Valeriana officinalis*) extract, bind to GABAA receptors (Benke et al., 2009). Reviews of studies using Valerian for sleep show inconsistent or weak results (Bent, Padula, Moore, Patterson, & Mehling, 2006; Fernandez-San-Martin et al., 2010; Krystal & Ressler, 2001), possibly due to differences in product quality, methods of extraction, doses, and patient populations. Valerian's anxiolytic activity has been attributed to GABAA receptor effects. Also the effect of valerian improves over time and maximal benefit may take 2 weeks. One advantage of valerian over other sedative/hypnotics is that there have been no cases of habituation or abuse and only one case of possible withdrawal symptoms. Valerian should be avoided in pregnancy. Valerian is more effective when combined with other herbs, but isolated cases of adverse reactions in combination with benzodiazepines have been reported.

NEUROHORMONES FOR ANXIETY AND INSOMNIA

7-KETO DHEA (3-ACETYL-7- OXO-DEHYDROEPI-ANDROSTERONE) FOR PTSD

To date there is no specific pharmacological treatment for dissociative disorder in PTSD. In a small case series five women with severe chronic PTSD due to extreme childhood abuse, who were treated with 50–75 mg/day of a metabolite of dehydroepiandrosterone (DHEA) known as 7-keto DHEA, experienced rapid, substantial improvement in dissociative symptoms, emotional numbing, avoidance, irritability, energy, mood, memory, concentration, cognitive function, libido, anxiety, and insomnia (Sageman & Brown, 2006). The patients had not responded previously to many years of psychotherapy and pharmacotherapy. No adverse side effects were reported. Previous studies have linked DHEA

cortisol-lowering effects in PTSD with improvements in memory, cognition, and mood (Rasmusson et al., 2004). Unlike DHEA, 7-keto DHEA is not converted to testosterone or estrogen. Consequently, 7-keto DHEA is less likely to cause acne, baldness, hirsutism, prostatic changes, or increased estrogenicity. Chronic treatment-resistant PTSD in patients with serum DHEA and DHEAS levels in the lower 50% of normal may benefit from 7-keto DHEA. Side effects are minimal. Agitation may occur in some patients and there is an increased risk of mania in bipolar patients.

MELATONIN FOR INSOMNIA

Melatonin (N-acetyl-5-methoxytryptamine), a hormone secreted by the pineal gland, affects sleep circadian rhythms. Generally safe and easy to use, melatonin does not disturb sleep architecture nor lead to habituation. DBRPC trials show that melatonin improves sleep, reduces sleep onset latency (Kayumov, Brown, Jindal, Buttoo, & Shapiro, 2001), and restores sleep efficiency (Zhdanova et al., 2001). It is also effective in treating insomnia in dementia and Parkinson's (Dowling et al., 2005), "sundowning" (Cohen-Mansfield, Garfinkel, & Lipson, 2000), and rapid eye movement behavior disorder (RBD) (Pandi-Perumal, Zisapel, Srinivasan, & Cardinali, 2005). RBD, a chronic progressive parasomnia, occurs in neurodegenerative disorders and in Parkinson's patients treated with dopamine agonists and levodopa. In RBD the motor paralysis that normally occurs during rapid eye movement (REM) sleep is lost, such that patients may act out dreams, thrashing and kicking, hurting themselves or their partners. Stimulants, tricyclic antidepressants (TCAs), and SSRIs can trigger RBD (Schenck, Bundlie, Ettinger, & Mahowald, 1986), although this is more likely in patients with neurodegenerative diseases. Clonazepam or carbamazepine, the standard treatments for RBD, can exacerbate cognitive dysfunction or cause ataxia (increasing the risk of falls). Side effects rarely occur with melatonin, even at 9–12 mg h.s., the doses necessary to treat RBD (Kunz & Bes, 1997; Paparrigopoulos, 2005). In a DBRPC study of elderly melatonin-deficient insomniacs, 2 mg sustained-release

melatonin given for 1 week improved sleep maintenance, while 2 mg fast-release melatonin improved sleep initiation with no adverse effects (Haimov et al., 1995). A review of 14 RCTs found that melatonin reduced sleep onset latency in people with delayed sleep phase syndrome (DSPS) more effectively than in those with a diagnosis of insomnia (Buscemi et al., 2005). The distinction between DSPS and insomnia accounted for much of the heterogeneity in previous studies. Melatonin has a low incidence of adverse events (headaches, drowsiness, dizziness, and nausea) with no difference between melatonin and placebo in any study. Furthermore, melatonin has strong antioxidant protective effects in the dopamine system.

MOOD DISORDERS

NUTRIENTS FOR MOOD DISORDERS

B Vitamins, Folic Acid, L-methylfolate

The most important vitamins for mental health, the B vitamins (including folic acid) are essential for the functioning of nerve cells and are the most likely to be depleted due to poor nutrition, malabsorption, rapid utilization, aging, chronic illness, diabetes, cancer, smoking, alcohol use, environmental stress, or the use of medications such as mood stabilizers, L-dopa, statins, oral antidiabetic drugs, and chemotherapy.

Dietary *folate* and *folic acid* (supplemental form) must be converted into *L-methylfolate* for use in numerous metabolic pathways, including the synthesis of neurotransmitters. The final step in this conversion depends upon methyltetrahydrofolate reductase (MTHFR), which is also required for production of methionine from homocysteine (see Figure 28.1 Methylation Cycle, Folate Cycle). Polymorphisms of the MTHFR gene affect the capacity of MTHFR to convert homocysteine to methionine, or methylene-tetrahydrofolate to L-methylfolate (see Box 28.1). For an in-depth discussion of the relationship between folate, other B vitamins,

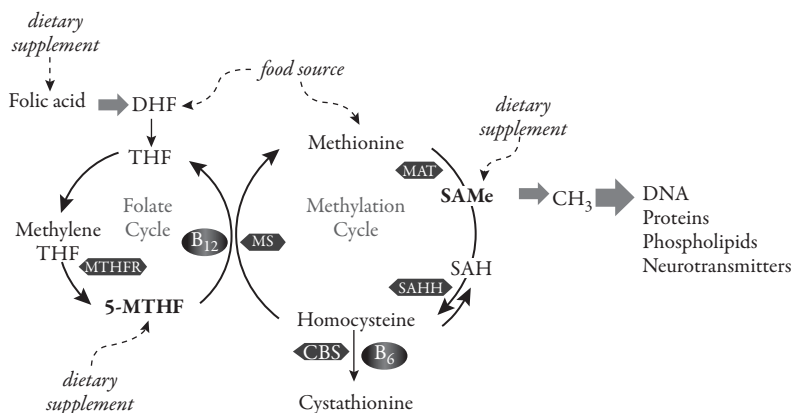

Figure 28.1 Methylation Cycle, Folate Cycle, SAMe, and B Vitamins. Key: Relationship between folate, vitamin B₁₂, and methylation. Abbreviations: DHF, dihydrofolate; THF, tetrahydrofolate; 5-MTHF, 5-methyltetrahydrofolate; SAMe, S-adenosylmethionine; SAH, S-adenosylhomocysteine; MTHFR, methyltetrahydrofolate reductase; MS, methionine synthase; MAT, methionine adenosyltransferase; SAHH, S-adenosylhomocysteine hydrolase. Reproduced with permission of Dr. Teodoro Bottiglieri, adapted from *Psychiatric Clinics of North America*, 2013, 36(1):3.

homocysteine, and depression, see the scholarly discussions by Papakostos and Bottiglieri (Papakostas et al., 2005; Bottiglieri, 2013). A mutation on the MTHFR gene at the 677 base position—due to a substitution of a cytosine base (C) by a thymine (T), a C→T polymorphism—results in a less active form of the enzyme. The normal genotype C/C has 100% MTHFR activity. However, MTHFR activity declines to 71% with C/T and 34% with T/T genotypes. The consequences of a C/T or T/T polymorphism are increased homocysteine and reduced folate concentrations. About 40%–50% of the population has C/T mutation, while 10%–12% has T/T genotype. In addition, S-adenosylmethionine (SAME) production may decline. Consequently, the reduction in SAME and the metabolism of folate, along with the increase in homocysteine, may contribute to depression, poor response to antidepressants, and progression of other illnesses such as cardiovascular disease. Supplementation with L-methylfolate may be more effective than folic acid in patients with polymorphisms, because it bypasses the final MTHFR conversion step. L-methylfolate is well absorbed and readily crosses the blood–brain barrier. For example, in a DBRPC study of 123 patients with major depression or schizophrenia, 33% had low or borderline folate levels. Among the low-folate patients on standard psychotropic medication, the addition of 15 mg/day methylfolate resulted in significantly greater improvements compared to placebo (Procter, 1991). Studies suggest that L-methylfolate 15 mg/day is useful in the treatment of SSRI-resistant depression. Two DBR parallel sequential trials in adults with major depression (total $n = 223$) found 2 weeks of 15 mg/day L-methylfolate augmentation of SSRI to be safe, well tolerated, and significantly better in improving response rates and reducing scores on Hamilton Depression Scale compared with SSRI augmentation with placebo or 7.5 mg/day L-methylfolate (Papakostas et al., 2012). Testing of MTHFR polymorphisms is becoming more widely used to identify patients who would be more likely to benefit. Deplin, a prescription form of L-methylfolate is available. However, most insurance companies do not cover the costs. Consumers can obtain the supplement online from established commercial brands less expensively.

In depressed patients and in the elderly, low levels of B₁₂ (cyanocobalamin) and folate have been associated with disorders of mood, memory, and cognition (Bottiglieri, 1996; Crellin, Bottiglieri, & Reynolds, 1993). Proton pump inhibitors interfere with B₁₂ absorption. If there is reason to think that a patient may have impaired B₁₂ absorption, for example, due to loss of intrinsic factor with aging or the use of a proton pump inhibitor (e.g., cimetidine, ranitidine, omeprazole, esomeprazole, famotidine), then sublingual B₁₂ should be administered. Testing for serum methylmalonic acid provides a more accurate indicator of intracellular B₁₂ than serum B₁₂ levels.

Studies of B vitamins and folic acid as solo treatments for depression show mixed results. Methylfolate and B vitamins are generally quite safe and low in side effects. Allergic reactions may occur. B Vitamins and folic acid stimulate endothelial proliferation and may accelerate occlusion of cardiac stents, but only in men whose baseline homocysteine level is

less than 15 mM/L (Lange et al., 2004). Poor gastric absorption of B₁₂ may contribute to B₁₂ deficiency, nonresponse to supplementation, and mixed results in clinical studies. Therefore, the use of sublingual B₁₂ tablets may be more effective.

Vitamin D₃

Vitamin D₃ (cholecalciferol) is critical for normal brain development. Evidence from preclinical studies suggests that vitamin D can affect neurotransmitters, calcium homeostasis, hypothalamic-pituitary-adrenal (HPA) axis function, inflammatory markers, and nerve growth factor. Population studies indicate an association between low vitamin D levels and depression, Alzheimer's disease (AD), Parkinson's disease, and cognitive decline. Vitamin D deficiency occurs at serum levels below 20 ng/ml 25-hydroxyvitamin D [25(OH)D]; insufficiency occurs below 30 ng/ml; and optimal levels are between 30–80 ng/ml. Although small clinical trials showed improvement in symptoms of depression with vitamin D, large population studies have yielded mixed results. A cross-sectional study of 12,594 adults in a primary care clinic revealed that individuals with a prior history of depression showed a significant correlation between high vitamin D levels and reduced risk of depression, whereas those with no prior history of depression did not (Hoang et al., 2011). Reduction of light exposure during winter months results in a decrease in production of vitamin D. The relationship between sun exposure, vitamin D levels, and seasonal affective disorder has been explored in several small randomized studies with mixed results (Bell et al., 1992).

In a study of 104 adolescents presenting for treatment for serious acute symptoms of mental illness, 34% had vitamin D deficiency and 38% insufficiency. Vitamin D deficiency was strongly associated with psychotic features (Gracious, Finucane, Freidman-Campbell, Messing, & Parkhurst, 2012).

Administration of vitamin D to all depressed patients is not justifiable based on current evidence. However, it is appropriate to check 25(OH)D levels in those at risk for deficiency due to prior history of depression, age above 65 years, adolescents with severe mental illness, lack of regular outdoor activity, and residence in northern latitudes with reduced sun exposure. Documented vitamin D deficiency can be treated acutely with high-dose vitamin D₃ (cholecalciferol) until serum levels reach normal, followed by a maintenance dose of 2000 to 6,000 IU/day.

S-adenosyl-L-methionine, Adometionine, SAME

SAME (S-adenosyl-L-methionine or S-adenosylmethionine), a first-line mainstream antidepressant and antiarthritic in many European countries, is still viewed as an alternative treatment in the United States. The FDA approved its use as an over-the-counter nutraceutical in 1998. The US Department of Health and Human Services Agency for Healthcare Research and Quality published an evidence report (Agency for Healthcare Research and Quality, 2007) concluding that SAME was equivalent to standard pharmacotherapy for treatment of

**Box 28.1 NEUROPROTECTIVE EFFECTS OF SAME,
FOLATE, AND VITAMIN B₁₂**

AD is associated with decreased plasma folate and increased plasma homocysteine. Substantial evidence associates increased serum homocysteine with AD (Coppede, 2010) and low brain SAmE levels with AD. Folate deficiency leads to a decline in SAmE with decreased DNA methylation and increased DNA breakage during aging and AD (See Figure 28.3). The reduction in folate and SAmE potentiates AD risk factors—increased neurotoxicity from elevated homocysteine, presenilin-1 (PS-1) over-expression, reduced use of glutathione, and increased beta-amyloid deposition. The C677T polymorphism of MTHFR uses folate to regenerate methionine from homocysteine. Condensation of ATP and methionine produce SAmE. Therefore, insufficiency of tetrahydrofolate leads to accumulation of homocysteine and decreased production of SAmE as methionine becomes less available.

In human neuronal cells folate and B₁₂ deprivation were associated with reduced production of SAmE and methylation of the promoter of the presenilin-1 (*PSEN1*) gene, resulting in increased production of presenilin-1 and amyloid precursor protein. This epigenetic modification in the *PSEN1* gene would result in increased beta-amyloid (A β) peptide production. Furthermore, addition of SAmE to human neuroblastoma cell cultures led to downregulation of *PSEN1* expression and a decrease in A β peptide production (Coppede, 2010). The MTHFR C677T polymorphism is an apolipoprotein E4-dependent risk factor for AD: as SAmE decreases, S-adenosylhomocysteine increases, further inhibiting methylation (Bottiglieri, 2013).

Cognitive impairment and increased aggression were found in mice lacking murine ApoE and mice expressing human E4 when fed a diet deficient in folic acid and vitamin E with iron-induced oxidative stress. Supplementation with SAmE attenuated these adverse effects. Furthermore, supplementation with SAmE improved cognitive performance in mice 9 to 12 months of age that were lacking murine ApoE and expressing human E2, E3, or E4 alleles. SAmE also indirectly contributed to acetylcholine synthesis (Chan, Tchantchou, Rogers, & Shea, 2009).

SAmE reduced impairments in primates and facilitated recovery from vascular lesions in motor and dorsolateral prefrontal cortex. In rats SAmE substantially decreased free radical production, increased glutathione, glutathione peroxidase, and transferase, and improved cholinergic function and learning. SAmE significantly improved survival when given within 24 hours of ischemia or hemorrhagic stroke (Monaco et al., 1996). In patients with traumatic brain injury (TBI), 1 month of SAmE decreased mean postconcussion symptom scores by 77% compared to 49% in a placebo group. Symptoms of headache, vertigo, depressed mood, cognitive slowing, slow thought, speech, and decreased concentration improved (Bacci Ballerini, Lopez Anguera, Alcaraz, & Hernandez Reyes, 1983).

depression and osteoarthritis. SAmE was also found to be more effective than placebo in reducing bilirubin and pruritis in intrahepatic cholestasis and cholestasis of pregnancy.

An essential molecule in hundreds of biochemical reactions within the cells of all organisms, SAmE is produced

through the condensation of methionine and ATP, a reaction catalyzed by methionine methyltransferase (MAT) (see Figure 28.3). SAmE donates methyl groups for production of DNA, proteins, phospholipids, neurotransmitters (serotonin, norepinephrine, and dopamine), and other cellular components. These methylation reactions are catalyzed by methyltransferase enzymes and require vitamin B₁₂ and folate as cofactors. SAmE also contributes sulfate groups for synthesis of the major endogenous antioxidant, glutathione (Bottiglieri, 2002, 2013). B₁₂ 1000 mcg/day, folic acid 400–800 mcg/day, and B₆ 50–100 mg/day can be effective for augmentation of SAmE and other antidepressants.

SAmE was shown to be safe and effective for the treatment of major depression in 16 open trials, 13 DBRPC studies, and 19 DBRCTs in comparison to standard antidepressants. See reviews of SAmE metabolism research (Brown, Gerbarg, & Bottiglieri, 2000; Bottiglieri, 2013) and clinical applications (Brown, Gerbarg, & Muskin, 2009).

A 12-week double-blind, randomized, placebo controlled trial of S-adenosylmethionine (SAmE) versus escitalopram in 189 outpatients with major depressive disorder (MDD) was reported as a failed trial by Mischoulon and colleagues (2014). No significant differences were found in response rates: 36% for SAmE, 34% for escitalopram, and 30% for placebo. Remission rates suggested that both SAmE and escitalopram had more robust effects compared to placebo: 28% for SAmE, 28% for escitalopram, and 17% for placebo. Placebo response rates $\geq 30\%$ are correlated with lower risk ratio of response to antidepressants versus placebo (Iovieno and Papakostas, 2012). Studies with placebo response rates $\geq 30\%$, as seen in this study, reported worse performance of drug versus placebo (Rutherford and Roose, 2013). Furthermore, the sample size was only 2/3 of the number for which the study was powered.

Bias was introduced in the discussion of the study results. Mischoulon and colleagues wrote that the sample was large enough to provide a “conclusive statement about the efficacy of SAmE as a monotherapy for MDD” and that “SAmE may be better suited as an augmentation therapy than as a monotherapy.” They made no such statement about escitalopram, though it performed no better than SAmE. A critique of this study noted, “The manner in which researchers discuss study results impacts clinical practice and can be particularly damaging in the case of less well known or less conventional treatments” and suggested that the causes for the failure of both treatments to produce higher response rates than placebo are “more likely be found in problems with the patient selection process and the heterogeneity within patient groups with respect to genomic and metabolic biomarkers. At the very least, until the true causes of invalidity are identified, such studies should not be used to create unwarranted doubt about the efficacy of highly beneficial treatments such as SAmE.” (Gerbarg, Muskin, Bottiglieri, & Brown, 2014).

As a natural metabolite, SAmE is very low in side effects compared with synthetic antidepressants and it has a more rapid onset of action. There are credible reports of adverse interactions with other medications. In fact, SAmE protects the liver and bone marrow from toxic effects of other

medications (Brown, Gerbarg, & Muskin, 2009). The most common side effect of SAME is nausea. This can usually be relieved by eating a light snack before taking SAME, using ginger capsules or tea, or by reducing the SAME dose. Loose bowels, flatulence, and abdominal pain can occur. Occasionally patients complain of headache. In rare cases patients with palpitations have complained of an increase in irregular heartbeats when given SAME, although it is generally well tolerated by individuals with cardiovascular disease. However, if it exacerbates symptoms it should be discontinued. The most serious potential side effect is the potential to induce mania in bipolar I patients.

As an activating antidepressant, SAME helps energize patients whose depression is characterized by low energy, tiredness, low motivation, and hypersomnia. It absorbs best when taken at least 20–30 minutes before breakfast and lunch on an empty stomach or 2 hours after a meal. If taken late in the day, it may interfere with sleep. For patients whose depression includes anxiety and agitation, it may be necessary to use an anxiolytic during the first few weeks to counteract the stimulative effects of SAME and to avoid exacerbating anxiety (as also occurs with stimulating antidepressants such as SSRIs). However, within 2–3 weeks, as the antidepressant action is established, it is usually possible to taper off of anxiolytics. SAME does not cause sexual side effects, sedation, weight gain, or cognitive interference. In patients who have medication sensitivities, significant anxiety, gastrointestinal problems, or serious medical conditions, one can start with a test dose of 200 mg SAME 20 minutes before breakfast for a few days. If this is well tolerated, it can be increased to 400 mg 20 minutes before breakfast for 3–7 days. The rate of increase in SAME doses depends on clinical assessment of the patient. For elderly, frail, or unstable patients, more time may be needed before each increase. If the patient reports side effects, then more time may be allowed before the next increase. In general, the dose for mild depression is 400–600 mg/day; moderate depression 600–1200 mg/day; severe depression 1200–1600 mg/day; and very severe, treatment-resistant depression 1600–2400 mg/day.

Clinical Applications and Practical Considerations

SAME has unique benefits in treating depression in patients with arthritis, fibromyalgia, liver disease, or HIV/AIDS. It should also be seriously considered for patients who take medications that may impair liver function, for example, statins and/or prescription antidepressants. SAME has no adverse hepatic effects and it protects against liver damage from prescription medications (Torta et al., 1988).

Cost is a major drawback for SAME because it is not yet covered by medical insurance in many countries. Prices vary from \$20 to \$60 for a package of 20 of the 400mg tablets. Patients can comparison shop (for quality brands) or get pharmaceutical grade SAME online (Brown, Gerbarg, & Muskin, 2009). Unfortunately, at higher doses many people cannot afford the expense of SAME. However, since SAME combines well with all other antidepressants, it is possible to combine a smaller dose of SAME with a reduced dose of a prescription antidepressant. This approach reduces side

effects of the prescription antidepressant and reduces the cost of SAME.

SAME to Augment Antidepressants

There are few pharmacological agents for treatment resistant depression and overall outcomes are poor. Results from the US National Institute of Mental Health's (NIMH) STAR*D (Sequenced Treatment Alternatives to Relieve Depression) programme indicate that after the failure of two treatment trials, the chances of remission decrease significantly (Shelton, Osuntokun, Heinloth, & Corya, 2010).

The neuronal effects of SAME overlap those of TCAs with additional dopamine stimulating effects, but SAME has fewer side effects. Three controlled studies have shown that SAME enhances the action of TCAs (Brown, Gerbarg, & Bottiglieri, 2000). One DBRPC trial ($n = 350$) demonstrated that SAME accelerated the response to imipramine (Berlanga, Ortega-Soto, Ontiveros, & Senties, 1992). SAME has been shown to enhance the effectiveness of prescription antidepressants and hasten onset of action. In an open trial at Massachusetts General Hospital, 30 depressed nonresponders to either SSRIs or venlafaxine were administered SAME (800–1600 mg/day). SAME augmentation showed a response rate of 50% and a remission rate of 43% (Alpert et al., 2004).

Further controlled trials for treatment resistant depression are warranted. A meta-analysis of European-licensed therapies in patients with MDD and inadequate response to antidepressant monotherapy identified 7 RCTs that met criteria for analysis. This meta-analysis concluded that the likelihood of response was significantly greater with SAME augmentation versus placebo or lithium (Turner, Kantaria, & Young, 2014).

The addition of SAME caused no adverse reactions in 500 patients on benzodiazepines, 60 on monoamine oxidase inhibitors (MAOIs), 45 on anticonvulsants, and 18 alcoholics on antidepressants or anticonvulsants. Moreover, SAME reversed or prevented liver toxicity, reducing the elevated levels of gamma-glutamyl-transpeptidase (GGT) in all patients taking MAOIs, anticonvulsants, or antidepressants (Torta et al., 1988). SAME is the only antidepressant that has been studied in combination with MAO inhibitors with good results and no adverse reactions. In addition to its antidepressant effects, SAME has numerous long-term health benefits in a wide range of serious medical conditions.

SAME for Treatment of Depression, Arthritis, and Fibromyalgia

Depression and arthritis are often comorbid and are exacerbated by chronic progressive pain, disrupted sleep, aging, debilitation, and side effects from antiinflammatory and pain medications. Twelve studies in more than 20,000 adults have shown that SAME provides analgesic and antiinflammatory effects equal to nonsteroidal antiinflammatories in osteoarthritis, but causes fewer side effects. Six studies reported that SAME improved both depression and pain in patients with fibromyalgia at doses equivalent to 800 mg/day with no side effects (Grassetto & Varatto, 1994; Ianiello et al.,

1994; Tavoni, Vitali, Bombardieri, & Pasero, 1987; Tavoni, Jeracitano, & Cirigliano, 1998).

SAMe for Treatment of Depression and Liver Disease

Patients with liver diseases often have comorbid depression that may be primary, secondary to the hepatic dysfunction, or due to medications (e.g., interferon). Moreover, psychotropic medications (particularly SSRIs) can cause elevations of liver function tests (LFTs) or exacerbate preexisting liver dysfunction. Alcohol abuse depletes the liver of SAMe and causes oxidative stress that contributes to tissue damage. Numerous studies have demonstrated that SAMe improves liver function and reverses biochemical markers (abnormal LFTs) in patients with cirrhosis or hepatitis due to alcohol, drugs, toxins, infections, or gallstones, including during pregnancy (Frezza, Centini, Cammareri, Le Grazie, & Di Padova, 1990; Friedel, Goa, & Benfield, 1989; Lieber, 1999; Mato et al., 1999; Milkiewicz et al., 1999). In a 2-year DBRPC study of alcohol-induced liver cirrhosis (Childs Class A and B cases) SAMe 1200 mg/day increased survival and delayed liver transplants (Mato et al., 1999). Many cases of undiagnosed hepatitis are discovered when LFTs rise in patients taking SSRIs for depression. Discontinuation of the prescription antidepressant and initiation of SAMe usually restores LFTs to normal range. Treatment of mildly elevated LFTs usually requires SAMe 800 mg in the morning (except in bipolar patients). In bipolar patients Ease-2 or Ease-Plus (CraneHerb)—Chinese herbal preparations containing bupleurum—may be used. Hepatoprotection by *Bupleurum kaoi* includes antiinflammatory and antifibrotic effects, enhanced glutathione production, and liver cell regeneration (Yen, Weng, Liu, Chai, & Lin, 2005). LFT increases greater than three times normal respond better to SAMe 1200–1600 mg/day enhanced with polyenylphosphatidylcholine. SAMe is depleted during the conversion of phosphatidyl ethanolamine to phosphatidylcholine. Taking polyenylphosphatidylcholine replenishes phosphatidylcholine supplies, preventing depletion of SAMe. As SAMe reserves increase, more glutathione is produced to counteract oxidative damage to the liver (Aleynik & Lieber, 2003; Lieber, 2001, 2005). In patients with serious underlying liver disease with documented fibrosis, adding B vitamins (including B₆) and alpha-lipoic acid can enhance response. If LFT elevations persist, betaine (trimethylglycine) can augment the response to SAMe by elevating glutathione (antioxidant), protecting the liver from chemical damage, and improving liver function (Barak, Beckenhauer, & Tuma, 1996; Kharbanda et al., 2005).

In a 24-week DBRPC trial, 37 outpatients with alcoholic liver disease were administered either SAMe 400 mg three times daily or placebo. No significant differences were found in LFTs or fibrosis in liver biopsies for the entire group. However, in the cases with less severe fibrosis, SAMe was more beneficial than placebo (Medici et al., 2011), but vitamin B₆ levels were subnormal. The negative results could be attributed to the severity of fibrosis, short duration of treatment compared with other studies, presence of subnormal

B₆ levels, and/or the absence of supplemental support for the SAMe treatment. In cases of significant hepatic fibrosis, it is necessary to augment SAMe with polyenylphosphatidylcholine, L-methylfolate, B₁₂, B₆, and sometimes herbal formulas containing bupleurum. Without the necessary cofactors and maintenance of SAMe supplies, the treatment is not as effective.

SAMe for Treatment of Depression and Parkinson's Disease

Carbidopa is a common treatment for Parkinson's disease, a degenerative disorder characterized by difficulty initiating movements, dyskinesias, stiffness, tremor, rigidity, mask-like facies (loss of facial expression), and unsteady gait. It often leads to social withdrawal and the loss of all spontaneous activity and communication. L-dopa treatment further reduces the already depleted brain stores of SAMe in patients with Parkinson's, exacerbating the depression which is highly resistant to treatment with standard antidepressants. In a double blind crossover study of 21 patients with Parkinson's disease, depression improved significantly in 8 of the patients given SAMe 1200 mg/day (Carrieri, Indaco, & Gentile, 1990). Depression also improved in 11 out of 13 subjects in an open series of Parkinson's patients given SAMe 1600–4000 mg/day (Di Rocco, Rogers, Brown, Werner, & Bottiglieri, 2000). At these doses, neurological symptoms such as dyskinesia and poor balance also improved in some cases. A Phase II 12-week DBRPC study compared SAMe 1200–2400 mg versus escitalopram (Lexapro) 10–20 mg in the treatment of depression associated with Parkinson's disease. Both SAMe and escitalopram significantly reduced depression (HAMD) scores with greater improvements on escitalopram. However, SAMe significantly improved motor symptoms compared to no change on escitalopram (Varanese, Birnbaum, Rossi, & Di Rocco, 2011).

SAMe for Treatment of Depression and HIV/AIDS

Depression occurs in about 30%–50% of HIV+ patients and is associated with low immune response, disease progression, and diminished quality of life. SAMe deficiency has been found in HIV-infected patients. An open 8-week study of 20 patients with HIV and major depression, given SAMe 400 mg twice a day with folic acid (800 mcg/day) and B₁₂ (1000 mcg/day), showed significant improvement in depression by week four (Shippy, Mendez, Jones, Cerngul, & Karpiak, 2004).

Perinatal Depression

Clinical studies show the safety and efficacy of SAMe for improving liver function in the treatment of cholestasis due to gallstones of pregnancy (Frezza et al., 1990; Friedel, Goa, & Benfield, 1989; Lieber, 1999; Mato et al., 1999; Milkiewicz et al., 1999). No adverse effects on infant development have been identified. The normal level of SAMe in the spinal fluid of infants is 3 to 7 times higher than that of adults (Surtees & Hyland, 1990). Studies of children with inborn errors of

metabolism affecting methyl transfer pathways found that SAME deficiency in the cerebrospinal fluid of children was associated with demyelination and that treatment with SAME was associated with remyelination (Surtees, Leonard, & Austin, 1991); therefore, it is unlikely that the administration of therapeutic doses of SAME to mothers experiencing perinatal depression would be harmful during pregnancy or breastfeeding (Brown, Gerbarg, & Muskin, 2009). Longer follow-up studies including neuropsychological testing of children would provide further assurance of safety during pregnancy.

SAME for Treatment of Depression in Children

There are no published controlled studies on the safety and efficacy of SAME in children. However, SAME has been used successfully to treat depression in children and adolescents in clinical practice. Three cases were reported including two sisters, aged 8 and 11, and one boy, aged 16. Both parents of the girls had strong family histories of depression and credited SAME with providing full relief of their own depressions. They did not want to expose their children to side effects from prescription medications. The girls had developed severe major depression including crying, withdrawal, sadness, and preoccupation with themes of death. The 11-year-old was started on 200 mg/day SAME. When her dose was increased to 600 mg/day, her depression rapidly and completely remitted with no side effects. Her 8-year-old sister's depression also remitted on 200 mg SAME twice a day (Schaller, Thomas, & Bazzan, 2004).

Quality and Potency of SAME Brands

SAME rapidly oxidizes when exposed to air. It is stabilized in the form of a salt. Tablets are enterically coated to resist degradation by gastric enzymes. The quality of the SAME and the quality of the tablet are critical for maintaining potency over time. If the manufacturing is flawed, tablets lose most of their potency while sitting on shelves. Unfortunately, some companies are producing low-grade SAME and selling it at bargain prices. Not only do these products lack efficacy, they can also cause more side effects. Patients should be advised to purchase only products of proven quality and those in which each tablet is protected within its own foil blister pack. SAME should *not* be refrigerated because tablets can be damaged by condensation of water within the blister packs. Also, tablets should not be cut because the enteric coating would be disrupted.

Omega-3-Fatty Acids for Depression and Bipolar Disorder

Omega-3 fatty acids (n-3FAs), particularly eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) help maintain cell membrane fluidity. EPA and DHA also reduce production of inflammatory eicosanoids and the release of proinflammatory cytokines. Data suggest that the substitution of omega-6FAs for n-3FAs in cell membranes is associated with unipolar and bipolar depression (Hirashima et al., 2004). The loss of membrane fluidity affecting membrane proteins

(enzymes, receptors, ion channels) may impair neurotransmission. Increased eicosanoids and proinflammatory cytokines may also be contributory. Omega-3 FA deficiency has been associated with increased depression and risk of suicide (McNamara et al., 2007; Sublette, Hibbeln, Galfalvy, Oquendo, & Mann, 2006), and n-3FA supplementation has been found to reduce depression and suicidality (Hallahan, Hibbeln, Davis, & Garland, 2007). For a clinical review of n-3FAs see Mischoulon and Freeman (2013). However, a meta-analysis of 13 RCTs, detecting heterogeneity and publication bias, concluded that although the balance of omega-3 to omega-6 fatty acids may be involved in the pathogenesis of depression, there was little evidence of significant benefit from n-3FAs in the treatment of major depressive disorder (Bloch & Hannestad, 2012).

Perinatal Depression

Omega 3-FAs are crucial for brain development in utero and after birth, particularly arachidonic acid (AA) and DHA. The recommended intake of DHA during pregnancy is 200–300 mg/day. During the first 6 months of life, a ratio of 4:10 n-6FA:n-3FAs is advised (Rombaldi Bernardi, de Souza Escobar, Ferreira, & Pelufo Silveira, 2012). Omega3 FAs are generally considered to be safe during pregnancy and breastfeeding, although an upper dose limit has not been established. Many prenatal vitamins and infant formulas contain n-3 FAs. In their review of n-FAs, Mischoulon and Freedman (2013) found that DBRCTs in pregnant and postpartum women yielded mixed results. They concluded that n-3FAs could help to alleviate perinatal depression in a ratio of 2:1 EPA:DHA as an alternative or adjunctive to standard treatment. Lin and colleagues (2012) observed that 5 meta-analyses concluded that n-3 FAs had antidepressant effects in patients with major depressive disorder based on *DSM* criteria, but that evidence did not support mood improvement in symptomatic individuals with unconfirmed diagnoses. They critiqued a meta-analysis that included studies that reported no benefits from n-FAs, in which the subjects were not evaluated for major depressive disorder with rigorous measures such as the HAMD.

Omega-3 Fatty Acids and Bipolar Disorder

Depressive symptoms in bipolar disorder respond better to adjunctive treatment with a combination of EPA and DHA using total daily doses ranging from 1–9 gm (Frangou, Lewis, & McCrone, 2006; Osher, Bersudsky, & Belmaker, 2005; Stoll et al., 1999). Although there have been some reports of n-3FAs triggering manic symptoms, this did not occur in the studies by Frangou, Osher, or Stoll. Anecdotally, some cases show marked improvement in both manic and depressive symptoms enabling reduction of prescription medication doses. In a meta-analysis of n-3FAs for bipolar disorder, Sarris and colleagues found a significant effect on bipolar depression and a nonspecific effect for mania (Sarris, Mischoulon, & Schweitzer, 2012).

Geriatric Depression

Depression in the elderly is often overlooked, and depletion of n-3FAs has been associated with depression. An 8-week

DBRPC parallel group study of 46 elderly (65–95 years) depressed women in a nursing home found that 2.5g/day of n-3FA (EPA:DHA of 2:1) significantly improved scores on the Geriatric Depression Scale and lowered the ratio of AA to EPA in whole blood and red cell membranes (Rizzo et al., 2012).

Side Effects and Dosages

The most common side effects of n-3FAs are gastrointestinal: nausea, heartburn, stomach pain, belching, bloating, or diarrhea. These are more likely to occur at doses above 6 g/day. The FDA has approved prescription forms of fish oil, Omacor and Lovaza, for treatment of hypertriglyceridemia (Medical Letter, 2006). Each 900mg capsule contains 465 mg EPA and 375 mg DHA. Nonprescription high-quality refined fish oil in concentrated liquid form has a light, non-fishy taste and is less likely to cause gastrointestinal side effects. Because n-3FAs reduce platelet aggregation, patients on anticoagulants should be monitored more closely when taking n-3FAs. It is best to refrigerate fish oil products to prevent them from turning rancid.

5-Hydroxy-L-Tryptophan (5-HTP)

The rationale for using the amino acid, 5-hydroxy-L-tryptophan (5-HTP) for depression is based on its role as the precursor for synthesis of serotonin. 5-HTP replaced L-tryptophan, which was taken off the market in 1989 after a contaminated product from a single manufacturer was linked to eosinophilia malignant syndrome. Since then, studies of 5-HTP have found no evidence of toxicity (Das, Bagchi, Bagchi, & Preuss, 2004). The efficacy of 5-HTP in depression has been reviewed (Das et al., 2004; Turner, Loftis, & Blackwell, 2006). Out of 27 studies 11 were DBRPC. Of the 11 DBRPC studies, 7 reported that 5-HTP performed better than placebo, but only 5 of those showed statistical significance. Several studies have shown that the addition of 5-HTP to prescription antidepressants such as nialamide, chlomipramine, and nomifensine significantly improved antidepressant response. The average dosage of 5-HTP in adults is 200–300 mg/day given in divided doses. Overall, studies suggest that 5-HTP may have limited benefit for depression with some support for its use as an augmentation. Common side effects include nausea, vomiting, and diarrhea. Less frequent side effects include headache and insomnia. Although rodent studies have shown that doses above 100 mg/kg/day induce serotonin syndrome, no cases of serotonin syndrome have been reported in humans using 5-HTP alone or in combination with SSRIs. Studies combining 5-HTP with MAOIs report no adverse effects. The use of a peripheral decarboxylase inhibitor such as carbidopa may increase the level of 5-HTP in serum 14-fold (Gijsman et al., 2002).

N-Acetylcysteine for Bipolar Disorder

N-acetylcysteine (NAC) is a precursor for synthesis of the antioxidant glutathione. In animal studies oral administration of NAC over time increased peripheral glutathione

levels and reduced markers of oxidative stress. Increased oxidative stress and disturbed glutathione metabolism have been associated with bipolar disorder and depression. In a 6-month DBRPC study of 75 patients with bipolar disorder, the addition of NAC 2g/day to the usual treatment regimen resulted in significant improvements on measures of depression, mania, quality of life, and social and occupational functioning compared to placebo. Response took 8–12 weeks with no significant side effects (Berk, Copolov, Dean, et al., 2008b).

Psychotropic medications, particularly antipsychotics, can damage fibers in the striatum leading to tremors, stiffness, or abnormal movements. In animal studies NAC protected rat striatum from oxidative stress and lipid peroxidation due to an antipsychotic medication, haloperidol (Haldol). This raises the possibility that NAC could protect patients from some of the adverse effects of treatment with antipsychotic medications. NAC has also been used to treat acetaminophen overdose and to reduce the risk of respiratory infections and flu. Because NAC is safe, well tolerated, and has additional health benefits, it is a useful complementary treatment. A positive response usually takes 8–12 weeks using daily doses of 2400–3600 mg/day.

HERBS FOR TREATMENT OF MOOD DISORDERS

Hypericum perforatum (St. John's Wort)

Meta-analyses of RCTs of St. John's wort for mild to moderate depression show significant benefits compared to placebo, effects comparable to imipramine and SSRIs, and far fewer side effects than synthetic antidepressants but slower onset of action (3–6 weeks imipramine vs. 6–12 weeks SJW) (Linde et al., 1996; Rahimi, Nikfar, & Abdollahi, 2009; Sarris et al., 2011, 2013). See section titled Herb–Drug Interactions.

Rigorous research has shown more consistent results in studies using adequate doses of better quality standardized pharmaceutical grade SJW extracts, such as Kira (LI 160) 600 mg three times daily (Vorbach, Arnoldt, & Hubner, 1997) or Remotiv (ZE 117) 500 mg/day (Schrader, 2000) for mild to moderate depression and Ws5570 900–1800 mg/day for moderate to severe depression (Szegeedi, Kohlen, Dienel, & Kieser, 2005). Treating severe depression with SJW requires higher doses (1800 mg/day) for longer periods of time (6–12 weeks). At higher doses SJW has side effects that are milder but similar to SSRIs, including nausea, heartburn, loose stools, sexual dysfunction, bruxism (teeth clenching), and restless leg syndrome. SJW can augment response to antidepressants such as tricyclics, bupropion, venlafaxine, and SAMe, but it should not be combined with MAOIs. Combining SJW with other serotonergic antidepressants may increase the risk of serotonin syndrome. SJW can induce mania in bipolar patients. A review of data from 35 DBRCTs found that dropout and adverse effects rates in patients receiving SJW extracts were similar to placebo. However, medically ill patients probably have higher rates of adverse reactions than patients selected for depression studies, which usually exclude serious medical illness

and patients on medication. Phototoxic rash occurs in less than 1% of people taking SJW 900 mg/day or more. SJW should be discontinued 2 or 3 weeks prior to surgery because it can affect heart rate and blood pressure during anesthesia. SJW has been found to interfere with absorption and metabolism of numerous medications in humans. See the section on Herb–Drug Interactions for discussion of clinically significant effects that are probably due to induction of cytochrome P450 3A4 and 1A2 enzymes as well as intestinal wall P-glycoprotein (Knuppel & Linde, 2004; Russo, Scicchitano, Whalley, Mazzitello, Ciriaco, Esposito, et al., 2014). Nevertheless, in some settings SJW is particularly beneficial, for example, in mild depression with wintertime seasonal affective disorder (Cott & Fugh-Berman, 1998; Hansgen, Vesper, & Ploch, 1994; Wheatley, 1999) and in somatoform disorder (Volz, Murck, Kasper, & Moller, 2002). The authors (PLG and RPB) usually do not recommend SJW as a first-line solo treatment for depression unless the patient has a history of good response to low dose SSRI (e.g., 5mg/day fluoxetine) but complains of intolerable side effects such as weight gain or sexual dysfunction. Because there is such variability in the quality of SJW products, selecting brands that are standardized (0.3%–0.5% hyperforin) and that have proven efficacy based on their use in clinical trials is advised.

Rhodiola rosea (Roseroot, Arctic Root, Golden Root)

Although *Rhodiola rosea* has mainly been used for fatigue, cognitive disorders, memory, and performance under stress (see below), it can alleviate depression, increase transport of tryptophan and 5-HT (serotonin) into the brain, and support cellular energy transport. In the first study of *R. rosea* as a treatment for depression, 128 patients with mixed types of depression were given 150 mg three times daily of *R. rosea* or placebo. Two-thirds of those on *R. rosea* improved significantly (Brichenko & Skorokhodova, 1987). Although this study did not fulfill modern methodological standards, it suggested positive effects. More recently, a standardized extract (SHR-5 from Swedish Herbal Institute) of *R. rosea* rhizomes was used in a DBRPC study of 89 adults between 18 and 70 years of age who met *DSM-IV* criteria for mild to moderate depression (HAMD scores 12–31). Subjects were randomly assigned to three groups. Group A received moderate doses of SHR-5 (340 mg/day); Group B received SHR-5 680 mg/day; and Group C received placebo. At the end of six weeks, mean HAMD scores dropped significantly in Groups A and B but not in Group C. No serious side effects were reported in any group (Darbinyan et al., 2007).

The authors routinely use *R. rosea* as augmentation in treating depression because it increases mental and physical energy, which are often low. It also improves mood and stress tolerance. Prescription antidepressants may alleviate negative mood states but often fall short of producing positive mood. Many patients anecdotally report that addition of *R. rosea* engenders a sense of well-being with increased motivation to get out of bed and do things. In the authors' clinical experience, patients with asthenia (mental and physical fatigue)

respond well to *R. rosea*. For a discussion of mechanisms of action, see the section titled Herbs for Treatment of Cognitive Dysfunction.

Rhodiola rosea for Depression in Menopause

Although it has not been formally studied in menopausal women for depression, fatigue, and memory decline, the authors (PLG and RPB) find that *R. rosea* restores energy, mental clarity, and sense of joyfulness. For further discussion, see subsections on Herbal Treatments for Cognitive Dysfunction and Herbs for Female Sexual Function.

Rhodiola rosea Side Effects and Dosage

R. rosea has an energizing or mildly stimulating effect but is usually emotionally calming. Unlike prescription stimulants (e.g., amphetamines) this adaptogen does not cause addiction, habituation, or withdrawal symptoms. Individuals who are sensitive to stimulants such as caffeine may initially feel more anxious, agitated, jittery, or “wired.” Patients should reduce their intake of caffeine when using this herb, because the stimulative effects can be additive. For those who are sensitive it is possible to give a fraction of the usual dose and then increase gradually as tolerated. Starting doses of 100–150 mg in the morning on the first 2 days for mild to moderate depression can be increased by one capsule every 3–7 days to a maximum of 600 mg/day. As an adjunctive treatment for depression, *R. rosea* is usually effective in doses of 200–400 mg/day. As a solo treatment, higher doses up to 750 mg/day are sometimes needed. Above 900 mg/day, mild effects on blood coagulation may occur with increased bruising. *R. rosea* should be given with caution and with close monitoring to patients taking anticoagulants. Physicians should question patients who use sports drinks, which can contain 1000 mg or more of *R. rosea* often in combination with caffeine. This may increase the risk of adverse effects such as tachycardia, particularly in athletes who may consume more than one bottle of such drinks to enhance sports performance. There is no evidence that increasing the dose of *R. rosea* above 900 mg/day provides greater benefits, and it may entail increased risks. *R. rosea* should be taken in the early part of the day to avoid interference with sleep. Some people report vivid dreams (not nightmares) during the first 2 weeks. Occasionally, the herb may cause mild nausea. This can usually be managed by taking two ginger capsules 20 minutes before ingesting *R. rosea* or by drinking ginger tea. For discussion of potential hormonal and anticarcinogenic effects, see the section on Adaptogens and Herbs with Adaptogenic Properties for Menopause and Herb–Drug Interactions.

Quality and Potency of *Rhodiola rosea*

R. rosea is one of the complex herbs whose quality can be affected by the factors described in the section on Standardization of Supplements. Among the dozens of medicinal compounds in *R. rosea* root extracts, salidroside and rosavins have been identified as active components and used as marker compounds, although no one has yet identified which combinations of the numerous antioxidants

and other bioactive constituents are responsible for its many effects. Also, it may be subject to the addition of marker compounds to products that have been adulterated with less expensive herbs. The marker compounds alone do not account for all of the medicinal effects; therefore, it is important to use only those brands that have been proven to be clinically effective or that have been tested for at least 6 marker compounds.

Eleutherococcus senticosus or *Acanthopanax senticosus*
(Siberian Ginseng)

Extracts from the fruit and seeds of *Eleutherococcus senticosus* were studied in the USSR for mental disorders. In their reviews, Panossian and Wikman found that the methodologies in most of the Soviet studies between 1950 and 1980 do not meet current standards. Nevertheless, the improvements reported in depression, bipolar disorder, schizophrenia, addictions, and alcoholic hallucinosis would be intriguing pathways for future research (Panossian & Wikman, 2009; Panossian, 2013). In a more recent study, *E. senticosus* 750 mg three times daily augmentation of lithium resulted in response and remission rates that were comparable to augmentation of lithium with fluoxetine 20 mg/day in a 6-week DBRCT of 79 Chinese adolescents with bipolar disorder. Furthermore, side effects and switching to mania were far less with *E. senticosus* than with fluoxetine (Weng, 2007).

Crocus sativus (Saffron)

Concentrated extracts of the stamen and petals of saffron were tested in two RCTs and found to significantly improve depression compared to placebo (Akhondzadeh et al., 2005; Moshiri et al., 2006). In three additional RCTs, the effects of *C. sativus* on HAMD scores were equivalent to the effects of imipramine and fluoxetine (Akhondzadeh Basti, et al., 2007; Moshiri, Noorbala, et al., 2007; Noorbala, Akhondzadeh, Tahmacebi-Pour, & Jamshidi, 2005). The occurrence of side effects including anxiety, tachycardia, nausea, dyspepsia, and appetite changes was not statistically significant compared to placebo. All of the studies thus far have been conducted by one group of researchers. Trials at other centers would help validate these encouraging findings. Evidence from one RCT suggested that saffron can reduce carbohydrate craving and help with weight loss (Gout, Bourges, & Paineau-Dubreuil, 2010). For a clinical review see Modabbernia and Akhondzadeh (2013).

Curcuma longa (Curcumin from Tumeric)

Curcuminoids from the spice, turmeric, piperine, the alkaloid that gives black pepper its taste, is used to enhance the absorption of nutrients.

A randomized double-blind placebo-controlled 8-week trial of curcumin 500 mg twice daily showed that curcumin was more effective than placebo in improving scores on the Inventory of Depressive Symptomatology and the Spielberger

State-Trait Anxiety inventory. Greater benefits were found in patients with atypical depression (Lopresti et al., 2014).

In a double-blind study, 11 adults with MDD were randomized to receive standard antidepressants or standard antidepressants augmented with curcuminoids-piperine combination 1000/10 mg/day). Reductions in BDI-II and MADRS were significantly greater in the group given curcuminoids versus control ($p < 0.001$) (Panahi et al., 2014).

Curcumin is very low in side effects, may be better absorbed in combination with piperine, and could serve as a useful add-on to standard antidepressants.

COGNITIVE FUNCTION

Disorders of cognition and memory develop from processes in which the damage to neurons compromises function and exceeds the capacity for repair. Nutrients and herbs that are neuroprotective and that support brain functions, energy production, cellular repair, and neuroplasticity will be reviewed. *Neural fatigue* or *neurasthenia* refers to a condition in which the patient experiences excess mental fatigue after a shorter than normal period of cognitive activity (resulting in reduced work capacity), increased perception of effort, and reduced endurance for sustained mental activity. It is more likely to occur under stress and/or following brain injury of any kind. Adaptogens have been shown to be particularly beneficial in patients with symptoms of neurasthenia or neural fatigue, which include a subjective sense of mental fatigue, reduced efficiency for mental tasks, and decreased work productivity (usually occurring with mental exertion), often with headache or malaise. The term *synaptic fatigue* attributes mental fatigue to depletion of presynaptic neurotransmitters, but more recently central fatigue has been linked to activation of microglia and/or increased cytokines and chemokines in the brain, implicating dysfunction in the ascending arousal system; pathways connecting basal ganglia, thalamus, limbic system, and higher cortical centers; sleep executive control areas; reward areas; and the suprachiasmatic nucleus. (Harrington, 2012).

PATHOPHYSIOLOGICAL TARGETS FOR INTEGRATIVE TREATMENTS

Nutrients and phytochemicals target mediators of the stress response, energy metabolism, neuroprotection, cellular repair, neuroplasticity, and the neuroendocrine system.

The membrane hypothesis of aging proposes that oxidative damage to cellular membranes leads to loss of permeability, increased intracellular density, accumulation of cross-linked proteins and lipofuscin (waste products), breaks in DNA, slowing of RNA synthesis, and decreased protein turnover and repair. Free radical damage to mitochondria compromises the ability of the cell to maintain sufficient energy production to sustain normal functions and to fuel cellular repair systems. Substances that have antioxidant properties or that increase production of antioxidants are candidates for prevention and treatment of age-associated cognitive and memory

Table 28.1 ANXIETY DISORDERS AND INSOMNIA IN THE MEDICAL PATIENT

	CONDITIONS/ SYMPTOMS	DOSE RANGES	SIDE EFFECTS*	DRUG INTERACTIONS	COMMENTS
NUTRIENTS					
Gamma amino-butyric acid GABA	Anxiety, stress phobias	100 mg/d	Minimal		
Magnesium	Anxiety Premenstrual syndrome	200–400 mg/d			Most studies are in combination with vitamins + minerals
Omega-3-fatty acids	Anxiety	2–4 gm/d	Belching, loose stools		EPA:DHA ratio 2:1
HERBS					
Butterbur <i>Petasites hybridus</i>	Migraines, allergic rhinitis	100 mg 2–4 times/d	Minimal	Poor quality brands may interact with CYP3A4 substrates	Use in combination with lemon balm, passion flower, valerian.
Chamomile <i>Matricaria recutita</i>	Minimal sedative Generalized Anxiety Disorder	200–1000 mg/d	Ragweed family—allergic reactions		Avoid during pregnancy
Ginkgo <i>Ginkgo biloba</i>	Anxiety depression dementia	240–280 mg/d	Minimal: headache	Anticoagulants**	Discontinue 2 weeks prior to surgery
Kava <i>Piper methysticum</i>	Anxiety, insomnia	100 mg standardized extract (70 mg kavalactones) t.i.d.	Gastrointestinal distress, allergic rash, photosensitivity, headache, Occasional: ↓ energy, drowsiness, tremor, restlessness, dystonia, hepatitis, liver failure.	↓ effects of levodopa	Avoid during pregnancy Toxicity may occur at doses > 240 mg kavalactones/d
Lemon balm <i>Melissa officianalis</i>	Anxiety, insomnia	(400–600 mg/d depending on preparation)	No serious side effects		Mild anxiolytic
Passionflower <i>Passiflora incarnate</i>	Anxiety, insomnia	500–1000 mg 2–4/d	Minimal		Mild anxiolytic

Rhodiola Arctic Root <i>Rhodiola rosea</i>	PTSD Combat stress	50–900 mg/d	Agitation, insomnia, anxiety, headache Rare: palpitations, chest pain	Doses > 750 mg/d may ↓ platelet aggregation	Can trigger mania in Bipolar disorder
St. John's wort <i>Hypericum perforatum</i>	Depression mild–mod	300–600 mg t.i.d.	Nausea, heartburn, loose bowels, jitteriness, insomnia, fatigue, bruxism, phototoxic rash, mania in bipolar.	Induces CYP 3A4, and P-glycoprotein: ↓ digoxin, warfarin, indinavir, cyclosporine, theophylline, birth control pills, anesthetics, and others.	Discontinue 2 weeks prior to surgery. Avoid during pregnancy. Evidence for use in depression is weak.
Theanine Green tea <i>Camellia sinensis</i>	Mild anxiety	200 mg 1–3x/d	Minimal	Anticoagulants	Monitor if given with anticoagulants
Valerian <i>Valeriana officianalis</i>	Sleep	450–900 mg h.s.	Occasional gastrointestinal distress, headaches, minimal hangover on high doses > 600 mg.		Avoid during pregnancy. Contraindication: hepatic disease
NEUROHORMONES					
7-keto DHEA	PTSD dissociative symptoms	25–200 mg/d	Bipolar patients may become agitated, irritable, anxious.		Contraindication: Estrogen sensitive or prostate cancer patients.
Melatonin	Sleep	1–12 mg h.s.	Occasional agitation, abdominal cramps, fatigue, dizziness, headache, vivid dreams.		Contraindication: pregnancy

*In addition to the listed side effects, rare side effects can occur. Most supplements have not been tested for safety during pregnancy and breastfeeding. Patients taking anticoagulants and those with high blood pressure, diabetes, hepatic disease, or any chronic or serious medical condition may be at increased risk for side effects and therefore require closer monitoring. Herbal side effects are more frequent with lower quality products which may contain contaminants or adulterants.

**No cases of bleeding have been reported with products containing pharmaceutical grade *Ginkgo biloba*, such as EGb761.

Key: PTSD, Posttraumatic stress disorder; EPA, eicosapentanoic acid; DHA, docosahexaenoic acid; hs, bedtime; b.i.d., twice a day; t.i.d., three times a day; gm, grams; mg, milligrams; mcg, microgram; ↓, decreases

decline as well as cerebrovascular and neurodegenerative diseases (Aliev, Palacios, & Obrenovich, 2011).

Mitochondrial energy enhancers support production of molecules such as ATP, necessary for energy transport within cells.

The *calcium hypothesis* of neuronal aging has been modified in tandem with increasing information about the role of subtle age-related changes in Ca^{2+} in mitochondrial dysfunction (Toescu & Verkhatsky, 2007). According to the *membrane hypothesis* (Long & Pekala, 1996; Zs-Nagy, 1997), reactive oxygen species damage cell membranes and organelles through lipid peroxidation that contributes to neurodegenerative disorders such as Alzheimer's (AD) and Parkinson's disease (PD).

Endothelial damage due to arteriosclerosis and free radicals leads to hypoperfusion in cerebrovascular diseases such as multi-infarct dementia and ischemic stroke. Cerebral vasodilators and antioxidants can be used to prevent or ameliorate perfusion-related problems. Membrane fluidity, which is essential for neurotransmission, enables receptors to fold and unfold for optimal opening and closing of membrane ion channels. Oxidative damage and loss of membrane n-3FAs contribute to increased membrane rigidity. Evidence suggests that sustained inflammation may also be a factor in neurodegenerative disorders such as AD and PD.

The *cholinergic hypothesis* attributes a significant role in the pathophysiology of AD to loss of cholinergic neurons resulting in synaptic changes in cerebral cortex, hippocampus, and other brain areas involved in cognitive functions (Arciniegas, 2001).

Neuroplasticity, involving changes in synaptic connectivity and neurogenesis depends on brain-derived neurotrophic factor (BDNF). BDNF and its receptor, tropomyosin receptor-related kinase B, modulate numerous neuroprotective functions. Long-term potentiation, a form of neuroplasticity, is based on increased interneuronal connectivity. N-methyl-D-aspartate (NMDA) excitatory amino acid receptors modulated by BDNF are involved in rapid connectivity changes such as long-term potentiation.

Mediators of stress response include neuropeptide Y, nitric oxide, membrane bound G-protein receptors, heat shock proteins, and others, and will be discussed in the section on Mediators of the Stress Response.

VITAMINS AND NUTRIENTS FOR COGNITIVE FUNCTION

Vitamins and trace elements are essential for energy production, brain development, cognitive function, neuroprotection, and recovery from damage (Bourre, 2006; Brown, Gerbarg, & Muskin, 2009; Brown & Gerbarg, 2011). Limited evidence suggests that a combination of Vitamins C and E may reduce the incidence of AD (Zandi et al., 2004). Synthetic vitamin E (d-alpha tocopherol) is no longer recommended for prevention of cognitive decline because a prospective study of 35,533 healthy men followed for 7 to 12 years found that the absolute increase in risk of prostate cancer per 1000 person-years was 1.6 for synthetic vitamin E (400 IU/d of all rac- α -tocopheryl acetate), 0.8 for selenium, and 0.4 for a combination of the two (Klein et al., 2011). Suboptimal vitamin D levels may be

a risk factor for cognitive decline and AD (Eyles, Burne, & McGrath, 2012; Annweiler et al., 2012). Stronger evidence supports the combined use of B vitamins, folic acid, S-adenosylmethionine, and n-3FAs in disorders of cognition, including age-related cognitive decline, dementia, AD, stroke, and traumatic brain injury.

B Vitamins, Folic Acid, S-adenosylmethionine (SAmE)

Methylation (donation of methyl groups) pathways, dependent on B vitamins and folate cofactors, are essential for synthesis of proteins, neurotransmitters, antioxidants, and other cellular components used to maintain function, membrane integrity, and repair of DNA and RNA (Bottiglieri, 1996, 2013; Hassing, Wahlin, Winblad, & Backman, 1999). SAmE, the body's most active donor of methyl groups, participates in more than 200 different biochemical reactions in humans, including three central metabolic pathways: transmethylation (donation of methyl groups, CH_3); transsulfuration (donation of sulfur); and transaminopropylation (donation of aminopropyl moieties; see Figure 28.3). Foods supply part of the body's need for SAmE, the remainder being generated by de novo synthesis from methionine and ATP—primarily in the liver, which produces 3 gms/day. SAmE levels are easily increased by oral supplementation.

Vitamin and Nutrient Formulas

Three studies using a vitamin/nutrient formula (NF) containing folic acid 400 mcg, B₁₂ 6 mcg, vitamin E alpha-tocopherol 30 IU, S-adenosylmethionine 400 mg, N-acetylcysteine 600 mg, and acetyl-L-carnitine 500 mg found positive effects on cognitive function. A DBRPC study of 115 community-dwelling adults aged 22–73 years without dementia found that after 2 weeks, the test scores of subjects taking NF improved significantly on the California Verbal Learning Test II (CLVT) and the Trail-making Test compared with those on placebo. This was followed by a 3-month open-label extension during which those taking NF showed additional improvement. During a 3-month discontinuation of NF, test measures reverted to baseline. Resumption of NF restored improvements (Chan et al., 2010). A 12-month open label study of the same NF given to 14 community-dwelling adults with early-stage AD rated mild to moderate on the Dementia Rating Scale (DRS) found that within 6 months, total performance on DRS improved significantly by about 30% ($p < .02$) with improvements maintained at 12 months (Chan, Paskavitz, Remington, Rasmussen, & Shea, 2008). Another DBRPC study of NF in 12 institutionalized patients with moderate to late-stage AD showed that those given the NF had clinically significant delay in decline on DRS and on the Clock Drawing Test (CLOX 1 and 2) over a period of 9 months compared to those given placebo (Remington, Chan, Paskavitz, & Shea, 2009). These small studies are promising but should be interpreted with some caution pending validation by large studies done by other research groups. Given recent controversy regarding increased risk of prostate cancer in men taking vitamin E, the vitamin/nutrient formula

may need to be modified. The composition of vitamin/nutrient/herbal formulas (VNHF) could include constituents that target as many as possible of the relevant pathophysiological mechanisms described above to optimize synergistic effects.

B Vitamins and Antioxidants

Combining B vitamins with antioxidants may be more effective than either alone. However, there may be differences in the absorption and activity of natural vitamins compared to synthetic. For example, natural folate is absorbed less than synthetic. The authors prefer to use a product called Bio-Strath containing natural vitamins produced by yeast cultivated with vitamin enriched nutrients. In a 3-month DBRPC trial, Bio-Strath (B vitamin + antioxidants) at double the usual adult dose was given to 75 patients aged 55–85 years with mild dementia. The placebo group deteriorated while the Bio-Strath group showed improvement in short-term memory with physical and emotional benefits at 3 months (Pelka & Leuchtgens, 1995). For geriatric patients with neurodegenerative disorders and cognitive decline, studies suggest a dose of 2 tablets three times a day or 1 tablespoon twice a day of the liquid preparation. In healthy adults, 3 tablets twice a day or 1 teaspoon three times daily is usually sufficient. Alternatively, patients can be treated with folic acid 400–800 mcg/day, B₁₂ 500 mcg/day (preferably sublingual), and B₆ in the range of 25 mg/day. Considering the importance of B vitamins for cognitive function and the low incidence of side effects, the authors use them in the treatment of patients with brain injury, dementia, and many other conditions affecting brain function. Sublingual B₁₂ is better absorbed than oral capsules, particularly in patients with impaired gastrointestinal absorption. Serum methylmalonic acid is a more accurate measure of intracellular B₁₂ than serum B₁₂.

In some studies folic acid, B₁₂, and B₆ have been found to lower homocysteine levels. A review of the literature found the evidence on the homocysteine-lowering effect of folic acid and B vitamin therapy in coronary artery restenosis to be contradictory (van Hattum, Doevendans, & Moll, 2007). In a 7-month DBRPC study of 205 patients following balloon angioplasty, among those treated with folic acid and B vitamins the rate of restenosis in subjects without stents was 10.3% versus placebo 41.9% ($p < 0.001$); in subjects with stents it was 20.6% versus 29.9% ($p = 0.32$) respectively (Schnyder et al., 2001). A 6-month DBRPC study of coronary stent replacement in 636 patients found that reduction in restenosis was associated with the lowering of homocysteine by folic acid and B vitamins, the greatest reductions occurring in women and men with baseline homocysteine levels above 15 $\mu\text{M/L}$. However, an 8% increase in the rate of restenosis was found only in men (not in women) with baseline homocysteine levels less than 15 $\mu\text{M/L}$, who were given folic acid with B₁₂ and B₆ supplementation (Lange et al., 2004). No study reported a significant difference in cardiovascular events in patients treated with folic acid versus placebo. There does not appear to be any increased risk of vascular occlusion in individuals who take folic acid and B vitamins and who do not have cardiac stents.

Omega-3 Fatty Acids (n-3FAs)

Polyunsaturated fatty acids (PUFAs), including the n-3FAs, DHA, EPA, and AA are necessary to maintain cell membrane function and the production of molecules involved in inflammatory modulation (Bourre, 2005). It is preferable to take a 1000mg/day blend of EPA and DHA in a 2:1 ratio. For mechanisms of action, dosages, and side effects, see the section on Omega-3 Fatty Acids for Depression and Bipolar Disorder.

Low levels of n-3FAs have been found in patients with dementia and AD. In an 8-year prospective study of 1,200 elderly subjects, those with low serum DHA had a 67% greater chance of developing AD than those with high DHA (Kyle & Arterburn, 1998). A 5-year prospective study of 210 healthy men aged 70–89 years found that those who ate fish equivalent to EPA/DHA 400 mg/day had slower cognitive decline than those who did not (van Gelder, Tijhuis, Kalmijn, & Kromhout, 2007). Another study of 2251 older adults found less decline in verbal ability in those with higher serum levels of EPA/DHA, especially in those with high blood pressure and high lipid levels (Beydoun, Kaufman, Satia, Rosamond, & Folsom, 2007).

DHA supplementation improved neurological symptoms in Alzheimer's patients (Nidecker, 1997). In a DBRPC study of 174 very mildly impaired Alzheimer's disease patients, 600 mg EPA slowed cognitive decline over a 6-month period (Freund-Levi et al., 2006). More studies are needed to confirm the neuroprotective effects of antioxidants and n-3FAs in patients with neurodegenerative conditions. Patients unwilling to eat fish regularly can be encouraged to take fish oil or flax oil capsules. In general, fish oils are preferable because only a fraction of the linolenic acid in flax oil gets converted into DHA. Credible evidence suggests that PUFAs enhance cognitive development and protect against neurodegeneration. While increasing dietary unsaturated nonhydrogenated fats may lower the risk of AD, large amounts of saturated trans fats increase the risk of AD (Morris et al., 2003).

Phosphatidylserine

Phosphatidylserine (Ptd Ser) is a naturally occurring phospholipid thought to contribute to nerve cell membrane fluidity. DBRPC studies of bovine-derived Ptd Ser (containing high amounts of DHA) showing modest memory improvements in age-associated memory decline have been reported with bovine Ptd Ser. However, the risk of acquiring prions, an infectious agent composed of misfolded protein from animals with Mad Cow disease, has not been assessed. At this time we advise limiting the use of Ptd Ser to products derived from fish, soy beans, or cows raised in New Zealand and Australia where surveillance for prion-related diseases is carefully regulated. Ptd Ser may be safer when derived from cow blood as opposed to neural tissues or organs where prions accumulate. Although studies of soy-derived Ptd Ser are limited, it appears to be of some benefit. Ptd Ser is often combined with other nutrients such as ginkgo (McDaniel, Maier, & Einstein, 2003). In clinical practice, soy-derived Ptd Ser may be a useful complementary treatment for age-associated

Table 28.2 MOOD DISORDERS IN THE MEDICAL PATIENT

	CONDITIONS/SYMPTOMS	DOSE RANGES	SIDE EFFECTS*	DRUG INTERACTIONS	COMMENTS
NUTRIENTS					
B vitamins	Depression Energy	B ₁₂ 1,000 mcg	Rare: activation		
Cholecalciferol Vitamin D3	Depression	2,000–6,000 IU/d			Use in vitamin D deficient patients
Folic acid L-methylfolate	Depression Depression	400 mcg/d 75–15 mg/d			8% ↑ risk occlusion cardiac stents men with baseline homocysteine < 15 mM/L** Use L-methylfolate for MTHFR polymorphisms
5-hydroxytryptophan 5-HTP	Depression	200–300 mg/d	Headache, insomnia, nausea, vomiting, diarrhea		
Inositol	Depression	12–20 g	Gas, loose bowels, mania		Caution: Bipolar
Choline	Mania	2,000–7,200 mg	Excess doses: depression		
N-acetylcysteine (NAC)	Bipolar depression and mania	2,400–3,600 mg/d	Rare: heartburn when taken on empty stomach		Response may take 8–12 weeks
Omega-3-fatty acids	Depression Bipolar depression	1–9 gm/day	Belching, loose stools, nausea, abdominal pain	Anticoagulants –monitor	EPA:DHA 2:1
S-adenosyl-L-methionine (SAMe)	Depression mild to severe Arthritis, fibromyalgia, liver disease Liver diseases Parkinson's depression	400–1,600mg/d 800–1,200 mg/d 800–1,200 mg/d 1,600–4,800 mg/d	Nausea, loose bowels, activation, anxiety, headache, occasional palpitations	None Use to augment other antidepressants	Can trigger mania in Bipolar
HERBS					
Eleuthero, Acanthopanax <i>Eleutherococcus senticosus</i>	Augmentation in depression and bipolar	750 mg t.i.d.	Minimal		
Rhodiola Arctic Root <i>Rhodiola rosea</i>	Depression, fatigue, amotivation Augment other antidepressants	50–900 mg/d	Agitation, insomnia, anxiety, headache. Rarely: palpitations, chest pain	Doses > 750 mg/d may affect platelet aggregation and ↑ bruising	Caution in Bipolar
Saffron <i>Crocus sativa</i>	Depression	88.25 mg 2–4 caps/d	Minimal Anticoagulants		Optimized saffron
St. John's wort <i>Hypericum perforatum</i>	Depression mild–moderate Seasonal affective disorder Somatoform	300–600 mg t.i.d.	Nausea, heartburn, loose bowels, jitteriness, insomnia, fatigue, bruxism, phototoxic rash, mania in bipolar patients, restless leg syndrome.	Induces CYP 3A4 and P-glycoprotein: ↓ digoxin, warfarin, indinavir, cyclosporine, theophylline, birth control pills, anaesthetics and other medications. Serotonin syndrome	Discontinue 2 weeks prior to surgery. Avoid during pregnancy.

* In addition to the listed side effects, rare side effects can occur. Most supplements have not been tested for safety during pregnancy and breastfeeding. Patients taking anticoagulants and those with high blood pressure, diabetes, hepatic disease, or any chronic or serious medical condition may be at increased risk for side effects and therefore require closer monitoring. Herbal side effects are more frequent with lower quality products which may contain contaminants or adulterants.

** Folate + B₁₂ + B₆ reduce the rate of cardiac stent restenosis in women and in men with baseline homocysteine level >15 mM/L.

Table Key: b.i.d., twice a day; t.i.d., three times a day; gm, grams; mg, milligrams; mcg, microgram; IU, International Units; ↑, increases; ↓, decreases; <, less than; >, more than

memory decline but not for more severe memory disorders. A marine source of PtS with omega-3 long chain polyunsaturated fatty acids attached to its backbone, PS-DHA, was used in a 15-week DBRPC study of 157 nondemented elderly persons with memory complaints. Those who received PS-DHA (300 mg PS/day) showed significant improvements in immediate verbal recall. Those with higher baseline cognitive status had additional improvements in delayed verbal recall, learning abilities, and time to copy figures (Vakhapova, Richter, Cohen, Herzog, & Korczyn, 2011).

Mitochondrial Energy Production and Antioxidant Protection

Substances that support mitochondrial ATP-producing electron transport help maintain adequate energy supplies for cellular function, production of antioxidants, cellular repair, and neurogenesis.

Acetyl-L-Carnitine and Propionyl-L-Carnitine

Derivatives of carnitine, an essential nutrient, improve mitochondrial function and reduce oxidative damage. Acetyl-L-carnitine (ALC) facilitates acetyl coenzyme A uptake into mitochondria during fatty acid oxidation and increases energy production via the oxidative phosphorylation chain (Pettegrew, Levine, & McClure, 2000; Abdul Muneer, Alikunju, Szlachetka, & Haorah, 2011). Malaguarrera (2012) reviewed preclinical and clinical studies of ALC, PLC, and other carnitines. Positive effects of ALC were reported in diabetic, antiretroviral, and chemotherapy-induced neuropathies, insulin resistance, hypertension, Peyronie's disease, coronary artery disease, hepatic encephalopathy, sperm motility, and fibromyalgia. In animal models, ALC was neuroprotective and enhanced recovery from stroke (Lolic, Fiskum, & Rosenthal, 1997). In a study of oxidative toxicity using 4-hydroxy-2-nonenal, ALC plus alpha-lipoic acid (see below) protected rat cortical neurons from protein oxidation, lipid peroxidation, antioxidant depletion, and apoptosis (Abdul & Butterfield, 2007). ALC protected neurons from ethanol-induced oxidative injury in animal brain tissue slices (Rump et al., 2010). In an in vitro study of human brain endothelial cells, ALC stabilized superoxide dismutase (antioxidant preventing mitochondrial membrane damage) and protected the blood-brain barrier, brain vascular tone, and vasodilation (Haorah, Floreani, Knipe, & Persidsky, 2011). ALC may be more effective in delaying age-related deterioration of mitochondria when combined with alpha-lipoic acid, CoQ10, and essential fatty acids (Di Donato et al., 1986; Lolic, Fiskum, & Rosenthal, 1997). Alcar showed modest slowing of the development of AD in subjects 60 years of age or younger (Brooks, Yesavage, Carta, & Bravi, 1998). In a DBPC study of 12 elderly subjects with cerebral vascular disease, alcar improved reaction time, memory, and cognitive performance (Arrigo, Casale, Buonocore, & Ciano, 1990). Alcar 1500 mg administered intravenously increased regional cerebral blood flow in 8 out of 10 men with cerebral ischemia (Rosadini, Marengo, Nobili, Novellone, & Rodriguez, 1990). Although studies of ALC in AD are weak, it may have a role in prevention

or in augmentation of cholinesterase inhibitors in mild AD (Bianchetti, Rozzini, & Trabucchi, 2003). In patients with TBI and cerebrovascular disease, the authors find that ALC 1500 mg twice daily often improves energy and cognitive function within 2 weeks. ALC is low-risk and has few side effects. Rarely, it may trigger mania in bipolar patients.

Alpha-Lipoic Acid

Alpha-lipoic acid (ALA), a metabolic antioxidant, has been used as a prescription drug in Europe for treatment of cardiac autonomic problems related to diabetic neuropathy as well as other consequences of diabetes. Neuroprotective effects have been described in cerebral ischemia/reperfusion animal models, excitotoxic amino acid brain injury, mitochondrial dysfunction, diabetic neuropathy, inborn errors of metabolism, and other causes of acute or chronic damage to nerve tissue including excess levels of iron, copper, or other metals (Packer & Colman, 1999). ALA and CoQ-10 may be helpful in poststroke recovery and ischemic heart disease. ALA generates large amounts of glutathione in animal brain models (similar to SAME). For patients who cannot afford SAME, ALA in combination with vinpocetine (cerebral vasodilator) can be helpful when ischemia is a major factor and in other brain injuries. The authors find an ALA dose of 300 mg three times daily to be useful in TBI.

Coenzyme Q-10 (Idebenone)

Coenzyme Q10 (CoQ10, idebenone) enhances ATP-producing mitochondrial electron transport (Gillis, Benefield, & McTavish, 1994; Matsumoto et al., 1998). CoQ10 variants which enhance both cellular energy production and antioxidant defense are of interest for prevention and treatment of neurodegenerative, cerebrovascular, and cardiovascular diseases. In clinical practice the authors find that sluggish, psychomotor-retarded patients respond well to idebenone, which improves alertness. For individuals who become overstimulated by prescription cholinesterase inhibitors (e.g., donepezil, Aricept), idebenone serves as a less stimulating alternative. Combined with other supplements, it is particularly useful in cerebrovascular disease (e.g., multi-infarct dementia) and disorders of mitochondrial function (e.g., Friedreich's Ataxia) (Brown & Gerbarg, 2011). Ubiquinol, a reduced form of CoQ10, is an effective antioxidant protecting membranes from peroxidation. Muscle biopsies from patients with myopathies (e.g., myofiber atrophy and muscular dystrophy) showed significant positive correlations between CoQ10 and ubiquinone concentrations versus the percentage of myofibrils containing mitochondrial aggregates (Miles et al., 2005). The authors find ubiquinol to be beneficial in treating statin-induced myopathy.

Creatine

Creatine enhances cellular energy production in brain injury, muscular dystrophy, and other mitochondrial cytopathies (Brown & Gerbarg, 2011). Phosphorylated creatine provides a phosphate group in the conversion of ADP to ATP. In an open-label RCT pilot study, 39 children with TBI were

Table 28.3 COGNITIVE DISORDERS IN THE MEDICAL PATIENT

	CONDITIONS/SYMPTOMS	DOSE RANGES	SIDE EFFECTS*	DRUG INTERACTIONS	COMMENTS
NUTRIENTS					
Acetyl-L-carnitine ALCAR	TBI, AD, CVA, CVD, Alzheimers, fatigue, energy, alertness	500 mg b.i.d. starting dose Up to maximum dose 1,500 mg b.i.d.	Mild gastric upset, heartburn.	None	May slow progression of AD Take with food.
Alpha-lipoic acid	CVD, TBI, ischemia	300 mg t.i.d			
(Apoaequorin Synthetic jelly fish protein)	TBI, memory	10–40 mg/day	Headache, drowsiness, allergic reactions	Unknown	One RCT (n = 218)
B-vitamins	TBI, stroke, dementia, cognitive decline Neurodegenerative disorders, energy	B ₁₂ 1,000 mcg	Rare: activation		
Centrophenoxine (Meclophenoxate)	TBI, Alzheimers Memory, alertness, focus	250 mg b.i.d starting dose Up to maximum dose 1,000 mg b.i.d.	Minimal, gastric upset, heartburn	When combined with other cholinergic agents: headache, muscle tension, insomnia, irritability, agitation, facial tics	
Citicholine CDP-Choline	CVD, TBI, acute ischemic stroke, ischemia, multi-infarct dementia	1,000–7,200 mg/d	Occasional: agitation Excess doses: depression		
Coenzyme Q10 Ubiquinol	CVD, TBI, Alzheimers, Neurodegenerative disease	270–900 mg/d	None		Less stimulating alternative to cholinesterase inhibitors
Creatine	TBI, memory, cognition, focus	0.4 gm/kg/d 5000 mg q.i.d for 5 days, then 5000 mg b.i.d.	Minimal		One study positive effects in children
Folic acid L-methylfolate	Depression, memory, cognition Depression, memory, cognition	400 mcg/d 7.5–15 mg/d			8% ↑ risk occlusion of cardiac stents in men with baseline homocysteine level < 15 mM/L**
L-Deprenyl	CVD, TBI, Alzheimers, Parkinsons's, cognitive, memory, preventive	2.5–5 mg/d	Minimal	None	<10 mg/d has no significant MAOI effect
Omega-3-fatty acids	Alzheimer's, neurodegeneration	2,000–3,000 mg/d	Belching, loose stools, nausea, abdominal pain	Anticoagulants: monitor	EFA:DHA ratio 2:1
Phosphatidyl serine	AAMI	Loading dose 300 mg/d for 1 month, Then 100 mg/d	Minimal	None	

Picamilon	TBI, CVA, CVD, ischemia, Parkinsons, toxic brain lesions	50 mg b.i.d. up to 100 mg t.i.d.	High dose: postural hypotension		In CVD improves alertness, confusion, anxiety, depression
Pyrrolodones Racetams aniracetam, piracetam, pramiracetam	Poststroke aphasia, dyslexia Med-related cognitive impairment	aniracetam 750 mg b.i.d.	Minimal. Rarely: anxiety, insomnia, agitation, irritability, headache		Safe in children
S-adenosyl-L-methionine (SAME)	Alzheimer's, Parkinson's TBI Depression Arthritis, liver diseases	400–4,000 mg/d in divided doses 400–1,600 mg/d 1,200–1,600 mg/d	Nausea, loose bowels, activation, anxiety, headache, occasional palpitations	Combines well and augments all classes of antidepressants tested. Give with L-dopa to reverse depletion of SAMe	
HERBS					
Eleuthero, Acanthopanax <i>Eleutherococcus senticosus</i>	Fatigue, alertness	750 mg t.i.d.	Uncommon: diarrhea, dizziness, insomnia, headache, hypertension, irregular or rapid heart beat	Interferes with some digoxin tests, but does not lower digoxin levels	Combine with R. rosea and other adaptogens
Galantamine <i>Galanthus nivalis</i>	Alzheimers, TBI, CVD	8–32 mg/d	Mild nausea, GI upset		
<i>Ginkgo biloba</i>	Neuropsychiatric symptoms in AAMI, MCI, CVD, VAD, Alzheimers. Attention, memory. Peripheral vascular disease, claudication. Vascular related vertigo and tinnitus.	60–120 mg b.i.d.	Minimal, headache, gastrointestinal upset, nausea, ↓ platelet aggregation. Rare agitation, allergic reactions. Reported cases of bleeding not confirmed by recent reviews**	Monitor with anticoagulants and antiplatelet drugs** Anesthetics	Combine with acetylcholinesterase inhibitors for better effect in demementia. Discontinue 2 weeks prior to surgery.
Ginseng <i>Panax ginseng</i>	Dementia, cognitive function, alertness, focus, neurasthenia	300–800 mg/d	Activation, gastrointestinal, anxiety, insomnia, tachycardia, ↓ platelet aggregation, diarrhea. Hormonal: vaginal bleeding, swollen breasts. Excess doses: headache, vomiting, nervousness. Doses > 3 gm/d may have toxic effects: ↑ blood pressure, agitation, confusion	Anticoagulants, steroids, MAOIs	For CVA, TBI: better combined with adaptogens. Caution: Bipolar, hypertension. Contraindication: hormone sensitive cancers.
Huperzine	Alzheimers, AAMI, TBI, vascular dementia	200–400 mcg/d	Minimal		
Maca <i>Lepidium myenii</i>	Neural fatigue, memory, hearing, energy	Approximately 750 mg t.i.d. (dose depends on preparation)	Occasional: overactivation, jitteriness, insomnia, headache		Human studies are needed. Contraindication: hormone sensitive cancers.

(continued)

Table 28.3 (CONTINUED)

	CONDITIONS/SYMPTOMS	DOSE RANGES	SIDE EFFECTS*	DRUG INTERACTIONS	COMMENTS
Rhodiola Arctic Root <i>Rhodiola rosea</i>	TBI, post CNS infection (e.g., Neuro-Lyme), post stroke, dementia for cognitive recovery and memory	50–900 mg/d	Occasional: Agitation, insomnia, anxiety, headache Rare: palpitations, chest pain	Doses >750 mg/d may ↓ platelet aggregation. Additive effects with other stimulants (eg. caffeine)	Caution in Bipolar: may benefit depression but may exacerbate mania
Saffron	Mild–moderate Alzheimers, cognition, ↓ agitation	88.25 mg 2–4 caps/d	Minimal	Anticoagulants	Optimized saffron
Schizandra <i>Schizandra chinensis</i>	Concentration, energy, agitation	110–200 mg/d	Heartburn, acid indigestion, stomach pain, allergic rashes		Emotional calming
St. John's wort <i>Hypericum perforatum</i>	Depression mild–moderate	300–600 mg t.i.d.	Nausea, heartburn, loose bowels, jitteriness, insomnia, fatigue, bruxism, phototoxic rash, mania in bipolar.	Induces CYP 3A4, and P-glycoprotein: ↓ digoxin, warfarin, indivir, cyclosporine, birth control pills, anesthetics, theophylline, and others.	Discontinue 2 weeks prior to surgery. Avoid during pregnancy.
Vinpocetine Snowdrop <i>Vinca minor</i>	CVA, CVD, ischemia	10 mg t.i.d.	Mild indigestion, nausea, dizziness, anxiety, facial flushing, insomnia, headache, drowsiness and dry mouth	Monitor closely with agents that ↓ platelet aggregation	
NEUROHORMONES					
Dehydro- epiandrosterone DHEA	Cognitive, memory	25–100 mg/d	Mild insomnia, irritability. Bipolar patients may become agitated, irritable, or anxious.	Steroids	Pharmaceutical grade is best. Benefits patients with low or low normal baseline DHEA levels. Contraindications: Estrogen sensitive or prostate cancer
Melatonin	Sleep, 'sundowning'	1–12 mg h.s.	Occasional agitation, abdominal cramps, fatigue, dizziness, headache, vivid dreams.		Avoid during pregnancy
<p>* In addition to the listed side effects, rare side effects can occur. Most supplements have not been tested for safety during pregnancy or breastfeeding. Patients taking anticoagulants and those with high blood pressure, diabetes, hepatic disease, or any chronic or serious medical condition may be at increased risk for side effects and therefore require closer monitoring. Herbal side effects are more frequent with lower quality products which may contain contaminants or adulterants.</p> <p>** Folate + B₁₂ + B₆ may increase the rate of cardiac stent restenosis in in men only with baseline homocysteine level <15 mM/L.</p> <p>***Recent trials with pharmaceutical grade <i>Ginkgo biloba</i>, EGb761 do not confirm earlier reports of bleeding (Diamond, 2013).</p> <p>Table Key: AAMI, Age Associated Memory Impairment; CVD, cerebrovascular disease; CVA, cerebrovascular accident; MCI, minimal cognitive impairment; TBI, traumatic brain injury; VAD, vascular dementia; h.s., bedtime; b.i.d., twice a day; t.i.d., three times a day; g, grams; mg, milligrams; mcg, microgram; ↓, decreases; ↑, increases; <, less than; >, more than.</p>					

randomized to standard treatment alone versus standard treatment plus creatine for 6 months. The duration of posttraumatic amnesia, intubation, and ICU stay were reduced in children treated with 0.4 g/kg/day creatine. Those given creatine showed significant improvement in headaches, dizziness, and fatigue compared with the standard treatment only group (Sakellaris et al., 2008). The authors note that creatine can ameliorate neural fatigue, dizziness, and headaches in TBI patients.

Cholinergic Enhancing Treatments

Cholinergic deficits underlie the main symptoms of AD. Treatments that enhance cholinergic transmission—by protecting cholinergic neurons, increasing availability of choline (precursor of acetyl choline), or reducing breakdown of acetyl choline (ACh)—improve cognitive function and delay deterioration in some studies of cerebrovascular accidents, AD, and other dementias and brain disorders (Akhondzadeh, Gerbarg, & Brown, 2013). Plant-derived alkaloid extracts that act as acetyl cholinesterase inhibitors (AChEI) are discussed in Herbal Treatments for Cognitive Dysfunction.

Citicoline (CDP-choline, Cch)

Cytidine 5'-diphosphocholine (CDP-choline), a phospholipid cholinergic precursor used to treat stroke, dementia, and brain injury (Alvarez et al., 1999) is well absorbed, crosses the blood-brain barrier, and breaks down into choline and cytidine (a ribonucleoside). Acetyl coenzyme A and choline form the neurotransmitter acetyl choline. Choline is incorporated into cell membrane phospholipids, improves mitochondrial metabolism, increases ATP levels and synthesis of phospholipids, reduces glutamate release, and raises levels of norepinephrine, dopamine, and 5HT. In animal models it alleviates cerebral hypoxia and protects against ischemia, edema, and neuronal death in the cerebral cortex, forebrain, and hippocampus (Baskaya, Dogan, Rao, & Dempsey, 2000; Hurtado et al., 2005; Rao, Hatcher, & Dempsey, 1999). In rat brain injury and aging models, CDP-choline improved memory and cognitive performance and potentiated neuroplasticity (Dixon, Ma, & Marion, 1997).

A 6-week study of 214 patients with acute middle cerebral artery ischemic stroke found that those given CDP-choline within the first 24 hours showed significantly less enlargement in lesion volume on repeat MRI 12 weeks after the stroke (Mitka, 2002). Meta-analysis of controlled trials of CDP-choline by the Cochrane Stroke Review Group concluded that there is some evidence that CDP-choline has positive effects on memory and behavior in the short to medium term in cerebral disorders in the elderly (Fioravanti & Yanagi, 2005). It may be necessary to start CDP-choline within 24 hours of stroke onset for benefits to occur (Parnetti, Mignini, Tomassoni, Traini, & Amenta, 2007). In a review of 4 trials with a total of 1,472 patients, oral CDP-choline improved recovery when started within 24 hours of the onset of stroke symptoms. Maintenance on CDP-choline in first-stroke patients for 6 months prevented cognitive decline and improved temporal orientation, attention, and executive functions (Alvarez-Sabin & Roman, 2011). A review of eight

studies (including three DBRPC trials) of TBI found evidence of acute and long-term benefits (Arenth, Russell, Ricker, H., & Zafonte, 2011). Davalos and colleagues (2012) conducted a 6-week multicenter DBRPC of CDP-choline 2000 mg/day in patients ($n = 2,298$) with moderate to severe acute ischemic stroke. Unlike previous studies, patients given CDP-choline did not have better outcomes than the placebo group. A subgroup analysis revealed better outcomes with CDP-choline in patients above 70 years old, those with moderate stroke severity, and those who were not being given a fibrinolytic (Davalos et al., 2012). A review of choline in mental and behavioral disorders by Akhondzadeh and colleagues pointed out that the multicenter study by Davalos used a dose of 2000 mg/day CDP-choline, which could have been subtherapeutic in comparison to findings from previous studies that doses greater than 2000 mg/day had greater efficacy (Akhondzadeh, Gerbarg, & Brown, 2013). Moreover, the duration (6 weeks) was short considering that benefits are generally seen 9–12 weeks after the initiation of treatment. A comprehensive review of drug surveillance studies in over 4,000 acute ischemic stroke patients concluded that CDP-choline was associated with better outcomes than standard treatment alone (Cho & Kim, 2009; Leon-Jimenez et al., 2010). CDP-choline is safe with virtually no side effects.

Cerebral Vasodilators

Picamilon

Picamilon, a cerebral vasodilator, is composed of GABA and Vitamin B₃ (niacin). Vasodilation through reduction of smooth muscle tone in the walls of cerebral blood vessels increases cerebral blood flow (Mirzoian, Gan'shina, Kosoi, Aleksandrin, & Aleksandrin, 1989). Picamilon has both a mild tranquilizing action that can reduce aggressive behavior and a mild stimulative action that can improve alertness and cognitive function. Picamilon readily crosses the blood-brain barrier (Dorofeev & Kholodov 1991) and has low toxicity in animal experiments (median lethal oral dose >10 g/kg of body weight). Large open clinical trials in 16 medical centers in Russia, using picamilon 20-50 mg 2 to 3 times a day in treatments ranging from 2 weeks to 3 months, showed the best results in patients with organic brain syndromes due to head trauma, cerebral atherosclerosis, and toxic brain lesions (Kruglikova, 1997). Controlled trials are warranted. In clinical practice the authors find picamilon to be beneficial in patients with cerebral vascular impairment, particularly with decreased alertness, confusion, anxiety, and depression as the following case illustrates.

CASE STUDY: 80 YEAR-OLD WOMAN WITH CEREBRAL INSUFFICIENCY RESPONDS TO CEREBRAL VASODILATOR

An active 80-year-old, Joyce managed her home, balanced the checkbook, and drove herself to the grocery store, church, and volunteer activities. Her mild bipolar disorder was well controlled with quetiapine 50 mg h.s. until she required surgery for hernia repair. After awakening from anesthesia, Joyce was in a

confusional state that persisted for 4 weeks after leaving the hospital. Her family took shifts caring for her, as she tended to sit for hours doing nothing unless prompted. Usually outspoken, her responses dwindled to a few barely audible words. Based on an fMRI showing reduced perfusion and the possibility that surgical anesthesia had further compromised cerebral circulation, she was treated with a cerebral vasodilator, picamilon 100 mg twice daily. Two days into treatment she began to improve. At follow-up three 3 weeks later Joyce was talkative, oriented, and reengaged in her previous activities. Nine months later, the patient's family brought her for re-evaluation of recurrent symptoms of confusion, reduced activity and paucity of speech. Joyce had stopped taking picamilon four weeks earlier when her supply ran out. Once she resumed taking the cerebral vasodilator, all of these symptoms remitted within two weeks.

Apoeaquorin (Aequorea Victoria)

Apoeaquorin is a calcium binding protein first isolated from jellyfish (*Aequorea victoria*). Potassium calcium channels in smooth muscle and endothelial cells are involved in regulation of vascular tone. Vascular dysfunction during ischemia reperfusion is associated with modulations of potassium and calcium. A company that marketings apoeaquorin conducted a 90-day DBRPC study in 218 adults aged 40 to 91 years with self-reported memory issues. Compared to placebo, subjects given apoeaquorin showed significant improvements on tests of recall performance, executive functioning, memory, delayed recall, and verbal learning. The study reported no adverse events and good tolerability (Underwood, Sivesind, Gabourie, & Lerner, 2011). Peer-reviewed studies by research groups are needed to evaluate apoeaquorin as a potential treatment for cognitive and memory decline. However, in light of the low risks, clinicians could offer patients the option of a 3-month to 6-month trial in doses of 10, 20, or 40 mg/day.

HERBAL TREATMENTS FOR COGNITIVE DYSFUNCTION

Medicinal plants contain bioactive substances in the roots, leaves, flowers, and fruit. Unlike most synthetic drugs with one target of action, the presence of numerous medicinal compounds within one herb results in multiple effects. While the active constituents have been identified in some herbs, in others they have not. Moreover, the synergistic effects of constituents can be more powerful than any one alone. See the excellent review by Howes and Perry on the mechanisms of action and the use of phytochemicals in prevention and treatment of dementia (Howes & Perry, 2011). In vitro and animal studies are shedding light on physiological and genetic aspects of herbal medicines. For example, the cognitive enhancing effects observed with galantamine and huperzine may be due to potentiation of cholinergic and NMDA activity (Narahashi, Moriguchi, Zhao, Marszalec, & Yeh, 2004).

Huperzia serrata (Huperzine-A)

Huperzine-A, an alkaloid derived from Chinese club moss (*Huperzia serrata*) is a strong, selective, reversible AChEI

with neuroprotective properties including protection against hydrogen peroxide free radicals, B-amyloid protein formation, glutamate, and ischemia (Zhao et al., 2011). It protects mitochondria, reduces oxidative stress, and upregulates nerve growth factor. Huperzine-A is rapidly absorbed, readily penetrates the blood-brain barrier, and has a relatively long duration of AChE inhibitory action. In animal and primate studies it improves learning and memory (Tang, 1996). Three DBRCTs with more than 450 people and one open trial done in China showed significant benefits in AD. Four trials in vascular dementia and AD, using huperzine-A in combination with other medicines, niger-goline (a nootropic antiinflammatory that upregulates neurotrophic factors in glial cells), and estrogen compounds or mental training, showed favorable outcomes. In a DBRPC study of 78 patients with mild to moderate vascular dementia (VaD), those given Huperzine A 0.1 mg twice daily significantly improved in scores on the Mini Mental Status Exam (MMSE), clinical dementia rating, and activities of daily living after 12 weeks ($p < .01$). No significant adverse events occurred (Xu et al., 2011). A 16-week DBRPC study of 210 individuals with mild-to-moderate AD reported cognitive enhancement only at doses above 0.4 mg/day at week 16 (Rafii et al., 2011). Other trials showed positive outcomes in vascular dementia, TBI, age-associate memory decline, and schizophrenia (Akhondzadeh & Abbasi, 2006; Wang, Yan, & Tang, 2006). Huperzine-A is well tolerated with few side effects and minimal peripheral cholinergic effects.

Galanthus nivalis (Snowdrop) Galantamine

An alkaloid extract of snowdrop (*Galanthus nivalis*) was used in folk medicines of Russia and Eastern Europe to preserve memory as people aged. Galantamine, FDA-approved for treatment of AD, is an allosteric modulator of nicotinic receptors and a weak inhibitor of acetylcholinesterase (Raskind, Peskind, Wessel, & Yuan, 2000). In an open-label study, 280 AD patients included in the Swedish Alzheimer Treatment Study were given galantamine starting with 8 mg/day and gradually increasing to 16 mg/day at 4 weeks and then 24 mg/day as tolerated. After 3 years, subjects had mean increases of 2.6 points on the MMSE and 5.6 points in Alzheimer's Disease Assessment Scale-Cognitive (ADAS-cog) (Wallin, Wattmo, & Minthon 2011). Many patients do not tolerate the gastrointestinal disturbances caused by prescription galantamine or donepezil. In the author's (RPB) clinical experience, the herbal extract of *Galanthus nivalis* combined with *R. rosea* can be as effective as galantamine and more tolerable.

Vinpocetine from *Vinca minor* (the Lesser Periwinkle)

Vinpocetine (ethylapovincaminatate), is a semisynthetic ethylester of an alkaloid extract from leaves of the lesser periwinkle (*Vinca minor*). As a cerebrovascular vasodilator, it has been used for treatment of cerebrovascular disorders. Studies show neuroprotectant and anticonvulsant activity through inhibition of calcium/

calmodulin–dependent cyclic guanosine monophosphate-phosphodiesterase, enhancing intracellular cyclic guanosine monophosphate levels in vascular smooth muscle, reducing resistance of cerebral blood vessels, and increasing blood flow without significantly affecting blood pressure or peripheral vascular resistance (Patyar, Prakash, Modi, & Medhi, 2011). Vinpocetine inhibits the molecular cascade caused by the rise of intracellular calcium and selectively inhibits voltage-sensitive sodium channels, reducing excess extracellular calcium associated with ischemia/reperfusion, edema, and glutamate toxicity (Brown & Gerbarg, 2011; Patyar et al., 2011). It scavenges hydroxyl radicals, inhibits IKB kinase complex, inhibits platelet aggregation, and increases erythrocyte deformability, reducing blood viscosity and further enhancing blood flow. Stimulation of locus ceruleus neurons may enhance alertness, concentration and information processing. In a DBRPC study of 43 stroke patients, transcranial Doppler and near infrared spectroscopy showed that vinpocetine improved cerebral perfusion in the peristroke area (Bönöczk et al., 2002). PET scans of 13 stroke patients showed improved peristroke cerebral glucose kinetics and blood flow (Szilagyi et al., 2005). In a 1-year study of 61 children with hypoxic ischemic encephalopathy due to intracranial birth trauma, vinpocetine reduced seizures, intracranial hypertension, and psychomotor sequelae (Dutov et al., 1991). Mild side effects include indigestion, nausea, dizziness, anxiety, facial flushing, insomnia, headache, drowsiness, and dry mouth. Patients taking other blood thinners concurrently should be closely monitored. The average dose is 10 mg three times a day. The authors find vinpocetine to be most helpful in cases with evidence of blood flow abnormalities on brain imaging studies.

Adaptogens: Rhodiola rosea, Schizandra chinensis, Eleutherococcus senticosus, Panax ginseng, Lepidium peruvianum Chacon

An adaptogen is a plant that increases resistance against multiple stressors (biological, chemical, or physical), normalizes physiological parameters, and does not disturb normal body functions more than necessary to improve resistance (Brekman & Dardymov, 1969). Adaptogens contain bioactive compounds that function as metabolic regulators. In reviewing the effects of adaptogens on the central nervous system, Panossian and Wagner (2005) suggest that extracts from adaptogenic herbs have synergistic effects on stress response. *R. rosea* qualified as an adaptogen because it protected every organism tested, from snails to humans, against physical and mental stress including fatigue, heat, cold, toxins, chemotherapy cytotoxicity, heavy metals, ischemia, hypoxia, and radiation (Panossian & Wagner, 2005; Brown, 2002; Brown & Gerbarg, 2004).

Panossian, Wikman, Wagner, and colleagues have been testing hypotheses regarding the mechanisms by which adaptogens exert numerous effects, including improving stress resilience, energy, mood, cognitive function, attention, memory, physical performance, and others (Panossian, 2013; Panossian & Wikman, 2009; Panossian, Wikman, Kaur, & Asea, 2012). They propose that adaptogens support homeostasis and regulation of the HPA axis via mediators of the

stress response. Furthermore, they propose that adaptogens modulate gene expression of key mediators of stress-induced transduction pathways (Panossian et al., 2013). A full discussion of these hypotheses and their evidence base is beyond the scope of this chapter. Here we briefly outline the hypotheses and refer to the works of Panossian and colleagues for the details.

MEDIATORS OF THE STRESS RESPONSE

Molecular Chaperones, Heat Shock Proteins

Heat shock proteins (HSP70) protect cellular proteins from free radicals and enable the repair of damaged proteins, the disposal of defective proteins, and the inhibition of cell death. ADAPT-232 (a fixed combination of *R. rosea*, *E. senticosus*, and *S. chinensis*) and salidroside (an active constituent of *R. rosea*) were found to increase serum levels of HSP70 in mice under stress and the expression and release of HSP70 from human neuroglial cells in vitro (See Figure 29.2).

Neuropeptide Y

During stress response, neuropeptide Y (NPY) is released from sympathetic nerves. Peripherally, it potentiates the stress response. Centrally NPY inhibits SNS activity and has an anxiolytic effect. NPY can promote ATP formation, inhibit NO synthesis (relieving the suppression of ATP formation by NO), reduce elevated protein kinases, affect modulators of immune response that control DNA transcription, and modulate the release of neuropeptides from the hypothalamus (See Figure 28.2). ADAPT-232 and salidroside have been shown to increase expression and release of NPY from human glioblastoma cells in culture. Panossian and colleagues hypothesize that, analogous to the strengthening effects of regular physical exercise, adaptogens act as mild stressors that increase stress tolerance and adaptation by stimulating the release of stress mediators HSP70 and NPY (Panossian et al., 2012; Panossian, 2014).

MODULATION OF GENE EXPRESSION

Genomic studies show that in combination, *R. rosea*, *E. senticosus*, and *S. chinensis* upregulate and downregulate a total of 2,188 genes in human neuroglial cells T98G. One active constituent, salidroside, alters expression of more than 700 genes. Among the genes affected by these adaptogens are those that encode cell membrane bound G-protein coupled receptors, including 5-HT₃ receptors involved in the release of neurotransmitters and neurohormones (Panossian et al., 2013). Adaptogens also target SERPIN1, the gene encoding neuroserpin, which is involved in growth of axons, development of synapses, and synaptic plasticity (Panossian, 2013). Further studies in human neuroglial cells found that extract of *Rhodiola* upregulated 336 genes and down-regulated 295. Downstream effects of these genes are associated with cardiovascular (72 genes), metabolic (63 genes), gastrointestinal (163 genes), neurological (95 genes), endocrine (60 genes),

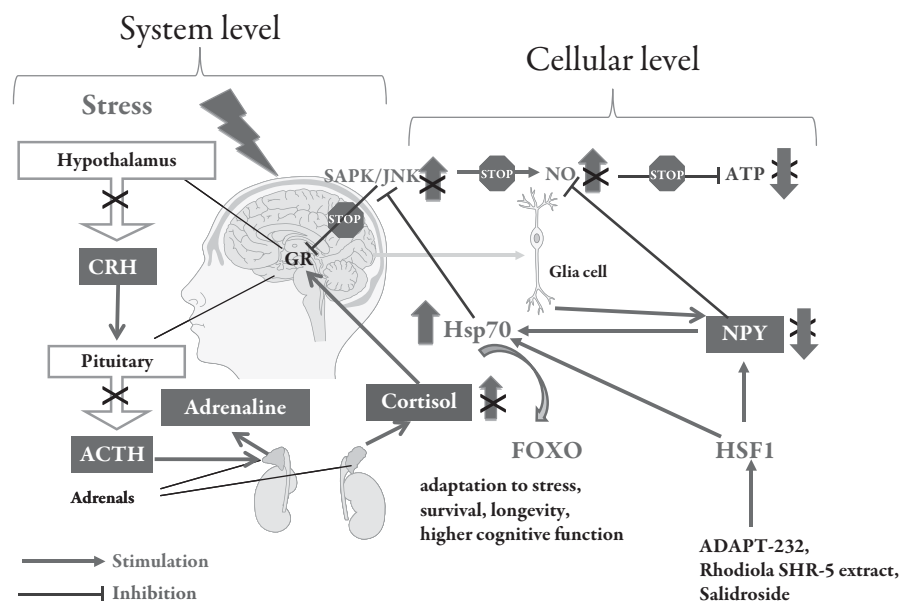

Figure 28.2 Hypothetical Mechanisms of Stress Protection by Adaptogens: Rhodiola SHR-5 extract, salidroside, and ADAPT-232. Reproduced with permission of Dr. Alexander Panossian (Panossian, 2013). Key: Stress induces hypothalamic release of corticotropin releasing hormone (CRH) followed by pituitary release of adrenocorticotrophic releasing hormone (ACTH), which stimulates release of adrenal hormones and Neuropeptide Y (NPY) to mobilize energy resources and cope with the stress. Feedback regulation of overreaction is initiated by cortisol release from adrenal cortex. Cortisol binds to glucocorticoid receptors (GR) in the brain, stopping further release of brain neurohormones and reducing the stress induced increase of cortisol down to baseline (pre-stress) levels. Although brief and mild stress (eustress or challenge) is essential to life, severe stress (distress or overload) is associated with extensive generation of oxygen free radicals, including nitric oxide (NO), which inhibit adenosine triphosphate (ATP) formation. Stress-activated protein kinases (SAPK/JNK/MAPK) inhibit GR, blocking this feedback downregulation such that serum cortisol remains high in fatigue, depression, and other stress-related conditions. Adaptogens normalize stress-induced elevated levels of cortisol and other extracellular and intracellular mediators of stress response, including elevated NO, SAPK (via upregulation of NPY expression), heat shock factor (HSF-1) and heat shock proteins (Hsp70), which inhibit SAPK. Consequently, NO generation is reduced and ATP production is no longer suppressed. Intracellularly Hsp70 enhances antiapoptotic mechanisms and protects proteins against mitochondria generated oxygen-containing radicals, including NO and superoxide anion. Hsp70 acts as an endogenous danger signal and has a vital role in immune stimulation. NPY is crucial in the HPA axis function and energy balance maintenance. Both NPY and Hsp70 are involved in enhancement of cellular adaptation to stress, survival, longevity and cognitive function. Hsp70 inhibits foxhead O transcription factor (FOXO), playing an important role in adaptation to stress and longevity. These pathways contribute to adaptogenic effects, such as antifatigue, improved attention and enhanced cognitive function. cognitivecognitive function.

behavioral (50 genes), and psychological disorders (62 genes) (Panossian, et al., 2014).

Rhodiola, Golden Root, Arctic Root, or Roseroot (*Rhodiola rosea*)

Although many of the 19 species in the *Rhodiola* genus are used as traditional medicines in Europe and Asia, *Rhodiola rosea* has been the most intensely studied. Starting in the 1950s under the Ministry of Defense of the former Soviet Union, 30 years of unpublished systematic research was kept in classified documents while the strategic use of *R. rosea* and other adaptogenic herbs to enhance physical, cognitive, and psychological functions was explored in military personnel, cosmonauts, Olympic athletes, scientists, and students (Baranov, 1994; Brown, Gerbarg, & Ramazanov, 2002; Brown & Gerbarg, 2004; Brown, Gerbarg, & Muskin, 2009; Stancheva, Mosharrof, & Petkov, 1986; Panossian, 2013). A formula called ADAPT, containing *Rhodiola rosea*, *Eleutherococcus senticosus*, and *Schizandra chinensis* was developed and tested the most extensively. Most of these studies were written as government reports, not for publication. However, current research is confirming many of the findings. Since the 1960s the Russian Pharmacopoeia has described the approved medicinal uses of root extracts of *R. rosea*. Soviet researchers observed therapeutic effects in posttraumatic and vascular brain lesions, especially in early post-injury stages. *Rhodiola* species

contain many antioxidant compounds and mitochondrial enhancers found to maintain higher levels of ATP and creatine phosphate (CP) in brain, muscle, liver, and blood (Furmanowa, Skopinska-Rozewska, Rogala, & Malgorzata, 1998; Kurkin & Zapesochaya, 1986a). In animal studies *R. rosea* was shown to increase brain norepinephrine, DA, and 5-HT and stimulate nicotinic cholinergic systems (Petkov et al., 1986; Stancheva & Mosharrof, 1987). *R. rosea* increases blood-brain barrier permeability to DA and 5-HT precursors, consistent with activation of the cerebral cortex and limbic systems. Extracts also reversed the blockage of acetylcholine in pathways ascending from limbic system to cortex that are involved in memory. Two flavonoid glycosides (gossypetin-7-O-l-rhamnopyranoside and rhodio-flavonoside) from the alcohol extract of *R. rosea* (5 g/L) were found to cause $58 \pm 15\%$ and $38 \pm 4\%$ AChE inhibition respectively and may account in part for cognitive and memory-enhancing properties (Hill-House, Ming, French, & Towers, 2004).

In healthy individuals, *R. rosea* enhances intellectual work capacity, abstract thinking, accuracy on tedious tasks, and reaction time (Shevtsov et al., 2003; Spasov, Mandrikov, & Mironova, 2000). For example, a DBRPC study of 60 first-year college students under stress found that those given low-dose *R. rosea* (100 mg/day) had significant improvement in mental fatigue, psychomotor function, overall well-being, physical work capacity, and heart rate (Spasov, Wikman, Mandrikov, Mironova, & Neumoin, 2000). The ADAPT

formula, now labeled ADAPT-232 (Swedish Herbal Institute) was recently tested in a DBRPC single-dose effect study in 40 healthy but psychologically stressed, tired women aged 20–68 years. Compared to the placebo group, within 2 hours of consuming 270 mg ADAPT-232 subjects gained significant improvements in attention, speed, and accuracy during stressful cognitive tasks (Aslanyan et al., 2010). *R. rosea* has no reported adverse interactions with drugs. However, caffeine and other stimulants can have additive effects. In older Soviet studies, *R. rosea* was reported to exacerbate a condition in patients described as “volatile or euphoric” (Saratikov & Krasnov, 1987). These were probably patients with bipolar disorder and there may be some risk of inducing mania in bipolar patients, as can occur with antidepressants and stimulants. However, in the authors’ (PLG and RPB) experience, *R. rosea* can be quite helpful for depression and for patients on mood stabilizers whose mood swings are primarily the depressed type with occasional mild hypomanic symptoms.

In patients with brain injury, *R. rosea* has a mild cognitive stimulant effect while it is also emotionally calming. Doses and precautions are the same as described in the section titled Herbs for Treatment of Mood Disorders. Highly anxious patients may not tolerate higher doses, because the activating effects sometimes exacerbate anxiety. *R. rosea* is best absorbed when ingested 20 minutes before breakfast and/or lunch when the stomach is empty, starting with 150 mg/day and increasing by 150 mg every 3–7 days. If tolerated, the entire dose can be given in the morning to increase compliance. In some cases the single morning dose has a better effect. Elderly, medically ill, or anxious patients should start by taking one-fourth to one-half of a capsule (37–75 mg) per day dissolved in tea or juice and increased slowly. Response takes 1–12 weeks.

Since *R. rosea* is known to have a mild effect on platelet aggregation at high doses, patients should be advised to watch for signs of increased bruising, especially at doses above 750 mg/day. Patients on coumadin or other medications that affect platelet aggregation or clotting factors should have their International Normalized Ratio (INR) checked (following each increase in *R. rosea* dose) and their coumadin doses adjusted accordingly (see section on Herb–Drug Interactions).

The authors find *R. rosea* to be effective in a variety of conditions: disorders of memory, cognition, and fatigue; enhancement of physical endurance, cognitive performance, memory, and energy in healthy individuals and in those with a wide range of disorders including age-related cognitive decline, poststroke, TBI, and cognitive impairment due to medical illness (e.g., cancer, HIV, or other chronic conditions); reduction of medication side effects; and recovery from central nervous system infections such as neuro-Lyme disease. Augmentation of *R. rosea* with *Eleutherococcus senticosus*, *Schizandra chinensis*, *Panax ginseng*, *Ginkgo biloba*, *Withania somnifera* (ashwaganda), and/or piracetam can further increase the beneficial effects on memory and cognition. Patients often report improved energy, mental clarity, and memory. Energy usually improves within the first week. Improvements in cognitive

function and memory may take 1–12 weeks. Some individuals experience a decline in effectiveness after 3 to 12 months. In such cases a dose increase or a 2-week “holiday” off of the herb may restore efficacy. Alternatively, using a well-tested, quality brand may increase and sustain the benefits longer. This adaptogen can be used intermittently, prior to and during times of increased stress, or continuously for chronic conditions. For example, *R. rosea* could be started 2 or 3 weeks before examinations to reduce stress and improve academic performance.

Schizandra chinensis (Schizandra or Schisandra)

Schizandra chinensis is a Chinese medicinal herb (Bei Wu Wei Zi or Chosen-Gomishi) used to improve concentration, energy, and physical endurance. Bioactive components (lignans), including schizandrin and gomisan A, are polyphenolic. Extracts of the schizandra fruit showed significant AChE inhibition (Hung et al., 2007) as well as antidepressant, anti-inflammatory, and hepatoprotective effects. The emotional calming effect of *S. chinensis* counterbalances the stimulating effect of *R. rosea* in patients who tend to become anxious. The pharmacology and clinical research on schizandra has been reviewed (Panossian & Wikman, 2008).

Eleutherococcus senticosus or *Acanthopanax senticosus* (Siberian Ginseng or Eleuthero)

Eleutherococcus senticosus is often called *Acanthopanax senticosus*, Oriental ginseng, or Siberian ginseng, though it is not in the ginseng family. A thorny shrub that grows in Siberia and northern China, it has a long history of use in Russia, China, Korea, and Japan as an adaptogen to enhance nonspecific resistance to stress and fatigue. Animal studies of bioactive compounds from *E. senticosus*, including eleutherosides and isoflaxidin, demonstrated reduced fatigue and improved recovery of natural killer cell activity and corticosterone levels following stress induced by swimming in mice. *E. senticosus*, used as an antiinflammatory in rheumatic diseases in oriental medicine, was found to downregulate inflammatory inducible nitric oxide synthase (iNOS) expression (Jung et al., 2007). Extracts have been used by athletes to enhance physical strength and endurance. While human studies of *E. senticosus* monotherapy are limited, it has been shown to contribute to the anti-fatigue and mental stimulatory effects of adaptogen combination formulas, particularly ADAPT-232 (Panossian & Wagner, 2005). Adverse events have been reported with intravenous administration but not with oral ingestions (Weng et al., 2007).

Panax ginseng (Korean or Asian Ginseng) and *Panax quinquefolius* (American Ginseng)

Ginsengs contain numerous bioactive compounds. *Panax ginseng* increases nitric oxide production in endothelial cells, which is essential for blood flow and oxygen delivery. *Panax ginseng* (400 mg/day) significantly improved abstract thinking and reaction time compared to placebo in a DBRPC

8-week study of healthy volunteers (age >40 years). However, there was no effect on memory or concentration (Sorensen & Sonne, 1996). *Panax ginseng* 100 mg also significantly improved reaction time, accuracy, calmness, and working memory in a DBRPC crossover study of 32 healthy adults aged 18–40 years (Reay, Scholey, & Kennedy, 2010). In a 12-week RCT of 97 Alzheimer disease patients, improvements were reported in cognitive function and MMSE (Lee, Chu, et al., 2008). However, literature reviews find methodological limitations in ginseng studies, a lack of convincing evidence, and a need for better quality studies (Geng et al., 2010).

A DBRPC trial in 32 healthy young adults found significant acute improvements in working memory in subjects given a single dose of 100, 200, and 400 mg American ginseng, *P. quinquefolius* (Cereboost, standardized to 10.65% ginsenosides) compared to those given placebo (Scholey et al., 2010). Of note, American ginseng (preparation HT100) significantly improved verbal memory and reduced extrapyramidal symptoms in a 4-week DBRPC study of 64 schizophrenic patients (Chen & Hui, 2012). American ginseng is less activating than *Panax ginseng*. The concentration of active ginsenosides in *P. ginseng* preparations can vary considerably.

In clinical practice, ginseng augments the activating effects of other agents, improving alertness, mental focus, energy, and cognitive function. One of the authors (RPB) attains better results by combining *P. ginseng*, American ginseng, and *E. senticosus* when treating cognitive dysfunction due to stroke, trauma, or vascular disease.

Lepidium myenii Walpers, *Lepidium peruvianum* Chacon (Maca)

Maca is a Peruvian adaptogenic herb that grows at high altitudes in the Andes. The Peruvian species has been referred to as *Lepidium myenii*, but the Peruvian government and universities chose to recognize its official name as *Lepidium peruvianum* Chacon. Its many active components include alkaloids, polyunsaturated acids, and their amides, and plant sterols. Maca is used as a nutritional supplement to improve alertness, mental focus, and physical resilience. Although it is mainly used to enhance sexual function and fertility, the roots have other medicinal properties. *L. peruvianum* is considered to be a nonhormonal phytomedicine that has the properties of an adaptogen. The key active constituents have not been identified. Among the 13 phenotypes of *L. peruvianum*, each has its own color and variation in the balance of active constituents. A review of maca studies discussed the following findings (Gonzales, 2012).

The black variety of maca shows positive effects on learning and memory in animal models. Black maca reduced human brain malondialdehyde levels (marker of oxidative stress) and decreased acetylcholinesterase levels in ovariectomized mice. Toxic effects have not been reported if the herb is boiled before consumption. It is neither teratogenic nor carcinogenic. The authors (PLG and RPB) find maca to be a useful adjunctive treatment for neural fatigue.

OTHER HERBS WITH NEUROPROTECTIVE AND COGNITIVE BENEFITS

Ginkgo biloba (Ginkgo) from Leaves of the Maidenhair Tree

Leaf extracts of *Ginkgo biloba* contain flavones associated with antioxidant effects and terpene lactones responsible for anti-platelet activating factor. The EEG profile associated with ginkgo is indicative of cognitive activation with increased alpha and low-beta frequencies as well as decreased slow theta and delta, a pattern typical of cognitive activators (such as donepezil) and stimulants. A review of 22 controlled ginkgo studies in cerebrovascular disease, memory impairment, cognitive impairment, AD, multi-infarct dementia, subarachnoid hemorrhage, aging, hypoxia, and vestibular disorder, and in healthy volunteers, found evidence for clinically meaningful (though subtle) improvements (Diamond et al., 2000; Diamond & Bailey, 2013). In a DBRPC 52-week study of 236 Alzheimer's patients, *G. biloba* (EGB 761) 120 mg/day improved cognitive performance in patients with mild to moderate cognitive impairment and slowed deterioration in patients with severe impairment. A DBRPC 22-week trial of 400 patients with mild to moderate dementia given 240 mg/day EGB 761 documented that the ginkgo group had better cognitive outcome compared to placebo (Napryeyenko, Borzenko, & Gindem-Np Study Group, 2007). Although 120 mg twice daily of ginkgo (EGB761) failed to prevent dementia in the DBRPC Ginkgo Evaluation of Memory study of over 3,000 subjects followed for an average of 6.1 years (DeKosky et al., 2008), issues of compliance and diagnostic heterogeneity limit conclusions. Other DBRPC studies indicate that ginkgo may be particularly beneficial for neuropsychiatric and behavioral symptoms in dementia, especially when combined with 10 mg/day donepezil (Bachinskaya, Hoerr, & Ihl, 2011; Ihl, 2012; Ihl et al., 2012). A comprehensive review of EGB761 by Diamond and Bailey (2013) noted that the largest proportion of cognitive effects in RCTs are in fluid intelligence, selective attention, short-term and long-term verbal and visual memory, and executive functions. They also reviewed RCTs showing EGB761 to be beneficial for multiple sclerosis and anxiety disorders (Diamond & Bailey, 2013). EGB761 is standardized to contain 24% ginkgo-flavone glycosides and 6% terpenoids with numerous other active constituents, which may account for its effects on cerebrovascular tone, neurotransmitter and receptor activity, glucose metabolism, and electrical activity.

The authors' clinical experience suggests that ginkgo is best used to augment centrophenoxine and racetams (see below) in patients with TBI because its effects alone are mild. Side effects are rare with occasional nausea, headache, or rash. Cases of bleeding in patients with poor quality ginkgo, and usually with concurrent antiplatelet or anticoagulant medications, have been reported. High quality pharmaceutical grade ginkgo such as EGB761 has not been shown to affect bleeding time and does not potentiate anticoagulant drugs (Weinmann, Roll, Schwarzbach, Vauth, & Willich, 2010). Nevertheless, the current recommendations in the medical literature are that ginkgo not be given with warfarin and that it be discontinued 2 weeks prior to surgery.

Labiatae Family: *Melissa officinalis* (Lemon Balm),
Salvia officianalis (Sage) and *Salvia lavandulaefolia*
(Spanish Sage)

Modabbernia and Akhondzadeh (2013) recently reviewed the use of Labiatae phytochemicals in mental health. Preliminary small RCTs suggest that lemon balm and sage may enhance cognition and reduce agitation in patients with dementia (Akhondzadeh & Abbasi, 2006; Akhondzadeh et al., 2003). In 4-week DBRPC trial in 71 severely demented patients, *M. officianalis* aromatherapy decreased agitation and withdrawal and improved activities of daily living. A DBRPC trial in 18 healthy volunteers found that a 300 mg/day dose improved math processing speed while maintaining accuracy. Furthermore, at 600 mg/day lemon balm reduced effects of stress and improved calmness (Kennedy, Little, & Scholey, 2004). Side effects are insignificant. The authors find that 800 mg lemon balm helps reduce agitation in patients with dementia.

A DBRPC crossover study in 24 healthy undergraduates (ages 18–37) found that those given 50 µl Spanish sage had significant improvements in speed of memory, alertness, calmness, and contentedness compared to those on placebo. Spanish sage (*S. lavandulaefolia*) was used instead of sage (*S. officianalis*) because it contains the same bioactive compounds as *S. officianalis* but has a lower concentration of thujone, a terpenoid ketone that can be toxic in high doses (Tildesley et al., 2005). Side effects and drug interactions of sage and Spanish sage are minimal. In the authors' experience with dementia, 50 drops of 1.5% tincture of Spanish sage improves memory and alertness while ameliorating agitation. The cognitive effects of these herbs warrant further study.

Crocus sativus (Saffron)

Preclinical and clinical evidence on the benefits of saffron have been reviewed (Modabbernia & Akhondzadeh, 2013). It may exert AChEI effects, antagonize glutamatergic activity at NMDA receptors, and inhibit aggregation and deposition of amyloid β. In a 16-week DBRPC trial of 46 patients with probable mild to moderate AD, those treated with saffron 15 mg twice daily (extracted from stigmas of saffron) improved significantly on tests of cognitive function and had markedly reduced agitation compared to placebo (Akhondzadeh, Sabet, et al., 2010). A DBRPC Phase II 22-week trial (n = 54) found saffron 15 mg b.i.d. to be as effective as donepezil 10 mg/day in community dwelling adults over the age of 55 years with mild-to-moderate Alzheimer's disease (Akhondzadeh, Shafiee Sabet, et al., 2010).

NOOTROPICS—CENTROPHENOXINE

(MECLOFENOXATE, LUCIDRIL), L-DEPRENYL
(SELEGILINE), PYRROLIDINONES (RACETAMS)

Nootropics are manufactured cognitive enhancing and neuroprotective agents that have been extensively studied and

prescribed in Europe, but are not well known in the United States. Froestl and colleagues recently proposed a nootropic classification system with 19 categories based on mechanisms of action—for example, interactions with receptors, enzymes, ion channels, nerve growth factors, reuptake transporters, antioxidants, metal chelators, and monoclonal antibodies interacting with amyloid-B and tau (Froestl, Muhs, & Pfeifer, 2012). They have reviewed the interactions of nootropics with enzymes, receptors, (Froestl, Muhs, & Pfeifer, 2013) and other targets (Froestl, Pfeifer, & Muhs, 2012). Evidence suggests that nootropics improve antioxidant status, membrane fluidity, mitochondrial function, neurotransmitter levels, mRNA protein synthesis, cerebral blood flow, neuroplasticity, and long-term potentiation (Brown, Gerbarg, & Muskin, 2009).

Pyrrrolidinones (Racetams): Piracetam, Aniracetam,
Pramiracetam

The modest neuroprotective effects of piracetam can be potentiated by CDP-choline, idebenone, vinpocetine, centrophenoxine, and deprenyl. Oxiracetam, aniracetam, and pramiracetam produce somewhat stronger effects than piracetam (Brown, Gerbarg, & Muskin, 2009). Large DBPC studies indicate that racetams improve symptoms in dyslexia and augment the benefits of speech therapy in poststroke aphasia (De Deyn, Reuck, Deberdt, Vlietinck, & Orgogozo, 1997). One PET scan study demonstrated improved task-related blood flow in left hemisphere speech areas (Kessler, Thiel, Karbe, & Heiss, 2000). In postconcussion syndrome, piracetam may reduce symptoms (especially vertigo and headache) and accelerate recovery with EEG normalization. In patients with dyslexia and aphasia, ginkgo improved attention and perception and augmented piracetam in cognitive retraining (Deberdt, 1994; Enderby, Broeckx, Hoppers, Schildermans, & Deberdt, 1994).

In a DBRPC study of cognitive impairment and ischemic stroke following coronary artery bypass surgery, 98 patients were randomized to either placebo or piracetam IV (150 mg/kg/day; 300 mg/kg on the day of surgery) starting 1 day before surgery to 6 days after surgery and then 12 mg/day orally for up to 6 weeks. Patients given piracetam showed significant improvement in cognitive function compared to placebo (Szalma et al., 2006).

Racetams are very low in side effects. The authors (PLG and RPB) use aniracetam 750 mg twice daily to improve cognitive function in adults and children with learning disabilities, dyslexia, stuttering, anticonvulsant-induced cognitive impairment, bipolar disorder, unipolar depressives on antidepressants, and chronic fatigue syndrome. For the treatment of children, pramiracetam is less activating and more calming than aniracetam.

L-Deprenyl (Eldepryl, Selegiline, Emsam, Jumex)

Although L-deprenyl is a prescription MAOI antidepressant in the United States, most physicians are not aware of its neuroprotective effects. In low doses (<10 mg/day) it

does not act as an MAO-A inhibitor and does not require a low tyramine diet. Preclinical evidence suggests that selegiline enhances mesencephalic drive regulation and resiliency under stress; increases release of BDNF, catecholamines, and 5HT, (most markedly in the hippocampus; see Knoll 2000, 2003); improves dopamine function and cognitive function; and exerts neuroprotective effects (particularly in catecholaminergic and cholinergic neurons) including protection against glutamate excitotoxicity (Ebadi et al., 2006). In ultra-low doses (2.5–5.0 mg/d) L-deprenyl may be modestly beneficial in treatment of TBI, AAMD, neurodegenerative or vascular cognitive impairment, AD, or a family history of dementia. As an enhancer regulator, L-deprenyl was associated with increased activity levels in enhancer-sensitive neurons that are associated with delay in age-related neurodegenerative changes, and it significantly increased longevity in 6 different animal species (Denes, Szilagyi, Gal, Bori, & Nagy, 2006). Further study on neuroprotection is needed.

Centrophenoxine (Meclofenoxate, Lucidril)

Dimethyl-aminoethanol (DMAE) is the precursor to phosphatidyl-DMAE, an avid scavenger of OH-radicals in cell membranes. Centrophenoxine (CPH) is an ester of DMAE and p-chlorophenoxyacetic acid, a synthetic form of a plant growth hormone (Nandy, 1978). CPH elevates levels of brain acetyl choline (ACh) and has antioxidant properties. CPH delivers DMAE rapidly to the brain where it is incorporated into nerve cell membranes as phosphatidyl-DMAE thereby providing antioxidant protective effects (Zs-Nagy, Dajko, Uray, & Zs-Nagy, 1994). In animal models of ischemia and in aged rats, CPH reduced cognitive deficits (Liao, Wang, & Tang, 2004). CPH increased activity of catalase, superoxide dismutase, glutathione reductase, and glutathione, as well as diminishing lipid peroxidation (Bhalla & Nehru, 2005). Significantly increased psychomotor and behavioral performance was observed in patients treated with centrophenoxine compared to placebo in an 8-week DBRPC trial in patients with moderate dementia (Pek, Fulop, & Zs-Nagy, 1989). In a 3-month DBRPC study 62 geriatric patients with mild to moderate AD, a preparation of CPH, vitamins, and nutrients (Antagonic Stress) was associated with significant improvements in memory, cognitive function, and behavior compared to nicergoline (Schneider et al., 1994). Nootropics may be more effective when combined with vitamins, minerals, and other nootropics (Fischer, Schmidt, & Wustmann, 1984).

HORMONES FOR COGNITIVE DYSFUNCTION

Dehydroepiandrosterone (DHEA)

Clinical studies of memory and cognitive enhancement with DHEA, produced primarily in the adrenal glands and secondarily in the ovaries and testes, show mixed results. In a 3-month study of normal older men, DHEA

showed no impact on cognition or well-being (van Niekerk, Huppert, & Herbert, 2001). Patients whose DHEA is low for age, menopausal women who have had ovariectomies and adrenalectomies (Gurnell & Chatterjee, 2001), and debilitated geriatric patients are more likely to respond to DHEA with improvements in energy, memory, mood, and weight maintenance. Side effects, including insomnia and irritability, are usually mild. Slight increases in estrogen, potential interactions with steroids, and effects on prostate are concerns. Serial prostate-specific antigen testing is advisable. Patients with a history of prostate cancer or other hormone-sensitive cancers should not be given DHEA. Pharmaceutical grade DHEA is preferable in doses sufficient to restore physiologic levels, usually 25–50 mg/day.

Melatonin

Melatonin, a methoxyindole neurohormone secreted primarily by the pineal gland, diffuses readily through membranes and enters cell organelles. Best known for its role in sleep and circadian rhythms, melatonin is also a robust neuroprotectant that avidly scavenges reactive oxygen species including reactive hydroxyl radicals, carbonate radicals, and reactive nitrogen species (Srinivasan, Pandi-Perumal, Cardinali, Poeggeler, & Hardeland, 2006). In addition, melatonin prevents excitation-dependent generation of free radicals, reduces lipid peroxidation, upregulates antioxidant enzymes, and potentiates other antioxidants. Melatonin levels decline with aging and in neurodegenerative conditions. Beneficial effects of melatonin in AD and PD may involve antioxidant protection of mitochondrial membranes and DNA, enhanced glutathione production and regeneration, improved electron transport capacity, and anti-amyloid- β and antifibrillogenic effects. In elderly patients, early AD, and mild cognitive impairment (MCI), small studies found that melatonin improved sleep, mood, memory, and sundowning, and possibly slowed progression of cognitive decline. In a DBPC study of 20 patients with AD, those given melatonin 3 mg at bedtime showed significantly greater improvements on ADAS cognitive and noncognitive behavioral scores compared to the placebo group, but no significant differences were found on MMSE (Asayama et al., 2003). A review of melatonin studies in patients with MCI included 5 DBRPC trials and 1 open-label retrospective study, and all concurred in finding that evening treatment with melatonin significantly improved sleep quality and cognitive performance (Cardinali, Furio, & Brusco, 2010). Studies with additional measures also showed better mood. Larger studies are needed to evaluate long-term benefits of melatonin on disease progression in AD. In elderly patients, including those with AD and PD, melatonin in doses of 3–9 mg at bedtime can help to improve sleep, mood, memory, and sundowning. It probably slows progression of cognitive decline in MCI and, possibly, early AD. Melatonin may have a role in long-term prevention of neurodegeneration, particularly if begun by age 45.

MENOPAUSE, ANDROPAUSE, AND SEXUAL FUNCTION

PHYTOESTROGENS AND OTHER HERBS FOR FEMALE MENOPAUSE

Recent reviews pertaining to the safety and efficacy of phytoestrogens for menopausal symptoms, bone loss, and breast cancer highlight difficulties interpreting research studies and the complexities of clinical decision making (Bedell, Nachtigall, & Naftolin, 2012; Lagari & Levis, 2012; Leclercq & Jacquot, 2012). Interest in alternatives to hormone replacement therapy (HRT) has been growing, particularly in light of long-term studies showing increased risk of breast and uterine cancer among women taking HRT. Evidence of risk versus benefit is insufficient to justify the use of HRT to prevent osteoporosis, cardiovascular disease, or dementia. Although dietary supplements and herbs are widely used for relief of menopausal symptoms, more research is needed to confirm their benefits and safety.

Phytoestrogens

Phytoestrogens are plant-derived selective estrogen receptor modulators (SERMs) with structural similarities to estradiol. They bind to estrogen receptors and may act as estrogen agonists or antagonists depending on the specific tissue, the presence of other SERMs, and their ability to recruit coactivator or corepressor complexes (Bedell, Nachtigall, & Naftolin, 2012). Current research on SERMs aims to reduce menopausal symptoms and the risk of bone fractures and cardiovascular disease without increasing the risk of breast, uterine, or ovarian cancer (Blizzard, 2008). An ideal SERM would exert agonistic effects on estrogen receptors in bone, the cardiovascular system, and the central nervous system, but have anti-estrogenic or no effects on healthy breast and endometrial tissues (Hendrix & McNealey, 2001). Tamoxifen, the first SERM used to reduce breast cancer risk, increased risks of endometrial cancer and blood clots (Cuzick et al., 2013). Other synthetic SERMs (e.g., ralozafen and bazedoxifene) have shown mixed results and side effects such as headache, arthralgias, hot flashes, and back pain (Gatti, Rossini, Sblendorio, & Lello, 2013; Kawate & Takayanagi, 2011). Research is needed on the potential role of plant-derived SERMs in treating menopausal symptoms and reducing risks of osteoporosis, cardiovascular disease, and breast cancer.

Plants containing phytoestrogens—for example, soy (*Glycine max*), red clover (*Trifolium pratense*), and hops (*Humulus lupulus*)—have been widely used and studied. Soy constituents include phytoestrogen isoflavones, diadzein, and genistein, as well as the precursor to mammalian lignans. Although the mechanisms of action are not entirely known, soy isoflavones show selective weak binding to estrogen receptors, preferentially estrogen receptor B. Mildly estrogenic isoflavones in red clover, similar to those in soy, also bind to human estrogen receptors (Booth et al., 2006). Extracts from red clover and hops upregulate progesterone receptor mRNA, interact with transcription factors (NF-KappaB), and possess

antioxidant activity (Overk et al., 2005). Hops, traditionally used to brew beer, binds to estrogen receptors in vitro but does not stimulate uterine growth in ovariectomized rats (Beckham, 1995; Fackelman, 1998). In vitro studies indicate that one constituent, 8-prenylnaringenin, has high estrogenic activity and binding to estrogen receptors A and B (Milligan et al., 2000). Hops may have mild additive effects with other sedative agents.

Epidemiologic data and animal studies suggest that the health benefits of soy (lowering cholesterol and cancer prevention) are best obtained from whole soy (i.e., whole food) rather than from isolated isoflavones. A review of 22 RCTs by the American Heart Association Nutrition Committee concluded that isolated soy protein with isoflavones, compared with milk or other proteins, decreased LDL cholesterol concentrations on average approximately 3%—a small change relative to the large amount of soy protein (averaging 50 g/day) tested. There were no significant effects on HDL cholesterol, triglycerides, lipoprotein, or blood pressure. Furthermore, in 19 studies of soy isoflavones, the average effect on LDL cholesterol and other lipid risk factors was nil.

Isoflavones exert estrogenic and anti-estrogenic effects, both stimulating and inhibiting growth in breast cancer cells in vitro. The net effect has been no change in the risks of breast, endometrial, or other cancers. A meta-analysis of soy studies identified a small reduction in breast cancer risk associated with the use of whole soy but not high-dose isoflavone supplements (Trock, Hilakivi-Clarke, & Clarke, 2006). A prospective study of 15,555 women aged 50–69 concluded that high intake of isoflavones had no significant relationship to breast cancer risk (Keinan-Boker, van Der Schouw, Grobbee, & Peeters, 2004).

The efficacy and safety of soy isoflavones for preventing or treating cancer of the breast, endometrium, and prostate are not established. No evidence from clinical trials points to increased risk of cancer. The use of isoflavone supplements in food or pills is not recommended. Earlier research indicating that soy protein has important favorable effects compared to other proteins has not been confirmed. The benefits of many soy products may be attributed partly to the high content of polyunsaturated fats, fiber, vitamins, and minerals, and low content of saturated fat (Sacks et al., 2006).

Animal studies suggest that red clover isoflavones decrease bone loss induced by ovariectomy, probably by reducing the rate of bone turnover via inhibition of bone resorption (Occhiuto et al., 2007). Most clinical studies show lack of effectiveness of isoflavones derived from soy or red clover in preventing menopause-related bone loss. However, three meta-analyses of RCTs in menopausal women found evidence that ingesting soy isoflavones for 6 months significantly but moderately improved bone marrow density in the lumbar spine but not in total hip, femoral neck, and trochanter. The supplements were associated with significant reductions in urine deoxypyridinoline (a bone resorption marker) but not serum alkaline phosphatase or osteocalcin (Taku, Melby, Nishi, Omori, & Kurzer, 2011). Further studies are needed to assess the magnitude of these effects and potential interactions between isoflavones and anti-osteoporosis drugs. In a

DBRPC study of women aged 45–60 years within 5 years of menopause, with baseline bone marrow density T score >–2.0, daily intake of 200 mg isoflavone tablets for 2 years did not prevent bone loss or menopausal symptoms (Levis et al., 2011). However, interpretation of this study should be cautious because it included women who were up to 5 years postmenopausal. Isoflavones in soy foods and red clover may have a modest positive effect on plasma lipid concentrations, bone mass density, and cognitive function.

The evidence for the therapeutic value of phytoestrogens in perimenopause is mixed with more positive results in recent studies. Stronger evidence supports the use of isoflavones for management of vasomotor symptoms (Molla, Hidalgo-Mora, & Soteras, 2011). For example, In a 12-week DBRPC study of 84 postmenopausal women, those given 30 mg/day synthetic genistein experienced a 51% decrease in the number and duration of hot flushes versus a 27% decrease in the placebo group ($p = 0.026$). There were no differences between groups in follicle stimulating hormone (FSH), 17- β -estradiol, endometrial thickness, or adverse events (Evans, Elliott, Sharma, Berman, & Guthrie, 2011). Assessment of risks and benefits of phytoestrogens in women with breast cancer and breast cancer survivors remains controversial. Recent studies have not found an increase in the risk of breast cancer or endometrial hyperplasia. However, trials specifically designed to detect cancer are needed. Lignans do not seem to increase risk of blood clots. Most studies suggest minimal health risks with phytoestrogens (Bedell, Nachtigall, & Naftolin, 2012). Including whole soy in the diet of postmenopausal women may be beneficial, but the optimal dose range remains unknown. Women could be informed that although there is some evidence of efficacy, it is not conclusive. While there is no evidence of harm, long-term safety studies in humans have not been done.

Recent assessments of previous reviews of hundreds of phytoestrogen studies find inconsistencies that could be attributed to several important factors.

1. Patient selection: The inclusion of women who are more than 1 year postmenopause, whose menopausal symptoms would wane naturally over time, reduces the likelihood of positive results.
2. Targets of measurements: Although it is easier to measure changes in frequency of hot flushes rather than severity, the latter is a better indicator of efficacy.
3. Increased consumption of phytoestrogens and exposure to endocrine disruptors: Longer term studies may be affected by the increasing consumption of phytoestrogens such as soy in commercial products and the exposure to estrogenic substances in products such as cosmetics, food containers, and meat from animals given hormones (Guerrero-Bosagna & Skinner, 2012).
4. Polymorphisms: Genetic polymorphisms of enzymes involved in metabolism of phytoestrogens play a role in the individual and ethnic differences that occur in digestion, absorption, and dose requirements for efficacy.

5. Gastrointestinal microflora: Soybean isoflavones are hydrolyzed to aglycone, diadzein, and genistein by intestinal enzymes and further metabolized to other compounds such as equol. The estrogen-agonist potency of equol is much higher than diadzein. Women who lack the intestinal microflora needed to convert diadzein to equol are called “nonproducers.” Equol production can be affected by diet, antibiotics, and illness. Consequently, women who are nonproducers of equol would have less response to the ingestion of isoflavones (Bedell, Nachtigall, & Naftolin, 2012). The differentiation of women’s capacities for equol production may be relevant for interpretation of study results and for adjusting either isoflavone dosages and/or correcting factors that may influence microflora.

Based on more recent research, Bedell and colleagues are more optimistic about phytoestrogens, particularly isoflavones, lignans, and coumestrols for treatment of vasomotor symptoms, vaginal atrophy, insomnia, and osteoporosis. They concluded that phytoestrogens reduce the intensity of hot flushes and that some combinations reduce the frequency. Their review indicates that phytoestrogens can reduce vaginal atrophy, improve sleep, cognition, and possibly bone health, primarily in the spine (Bedell, Nachtigall, & Naftolin, 2012). Leclercq and colleagues note that phytoestrogens can induce epigenetic change in genes involved in estrogen receptor regulation, for example, DNA methylation and histone acetylation/methylation. Their investigations in breast cancer cell lines incubated with genistein and daidzein documented effects on DNA hypermethylation and the restoration of the expression of BRCA1 and BRCA2 oncosuppressor gene expression. They support a quest for specific estrogen receptor ligands to treat endocrine-disrupting diseases, including breast cancer (Leclercq & Jacquot, 2012).

Data from large RCTs suggest that SSRIs and SNRIs are promising treatments for perimenopausal vasomotor and mood symptoms. However, SSRIs (e.g., fluoxetine, paroxetine) inhibit CYP2D6 and can interfere with the clinical benefit of anticancer drugs such as tamoxifen. While estrogen receptor modulators (e.g., raloxifene and bazedoxifene) may reduce vulvovaginal atrophy, vasomotor symptoms, and the risk of osteoporosis, they impart an increased risk of venous thrombosis, stroke, or blood clots in the legs, lungs, or eyes. Other side effects of raloxifene are vasodilation (hot flushes), affecting about 10%–25% of users, and leg cramps, affecting about 7% (Wooltorton, 2006). The long-term safety (beyond 3 years) of SERMs regarding cancer and cardiovascular risks has not yet been established (Levine, 2011). Women who object to raloxifene and bazedoxifene, find them intolerable, or cannot afford the costs may consider herbal or nutritional therapy after being fully informed of the risks and limitations of the evidence of safety and efficacy.

Black Cohosh (Cimicifuga racemosa or Actaea racemosa)

Black cohosh has been used for over 60 years in Europe for its ability to decrease hot flushes by reducing the level of

luteinizing hormone (LH). Studies show no binding to estrogen receptors in vitro, no clinical estrogenic effect, no carcinogenicity, and no more side effects than placebo at usual dosages. In fact, black cohosh augmented the antiproliferative activity of tamoxifen in vitro (Fackelman, 1998; Foster, 1999; Lieberman, 1998). Although stimulation of some uterine growth in ovariectomized rats had been reported, in a multinational study of 400 postmenopausal women given 40 mg/day black cohosh (*Cimicifuga racemosa* BNO 1055) for 52 weeks, there were no cases of endometrial hyperplasia. The number and intensity of hot flashes was markedly reduced and the herb was well tolerated (Raus, Brucker, Gorkow, & Wuttke, 2006). Several controlled studies, including one DBRPC study, showed efficacy equivalent to estrogen replacement therapy (Foster, 1999; Lieberman, 1998).

Studies of black cohosh have yielded inconsistent results. For example, a DBRPC 12-week study assigned 62 postmenopausal women to *Cimicifuga racemosa* extract (CR BNO 1055), the equivalent of 40 mg/day of the raw herb; conjugated estrogens (0.6 mg/day); or placebo. Women in the groups receiving conjugated estrogens or black cohosh extract had better sleep quality and fewer menopausal symptoms than those taking placebo. Both CR BNO 1055 and conjugated estrogens increased vaginal superficial cells; CR BNO 1055 had no effect on endometrial thickness, which was significantly increased by conjugated estrogens (Wuttke, Seidlova-Wuttke, & Gorkow, 2003). In contrast, a one-year DBRPC study of 351 women (ages 45–55 years) found no difference between frequency or intensity of vasomotor symptoms in those given a different herbal preparation of 160 mg/day black cohosh (Pure World, Inc. *Cimicifuga racemosa*; 2.5% triterpene glycosides; 70% ethanol extract) versus placebo (Newton et al., 2006). This study was limited to women in late menopausal transition or postmenopause. Although this study concluded that black cohosh is unlikely to have an important role in the treatment of vasomotor symptoms, the findings may not be generalizable because in late menopause hot flashes usually subside within a year, the length of the study.

Differences in the outcomes of DBRPCs may be due to differences in herbal preparations, patient selection criteria, length of study, and symptom measurements. Levels of bioactive compounds can be significantly affected by extraction procedures. A major problem in assessing this research is that studies using proprietary components may not reveal the process that makes their product “special.” This leaves open the question of whether the difference in outcomes of studies using BNO 1055 versus other brands could be due to significant differences in the quality and efficacy of the products or to other factors. Nonetheless, given the excellent safety profile of black cohosh, it could be recommended for relief of menopausal symptoms in women who do not want or do not respond well to conventional treatments such as SSRIs, SNRIs, or synthetic SERMs. Compared to synthetic SERMs, black cohosh reduces menopausal symptoms without stimulating uterine estrogen receptors, has fewer side effects, and provides additional health benefits.

Dong Quai (Angelica sinensis)

Dong quai has been used in traditional Chinese medicine in tonics for thousands of years. Now it is added to many combination products. Evidence of estrogenicity includes strong binding to estrogen receptors in vitro, stimulation of uterine growth in ovariectomized rats, and induction of progesterone secretion (Belford-Courtney, 1993). The water-soluble extract regulates uterine contractions, while the essential oil relaxes uterine muscles. One DBRPC trial of dong quai as a monotherapy found no benefits for menopause (Hirata et al., 1997). The use of dong quai for perimenopausal symptoms, especially in women with breast cancer may entail some risks due to estrogen agonist effects. Considering the lack of evidence for effectiveness and the well-documented risks, the use of dong quai is not recommended.

Vitex (Vitex agnus castus)

Vitex from chaste tree berry, often used to relieve symptoms in premenstrual syndrome, modulates prolactin secretion and binds to dopamine receptors. Vitex slightly binds to estrogen receptors in vitro and modestly stimulates uterine growth in ovariectomized rats. Although vitex has not been studied in menopause, anecdotal reports suggest beneficial effects for hot flashes, fluid retention, and weight gain. It has been used to treat hyperprolactinemia (Wuttke, Jarry, Christoffel, Spengler, & Seidlova-Wuttke, 2003). One of the authors (RPB) finds vitex to effectively counteract elevations in prolactin levels induced by antipsychotic medications without interfering with antipsychotic effects. Vitex has been shown to be safe in studies lasting up to 18 months. Infrequent side effects include gastrointestinal upset, headache, diarrhea, nausea, itching, urticaria, rash, acne, insomnia, weight gain, and irregular menstrual bleeding. It may be unsafe during pregnancy.

ADAPTOGENS AND HERBS WITH ADAPTOGENIC PROPERTIES FOR MENOPAUSE

Rhodiola, Arctic Root, Golden Root, Roseroot (*Rhodiola rosea*)

Rhodiola rosea has been used for centuries in Russia, Asia, Eastern Europe, and Scandinavia to enhance fertility and sexual function in people living at high altitudes, where it grows naturally in cold climates. The authors (PLG) found evidence for the use of *R. rosea* in an epic poem dating back to Bronze Age Greece (Brown & Gerbarg, 2004).

In an open study of 40 women with primary and secondary amenorrhea given *R. rosea* extract 100 mg twice daily, normal menstrual cycles were restored and uterine length increased to normal size in 25 women. Of these, 11 became pregnant (Gerasimova, 1970). Dr. Patricia Eagon at the University of Pittsburgh discovered that *R. rosea* showed strong estrogen receptor binding in vitro, but it did not activate estrogen receptors, elevate circulating estradiol levels, nor increase uterine size in ovariectomized rats (Eagon et al., 2003). These findings indicate that *R. rosea* could

also be considered to contain selective estrogen receptor modulator(s). Of note, Eagon also found that when ovariectomized rats given estrogen implants (which elevate circulating estradiol to levels above normal) were fed *R. rosea*, the excess estradiol levels decreased toward normal. This is an example of the normalizing effect of adaptogens. The discrepancy between the lack of estrogenicity in the Eagon study versus Gerasimova's observations is most likely due to differences in the method of preparation and/or route of administration. Gerasimova administered the herb intraperitoneally. Dr. Eagon fed the animals a proprietary *Rhodiola rosea* product, Rosavin (Ameriden International) that is used in humans. Digestion and metabolism of the orally ingested herb alters the properties of constituents. Other differences were in the source of the herb (wild-grown versus cultivated) and extraction procedures. Evidence suggests that *R. rosea* may exert anticarcinogenic as well as hepatoprotective effects (see section on Adaptogens in Cancer Treatment).

In clinical practice, the authors (PLG and RPB) find that *R. rosea* can reduce vaginal dryness and improve libido in many cases. It is particularly beneficial in menopausal women for symptoms of fatigue, forgetfulness, cognitive dysfunction, and depressed mood.

Many women who delay childbirth encounter problems with infertility. The onset of menopause can range from the mid 30s to the late 50s and is generally not predictable. It may be possible for women who delay childbearing past the age of 35 to use *R. rosea*, maca, and vitex to prolong fertility and possibly delay the onset of menopause. Given a choice, some women would opt to start *R. rosea* by age 35 to possibly maintain fertility if they find it necessary to delay childbearing.

Studies show that *R. rosea* enhances cognitive function (see section on Adaptogens for Cognitive Dysfunction). Although no specific studies have been done on perimenopausal women, the authors (PLG and RPB) have found in more than 100 cases that it is particularly helpful in improving memory, mental clarity, cognitive speed, energy, and mood in women before, during, and after menopause. These clinical observations should be extended through research on the mechanisms of action and clinical applications of *R. rosea* in treating perimenopausal decline in memory and cognitive functions, as well as other hormone-related conditions.

Ginkgo biloba and *Panax ginseng* (Ginkgo and Asian Ginseng)

Trials of *G. biloba* for fatigue and cognitive decline in menopause have had mixed results. In a 6-week DBRPC study of *G. biloba* in postmenopausal women, those in Stage +1 (mean age 55) performed better than those in Stage +2 (mean age 61) at baseline on tests of memory and cognitive function. After 6 weeks, in the ginkgo group the only clear benefit was greater mental flexibility among Stage +2 women (Elsabagh, Hartley, & File, 2005). In a 12-week DBRPC study, 57 postmenopausal women (aged 51–66 years) were given *G. biloba* 120 mg plus *P. ginseng* 200 mg or placebo. No significant effects were found

on mood, menopausal symptoms, attention, or memory (Hartley, Elsabagh, & File, 2004).

Lepidium peruvianum Chacon, formerly *Lepidium meyenii* (Maca)

In the Andean region of Peru, people living in the mountains traditionally use maca to enhance fertility in humans and in livestock, particularly at high altitudes (see section on Herbs for Female Sexual Function). A systematic review found four RCTs showing positive benefits for menopausal symptoms. Due to the small sample size and mixed quality of methodologies, no firm conclusions were drawn (Lee, Shin, Yang, Lim, & Ernst, 2011). Estrogenic effects are a contraindication for use in women with fibroids, breast cancer, or endometriosis. Effects on long-term cancer risk are unknown.

Hypericum perforatum (St. John's Wort)

St. John's wort 900 mg/day given to 111 menopausal women in a 12-week open series significantly improved self-esteem, self-image, irritability, anxiety, and depression. Improvements not reaching statistical significance were observed in psychosomatic symptoms (insomnia, headache, and palpitations), vasomotor symptoms (sweating, flushing, and dizziness), and sexual desire (Grube, Walper, & Wheatley, 1999). In clinical practice, the authors find SJW to be mildly helpful in menopause, but the risk of drug interactions and phototoxicity may outweigh the benefits.

Linum usitatissimum (Flaxseed) and *Triticum aestivum* or *vulgaris* (Wheat germ)

Flaxseed and wheat germ have been used to relieve hot flashes and night sweats. A DBRPC trial comparing flaxseed to wheat germ in menopausal women found them equally helpful in relieving hot flashes, but neither improved bone mineral density or lipid profile (Dodin et al., 2005). Flaxseed is rich in lignans which have weak estrogenic and weak anti-estrogenic effects. Lignans and their metabolites increase serum estrogens by stimulating synthesis of sex hormone binding globulin (SHBG), which reduces clearance of circulating estrogens. Lignans also bind to estrogen receptors, act as SERMs, and theoretically could impede tumor genesis (Bedell, Nachtigall, & Naftolin, 2012).

HORMONAL TREATMENTS FOR FEMALE MENOPAUSE

Dehydroepiandrosterone (DHEA), dehydroepiandrosterone sulfate (DHEAS) and 7-keto DHEA

The authors have found that patients whose DHEA and/or DHEAS levels are low normal or below normal for age (particularly menopausal women) often respond to treatment with DHEA 25–75 mg/day with enhanced mood, cognitive function, memory, energy, and sexual function

(see discussion of DHEA in the sections Hormones for Treatment of Cognitive Dysfunction, Menopause, Andropause, and Sexual Function). A starting daily morning dose of DHEA 25 mg and a maintenance dose of 50 mg each morning are generally sufficient for menopausal symptoms. Side effects are usually minimal and include activation, anxiety, agitation, and occasionally seborrhea. DHEA, DHEAS, and total and free testosterone levels should be checked before treatment. If testosterone is low, DHEA may modestly increase levels enough to alleviate cognitive and sexual dysfunction but not enough to correct androgen deficiency states. However, treatment with testosterone resulting in higher testosterone levels may increase long-term risk of breast cancer. Therefore, in comparison to treatment with testosterone DHEA may provide a more modest but safer elevation of testosterone into the low normal range, enhancing DHEAS and sexual function. Because there are no clear data on DHEA and long-term risk of breast cancer, DHEA is relatively contraindicated in women with a personal or family history of breast cancer. In such cases 7-keto DHEA would be preferable, as it does not convert to testosterone, estrogen, or progesterone.

Intravaginal DHEA is a promising treatment for sexual function (Tan, Bradshaw, & Carr, 2012). In a 12-week DBRPC Phase II trial, 216 postmenopausal women were randomized to four groups. Each group was instructed to insert at bedtime a different concentration of DHEA: 0 mg, 3.25 mg, 6.5 mg, or 13 mg. Sexual function showed significant time-dependent and dose-dependent improvements in desire, arousal/sensation, arousal/lubrication, orgasm, and dryness during intercourse. The doses of DHEA were low enough that serum steroids stayed within normal postmenopausal range. Unlike estrogens, which only affect superficial epithelial cells, the DHEA transforms into androgens and/or estrogens locally and appears to affect cells in all three layers of the vagina (epithelium, lamina propria, and muscularis) (Labrie et al., 2009). Long-term trials are needed to verify safety.

INTEGRATIVE APPROACH FOR MENOPAUSE-RELATED DISORDERS

Evaluating patients who might benefit from integrative treatments begins with obtaining the personal and family history regarding menstruation, menopause, cancer, and cancer risk factors to identify contraindications for hormonal, phytoestrogen, or other herbal treatments. Target symptoms of concern to the patient may include hot flushes, vaginal dryness, dyspareunia, sexual dysfunction, insomnia, cognitive impairment, memory decline, fatigue, low energy, or mood changes. If the history reveals insomnia, daytime fatigue, snoring, gaps in breathing, leg movements at night, or uncomfortable leg sensations relieved by walking, a sleep evaluation (often followed by polysomnography) is indicated to rule out sleep apnea and restless leg syndrome. Appropriate laboratory testing of hormone levels includes FSH, LH, estrogens, progesterone, DHEA, DHEAS, free testosterone, total testosterone, thyroid functions, and possibly prolactin.

In addition to dietary improvements, exercise, sleep hygiene, and stress reduction, the following integrative treatments can be considered for specific target symptoms. Each treatment can be added to the others sequentially for stronger synergistic effects.

1. Hot flushes: black cohosh.
2. Vaginal dryness, dyspareunia: intravaginal DHEA as an alternative to estrogen cream, DHEA, *R. rosea*.
3. Hot flushes with cognitive/memory impairment and low energy: black cohosh plus *R. rosea*.
4. Primarily complaints of cognition/memory decline: *R. rosea* and/or DHEA or 7-keto DHEA (in women with low DHEA or DHEAS).
5. Low energy, fatigue: *R. rosea*.
6. Sexual dysfunction:
 - a. low libido: maca, *R. rosea*, *P. ginseng*, marapuama, DHEA, 7-keto DHEA
 - b. problems of arousal, sensation or orgasm: *R. rosea*, maca, *P. ginseng*, L-arginine, DHEA, 7-keto DHEA
7. Mood changes or depression: DHEA, 7-keto DHEA, *R. rosea*.
8. Pervasive complaints (hot flushes, cognitive, memory, low energy, sexual dysfunction) in women with low DHEA or DHEAS (lower quartile or subnormal), a trial of DHEA or 7-keto DHEA with cognitive enhancers is often helpful.

FEMALE SEXUAL ENHANCEMENT

Sexual function in women can be affected by psychological or physical stressors, age-related hormonal changes, relationship issues, medical illnesses, or medications. In many cultures potions from plants and animal parts have been used for centuries as aphrodisiacs. Scientific evidence for improvement in sexual function using herbs and nutrients is limited. Nevertheless, products promising sexual enhancement are sold widely. Possible mechanisms of action include vasodilation, improved circulation, antiinflammatory, antioxidant, hormonal, stimulant, and mood enhancement (Rowland & Tai, 2003). This discussion is limited to sexual enhancers for which there is some research evidence, frequent consumer use, and/or positive clinical experience. Herbs and nutrients can be helpful adjuncts to standard treatments including psychotherapy, pharmacotherapy, couples counseling, sex therapy, and life style changes to improve physical fitness and to reduce stress, fatigue, and substance abuse.

Herbs for Female Sexual Function

Panax ginseng (Asian or Korean Ginseng)

In a DBRPC trial, 32 postmenopausal women aged 40–60 years who had no menses for 1 year were given 1 g Korean

red ginseng three times daily or placebo. Twenty-eight out of 32 reported improved sexual arousal with ginseng compared to placebo. Two cases of vaginal bleeding were reported (Oh et al., 2010). Infrequent side effects include insomnia, amenorrhea, pruritus, headache, and vertigo. Human studies suggest that ginseng does not affect platelet aggregation. Because ginseng may have hypoglycemic effects, insulin-dependent patients may require dose reductions when taking ginseng (Natural Medicines Database, 2010, pp. 780–781).

Lepidium peruvianum Chacon, Lepidium myenii (Maca)

Maca is a Peruvian adaptogen used to improve energy, sexual function, fertility at high altitudes, stress tolerance, nutritional status, and menopausal symptoms; it contains sterols, glucosinolates, and alkaloid components. Increased FSH, estrogen, and testosterone levels were noted in female rats given doses far in excess of those used clinically (Quiros & Cardenas, 1997; Chacon, 1997). These effects have not been found to occur in humans using clinical doses. An aqueous extract of yellow maca increased litter size in female mice and increased uterine weight in ovariectomized rodents, evidence of estrogenic effects (Ruiz-Luna et al., 2005). These findings cannot be extrapolated to humans without further clinical trials. Excess doses may cause overactivation or breast tenderness. Maca should not be used in patients with fibroids, estrogen receptor-related cancer risk, family history of breast cancer, or endometriosis. No behavioral toxicity has been reported in human or animal studies. However, the authors find that maca may precipitate agitation or mania in bipolar patients. Therefore, it should be used cautiously and in lower doses in cases of bipolar disorder. In clinical practice, the authors (RPB and PLG) find that monotherapy with a good quality brand of maca at doses between 3000 and 6000 mg/day can help many men and women improve libido, arousal, sensation, and orgasm. The effects may be mild, moderate, or strong. Maca can be useful in treating sexual dysfunction due to medical illness or medications (SSRI, SNRI, or antipsychotics). In a DBRCT in subjects (intent-to-treat $n = 16$) with SSRI-induced sexual dysfunction, 3.0 g/day of maca significantly improved libido ($p < 0.05$) on the Arizona Sexual Scale and the Massachusetts General Hospital Function Questionnaire (Dording et al., 2008). The benefits can be augmented with *R. rosea*, *P. ginseng*, and occasionally *Epimedium sagittatum* (see below).

Ptychopetalum olacoides or Uncinatum guyanna (Muirapuama or Marapuama)

Marapuama, from the rain forests of Brazil, is used as an aphrodisiac, nerve tonic, and antiarthritic (Mowrey, 1996). An open trial in 202 healthy women complaining of low sex drive found that after 1 month of taking marapuama combined with *G. biloba* 65% reported improvements in libido, intercourse, sexual satisfaction, intensity of orgasm, and other measures (Waynberg & Brewer, 2000). Mechanisms of action, side effects, and drug interactions have not been studied. Controlled studies with objective measures are needed.

Crocus sativus (Saffron)

The ability of saffron to reverse SSRI-induced sexual dysfunction was evaluated in a DBRPC study of 38 women (ages 18–45 years) with major depressive disorder who had responded to fluoxetine 40 mg/day with at least 50% improvement in depression. All of the women continued fluoxetine 40 mg/day. Those who were also given saffron 15 mg twice daily had significantly greater improvements in sexual arousal on the Female Sexual Function Inventory, lubrication, and reduction in pain with intercourse. The reduction in pain may be attributed to antinociceptive effects of saffron (Kashani et al., 2012).

Nutrients and Combination Formulas for Female Sexual Function

L-Arginine (2-amino-5-guanidinopentanoic acid)

L-arginine is the precursor to nitric oxide (NO), which is involved in vasodilation of genitalia during sexual arousal. Arginine in combination products has been used to enhance sexual dysfunction in women. A multi-herb supplement, ArginMax comes in two gender-specific forms. Arginmax for Women contains L-arginine, *P. ginseng*, *G. biloba*, damiana leaf (*Turnera diffusa*), multiple B-vitamins, folic acid, vitamins A, C, and E, calcium, iron, and zinc. Damiana is considered safe in medicinal doses, but excess amounts may have adverse effects.

In a 4-week DBRPC study of 77 women, 73.5% of the subjects taking ArginMax reported improvements in their sex lives, including improved desire, vaginal lubrication, frequency of intercourse and orgasm, and clitoral sensation, versus 37.2% of those on placebo. ArginMax had no significant side effects (Ito, Trant, & Polan, 2001). In a 4-week DBRPC trial, ArginMax for Women was studied in 108 women (aged 22–73 years) who had reported lack of sexual desire. Among the premenopausal subjects, those taking ArginMax reported significant improvements in sexual desire, frequency of intercourse, and satisfaction with sex life compared with the placebo group. Perimenopausal women reported improvements in frequency of intercourse, less vaginal dryness, and greater satisfaction with their sexual relationships compared with the placebo group. Postmenopausal women showed an increased level of sexual desire (51%) compared with placebo (8%). Anecdotally, the authors find ArginMax to be beneficial for sexual dysfunction secondary to medical illness or medications. This study highlights two important issues. First, the effects of herbal treatments can vary with hormonal status. Second, combinations of synergistic herbs and other nutrients can be more effective than monotherapies.

In vitro studies of ArginMax have not shown estrogenic activity (Ito, Polan, Whipple, & Trant, 2006). Infrequent side effects included abdominal pain, bloating, gout, allergic response, or exacerbation of airway inflammation in asthma (Jellin et al., 2010). There have been no long-term toxicity studies. The balance of L-arginine and lysine affects replication of herpes virus. In practice, the authors (RPB and PLG) have seen outbreaks of oral-buccal herpes in patients who take L-arginine or ArginMax. This can be prevented or treated by the addition of lysine tablets and/or lip balm.

Hormones for Female Sexual Function

Dehydroepiandrosterone (DHEA) for Sexual Arousal

A double-blind randomized crossover study of 16 postmenopausal sexually active women showed that a single oral dose of 300 mg DHEA taken 60 minutes before viewing an erotic video increased subjective ratings of physical ($p < 0.036$) and mental ($p < 0.016$) arousal compared to placebo (Hackbert & Heiman, 2002). The possible risks of intermittent use of relatively high-dose DHEA for sexual enhancement compared with the risks of testosterone or other treatments has not been studied.

Integrative Approach to Sexual Dysfunction in Women

1. History and physical examination.
2. Rule out medical conditions that could affect sexual function. Also, evaluate for iatrogenic factors such as medications that may impair libido, arousal, and/or orgasm, such as birth control pills or other hormonal products, antidepressants (particularly SSRIs, venlafaxine), antipsychotics, blood pressure medications, and over-the-counter preparations.
3. Evaluate psychological, emotional, and relationship factors contributing to sexual dysfunction.
4. Obtain the following laboratory studies: DHEA, DHEAS, free testosterone, total testosterone, and prolactin. DHEA or DHEAS levels in the lower quartile may be worth treating in patients with sexual dysfunction or depression. Increased levels of prolactin—not uncommon in patients taking antipsychotics or SSRIs—are often missed.
5. If stress or lack of sleep are significant causative factors, then advise life style changes and mind-body practices such as yoga breathing, yoga postures, meditation, and exercise.
6. For lack of libido in women, try maca, *R. rosea*, Herbal-vX (*Muira puama* + ginkgo), or DHEA.
7. For problems with arousal or orgasm, suggest ArginMax, maca, *R. rosea*, DHEA or 7-keto-DHEA. These treatments can be layered for combined effects.

MALE SEXUAL FUNCTION AND ANDROPAUSE

Physical or psychological stress, anxiety, depression, fatigue, poor nutrition, substance abuse, low hormone levels, environmental toxins, alcohol abuse, medical conditions (e.g., benign prostatic hypertrophy, hypertension, and vascular disease), and medications such as nonthiazide diuretics, benzodiazepines, antidepressants (particularly SSRIs and venlafaxine) can adversely affect sexual function in men. Although low libido, disorders of arousal, premature ejaculation, and inability to climax can occur at any age, these problems tend to worsen after age 45 during andropause when changes in hormone levels and prostatic enlargement are occurring.

While standard treatments for sexual performance (e.g., phosphodiesterase-5 inhibitors) can be helpful in many cases, conventional treatments for loss of libido are more limited. Herbs and nutrients for treatment of sexual dysfunction will be discussed first, followed by treatments for benign prostatic hypertrophy.

Erectile Dysfunction

Erectile dysfunction (ED) is the most frequent among male sexual function disorders. Although 60%–70% of men respond to phosphodiesterase-5 inhibitors such as sildenafil with improved erectile function, many cannot tolerate side effects such as headache, gastrointestinal upset, and nasal congestion. Rare side effects include anterior ischemic optic neuropathy and deafness. Serious risks with this class of drugs involve interactions with nitrates, pulmonary hypertension, rarely anterior ischemic optic neuropathy, and deafness, especially with long-acting phosphodiesterase-5 inhibitors such as tadalafil (Cialis).

Herbs for Male Sexual Function

Panax ginseng (Asian or Korean ginseng)

Panax ginseng is a sexual stimulant often found in herbal preparations. It has been shown to increase nitric oxide synthesis, sperm count, testicular weight, testosterone level, and mating counts in animal studies (Kang, Kim, Schini, & Kim, 1995). *P. ginseng* 300 mg/day improved sexual performance more than placebo in a 3-month controlled study of 60 men (Choi, Seong, & Rha, 1995). In an 8-week DBRPC study 143 men with ED were given 1000 mg twice daily *P. ginseng*. Among the 86 completers, the ginseng extract significantly improved libido, erectile function, and orgasmic function compared to placebo. Insignificant changes in testosterone levels were found in the ginseng group. Levels of FSH, LH, prolactin, and estradiol did not change significantly (Kim et al., 2009). There have been anecdotal reports of hypersexual behavior induced by ginseng. Further studies are needed.

Ginkgo biloba (Ginkgo)

Ginkgo increases blood flow to the brain and genitalia. In an open 6-month nonblinded study of 50 men with ED with antidepressant-induced sexual dysfunction, ginkgo (EGb761) was reported to improve erectile function (Sohn & Sikora, 1991). These studies suffered from poor methodology. Furthermore, studies of treatments for sexual dysfunction tend to have high rates of placebo response. An 8-week DBRPC study ($n=37$) of antidepressant-induced sexual dysfunction found no difference between *G. biloba* and placebo (Kang, Lee, Kim, & Cho, 2002). Limited evidence supports benefits of ginkgo monotherapy for mild symptoms of impotence in middle-aged men, but not for problems with libido or orgasm, when given alone.

Maca (Lepidium myenii)

Peruvians living at high altitudes where maca (*Lepidium myenii*) grows have used it for centuries to enhance sexual

function and fertility. In reviewing maca research, Gonzales noted that, in rodent studies, black maca increased testosterone levels and spermatogenesis, prevented high-altitude spermatogenic disruption, and improved sexual performance in normal rats and in those with erectile dysfunction (Gonzales, 2012). One small study ($n = 9$) of normal men found that 4 months of taking maca resulted in increased seminal volume, sperm count, and sperm motility. Serum hormone levels were not changed by maca. Larger studies are needed to confirm long-term safety and efficacy (Gonzales et al., 2001). In a 12-week DBRPC trial of two different maca doses (1500 mg or 3000 mg/day), among the 57 men taking maca 40% reported significant improvements in self-perception of sexual desire at week 8 and 42.2% at week 12 compared to 0.0% in the placebo group. Nine men who were treated with maca in this study were selected for additional testing, which showed no increases in serum testosterone, LH, FSH, prolactin, or estradiol, and no change in ratings for depression (or anxiety). A weakness in this study was that the assessment of sexual desire was based on one question only with a scale of 0–5 (Gonzales et al., 2002). It would be worthwhile to replicate these findings using additional validated assessments of desire. No major side effects have been reported in human or animal studies. Excess doses may cause overactivation. Prostate cancer may be a contraindication to the use of maca.

Ptychopetalium olacoides or *Ptychopetalium unicum*
(*Muira Puama* or *Marpuama*) and *Ptychopetalum lignum* (*Muira Puama Wood*)

Extracts from the bark and roots of small trees in the Amazon rainforest, *Ptychopetalium olacoides* or *Ptychopetalium unicum*, are used to make an aphrodisiac called “muira puama.”

In an open study of 262 men complaining of lack of sexual desire and impotence who were treated with muira puama 1500 mg/day for 2 weeks, 62% reported enhanced libido and 51% reported better erections (Waynberg, 1990). Controlled studies with objective measures are needed to confirm these findings. The authors (RPB and PLG) observe that some patients report significant improvement in sexual desire and satisfaction with muira puama, whereas most have no response. Side effects tend to be mild.

Pinus maritime (*French Maritime Pine Bark*,
Pycnogenol)

A standardized extract of *Pinus maritime* called “pycnogenol” inhibits cyclo-oxygenase and reduces prostaglandin production and inflammation. When combined with the substrate L-arginine, pycnogenol increases production of NO by nitric oxide synthase, relaxing the cavernous smooth muscle that is necessary for penile erection. A 3-month open study of men with ED compared L-arginine (1.7 g/day) with L-arginine (1.7 g/day) plus pycnogenol (40 mg twice daily for 2 months, then 40 mg three times daily for the third month). Of the men given the combination, 92.5% reported normal erections (Stanislavov & Nikolova, 2003). The lack of placebo control or objective documentation of erectile function limits the import of this study. Pycnogenol showed no mutagenicity,

teratogenicity, effects on fertility, or other adverse effects in dogs given 150 mg/kg. Among 2,000 patients, a 1.5% incidence of minor side effects was reported including gastrointestinal disturbance, dizziness, nausea, and headache (Rohdewald, 2002). Evidence suggests that pycnogenol may impart long-term health benefits, including antioxidant, anti-inflammatory, antihypertensive, and cognitive enhancement.

Combination Formulas for Male Sexual Function

Arginine and ArginMax for Men

ArginMax for Men contains L-arginine, *P. ginseng*, ginkgo, and 13 vitamins and minerals. L-Arginine is a precursor to nitric oxide (NO). The NO signaling pathway affects specific sexual dysfunctions. In a small DBRPC study of 50 men with ED, L-arginine monotherapy resulted in 9/29 responders versus 2/17 on placebo. All nine responders had reduced NO excretion or production at baseline (Chen et al., 1999). A 2-week DBRPC crossover study of 45 men with ED compared a combination of L-arginine glutamate 6 gm/day plus yohimbine 6 mg/day; yohimbine 6 mg/day alone; and placebo taken 1–2 hours prior to sexual intercourse. At the end of each treatment period, erectile function domain scores for L-arginine plus yohimbine, yohimbine alone, and placebo were 17.2 ± 7.17 , 15.4 ± 6.49 and 14.1 ± 6.56 , respectively. The difference between L-arginine plus yohimbine versus placebo reached statistical significance ($p = 0.006$). Stratification according to baseline scores above 14 indicated that patients with mild to moderate ED had better erectile function domain responses to both treatments compared to placebo (Lebret, Herve, Gorny, Worcel, & Botto, 2002).

Prelox is a proprietary blend containing 720 mg total of L-arginine HCl, aspartic acid, pycnogenol, and 50 mg of *Epimedium sagittatum* extract standardized to 60.0% (30 mg) icariin. *E. sagittatum* is used in traditional Chinese medicine to prolong male sexual response. A DBRPC study of 50 men with mild to moderate ED found that those given Prelox more than doubled the mean number of intercourse events and significantly increased testosterone levels. Systolic and diastolic blood pressure both declined. No adverse effects were observed. The onset of action required 1–9 days (Stanislova, Nikolova, & Rohdewald, 2008). In a 6-month DBRPC study of 124 men ages 30–50 years with moderate ED and normal baseline testosterone levels, Prelox significantly improved ED and testosterone levels compared to placebo (Ledda, Belcaro, Cesarone, Dugall, & Schonlau, 2010). For a discussion of side effects see Nutrients and Combination Formulas for Female Sexual Function. In most studies and in clinical practice, L-arginine is effective when combined with other herbs.

Yohimbine (Pausinystalia yohimbe or Corynanthe johimbe)

Yohimbine, extracted from the bark of a tropical African tree (*P. yohimbe*), contains an alkaloid chemically similar to reserpine. Yohimbine inhibits adrenergic receptors that innervate the genitals. A meta-analysis of seven well-done DBPC studies surmised that 15–43 mg/day yohimbine

alleviated ED more effectively than placebo in 40% of men with sexual dysfunction (Ernst & Pittler, 1998). Higher quality prescription yohimbine is preferable in 5.4 mg pills, with a usual dose of 18–42 mg/day. Over-the-counter products account for 98% of reported side effects and these often contain only negligible amounts of yohimbine (Betz, White, & der Marderosian, 1995). Some patients, for example the elderly, are unable to tolerate yohimbine side effects such as anxiety, nausea, dizziness, chills, sweating, headache, insomnia, and, at higher doses, increased blood pressure. Yohimbine can exacerbate symptoms in patients with anxiety, panic, obsessive compulsive disorder, or posttraumatic stress disorder.

Epimedium sagittatum (Horny Goat Weed)

Epimedium sagittatum contains the phytoestrogens icariin, genistein, and daidzein. Icariin inhibits phosphodiesterase-5 and enhances cGMP in cells of cavernous smooth muscle. It is used in traditional Chinese medicine to prolong male sexual response. In vitro and animal studies of icariin and of herbal products containing *E. sagittatum* show no serious adverse effects and stronger phosphodiesterase inhibition than sildenafil (Ning et al., 2006). However, human safety and efficacy trials are needed. The authors use *E. sagittatum* occasionally to augment other herbs.

Hormones for Male Sexual Function

Dehydroepiandrosterone (DHEA)

Serum DHEA-S levels were found to be inversely correlated with the prevalence of ED in the Massachusetts Male Aging Study (Feldman, Goldstein, Hatzichristou, Krane, & McKinlay, 1994). In 40 men with serum DHEA-S levels below 1.5 $\mu\text{mol/L}$, a 24-week DBRPC study revealed that the men given DHEA 50 mg/day achieved significantly greater improvements in erectile function, orgasmic function, sexual desire, and intercourse satisfaction than those given placebo (Reiter et al., 2001).

Nutrients for Male Sexual Function

Acetyl-L-carnitine (ALC) and propionyl-L-carnitine (PLC)

In a DBRPC study of 96 men after bilateral nerve-sparing retropubic prostatectomy, ALC significantly augmented sildenafil in alleviating ED in comparison to men given sildenafil monotherapy or placebo. ALC plus sildenafil resulted in significantly greater improvements in ED, sexual intercourse satisfaction, orgasm, and general sexual well-being (Cavallini, Modenini, Vitali, & Koverech, 2005). In a 6-month DBRPC study of 120 men aged 60–74 years, those who received testosterone undecanoate 160 mg/day plus ALC 2 g/day plus PLC 2 g/day had significantly more improvement in erectile function score, depression melancholia scale score, and fatigue than those given testosterone plus placebo. Carnitines had more effect on erectile function score than testosterone alone. Unlike testosterone supplementation, carnitines do not increase prostate volume (Cavallini, Caracciolo, Vitali,

Modenini, & Biagiotti, 2004). Evidence suggests that carnitines can enhance the response to sildenafil.

Prostatic Enlargement and Sexual Dysfunction

Pygeum (*Pygeum africanum*), *Saw Palmetto* (*Serenoa repens*), and *Stinging Nettle Root* (*Urtica dioica*)

Prostatic enlargement is a common factor in sexual dysfunction in middle and late life. Free testosterone declines, and the prostate is stimulated by increasing levels of estradiol, prolactin, SHBG, and dihydrotestosterone. Reducing the size of an enlarged prostate sometimes improves sexual function. Treatments for benign prostatic hypertrophy (BPH) include finasteride, alpha-adrenergic blockers (terazosin, doxazosin, or tamsulosin), and surgery. Surgical procedures are expensive and may exacerbate sexual dysfunction. Alpha adrenergic blockers can cause tiredness, dizziness, depression, headache, abnormal ejaculation, and rhinitis (Medical Letter, 1997). Reduction of BPH has been reported for three herbs: saw palmetto (*Serenoa repens*), pygeum (*Pygeum africanum*), and stinging nettle root (*Urtica dioica*). Recent studies and systematic reviews of saw palmetto find no evidence to support its use for sexual dysfunction related to BPH (Barry et al., 2011; Tacklind, Macdonald, Rutks, Stanke, & Wilt, 2012).

Pygeum Bark (*Pygeum africanum*) and *Stinging Nettle* (*Urtica dioica*)

Production of extracts from the fragile African pygeum tree may not be ecologically sustainable. Pygeum bark extract increases prostate secretions and inhibits prostate cell growth and aromatase, which reduces the estrogen/testosterone ratio. It also reduces prolactin, inflammation, cholesterol, and the uptake of testosterone in the prostate (Bassi et al., 1987). Pygeum has been shown to significantly improve lower urinary tract symptoms (LUTS) without side effects in DBRPC trials (Barlet et al., 1990), but only one small open study supports its use for sexual activity in older men (Carani et al., 1991). Several DBRPC studies indicate that stinging nettle root alone and in combination with other plant extracts improves LUTS without adverse effects in men with BPH. However, effects on sexual function have not been adequately studied. Reduction in LUTS and prostatic volume have been attributed to blockage of prostate cell growth receptors and 5-alpha-reductase, inhibition of aromatase and SHBG binding, and antiinflammatory activity (Lichius & Muth, 1997; Sokeland & Albrecht, 1997). These benefits were demonstrated at a dose of 300 mg/day (Safarinejad, 2005). In a 60-week DBRPC of 140 elderly outpatients, a combination of 160 mg WS1473 saw palmetto and 120 mg WS1031 stinging nettle (PRO 160/120) was as effective as tamsulosin (alpha1-adrenoceptor antagonist) for LUTS caused by BPH (Engelmann, Walther, Bondarenko, Funk, & Schlafke, 2006).

HERB-DRUG INTERACTIONS

Concerns about herb–drug interactions (HDIs) prevent many clinicians from offering patients the full range of treatment

options. Phytomedicines can either interfere with or enhance the benefits of synthetic drugs such as psychotropics, anticoagulants, or chemotherapy agents. Among the herbs discussed in this chapter, only a few pose clinically significant risks of HDIs. Assessing the likelihood of HDIs and methods to minimize or obviate risks will be highlighted before addressing specific herbs. Understanding these issues will enable clinicians to take advantage of the therapeutic contribution of phytomedicines while avoiding adverse effects.

PHARMACOKINETIC AND PHARMACODYNAMIC INTERACTIONS

The two main aspects of pharmacokinetic interactions that can affect medication serum levels are the induction or inhibition of cytochrome P450 (CYP) isozymes and p-glycoproteins. Pharmacodynamic interactions include risks of increased CNS side effects (e.g., serotonin syndrome), hepatotoxicity, or bleeding. Additive effects such as excess sedation or activation can occur in the absence of pharmacokinetic or pharmacodynamic interactions. In a systematic review of 21 whole herb extracts (not isolated constituents) with human-level evidence regarding HDIs, Kennedy and Seely (2010) acknowledge the limitations of the information about potential HDIs. When isolated, the concentration of a constituent far exceeds that which occurs in the whole herb extract. This review made several important points.

1. Many herb–drug combinations that had preclinical evidence of drug interaction in vitro and in animal studies showed no evidence of interaction in humans.
2. For most of the herbs that had evidence of drug interaction in preclinical studies, the actual effect on serum levels of medications is quite small and of no clinical significance.
3. Caution is most needed when combining herbs with drugs that have a narrow therapeutic window such as warfarin or digoxin.
4. The effects of whole herbs or whole herbal extracts are often different from those of single isolated constituents.
5. The impact of a botanical extract on the CYP450 metabolism of one drug does not necessarily generalize to other drugs that are processed by the same isoenzyme because they may have different binding affinities. The affinity of the botanical extract could be stronger for one drug but weaker for another.
6. The interaction of herbs with many anesthetics and antidepressants requires further study.

The impact of a botanical extract on CYP450 metabolism from in vitro and in vivo animal studies is often not seen in human studies and may merely indicate a need for additional information. For example, not only phytomedicinals but also common fruits and vegetables consumed in our daily diet inhibit or induce CYP450 isozymes in vitro but have no

significant HDIs in humans. The gastrointestinal digestion, absorption, and metabolism of herbal constituents alter their properties and, therefore, their effects in living organisms as opposed to tissue cultures. Potential risks can be minimized by systematic monitoring for efficacy, side effects, and serum levels of medications that have a low therapeutic index (a small margin of safety between therapeutic and toxic effects or between therapeutic and subtherapeutic benefits) and meaningful serum levels. Herbs that have demonstrated, verified, serious HDIs in humans should not be used in combination with those specific medications. For extensive reviews showing the level of the evidence on HDIs, including whether the study is based on in vitro, in vivo, animal, or human trials, see Kennedy and Seely (2010). In his highly recommended book, *Herbal Contraindications and Drug Interactions*, Francis Brinker not only provides extensive details on HDIs and the evidence sources but also differentiates herbal effects on each of three phases of metabolism: Phase I, CYP450 system of isozymes; Phase II, conjugating enzymes; and phase III, transporter proteins (Brinker, 2010).

Phytomedicines can potentially enhance the effectiveness of chemotherapy agents and reduce chemotoxic effects. Studies of human tumors in animals with metabolizing enzyme systems similar to humans would clarify when to use and when to avoid herbals in patients undergoing cancer treatments. To date most cancer-related studies have been done in cell cultures or in rodents whose enzyme systems differ too much from human systems to permit extrapolation of results. However, clinical studies are appearing that will take into account the digestive and metabolic factors as well as tissue-specific and tumor-specific effects. Overall, the available evidence indicates potential for highly significant benefits of phytomedicinals in cancer treatment.

Actea racemosa (Black Cohosh)

Human studies of black cohosh demonstrate no impact on CYP3A4, CYP1A2, CYP2E1, or digoxin pharmacokinetics. At doses above therapeutic level, there was weak, insignificant inhibition of CYP2D6. In vitro studies of estrogen-responsive breast cancer cells showed that black cohosh enhanced the antiproliferative activity of tamoxifen (Kennedy & Seely, 2010).

Curcuma longa or *Curcuma domestica* (Curcumin)

No adverse interactions with drugs have been reported. In vitro and animal studies indicate that curcumin at high doses (over 15 gms/day) can inhibit platelet aggregation. Curcumin extract reduced or enhanced antitumor effects of chemotherapy agents and reduced hepatotoxic and cardiotoxic effects in vitro and in animal studies, depending on the type of cancer (Brinker, 2010).

Angelica sinensis (Dong Quai)

In vitro and animal studies found that water and ethanol extracts of dong quai increased activity of CYP2D6 and

CYP3A subfamily. Dong quai is not recommended for patients taking chemotherapy medications such as tamoxifen, temsirolimus, and other drugs metabolized by these enzymes (Yap, Kuo, Lee, Chui, & Chan, 2010). Individual case reports showed that concurrent use of dong quai with warfarin increased prothrombin time and INR (Brinker, 2010). Theoretically, antiplatelet/anticoagulant effects of dong quai could increase the risk of bleeding in patients on anticoagulants. The clinical use of dong quai is not recommended.

Camellia sinensis (Green Tea)

A supplement containing decaffeinated green tea had no effect on CYP3A4 or CYP2D6. A study using drug probes found no impact on CYP2D6, 1A2, or 2C9. A 20% increase in buspirone area under the curve (AUC), indicating some inhibition of CYP3A4, was deemed not to be clinically significant (Kennedy & Seely, 2010).

Eleuthero, Siberian Ginseng (*Eleutherococcus senticosus*, *Acanthopanax*)

Preliminary evidence from in vitro and animal studies of *E. senticosus* suggested possible inhibition of P450 enzymes 1A2, 2C9, 2D6, and 3A4. However, human studies of *E. senticosus* show no impact on any of these isozymes and no evidence of effects on digoxin levels (Kennedy & Seely, 2010). Mild hypoglycemic effects indicate a need to monitor serum blood sugar of insulin dependent diabetics and adjust the dosage of anti-diabetic medications as needed.

Zingiber officinale (Ginger)

Although ginger has exhibited antiinflammatory and antiplatelet activity, it did not alter clotting states or warfarin pharmacokinetics at doses of 3.6 gms/day for one week or 100 mg/kg for 4 days in human trials (Kennedy & Seely, 2010). Rare cases of increased bleeding have been reported in patients on long-term phenprocoumon.

Ginkgo biloba (Ginkgo)

In reviewing studies of ginkgo, Diamond and Bailey (2013) pointed out that flavones, ginkgolides A and B, and bilobalide are thought to be involved in antioxidant, metabolic, neurotransmitter, and regulatory actions. Ginkgolides inhibit platelet anti-activating factor. Although ginkgo has been shown to reduce blood viscosity and to thereby increase perfusion in elderly patients and in peripheral artery disease, it has not shown significant effects on platelet aggregation, fibrinogen, partial thromboplastin time, or prothrombin time. Case reports of increased bleeding include patients on warfarin, aspirin, nonsteroidal antiinflammatories, and other drugs. Attribution of bleeding to ginkgo is unsubstantiated in most cases. Reviews of RCTs and case reports did not find changes in objective measures of coagulation (Diamond & Bailey, 2013). Induction of

CYP3A2 by higher than therapeutic doses occurred in an animal study. Diamond and Bailey (2013) concluded that in therapeutic doses (80 to 720 mg/day in divided doses), standardized high quality ginkgo extracts are generally safe but may entail synergistic effects when administered with anticoagulants such as warfarin or aspirin (Diamond & Bailey, 2013).

Panax ginseng (Asian or Korean Ginseng)

Human studies had shown no impact of *P. ginseng* on probe substrates of CYP2D6, CYP3A4, CYP2E1 or CYP1A2. The herb also had no effect of serum levels of warfarin (Kennedy & Seely, 2010). However, in a more recent study, 12 healthy adults were given an oral dose of midazolam 8 mg (a CYP3A substrate) and fexofenadine 120 mg (probe for P-gp function) before and after taking *P. ginseng* 500 mg twice daily (Vitamar Laboratories, 5% ginsenosides from whole root powder) for 28 days. Pharmacokinetic calculations comparing before and after midazolam serum levels found reductions in AUC of 0.66 (0.55–0.78), half-life of 0.71 (0.53–0.90), and maximum concentration of 0.74 (0.56–0.93). No change occurred in fexofenadine pharmacokinetics (Malati et al., 2012). As a CYP3A probe, the metabolism of midazolam can vary significantly depending on CYP3A polymorphisms (Elens et al., 2013).

Panax quinquefolius (American Ginseng)

American ginseng extract (1 g q8 hrs for 14 days) had no effect on the pharmacokinetics of indinavir (800 mg q8 hrs for 3 days) (Andrade et al., 2008). Two weeks of American ginseng extract 200 mg twice daily did not alter zidovudine pharmacokinetics, but it did reduce oxidative stress markers (Lee, Wise, et al., 2008). However, in a 4-week DBRPC study, 20 healthy subjects were given warfarin 5 mg/day for 3 consecutive days during weeks 1 and 4. After the first week they received either American ginseng 1.0 g/day or placebo for 3 weeks. The peak INR, peak plasma warfarin level, and warfarin AUC significantly decreased after 2 weeks of ginseng administration, indicating that American ginseng can reduce the anticoagulant effect of warfarin (Yuan et al., 2004).

Piper methysticum (Kava)

In vitro studies of the effects of kava extract and kava lactones on human liver microsomes found significant inhibition of P450 enzymes (CYP1A2, 2C9, 2C19, 2D6, 3A4, and 4A9/11) (Mathews, Etheridge, & Black, 2002) and CYP2E1 (Gurley et al., 2005) involved in the metabolism of many pharmaceuticals. Taking kava with alcohol, sedatives, or muscle relaxants can induce coma (Almeida & Grimsley, 1996). Hepatotoxic effects have been reported, particularly when kava is consumed by individuals who regularly drink alcohol.

Rhodiola, Arctic Root, Rose Root (*Rhodiola rosea*)

An in vitro study found that 95% ethanol extracts from *R. rosea* plants grown in different areas of Norway showed inhibition of CYP3A4 and P-glycoprotein (P-gp) in cell cultures (Hellum et al., 2010). There was no correlation between the concentrations of the six marker constituents (which were presumed to be active) with these inhibitory effects. The component(s) responsible for in vitro inhibition of CYP3A4 and P-gp have not been identified. However, as with other herbs, CYP3A4 inhibitory activity in vitro did not translate to CYP3A4 inhibitory activity in vivo or in humans. In a rat study, *R. rosea* (SHR-5) was given with either warfarin (CYP450 test substrate) or theophylline (CYP1A2 substrate). No significant effects on drug pharmacokinetics were found and there were no significant changes in the anticoagulant activity of warfarin (Panossian, Hovhannisyan, Abrahamyan, Gabrielyan, & Wikman, 2009). The authors (RPB and PLG) have used *R. rosea* in patients taking many different medications without adverse effects (Brown, Gerbarg, Muskin 2009). One author (RPB) treated one patient on warfarin with *R. rosea* 150 mg/day and another on warfarin with *R. rosea* 300 mg/day. There was no change in INR in either case. Without information from in vivo and human studies, it cannot be assumed that *R. rosea* would interact adversely with medications. Nevertheless, the checking of serum levels (eg, digoxin) and INR (eg, warfarin) would minimize any potential risks.

Serenoa repens (Saw Palmetto)

Two studies indicate that saw palmetto does not affect CYP3A4, CYP1A2, CYP2D6, or CYP2E1 activity (Kennedy & Seely, 2010). A study of 10 adults given saw palmetto for 2 weeks found no increase in coagulation time or platelet function. One case of intraoperative hemorrhage in association with saw palmetto use was reported. In vitro studies of saw palmetto extracts show inhibition of tamsulosin binding to α_1 -adrenoceptors. Saw palmetto α_1 -adrenoceptors antagonism was less than for prazosin in human trials (Brinker, 2010). Until more studies are completed, discontinuation of saw palmetto 2 weeks prior to surgery is advised. Given the lack of clinical effect in the most recent studies and reviews, it is hard to justify the use of saw palmetto (Tacklind et al., 2012).

Schizandra chinensis and *Schizandra sphenanthera* (Schisandra)

In vitro studies show that schisandra inhibits CYP3A4 enzymes. However, schisandra induces the same enzymes in in vivo animal studies. Molecular changes that occur through digestion of herbals can alter their effects on CYP450 enzymes. In animal models schisandra reduced warfarin levels, but this has not been demonstrated in human subjects. Until more is known, INR should be monitored in patients taking anticoagulants who are given schisandra. In rat studies multiple dosing of *Schizandra chinensis* alcoholic extract (1.5

g \times kg (-1) , qd \times 7d) significantly induced CYP2E1, inhibited CYP2D2, and had no effect on CYP2C6, CYP3A1/2, CYP1A2 or (Wang, Hu, Sheng, & Li, 2011). In China *Schisandra sphenanthera* is commonly used with tacrolimus, an immunosuppressant that reduces organ rejection in transplant patients. Compared to treatments with tacrolimus alone, liver transplant patients given both tacrolimus and schisandra showed markedly increased serum concentrations of tacrolimus, improved liver function, and reduced incidence of tacrolimus-associated side effects of diarrhea and agitation (Jiang, Wang, Xu, & Kong, 2010).

Hypericum perforatum (St. John's Wort)

St. John's wort extracts induce cytochrome P450 isozymes including CYP3A4, 2C19, 2C9, and 1A2, as well as intestinal wall p-glycoprotein (P-gp) transporter. Case reports and human studies indicate SJW can interfere with absorption, metabolism, and clinical effectiveness of numerous medications including digoxin, warfarin, phenprocoumon, HIV protease inhibitors, reverse transcriptase inhibitors, indinavir, irinotecan, theophylline, cyclosporine, alprazolam, amitriptyline, clonazapine, dextromethorphan, simvastatin, tacrolimus, and oral contraceptives (Knuppel & Linde, 2004; Van Strater & Bogers, 2012). SJW constituents hypericin, hyperforin, and flavones are used for standardization. The hypericin content is associated with antidepressant effects and hyperforin is associated with CYP3A4 induction. An excellent review of SJW by Sarris noted that studies using high-dose hyperforin extracts >10 mg/day induced CYP3A4, whereas those containing low-dose hyperforin <4 mg/day showed no significant effects on CYP3A4 (Sarris, 2013). However, low-dose hyperforin extracts are not clinically effective. SJW should be discontinued 2–3 weeks prior to surgery because it can affect heart rate and blood pressure during anesthesia.

Valeriana officianalis (Valerian)

Two studies evaluating valerian did not find any effects on CYP1A2, CYP2E1, CYP2D6, or CYP3A4/5 activity (Kennedy & Seely, 2010). However, in 12 healthy subjects the maximum concentration of alprazolam (CYP3A4 substrate) at baseline was significantly increased after 14 days of taking 1000 mg nightly of valerian extract (1.1% valerenic acids), a dose that is greater than the usual clinical dose (Donovan et al., 2004). In a study of 12 adults taking 375 mg/day for 28 days of a valerian root extract that did not contain valerenic acids, there was no effect on metabolism of the CYP3A4 substrate midazolam (Brinker, 2010). The absence of the active compound, valerenic acid, limits the clinical usefulness of this study. This illustrates the point that differences in the content of extracts and variations in affinities among substrates of the same isozymes can yield different effects. Based on animal studies, valerian could potentiate the action of sedative drugs, possibly by additive effects.

Vitex agnes-castus (Vitex, Chaste Tree)

In fluorogenic in vitro assays a vitex preparation did not affect CYP1A1 or CYP2C9, but it impacted CYP2C19 and CYP3A4 (Ho, Singh, Holloway, & Crankshaw, 2011). No HDIs involving vitex in humans have been reported, although caution is recommended when used with dopamine agonists, hormone replacement therapy, and possibly birth control pills. A systematic review of adverse events based on data from clinical trials, postmarketing surveillance studies, surveys, spontaneous reporting, manufacturers, and herbalist organizations reported no drug interactions (Daniele, Thompson Coon, Pittler, & Ernst, 2005).

SUMMARY

Many physicians are reluctant to recommend or condone the use of herbal medicines because they lack familiarity with the benefits, the potential side effects, and the simple methods to minimize risks. In contrast, most physicians become comfortable prescribing medications that are known to have more frequent and more severe drug interactions and side effects. Although the number of phytomedicines may seem daunting at first, in reality only a handful of them would have a significant impact in most clinical practices. Knowledge of just a few of the most useful herbs, how to monitor for benefits and side effects, and where to obtain reliable brands, would enable the physician to responsibly integrate phytomedicines with standard treatments to optimize patient outcomes (Brown, Gerbarg, & Muskin, 2009).

COUNTERACTING MEDICATION SIDE EFFECTS WITH NUTRIENTS AND HERBS

Intolerance of medication side effects is a major cause of non-compliance. When dose reduction or switching medications is ineffective, herbs, nutrients, and hormones can be used either to substitute for the offending medication or to counteract side effects of medications that cannot be discontinued. Although only a few natural medicines have been studied as antidotes to side effects, in clinical practice, the authors find the following treatments to be useful in preventing or reversing medication-induced side effects. Dosage guidelines are included for some supplements. Where there is no specific dose recommended, the practitioner should start by following the instructions on the product label and increase gradually while monitoring for symptom relief and side effects.

ASTHENIA, FATIGUE, SOMNOLENCE

Many drugs cause fatigue or somnolence, particularly psychotropics, antihypertensives, antihistamines, opiates, beta blockers, tamsulosin, and chemotherapy treatments. If it is not possible to change the medication, the following treatments can be combined to increase daytime energy (mental and physical) without causing addiction: *R. rosea* (300–750 mg/day), *E. senticosus* (500 mg b.i.d.), and *P. ginseng* (300

mg or more/day). If this combination is not effective enough, maca (3–4 × 750 mg tablets b.i.d.) may be added. ADAPT-232 (2–4 tablets/day) contains *R. rosea*, *E. senticosus*, and *S. chinensis*.

CACHEXIA IN CANCER PATIENTS ON CHEMOTHERAPY OR RADIATION THERAPY

Cancer cachexia is characterized by anorexia, weight loss, muscle wasting, weakness, fatigue, and changes in metabolism of carbohydrates, lipids, and proteins. Oxidative stress and systemic inflammation are considered to be contributory factors.

Bio-Strath

Bio-Strath, a traditional Swiss herbal preparation derived from brewer's yeast grown on a bed rich in medicinal alpine herbs, contains a high concentration of B Vitamins and antioxidants. A DBRPC stratified trial in 177 cancer patients undergoing radiation therapy found that those who were administered Bio-Strath showed improved energy, appetite, weight gain, and red blood cell counts compared with placebo. Bio-Strath did not affect tumor growth or the antitumor effect of radiotherapy (Schwarzenbach & Brunner, 1996).

L-Carnitine

A review of L-carnitine found evidence that it can reduce chronic inflammation and oxidative stress in cancer patients. Cancer patients are at risk for carnitine deficiency due to reduced food intake, increased metabolic demands, and interference by chemotherapy drugs with carnitine absorption, synthesis, and excretion. Studies of carnitine (4 g/day) in cancer patients find improvement in fatigue, mood, sleep, and appetite, with an increase in lean body mass (Silverio, Laviano, Rossi Fanelli, & Seelaender, 2011). A review of L-carnitine reported evidence that it helps reduce the side effects of radiochemotherapy (Kahn, 2004). Animal studies demonstrate protection against radiation-induced germ cell apoptosis and reduced damage to brain, retina, cochlea, and kidneys. L-carnitine has been used to prevent cardiotoxicity from chemotherapy.

Rhodiola rosea

A nonblinded 28-week RCT in 58 patients with advanced nonsmall-cell lung cancer showed that those who were given 10 intravenous 30-hour ATP infusions at 2- to 4-week intervals had statistically significant improvements in weight, serum albumin, muscle strength, energy and fatigue ($p < 0.0001$), and quality of life. Side effects included chest heaviness (Agteresch, Dagnelie, van der Gaast, Stijnen, & Wilson, 2000). While this treatment was effective, it has limited practicality because of the need for intravenous infusion. However, since *R. rosea* can be easily given by mouth it would be worthwhile to study this as a simpler way to increase ATP (Panossian, 2013), particularly because it has already been

found to improve muscle strength, energy, and fatigue in animal studies, normal subjects, and patients with other illnesses.

NAUSEA AND VOMITING

Nausea and vomiting sometimes respond to ginger tea or ginger capsules taken 40 minutes prior to medication. A small container of candied ginger can be carried easily for sudden episodes of nausea. Nausea can also be relieved using acupressure bands applied to acupressure points at the wrist. Amrit Kalash (two complex Ayurvedic herbal formulas) can be used for severe nausea, fatigue, and other side effects of chemotherapy.

HEPATIC DYSFUNCTION

Many medications can cause hepatitis as indicated by elevations in liver enzymes. See the section titled Nutrients for Mood Disorders for a discussion of the hepatoprotection by SAME, polyenolphosphatidyl serine, and bupleurum.

CONSTIPATION, HEMORRHOIDS, AND VARICOSE VEINS

Constipation caused by medications often responds to triphala 2–4 capsules/day (an Ayurvedic herbal preparation) (Munshi et al., 2011) or magnesium 600–800 mg/day (Guerrera, Volpe, & Mao, 2009). Patients who become constipated on medications (e.g., opioids) may engage in constipation-prolonged forceful valsalva during defecation, which can exacerbate hemorrhoids. Herbs that strengthen the walls of blood vessels and help to heal and prevent hemorrhoids and varicose veins include *Ruscus aculeatus* (butchers broom; CircuCaps) and *Aesculus hippocastanum* (horse chestnut extract). These vasotonic herbs also reduce capillary filtration rate and edema in chronic venous insufficiency (MacKay, 2001). In addition, butcher's broom has antiinflammatory properties and inhibits macromolecular permeability and elastase. Meta-analysis of 20 clinical trials of Cyclo 3 Fort (root extract of the *Ruscus aculeatus* 150 mg, hesperidin methyl chalcone 150 mg, and ascorbic acid 100 mg)—including 20 placebo controlled, randomized double blind studies and 5 randomized studies against a comparator drug—found strong evidence of efficacy in the treatment of chronic venous insufficiency (Boyle, Diehm, & Robertson, 2003). Horse chestnut exhibits vasotonic, vascular protective, antiinflammatory, and free-radical scavenging properties. In vitro studies demonstrated inhibition of the enzymes elastase and hyaluronidase. These herbs are safe and generally well tolerated. Isolated adverse effects of horse chestnut have been reported in one patient on anticoagulant medication with angiomyolipoma and in one anorexic patient with renal insufficiency.

NERVOUS SYSTEM

Extrapyramidal Symptoms

Controlled studies of herbs and nutrients in psychotic disorders are limited. However, considering the devastating effects

of psychotic disorders, the severity of antipsychotic medication side effects (e.g., weight gain, diabetes, cardiovascular disease, sedation, fatigue, extrapyramidal symptoms, and tardive dyskinesia) and the low side-effect risk with herbs and nutrients, a lower threshold of evidence is reasonable in offering complementary treatments. Oxidative stress causing damage to neurotransmitter systems, particularly dopaminergic nerves in striatal tissues, has been implicated in the pathogenesis of the following psychotropic medication side effects:

1. Extrapyramidal symptoms: dystonias (muscle spasms), oculogyric crises (spasm of muscles controlling eye movements), pseudoparkinsonism (muscle rigidity, tremor, bradykinesia, mask-like facies), akinesia (difficulty initiating movement), akathisia (motor restlessness), restless legs, bruxism (jaw clenching), and blepharospasm (eyelid spasms).
2. Tardive dyskinesia (TD): involuntary movements of the tongue, jaw, trunk, or extremities may be choreiform (rapid, jerky, discontinuous) or athetoid (slow, sinuous, continuous).

Reduced levels of antioxidant defense enzymes in schizophrenic patients, oxidative damage, toxins, and inflammatory processes may contribute to the development of schizophrenia and medication side effects (Sivrioglu, Kirli, Sipahioglu, Gursoy, & Sarandol, 2007). The incidence and severity of side effects could be ameliorated by substances with known neuroprotective, cognitive enhancing, antioxidant, and antiinflammatory actions in patients taking antipsychotic medications.

Ginkgo Biloba

Ginkgo increases circulating and membrane PUFAs (particularly eicosapentanoic acid) and protects against oxidative stress in vivo (Drieu et al., 2000). Reducing oxidative damage to neurons by increasing PUFAs could help alleviate adverse effects of antipsychotic medications. Ginkgo may protect against the neural damage associated with antipsychotics and extrapyramidal symptoms. For example, a 12-week DBRPC trial in patients with treatment-resistant schizophrenia compared ($n = 56$) ginkgo 360 mg/day plus haloperidol 0.25 mg/kg/day with ($n = 53$) placebo plus haloperidol 0.25 mg/kg/day; 57% of the ginkgo group were rated as responders versus 38% of the placebo group. The ginkgo group showed a lower incidence of extrapyramidal symptoms and greater improvement in positive symptoms of schizophrenia such as delusions, hallucinations, disorganized speech, grossly disorganized or catatonic behavior, and in negative symptoms such as flattening of affect, avolition (restriction in the fluency and productivity of thought and speech), and avolition (restriction in goal-directed behavior) (Zhang et al., 2001). Similarly, in an 8-week DBRCT of schizophrenic patients those given olanzapine with ginkgo (EGB) augmentation ($n = 15$) had a significant reduction on the Positive Syndrome Scale (PANSS) versus those given olanzapine alone ($n = 14$).

The group taking ginkgo had significantly greater reductions in superoxide dismutase and catalase, indicating reduced oxidative stress (Atmaca, Tezcan, Kuloglu, Ustundag, & Kirtas, 2005).

B Vitamins

Pyridoxine (vitamin B₆) may reduce side effects of antipsychotic medications. In a 4-week DBPCR trial in 15 schizophrenic and schizo-affective patients with TD, B₆ 400 mg/day markedly reduced TD symptoms (Lerner et al., 2001). A 5-day DBRPC study of 20 schizophrenic and schizo-affective patients with neuroleptic-induced akathisia found B₆ 600 mg b.i.d. improved the subjective sense of restlessness, distress and global ratings significantly more than placebo (Lerner, Bergman, Statsenko, & Miodownik, 2004). In another DBRPC trial, 60 schizophrenia and schizoaffective inpatients with neuroleptic-induced akathisia were randomized to receive vitamin B₆ 1200 mg/day, mianserin 15 mg/day (tricyclic noradrenergic and specific serotonergic antidepressant), or placebo for 5 days. Compared with the placebo group, the vitamin B₆-treated and mianserin-treated patients had a significant improvement in subjective distress and Clinical Global Impression subscales, but not in the objective subscale. A reduction of at least 2 points on the Barnes Akathisia Rating Scale global subscale was noted in the vitamin B₆ group (13/23, 56%) and in the mianserin groups (13/20, 65%) compared to only one patient in the placebo group (Miodownik et al., 2006). High doses of B₆ with low doses of mianserin may be a useful addition to current treatments of neuroleptic-induced akathisia.

Combination Supplement—Omega-3 FA, Vitamin E, and Vitamin C

In an open study, 17 schizophrenic patients being treated with haloperidol were given a 1000 mg capsule of n-3 FAs (180 mg EPA + 120 mg DHA) twice daily, vitamin E 400 IU twice daily and vitamin C 1000 mg/day for 4 months. At the end of the study, scores were significantly lower compared to baseline on the Brief Psychiatric Rating Scale, Scale for the Assessment of Negative Symptoms, Simpson Angus Scale, and Barnes Akathisia Rating Scale. In addition, superoxide dismutase levels were significantly lower at the end of study, but glutathione peroxidase, malondialdehyde, vitamin E and C levels were not (Sivrioglu et al., 2007).

N-acetylcysteine

N-acetylcysteine scavenges for free radicals and increases intracellular glutathione, the primary neuroprotective antioxidant in the brain. Studies of animals given haloperidol 1.5 mg/kg/day for 21 days showed significant elevations in striatal superoxide (free radicals) and lipid peroxidation (free radical damage to membranes) compared with animals not given haloperidol. Next, both groups of animals were given N-acetylcysteine (NAC) for 21 days in 3 different doses: 50 mg/day, 500 mg/day, and 1500 mg/day. All three doses of NAC prevented the haloperidol-induced increase in superoxide (free radical) levels. The 1500 mg/day dose of NAC prevented haloperidol-induced

increase in lipid peroxidation and improved the glutathione/reduced glutathione ratio. In animals not pretreated with haloperidol, 50 mg/day and 500 mg/day NAC reduced oxidative stress markers, but 1500 mg/day increased levels of superoxide, decreased lipid peroxidation, and increased consumption of reduced glutathione (Harvey, Joubert, du Preez, & Berk, 2007). Doses up to 1800 mg twice daily are being used in human studies. Excessive doses of NAC may promote oxidative processes. Caution is advised in the use of high-dose intravenous NAC. The use of NAC in addiction, compulsive and grooming disorders, schizophrenia, and bipolar disorder has been reviewed (Dean, Giorlando, & Berk 2011).

In a 6-month DBRPC study of 140 patients with schizophrenia, NAC 1000 mg twice daily reduced symptoms of akathisia and improved Clinical Global Impression (effect size = 0.40) compared to placebo (Berk, Copolov, Dean, et al., 2008a). In appropriate doses, NAC may reduce prevent or reduce medication-induced damage to striatal tissues and the ensuing side effects. NAC is available in 600 mg tablets in the United States. Two 600mg tablets twice a day would have about the same effect as the doses used in clinical trials.

Dehydroepiandrosterone (DHEA)

In a 12-week DBRPC study of chronic schizophrenic patients (n = 40), DHEA (up to 150 mg/day) reduced negative symptoms, extrapyramidal symptoms, akathisia, and glucose levels better than placebo (Strous et al., 2007). The reduction in negative symptoms and medication side effects may be attributable to potentiation of NMDA-receptor activity, suppression of GABA inhibition, and enhancement of frontal dopamine release.

Melatonin

Melatonin (10 mg/day sustained release) alleviated symptoms of TD in 17 out of 22 patients with schizophrenia (mean duration of 25 years) in a 6-week DBPC crossover study. Scores on the Abnormal Involuntary Movement Scale decreased 3 points in seven patients on melatonin versus one patient on placebo (Shamir et al., 2001).

Restless Leg Syndrome

Restless leg syndrome is characterized by abnormal uncomfortable sensations and/or movements of the legs, usually worse at night or at rest and often relieved by walking around. Antipsychotics and antidepressants, particularly SSRIs, can cause restless leg syndrome with secondary loss of sleep. A combination of lemon balm, passion flower, and valerian can be helpful.

Cognition, Memory, and Word Finding

Patients often complain of cognitive impairment, decreased memory, and/or word-finding problems related to medication. Many of the treatments described in the section titled Cognitive Function can help to counteract

cognitive and memory dysfunction due to medication side effects, including the following: *R. rosea* 450–750 mg/day; ADAPT-232 2–4 tablets/day; Aniracetam 750 mg twice daily; and Huperzine-A 200–400 mg twice daily. Artichoke extract may be of benefit in cognitive impairment secondary to chronic use of benzodiazepines, based on animal studies.

In a DBRCT of schizophrenic inpatients ($n = 42$) with elevated homocysteine (increased oxidative stress), those who were given a daily vitamin combination (folic acid 2 mg, B₁₂ 400 mcg, B₆ 25 mg) showed significantly greater reduction in homocysteine levels and PANSS scores and improved cognitive function compared to the placebo group (Levine et al., 2006).

Insomnia

Medication-induced insomnia can respond to Melatonin 3–9 mg hs. Melatonin reduces sleep onset latency; extended release melatonin maintains sleep. Chronic schizophrenic patients have shown blunted nocturnal melatonin levels. A DBRPC study in schizophrenic outpatients ($n = 40$) demonstrated that in patients receiving haloperidol 10–15 mg/day, melatonin 3 mg hs improved sleep measures and quality of life in comparison to placebo (Kumar, Andrade, Bhakta, & Singh, 2007).

CARDIOVASCULAR SYSTEM

Pedal Edema

Antipsychotics, mood stabilizers (such as valproate and lithium carbonate), SSRIs, and other medications can cause pedal edema (swelling of the feet and ankles due to leakage of fluid from veins into tissues. (See section on constipation, hemorrhoids, and venous insufficiency.) By strengthening the veins, butcher's broom (Sanhelios CircuCaps 900 mg/d) and horse chestnut extract (Natures Way Standardized Extract 1 tablet b.i.d.) can reduce pedal edema.

MUSCULOSKELETAL SYSTEM

In a university department of cardiology clinic, more than 30% of patients taking statins reported myopathy, myalgia, or myositis (Riphagen, van der Veer, Muskiet, & DeJongste, 2012). Statin myotoxicity has been linked to impairment of mitochondrial functions, such as electron transport, and depletion of CoQ10. Preliminary studies of CoQ10 supplementation to relieve statin-induced myalgia and muscle weakness have yielded inconsistent results. Patients on maintenance statin treatment should have CoQ10 levels monitored. If the levels are low, or if the patient develops symptoms of muscle pain or weakness, then supplemental CoQ10 (preferably ubiquinol, a reduced form of CoQ10) is indicated. The ongoing *Co-Enzyme Q10 in Statin Myopathy* study intends to determine the effects of CoQ10 on pain intensity in patients with statin-induced myalgia who are being treated for hypercholesterolemia (Parker et al., 2013).

HEMATOLOGICAL DISORDERS, IMMUNE DEFENSE, CHEMOTHERAPY TOXICITY

Erythrocytes

Medication-induced decreases in red blood cell count with a hematocrit >32 can be reversed with *R. rosea*, *E. senticosus*, and/or shark liver oil. Toxicity from contaminants and gastrointestinal disturbances with low-quality shark liver oil products has been reported. Therefore, the authors recommend only high-quality shark oil products such as Immunofin 2–6 capsules/day (Lane Labs) or shark liver oil (Life Extension Foundation) (Brown et al., 2009).

Leukocytes

Medication-induced decreases in white cells with a total count >3500 and a neutrophil count >1500, can be reversed using shark liver oil (2–6 capsules/day Immunofin,) *E. senticosus* 500 mg b.i.d., Astragalus, and/or lithium 600 mg/day or more (Brown et al., 2009).

Platelets

Medication-induced decreases in platelets, when the count is >80,000 and without bruising or bleeding, can sometimes be treated with shark liver oil (Immunofin) 2–6 capsules/day. The platelet count should be monitored to avoid supranormal levels (Brown et al., 2009).

If erythrocyte, leukocyte, or platelet counts drop below the minimal levels mentioned above, then the offending medication should be discontinued and the natural treatments continued until cell counts return to normal. If cell counts continue to decline or fail to improve, a hematologist should be consulted.

ADAPTOGENS IN CANCER TREATMENT REDUCE CHEMOTOXIC EFFECTS ON BONE MARROW AND LIVER

Chemotherapy drugs often damage stem cells in the liver and bone marrow, resulting in increased susceptibility to infections and other medical problems. When blood cell counts fall too low, chemotherapy may be interrupted.

Rhodiola rosea extracts demonstrated antitumor and antimetastatic activity in studies of human cancers transplanted into mice (Lewis lung carcinoma, Ehrlich's sarcoma, Pliss lymphosarcoma, NK/Ly tumor, and melanoma B16). Moreover, *R. rosea* protected liver and bone marrow cells from chemotoxic effects of adriamycin and cyclophosphamide, while at the same time enhancing the effectiveness of the chemotherapy in destroying cancer cells and reducing metastases (Dement'eva & Iaremenko, 1987; Razina, Zueva, Amosova, & Krylova, 2000; Udintsev, Krylova, & Fomina, 1992; Udintsev & Schakhov, 1989, 1990, 1991).

In 12 patients with superficial bladder carcinoma, *R. rosea* improved urothelial tissue, leukocyte integrines, and T-cell immunity with a trend toward reduction in frequency of relapse (Bocharova et al., 1995). A 95% ethanol extract of

R. rosea stems exhibited cytotoxic activity against prostate cancer cells (Ming et al., 2005).

Studies in rodents with transplants of human cancers (Lewis lung sarcoma, Pliss lymphosarcoma, Ehrlich's sarcoma, NKY/LY tumor, and melanoma B16) given adriamycin or cyclophosphamide found that the addition of *R. rosea* did not interfere with the actions of the chemotherapy agents. In fact, the *R. rosea* increased the effectiveness of the chemotherapy drugs, reduced metastases, and protected the liver and bone marrow stem cells from toxic effects of the chemotherapy. *R. rosea* is administered to cancer patients in the former Soviet Union. RCTs are needed to confirm safety and efficacy. Since fatigue is the most common complaint among cancer patients and since *R. rosea* is so beneficial for fatigue, trials would be helpful in cancer treatment and recovery.

The inaccessibility of *R. rosea* cancer research (much of which is published in foreign language journals) combined with reluctance to use herbal preparations in cancer patients and lack of funding to study adaptogens has prevented oncologists from discovering the potential benefits of *R. rosea* and other adaptogenic herbs.

Adaptogen Combination Treatments

In a study of 28 women with stage III–IV ovarian cancer treated with cisplatin and cyclophosphamide, subjects who took AdMax 270 mg/day (combination of extracts from roots of *Leuzea carthamoides*, *R. rosea*, *E. senticosus*, and fruits of *S. chinensis*) for 4 weeks following chemotherapy showed increases in T cell subclasses (CD3, CD4, CD5, and CD8), IgG and IgM compared with those who did not (Kormosh, Laktionov, & Antoshechkina, 2006).

Ashwagandha (Withania somnifera)

Ashwagandha is an adaptogenic herb known in Indian medicine for its antistress, antiinflammatory, antioxidant, analgesic, antidepressant, and immunomodulatory effects. An in vitro and in vivo study of selective tumor inhibition by an ashwagandha leaf extract found that one of the constituents, withanone, activated p53, a gene responsible for tumor cell apoptosis. The herbal extract selectively killed various human tumor cells but not normal human cells (Widodo et al., 2007). However, because ashwagandha has estrogenic properties, further studies are needed regarding long-term safety in women.

Amrit Kalash

Amrit Kalash, a proprietary Ayurvedic formula containing many herbs including ashwagandha, enhanced immune function and protected against free radical damage and toxic effects of chemotherapy in animal and cell culture studies. Amrit Nectar tablets (MA-7, containing 38 herbs) showed antioxidant activity and protected against toxicity from adriamycin and cisplatin (Dwivedi, Natarajan, & Matthees, 2005). It is reported to improve energy, well being, sleep, appetite, vomiting, diarrhea, and tolerance of cancer treatment without interfering with chemotherapy agents. Additional RCTs are needed to confirm safety and efficacy for cancer patients. In

clinical practice the authors find that patients who take Amrit Kalash during a course of chemotherapy report improved energy, digestion, and sense of well-being, as well as little or no hair loss.

RESPIRATORY INFECTIONS

Certain medications (e.g., modafinil) increase the occurrence of upper respiratory infections. Herbs and vitamins for stimulating immune defense include sambucol (concentrated extract of elderberries) and astragalus, reishi, shiitake, and maitake mushrooms. Red mangrove (*Rhizophora mangle*) bark extract from Fiji (Nature's Nurse, Respigard) is used to increase resistance to respiratory infection and to accelerate recovery. Traditional Polynesian medicine uses red mangrove for its astringent, antiseptic, hemostatic, antifungal, and anti-ulcerogenic properties (de Armas, Sarracent, Marrero, Fernandez, & Branford-White, 2005; Marrero et al., 2006). Based on in vitro and in vivo studies, *Andrographis paniculata* (king of bitters), an Asian phytomedicinal, manifests anticancer, antiinflammatory, and immunomodulatory action, and possibly reduction of autoimmune responses (Denzler, Waters, Jacobs, Rochon, & Langland, 2010; Iruretagoyena et al., 2005; Yang et al., 2010).

SUMMARY

Phytomedicines, nutrients, and neurohormones have the potential to relieve psychological and physical symptoms in medical patients. The growing reliance on synthetic medications has brought unintended consequences: side effects, serious adverse reactions, drug interactions, high costs of development passed on to consumers, substance abuse, and withdrawal symptoms. In addition, the manufacturing of synthetic drugs creates environmental pollutants, and the disposal of nonbiodegradable medications contributes to toxic water pollution. In comparison, herbs and nutrients have far fewer side effects, less addiction potential, and lower costs.

Biodiversity in medicinal plants and their innumerable related species is an untapped resource for the future development of medical treatments. Once the bioactive constituents are identified in a plant part, it is possible to alter the relative concentrations of therapeutic compounds by cross-breeding and by changing the composition of nutrients in the soil and water. Such methods mimic some of the forces of natural evolution and, therefore, are less likely to produce harmful new compounds with unexpected effects as compared to artificial synthetic processes or genetic insertions. Genomic analysis is expanding our understanding of speciation and the subtle genetic differences that may determine therapeutic effectiveness. Furthermore, phytomedicines are a natural, renewable resource that can help farming communities flourish.

CLINICAL PEARLS

- Considerable progress has been made in the standardization of botanical extracts based on the concentration of marker compounds believed to be essential for therapeutic activity and/or to be unique to the species.
- The ultimate test of an extract is proven efficacy in a good quality controlled trial published in a peer-reviewed journal.
- Safety of most herbs during pregnancy and breastfeeding has not been adequately studied.
- Certain complex products are more affected by differences in cultivation and extraction procedures; for example *Ginkgo biloba*, *Hypericum perforatum* (St. John's wort) and *Rhodiola rosea* (Arctic root).
- Product labels rarely state the source of extracts; *Ginkgo biloba* is one exception.
- In determining dosage, take note not only of the milligrams of the marker compounds but also of the percentage of the same marker compounds.
- ConsumerLab.com is one of the best nongovernmental resources for up-to-date, detailed, practical information on most of the supplements encountered in clinical practice.
- Natural GABA, produced by fermentation, is widely used as a functional food supplement in Japan
- Herbs and nutritional supplements have a role in treatment of anxiety, mood, cognitive function, menopause, andropause, and sexual function.
- Kava and kava lactones carry risk of intoxication, abuse, dependency, medication interactions, and rarely severe adverse reactions (e.g., liver injury). Only high quality Kava should be considered for clinical use.
- Supplementation with l-methylfolate may be more effective than folic acid in patients with polymorphisms because it bypasses the final MTHFR conversion step.
- The quality of S-adenosyl-L-methionine (SAME) and the quality of the tablet are critical for maintaining potency over time.
- In herb–drug interactions, pharmacodynamic interactions include risks of increased CNS side effects (e.g., serotonin syndrome), hepatotoxicity, or bleeding. Pharmacokinetic concerns entail effects on the P450 cytochrome system.

ACKNOWLEDGMENTS

We wish to thank Dr. Teodoro Bottiglieri and Dr. Alexander Panossian for their support in the preparation of this chapter.

DISCLOSURE STATEMENTS

Dr. Richard P. Brown holds a patent for the use of 3-acetyl-7-oxo-dehydroepi-androsterone (7-Keto DHEA) in the treatments of PTSD and dissociative disorders. He has no other conflicts of interest.

Dr. Patricia L. Gerbarg is married to Dr. Richard P. Brown who holds a patent on the use of 3-acetyl-7-oxo-dehydroepi-androsterone (7-Keto DHEA) in the treatments of PTSD and dissociative disorders. She has no other conflicts of interest.

PART IV

MAJOR SYMPTOMS AND SYNDROMES

GRIEF, COMPLICATED GRIEF, AND BEREAVEMENT-RELATED DEPRESSION

Alana Iglewicz and Sidney Zisook

INTRODUCTION

Grief is a universal mammalian experience. Generally, grief is considered to be self-limited, adaptive, and outside the general domain of psychiatric concerns. However, there are times when grieving persons can and should be referred for mental health care, such as when the death of a loved one also triggers a major depressive disorder, a prolonged stress or trauma reaction, or when healing does not occur spontaneously—a condition called “complicated grief.” In those circumstances grief can be associated with important general medical and mental health consequences (Ajdacic-Gross et al., 2008; M. K. Shear et al., 2011; Stroebe, Stroebe, & Abakoumkin, 2005; Zisook & Shear, 2009). This chapter will cover the clinical features of “normal” grief, the complex relationship between grief and depression (where does one end and the other begin?), the clinical features of complicated grief (CG), and evidence-based interventions for bereavement-related depression and CG.

TERMINOLOGY

Since terms used to describe emotions and behaviors following the death of a loved one are imprecise and used idiosyncratically by clinicians and experts alike, it is useful to review contemporary definitions of key terms. *Grief* may be defined as the constellation of feelings, cognitions, behaviors, and changes in function associated with loss of any kind. This definition applies to the medically ill population, as many medically ill individuals are grieving numerous losses including their loss of health, function, and independence; and to individuals undergoing any number of other losses, such as divorce, financial security, employment, and home. Alternatively, *bereavement*, the state of having lost a loved one or someone close specifically through death, is sometimes used to connote grief after the death of a loved one (Stroebe, Hansson, Stroebe, & Schut, 2001). For the purposes of the rest of this chapter, *grief* and *bereavement* will be used interchangeably. Another term that sometimes is used to refer to grief reactions is *mourning*. We define mourning as the social, cultural, and behavioral rituals of grief, while Shear et al. define mourning as the psychosocial process by which one transitions from acute to integrated grief (M. K. Shear et al., 2011).

ACUTE, INTEGRATED, AND COMPLICATED GRIEF

Grief can be further subcategorized as *acute grief*, the initial painful response, and *integrated grief*, the ongoing, attenuated adaptation to the death of a loved one. *Complicated grief*, sometimes called prolonged, traumatic, or unresolved grief, refers to *acute* grief that remains intense and persistent without transitioning into integrated grief.

ACUTE GRIEF

Grief is conceptualized as a universal, natural, adaptive, and instinctual reaction to the loss of a loved one. The *acute* manifestations of grief can span the full gamut of intensity from barely noticeable discomfort and dysfunction to among the most painful, distressing, and debilitating experiences of a person's life. In acute grief there may be disbelief and difficulty comprehending the finality of the loss. Acute grief is a preoccupying experience in which feelings of yearning and longing for the deceased are accompanied by pangs of intense emotions, often experienced as unfamiliar and difficult to control. The bereaved person is consumed with thoughts and memories of the deceased and relatively uninterested in other people and usual life occupations. However, even when the predominant features are pain and loss, pleasant and positive emotions also occur. The bereaved person may experience enjoyment in recalling happy times and sharing amusing anecdotes, warmth in recalling closeness, pride in honoring the deceased, relief from the burden, and joy in being alive (Bonanno, Moskowitz, Papa, & Folkman, 2005). Typically, intense emotions come in waves, the so-called *pangs* of grief, which gradually become less frequent and intense. While there is no accepted time frame for grief to last, the current consensus is that the most painful features at least begin to abate by about 6 months. By then, wounds begin to heal, and the bereaved person finds his or her way back to a fulfilling life. The reality and meaning of the death are assimilated, and the bereaved are able to engage once again in pleasurable and satisfying relationships and activities (Zisook & Shear, 2009).

INTEGRATED GRIEF

Normally, acute grief instinctively transitions to *integrated grief* within several months. As the permanence of the loss is comprehended, acute grief resolves, and memories of the deceased are integrated into the ongoing psychological life of the bereaved. Engagement in constructive daily occupations is reestablished, and the person is able to fully resume old roles and functions as well as develop new ones that may be necessary for ongoing life. Thoughts and memories of the deceased remain accessible but are no longer preoccupying. After such integration there is diminished intensity of sadness and retreat of preoccupying thoughts. Integrated grief may be life-long and often continues to evolve over time (M. K. Shear, 2010). Notably, symptoms of acute grief can recur transiently, oftentimes during anniversaries, holidays, stresses, special occasions, and other losses.

COMPLICATED GRIEF

Complicated grief is a recognizable syndrome of prolonged, intense grief that occurs when acute grief does not transition to integrated grief by 6 months (Zisook, Simon et al., 2010). Time moves on, but healing does not. It is not always clear why the natural healing process of grief is impeded in any given individual, but several risk factors have been identified. For example, CG has been found more often after suicide or when the deceased is a “soul-mate” (Jordan, 2008; M. K. Shear et al., 2011). Past and current major depressive disorder also is associated with increased risk for CG. Sometimes, the resolution of grief is impeded by maladaptive attitudes and behaviors such as intense blame of self or others, fear of being overwhelmed by the intensity of grief, persistent avoidance of reminders of the deceased, the prospect of life without the deceased, or a disinclination to engage in activities that were shared with the deceased (Boelen, van den Bout, & van den Hout, 2006; K. Shear et al., 2007). On occasion, practical and/or interpersonal problems may complicate the adjustment process and delay the healing of grief. Persistent avoidance of reminders of the loss is another major impediment to adjustment. When resolution of acute grief is blocked, the resulting complicated grief can persist for years, decades, or even a lifetime, with prolonged suffering and failure to find avenues for constructive activities in a world without the deceased.

Approximately 10% of bereaved individuals may experience CG (Middleton, Raphael, Burnett, & Martinek, 1998; H. G. Prigerson et al., 2009). A recent large population-based study of older adults in the Netherlands indicates a CG prevalence of 4.8% of the general older adult population, 7% of the general 75–85-year-old population, and 25.4% of the older grieving population (Newson, Boelen, Hek, Hofman, & Tiemeier, 2011). CG is observed across various ethnic groups in the United States (Cruz et al., 2007; Goldsmith, Morrison, Vanderwerker, & Prigerson, 2008) and cultures throughout the world (Bonanno, Papa, Lalande, Zhang, & Noll, 2005; Ghaffari-Nejad, Ahmadi-Mousavi, Gandomkar, & Reihani-Kermani, 2007; Kersting et al., 2007; Langner & Maercker, 2005; Momartin, Silove, Manicavasagar, & Steel,

2004; Morina, Rudari, Bleichhardt, & Prigerson, 2010; H. Prigerson et al., 2002; Schaal, Elbert, & Neuner, 2009).

Box 29.1 provides a brief screening questionnaire for CG. The clinical symptoms of CG include persistent difficulty accepting the death, preoccupation with thoughts and images of the deceased, recurrent pangs of intense grief, avoidance of reminders of the loss, anger, guilt, and difficulty adjusting to life without the deceased (H. G. Prigerson et al., 1995; M. K. Shear, 2010). Excessive proximity-seeking is common, and in its most extreme form can manifest as wishes to die or suicidal behavior with the belief that life has no purpose or meaning without the deceased. Additionally, individuals with CG often experience ruminating thoughts about the circumstances around the death (M. K. Shear et al., 2011). Without treatment, CG tends to persist indefinitely.

Although CG often is comorbid with major depressive disorder (MDD)—either as a risk and/or as a consequence—it is important to differentiate between the two conditions, as treatments and prognosis vary (M. K. Shear et al., 2011). A key difference is that the core features of CG—longing, pining, preoccupation, and avoidance—are not characteristic features of MDD. The core features of MDD (persistent and pervasive sadness, anhedonia, and low self esteem) are not characteristic features of CG. Table 29.1 summarizes phenomenological and clinical distinctions between CG and MDD. CG also shares many features with posttraumatic stress disorder (PTSD) and often co-occurs with PTSD, but they can be differentiated by several key distinguishing features (M. K. Shear et al., 2011). The predominant trauma in CG is loss-related, while the major trauma in PTSD is threat-related. The characteristic affects of CG (longing and yearning) are not the same as the predominant affect of PTSD (fear).

CG is associated with functional impairment in multiple modalities, including daily activities (Monk, Houck, & Shear, 2006), socializing (Boelen & Prigerson, 2007; Melhem, Moritz, Walker, Shear, & Brent, 2007), work (Lannen, Wolfe, Prigerson, Onelov, & Kreichbergs, 2008; H. G. Prigerson et al., 1997), and relationships (Monk, Houck, & Shear, 2006). Additionally, individuals with CG have increased rates of

Box 29.1 BRIEF GRIEF QUESTIONNAIRE: A SCREENING TOOL FOR COMPLICATED GRIEF

Rate as: 0 = Not at all, 1 = Somewhat, 2 = A lot
Screen positive: Scores ≥ 4

1. How much trouble are you having accepting the death?
2. How much does grief interfere with your life?
3. Are you having troublesome or preoccupying images or thoughts of _____?
4. Are there things you used to do when _____ was alive that you don't feel comfortable doing anymore, that you avoid?
5. How much are you feeling cut off or distant from other people since _____ died?

(Shear et al., Psychiatric Service, 2006).

Table 29.1 PHENOMENOLOGICAL DIFFERENCES BETWEEN COMPLICATED GRIEF AND DEPRESSION
(ZISOOK ET AL, JCP 2010)

	COMPLICATED GRIEF	MAJOR DEPRESSIVE DISORDER
Mood/Sadness	Pangs of emotion triggered by reminders of the loss	Pervasive
Anhedonia	Related to missing loved one	Pervasive
Suicidal Ideation	If present, focused on joining the deceased loved one	Frequent, focused on not being worthy of living
Preoccupying Thoughts	Of the deceased; guilt and self blame focused on the deceased	Of low self esteem and related to a sense of guilt or shame
Avoidance	Avoidance of activities, situations and people because of the death	General withdrawal from activities and people
Intrusive Images	Prominent—of the deceased	Not prominent
Yearning and Longing	Frequent—for the deceased	Not typically seen

psychiatric comorbidity (Newson, Boelen, Hek, Hofman, & Tiemeier, 2011; Simon et al., 2007), worsening symptoms of other psychiatric illnesses (M. K. Shear et al., 2011), and insomnia (Hardison, Neimeyer, & Lichstein, 2005). Importantly, CG is associated with increased suicidal ideation and behavior across various age groups (Latham & Prigerson, 2004; Mitchell, Kim, Prigerson, & Mortimer, 2005; H. G. Prigerson et al., 1999; Szanto, Prigerson, Houck, Ehrenpreis, & Reynolds, 1997; Szanto et al., 2006).

In addition, CG negatively affects individuals' physical health outcomes (Lichtenthal, Cruess, & Prigerson, 2004; M. Stroebe et al., 2007). CG is associated with increased tobacco and alcohol use (Zisook, Shuchter, & Lyons, 1987). In their study of bereaved widows and widowers, H. G. Prigerson et al. (1997) found that CG predicted numerous negative health changes. Individuals with CG had increased rates of cancer, cardiac disease, and hypertension. Moreover, widows and widowers with CG had significantly higher rates of the flu, headaches, and cardiac issues around the anniversary of the death of their spouse than did bereaved spouses without CG. Gender differences exist in these health outcomes. Widowers with CG tend to have worse health outcomes than do widows (Chen et al., 1999). Despite their increased risk for developing health problems, individuals with CG underutilize health services (H. Prigerson et al., 2001). Overall, untreated CG results in suffering, impairment, and poor health outcomes.

TREATMENT OF COMPLICATED GRIEF

Considering that grief is a normal, adaptive response to loss, noncomplicated grief that is not comorbid with depression does not warrant any intervention in most circumstances. When support, reassurance, and information generally provided by family, friends, and sometimes clergy, is not available or sufficient, bereavement support groups may help fill the gap (Lieberman & Videkasherman, 1986; Marmar, Horowitz, Weiss, Wilner, & Kaltreider, 1988). Support groups can be particularly helpful after traumatic losses such as the death of a child, a death after suicide, or deaths from other “unnatural” causes. While we do not mean to imply that acute grief

is a pathological condition, certain individuals find that their desire to explore and make sense of their grief motivates them to initiate a productive exploratory or supportive therapy.

Uncomplicated acute and integrated grief generally do not require formal interventions—but CG does. Without treatment, CG symptoms follow an unrelenting course. The effectiveness and role of pharmacologic management of CG is not yet established. An open pilot study (Pasternak et al., 1991) and a randomized controlled trial (Reynolds et al., 1999) of bereavement-related major depression in patients—many of whom also had symptoms of CG—demonstrated little response in grief symptoms to nortriptyline. Another small, open trial of sustained-release bupropion for recently bereaved individuals with bereavement-related depression was associated with an improvement in both grief and depressive symptoms (Zisook, Shuchter, Pedrelli, Sable, & Deaciuc, 2001), but CG was not targeted in this study. However, a small case series of participants with CG suggested that escitalopram may be an effective treatment for CG (Simon, Thompson, Pollack, & Shear, 2007), and another study indicated that the response of individuals with CG to two forms of psychotherapy improved with concurrent escitalopram treatment (Simon et al., 2008). In light of these findings suggesting a potential role for pharmacological interventions for CG, a large multisite randomized controlled trial exploring the efficacy of citalopram for the treatment of CG is currently in progress (<http://clinicaltrials.gov/ct2/show/NCT01179568>).

A recent meta-analysis of studies assessing psychotherapeutic strategies for the prevention and treatment of CG was not able to confirm the effectiveness of preventive interventions, but it did show that certain psychotherapy interventions are effective. Moreover, benefits increase over time (Wittouck, Van Auteurs, De Jaegere, Portzky, & van Heeringen, 2011). Studies substantiate the use of cognitive behavioral therapy (Boelen & Prigerson, 2007; Wagner, Knaevelsrud, & Maercker, 2006), time-limited interpretive group therapy (Piper, McCallum, Joyce, Rosie, & Ogrodniczuk, 2001; Piper, Ogrodniczuk, Joyce, Weideman, & Rosie, 2007; Saindon et al., 2014), and complicated grief therapy (K. Shear, Frank, Houck, & Reynolds, 2005).

Complicated grief therapy (CGT) was developed specifically for persons with complicated grief. The basic principle underlying CGT is that acute grief will progress instinctively to integrated grief if the complications of the grief are addressed and the natural mourning process is supported. Integrating treatment strategies from cognitive behavioral, interpersonal, exposure, motivational, and gestalt therapies, CGT focuses both (1) on the *loss* (e.g., through imaginal revisiting exercises, in vivo exposure, imaginal conversations, actual revisiting of painful places and activities, review of pictures, etc.) and (2) on *life* without the deceased (e.g., through goal-setting exercises, planning for holidays and special occasions, and working on interpersonal difficulties). Significant others are educated, supported, and asked to participate in treatment both during certain sessions and between sessions. Pilot (M. K. Shear et al., 2001) and two randomized controlled trials funded by the National Institute of Mental Health (NIMH) (Shear, Frank, Houck, & Reynolds, 2005; Simon et al., 2008) support the robust efficacy of CGT for the treatment of CG.

BEREAVEMENT-RELATED DEPRESSION AND THE BEREAVEMENT EXCLUSION

MDD is a heterogeneous group of disorders that often, but not invariably, is triggered by stressful life events. Bereavement bears a special relationship to MDD, as it is simultaneously one of the most virulent precipitants of major depressive episodes (MDE) while also being the only life event that might have, according to *DSM-III* and *IV* conventions, negated the diagnosis of MDD. Thus, when an MDE was ostensibly triggered by other losses—such as divorce, terminal illness, unemployment, homelessness, or new onset disability—if full symptomatic criteria were met for >2 weeks, the diagnosis of MDE was made. Not so for depression that occurred in the context of the death of a loved one based on the *DSM-III* and *IV*. In this singular instance, unless the depression was particularly severe or prolonged (described in more detail below), a V-code (no mental illness) of “bereavement” was given rather than a clinical diagnosis of MDE. Of note, this diagnostic distinction afforded depression following bereavement, the so called “bereavement exclusion,” is not provided by the *International Diagnostic Classification of Diseases*–10. Based on the literature subsequently reviewed in this chapter, the bereavement exclusion was removed from the *DSM-5*. The removal of the bereavement exclusion was one of the most heavily debated changes in the *DSM-5*. Because of the unique status afforded to bereavement there remains great confusion in the United States and in other countries that use the *DSM* for diagnosis about when and how to diagnose and treat depression occurring in the context of the death of a loved one. The rest of this chapter will attempt to clarify those uncertainties.

History of the Bereavement Exclusion in *DSM III* and *IV*

Diagnosing MDE in the aftermath of the death of a loved one is complicated by the fact that bereavement was an exclusion

criterion for depression in the *DSM-IV-TR*. According to *DSM-IV-TR*, if the depressive symptoms begin within 2 months of the death of a loved one and do not continue beyond these 2 months, then the diagnosis of depression should not be made. Several exceptions existed, including if the symptoms were associated with marked functional impairment or if one or more of the following “conditional” features were present: suicidal ideation, morbid preoccupation with worthlessness, psychotic symptoms, and/or profound psychomotor retardation.

The bereavement exclusion criteria were first introduced in the *DSM III*, mainly based on the pivotal work of Clayton et al. (Clayton, Desmarai, & Winokur, 1968; Clayton, 1990; Clayton & Darvish, 1979) who showed a high rate of major depressive syndromes in recently bereaved individuals. These depressive syndromes were relatively mild, differed from clinical depression in several aspects, and often resolved over time without treatment. Notably, there are no such exclusion criteria in the International Diagnostic Classification of Diseases.

Research Indicating a Reconsideration of the Validity of the Bereavement Exclusion and Changes in the *DSM-5*

Several comprehensive reviews (Iglewicz, Seay, Vigeant, et al., 2013; Iglewicz, Seay, Zetumer, & Zisook, 2013; Zisook, Corruble, Duan, et al., 2012; Zisook & Kendler, 2007; Zisook, Shear, & Kendler, 2007) and data from subsequent studies focusing on the validity of the bereavement exclusion for the diagnosis of MDD suggested that it was time to eliminate the bereavement exclusion (Brent, Melhem, Donohoe, & Walker, 2009; Corruble, Chouinard, Letierce, Gorwood, & Chouinard, 2009; Corruble, Falissard, & Gorwood, 2011; Corruble, Gorwood, & Chouinard, 2010; Karam et al., 2009; Kendler, Myers, & Zisook, 2008; Kessing, Bukh, Bock, Vinberg, & Gether, 2010; Wakefield, Schmitz, First, & Horwitz, 2007).

First, in a secondary analysis of the National Comorbidity Study, Wakefield and colleagues (2007) compared MDD after bereavement to depressive syndromes occurring after other stressful life events. They found that MDD after bereavement was far more similar than different to MDD after other life events. Although the investigators did not conclude that the data support removal of the bereavement exclusion, other experts have debated these conclusions (Kendler & Zisook, 2009; Pies & Zisook, 2010; Wakefield, Schmitz, First, & Horwitz, 2009).

In another secondary analysis of a large community-based study, Kendler, Myers, and Zisook (2008) also compared individuals with bereavement-related depression to those with MDD related to other stressful life events and found that bereavement-related depressions were strikingly similar to non-bereavement, stress-related depressions in most demographic risk factors, familiarity, past histories of MDD, personality characteristics, comorbidity, symptom patterns, intensity, impairment, and course. The investigators concluded that there was no rational reason to single out bereavement as the lone disqualifying life event for the diagnosis of MDD. Thus, they recommended removing the bereavement exclusion from

future editions of the *DSM*. Similar results were found in population-based studies in Lebanon (Karam et al., 2009), in US children who lost parents to suicide, accident, or sudden natural death (Brent, Melhem, Donohoe, & Walker, 2009), and in studies of clinical populations in Denmark (Kessing, Bukh, Bock, Vinberg, & Gether, 2010) and France (Corruble, Chouinard, Letierce, Gorwood, & Chouinard, 2009; Corruble, Falissard, & Gorwood, 2011; Corruble, Gorwood, & Chouinard, 2010). In the latter series of studies, participants who were not given the diagnosis of MDE on the basis of clinicians' understanding of *DSM-IV* criteria were found to have more severe symptoms of depression than were MDE controls without bereavement, and they responded at least as well to antidepressant medications. In addition, many individuals who should have been excluded based on *DSM-IV* criteria were not, suggesting that the bereavement exclusion is not being used as intended and may lead to more confusion than clarity of diagnosis (Corruble, 2013; Corruble, Chouinard, Letierce, Gorwood, & Chouinard, 2009; Corruble, Falissard, & Gorwood, 2011). These studies made a strong argument that bereavement-related depression is more similar than not to other, nonbereavement-related instances of MDD, laid the foundation for the American Psychiatric Association's *DSM-5* Mood Disorders Taskforce proposal to eliminate the bereavement exclusion from *DSM-5* (M. K. Shear et al., 2011; <http://www.dsm5.org/proposedrevision/Pages/DepressiveDisorders.aspx>), and ultimately set the stage for the removal of the bereavement exclusion from the *DSM-5*. The respective changes in the *DSM-5* regarding diagnostic criteria for a major depressive disorder denote that depressive syndromes occurring in the context of bereavement should be taken as seriously as depressive symptoms occurring in any other context.

DISTINGUISHING BETWEEN GRIEF AND DEPRESSION

Diagnosing MDD in the context of acute grief can challenge even the most experienced clinicians. Several features of "normal" grief and depression overlap. Mood changes, anhedonia, guilt, sleep disturbance, and, at times, suicidal ideation may be present in both conditions (Lamb, Pies, & Zisook, 2010; Pies, 2009; Zisook, Reynolds et al., 2010). Yet, the quality of these symptoms differs between grief and depression (Lamb, Pies, &

Zisook, 2010; Zisook, Reynolds, et al., 2010). These qualitative differences are thus key aspects of differential diagnosis. Although sadness is present in both grief and depression, the sadness typically is pervasive in depression, whereas with grief the sadness comes in waves and is intermixed with pleasant emotions and memories. Similarly, the anhedonia in depression is omnipresent, whereas the anhedonia in grief is tied specifically to longing for the deceased. Depression-related guilt is often associated with feelings of worthlessness. Meanwhile, grief-related guilt characteristically centers on thoughts of letting the deceased loved one down (i.e., not doing enough for them while they were alive, the "could haves" and "should haves"). In the absence of co-occurring MDD, grieving individuals are rarely suicidal. However, when thoughts of dying are present in bereaved individuals they tend to be focused on a longing for reunion with the deceased. In contrast, suicidal ideation in depressed individuals often relates to feelings of worthlessness and not deserving to live (Zisook & Shear, 2009). Even the perception of time can be used to distinguish between grief and depression. Grieving individuals often understand that grief is limited and life will improve over time. But, depressed individuals can experience time as slowed or frozen and their depression as inexhaustible (Lamb, Pies, & Zisook, 2010).

Table 29.2 compares the distinguishing phenomenology of grief and depression. Yet, even when one is cognizant of the distinguishing qualitative features, determining whether an independent MDE is present in an acutely bereaved individual can be perplexing. It is important for the clinician to remember that the timing of the onset of symptoms is just one of many features to consider. Even more important are severity and pervasiveness of symptoms and their effects on functioning. When in doubt, past and family histories can be helpful. It is useful for clinicians to remember that the death of a loved one may trigger **BOTH** acute grief **AND** the onset or worsening of an MDE; grief and depression often occur simultaneously. Subsequently, the decision regarding whether a bereaved person is "just grieving" or also has a co-occurring MDE should not be reduced to an either/or conundrum. Recognizing the possibility of MDD in the context of bereavement is not meant to "medicalize" grief; rather, it is meant to facilitate accurate diagnosis and appropriate treatment for those bereaved individuals suffering from an episode of major depression.

Table 29.2 QUALITATIVE PHENOMENOLOGICAL DIFFERENCES BETWEEN GRIEF AND DEPRESSION

	GRIEF	MAJOR DEPRESSIVE DISORDER
Mood/Sadness	Comes in waves and mixed with happy emotions, especially when recounting pleasant memories of the deceased loved one	Pervasive
Anhedonia	Related to longing for the deceased loved one	Pervasive
Suicidal Ideation	Connected with longing for reunion with the deceased loved one	Connected with feelings of not deserving to live
Guilt	Focused on letting the deceased loved one down	Focused on self loathing and worthlessness
Functional Impairment	Intermittent, typically lasts days to weeks	Pervasive, often lasts weeks to months

CONCURRENT GRIEF AND DEPRESSION

Bereavement is a stressor that places vulnerable individuals at higher risk for developing a clinically significant MDE (Umberson, Wortman, & Kessler, 1992). A systematic review of risk factors for MDE in older adults indicates that recent bereavement is a stronger predictor of the development of MDE than are prior episodes of depression, female gender, disability, and sleep disturbance (odds ratio of 3.3 compared to 2.3, 1.4, 2.5, and 2.6 respectively; see Cole & Dendukuri, 2003). Approximately 20% of bereaved adults (Zisook, Paulus, Shuchter, & Judd, 1997; Zisook & Shuchter, 1993) and children (D. Brent, Melhem, Donohoe, & Walker, 2009; D. A. Brent, Peters, & Weller, 1994; Melhem, Walker, Moritz, & Brent, 2008) may experience a comorbid MDE. Although the rates of MDE decrease over time after the loss, the best predictor of MDE 13 months after the loss of a loved one is MDE at 2 months after the loss, even more so than other risk factors such as a family history of MDD, lack of treatment, and the deceased having died by suicide (Zisook, Paulus, Shuchter, & Judd, 1997). When grief and depression occur together, the grief is more protracted and severe than grief without depression. For example, bereaved widows who develop MDE within 2 months of their loss have more difficult physical and emotional experiences with grief than do bereaved widows without comorbid depression (Zisook & Shuchter, 1993). Since bereavement is a universal stressor that places certain individuals at higher risk for depression and concurrent grief, and depression is associated with worse physical and psychological outcomes than grief alone, it is imperative that we recognize and treat depression in grieving individuals.

TREATMENT OF BEREAVEMENT-RELATED DEPRESSION

The two key questions are (1) when to treat and (2) how to treat. Regarding the first, decisions likely should be made just as in depressions triggered by other stressful life circumstances. The diagnosis of MDD is not enough to warrant active treatment, as many episodes are short-lived and may remit without formal interventions (Posternak et al., 2006). As in other, nonbereavement instances of MDD, the decision rests on the severity, intensity, and pervasiveness of symptoms; past history of MDD; previous outcomes to treatment; comorbidities; safety; and patient preferences. Sometimes the best initial treatment combines support, education, and watchful waiting; but if symptoms worsen, persist, or interfere with functioning, more active treatment should be considered. For someone with a past history of severe or life-threatening MDD who is not currently on maintenance treatment, the clinician might strongly consider reinstituting treatment even before symptoms emerge when there is either an impending or recent death of a loved one.

The second question, how to treat, also bears resemblance to optimizing treatment options for any bereavement or nonbereavement related depressions. At present there is a paucity of data confirming the effectiveness of psychotherapy for either preventing or treating MDD associated with bereavement. Yet, there is no reason to suspect that psychotherapy should not be as

effective, either alone or in combination with medications, as it is in other, nonbereavement-related instances of MDD. On the other hand, there are at least eight studies documenting the effectiveness of antidepressant medications for bereavement-related depression (Corruble, Falissard, & Gorwood, 2011; Hensley, Slonimski, Uhlenhuth, & Clayton, 2009; Jacobs, Nelson, & Zisook, 1987; Kessing, Bukh, Bock, Vinberg, & Gether, 2010; Pasternak et al., 1991; Reynolds et al., 1999; Zisook, Shuchter, Pedrelli, Sable, & Deaciuc, 2001). The authors favor following American Psychiatric Association Treatment Guidelines (American Psychiatric Association, 2010), which suggest either psychotherapy or medications for relatively mild depressions depending on past responses, availability, costs, and patient preferences. For more severe depressions, medications play a more predominant role, but combinations of psychotherapy and medications are the treatments of choice for very severe or complicated MDD or when a single approach has not been sufficient. The key is to not dismiss treating depression when grief is present, falsely rationalizing that depression is “understandable.” Rather, in light of the profound physical and psychological burden of concurrent grief and depression, the depression should be recognized and treated with the same compassion and diligence utilized when treating depression associated with other life stressors (Ganadjian & Zisook, 2009; Zisook, Reynolds et al., 2010).

SUMMARY

Bereavement is a severe psychosocial stressor which often triggers a grief response that, albeit painful and distressing, is self-limiting, becomes integrated into the ongoing fabric of one's being, and does not require professional attention. However, in vulnerable individuals the grief process can become derailed, impeding healing and leading to the syndrome of CG. In addition, bereavement may trigger MDD in vulnerable individuals whether or not CG occurs. Each of these untoward adverse consequences of bereavement is fraught with diagnostic challenges, is often missed in clinical populations, and may lead to ongoing suffering and morbidity. When accurately diagnosed, both CG and MDD associated with bereavement respond to targeted treatments that can profoundly improve the quality of life of certain grieving individuals, oftentimes making the difference between a life of ongoing suffering and disability and a life filled with meaning and satisfaction. Studies of CG and bereavement-related depression are in their infancy, but as these conditions become better known, understood, and legitimized as appropriate targets for scientific study, future investigations will no doubt lead to more refined diagnostic strategies and treatment guidelines.

CLINICAL PEARLS

- Up to 10% may have complicated grief.
- Maladaptive attitudes and behaviors that impede resolution of grief include the following: intense blame of self or others, fear of being overwhelmed by the intensity of grief,

persistent avoidance of reminders of the deceased, the prospect of life without the deceased, or a disinclination to engage in activities that were shared with the deceased.

- Death by suicide or death of soul mate are additional risk factors for complicated grief.
- The core features of complicated grief—longing, pining, preoccupation and avoidance—are not characteristic features of major depressive disorder.
- Complicated grief often co-occurs with PTSD, but the predominant affect of complicated grief is longing and yearning rather than fear.
- It is useful for clinicians to remember that the death of a loved one may trigger **BOTH** acute grief **AND** the onset or worsening of a major depressive episode.
- A meaningful minority of bereaved adults and children will experience a clinically meaningful and persistent major depressive episode in the wake of their loss.
- The best predictor of a major depressive episode 13 months after the loss of a loved one is a major depressive episode at 2 months after the loss.
- For someone with a past history of severe or life-threatening major depressive disorder who is not currently on maintenance treatment, the clinician might strongly consider reinstituting treatment (psychotherapy and/or medication) even before symptoms emerge when there is either an impending or recent death of a loved one.

DISCLOSURE STATEMENTS

Dr. Iglewicz has no potential conflicts, direct or indirect, financial or otherwise, to disclose in connection with the chapter submitted.

Dr. Zisook has no conflicts of interest or relationships with industry to disclose.

ACUTE AND CHRONIC REACTIONS TO TRAUMA

T. H. Eric Bui, M. Alexandra Kredlow, Meredith E. Charney, Mary C. Zeng, and Naomi M. Simon

INTRODUCTION

Psychological reactions to trauma have been vividly described since antiquity (Birmes et al., 2010). According to Plutarch (1920), in his biography of famous lives, general and Roman consul Caius Marius (157–86 BC), when presented with a reminder of one of his dreaded enemies, was gripped with an “overpowering thought of a new war, of fresh struggles, of terrors known by experience to be dreadful” and descended “into a state of dreadful despair, and was prey to nightly terrors and harassing dreams.” Although described since antiquity, these psychological responses had not been viewed under a pathological lens until the first descriptions of “traumatic neuroses” in the 19th century (Oppenheim, 1889). Finally, it was in the aftermath of the Vietnam War that trauma-related psychological disturbances truly became an independent field of research.

Exposure to a traumatic event may lead to the development of a variety of reactions ranging from relatively mild (causing minor disruptions in the individual’s life) to severe and debilitating. It is worth highlighting that most traumatized people will develop some level of psychological stress responses which are generally brief and short lived. In some, however, symptoms do not spontaneously remit and instead become clinically significant, persistent, and impairing.

Reactions to trauma exposure have thus been defined according to their time frame: immediate or peritraumatic reactions, lasting minutes to hours; acute stress disorder (ASD), which lasts between 2 days and 1 month; and post-traumatic stress disorder (PTSD), when symptoms persist for more than a month. PTSD can also occur after a symptom-free period of up to several years. However, by definition, delayed-onset PTSD refers to cases in which symptoms occur at least 6 months after the trauma. Although other psychiatric conditions such as depression might also result from traumatization, in this chapter we will review the different types of psychopathological reactions specific to trauma.

TRAUMA AND TRAUMATIC EVENTS

DEFINITIONS

Trauma, which derives from the Greek word *τραῦμα*, meaning *wound*, has been medically defined for centuries as “an

injury (as a wound) to living tissue caused by an extrinsic agent” (Merriam-Webster, 1995). It was not until 1889, however, that this word was applied to the field that was yet to be known as mental health, by Oppenheim (1889) in his clinical descriptions of “traumatic neuroses” in victims of railroad accidents. From then on, the term *trauma* endorsed both a physical and a psychological signification.

A traumatic event has been commonly described as presenting three characteristics: (1) it happens suddenly and unexpectedly, (2) it threatens the individual’s physical integrity, and (3) it does not belong in the normal range of events experienced during life. These three specific features differentiate it from other distressing events such as grief, medical disease, or romantic breakups. Furthermore, Terr suggested that psychological trauma, regardless of its being sudden or not, should be defined based on whether the traumatic events are repeated or not (Terr, 1991). According to her, type I traumas are time-limited single traumatic events (accident, disaster, etc.), and type II concern long-standing or repeated exposure to traumatic events that can be without the element of surprise (abuse, torture, combat situation, etc.).

While in the fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders (DSM-IV)* traumatic events were defined as “events that involve actual or threatened death or serious injury, or a threat to the physical integrity of oneself or others” (criterion A1) accompanied by a feeling of “intense fear, helplessness, or horror” (criterion A2), the fifth edition (*DSM-5*) has dropped the required subjective reaction (A2) to the trauma (APA, 2013). Traumatic events include direct exposure (i.e., being a victim), witnessing a traumatic event, or learning that it occurred to someone close. The new definition also includes extreme and repeated exposure to trauma details (as experienced by first responders), but excludes exposure through the media unless it is work-related.

Of note, while the stressor criteria of the *DSM-III-R* (APA, 1983) necessitated that the traumatic event be “outside the range of normal human experience,” this is no longer the case in either the *DSM-IV-TR* or the *DSM-5*. Thus, while the *DSM-III-R* excluded life-threatening illness as a stressor qualifying for criterion A of the PTSD diagnosis, the *DSM-IV-TR* and *DSM-5* include it as a potential traumatic event.

This subsequently paved the way for an increasing number of studies on the traumatizing effects of medical illnesses, such as cancer. Thus, potential cancer-related traumatic

events could be receiving the diagnosis, fear of the surgery and chemotherapy, or detecting a lump (Mehnert & Koch, 2007). This is important as it suggests that clinicians should be aware that giving a diagnosis of cancer may result in PTSD, which may in turn result in poorer psychological and physical outcome. Further, death may also be considered an A1 qualifying event.

EPIDEMIOLOGY

Estimates of the lifetime prevalence of exposure to a traumatic event range from 39% to 74% for the United States and Canada (Kessler, Sonnega, Bromet, Hughes, & Nelson, 1995; Norris, 1992; Resnick, Kilpatrick, Dansky, Saunders, & Best, 1993); some other developed countries (e.g., Netherlands and New Zealand) fall within that range but some studies suggest a lower rate for others (Hepp et al., 2006; Perkonig, Kessler, Storz, & Wittchen, 2000; Vaiva et al., 2008). Variances might be accounted for by confounders such as age, gender, or type of events (Breslau, 2001). Additionally, discrepancies might result from differences in measurement methods and the way traumatic events have been defined (Solomon & Davidson, 1997).

Although research on the prevalence of medical illness-related traumatic events is scarce, some studies reported that a substantial amount of life threatening illness patients met *DSM-IV* PTSD criterion A, as is typical in 41%–54% of breast cancer patients (Mehnert & Koch, 2007; Palmer, Kagee, Coyne, & DeMichele, 2004).

PERITRAUMATIC REACTIONS

When confronted with a traumatic event, individuals often develop immediate reactions of distress. Reactions experienced during and immediately after trauma are called *peritraumatic* and recent developments have identified certain trauma-specific peritraumatic reactions (distress defined in a specific way) and dissociation as robust predictors of the development of chronic and debilitating PTSD (Brewin, Andrews, & Valentine, 2000; Ozer, Best, Lipsey, & Weiss, 2003). While peritraumatic dissociation has been studied for a significant period of time, peritraumatic distress has only become the focus of attention lately.

Peritraumatic distress was proposed as a measure of the intensity of *DSM-IV* PTSD criterion A2 (Brunet et al., 2001)—the feeling of “fear, helplessness and horror” experienced by an individual during or immediately after exposure to a traumatizing event. Furthermore, this dimension also includes such phenomena as “feeling ashamed of one’s emotional reactions” or “having difficulty controlling one’s bowel and bladder.” The Peritraumatic Distress Inventory (PDI) was introduced in 2001 as a measure of peritraumatic distress criterion A2 (Brunet et al., 2001) and evaluates feelings of helplessness, sadness, guilt, shame, frustration, fright, horror, passing out, worry for others, loss of bowel and bladder control, physical reactions, and thoughts of dying. The self-report PDI includes 13 Likert-type items scored from 0–4 (“not at all true” to “extremely true”) with a total score ranging from 0 to 52 (Table 30.1). To date, no cut-off has been reported

Table 30.1 PERITRAUMATIC DISTRESS INVENTORY

Please check the boxes corresponding to the best to what you felt during and immediately after the event. If the phrase doesn’t apply to how you experienced the event, check the box “*not true at all*.”

HOW MUCH IS EACH OF THE FOLLOWING STATEMENTS TRUE OF YOU?	NOT AT ALL TRUE				EXTREMELY TRUE
1. I felt helpless to do more	0	1	2	3	4
2. I felt sadness and grief	0	1	2	3	4
3. I felt frustrated or angry I could not do more	0	1	2	3	4
4. I felt afraid for my safety	0	1	2	3	4
5. I felt guilt that more was not done	0	1	2	3	4
6. I felt ashamed of my emotional reactions	0	1	2	3	4
7. I felt worried about the safety of others	0	1	2	3	4
8. I had the feeling I was about to lose control of my emotions	0	1	2	3	4
9. I had difficulty controlling my bowel and bladder	0	1	2	3	4
10. I was horrified by what happened	0	1	2	3	4
11. I had physical reactions like sweating, shaking, and pounding heart	0	1	2	3	4
12. I felt I might pass out	0	1	2	3	4
13. I thought I might die	0	1	2	3	4

(Brunet et al., 2001)

in the literature. Peritraumatic distress might be considered to be a predictor of PTSD because psychological (Brewin & Holmes, 2003) and neurobiological (Cahill, Prins, Weber, & McGaugh, 1994) models of PTSD both emphasize perceived life threat as a key component in the development of this disorder. In line with this, a number of prospective studies reported that individuals experiencing increased levels of peritraumatic distress were also at risk for PTSD symptoms (Allenou et al., 2010; Bui, Brunet, et al., 2010; Bui, Joubert, et al., 2010). On a conceptual level, PTSD is a fear-based disorder and patients do not really *develop* this disorder per se, but rather still present clinical symptoms of distress and dysfunction 1 month after the trauma. In this sense, *peritraumatic distress* would be more accurately described as a risk factor for the continuation of clinically significant symptoms 1 month after the trauma. In other words, the more “frightened” the individual is during the trauma, the more likely he is to still be frightened 1 month later.

Peritraumatic dissociation refers to alterations in an individual’s experience of time, place and person during or shortly after exposure to a traumatic event. The 10-item Peritraumatic Dissociative Experiences Questionnaire has been proposed as a measure of peritraumatic dissociation (Marmar et al., 2007; Tichenor, Marmar, Weiss, Metzler, & Ronfeldt, 1996) and includes items measuring blanking out, a feeling that one is on autopilot, time distortion (“slow motion”), depersonalization (feeling of watching oneself act while having no control over the situation), derealization (feeling of strangeness and unreality of the external world), confusion, amnesia, and reduced awareness.

Dissociative reactions to an extreme stress factor were previously conceptualized as adaptive, viewed as a way to remove oneself from experiencing feelings that are too intense (van der Hart, van Ochten, van Son, Steele, & Lensvelt-Mulders, 2008). Contrary to this belief, empirical studies have recently found that dissociation did not prevent the development of psychopathology and was in fact a risk factor for PTSD (Ozer et al., 2003). These findings are in line with an older theory according to which dissociative reactions reflect a failure in coping and other adaptive psychological mechanisms (Janet, 1909).

Besides these two trauma-specific immediate reactions, traumatized individuals may also develop immediate non-specific reactions, such as somatic functional symptoms or they might experience aggravation of a preexisting psychiatric condition.

One possible cause of the discrepancy between the prevalence of trauma exposure and the prevalence of PTSD might lie in an interindividual variability of what people experience as traumatizing. Based on data from the National Comorbidity Survey (Kessler et al., 1995), Table 30.2 presents the lifetime prevalence of different trauma types and the probability that a particular trauma type, once selected as the basis for the assessment of PTSD, will be associated with PTSD.

The issue of whether exposure to an event has to be accompanied by a negative subjective reaction (such as fear) to be qualified as “traumatic” has been an ongoing source of discussion. Including negative immediate reactions in the definition of a traumatic event and the diagnostic criteria for PTSD suggests that the trauma is a subjective experience and that it

Table 30.2 LIFETIME PREVALENCE OF TRAUMA AND PROBABILITY TO DEVELOP PTSD BASED ON THE NATIONAL COMORBID SURVEY

Traumatic Event	LIFETIME PREVALENCE OF TRAUMA % (SE)		PROBABILITY OF PTSD* % (SE)	
	Men (n = 2812)	Women (n = 3065)	Men (n = 2812)	Women (n = 3065)
Rape	0.7% (0.2)	9.2% (0.8)	65.0% (15.6)	45.9% (5.9)
Molestation	2.8% (0.5)	12.3% (1.0)	12.2% (5.3)	26.5% (4.0)
Physical attack	11.1% (1.0)	6.9% (0.9)	1.8% (0.9)	21.3% (7.3)
Combat	6.4% (0.9)	0% (n/a)	38.8% (9.9)	n/a
Shock	11.4% (1.1)	12.4% (1.1)	4.4% (1.4)	10.4% (2.0)
Threat with weapon	19% (1.3)	6.8% (0.6)	1.9% (0.8)	32.6% (7.8)
Accident	25% (1.2)	13.8% (1.1)	6.3% (1.8)	8.8% (4.3)
Natural disaster with fire	18.9% (1.4)	15.2% (1.2)	3.7% (1.8)	5.4% (3.8)
Witness	35.6% (2.0)	14.5% (0.7)	6.4% (1.2)	7.5% (1.7)
Neglect	2.1% (0.4)	3.4% (0.5)	23.9% (10.3)	19.7% (7.7)
Physical abuse	3.2% (0.4)	4.8% (0.6)	22.3% (5.2)	48.5% (9.5)
Other qualifying trauma	2.2% (0.5)	2.7% (0.4)	12.7% (4.8)	33.4% (8.0)
Any trauma	60.7% (1.9)	51.2% (1.9)	8.1% (1.0)	20.4% (1.5)

* The probability that a particular trauma type, once selected as the basis for the assessment of PTSD, will be associated with PTSD.

is this subjective negative experience of an event that results in PTSD. Excluding this requirement suggests that only the objective events, in themselves, can result in PTSD. In other words, the question is whether it is the actual event that produces the symptoms.

However, the retention of the negative subjective experience of the stressor (criterion A2) in the current revision of the *DSM* has been the focus of much recent debate, as it has been suggested to confound the stressor and its reaction (Friedman, Resick, Bryant, & Brewin, 2011; Karam et al., 2010). This resulted in the removal of the requirement for a negative subjective experience of the stressor from the PTSD criteria in the current *DSM-5*.

ACUTE STRESS DISORDER

CLINICAL FEATURES

Acute stress disorder, which is a clinical entity occurring in a limited timeframe after trauma exposure, was introduced in the *DSM-IV* in order to differentiate between PTSD, a chronic condition, and short-lived, self-limited, distressing, and impairing reactions to trauma (Koopman, Classen, Cardena, & Spiegel, 1995). Patients with ASD are individuals at risk for a diagnosis of PTSD one month later (Spiegel, Koopman, Cardena, & Classen, 1996).

According to the *DSM-5* criteria, ASD may occur when an individual is exposed to a traumatic event through direct exposure (i.e., being a victim) to a life-threatening event, witnessing it, or learning that it occurred to someone close. Clinical presentation is characterized by a cluster of anxiety and dissociative symptoms. In *DSM-IV-TR*, the requisite criteria for diagnosis comprise at least three dissociative symptoms (such as numbing, detachment, reduction in awareness of one's surroundings, derealization, depersonalization, dissociative amnesia), one reexperiencing symptom (such as recurrent images, thoughts, nightmares, or flashback episodes, or distress when confronted with reminders of the traumatic event), avoidance of reminders, and hyperarousal. This is no longer the case in *DSM-V*. The main diagnostic criterion now requires meeting 9 of 14 symptoms, without any particular cluster. Furthermore, like all psychiatric disorder diagnoses, marked distress or impairment is also required. The differences between ASD and PTSD lie in the presence of dissociative symptoms among the symptoms of ASD and the different timeframes: ASD occurs between 3 days and 4 weeks following the traumatic event (Criteria G), while symptoms lasting over 1 month point to a diagnosis of PTSD.

EPIDEMIOLOGY

Across different studies, prevalence rates of ASD in trauma exposed individuals range from 7% to 59% (Bryant, Creamer, O'Donnell, Silove, & McFarlane, 2008; Elklit & Christiansen, 2010) with a mean prevalence of 17.4% (Bryant, 2011). Although one study (Mehnert & Koch, 2007) reported

a relatively low prevalence rate for cancer-related ASD (2.4%), the majority of the literature found rates ranging from 28%–35% (Kangas, Henry, & Bryant, 2005; McGarvey et al., 1998; Pedersen & Zachariae, 2010).

RELATIONSHIP OF ASD TO PTSD

Given that ASD was introduced in order to identify individuals at risk for PTSD and shares similarities with PTSD, studies reported that ASD symptoms significantly predicted the occurrence of PTSD symptoms (Bui, Tremblay, et al., 2010; McKibben, Bresnick, Wiechman Askay, & Fauerbach, 2008; Yasan, Guzel, Tamam, & Ozkan, 2009). It has been consistently found, however, that the majority of persons who experience early posttraumatic symptoms adjust in the following weeks or months (Blanchard et al., 1996; Hamanaka et al., 2006). Furthermore, recent developments have found that ASD symptoms fail to adequately identify people who will later suffer from PTSD. More precisely, a recent systematic review of the literature on 22 published longitudinal studies reported that while ASD's positive predictive power was reasonable, its sensitivity (proportion of people meeting ASD criteria who eventually develop PTSD) was poor (20%–72%), suggesting that most trauma survivors who subsequently develop PTSD do not meet full criteria for ASD (Bryant, 2011).

In conclusion, ASD should be considered as an entity that captures a significant level of distress and impairment and identifies individuals who might require clinical attention. Nonetheless, ASD symptoms or subsyndromal ASD (i.e., symptoms of reexperiencing, arousal, and avoidance, but without dissociation) might still be indicative of a possible subsequent PTSD diagnosis (Bryant, 2011).

ASSESSMENT

The Stanford Acute Stress Reaction Questionnaire (Cardena, Koopman, Classen, Waelde, & Spiegel, 2000), a self-report questionnaire composed of 30 items rated from 0–5 (Box 30.1), has been developed to evaluate ASD symptoms. The Acute Stress Disorder Interview (Bryant, Harvey, Dang, & Sackville, 1998), a 19-item dichotomously scored interview, has been developed to identify individuals suffering from ASD. Both instruments have shown sound psychometric properties and can be used in clinical settings (Bryant, et al., 1998; Cardena, et al., 2000). Because clinician-administered interviews are usually time consuming, self-report measures are preferred for screening purposes.

POSTTRAUMATIC STRESS DISORDER

CLINICAL FEATURES

Consistent with the ASD diagnostic criteria, the *DSM-5* requires for PTSD diagnosis that the individual be subject to a traumatic event (direct exposure, witnessing it, or learning that it occurred to someone close; criterion A). Again,

Stanford Acute Stress Reaction Questionnaire

Recall the stressful events that occurred in your life during the PAST MONTH.

Briefly describe the one event that was the most disturbing on the lines below:

How disturbing was this event to you? (Please mark one):

- Not at all disturbing _____
- Somewhat disturbing _____
- Moderately disturbing _____
- Very disturbing _____
- Extremely disturbing _____

Below is a list of experiences people sometimes have during and after a stressful event. Please read each item carefully and decide how well it describes your experience since the stressful event described above. Refer to this event in answering the items that mention "the stressful event." Use the 0–5 point scale shown below and circle the number that best describes your experience. (0 = not experienced, 1 = very rarely experienced, 2 = rarely experienced, 3 = sometimes experienced, 4 = often experienced, 5 = very often experienced)

1. I had difficulty falling or staying asleep.
2. I felt restless.
3. I felt a sense of timelessness.
4. I was slow to respond.
5. I tried to avoid feelings about the stressful event.
6. I had repeated distressing dreams of the stressful event.
7. I felt extremely upset if exposed to events that reminded me of an aspect of the stressful event.
8. I would jump in surprise at the least thing.
9. The stressful event made it difficult for me to perform work or other things I needed to do.
10. I did not have the usual sense of who I am.
11. I tried to avoid activities that reminded me of the stressful event.
12. I felt hypervigilant or "on edge".
13. I experienced myself as though I were a stranger.
14. I tried to avoid conversations about the stressful event.
15. I had a bodily reaction when exposed to reminders of the stressful event.
16. I had problems remembering important details about the stressful event.
17. I tried to avoid thoughts about the stressful event.
18. Things I saw looked different to me from how I know they really looked.
19. I had repeated and unwanted memories of the stressful event.
20. I felt distant from my own emotions.
21. I felt irritable or had outbursts of anger.
22. I avoided contact with people who reminded me of the stressful event.
23. I would suddenly act or feel as if the stressful event was happening again.
24. My mind went blank.
25. I had amnesia for large periods of the stressful event.
26. The stressful event caused problems in my relationships with other people.
27. I had difficulty concentrating.
28. I felt estranged or detached from other people.
29. I had a vivid sense that the stressful event was happening all over again.
30. I tried to stay away from places that reminded me of the stressful event.

On how many days did you experience any of the above symptoms of distress? (Please mark one):

- No days _____
- One day _____
- Two days _____
- Three days _____
- Four days _____
- Five or more days _____

From Stanford Center on Stress and Health website: <http://stresshealthcenter.stanford.edu/research/measures.html>

life-threatening situations are diverse. Contrary to some earlier concepts of nosology, the life-threatening situation that is the basis of PTSD does not need to be outside the range of normal human experience.

The diagnosis is further defined in criteria B–E as necessitating the presence of symptoms in the four clusters of intrusion, avoidance, alterations in mood and cognition, and alterations in arousal and reactivity. In particular, the

following symptoms related to the traumatic event are additionally required for diagnosis:

Criterion B—one or more intrusion symptoms (recurrent, distressing memories or dreams; dissociative experiences such as flashbacks; intense or prolonged psychological distress; and marked physiological reactions);

Criterion C—one or both avoidance symptoms (efforts to avoid distressing memories, thoughts, or feelings; and efforts to avoid external reminders);

Criterion D—two or more negative alterations in cognitions and mood (including dissociative amnesia, exaggerated negative beliefs about the self, diminished interest, feelings of detachment, and inability to experience positive emotions); and

Criterion E—two or more alterations in arousal and reactivity (including irritable or self-destructive behavior, hypervigilance, exaggerated startle response, difficulty with sleep, and difficulty with concentration).

The duration of the disturbance due to criteria B–E symptoms must last for at least 1 month (criterion F), must cause significant functional impairment (criterion G), and must not be attributable to the effects of a substance or better explained by another medical or psychiatric condition (criterion H).

In contrast to ASD, dissociative symptoms are not included in the diagnostic criteria for PTSD in the *DSM-5*. They are, instead, utilized as a specifier for a PTSD diagnosis. Therefore, if an individual who meets the criteria for PTSD also experiences the symptoms of either depersonalization (“persistent or recurrent experiences of feeling detached from, and as if one were an outside observer of, one’s mental processes or body”) or derealization (“persistent or recurrent experiences of unreality of surroundings”), that individual is diagnosed with PTSD with dissociative symptoms. The *DSM-5* also includes a specifier for delayed-onset PTSD, which is described as “with delayed expression” if the interval between the traumatic event and the onset of symptoms is more than 6 months; these cases are rare, and patients usually present with some subsyndromal distress prior to developing full-blown PTSD. Clinically significant distress and impairment in the context of a subthreshold PTSD might warrant clinical attention.

Of note, the criteria listed for PTSD above apply to individuals over the age of six years. For children six years and younger, the *DSM-5* has outlined separate but similar diagnostic criteria in an effort to improve the recognition of this disorder in young children.

EPIDEMIOLOGY

Although lifetime prevalence rates reported in Europe are somewhat lower—for example, 1.9% in six European countries (Alonso et al., 2004b)—it is estimated that 6.8%–9.2% of people in North America have suffered from PTSD over the course of their lifetime (Breslau, Davis, Andreski, & Peterson, 1991; Kessler et al., 2005; Kessler, et al., 1995). Twelve-month prevalence rates have been shown to range from 3.5%–4.9%

in North America (Kessler, Chiu, Demler, Merikangas, & Walters, 2005; Kilpatrick et al., 2003; Norris, 1992; Resnick, et al., 1993), again contrasting with somewhat lower reported rates in Europe (Alonso, et al., 2004b; Darves-Bornoz et al., 2008; Hepp, et al., 2006; Perkonig, et al., 2000; Vaiva, et al., 2008; van Zelst, de Beurs, Beekman, Deeg, & van Dyck, 2003).

Rates of PTSD or PTSD symptoms ranging from 5%–63% have been reported among intensive care unit survivors, depending on the assessment methods and the populations (Jackson et al., 2007), with an estimated prevalence ranging from 19%–22% (Davydow, Gifford, Desai, Needham, & Bienvenu, 2008). Prevalence rates of PTSD for those with cancer reported in the literature are also divergent, ranging from 0% to 32% (Matsuoka et al., 2002; Naidich & Motta, 2000). However, a recent large epidemiological study reported that significant PTSD symptoms were present in 20.1% and 14.3% of Danish breast cancer survivors, 3 and 15 months after surgery, respectively (O’Connor, Christensen, Jensen, Moller, & Zachariae, 2011).

Posttraumatic stress disorder is a distressing and debilitating condition at the individual level, and it represents a significant burden to society because of its prevalence (Kessler, 2000). In addition to being a risk factor for other psychiatric conditions, such as substance abuse or depression, PTSD also leads to an increased likelihood of divorce, unemployment, academic failure, and early pregnancy. In terms of work days lost, PTSD is among the most impairing conditions ahead of even a number of somatic illnesses, such as heart disease (Alonso et al., 2004a).

A number of studies have investigated risk factors for PTSD. Pretraumatic risk factors included female gender (Breslau et al., 1991; Brewin et al., 2000; Yehuda, 2004), low education, previous trauma, history of childhood adversity, and prior personal or familial psychiatric history (Brewin et al., 2000; Ozer et al., 2003). Lack of social support is a strong posttraumatic risk factor for PTSD (Ozer et al., 2003). Severe peritraumatic distress is a predictor of PTSD (Brewin et al., 2000; Ozer et al., 2003). Finally, the type of trauma also influences the likelihood of developing PTSD; interpersonal trauma and sexual assault in particular have been shown to more frequently result in PTSD than non-interpersonal trauma such as natural disaster (Adler et al., 2008; Rose, Bisson, Churchill, & Wessely, 2002). In the community, it is estimated that one in five victims of assaultive violence develops PTSD compared to 6% of victims of other injury (Rose et al., 2002).

Because of their high rates of exposure to trauma, prevalence rates of PTSD are high in veterans. It is estimated that 12%–13% of veterans returning from the Gulf and Afghanistan wars suffered from PTSD (Seal, Bertenthal, Miner, Sen, & Marmar, 2007; Board on Population Health and Public Health Practice at the National Academies of Science, 2008). Furthermore, among veterans this disorder tends to become chronic—9% of Vietnam veterans still suffered from symptoms of PTSD in 1990 (Dohrenwend et al., 2006). Recently, it has been reported that among National Guard members preparing for deployment to Iraq, those previously deployed in Afghanistan (Operation Enduring Freedom) or Iraq (Operation Iraqi Freedom) were more than 3 times more likely to screen positive for PTSD (Kline et al., 2010).

Table 30.3 COMMONLY USED INSTRUMENTS FOR ASSESSING POSTTRAUMATIC STRESS DISORDER IN MEDICAL PATIENTS

INSTRUMENT	ABBREVIATION	METHOD OF ADMINISTRATION	# ITEMS	ADVANTAGES	LIMITATIONS	COMMENTS	TIME REQUIREMENT
Structured Clinical Interview for the <i>DSM-IV</i>	SCID-I	Interviewer-rated	21	Comprehensive assessment tool; Flexibility in administration	Dichotomous rating; focus on “worst event” experienced; lengthy; recommended for only trained clinicians	Can use only the PTSD module; Anxiety disorders, mood disorders, and substance use disorders modules recommended	2–10 minutes for PTSD module, 20 mins—several hours for the entire instrument
Clinician Administered PTSD Scale	CAPS	Interviewer-rated	30	Separate ratings for frequency and intensity; Flexibility in administration	Needs training; Time-consuming	Shorten by only assessing 17 core symptoms; Child Adolescent Version CAPS-CA	30 mins—1 hour
PTSD Symptom Scale Interview	PSS-I	Interviewer-rated	17	Can be administered by trained paraprofessionals	Measures symptoms over past 2 weeks rather than 1 month	Recommended for use with sexual assault survivors; Child Adolescent Version CPSS	20 mins
Structured Interview for PTSD	SI-PTSD	Interviewer-rated	27	Can be administered by trained paraprofessionals		Also assesses survival and behavioral guilt	10–30 mins
Anxiety Disorders Interview Schedule-PTSD	ADIS-PTSD	Interviewer-rated		Yields both dichotomous and continuous information	Mixed results in reliability and validity studies; recommended for only trained interviewers	Module of ADIS-IV	
Short Post-Traumatic Stress Disorder Rating Interview	SPRINT	Interviewer-rated	8	Used for screening	Not diagnostic	Sensitive to change	3 min
PTSD-Interview	PTSD-I	Interviewer-rated / Self-report		Yields both dichotomous and continuous information		Patients are given a copy of the scale to read along with interviewer	
Impact of Event Scale—Revised	IES-R	Self-report	22	Short; Widely used, enabling comparisons	Does not closely match <i>DSM-IV</i> criteria	Widely used	10 mins
Mississippi Scale for Combat-Related PTSD	M-PTSD	Self-report	35	Well validated for combat-related PTSD	Correspond to <i>DSM-III</i> criteria	Recommended for use with combat-related PTSD	10–15 mins
Keane PTSD Scale of the MMPI-2	MMPI-2, PK	Self-report	46		Dichotomous rating	Recommended for use with veterans	15 mins
Posttraumatic Stress Diagnostic Scale	PDS	Self-report	49	Yields both dichotomous and continuous information			10–15 mins
PTSD Checklist	PCL	Self-report	17	Closely match <i>DSM-IV</i> criteria	Does not provide diagnosis	Civilian Version (PCL-C), Military Version (PCL-M) and Specific Version (PCL-S)	5–10 mins
Los Angeles Symptom Checklist	LASC	Self-report	43	Yields both dichotomous and continuous information		Also assesses general psychological distress	15 mins
Distressing Events Questionnaire	DEQ	Self-report	35	Yields both dichotomous and continuous information	Does not assess criterion A1	Also assesses guilt, anger, and grief	5–7 mins

DIFFERENTIAL DIAGNOSES

The time elapsed since the trauma is the main point to consider when determining the difference between PTSD and ASD, although ASD also comprises dissociative symptom that are not included in the syndrome of PTSD except as a specifier. Generally, ASD occurs within the first month after trauma exposure, while PTSD is diagnosed beyond that.

Patients with anxiety disorders (panic disorder, general anxiety disorder, social anxiety disorder, etc) also may experience a certain level of hyperarousal and avoidant behaviors; however, both the trauma exposure and the reexperiencing of symptoms are missing from their clinical presentation. Depressive disorders may be triggered by a stressful experience and can also include concentration difficulties, insomnia, social withdrawal or detachment, and anhedonia, but they do not include trauma reexperiencing or trauma-related avoidance. Finally, an adjustment disorder can also occur after exposure to a stressor. However, in that condition either the stressor is not extreme or life threatening (e.g., divorce or job loss) and/or the reaction to it is not severe enough to meet criteria for PTSD. Furthermore, according to criterion C for adjustment disorder, meeting the criteria for any other mental disorder preempts a diagnosis of adjustment disorder.

COMORBIDITIES

PTSD commonly co-occurs with other psychiatric disorders, such as other anxiety disorders, affective disorders (depression, dysthymia, bipolar disorder), and substance use disorders (Kessler et al., 1995). Typically, PTSD precedes the development of the comorbid condition (Kessler et al., 1995; Perkonig et al., 2000), although PTSD can occur before, after, or concurrently with any other mental disorder. As noted, preexisting psychiatric conditions serve as risk factors for PTSD in the face of trauma exposure. Regarding comorbidity of PTSD and other conditions, it may be important to address PTSD first in order to adequately treat the comorbid problem. A recent study of women treated for comorbid PTSD and substance dependence showed that a reduction in

PTSD symptoms with specific PTSD treatment was associated with a reduction in substance use. In contrast, reduction in substance use did not necessarily reduce PTSD symptoms in this study (Hien et al., 2010).

PTSD is also comorbid with physical conditions. A recent study reported that even after adjusting for sociodemographics and comorbid psychiatric disorders, PTSD was significantly associated with an increased likelihood of suffering from a physical disorder in the past year, including neurological, vascular, gastrointestinal, metabolic, as well as autoimmune, bone, and joint conditions (Sareen, Cox, Clara, & Asmundson, 2005). Thus, chronic PTSD and chronic medical conditions can influence one another adversely. Medical conditions that are painful or life-threatening can increase arousal and thereby aggravate PTSD symptoms. At the same time patients with PTSD may have problems with medical treatment adherence, may have unhealthy behavior, and may show adverse physiologic effects of their chronic stress (Shemesh et al., 2001). There is evidence that PTSD is accompanied by dysregulation in the hypothalamic-pituitary-adrenal axis, associated with low cortisol levels frequently found in PTSD patients (Meewisse, Reitsma, de Vries, Gersons, & Olff, 2007). Further, recent data also suggest that patients with PTSD may exhibit immune modifications including increased circulating inflammatory markers, reactivity to antigen skin tests, and lower natural killer cell activity or total T lymphocyte counts (Pace & Heim, 2011).

ASSESSMENT

A range of both lengthy interviewer-based and brief self-rated instruments have been developed to assess or screen for PTSD (Pratt, Brief, & Keane, 2006). Although exhaustive description of all available instruments is beyond the scope of the present chapter, Table 30.3 reports those most commonly used in clinical practice, along with their usefulness and the time needed to administer them. Of note, the gold standard to assess PTSD is not the SCID, but the clinician-administered PTSD scale (Blake et al., 1995), which usually takes up to one hour to be administered. A number of the self-report scales, such as the Impact of Event Scale–Revised and the Posttraumatic Stress Diagnostic Scale have been used as screening instruments in medical settings with consistently strong results (Davydow, et al., 2008). Recently, a 4-item screening instrument has been developed for use in primary care (Box 30.2). Endorsing three items (yes/no) yields a sensitivity of 0.77 with a specificity of 0.85 for detecting PTSD (Prins et al., 2004).

Box 30.2 PRIMARY CARE PTSD SCREEN

In your life, have you ever had any experience that was so frightening, horrible, or upsetting that, in the past month, you . . .

1. Have had nightmares about it or thought about it when you did not want to?
YES NO
2. Tried hard not to think about it or went out of your way to avoid situations that reminded you of it?
YES NO
3. Were constantly on guard, watchful, or easily startled?
YES NO
4. Felt numb or detached from others, activities, or your surroundings?
YES NO

TREATMENTS AND PREVENTION

PRINCIPLES OF ACUTE STRESS DISORDER TREATMENT AND POSTTRAUMATIC STRESS DISORDER PREVENTION

It is worth highlighting that many individuals will experience a range of psychological and somatic stress response symptoms in the wake of trauma such as hyperarousal, anxiety,

Table 30.4 BRIEF PSYCHOTHERAPY AND PHARMACOLOGICAL STUDIES TO PREVENT THE DEVELOPMENT OF PTSD

	AUTHOR, YEAR	RESULTS
<i>Brief Psychotherapy</i>		
Cognitive Behavioral Therapy (CBT)	Bryant, 1998a	Brief (5 sessions) CBT within 2 weeks > Supportive counseling in preventing PTSD
	Bryant, 1999	Brief (5 sessions) PE or PE + Anxiety mgmt > Supportive counseling in preventing PTSD
	Bryant, 2003	Brief (5 sessions) CBT > Supportive Counseling in preventing PTSD
	Bryant, 2008a	Brief (5 sessions) ET > CT > No Tx in preventing PTSD
	Resnick, 2007	Video intervention reduces PTSD vs. standard care
Self-Help (SH)	Scholes, 2007	no group differences between SH and no Tx
	Turpin, 2005	no group differences in PTSD between SH and no Tx
Structured Writing Therapy (SWT)	van Emmerik, 2008	Efficacy of SWT was comparable to CBT
	Bugg, 2009	No differences between writing and self help (information only) groups
Memory Structured Intervention (MSI)	Gidron, 2007	No differences between MSI and supportive listening
<i>Pharmacotherapy</i>		
Propranolol	Pitman, 2002	Significant improvement post-acute stress
	Stein, 2007	No difference from placebo (gabapentin or propranolol)
	Reist, 2001	Recall of arousing story was reduced
	Vaiva, 2003	PTSD rate and symptoms lower in the propranolol group
Cortisol	Schelling, 2004	Hydrocortisone administered during cardiac surgery reduced chronic stress symptom scores
	Aerni, 2004	Low-dose cortisol for 1 month reduces the cardinal symptoms of PTSD
Morphine	Bryant et al. (2008c)	Patients with PTSD received significantly less morphine than those who did not develop PTSD
	Holbrook et al. (2010)	Wounded, morphine shortly after the injury reduced development of PTSD

From 2010 VA/DOD *Clinical Practice Guidelines for Management of Post-Traumatic Stress*.

and emotional distress. These may not show enough severity or impairment to meet ASD criteria; when they do not, they usually do not require professional intervention and the symptoms generally resolve spontaneously. Requiring acutely traumatized individuals to “debrief” in a group setting, termed *critical incident debriefing*, may actually increase rates of PTSD and related distress through interference with individuals’ spontaneous coping mechanisms (Adler et al., 2008; Rose et al., 2002; van Emmerik, Kamphuis, Hulsbosch, & Emmelkamp, 2002). While those who seek professional

assistance following a traumatic event and those who display the syndrome of ASD should always be offered care, it is not advisable to require or urge all individuals exposed to a trauma to talk about the trauma in detail, to participate in groups, or to receive services from a mental health professional. It is enough to ensure that trauma survivors have access to information about the usual course and reactions to trauma, to focus on basic medical and safety needs and to facilitate access to social supports (Zohar, Sonnino, Juven-Wetzler, & Cohen, 2009).

Because of the short timeframe in which ASD occurs and its potential role in predicting PTSD, naturally studies investigating its treatment somewhat overlap with those aiming to prevent PTSD (Table 30.4). Available research indicates that effective treatment techniques exist for treating ASD in trauma-exposed populations including sexual and nonsexual assault survivors, motor vehicle accident survivors, and survivors of industrial accidents. In particular, brief trauma-focused cognitive behavioral therapy has been shown to be effective in treating ASD and preventing development of PTSD (Roberts, Kitchiner, Kenardy, & Bisson, 2010). However, the administration of psychological interventions requires trained therapists. Unfortunately, there remains insufficient availability of professionals trained to administer these types of treatments, particularly in medical settings.

Another potential approach to treatment of ASD and prevention of PTSD could be a pharmacological one (Friedman, 2010), which is often more readily available across treatment settings; unfortunately, to date no data support the efficacy of any pharmacological agent for this indication. Limited and mixed evidence suggest that propranolol (McGhee et al., 2009; Pitman et al., 2002; Vaiva et al., 2003), hydrocortisone (Schelling et al., 2004), and morphine (Holbrook, Galarneau, Dye, Quinn, & Dougherty, 2010) might be potential candidates for further investigations. In addition, studies are under way using selective serotonin reuptake inhibitors (SSRIs) for this indication (Zohar et al., 2009), although data from children suffering from burns and ASD symptoms did not demonstrate greater benefit from imipramine or fluoxetine than from placebo (Robert et al., 2008). Finally, although trauma patients usually present with acute signs of anxiety and benzodiazepines are well known for their efficient and rapid action on these symptoms, including insomnia, their benefit in trauma patients is much less clear. Recent studies found that not only do benzodiazepines not seem to prevent the development of PTSD, they might actually even increase the risk for this condition (Davydow, et al., 2008; Gelpin, Bonne, Peri, Brandes, & Shalev, 1996; Mellman, Bustamante, David, & Fins, 2002). This may in part be due to interference with natural resolution of fear responses to trauma that occur with time (i.e., extinction learning). Animal data have also suggested that early benzodiazepine administration after a stressor may interfere with successful responses to stress exposures later on, potentially via effects on the HPA axis (Matar, Zohar, Kaplan, & Cohen, 2009). In other words, while no strong data support the use of any medication in the early aftermath after trauma exposure, clinicians should at least avoid using benzodiazepines during that period.

PRINCIPLES OF POSTTRAUMATIC STRESS DISORDER TREATMENT

Two primary types of treatments are available for PTSD: psychological interventions and pharmacotherapy. Psychotherapeutic techniques that have yielded the most consistent findings in PTSD are different forms of

cognitive-behavioral therapies (CBT). CBT adapted to PTSD usually includes elements of exposure therapy, and, to date, results from over 30 randomized controlled trials (RCT) provide evidence for the use of individual CBT as a first-line treatment in PTSD (Orsillo, Raja, & Hammond, 2002). Two types of CBT with strong randomized controlled data supporting safety and efficacy in the treatment of PTSD are *Prolonged Exposure (PE) Therapy* (Foa et al., 2005; Schnurr et al., 2007) and *Cognitive Processing (CP) Therapy* (Monson et al., 2006; Resick et al., 2008; Resick, Nishith, Weaver, Astin, & Feuer, 2002). There is no evidence supporting differential efficacy for PE compared to CPT for PTSD to date, although there may be individual patient or clinician preferences (Resick et al., 2002). PE focuses on repeated imaginal exposure to the traumatic event as well as repeated in vivo exposure to safe situations that are currently avoided as they trigger traumatic reminders. These exposures promote extinction learning and resolution of symptoms. CPT focuses predominantly on cognitive interventions including challenging and modifying dysfunctional beliefs related to the trauma (e.g., lack of safety, difficulty trusting others), but also includes exposure via writing about the trauma.

Another technique found to be effective in PTSD is eye movement desensitization and reprocessing (EMDR). Although EMDR integrates elements of psychodynamic, cognitive behavioral, cognitive, interpersonal, systems, and body-oriented therapies (Seiffge-Krenke & Klessinger, 2000), it possesses a unique feature of bilateral brain stimulation (e.g., eye movements). This therapy follows an eight-phase structure and aims to allow patients to develop more adaptive coping mechanisms by processing distressing memories and reducing their influence. It has been suggested that EMDR makes use of a dual attention awareness to allow the patient to alternate between the traumatic memories and the safety of the present moment. A body of literature found that this therapy is effective in the treatment of PTSD (Amoyal et al., 2011; Orsillo et al., 2002); this suggests that it may be considered a first-line psychological treatment (Bisson et al., 2007). However, there is evidence that the eye movements may be an unnecessary part of the treatment and that the treatment effect is a result of the exposure component (P. R. Davidson & Parker, 2001). Although group CBT and stress management seem to be effective in PTSD, the effect has been reported to be weaker than individual CBT and EMDR, which prevents their use as first-line treatments (Bisson et al., 2007). Please see Table 30.5 for a comparison of EMDR, cognitive-based therapies, and exposure-based therapies. Other psychotherapeutic interventions such as couple and family therapy, psychodynamic therapy, hypnosis, creative therapy, etc., have also been proposed; however, to date, strong empirical support for their efficacy in PTSD is still lacking (Bisson, et al., 2007). A detailed review of available data supporting the different psychotherapy treatment approaches is available in the recent VA/DoD Clinical Practice Guidelines for the Management of Posttraumatic Stress (Department of Veterans Affairs & Department of Defense, 2010).

Table 30.5 ELEMENTS OF PSYCHOTHERAPEUTIC APPROACHES VALIDATED FOR POSTTRAUMATIC STRESS DISORDER

CORE COMPONENTS	ADDITIONAL POSSIBLE COMPONENTS
<i>Exposure-based therapies</i>	
In-vivo, imaginal, and narrative exposure to the traumatic event	Cognitive restructuring Relaxation techniques Self-monitoring of anxiety
<i>Cognitive-based therapies</i>	
Cognitive restructuring (challenging automatic or acquired beliefs connected to the traumatic event)	Relaxation techniques Discussion/narration of the traumatic event
<i>Eye Movement Desensitization and Reprocessing (EMDR)</i>	
Alternating eye-movements or attention to tones, tapping, or other stimuli	Imaginal and/or narrative exposure to the traumatic event Cognitive restructuring Relaxation techniques Self-monitoring of anxiety

First-line pharmacological treatment of PTSD focuses on SSRIs, with some support for comparable efficacy of serotonin norepinephrine reuptake inhibitors such as venlafaxine (J. Davidson et al., 2006). Although recent research suggests that SSRIs might not be as effective as previously thought (Orsillo et al., 2002; van Emmerik et al., 2002) and that chronic combat-related PTSD may be somewhat less responsive, there is strong empirical evidence suggesting that SSRIs should be the preferred first-line medication for PTSD based on results from a number of well-conducted random controlled trials. To date, two agents have been approved by the Food and Drug Administration for the treatment of PTSD: sertraline and paroxetine. SSRIs are well tolerated and may also be useful to treat comorbid depression; however, because of a possible initial increase in anxiety symptoms, they should be initiated more slowly than in depression. Other medications that have been studied as monotherapy in the treatment of PTSD include other antidepressants, anticonvulsants, antipsychotics, and antihypertensive drugs. While evidence supporting their use as first-line treatments is limited by the lack of large randomized controlled trials, several antidepressants including mirtazapine, nefazodone, amitriptyline, imipramine and phenelzine might be considered as second-line choices for monotherapy (Department of Veterans Affairs & Department of Defense, 2010).

Although atypical antipsychotics such as risperidone and olanzapine have not been shown to be effective in monotherapy on PTSD symptoms, some evidence suggests that their use as adjunctive may be beneficial on associated symptoms of psychosis (Department of Veterans Affairs & Department of Defense, 2010). No large randomized studies support the efficacy of benzodiazepines for PTSD. While they may be useful

as adjunctive agents in limited cases, those with PTSD are at heightened risk for substance abuse and dependence. In addition, benzodiazepines may interfere with CBT efficacy, potentially even more so when used on an as needed basis. Some data support the use of alternative agents for insomnia and nightmares in patients with PTSD. These include the alpha blocker prazosin and newer sleep agents such as eszopiclone (Pollack et al., 2011; Taylor et al., 2008). Again, an excellent review of evidence for pharmacotherapy approaches beyond the scope of this chapter is available in the recent VA/DoD *Clinical Practice Guidelines for the Management of Post-traumatic Stress* (Department of Veterans Affairs & Department of Defense, 2010).

FUTURE AND CONTROVERSIES

The fifth revision of the *DSM* includes a number of changes in the formulation of the diagnostic criteria for acute and chronic reactions to trauma. ASD and PTSD no longer belong to the anxiety disorder spectrum, but to a new class of trauma and stressor-related disorders. The requirement for a subjective negative response to the stressor (*DSM-IV-TR* criterion A2, “intense fear, helplessness, horror”) has been suppressed in both ASD and PTSD. Finally, in the *DSM-V*, ASD symptoms are no longer organized in four symptom clusters but are now grouped into one single criterion. PTSD symptoms are now reclassified into four clusters (reexperiencing, avoidance, alterations in cognition and mood, hyperarousal) instead of three. Future studies will determine whether these changes in symptoms criteria will result in changes in prevalence rates, and yield significant clinical implications.

SUMMARY

In recent years research has blossomed in understanding the underlying risk factors, phenomenology and biology, prevention and early intervention, and treatment for ASD and PTSD. However, more data are needed to guide the optimal identification of trauma-exposed individuals at risk and to provide optimal prevention and intervention strategies. Perhaps the greatest advances have been in the development of exposure based psychotherapies, which can be considered first line for ASD and PTSD. Although many more practitioners are now aware of these treatments, additional dissemination of these evidence based psychotherapies is needed to increase availability. Further, the avoidance and stigma associated with PTSD can interfere with patients seeking or continuing with treatment, suggesting it is important for practitioners to screen for and educate about PTSD amongst trauma exposed individuals. First-line pharmacotherapy for PTSD is an antidepressant drug, but not all patients respond. PTSD is a heterogeneous condition associated with high rates of psychiatric, substance, and medical comorbidities that should be assessed and may require targeted treatment. More research is needed to develop novel pharmacotherapies and increase the evidence base for commonly employed pharmacotherapeutic approaches to PTSD. With many basic science and clinical research studies ongoing and increasing attention to the field, it is hopeful that growing scientific knowledge will lead to improved prevention and better outcomes in the coming years.

CLINICAL PEARLS

- Peritraumatic reactions are those experienced during and immediately after trauma. Certain trauma-specific peritraumatic reactions—distress and dissociation—are robust predictors of the development of chronic and debilitating PTSD (Brewin et al., 2000; Ozer et al., 2003). In other words, the more “frightened” the individual is during the trauma, the more likely he is to still be frightened 1 month later.
- The majority of persons who experience early post-traumatic symptoms adjust in the following weeks or months (Blanchard et al., 1996; Hamanaka et al., 2006).
- Most trauma survivors who subsequently develop PTSD do not meet full criteria for ASD (R. A. Bryant, 2011).
- Risk factors for PTSD included female gender (Breslau et al., 1991; Brewin et al., 2000; Yehuda, 2004), low education, previous trauma, history of childhood adversity, and prior personal or familial psychiatric history (Brewin et al., 2000; Ozer et al., 2003), lack of social support (Ozer et al., 2003), severe peritraumatic distress (Brewin et al., 2000; Ozer et al., 2003), and, finally, interpersonal trauma and sexual assault (Adler et al., 2008; Rose et al., 2002).

- In the community, it is estimated that one of five victims of assaultive violence develops PTSD compared to 6% of victims of other injury (Rose et al., 2002).
- Among National Guard members preparing for deployment to Iraq, those previously deployed in Afghanistan (Operation Enduring Freedom) or Iraq (Operation Iraqi Freedom) were more than 3 times more likely to screen positive for PTSD (Kline et al., 2010).
- Patients with other anxiety disorders (panic disorder, general anxiety disorder, social anxiety disorder, etc) also may experience a certain level of hyperarousal and avoidant behaviors; however, both the trauma exposure and the reexperiencing symptoms are missing from their clinical presentation.
- A recent study of women treated for comorbid PTSD and substance dependence showed that a reduction in PTSD symptoms with specific PTSD treatment was associated with a reduction in substance use. In contrast, in this study, reduction in substance use did not necessarily reduce PTSD symptoms (Hien et al., 2010).
- Medical conditions that are painful or life-threatening can increase arousal and thereby aggravate PTSD symptoms.
- Requiring acutely traumatized individuals to “debrief” in a group setting, termed *critical incident debriefing*, may actually increase rates of PTSD and related distress through interference with individuals’ spontaneous coping mechanisms (Adler et al., 2008; Rose et al., 2002; van Emmerik et al., 2002).
- It is not advisable to require or urge all individuals exposed to a trauma to talk about the trauma in detail, to participate in groups, or to receive services from a mental health professional. It is enough to ensure that trauma survivors have access to information about the usual course and reactions to trauma, to focus on basic medical and safety needs and to facilitate access to social supports (Zohar et al., 2009).
- Brief trauma-focused cognitive behavioral therapy has been shown to be effective in treating ASD and preventing development of PTSD (Roberts et al., 2010).
- Benzodiazepines do not seem to prevent the development of PTSD, but they might actually even increase the risk for this condition.
- Strong empirical evidence suggests that SSRIs should be the preferred first-line medication for PTSD based on results from a number of well-conducted random controlled trials.

DISCLOSURE STATEMENTS

Dr. Bui does not have any conflict of interest to disclose.

Dr. Charney does not have any conflict of interest to disclose.

Ms. Kredlow does not have any conflict of interest to disclose.

Dr. Simon receives grant support from NIH, DOD, AFSP, ACS, Highland Street Foundation, Forest Laboratories, Inc. She receives financial compensation from the MGH Psychiatry Academy. Her spouse receives equity from Elan, Dandreon, G-Zero, Gatekeeper.

Dr. Zeng does not have any conflict of interest to disclose.

ANXIETY IN THE MEDICALLY ILL

Richard J. Goldberg and Donna B. Greenberg

INTRODUCTION

The anxiety that accompanies medical illness contributes greatly to each patient's functional impairment (Marcus et al., 1997). Recognition and reduction of excessive anxiety facilitates the ability to cope. This chapter presents an approach to the evaluation and treatment of anxiety in medical patients that includes both biological and psychological dimensions and requires full medical and psychiatric consideration. First, we review medication-induced or substance-induced symptoms and notable underlying medical bases for anxiety. Once these possibilities have been considered, a clinician draws on the patient's personal and psychiatric history to determine whether anxiety is part of an underlying psychiatric disorder, such as panic disorder, mood disorder, or personality disorder. Simultaneously, the clinician assesses the anxiety as a reactive psychological adjustment response.

MEDICAL DISORDERS THAT PRESENT AS ANXIETY

Medical disorders can produce anxiety directly or indirectly. Some medical disorders have specific effects on neurotransmitter systems that stimulate anxiety, such as hyperthyroidism (Hall, 1983; MacCrimmon et al., 1979); others have specific effects on neuroanatomic sites associated directly with the production of anxiety, for example, tumors of the temporal lobe (Dietch, 1984). Other medical disorders produce anxiety through autonomic arousal, which the patient interprets as a psychological state. Medical disorders that can present with anxiety as a prominent symptom are listed in Box 31.1.

TOXIC AND WITHDRAWAL EFFECTS OF DRUGS

The toxic and withdrawal effects of drugs are a common cause of anxiety in medical patients See Box 31.2. If there is any doubt about what drugs the patient has been taking, a toxicology screen should be ordered. Such screening is especially useful when the patient is suspected of surreptitious drug use. Review of the patient's medication list should also pay attention to what drugs have been stopped.

Caffeine

Caffeine is one of the most widely used psychotropic drugs in the United States and one which causes anxiety; it is found in many beverages and drug combinations (Abelson & Fishburne, 1976). The approximate amount of caffeine in a cup of coffee is 150 mg; tea generally has about 50–100 mg per cup; cola drinks have about 40–50 mg/12 oz.; and a small chocolate bar has about 15–25 mg. Caffeine-containing medications (as it is usually combined with aspirin or acetaminophen) have about 32 mg of caffeine per tablet. Consumption of these medications is associated with an increase in sleep difficulties (Brown et al., 1995). Although sensitivity varies, symptoms of caffeinism may occur at doses of only 200 mg (Victor, Lubetsky, & Greden, 1981). Patients with generalized anxiety disorder are abnormally sensitive to caffeine for both subjective and physiologic arousal measures (Bruce et al., 1992). Caffeine increases norepinephrine levels in the plasma and urine (Robertson et al., 1978), inhibits phosphodiesterase breakdown of cyclic adenosine monophosphate in the central nervous system (CNS), and sensitizes central catecholamine receptors, particularly for dopamine (Waldeck, 1975). Caffeine can precipitate an actual panic attack in patients with panic disorder (Charney, Heninger, & Jatlow, 1985). In chronic users, caffeine abstinence should also be considered as a possible source of intermittent anxiety (White et al., 1980). After ceasing consumption, people who have consumed even low or moderate amounts of caffeine (mean amounts of 235 mg/day, which is equivalent to 2.5 cups of coffee) may have withdrawal syndromes such as moderate to severe headache, fatigue, or psychic distress (Silverman et al., 1992). Since caffeine is like other psychoactive drugs with the development of dependence and withdrawal syndrome (Strain et al., 1994), patients should be advised to taper off caffeine gradually rather than stop abruptly.

Energy drinks have moderate to relatively high levels and concentrations of caffeine (2.5–35.7 mg per oz) compared to other caffeinated beverages such as a 12oz. cola or 6oz. cup of coffee (see Box 31.3). Energy shots are low volume (1–2oz.) and have an even higher concentration of caffeine than other energy drinks. Also, hot beverages like coffee are usually drunk more slowly than cold energy drinks, so in the latter case larger quantities of caffeine can be consumed in short order. Energy drinks have also been linked to drinking high

**Box 31.1 MEDICAL CONDITIONS ASSOCIATED
WITH ANXIETY SYMPTOMS**

Cardiovascular Conditions

Angina pectoris
Arrhythmias
Congestive heart failure
Hypovolemia
Myocardial infarction
Valvular disease

Endocrine Conditions

Carcinoid syndrome
Hyperadrenalism
Hypercalcemia
Hyperthyroidism
Hypocalcemia
Hypothyroidism
Pheochromocytoma

Metabolic Conditions

Hyperkalemia
Hyperthermia
Hypoglycemia
Hyponatremia
Hypoxia
Porphyria

Neurologic Conditions

Akathisia
Encephalopathy
Mass lesion
Postconcussion syndrome
Seizure disorder
Vertigo

Peptic Ulcer Disease

Respiratory Conditions

Asthma
Chronic obstructive pulmonary disease
Pneumothorax
Pulmonary edema
Pulmonary embolism

Immunologic Conditions

Anaphylaxis
Systemic lupus erythematosus

Box 31.2 DRUGS THAT CAUSE ANXIETY

Stimulants

Amphetamines
Aminophylline
Caffeine
Cocaine
Methylphenidate
Theophylline

Sympathomimetics

Ephedrine
Epinephrine
Phentermine
Phenylpropanolamine
Pseudoephedrine

Drug Withdrawal

Benzodiazepines
Narcotics
Barbiturates
Sedatives
Alcohol

Anticholinergics

Trihexyphenidyl
Benztrapine
Diphenhydramine
Oxybutynin
Propantheline
Meperidine
Tricyclics
Pilocarpine (including ocular)

Dopaminergics

Amantadine
Bromocriptine
L-dopa
Carbidopa-levodopa
Metoclopramide
Neuroleptics
Pergolide

Miscellaneous

Baclofen
Cycloserine
Hallucinogens
Indomethacin
Anabolic steroids
Captopril
Disopyramide
Dronabinol
Estrogens
Fluoroquinolone antibiotics
Metrizamide

volumes of alcohol per drinking session, with more injudicious consequences (Arria & O'Brien, 2011). The American Academy of Pediatrics recommends that adolescents should not have more than 100 mg of caffeine each day, and adults should limit caffeine to 500 mg per day. Older patients may be

Metronidazole
 Procaine derivatives
 Progestins
 Sumatriptan and other triptans

Other

SSRIs (may be confused with akathisia)
 Interferon

more sensitive to caffeine (Brown & Stoudemire, 1998; Torpy & Livingston, 2013; American Academy of Pediatrics, 2011).

Cocaine, Methamphetamine and Marijuana

Symptoms of anxiety, irritability, tremulousness, fatigue, or depression may appear soon after the initial euphoriant effects of cocaine (Resnick, Kestenbaum, & Schwartz, 1976; Abramowicz, 1986). Cocaine has been reported to induce

panic attacks in susceptible individuals and actually to precipitate panic disorder, which continues autonomously even after the cocaine use is discontinued (Aronson & Craig, 1986). Detectable amounts of cocaine are found in the urine or plasma only for a few hours after use, although one of the metabolites, benzoylecgonine, can be detected in a urine sample for as long as 48 hours after use and longer after chronic use (Preston et al., 2002). Abuse of methamphetamine, which has a half-life of 12 hours (longer than cocaine), can present with anxiety in the setting of intoxication or withdrawal. In withdrawal, the depression may be more prolonged and worse than that of cocaine withdrawal (Winslow, Voorhees, & Pehl, 2007). Among marijuana users anxiety is prominent with panic reactions noted most often in naïve users (Green et al., 2003). Tolerance to the intoxicating effects of marijuana can develop, and anxiety, insomnia, appetite disturbance, and depression can occur upon withdrawal (Budeney & Hughes, 2006; Maldonado et al., 2011).

Alcohol and Sedative Withdrawal

Since many hospitalized medical patients have unhealthy alcohol use (Moore, 1985; Saltz et al., 2005), alcohol withdrawal (Lerner & Fallon, 1985) is a frequent etiology for agitation and anxiety in this population. Minor abstinence syndrome, which has its modal onset about 24 hours after cessation of drinking, presents with anxiety, tremulousness (the shakes), and insomnia. The major concern is whether such symptoms are the harbinger of alcohol withdrawal delirium (delirium tremens), which has a modal onset 72 hours following cessation or significant reduction of drinking but can also occur as early as 24 hours or up to 7 days later. In major abstinence, anxiety and tremulousness are accompanied by symptoms of autonomic arousal, and should be considered a serious medical problem that requires supervised medical management (Sellers & Kalant, 1976). The classic signs and symptoms of sedative withdrawal can be masked by the concurrent use of other medications. For example, mydriasis may be absent if the patient is on narcotics, and tachycardia may be masked by beta-blockers. Because of the association of Wernicke-Korsakoff syndrome with alcohol use (Reuler, Girard, & Cooney, 1985), such patients should always be given thiamine.

Opiate Withdrawal

Narcotic abstinence is always accompanied by anxiety. Iatrogenic withdrawal (and recurrent pain) may occur when patients are changed from parenteral to oral narcotics without consideration of differences in oral/parenteral potency ratios.

Neuroleptics and Other Dopamine Blockers

Akathisia, an extrapyramidal side effect of typical neuroleptics, mimics anxiety. Patients may be aware of inability

Box 31.3 CAFFEINE CONTENT OF BEVERAGES AND OTHER PRODUCTS

Energy Drinks and Caffeine Content (mg)

5-hour Energy 207
 Amp, 16 oz. 143
 BAWLS guarana 16 oz. 100
 Full throttle, 16 oz. 197
 Monster, 16 oz. 160
 No Fear, 16 oz. 174
 NOS, 16 oz. 260
 Red Bull, 16 oz. 152
 Rip it 16 oz. 200
 Rockstar, 16 oz. 160
 SPIKE Shooter 286

Sodas and Caffeine Content (mg)

Coca Cola 20 oz. bottle 58
 Dr. Pepper 20 oz. bottle 70
 Mountain Dew 20 oz. bottle 90
 Pepsi, 20 oz. bottle 63
 Pepsi MAX 20 oz. bottle 115
 Vault 20 oz. bottle 118

Other

Arizona Iced Tea, green 16 oz. 15
 Black tea (brwed) 8 oz. 55
 Coffee (brewed) 16 oz. 170
 Excedrin Extra Strength 2 pills 130
 Hot chocolate 8 oz. 9
 NoDoz Maimum Strength 1 pill 200
 StayAlert gum 1 piece 100
 Vivarin 1 pill 200

to keep their legs still and their desire to move. They may rock from foot to foot, and may have insomnia. Signs of akathisia range from occasional fidgety movements to walking on the spot. In the outpatient setting patients may get up from their chair as they describe anxiety and insomnia and pace around the room (Barnes, 2003). Typical antipsychotics as well as prochlorperazine and other dopamine receptor blockers like metoclopramide can cause akathisia. Risperidone, ziprasidone, and aripiprazole have a higher risk of akathisia than the atypical antipsychotics olanzapine, or quetiapine (Kumar & Sachdev, 2009). Patients with bipolar disorder and depression are more prone to akathisia than those with schizophrenia. Akathisia with aripiprazole in schizophrenic patients occurred in 12.5% as compared to 24% with haloperidol (Kane et al., 2010). Among schizophrenic patients in a large study (the Clinical Antipsychotic Trials of Intervention Effectiveness Schizophrenia Trial), a moderate dose of perphenazine produced comparable rates of akathisia to ziprasidone, risperidone, and olanzapine (Caroff, Hurford, Lybrand, & Campbell, 2011).

Akathisia may be treated by lowering the neuroleptic dose of the offending drug or by a switch to an atypical agent with less potential for akathisia. While other extrapyramidal side effects like acute dystonia and parkinsonism respond to anticholinergic drugs, it is not clear that they are helpful for akathisia. Benzodiazepines such as lorazepam 0.5 mg three times daily or clonazepam 0.5 mg once daily offer another treatment option (Fleischacker, Roth, & Kane, 1990; Wells et al., 1991; Rathbone & Soares-Weiser, 2006). Propranolol 40–80 mg twice daily has been effective. Mirtazapine 15 mg each day may also be effective (Poyurovsky, 2010).

Antidepressants

Akathisia-like jitteriness is a common side effect of fluoxetine and other specific serotonin reuptake inhibitors (SSRI) (Lipinski et al., 1989) characterized by motor restlessness and anxiety that is indistinguishable from neuroleptic-induced anxiety. The side effect appears to be similar to the jitteriness associated with tricyclic antidepressants (TCAs) (Nierenberg & Cole, 1991; Pohl et al., 1988). Such jitteriness (including increased anxiety and insomnia) can occur even at low doses. A review of anti-depressant induced jitteriness/anxiety syndrome did not find robust evidence of a different incidence between tricyclics and SSRIs. This jitteriness syndrome is sometimes thought to be distinct from the akathisia typical of neuroleptics. Common treatment strategies are slower titration of antidepressants and the addition of benzodiazepines (Sinclair et al., 2009).

Agitation, insomnia, and tremor are also among the most common side effects of bupropion (Bryant, Guernsey, & Ingram, 1983; Gardner, 1983). Tolerance usually develops with continuation of treatment. As with neuroleptic-induced akathisia, beta-adrenergic blockers or benzodiazepines may be helpful in reducing or abolishing the symptoms, although dose reduction is often necessary.

Other Drugs

Alpha-adrenergic stimulants such as pseudoephedrine are often included in over-the-counter decongestants. These agents are closely related to amphetamines and can produce symptoms of anxiety, restlessness, irritability, and insomnia (Weiner, 1980).

Bronchodilators, which chemically resemble the catecholamines (such as isoproterenol and albuterol), have peripheral effects that include increased heart rate and blood pressure that contribute to feelings of anxiety. Systemic effects, reported even with metered-dose inhalers (Harris, 1985), include symptoms of anxiety, restlessness, nervousness, tremor, irritability, insomnia, and emotional lability.

Theophylline, a methylxanthine related chemically to caffeine, is capable of producing powerful cardiovascular effects with tachycardia, along with nervousness and anxiety states (Jacobs, Senior, & Kessler, 1976).

Nifedipine and verapamil have been reported to produce neuropsychiatric symptoms that include anxiety, tremulousness, jitteriness, and sleep disturbance (Bela & Raftery, 1980; Mueller & Chahine, 1981; Rinkenberger et al., 1980; Singh, Ellrodt, & Peter, 1978).

Other drugs reported to produce anxiety as a side effect include amphetamines and similar anorexic agents, antihistamines, cycloserine, and indomethacin (Abramowicz, 1989).

OTHER MEDICAL DISORDERS

Hypoglycemia

Diabetes has a high rate of comorbid depression and anxiety disorder; however, anxiety symptoms must be evaluated with consideration of hypoglycemia. Hypoglycemia provokes adrenergic or catecholamine-mediated symptoms that may include anxiety, tachycardia, diaphoresis, tremor, weakness, hunger, irritability, and palpitations. Patients taking insulin, glinides, metformin, or sulfonuria are most at risk. Patients can be educated to be alert to glucose readings below 70 mg/dL. This threshold allows for inaccurate readings and comes before symptoms develop. Patients need not always treat themselves with glucose at this reading but should avoid exercise or driving until the glucose is higher. Older patients and patients who have recurrent hypoglycemia are less likely to have the sympathetic symptoms and are more at risk of becoming confused without the forewarning of anxiety (Sequist et al., 2013). Hypoglycemia is discussed further in Chapter 6.

Complex Partial Seizures

Anxiety is the most common ictal emotion associated with temporal lobe epilepsy (Weil, 1959). Simple partial seizures from a mesial temporal structural lesion can mimic panic disorder (Young et al., 1995). The phenomenology of panic attacks and temporal lobe epilepsy can be difficult to distinguish, especially when the electroencephalogram (EEG) does not support the diagnosis of temporal lobe epilepsy. McNamara and Fogel (1990) reported five cases of patients with panic attacks with associated paroxysmal emotional,

autonomic, or psychosensory symptoms. The EEG findings, although compatible with interictal temporal lobe epilepsy, were nonspecific. However, the cases responded well to anticonvulsant therapy. The likelihood of complex partial seizures is increased if the patient has a history of head injury, febrile convulsions in childhood, birth trauma, or encephalitis, or a personal or family history of seizures.

The characteristic abnormality in temporal lobe seizures is the anterior temporal spike focus; however, in the waking state at least one half of patients have normal EEGs (Gibbs & Gibbs, 1952). A sleep record does increase the percentage of abnormal EEGs in epileptic patients, although the measure of false negatives remains about 30% to 40%. The value of nasopharyngeal and sphenoidal leads is uncertain, although the use of continuous ambulatory EEG monitoring (Kristensen & Sendrup, 1978; Lieb et al., 1976; McNamara & Fogel, 1990; Zijlmans et al., 2008) can increase the diagnostic yield (see Chapter 43). Because of the high incidence of false-negatives, the EEG is not a definitive test, and the diagnosis of temporal lobe seizure disorder often must be made on clinical grounds and tested by an empiric trial of anticonvulsants.

Angina Pectoris

Angina may present as anxiety with episodes of dyspnea and palpitations accompanied by only mild chest discomfort. When such episodes are precipitated by exercise or emotional stress, angina should be suspected and cardiac evaluation considered, especially in patients over 40 years of age or those with a cardiac history. However, when such evaluations are done, panic disorder is found to be a common cause of chest pain in patients with negative cardiac test results (Katon, 1990).

Cardiac Arrhythmias

Because cardiac arrhythmias may produce symptoms mistaken for anxiety, pulse regularity should always be checked during an episode of anxiety. For instance, paroxysmal supraventricular tachycardia may be misdiagnosed as panic disorder (McCrank, Schurmans, & Lefkoe, 1998). If the diagnosis of recurrent arrhythmias is suspected, ambulatory monitoring may be helpful. For those patients with arrhythmias, a host of medical conditions that are also associated with anxiety symptoms need to be considered, such as hyperthyroidism, caffeinism, and nicotine abuse (Lynch et al., 1977). Implantable defibrillators have been reported to cause PTSD after repeated discharges. (Habibovic, van den Broek, Alings, van der Voort, & Denollet, 2012; Hamner et al., 1999).

Mitral Valve Prolapse

Both patients with panic disorder and patients with mitral valve prolapse complain of chest pain, dyspnea, fatigue, dizziness, and a fainting sensation. About half of patients with mitral valve prolapse at one time or another complain of palpitations, but continuous cardiac monitoring of such patients

often reveals no relationship between the complaint of palpitations and any form of cardiac rhythm disturbance (Devereux et al., 1976; Shear et al., 1984). Studies looking for an association between the two syndromes have provided inconsistent results over the last 40 years, and more recent studies have not found an association (Filho et al., 2008, 2011).

Recurrent Pulmonary Emboli

Recurrent pulmonary emboli can present as repeated episodes of acute anxiety associated with hyperventilation and dyspnea (Ferrer, 1968). The most common symptoms of pulmonary embolus in patients who did not have preexisting cardiopulmonary disease (as noted in the Prospective Investigation of Pulmonary Embolism Diagnosis II) were dyspnea at rest or with exertion, pleuritic pain, cough, more than two-pillow orthopnea, calf or thigh pain/swelling, and wheezing. Tachypnea and tachycardia were the most common signs (Stein et al., 2007).

Arterial blood gases may reveal decreased partial pressure of oxygen during an episode but not always, and the confirmatory tests most in use are the computerized tomography pulmonary angiography (CT-PA), ventilation-perfusion lung scan and D-dimer. This diagnosis should be considered in those patients who have some predisposition, such as immobilization, surgery within the last 3 months, stroke, paresis, paralysis, central venous instrumentation within the last 3 months, cancer, chronic heart disease, autoimmune diseases, and history of venous thromboembolism (Thompson & Hales, 2014).

Heart Failure and Pulmonary Edema

Insomnia and anxiety may be early signs of heart failure, as patients find their sleep disrupted, must sit up or sleep with pillows due to orthopnea, and have paroxysmal nocturnal dyspnea.

Hyperthyroidism

Hyperthyroidism usually presents with symptoms of nervousness, palpitations, diaphoresis, heat intolerance, and diarrhea. Signs include tachycardia, tremor, weight loss, and hot, moist skin. The contribution of hyperthyroidism to anxiety, along with its diagnosis and treatment, are discussed in Chapters 6 and 55.

Pheochromocytoma

Pheochromocytoma is a rare tumor of the adrenal medulla or sympathetic ganglia (paragangliomas) which can secrete catecholamines (norepinephrine, epinephrine, or dopamine) (Hodin, 2014). The output of catecholamines may be episodic or continuous, producing acute or chronic symptoms of anxiety that are often accompanied by headache, sweating, and flushing (Lishman, 1987). Although anxiety symptoms may be prominent, panic attacks are not always seen (Starkman et al., 1985). Episodes of palpitations and anxiety may be subtle,

and the classic signs of flushing and headache may be absent (Hodin, 2014). Hypertension is usually present during acute episodes, and 60% to 80% of patients have sustained hypertension. Urinary and plasma catecholamines and fractionated metanephrine and normetanephrine are assessed for diagnosis. Plasma free metanephrine levels and fractionated metanephrine levels in the urine are most sensitive to exclude the tumor (Pacak et al., 2005). The diagnosis is pursued in the setting of resistant hypertension, hyperadrenergic episodes, an incidental adrenal tumor on imaging, cardiomyopathy in a young person, and family history of a predisposing syndrome. Familial syndromes are multiple endocrine neoplasia type 2, von Hippel-Lindau syndrome, neurofibromatosis type 1, and familial paraganglioma. Further details of the evaluation can be found in Chapter 6.

Hyperventilation Syndrome

Hyperventilation syndrome (HVS), like panic disorder, is a syndrome that harks back to descriptions of nineteenth century soldiers with an irritable heart and predates the current definition of panic disorder. It was estimated to have a prevalence of 10% in a general medical clinic years ago (Rice, 1950), and 5% in a neurology clinic practice (Pincus & Tucker, 1985). Anxiety is a cardinal symptom along with a variety of other medical symptoms, including faintness, visual disturbances, nausea, vertigo, headache, palpitations, dyspnea, diaphoresis, and paresthesias. Patients may or may not be aware that they are hyperventilating, and repeated sighing is often a visible sign. The diagnosis of HVS can be made on the basis of the patient's response to overbreathing (breathing by mouth for up to 3 minutes or until dizzy). If the symptoms in question are entirely reproduced, without an alternative explanation by physical examination, medical history, or laboratory tests, the diagnosis can be established.

Hyperventilation syndrome probably represents a form of panic disorder in most cases, and patients may qualify for both syndromes (Cowley & Roy-Byrne, 1987). Hyperventilation leads to excessive elimination of carbon dioxide, acute respiratory alkalosis, and cerebral arterial constriction. In 240 seconds of overbreathing, cerebral blood flow can be reduced by 40% (Plum & Posner, 1972), causing EEG slowing (Gotoh, Meyer, & Takagi, 1965). Muscular tension is heightened by a decreased ionization of calcium associated with the increase in pH (Neill & Hattenhauer, 1975). Hyperventilation also causes increased coronary artery resistance and can cause chest discomfort that is difficult to distinguish from angina pectoris (Evans & Lum, 1977), along with nonspecific downward depression of the ST segment and T wave flattening (Christensen, 1946). Unlike ischemic ST changes, those caused by hyperventilation usually appear early during exercise and tend to disappear as exercise continues (McHenry et al., 1970).

Postconcussion Syndrome

Cerebral concussion is classically regarded as a disorder that produces no irreversible anatomic lesions. Clinically,

concussion results in an instantaneous diminution of function or loss of consciousness followed by rapid and complete recovery. The episode may be surrounded by a sphere of amnesia, with about one-tenth of the total as retrograde amnesia (Parkinson, 1977). Mild head trauma (1-minute to 2-minute loss of consciousness without external signs of trauma) has been reported to lead to an increase in catecholamines lasting for about 4 months (Wortsman et al., 1980). Initially patients complain of feeling fuzzy or slowed down, unable to sleep, tired, headache or dizzy with visual problems. They feel anxious, irritable or depressed (Silver, 2014). For most patients, the symptoms abate after a few weeks to a few months. A fraction of patients have persistent symptoms for more than a few months after a concussion associated with pre-trauma conditions like substance abuse and mood disorder and social factors: lack of social support or anticipated litigation and compensation (Silver, 2014).

There has been controversy about whether postconcussive syndrome is a long-term consequence of mild traumatic brain injury. A study of the prospective course of postconcussion syndrome found that mild traumatic brain injury did not predict postconcussive syndrome among those who entered a Level 1 trauma unit after mild traumatic brain injury. A pre-injury depressive or anxiety disorder and acute posttraumatic stress were early markers of postconcussive syndrome regardless of brain injury (Meares, Shores, Taylor, Batchelor, & Bryant, 2011). Anxiety in patients was endorsed by 16% at 5 days and 29% at 106 days, along with the symptoms of headache, dizziness, irritability, impairment of memory and concentration, fatigue, noise intolerance, depression, mood swings, insomnia, and malaise.

Psychiatric aspects of head trauma are discussed in Chapter 45.

Nonspecific Medical Causes

Many medical disorders may be associated with a broad array of psychiatric symptoms, including anxiety as a nonspecific reaction to delirium, although not as a prominent feature. Such disorders include Cushing's syndrome (Lishman, 1987), hyponatremia (Gehi et al., 1981), renal failure (Marshall, 1979), hypoparathyroidism (Denko & Kaelbling, 1962), and other electrolyte imbalances (Webb & Gehi, 1981). Hypomagnesemia (Hall & Joffe, 1973) in particular may be associated with hypocalcemia, and the drop of ionized calcium with hyperventilation may be accentuated by symptoms of tetany. The diagnostic workup for a physiologic cause of anxiety must be guided by the clinical review of systems and a complete survey of current and recently discontinued drugs and medications, and known concurrent medical conditions. In an otherwise healthy patient with significant sustained anxiety, thyroid screening alone might be sufficient. At the other end of the spectrum (e.g., new-onset sustained anxiety in the elderly), a comprehensive metabolic and neurologic assessment is needed.

CONCURRENT PSYCHIATRIC DISORDERS IN MEDICAL PATIENTS

The second step in evaluating the presentation of anxiety in a medical or surgical patient is to evaluate for the possibility of underlying psychiatric disorder, exploring past history and family history. Anxiety disorder is the most common psychiatric diagnosis with a lifetime prevalence of 29% (Kessler et al., 2005). In primary care as many as 20 percent of patients have at least one anxiety disorder with a range of 6–9% for post-traumatic stress disorder, panic disorder, social anxiety disorder, and generalized anxiety disorder (Kroenke et al., 2007). Higher rates are seen in selected subgroups such as those with Parkinson's disease (Stein et al., 1990), chest pain patients with normal coronary angiograms (Beitman et al., 1991), irritable bowel syndrome (Lydiard et al., 1993) and high utilizers of medical care (Katon et al., 1990).

Panic disorder is associated with an array of somatic symptoms and fear of symptoms, leading to more evaluation by doctors (Barsky et al., 1999; Rudaz et al., 2010). In primary care, the most common panic disorder symptoms are cardiac, neurological, and gastrointestinal (Katon, 1986). In addition, vestibular and respiratory clusters of symptoms help to define which specialist will subsequently be seeing the patient (Sansone & Sansone, 2009). Palpitations, shortness of breath, choking, chest pain, and numbness, have defined a cardio-respiratory type associated with fear of dying. A second constellation includes sweating, trembling, nausea, hot flashes, and dizziness. The thoughts that accompany panic attacks, a cognitive constellation: a feeling of unreality, fear of going crazy, and fear of losing control serve as clues to the diagnosis of panic disorder (Meuret et al., 2006).

Anxiety is often a significant component of a mood disorder. Anxiety disorders may predate a secondary depression or panic attacks may present at the onset of a clinical depression. In fact, anxiety disorder and depression are often seen together in patients coming to primary care physicians with first complaints (McLaughlin, et al., 2006; Toft et al., 2005). Anxious depression has a more chronic course of illness, an increased incidence of suicidal thoughts, and greater occupational impairment among patients with depressive disorder (Rao & Zisook, 2009). Patients with comorbid major depressive disorder and panic disorder before and after treatment with SSRIs have poorer quality of life and more impairment of function than patients with major depressive disorder alone (IsHak et al., 2014).

Those with anxiety and depression have more somatic symptoms without an identified medical cause; the more the symptoms the more likely the patient has anxiety and depression (Kroenke et al., 1994; Katon et al., 2007). Those patients preoccupied with somatic symptoms much of the time for at least 6 months such that they are distressed or have significant disruption of functioning as well as excessive and disproportionate thoughts, feelings, and behaviors around the symptoms are diagnosed as having somatic symptom disorder (APA, 2013). Those with persistent anxiety about illness who constantly check for illness or avoid doctors but have no somatic symptoms carry the diagnosis of illness anxiety

disorder. What had been called hypochondriasis is now subsumed under somatic symptom disorder if both anxiety and somatic symptoms are present (APA, 2013; Warwick & Salkovskis, 1990).

For those with somatic symptom disorder the contribution of anxiety disorder and anxious depression should be considered seriously and treated as part of management (Croicu et al., 2014). Substance abuse should be tracked and its contribution considered in the differential diagnosis.

In addition to clinical evaluation of anxiety and depressive disorders, the Patient Health Questionnaire-9 (PHQ 9) and the Generalized Anxiety Disorder Questionnaire 7 (GAD 7) (Kroenke et al., 2007, 2010; Spitzer et al., 2006) have been useful self-report questionnaires. The Somatic Symptom Scale-8 measures somatic symptom burden and its severity and can be used to follow patients (Barsky, 2014; Gierk et al., 2014). Other aspects of management of illness behavior are discussed in Chapter 37.

Patients with anxiety disorders often come to attention in the medical setting because of their claustrophobia, which prevents magnetic resonance imaging, or because they have phobias of having blood drawn. They may not be able to take the elevator to the doctor's office or acquiesce to radiation treatment. Patients may be especially anxious when trapped by traction in the orthopedic setting. These patients often have great anticipatory anxiety and are likely to focus on catastrophic events 6 months down the line when the physician is speaking to them about a treatment plan for the current week. Conditioned anxiety can be seen after multiple treatments of chemotherapy or dressing changes and can be triggered when patients approach the hospital or other territory that reminds them of past treatment.

Anxiety has both positive and negative symptoms; the positive symptoms of panic attacks and sympathetic arousal are more visible in the medical setting than the negative symptoms of avoidance, non-compliance, and indecision. Patients avoid the settings of past anxiety attacks and challenges that may arouse anxiety; therefore, they may avoid coming to medical appointments. The ways that anxiety has restricted the lives of patients, the way that they do not move into the social sphere or try new things may not be as obvious to the clinician or to the patient unless the clinician considers the negative symptoms of anxiety in a fuller evaluation.

A full psychiatric evaluation may also recognize that anxiety presents in the setting of psychotic disorder, borderline personality disorder (Nisenson et al., 1998) or cognitive impairment, and incipient dementia.

PSYCHOSOCIAL ISSUES AND ANXIETY IN MEDICAL PATIENTS

No evaluation of the anxious medical patient is complete without an inquiry into the psychosocial dimension of the patient's experience. The psychosocial dimension encompasses the intrapsychic meanings that patients attach to experiences and their behaviorally conditioned responses. Although physicians often assume that the distress associated

with illness is accounted for by the physical morbidity, a significant component of the distress associated with cancer, for example, relates to psychosocial adjustment (Goldberg & Cullen, 1985). It is often therapeutic to help the patient identify emotional problem areas that are being transformed into symptoms and to help contain the anxiety by putting it into words. The following sections discuss four major areas worth reviewing in terms of understanding potential psychological sources of anxiety.

ALIENATION

Social support plays an important role in maintaining mental and physical health. Anxiety over separation, loss, abandonment, and isolation can be even more important than fear associated with the disease itself. The physician should identify the patient's major social supports and assess their involvement. Whenever possible, the physician should meet with patient and key supports together to observe their interaction and to facilitate better sharing and communication. The patient's intrapsychic concern about abandonment is sometimes best dealt with by a concrete intervention, such as arranging homemaker or visiting nurse assistance.

As disease progresses, patients may become anxious because of a growing sense of distance from the physician. Patients nearing the end of an intensive treatment program are noted to experience an increase in anxiety rather than a sense of relief (Mastrovito, 1972; Peck & Boland, 1977), fearing that the detachment will jeopardize their survival. Maintenance of a regular contact and communication of concern are valuable positive interventions, although to the action-oriented physician such visits may seem like doing very little.

LOSS OF CONTROL

For many patients, the loss of control inherent in illness may be the crucial factor underlying anxiety symptoms. The consultant must be creative in identifying areas in which the patient can exercise some control without jeopardizing medical treatment. Intellectual mastery is another means of reasserting control for some patients. Sharing information in a way appropriate to the patient's personality style should therefore be considered an important means of reducing anxiety, although physicians often worry that patients may become more upset by hearing about their diagnosis (Goldberg, 1983).

PHYSICAL DAMAGE

Threatened or real loss of bodily integrity or a body part can trigger profound anxiety, along with insomnia, anorexia, and difficulty in concentrating. Patients who view themselves as less than whole may withdraw from relationships because of anxiety over rejection. Before surgery, patients can become panicked and feel they have a poor chance of

survival (Bard & Sutherland, 1977). It is always important to explore what patients have heard from others about the procedure they are awaiting because misconceptions can arise from stories about a friend or relative who did poorly in a similar situation or information gleaned from chat rooms. Preoperative review of potential misconceptions may even decrease certain surgical complications (Egbert et al., 1964).

With anxious patients who ask, "Am I going to be all right?", there is a tendency to reassure prematurely rather than to explore difficult feelings. Furthermore, some preoperative anxiety can be helpful, since it stimulates realistic planning. Patients who are extraordinarily calm may be masking fears that place them at higher risk for not coping with later inevitable events (Sutherland et al., 1977).

DEATH

The issue of dying may or may not be brought up directly by the patient; it may emerge instead through some related symptoms of anxiety. As long as patients with life-threatening illness function adaptively, elements of denial play an important role in continued function (Dimsdale & Hackett, 1982). The natural course of progressive illness, however, usually challenges the patient to slowly adjust denial mechanisms to the emerging medical reality (Weisman, 1979). Recurrence of disease often erodes initial optimism and creates a situation in which the patient for the first time deals with issues of dying. Signs of physician willingness to engage the patient on these issues are important in allaying fears, which otherwise would remain unexpressed. Dealing in some way with their own sense of mortality probably is important for clinicians to be effective in dealing with patients' anxiety about death. See Chapters 81 and 84 on end of life issues for children and adults.

PHARMACOLOGICAL MANAGEMENT

BENZODIAZEPINES

The best indication for using benzodiazepines is for relief when a time-limited cause of anxiety can be identified, as in the case of the patient awaiting a cardiac catheterization. Benzodiazepines are also helpful in treating primary anxiety disorders, and adjunctively for patients with physiologic/endogenous anxiety syndromes (see Chapter 21). They are particularly helpful when they mitigate the suffering of acute medical management. Alternatives to benzodiazepines are sought for chronic anxiety because patients may become tolerant and dependent to these medications, and those with a history of substance abuse may add benzodiazepines to alcohol or narcotics.

Pharmacokinetics

All the benzodiazepines are well absorbed orally and reach peak blood levels after a single oral dose in times varying from 1 to 6

hours. The differences in time to reach peak plasma level largely reflect differences in gastrointestinal absorption. As metabolites reach a steady state, however, initial differences related to absorption and distribution disappear and differences related to metabolism become prominent. Chlordiazepoxide (Greenblatt et al., 1974) and diazepam (Greenblatt & Koch-Weser, 1976) are poorly and unpredictably absorbed from intramuscular (IM) sites, whereas lorazepam and midazolam have the distinct property of prompt and reliable IM absorption (Greenblatt et al., 1982). The metabolic fate of various benzodiazepines may be simplified by appreciating that they fall into two classes—long acting and short acting (see Table 31.1).

Drug accumulation, with potential impairment of cognitive and motor performance, is a special risk to be kept in mind with long-acting agents, especially for older patients and those with liver impairment (Greenblatt et al., 1980; Greenblatt, Miller, & Shader, 1987). Despite the long half-lives and accumulation of active substances, chronic use of these drugs usually does not lead to oversedation. The sedative and anti-anxiety effects of benzodiazepines appear to be distinct, and the CNS seems to adapt to the nonspecific sedative effects as a steady state is reached (Johnson & Chernik, 1982). However, there is an age-related increase in the sensitivity of elderly individuals to the central depressant effects of long-acting benzodiazepines (Pomara et al., 1985).

Drug Interactions

Benzodiazepines have relatively few significant adverse drug interactions. Their major drug interaction, augmentation of other CNS depressants, can be controlled by adjusting dosage downward. An extensive discussion of benzodiazepines can be found in Chapters 21, 22, and 23.

Side Effects

The most common adverse effects of the benzodiazepines involve CNS depression: muscle weakness, ataxia, dysarthria, vertigo, somnolence, and confusion. These side effects can be a major problem, especially for the medically ill patient who may be weak from prolonged bed rest or already impaired by other CNS illness. Older patients are especially susceptible to psychomotor impairment and falls (Ray, Griffin, & Downey, 1989; Tinetti, Speechley, & Ginter, 1988). There is always the risk that treating anxiety secondary to depression may not only mask the depression but actually exacerbate it.

There is some question whether or not benzodiazepines may stimulate some people (Hall & Joffe, 1972) or release hostility and rage reactions (Karch, 1979). Such instances are infrequent (Dietch & Jennings, 1988). Disinhibition seems most common in patients with preexisting personality disorders, substance abuse, or underlying organic brain disorders. However, benzodiazepines can produce or increase depressive symptomatology (Greenblatt & Shader, 1974; Ryan et al., 1968).

Van der Kropf (1979) first reported finding depersonalization, anxiety, and paranoia in subjects with chronic insomnia treated with triazolam. Benzodiazepines impair memory

function in two ways. The first is an acute anterograde amnesic effect, usually after intravenous use. However, this effect is also reported with therapeutic oral doses of the high-potency and short half-life benzodiazepines such as triazolam, especially if taken with alcohol (Healey et al., 1983; Scharf et al., 1984; Shader et al., 1986; Wolkowitz et al., 1987). The second type of memory impairment involves recall during chronic use. Because benzodiazepines interfere with memory consolidation, users, especially the elderly (Nikaido et al., 1987), may have impaired long-term recall (Angus & Romney, 1984; Lucki, Rickels, & Geller, 1986).

Large doses of benzodiazepines produce only minor changes in cardiovascular function even in patients with underlying cardiac disease (Rao et al., 1973). In patients without pulmonary disease, changes in tidal volume and response to elevated $p\text{CO}_2$ are barely detectable (Lakshminarayan et al., 1976). In a single-blind study, diazepam actually improved the breathlessness of patients with chronic airflow obstruction associated with emphysema (Mitchells-Heggs et al., 1980).

The respiratory depressant effects of benzodiazepines appear to be most marked in patients with carbon dioxide retention. Benzodiazepines should not be given to patients with clinically significant pulmonary disease who might be retaining carbon dioxide before measuring arterial blood gases. Anxious carbon dioxide retainers may be treated with buspirone or low-dose neuroleptics, which do not alter respiratory drive. Intravenous benzodiazepines given concurrently with parenteral narcotics produce significant respiratory depression of a greater degree than is found with opiates alone, especially in patients with some pulmonary impairment (Cohen, Finn, & Steen, 1969).

Toxicity and Dependence

Benzodiazepines are relatively nonlethal in overdose. In the medical literature there have been fewer than a dozen reported suicides by diazepam ingestion alone (Finkel, McCloskey, & Goodman, 1979). However, benzodiazepines are often used in combination with other sedative drugs and ethanol in fatal overdoses.

Overall, the risks of overuse, dependence, and addiction are low considering the widespread use of benzodiazepines (Rifkin et al., 1989; Uhlenhuth et al., 1988; O'Brien, 2005). However, abuse can occur in high-risk patients for chemical dependency and abuse when benzodiazepines are used regularly for at least several months. The potential for addiction is greater for alcoholic patients (Ciraulo, Sands, & Shader, 1988).

Withdrawal

Symptoms of benzodiazepine withdrawal may include anxiety, insomnia, dizziness, headache, anorexia, hypotension, hyperthermia, neuromuscular irritability, tinnitus, blurred vision, shakiness, and psychosis. Higher doses taken over longer durations create a greater risk of moderate to severe withdrawal (Hollister, Motzenbecker, & Degnan, 1961). There are reports of abstinence phenomena beginning at 5–7 days and lasting 2–4 weeks after cessation of usual therapeutic

Table 31.1 PHARMACOKINETIC SUMMARY COMPARISON OF BENZODIAZEPINES

DRUG GIVEN	PEAK PLASMA LEVEL (HOURS)	MEAN (RANGE) ELIMINATION HALF-LIFE (HOURS) [†]	ACTIVE METABOLITES	MEAN (RANGE) ELIMINATION HALF-LIFE (HOURS)	APPROXIMATE DOSE EQUIVALENT (MG) [‡]

doses of diazepam (Busto et al., 1986; Pevnick, Jasinski, & Haertzen, 1978; Winokur et al., 1980). There are also reports of seizures occurring in association with the discontinuation of moderate doses of lorazepam (de la Fuente et al., 1980) and triazolam (Tien & Gujavarty, 1985). One advantage of long-acting benzodiazepines such as clonazepam is that they tend to self-taper if discontinued. Although abrupt discontinuation of long-acting benzodiazepines is usually not dangerous, it can lead to a persistent state of heightened anxiety. The short-acting benzodiazepines are associated with a greater

prevalence and severity of withdrawal reactions, because their plasma concentrations decline more rapidly following discontinuation. Withdrawal symptoms can be minimized by slow tapering rather than abruptly discontinuing the drug.

During withdrawal, autonomic symptoms can be relieved by a beta-adrenergic blocker (Abernethy, Greenblatt, & Shader, 1981) and possibly by carbamazepine as well (Malcolm et al., 1989; Ries et al., 1989). It should be kept in mind that withdrawal symptoms from alprazolam and triazolam may not be fully covered by other benzodiazepines (Schneider, Syapin, &

Table 31.2 COMPARISON OF BENZODIAZEPINES AND BUSPIRONE

Withdrawal	1	2
Muscle relaxation	1	2
Anticonvulsant	1	2

Pawluczyk, 1987; Zipursky, Baker, & Zimmer, 1985). In these cases, substitution with clonazepam is an effective alternative (Albeck, 1987; Patterson, 1988). Benzodiazepine withdrawal may take months to accomplish. We recommend approximately a 10% dose reduction per week for patients who have been treated with these drugs for 12 months or longer.

Clonazepam

Clonazepam has achieved widespread use for the treatment of anxiety. Originally introduced in the United States for the treatment of specific seizure disorders, it has also found application for the treatment of myoclonus, restless leg syndrome, akathisia, bipolar disorder, acute mania, and neuroleptic-induced somnambulism. Clonazepam is mainly metabolized in the liver by nitro reduction, which may be slightly impaired by cimetidine, but does not appear to be affected by age (Greenblatt et al., 1985). Clonazepam's half-life is approximately 24 hours. Compared to alprazolam, which has a half-life of 10–12 hours, there is less likelihood of symptom rebound (such as symptoms associated with a missed dose) or interdose rebound. While many clinicians now prefer to cross alprazolam patients over to clonazepam to facilitate withdrawal, one study found that gradual reduction of alprazolam worked just as well (Schweizer et al., 1990). The long-hour half-life of clonazepam does not mitigate against the possibility of significant withdrawal symptoms (including delirium and psychosis) if the medication is suddenly stopped (Freeman, 1997). Like any other benzodiazepine, clonazepam effectively reduces a wide variety of anxiety symptoms. Daily doses of about 1.0–2.0 mg/day are generally effective for the treatment of panic disorder (Rosenbaum et al., 1997), with increased rates of somnolence and ataxia at daily doses of 3.0 mg/day. Higher doses have been associated with depression, dizziness, fatigue, and irritability as adverse effects similar to other benzodiazepines.

BUSPIRONE

Buspirone is a nonbenzodiazepine anxiolytic that has an anxiolytic effect without the sedative or cognitive side effects associated with the benzodiazepines. Its mechanism of action is thought to involve its function as a partial agonist at the serotonin 1A receptor (Eison & Eison, 1984; Eison & Temple, 1986).

Table 31.1 summarizes the pertinent clinical issues involving buspirone, in comparison with benzodiazepines. Buspirone does not have acute effects. In fact, it usually takes at least 7 to 10 days (and often 4 weeks) to have an effect. Therefore, it is best used for patients with chronic generalized anxiety.

Aside from generalized anxiety disorder itself for which buspirone is approved by the Federal Drug Administration, medical patients with chronic symptoms related to autonomic arousal may benefit from buspirone. These groups include, for example, patients with irritable bowel syndrome, asthma, and chronic obstructive pulmonary disease (COPD) with anxiety-related dyspnea. Patients whose symptoms are increased by anxiety, such as those with epilepsy, may benefit from anxiety reduction with buspirone.

There are, in addition, several niches for buspirone that emerge from its clinical profile. Because buspirone does not augment other sedative drug effects, it may be particularly helpful for those anxious patients who are prone to misuse or who are taking concomitant sedatives. For example, buspirone has helped reduce anxiety in anxious drug users with AIDS (Batkai, 1990). Buspirone does not impair respiratory drive as the benzodiazepines do, and in fact may be somewhat of a respiratory stimulant (Garner et al., 1989; Rapoport & Mendelson, 1989). Therefore, it is safe to treat anxious carbon dioxide–retaining patients with buspirone, whereas it would not be safe to do so with a benzodiazepine. Buspirone also does not augment the sedative potential of other CNS sedatives. Therefore, anxious patients on other sedatives (such as anticonvulsants, antihistamines, and narcotic analgesics) may be able to benefit from anxiolytic treatment without the additive sedative effects associated with the benzodiazepines. Unlike the benzodiazepines, buspirone lacks muscle relaxant, anticonvulsant, and hypnotic activities; it does not block the withdrawal syndrome associated with CNS sedatives (Schweizer & Rickels, 1986).

Pharmacokinetics

Buspirone is rapidly and completely absorbed from the gastrointestinal tract, with extensive first-pass hepatic metabolism. Taking the drug with food appears to decrease its rate of absorption and its first-pass metabolism, making more of the drug available. Peak plasma level is reached in about 1 hour. Average elimination half-life is 2.5 hours. About 65% is eliminated by the kidneys, mostly in a metabolized form, and 35% undergoes fecal elimination. There have not been any adverse reports about liver or renal impairment on drug effects.

Side Effects

The major side effects include dizziness, headache, and nervousness. Buspirone is not sedative, which is one of its primary advantages (Cohn & Wilcox, 1986; Newton et al., 1986). In fact, buspirone causes no more drowsiness than placebo and does not impair psychomotor performance skills, such as driving. There have been no deaths reported as a result of buspirone overdose in more than 375 cases. Major sequelae of overdose have included nausea and vomiting, dizziness, drowsiness, and miosis. No withdrawal syndrome has been reported following the abrupt discontinuation of its use.

Buspirone has no abuse potential (Griffith, Jasinski, & McKinney, 1986), lacking euphoric properties and actually having some dysphoric properties with repeated excessive use and higher dose. This property, coupled with the fact that it does not potentiate the sedative effects of alcohol (or other CNS sedatives), seems to make buspirone a good drug for the treatment of anxiety in chemically dependent or abuse patients (Kastenholz & Crismon, 1984; Meyer, 1986).

Drug Interactions

There are few reports of drug interactions in humans; use of buspirone with monoamine oxidase inhibitors is considered contraindicated because of potential hypertensive reactions or serotonin syndrome. The calcium channel inhibitors verapamil and diltiazem may increase buspirone levels (Lamberg et al., 1998).

Clinical Use

Buspirone has been demonstrated to have clinical anxiolytic efficacy comparable to that of the benzodiazepines (Cohn et al., 1986; Rickels et al., 1982; Schuckit, 1984). However, a dose of 5 mg three times daily often is inadequate. More patients show a response to 10 mg three times daily but some cannot start this high without developing tinnitus, light-headedness, or aggravation of anxiety. From 10 mg, dosage should be raised by 10mg/day increments every 7 to 10 days as needed up to a maximum of 60 mg/day. Since the anxiolytic effects of buspirone may take several weeks to occur, the patient may become prematurely discouraged about the potential effectiveness of this medication. An additional issue, the significance of which is yet to be determined, is that some patients who have been on benzodiazepines appear not to report comparable anxiolytic benefit from buspirone (Schweizer, Rickels, & Lucki, 1986). However, buspirone may be helpful in concurrent use with benzodiazepines in treating panic disorder and helping prevent relapse after withdrawal of benzodiazepines.

Buspirone also appears to have a clinically relevant antiaggression effect and can suppress disinhibition which may be helpful in populations with different types of brain damage, including the episodic hyperarousal that accompanies head injury (Levine, 1988), mental retardation (Ratey et al., 1989), dementia (Colenda, 1988), and attention deficit disorder (Balon, 1990). In these patients, a lower initial dose (no more

than 5 mg three times daily) is recommended because some patients with brain damage can show an agitation response at a higher initial dose.

BETA-ADRENERGIC BLOCKING AGENTS

Autonomic symptoms associated with anxiety (such as palpitations and tremulousness) are mediated by beta-adrenergic sympathetic activity. Beta-adrenergic blocking agents, such as propranolol which has highly lipophilic properties to cross the blood-brain barrier, have been demonstrated to antagonize both the somatic (Granville-Grossman & Turner, 1966; Tyrer & Lader, 1974) and the emotional (Kathol et al., 1980) symptoms of anxiety.

It has been suggested that propranolol has a unique role for patients with acute situational distress, such as public performance anxiety, in which the psychomotor intellectual impairment produced by benzodiazepines is not desirable. Forty milligrams of propranolol given 90 minutes before performance was shown to have a positive effect in decreasing performance anxiety in a group of musicians (James et al., 1978).

Evaluation of the effectiveness of beta-blockers in anxiety has become more complex with the recognition that these agents (especially propranolol) enter the CNS and can produce direct neurologic and behavioral effects. Although weakness and depression are the most common neuropsychiatric symptoms associated with propranolol, patients may also have insomnia, vivid nightmares, hypnagogic hallucinations, or toxic psychosis, even at relatively low doses (Fraser & Carr, 1976; Gershon et al., 1979). Such mental changes tend to reverse within 48 hours after discontinuation of propranolol. Nadolol and atenolol are beta-blockers that do not cross the blood-brain barrier to any significant clinical extent but also seem to improve some components of anxiety. It may be that the central effects are exerted by some kind of neurohumoral feedback to the CNS rather than by a direct action. Finally, pindolol (with intrinsic sympathomimetic activity) and labetalol (with α_1 -blocking activity) are beta-blockers that do not tend to lower pulse rate. However, their antianxiety effects remain relatively unproven. Pindolol has been studied as an augmenting agent for SSRIs (Whale, Terao, Cowen, Freemantle, & Geddes, 2010).

Issues in Prescribing

Propranolol is almost completely absorbed following oral administration. It undergoes extensive first-pass metabolism in the liver, and variation in this component results in as much as 20-fold variability in plasma concentration among individuals on comparable doses. The half-life is initially about 3 hours, which may increase to 4 hours during chronic use. It is 90%–95% bound to plasma protein, which also may contribute to its variabilities in plasma concentrations. Propranolol is almost completely metabolized in the liver before urinary excretion. Nadolol is poorly absorbed from the gastrointestinal tract (Dreyfuss et al., 1979) and is excreted largely by the kidney in unchanged form (Frishman, 1981). The elimination half-life is 14–24

hours, which increases dramatically in patients with renal dysfunction. Contraindications to the use of beta-blockers include bradycardia and atrioventricular block. Beta blockers may be used in patients with heart failure or may exacerbate heart failure depending on the context; so its use should be worked out with physicians managing the heart condition. In patients with angina, the cessation of chronic beta blockade may worsen chest pain. Because of their effects on bronchial smooth muscle, beta-blockers are relatively contraindicated in patients with bronchospastic disease or COPD. They should be used cautiously in diabetics because they can mask clinical signs of hypoglycemia and interfere with glycogenolysis during hypoglycemia.

Beta-receptor blockade has little effect on the normal heart at rest, although there is some decrease in heart rate, cardiac output, and blood pressure. During exercise and anxiety, however, sympathetic responses may be significantly blocked. Maximum exercise tolerance may therefore be decreased in otherwise normal patients.

ANTIDEPRESSANTS

Antidepressants treat not only depression but also the anxiety symptoms that accompany depression, as well as primary anxiety disorders such as panic disorder, generalized anxiety disorder, obsessive-compulsive disorder, and PTSD, probably on the basis of serotonergic augmentation. For many years, the tricyclic antidepressants (TCAs) and monoamine oxidase inhibitors were recommended for the treatment of panic attacks (Klein, 1982; Pohl, Berchou, & Rainey, 1982; Sheehan, Ballenger, & Jacobsen, 1980; Zitrin, Klein, & Woerner, 1978). Both groups of drugs were also effective in patients with mixed anxiety and depression (Paykel et al., 1982; Rickels et al., 1974), especially in so-called *atypical depressions*, which were characterized by high levels of anxiety (Robinson et al., 1973). It was also noted that TCAs were effective in the treatment of some patients with chronic anxiety alone (Lipman et al., 1981; Kahn et al., 1986). In a double blind placebo controlled study (even eliminating patients with panic-phobic syndromes) of the treatment of anxiety with imipramine, chlorthalidoxepine, or placebo, the antianxiety effects of imipramine were superior to those of the others by the second treatment week and became clearly more significant thereafter, independent of baseline levels of depression and anxiety (Kahn et al., 1986).

SSRIs have a similar efficacy as tricyclics for generalized anxiety disorder. Paroxetine, citalopram, escitalopram, and the serotonin-noradrenaline reuptake inhibitor venlafaxine extended-release have proved their effectiveness (Fricchione, 2004). Our practice is to start with very low doses and increase the dosage slowly. Benzodiazepines can be a useful adjunct in the first weeks of adjusting to the antidepressant. For patients who are more problematic, it is helpful to know that benzodiazepine-antidepressant treatment with SSRIs have been shown to be effective, and fewer patients did not complete the studies (Furukawa, Streiner, & Young, 2002).

NEUROLEPTICS

There are certain situations in which neuroleptics can be effectively used to treat anxiety, especially for short periods of time so the risk of tardive dyskinesia is much less of an issue (Rickels, 1983; Fann, Lake, & Majors, 1974). These situations include acute anxiety in patients with carbon dioxide retention, in whom suppression of the hypoxic respiratory drive by benzodiazepines should be avoided, anxiety that represents an incipient psychotic disorganization (as in some borderline personality-disordered patients under stress), schizophrenia, anxiety syndromes due to medical causes with disorganized cognition or behavior (as in the severely anxious patient with racing thoughts precipitated by steroids), and anxiety in the context of significant delirium. Some of the more sedative typical neuroleptics, such as thioridazine and perphenazine, are more anxiolytic than high-potency agents such as haloperidol. Atypical antipsychotics are similarly more sedating. However, no neuroleptic maintains a Food and Drug Administration indication for treating anxiety alone. We have grown to prefer olanzapine and quetiapine for use in the medically ill because of lower rates of akathisia and extrapyramidal symptoms (EPS). It makes sense to monitor postural signs and anticholinergic side effects when atypical agents are used acutely. In studies of off-label uses of atypical antipsychotics, quetiapine has shown benefit for generalized anxiety disorder, and risperidone for obsessive-compulsive disorder. The side effects in non-elderly adults are weight gain (particularly for olanzapine), fatigue, sedation, akathisia (for aripiprazole) and EPS (Maher et al., 2011).

ANTI-HISTAMINES

Antihistamines such as hydroxyzine and diphenhydramine are sometimes prescribed to treat anxiety. They have no specific anxiolytic properties (Rickels et al., 1970), although patients may feel less anxious on them because of their sedative effects. There is little rationale to support their use; they have a number of unwanted side effects such as anticholinergic properties, especially if used in repeated doses. However, review of limited studies with hydroxyzine has found it more effective for generalized anxiety disorder than placebo, and more sedating (Guaiana, Barbui, & Cipriani, 2010). Diphenhydramine is less effective than benzodiazepines for sleep induction (Rickels et al., 1983). The only situation involving anxiety in which antihistamines might have a special use would be when anxiety is the accompaniment of an allergic response for which their antihistaminic properties are of primary value.

GABAPENTIN AND PREGABALIN

Both gabapentin and pregabalin are anticonvulsants that may reduce anxiety although their most recognized indication is treatment of neuropathic pain and fibromyalgia (Wiffen et al., 2013). They selectively bind at alpha2-delta subunit of presynaptic voltage-dependent calcium channels. While

the drugs are analogues of GABA, they do not act at GABA receptors.

In patients with generalized anxiety disorder, pregabalin reduces anxiety relatively rapidly, usually in less than a week. It affects both somatic and cognitive symptoms of anxiety. Its acute side effects are somnolence, dizziness. (Frampton, 2014) For treatment of generalized anxiety disorder it has been approved in Europe. Although it has not been compared directly to serotonin reuptake inhibitors, pregabalin has been used for augmentation (Rickels et al., 2012) and also to facilitate taper of long-term benzodiazepines (Hadley, Mandel, & Schweitzer, 2012; Frampton, 2014).

Pregabalin can also reduce preoperative anxiety, postoperative pain, and prevent chronic post-surgical pain, nausea, and vomiting. At doses of 150–450 mg per day it has helped to prevent relapse of alcohol dependence (Guglielmo et al., 2012).

Gabapentin has reduced anxiety symptoms in the medical setting, for instance, for breast cancer survivors who may also benefit from its effect on hot flashes (Lavigne et al., 2012). It treats preoperative anxiety and postoperative nausea and vomiting (Guttuso, 2014) as well as social anxiety disorder (Blanco et al., 2013; Pande, 1999) and alcohol dependence (Mason et al., 2014). Common side effects are dizziness, ataxia, somnolence, and occasionally peripheral edema.

Both these agents are metabolized by the kidney, and dose reduction is warranted in those with renal impairment. These medications should be tapered over a week or more.

SELF-REGULATION METHODS

It is now well established that most patients can be taught techniques that induce relaxation. These techniques should be considered appropriate for generalized anxiety, for desensitization therapy in specific anxiety-producing situations, and for reduction of medical symptoms sustained by chronic stress.

MUSCLE RELAXATION THERAPIES

Learning to specifically sense and control muscle tension is a widely utilized and effective method for anxiety reduction. The Jacobson method of progressive relaxation depends on systematically tensing and relaxing muscle groups starting with the feet and eventually involving the entire body (Jacobson, 1938). Of course, it is important to discuss the intent of the procedure with the patient beforehand and to elicit any specific questions, misconceptions, or concerns the patient might have. A comfortable and quiet setting without interruptions is important. Although tape-recorded or printed instructions can be used, the initial session with the physician can be an important factor in establishing a positive alliance for future work.

ELECTROMYOGRAPHIC BIOFEEDBACK

The Jacobson method was devised to induce relaxation by heightening awareness of muscle tension. Electromyographic

(EMG) biofeedback goes one step further by providing the person with precise information about the electrical potentials of selected muscle groups. In EMG biofeedback treatment of anxiety, the frontalis muscle is usually selected for monitoring because the frontalis EMG activity level is regarded as an index of overall physiologic arousal. Patients learn to reduce muscle tension, but the benefit is related to the importance of muscle tension as a symptom of anxiety. A review of studies of biofeedback for chronic anxiety suggested that multimodal treatment using EMG with EEG feedback or with thermal feedback may be most effective (Schoenberg & David, 2014).

MEDITATION TECHNIQUES AND THE RELAXATION RESPONSE

Meditation has been shown to produce a physiologic state of restful alertness that is different from sleeping or waking (Wallace, 1970). Physiologic findings during meditation are generally opposite to those encountered in an anxiety patient. After reviewing a range of meditative practices, Benson concluded that within the apparent multiplicity of practices common features reside that could serve as the basis for a non-sectarian form of practice capable of inducing a state he called the *relaxation response* (Benson, Beary, & Carol, 1974). The technique for eliciting the relaxation response consists of four basic elements:

1. *A mental device.* There needs to be some constant stimulus—for example, a sound, a word (such as “one”), or a phrase repeated silently or audibly. Fixed gazing at an object is a suitable alternative. The purpose of this procedure is to focus attention away from the continuous flow of sensory distractions and intellectual preoccupations.
2. *A passive attitude.* During the aural or visual practice, distracting thoughts are to be disregarded. One should not be concerned with performance standards. When lapses are recognized, the practitioner should patiently return to the mental device without self-criticism or concern about success or failure.
3. *Decreased muscle tone.* The subject should be in a comfortable position to minimize any muscular strain or tension.
4. *A quiet environment.* A suitable room should be chosen with decreased stimuli and where there is no concern about unexpected interruptions. Most techniques instruct the practitioner to close the eyes.

The relaxation response has achieved wide recognition and has emerged as a technique to manage anxiety and a wide array of stress-related disorders (Chang, Dusek, & Benson, 2011; Goldberg, 1982a, b; Nakao et al., 2001). Chapter 17 discusses the concepts of mind-body medicine that have evolved from this recognition, and Chapter 16 discusses the use of hypnosis for anxiety and procedural phobias.

BEHAVIORAL TECHNIQUES USED WITH ANXIETY DISORDER PATIENTS AND THE MEDICALLY ILL

Cognitive behavioral treatment is an effective evidence-based treatment for anxiety in the medical setting. It can be used as an adjunct to medication but becomes even more important in cases in which the patient is hesitant to take medication or when medication alone is not enough or is completely contraindicated. It is typically both structured and time-limited form of treatment. Cognitive behavioral treatments for patients with anxiety disorders as well as the anxiety-provoking challenges of medical illness are discussed in Chapter 14. For the very ill, the challenge may be to tailor the structured treatment so that it is available on the same day as other medical visits or via telephone or video-conference. The skills to reduce chronic anxiety may be modified to offer additional strategies for patients to cope with the realistic adverse events that may be most likely (Greer et al., 2012).

One area in which behavioral techniques have proven successful is in the management of blood and injury phobias. Blood phobias are unique in that, unlike other phobias, they do not result in the typical sympathetic arousal, tachycardia, dyspnea, and paresthesias. Rather, blood phobias usually result in an initial rise in heart rate that is often quickly followed by vasovagal bradycardia, decrease in blood pressure, and eventually syncope. It is estimated that approximately 3.1% of the normal population experience severe blood phobia (Agras, Sylvester, & Oliveau, 1969). Such a phobia can represent a severe threat if it results in avoidance of life-saving medical procedures such as insulin injections, surgery, and blood transfusions.

A variety of behavioral treatments for blood and injury phobia have been elaborated. Of all these treatments, the most frequently reported have been in vivo exposure to needles and blood (Leitenberg et al., 1970) and exposure to films of venipuncture, surgery, and injury in an emergency room (Marks et al., 1977). However, a variety of other behavioral treatments, such as systematic desensitization (Cohn, Kron, & Brady, 1976), controlled breathing and modeling (Moore, Geffken, & Royal, 1995), implosion (Ollendick & Gruen, 1972), an applied tension procedure (Ost, Sterner, & Fellenius, 1989) and relaxation techniques (Ost et al., 1984), have been used with varying degrees of success. Another area in which behavioral techniques such as progressive relaxation and biofeedback have been shown to be beneficial has been with patients who suffer from asthma and chronic obstructive pulmonary disease (COPD) (Gift, Moore, & Seeken, 1992; Hock et al., 1978). Dyspnea often leads the patient to become more anxious, which results in increased muscle tension and increased need for oxygen. As this happens, dyspnea becomes magnified and a vicious cycle of increasing muscle tension, anxiety, and dyspnea ensues. Biofeedback (Acosta, 1988; Hannich et al., 2004) hypnosis (Treggiari-Venzi, Suter, De Tonnac, & Romand, 2000), coaching (especially by a familiar nurse), verbal reassurance, distraction, and music have also been used to address

the anxiety associated with weaning from a ventilator. See Chapter 27 on dyspnea.

Finally, the relaxation response has reduced stress and psychophysiologic reactivity in postmyocardial infarction patients (Gatchel, Gaffney, & Smith, 1986). It reduces preoperative anxiety in ambulatory surgery patients (Domar, Noe, & Benson, 1987) and reduces anxiety and esophageal acid exposure in patients with gastroesophageal reflux disease (McDonald-Haile et al., 1999).

While we mentioned specifically CBT and mind-body medicine, all psychotherapeutic modalities (Part II) considered in this book including individual and group psychotherapy, family therapy and parent guidance, and attention to spiritual issues deepen the approach to this complex symptom.

CLINICAL PEARLS

- The approach to evaluation of anxiety in the medical setting requires a synthetic medical and psychiatric assessment including review of medications and recreational substances that have been started or stopped and medical disorders that present with anxiety. The history should allow assessment of psychiatric diagnoses as well as the psychological challenge of the patient's predicament.
- Alienation (fear of separation and abandonment), loss of control, threat to body integrity, and fear of death are themes to be explored.
- Energy drinks have moderate to relatively high levels and concentrations of caffeine (2.5–35.7 mg per oz.) compared to other caffeinated beverages such as a 12oz. cola or a 6oz. cup of coffee.
- Abuse of methamphetamine, which has a half-life of 12 hours (longer than cocaine) can present with anxiety in the setting of intoxication or withdrawal. In withdrawal, the depression may be more prolonged and worse than that of cocaine withdrawal (Winslow, Voorhees, & Pehl, 2007).
- The most common symptoms of pulmonary embolus in patients who did not have preexisting cardiopulmonary disease (noted in the Prospective Investigation of Pulmonary Embolism Diagnosis II) were dyspnea at rest or with exertion, pleuritic pain, cough, more than two-pillow orthopnea, calf or thigh pain/swelling, and wheezing. Tachypnea and tachycardia were the most common signs (Stein et al., 2007).
- In order to avoid episodes of hypoglycemia, diabetic patients can be educated to be alert to glucose readings below 70 mg/dL (Seaquist et al., 2013).
- Among schizophrenic patients in a large study (CATIE), a moderate dose of perphenazine produced comparable rates of akathisia to ziprasidone, risperidone, and olanzapine (Caroff et al., 2011).

- In addition to benzodiazepines and propranolol, mirtazapine 15 mg each day may also be effective for treatment of akathisia (Poyurovsky, 2010).
- Anxious depression has a more chronic course of illness, an increased incidence of suicidal thoughts, and greater occupational impairment (Rao & Zisook, 2009).
- The Somatic Symptom Scale-8 measures somatic symptom burden and its severity and can be used to follow patients (Barsky, 2014; Gierk et al., 2014).
- The ways that anxiety has restricted the lives of patients, the way that they do not move into the social sphere or try new things may not be as obvious to the clinician or to the patient unless the clinician considers the negative symptoms of anxiety (avoidance) in a fuller evaluation.

DISCLOSURE STATEMENTS

Dr. Goldberg had no conflicts related to his contribution to this chapter.

Dr. Greenberg has no conflicts of interest to disclose.

EATING DISORDERS

Megan Moore Brennan, Caitlin M. Nevins, and Jennifer J. Thomas

INTRODUCTION

Eating disorders (EDs) are common, especially among young women. EDs are serious illnesses associated with significant medical and psychiatric morbidity. Particularly when chronic and severe, EDs have relatively high mortality rates when compared with other psychiatric disorders. Because of the ego-syntonic nature of many EDs, patients often first present in the medical sector due to the unwanted and unintended physical consequences. Frequently patients are embarrassed about the underlying behaviors causing their physical problems and are therefore reluctant to report disordered eating. For these reasons, it is crucial that clinicians be knowledgeable about EDs and know when to suspect that one is present. Early identification and treatment can help prevent the associated morbidity and mortality.

DIAGNOSIS

In 2013, the *Diagnostic and Statistical Manual of Mental Disorders fourth edition text revision (DSM-IV-TR)* was updated to the *fifth edition (DSM-5)*. The Eating Disorders Work Group made several revisions to enhance the clinical utility of ED diagnoses in *DSM-5*. The primary *DSM-5* changes included combining feeding disorders and EDs into a single chapter; broadening and clarifying the criteria for anorexia nervosa (AN) and bulimia nervosa (BN); adding binge eating disorder (BED) as a formal diagnosis; and re-classifying feeding disorder of infancy or early childhood as avoidant/restrictive food intake disorder (ARFID). Moreover, *DSM-5* separated the single *DSM-IV* residual category of eating disorder not otherwise specified (EDNOS) into two separate residual categories of other specified feeding or eating disorder (OSFED) and unspecified feeding or eating disorder (UFED). OSFED comprises a list of five example presentations, whereas UFED is reserved for cases in which a clinically significant ED is present but the clinician does not have sufficient information to characterize the presentation (e.g., in an emergency room setting) (see below). In this chapter, we will focus mainly on AN, BN and BED because their phenomenology and treatment is currently better understood, and clinicians treating adults are most likely to encounter patients with these diagnoses. See Table 32.1 for descriptions of each ED diagnosis.

The hallmark of AN is low body weight for sex and age. To meet criteria for AN, individuals must either express an intense fear of becoming fat or exhibit behaviors that interfere with weight restoration; and exhibit a lack of recognition of the possible health consequences of low weight. *DSM-5* no longer requires cessation of menstruation for 3 months (American Psychiatric Association, 2013). Low body weight is considered a body mass index (BMI) < 18.5 for adults, or a BMI < 5th percentile for sex and age using growth charts for children and adolescents (American Psychiatric Association, 2013).

In contrast to those with AN, individuals with BN are normal weight, overweight, or obese. BN is characterized by a pattern of binge eating followed by compensatory behaviors to make up for calories consumed, occurring at least once weekly for at least 3 months. Compensatory behavior may comprise purging (i.e., self-induced vomiting, laxative or diuretic misuse) or non-purging (i.e., fasting, excessive exercise) symptoms. Similar to AN, the self-image of individuals with BN is dominated by their weight and shape. *DSM-5* differentiates subtypes of AN (restricting and binge-eating/purging type), such that an individual who meets criteria for both disorders would be diagnosed as AN binge-eating/purging type (American Psychiatric Association, 2013).

BED is characterized by frequent episodes of binge eating, but does not feature the compensatory behaviors that characterize BN. To meet diagnostic criteria, binge episodes must be associated with at least 3 of 5 key physical and psychological characteristics (e.g., eating rapidly or when not hungry; feeling disgusted or guilty after bingeing). To distinguish binge eating from simple overeating, binges are defined as consuming a large amount of food in a short period of time while concurrently feeling out of control (i.e., unable to stop eating) (American Psychiatric Publishing, 2013).

OSFED, previously referred as EDNOS, comprises five non-exhaustive example presentations: atypical anorexia nervosa (anorexic features without low weight), subthreshold BN (bingeing and purging less than once per week or for fewer than 3 months), subthreshold BED (binge eating less than once per week or for fewer than 3 months), purging disorder (regular purging in the absence of binge eating), and night eating syndrome (characterized by nocturnal eating episodes after awakening from sleep, or consuming a large proportion of daily calories after the evening meal). Although many *DSM-5* changes aimed to reduce the large number of patients

Table 32.1 EATING DISORDERS

EATING DISORDER	DESCRIPTION
Anorexia Nervosa	Low body weight for sex and age accompanied by an intense fear of becoming fat and/or persistent behaviors that interfere with gaining weight; and lack of recognition of the possible health consequences of low weight. Subtypes are based on whether low weight is maintained by pure restriction or by bingeing and/or purging.
Bulimia Nervosa	Binge eating followed by compensatory behaviors to make up for calories consumed, occurring at least once weekly for at least 3 months. Self-image is dominated by weight and shape. Individuals with BN can be normal weight, overweight, or obese.
Binge Eating Disorder	Frequent episodes of binge eating that are not followed by compensatory behaviors. During binges individuals feel out of control. Afterward, they may feel embarrassed, disgusted with themselves, depressed, and/or guilty. Patients can be normal weight, overweight, or obese.
Other Specified Feeding or Eating Disorder	This group comprises eating disturbances that cause clinical impairment but do not meet diagnostic criteria for AN, BN, BED, or ARFID. Specific examples include partial syndromes of either AN or BN, as well as other forms of ED such as repeatedly purging in the absence of binge eating, or night eating syndrome.

falling into this residual category, available data suggest that a substantial minority of cases will still receive an OSFED or UFED diagnosis (Thomas et al., under review).

EPIDEMIOLOGY

Although epidemiological data on EDs are limited, findings from the National Comorbidity Survey Replication (NCS-R) provide estimates (Hudson, Hiripi, Pope, & Kessler, 2007). Lifetime prevalence estimates for women and men are 0.9% and 0.3% for AN, 1.5% and 0.5% for BN, and 3.5% and 2.0% for BED, respectively (Hudson et al., 2007). These are likely underestimates, given that individuals with disordered eating may be reluctant to report behaviors and also because the NCS-R did not include operational definitions, OSFED examples or new *DSM-5* presentations such as ARFID.

Also according to NCS-R data, only a minority of individuals with EDs seek mental health treatment. In this representative study, only 50%–63% of those with lifetime EDs had ever sought treatment for emotional problems, and less than 50% had ever sought treatment specifically for EDs. For those patients with 12-month histories of ED, only 15.6% of those with BN and 28.5% of those with BED reported seeking treatment for emotional problems in the preceding 12 months.

The most common site of treatment in the NCS-R study was the medical sector (e.g., primary care). In medical settings patients rarely present with a chief complaint of disordered eating (e.g., restricting food, purging, using laxatives); rather, most present with nonspecific physical or emotional complaints. For example, patients with AN may report lightheadedness or constipation; patients with BN may present with acid reflux or other gastrointestinal problems; and patients with BED may present with obesity or depression. In our clinical experience, it is sometimes only after months of frustrating and seemingly treatment-resistant physical symptoms that suspicion of an ED develops.

At times a patient is relieved when a clinician ascertains a covert ED. In turn, the patient may become forthcoming with information and motivated to accept treatment. This is satisfying for both patient and clinician. However, when a patient continues to deny there is an eating problem and refuses recommended treatments, the clinician may feel frustrated, exhausted, and unsure how to proceed—especially when behaviors have potentially dangerous medical consequences. Although difficult for all involved, this is a crucial time to strengthen the patient–clinician alliance and motivate the patient toward ED treatment.

COMORBIDITY

EDs are typically comorbid with other psychiatric disorders. Traits common to AN and BN include perfectionism and dysphoric mood. Other traits presage the specific ED symptoms that an individual may ultimately adopt. For example, obsessive compulsive traits contribute to restrictive eating patterns, whereas borderline personality traits promote impulsive eating patterns such as binge eating and self-induced vomiting (Sansone & Sansone, 2010). Similarly, high constraint, constricted affect, and asceticism are often associated with AN, whereas high impulsivity and sensation-seeking are associated with BN (Kaye, 2008). Impulse control disorders have been associated with both normal-weight and obese presentations of BED (Keel, Holm-Denoma, & Crosby, 2011).

The majority of individuals with EDs in the NCS-R also had a lifetime history of another psychiatric disorder. Anxiety, mood, and substance use disorders are highly comorbid with EDs. Rates of lifetime anxiety disorders among patients with EDs range from 54%–83% (Kaye, 2007). Patients with AN who binge and purge have higher rates of substance use disorders than patients with restricting-type AN (Root et al., 2010). Higher comorbidity is typically associated with worse overall ED outcome.

Personality disorders are also common among patients with EDs, but available data raise questions about the reliability of personality disorder diagnoses at initial consultation, when erratic or isolative behaviors may be secondary to nutritional compromise. For example, one study demonstrated that at 5-year follow-up from initial inpatient treatment, 43% of ED patients had a diagnosable personality disorder compared to 78% during the inpatient baseline (Vrabel, Ro, Martinsen, Hoffart, & Rosenvinge, 2010). Additionally, a 5-year naturalistic study of patients with BN and EDNOS found that the presence of comorbid personality disorders did not significantly alter time to remission or relapse (Grilo et al., 2007), suggesting that ED outcomes may be independent of personality pathology. These more recent studies provide optimism that patients with comorbid eating and personality disorders can and do improve.

Lastly, but importantly, suicidality is common among individuals with ED. AN has among the highest mortality rates of any psychiatric disorder, with the majority of deaths attributable to malnutrition-related medical complications and suicide (Harris & Barraclough, 1998; Papadopoulos, Ekbom, Brandt, & Ekselius, 2009). Despite a higher mortality rate related to completed suicides in patients with AN, a higher percentage of patients with BN make suicide attempts: 3%–20% in AN and 25%–35% in BN (Franko & Keel, 2006). A combination of traits including low self-directedness, reward dependence, and impulsivity may increase the risk of making suicide attempts in individuals with BN (Forcano et al., 2009). Additionally, literature suggests that a switch from restrictive-type AN to binge-purge type increases risk of suicidal behavior (Foulon et al., 2007). A review of suicidality among patients with EDs identified purging behaviors, depression, substance abuse, and a history of childhood physical or sexual abuse as correlates of suicidality (Franko & Keel, 2006).

COURSE OF ILLNESS

Research on ED course and outcomes is limited, and outcomes vary substantially depending on study duration and level of care.

ANOREXIA NERVOSA

Compared to BN and BED, adult AN tends to be more diagnostically stable over time and follow a more chronic course with overall worse outcomes (Fichter & Quadflieg, 2007). Studies demonstrate that even when remission from AN is achieved, patients persistently have higher anxious, depressive, and obsessive symptoms compared to controls (Wagner et al., 2006). Follow-up studies of AN range from 2.5 years (Clausen, 2008) to 18 years (Wentz, Gillber, Anckarsater, Gillberg, & Rastam, 2006). One 12-year course and outcome study of inpatients with AN reported global outcome scores with 27.5% having a good outcome, 25.3% an intermediate outcome, 39.6% a poor outcome, and 7.7% deceased (Fichter, Quadflieg, & Hedlund, 2006). In this study a poor outcome

was defined as never achieving normal weight. Impulsivity, baseline symptom severity, and chronicity predicted a worse 12-year outcome. Given that the point of entry for this study was an inpatient unit, a selection bias likely makes the outcomes appear graver than for the broader AN population. Follow-up studies with less severely ill populations demonstrate more optimistic outcome data, for example, remission rates of 76% at 5 years and 82% at 8 years. In a recent review of outcomes in AN, mortality rates ranged from zero to 8% across studies with a cumulative mortality rate of 2.8% (9 deaths in 318 cases who were followed for an average of 11 years; see Keel et al., 2010). Another study reviewed 177 cases and found crude mortality rates of 4% (Crow et al., 2009).

BULIMIA NERVOSA

Overall, outcomes for individuals with BN are better than for AN. Remission rates in shorter duration studies are close to 30% and increase to 70% at 10-year follow-up (Keel et al., 2010). Similar to studies of AN, outcome studies for BN range from a few months to 20 years (Keel et al., 2010), and, as length of time to follow-up increases, so do response and remission rates. That said, studies demonstrate that similar to AN, even when remission is achieved patients persistently have psychopathology and altered serotonin function (Wagner et al., 2006; Kaye et al., 1998). In a recent review of outcomes in BN, mortality rates ranged from zero to 2% across studies with a cumulative mortality rate of 0.4% (2 deaths in 459 cases who were followed for an average of 7 years) (Keel & Brown, 2010). Another study of 906 patients with BN reported a crude mortality rate of 3.9% over 8–25 years (Crow et al., 2009).

BINGE EATING DISORDER

Because it is a more recently defined disorder, outcomes for BED are not as well studied as those for AN and BN. Available data suggest that, although individuals with BED may relapse after first remission, many are able to achieve lasting remission over time. One longitudinal study of 104 patients with BED, recruited from college campuses, demonstrated high rates of relapse for individuals with BED within the first 6 months after remission (Agras, Crow, Mitchell, Halmi & Bryson, 2009). However, the same study also demonstrated that 82% of individuals with BED had remitted after 4 years compared with just 47% of the BN group and 57% of the AN group (Agras et al., 2009). At a 12-year follow-up another study reported a 67% remission rate for 68 female patients with BED who were first recruited during inpatient treatment (Fichter et al., 2008).

IDENTIFICATION AND DIAGNOSIS

Often long before ED patients are willing to accept treatment, they seek substitute treatment for care for the unintended—and often distressing and dangerous—physical consequences (Ogg, Millar, Pusztai, & Thom, 1997). Many patients with ED, particularly AN and BN, present with

medical complaints that are atypical or more severe than would be expected given their demographics and otherwise healthy status. For example, a high-school girl may present with hair loss, early satiety, and constipation; or an undergraduate male may present with a 20-pound weight gain over 1 year, insomnia, and heartburn. While hypothyroidism in the former case and numerous medical conditions in the latter should be considered on the differential diagnosis, EDs are common in otherwise healthy youth and should be investigated before embarking on extensive and costly medical tests. Indeed, if the patient exhibits signs and symptoms clearly consistent with an ED, and in the absence of any atypical medical or neurological symptoms, there is no need to exhaust all possible alternative medical explanations before intervening (Mehler & Andersen, 2010). There are very few case reports of serious illness masquerading as an ED, for example, a right frontal brain tumor presenting as AN (Houy, Debono, Dechelotte, & Thibaut, 2007). These cases typically have unusual manifestations (e.g., neurological symptoms) that distinguish them from typical EDs and cue the physician to investigate further.

Many patients do not report ED behaviors to health professionals unless directly queried about eating and weight concerns (Becker, Thomas, Franko, & Herzog, 2005). This is rarely due to any specific gain in lying or deceiving clinicians; usually it is out of embarrassment, fear the clinician will not understand, or a reluctance to give up valued behaviors. However maladaptive and destructive the behaviors appear to the outside observer, they likely serve crucial functions for patients (e.g., providing a sense of control, regulating emotions). Although the patient's illness and life may appear out of control and would seem improved with less disordered eating, paradoxically, patients often feel their lives are *only* in control with the ED and believe that their lives will spiral further out of control or feel intolerable without the behaviors.

SCREENING PATIENTS FOR EATING DISORDERS IN GENERAL MEDICAL SETTINGS

The SCOFF questionnaire is a brief, 5-item screening tool that is easy to administer in clinical settings (Morgan, Reid, & Lacey, 1999; see Table 32.2). It is similar in format to the CAGE questions used to screen for alcohol abuse (Ewing, 1984). It is rapid, sensitive, and requires no special training to use. Validity was initially tested in a group of patients with known AN or BN and a group of controls with no known EDs. With a threshold of two or more positive answers raising concern for a probable ED, there was 100% sensitivity and 87.5% specificity for AN and BN, and 87.5% specificity for controls. The false positive rate was just 12.5%, a reasonable trade-off for the high sensitivity.

In a follow-up study of 341 women ages 18–50 within general practice (Luck et al., 2002), the SCOFF questionnaire detected all cases of AN and BN (4 total) and nearly all cases of EDNOS (7 of 9). One of the EDNOS cases was missed due

Table 32.2 SCOFF QUESTIONS

S	1. Do you make yourself <i>Sick</i> because you feel uncomfortably full?
C	2. Do you worry you have lost <i>Control</i> over how much you eat?
O	3. Have you recently lost more than <i>One</i> stone (about 15 pounds) in a 3-month period?
F	4. Do you believe yourself to be <i>Fat</i> when others say you are too thin?
F	5. Would you say that <i>Food</i> dominates your life?
Scoring	One point for every “yes”; a score of ≥ 2 indicates a likely case of AN or BN

From Morgan, Reid, & Lacey, 1999.

to patient nondisclosure. There is some evidence that disclosure increases when patients answer the SCOFF questions privately in written format before their appointments (Perry et al., 2002). The sensitivity was 84.6%, specificity 89.6%, and there were 34 false positives.

One SCOFF feasibility study demonstrated that although clinicians found the screening tool easy to use they did not know what to do with positive results, rarely recorded the results in medical notes, and infrequently offered treatment (Johnston, Fornal, Cabrini, & Kendrick, 2007). The study suggests that screening should be augmented by a standard protocol for triaging patients with likely EDs. Also important to note, the SCOFF was specifically designed to screen for AN and BN, so its sensitivity and specificity for other *DSM-5* ED presentations (e.g., BED, OSFED) remains unknown.

Once suspicion is raised for a possible ED, the next step is to clarify the specific diagnosis. There is significant overlap in symptoms and behaviors among patients with AN and BN; there is less overlap between AN and BED. Patients with restricting type anorexia, who do not engage in bingeing or inappropriate compensatory behaviors (e.g., self-induced vomiting, laxative use), are more easily distinguished from patients with BN. To meet criteria for AN, patients must be significantly underweight ($\text{BMI} < 18.5$ in adults). Moreover, fear of gaining weight or becoming fat is thought to be a central feature and driving force in perpetuating the illness. Interestingly, there is a subset of patients with *DSM-5* AN who do not explicitly endorse fear of fatness but nonetheless exhibit behaviors that interfere with weight restoration. Such patients are especially common in culturally non-Western and youth populations (Becker, Thomas, & Pike, 2009). These patients are characterized as *non-fat phobic AN*, and it is unclear how they may differ from patients with classic AN in terms of diagnosis, treatment, and outcomes (Becker et al., 2009).

Patients with bingeing and purging present more of a diagnostic challenge. Regular bingeing and compensatory behaviors are a core and highly distressing feature of BN,

and one or both are also present in the AN binge-eating/purge subtype. The key distinction is that AN patients are significantly underweight, whereas BN patients are normal weight or overweight. In some ways, AN is an illness marked by over-control of behaviors and BN by out-of-control behaviors.

In the evaluation of BED, it is important to distinguish simple overeating from a bona fide ED. Although patients who overeat may be unhappy about it, patients with BED engage in discrete, episodic binges during which they eat large amounts of food, feel out of control, and are highly distressed.

EVALUATION OF PATIENTS WITH EATING DISORDERS

In the initial evaluation of ED patients, it is important to assess current psychiatric and medical issues and to determine their acuity.

PSYCHIATRIC ASSESSMENT

Psychiatric assessments should explore ED symptoms as well as any co-occurring mental illnesses and safety concerns.

Beginning with assessment of the ED, it is critical to investigate daily food consumption in detail. This can vary from complete food and water refusal to bingeing on upwards of 10,000 kilocalories several times per day. A direct and specific, yet empathic, approach will maximize information gathering.

During the initial evaluation we suggest asking patients specifically what they ate and drank for all meals and snacks on the day prior to evaluation. This circumvents vague answers and also exposes distorted perceptions of food. With less targeted questions about what is typically eaten, patients may respond with vague answers such as “three pretty good meals.” When asked what these meals comprise it would not be uncommon to discover that “three pretty good meals” is actually a half a cup of cereal with skim milk and a large coffee for breakfast, two cups of lettuce with nonfat dressing for lunch, and one cup of stir-fried vegetables for dinner. As the day reported may not represent most days, it is helpful to ask whether food intake varies from day to day. If it does, ask the patient to describe a highest and lowest intake day. Individuals with BN may respond well to queries about the differences in food consumption on binge days (during which eating restraint is relaxed) versus nonbinge days (when eating is typically more restrictive).

If patients are willing, it is often helpful to have them keep a food diary where they write down everything eaten immediately following consumption. Then, at follow-up appointments, the food diary can be scanned briefly rather than using a lot of time drawing out the information on interview. Characterizing the predominant pattern of eating sheds light on diagnosis—a restrictive eating pattern with no objective

binges is consistent with AN (restricting type); frequent bingeing and compensatory behaviors is consistent with BN (or AN binge eating/purging type); and regular eating, overeating, or grazing with frequent episodes of bingeing is consistent with BED.

In addition to assessing food intake, behaviors used to maintain weight or compensate for specific eating episodes should be evaluated. This is crucial, especially since these behaviors contribute to much of the morbidity associated with EDs. Compensatory behaviors include vomiting (either self-induced or with emetics), laxatives, diuretics, fasting, and excessive exercise. Compensatory behaviors are a core feature of BN, as well as the AN binge-eating/purging subtype. When purging becomes frequent, medical morbidity increases significantly. It can be helpful to ask in a way that decreases shame, for example, “Some patients who are struggling with controlling their eating and weight induce vomiting or use laxatives. Have you found yourself doing this?” If patients endorse purging it is important to assess the frequency and method. A review of systems and physical exam will be important to identify the presence of purging-related medical complications.

Regarding excessive exercise, a common compensatory behavior to control weight, try to evaluate the quality and quantity of exercise per day and week. Although the definition of recommended and excessive exercise varies, anything more than the 30 minutes of moderate to high-intensity physical activity recommended by the US Surgeon General should be carefully explored. Excessive exercise may also be defined as compulsively exercising even when injured or sick, or exercising more than what coaches or physicians recommend. Patients with EDs are known to underreport the extent of their physical activity (Bratland et al., 2010). Patients trying to hide their ED also may exercise covertly in their daily routines (e.g., walking everywhere instead of driving, standing at times it would be more socially appropriate to sit), so it is helpful to specifically ask how much of their day is spent active (i.e., not sitting down).

While disordered eating behaviors are immediately salient, cognitive and emotional aspects of the illness are intimately related with the behaviors but may go unnoticed if not explored. Simply asking patients how distressed or preoccupied they are by thoughts about food and weight can suggest their level of impairment. Some patients are so consumed by their illness that 95% of their mental time and activities are spent thinking about or acting out behaviors related to the illness. This leaves little time for other activities, and it is common for patients to forgo their usual activities and pleasures to engage in ED behaviors. The 16-item Clinical Impairment Assessment (Fairburn & Bohn, 2008) is an easy-to-administer inventory of the myriad life domains that may be impaired by a patient's ED.

For all patients with ED, regardless of the type, it is equally important to assess for comorbid psychiatric illness and patient safety (i.e., self-injurious behavior, suicidality, and homicidality). As mentioned previously, EDs are highly comorbid with mood, anxiety, personality, and substance use

disorders. Therefore, it is important to screen for any concurrent depressive and anxiety disorders, and in particular, alcohol/drug use and safety concerns (dangerousness to self or others).

Some patients may not be ready to accept ED treatment; however, they may accept treatment for comorbid mood or anxiety problems. In general, severity of distress level, depression, anxiety, self-injurious behavior, and suicidal thoughts will determine how rapidly patients need to be referred for further psychiatric evaluation. Any patients who are moderately to severely distressed, depressed or anxious, or who have histories of self-injury or suicide attempts should be referred rapidly to psychiatry (within a few weeks) and have frequent follow-up with the treating clinician as well as instructions for what to do if symptoms worsen (e.g., call the medical clinic or go to the emergency room) until the referral to psychiatry is completed. Patients with severe distress, depression, or recent or current self-injurious or suicidal thoughts and behaviors should be referred for emergent evaluation (either same-day or emergency room).

MEDICAL ASSESSMENT

Medical assessment of ED patients is crucial given high rates of medical morbidity associated with malnutrition and disordered eating behaviors. Routine examination with a comprehensive history, review of systems, weight, height, vital signs, and physical exam is likely to identify ED signs and symptoms as well as related medical complications. Information gathered in the history, physical, and laboratory evaluations will determine medical acuity.

The review of systems is an important part of the general medical assessment of patients with EDs. Given the often severe and widespread physical ramifications of ED, there

may be pertinent positives and negatives in nearly all systems. Table 32.3 outlines symptoms commonly elicited on review of systems.

When evaluating the ED it is also helpful to assess how rapidly weight is changing. Barring other uncommon factors accountable for weight change, rapid weight gain or loss typically indicates a severe degree of behaviors such as restricting, bingeing, purging, or excessive exercising. Although some patients avoid weighing themselves, others obsessively weigh themselves—sometimes several times per day. Begin by asking patients if they know their weight and if it has changed in the past few months or weeks. It is also helpful to know patients' lifetime highest and lowest weights to get a sense of how severe the illness has been in the past and how their current status compares. While these conversations can yield important information, obtaining a current, accurate, objective weight is necessary to determine acuity and identify possible underreporting of symptoms.

Recording weight and height allows for calculation of body mass index (BMI), an important factor in diagnostic assessment and treatment planning. BMI can be calculated by hand (i.e., weight in kilograms divided by height [in meters] squared) or through an online calculator or mobile app. For adults, BMI < 18.5 kg/mg² is underweight (and possibly consistent with a diagnosis of AN), BMI > 18.5 kg/mg² but < 25.0 kg/mg² is healthy weight, and BMI ≥ 25.0 kg/mg² is overweight. For children and adolescents, BMI < 5th percentile for age and height is underweight, BMI > 5th percentile but < 85th percentile is healthy weight, and BMI ≥ 85th percentile is overweight. Of note, patients with AN or who are underweight should be weighed in a hospital gown to prevent patients putting weights and other heavy objects in pockets and orifices to falsely elevate weight. Additionally, patients may “water load” (drink excessive amounts of water) prior to

Table 32.3 PERTINENT FINDINGS ON REVIEW OF SYSTEMS IN PATIENTS WITH EATING DISORDERS

SYSTEM	SYMPTOMS	ASSOCIATED EATING DISORDER BEHAVIOR
General	High, low, or dramatic change in weight Lethargy	Restricting, bingeing and/or purging Restricting/starvation
HEENT	Dental cavities, halitosis, throat pain	Purging
GI	Altered appetite, early fullness, constipation, bloating Heartburn Diarrhea, rectal prolapse	Starvation/restricting Purging Laxative abuse
Gyn	Irregular menses or amenorrhea	Low body fat and/or low weight, stress
MSK	Joint pain, stress fractures, muscle/tendon injuries Bone fractures	Excessive exercise Osteoporosis from prolonged restriction/starvation
Endocrine	Cold sensitivity, brittle/thinning hair	Restricting/starvation
Neuro	Lightheadedness, fainting Numbness, tingling	Food/fluid restriction, low weight/starvation, excessive exercise Starvation (vitamin deficiencies)

Key: HEENT—head, eyes, ears, nose, throat. GI—Gastrointestinal. Gyn—gynecological. MSK—musculoskeletal. Neuro—neurological.

Table 32.4 COMMON SIGNS ON PHYSICAL EXAM

EATING DISORDER	PHYSICAL SIGNS
Anorexia Nervosa	<ul style="list-style-type: none"> • Sinus bradycardia, hypotension, orthostatic hypotension, and hypothermia • Cachexia • Parotid and submandibular gland swelling (if purging) • Brittle and thinning head hair and presence of lanugo • Acrocyanosis • Breast atrophy • Diminished bowel sounds
Bulimia Nervosa	<ul style="list-style-type: none"> • Hypotension and tachycardia • Bilateral parotid gland swelling • Erosion of enamel on the lingual surface of teeth • Periodontal disease and dental carries • Russell's sign (scarring and abrasions on the knuckles of the dominant hand from repeated self-induced vomiting) • Pedal edema (protein malnourishment)
Binge Eating Disorder	<ul style="list-style-type: none"> • Obesity • Hypertension

the weigh-in to falsely increase weight. Checking urine specific gravity can help rule out water loading.

For many patients, being weighed is highly distressing. It is therefore a difficult procedure for clinicians who are working diligently to decrease patients' distress, not increase it. Instead of forgoing the weighing procedure entirely or engaging in lengthy struggles with patients, we suggest taking an empathic but firm approach with patients. The following statement may be used: "I realize getting weighed may be difficult for you. In order for me to provide you with good and safe care, I will have to weigh you at each visit. It is likely to be more difficult in the beginning and get easier with time. Let's go ahead and get it out of the way for today's visit." The majority of patients, however reluctant, typically agree to be weighed.

Although the physical signs common to EDs are nonspecific, patterns or combinations of physical signs can help identify an ED and support diagnosis. Table 32.4 outlines some of the physical signs common to EDs.

Attention to vital signs is important for all ED patients, but particularly for those who are significantly underweight or with severe bingeing, purging, or hyper-exercise. Sinus bradycardia, low blood pressure, orthostatic hypotension, and hypothermia are ominous signs of starvation and typically indications for inpatient hospitalization on a medical unit to begin weight restoration and nutrition repletion. In a study of medical findings in community-dwelling patients with AN, 41.3% had bradycardia, 16.1% hypotension, and 22.4% had hypothermia (Miller et al., 2005). In normal-weight patients with BN, changes in heart rate and blood pressure, particularly hypotension and tachycardia, may indicate presence of rapid fluid shifts and dehydration from bingeing and purging as well as more concerning behaviors such as ipecac use, which is known to cause cardiomyopathy (Rashid, 2006; Schneider et al., 1996).

Medical Assessment in Anorexia Nervosa

Physical signs common to patients with AN are related to food restriction, malnutrition, and bingeing/purging if those behaviors are present. On physical exam, cachexia, parotid and submandibular gland swelling (if purging type), brittle and thinning head hair, lanugo, acrocyanosis, and breast atrophy are typical. Assessment of the cardiovascular system on physical exam typically reveals sinus bradycardia. There may be signs associated with mitral valve prolapse, which occurs related to reduced left ventricular mass (Cooke & Chambers, 1995). Echocardiograms of patients with AN often demonstrate atrophic myocardium and low cardiac output (Casiero, 2006). In very underweight patients (e.g. BMI less than or equal to 13.5 kg/mg²), pericardial effusion may be present. It is most often asymptomatic but in rare cases may require pericardiocentesis to prevent tamponade (Docx et al., 2010; Polli et al., 2006). Electrocardiogram may demonstrate prolongation of the QTc and PR intervals, first-degree heart block, and ST-T wave abnormalities. Most cardiac abnormalities improve with careful nutritional rehabilitation.

Evaluation of the gastrointestinal system in patients with AN may reveal diminished bowel sounds consistent with inactivity and slowed metabolism. Although rare, there have been several reports of patients with AN having massive gastric dilatation following binges (Barada et al., 2006; Mathevon, Rougier, Ducher, Pic, Garcier, & Schmidt, 2004), as well as gastric rupture and death (Sinicina, Pankratz, Büttner, & Mall, 2005). Patients with common complaints of early fullness, nausea, and bloating are often referred to gastroenterology to rule out organic pathology. Gastric and bowel studies, in the absence of organic pathology, are often positive for delayed emptying (Zipfel et al., 2006; Hultson & Wald, 1990; Benini et al., 2004) and increased whole bowel and colonic transit time (Waldholtz & Andersen, 1990). Studies demonstrate that nutritional rehabilitation improves gastrointestinal dysfunction (Rigaud et al., 1988).

Muskuloskeletal problems are common to patients with AN, particularly in those with a chronic and severe course and who engage in hyper-exercise. Long-standing starvation can lead to early osteoporosis and fractures, and hyper-exercise often leads to overuse injuries. In younger patients, starvation may lead to deficits in bone mass accrual and arrested skeletal growth (Misra, 2008; Lacey, Crisp, Hart, & Kirkwood, 1979).

Lab abnormalities in AN patients typically reflect changes associated with starvation, as well as with purging (if present). One study demonstrated that among 214 community-dwelling patients with AN, 38.6% had anemia, 34.4% leucopenia, 19.7% hyponatremia, 19.7% hypokalemia, and 12.2% elevated alanine aminotransferase concentration (Miller et al., 2005).

Medical Assessment in Bulimia Nervosa

Compared to patients with AN, patients with BN have fewer physical findings associated with starvation and more medical morbidity related to bingeing and especially to compensatory behaviors. Some patients have a normal physical exam; however, as disease severity increases there are typically physical signs that may include bilateral parotid gland swelling, erosion of enamel on the lingual surface of teeth, periodontal disease, dental caries, and pedal edema (protein malnourishment). Russell's sign (scarring and abrasions on the knuckles of the dominant hand from repeated self-induced vomiting) is more common in the beginning of the illness as individuals with chronic BN can typically induce vomiting at will.

The cardiovascular system of patients with BN may be affected by both malnourishment and bingeing and purging behaviors, which can lead to fluid shifts and electrolyte abnormalities that destabilize the electrical activity of the heart. Electrocardiograms may demonstrate QTc prolongation (Takimoto et al., 2004; Contaldo, Di Paolo, Mazzacano, Di Biase, & Giumetti, 1990), increased PR interval, hypokalemia-related widened QRS complex, and *torsade de pointes* (Suri, Poist, Hager, & Gross, 1999), as well as increased supraventricular and ventricular ectopic rhythms and arrhythmias (Takimoto, Yoshiuchi, Kumano, & Kuboki, 2006).

In BN, bingeing and purging behaviors are the main cause of gastrointestinal complications. Recurrent vomiting exposes the esophagus to acidic gastric contents potentially leading to esophagitis, esophageal ulcers, strictures, vascular tears (Mallory-Weiss tear), and even rupture. Esophagitis is a risk factor for esophageal cancer, and cases have been reported in otherwise healthy women with BN (Navab, Avunduk, Gang, & Frankel, 1996). Lowered esophageal sphincter tone from recurrent vomiting often leads to gastroesophageal reflux disease. Although uncommon, bingeing can lead to acute gastric dilatation, sometimes with fatal outcomes (Pandey, Maqbool, & Jayachandran, 2009; Bravender & Story, 2007; Gyurkovics et al., 2006).

Patients who purge with stimulant laxatives often develop complications of the colon and rectum. Chronic use of laxatives can lead to a vicious cycle of decreased colonic tone, chronic constipation, and further dependence on laxatives to move fecal matter. Rectal prolapse has also been associated with laxative abuse (Malik, Stratton, & Sweeney, 1997).

Similar to patients with AN, patients with BN are often referred to gastroenterology for evaluation of common complaints (e.g., dyspepsia, nausea, bloating) and may have delayed gastric emptying and slowed motility (Kamal et al., 1991) in the absence of primary gastrointestinal pathology.

Patients with severe BN may develop lower extremity edema from two processes, either protein malnutrition or abrupt cessation of purging behaviors, which leads to unopposed high aldosterone levels and salt retention (Mehler & Andersen, 2004). The latter scenario can be a vicious cycle as patients then try to solve the edema by taking more diuretics and laxatives.

Dental problems are nearly universal in patients who engage in purging by vomiting, and enamel erosions can be seen after just 6 months (Altshuler, Dechow, Waller, & Hardy, 1990). The American Dental Association currently recommends that patients not brush their teeth immediately after vomiting but rather rinse with baking soda, which helps to neutralize the destructive effects of the stomach acid (<http://www.mouthhealthy.org/en/az-topics/e/eating-disorders>).

Laboratory findings in patients with BN are variable depending on nutrition status, frequency of bingeing and purging, and methods of purging. Hypokalemia, hypochloremia, hyperphosphatemia, and metabolic alkalosis are common, especially in underweight patients with BN who frequently induce vomiting (Rushing, Jones, & Carney, 2003). Patients who primarily abuse laxatives may present with metabolic acidosis due to alkaline fluid loss from the bowels (Mitchell, Hatsukami, & Pyle, 1987), and patients using multiple purging methods may have mixed acid-base findings making it difficult to diagnose the purging method by lab results. BN patients with severe hypokalemia and hypovolemia often need aggressive fluid repletion in order to correct the hypokalemia; as volume status improves the metabolic alkalosis corrects and inactivates the rennin-angiotensin axis (Mehler & Andersen, 2004).

Serum amylase is commonly elevated in patients who regularly vomit; however, only the salivary fractionate has been shown to be useful in differentiating patients with elevated amylase due to purging behaviors (Walsh, Wong, Pesce, Hadigan, & Bodourian, 1990). In the majority of patients, extent of amylase elevation is correlated with frequency of vomiting (Kinzl, Biebl, & Herold, 1993). Salivary amylase can be a sensitive laboratory test for detecting surreptitious vomiting.

Patients with suppressed TSH in the absence of primary thyroid disorder may be abusing thyroid hormone in an effort to lose weight (Kaplan, 1998).

Medical Assessment in Binge Eating Disorder

BED is associated with a range of physical problems different from patients with AN and BN. The physical exam of BED patients is typically remarkable for obesity. Related more to obesity than to BED, patients commonly have hypertension, gall bladder disease, musculoskeletal problems, and obstructive sleep apnea. Laboratory tests often demonstrate presence of metabolic syndromes including diabetes and

dyslipidemia. Interestingly, a recent study suggested that individuals with BED have a higher risk of metabolic syndrome over and above the risk conferred by obesity alone (Hudson et al., 2010).

In addition to a comprehensive history and physical, Table 32.5 (adapted from the American Psychiatric Association practice guideline for EDs) outlines laboratory and diagnostic tests to obtain as part of the initial evaluation.

TREATMENT

The goals of care for all EDs are similar and include establishing regular eating patterns, nutritional rehabilitation, and restoration of a healthy weight range; treating the emotional, cognitive, and behavioral aspects of the disorder as well as any psychiatric comorbidities; and providing regular medical surveillance and treatment.

For patients with severe illness, an interdisciplinary team composed of a primary care physician, therapist, psychiatrist, and dietitian—preferably with some or all members having experience in treating EDs—is ideal. For less complicated

patients, other combinations can sufficiently comprise a team. For example, a therapist experienced with ED, along with a primary care physician, can adequately treat patients with milder forms of illness. Patients who lack significant psychiatric comorbidities do not necessarily need a psychiatrist. Indeed, BN is the only ED that has an FDA-approved medication (fluoxetine), and primary care physicians are often comfortable prescribing this. It is helpful to assess at the outset, and periodically through treatment, patients' particular needs and clinicians' level of comfort treating patients with EDs, in order to readjust as indicated.

Medical, psychological, and pharmacological treatments for each ED are reviewed below. Table 32.6 outlines current psychological treatments for EDs.

ANOREXIA NERVOSA

The initial treatment focus for patients with AN is nutritional rehabilitation and weight restoration. The importance of weight restoration is underscored in recent studies, with the most significant predictor of weight maintenance following intensive treatment for AN being higher BMI at discharge

Table 32.5 RECOMMENDED LABORATORY AND DIAGNOSTIC TESTS

PATIENT INDICATION	LABORATORY TESTS	DIAGNOSTIC STUDIES
All patients	Serum electrolytes, blood urea nitrogen, creatinine, TSH, CBC with differential, erythrocyte sedimentation rate, aspartate aminotransferase, alanine aminotransferase, alkaline phosphatase, urinalysis	
Malnourished and severely symptomatic patients	Complement component 3a, serum calcium, magnesium, phosphorus, ferritin, 24-hour urine for creatinine clearance	Electrocardiogram
Amenorrheic >6 months		Dual-energy X-ray absorptiometry, serum estradiol in female patients
Suspected substance use	Toxicology screen	
Suspected surreptitious vomiting	Serum amylase (fractionated for salivary gland isoenzyme)	
Persistent amenorrhea but normal weight	Serum luteinizing hormone, follicle-stimulating hormone, B-human chorionic gonadotropin, prolactin	
Significant cognitive deficits, neurological soft signs, unremitting course or other atypical features		Brain magnetic resonance imaging, computed tomography
Suspected GI bleeding		Stool guaiac
Suspected laxative abuse	Stool or urine for bisacodyl, emodin, aloe-emodin, rhein*	
Obesity	Cholesterol (total, HDL, LDL), triglycerides, fasting glucose	

Adapted from American Psychiatric Association, 2006.

*Rhein, emodin, and aloe-emodin are common ingredients and active metabolites found in laxatives.

Table 32.6 SUMMARY OF PSYCHOLOGICAL TREATMENTS FOR EDS

DIAGNOSIS	TREATMENT	SUMMARY	EVIDENCE OF EFFICACY IN AT LEAST 2 RCTS
Anorexia Nervosa	Family Based Treatment	Parents restore patient's weight by taking charge of refeeding their child, exploring how the illness affects family dynamics, and working to support patient's ability to make proper food choices.	Yes
	Cognitive Behavioral Therapy	Educates patients about how thoughts and behaviors maintain AN. Patients normalize their eating while concurrently challenging and reducing thoughts and behaviors that maintain AN.	Yes
	Specialist Supportive Clinical Management	Interventions are similar to CBT, but with a broader focus on supportive therapy techniques such as active listening, validation, and praise.	Yes
	Cognitive Remediation Therapy	Patients identify and examine how rigid and narrow thought patterns maintain AN behaviors. In-session exercises promote cognitive flexibility and big-picture thinking.	No
	Uniting Couples in the Treatment of Anorexia Nervosa	Educates patients and their partners about AN and teaches couples how to deal with interpersonal issues that arise from AN symptoms.	No
	Emotion Acceptance Behavior Therapy	Educates patients about how AN is used for emotion avoidance and helps patients return to regular life activities.	No
	Exposure and Response Prevention	Assists patients in developing a hierarchy of fear foods and then systematically incorporates these foods while refraining from avoidance behaviors.	No
Bulimia Nervosa	Cognitive Behavior Therapy	Patients learn how thoughts and behaviors maintain BN. Patients normalize their eating while concurrently challenging and reducing thoughts and behaviors that maintain BN. Patients also identify and reduce triggers for binge eating such as dietary restriction, poor body image, and mood intolerance.	Yes
	Family Based Treatment	Enlists parents in helping patients refrain from bingeing and purging, exploring how the illness affects family dynamics, and working to support the patient's ability to make proper food choices.	Yes
	Interpersonal Psychotherapy	Identifies interpersonal difficulties that are influencing BN behaviors. Patients focus on one of four interpersonal issues during therapy including interpersonal deficits, interpersonal role disputes, role transitions, and grief.	Yes
	Dialectical Behavioral Therapy	Focuses on emotion regulation, distress tolerance, interpersonal effectiveness, and mindfulness.	No
	Integrative Cognitive Affective Therapy	Identifies how self-directed behaviors (i.e., dieting or purging) are used to cope with perceived discrepancies between the actual and ideal self.	No

(continued)

Table 32.6 (CONTINUED)

DIAGNOSIS	TREATMENT	SUMMARY	EVIDENCE OF EFFICACY IN AT LEAST 2 RCTS
Binge Eating Disorder	Cognitive Behavioral Therapy	Normalizes eating behaviors and decreases maladaptive thoughts about weight and shape. Emphasizes healthy dietary restraint with patients who are overweight.	Yes
	Interpersonal Psychotherapy	Identifies interpersonal difficulties that are influencing BED behaviors. Patients focus on one of four interpersonal issues during therapy including interpersonal deficits, interpersonal role disputes, role transitions, and grief.	Yes
	Behavioral Weight Loss Treatment	Regulates eating patterns and promotes healthy dietary restraint to facilitate modest weight loss and reduce obesity-related risks to mental and physical health.	Yes

and slower rate of weight loss following discharge (Kaplan et al., 2009). More specifically, lower rates of weight loss over the first 28 days postdischarge predicted better weight maintenance at 6 and 12 months (Kaplan et al., 2009). Additionally, many of the medical complications improve or entirely reverse with weight restoration.

For the most acute patients, inpatient medical and/or psychiatric hospitalization is necessary. Psychiatric units vary considerably in their capacity to manage medically ill patients; inpatient medical admission is indicated if BMI is very low or if any of the following are present: significant bradycardia (<40bpm), hypothermia, significant or symptomatic orthostatic hypotension, hypokalemia or electrolyte disarray, signs of organ failure, or any acute medical complications (e.g., hematemesis).

Given the risks associated with refeeding syndrome—a potentially life-threatening syndrome involving large fluid and electrolyte shifts associated with introducing nutrition to the severely malnourished—refeeding severely underweight patients (i.e., BMI < 16.0 kg/m², Mehler et al., 2010) is done in a medically monitored setting. Refeeding syndrome is associated with hypophosphatemia, hypomagnesemia, hypokalemia, congestive heart failure, edema, delirium, coma, and even death (Gunaratne, McKay, Pillans, McKinlay, & Crockett, 2010). It can be prevented by gradually introducing nutrition and closely monitoring electrolytes, volume status, and vital organ function. In general, nutrition starts very slowly to make sure organ systems demonstrate capacity to withstand the stress of reintroducing nutrition. During acute starvation, AN patients typically have a suppressed resting metabolic rate even when accounting for their low weight. Therefore, during refeeding patients' metabolic rates increase substantially and they often require a very high daily caloric intake to gain weight, for example, as much as 100 kcal/kg per day. Consulting dietitians with experience refeeding severely malnourished patients is essential for safe and effective treatment. Patients can be transitioned to other levels of care once they reach reasonable medical stability. "Medical stability" is somewhat vague, but in general it is when patients are no longer at risk of refeeding syndrome, demonstrate stable

vital organ function, and have achieved steady weight gain. This is a critical transition period, and, without ongoing intensive treatment, patients tend to relapse rapidly.

Patients with AN are generally hospitalized on inpatient psychiatry units for any of the following combinations of criteria: underweight or rapidly changing weight but not yet significantly medically compromised, moderate to severe ED behaviors (e.g., bingeing and purging multiple times per day, severe restriction), moderate to severe comorbid psychiatric illness (e.g., major depression), self-injurious behavior and/or suicidality (intensifying or active thoughts, developing intentions or plans to act on thoughts). In our experience, insurance companies will generally approve inpatient treatment when patients meet any of the above criteria. For patients who are on the borderline of these criteria, lower levels of care such as residential or intensive outpatient programs may be covered. If physicians come up against resistance from insurance companies, it is helpful to emphasize that patients are failing the current level of treatment and, therefore, no less intensive option exists.

Given high rates of relapse following inpatient treatment for refeeding, a range of treatment options between the inpatient and outpatient setting have developed in recent years including residential (Delinsky et al., 2010), day hospital, and intensive outpatient treatments.

Psychological Treatments for Anorexia Nervosa

Family-Based Treatment

The psychosocial treatment modality for AN with the greatest empirical support is a three-phase manualized family-based treatment (FBT) designed for the outpatient care of adolescent patients (Lock, le Grange, Agras, & Dare, 2001). In phase one, the patient's parents are encouraged to correct the patient's malnutrition by planning and implementing a nutritious, calorie-dense meal plan. The therapist supports the parents in their efforts by absolving them of blame for the etiology of the illness and helping them encourage their child to eat adequately during an

in-session family meal. After steady weight gain has been established, food choices are gradually returned to the patient during phase two, and the family is encouraged to explore the ways in which AN has affected familial dynamics. In the final phase, when the patient has reached a stable weight, therapy focuses on enhancing the patient's autonomy and orchestrating a smooth return to normal adolescent development. Elements of FBT have been adapted for delivery in separate but simultaneous parents-only and patient-only sessions (Eisler, Simic, Russell, & Dare, 2007), and in a multi-family group format (Zucker, Marcus, & Bulik, 2006). The professionally moderated website <http://www.maudsleyparents.org/> is a helpful resource for parents who would like to learn more about FBT through articles, videos, and interactive online discussion.

In comparison to individual therapy, FBT has produced greater improvements in body weight and ED psychopathology at 1-year (Lock et al., 2010) and 5-year (Eisler et al., 1997) follow-up—especially among young patients with a short duration of illness (Eisler et al., 1997). However, data suggest that FBT is less effective with non-intact versus intact families (Lock, Agras, Bryson, & Kraemer, 2005) and highly critical versus less critical parents (Eisler et al., 2007). Furthermore, FBT's lack of applicability to older patients (trials typically don't include young adults who are over 18) highlights the ongoing need for novel therapy development.

Cognitive Behavioral Therapy

The most recent version of cognitive behavioral therapy (CBT) for AN (Fairburn, 2008) provides psychoeducation on the consequences of starvation, encourages the patient to consider the long-term advantages of achieving a healthy body weight, and addresses the patient's overvaluation of shape and weight by reducing body checking and avoidance behaviors. In contrast to the parental control of meal planning in FBT, in CBT patients are encouraged to make their own food choices as long as they eat three meals and two-three snacks per day. The therapist facilitates weight gain by helping the patient to design behavioral experiments in which the patient purposefully breaks dietary rules in order to evaluate whether feared consequences—such as instantaneous obesity or never-ending anxiety—actually occur.

Although CBT is the gold standard treatment for adult BN, its evidence base in AN is mixed. CBT was superior to the nutrition counseling alone in a post-hospitalization relapse prevention trial for AN (Pike, Walsh, Vitousek, Wilson, & Bauer, 2003) but no better than specialist supportive clinical management or interpersonal psychotherapy in a randomized outpatient trial (McIntosh et al., 2005). Moreover, in a placebo-controlled medication trial in which all patients received CBT, approximately half of patients in both groups either relapsed or dropped out within 1 year (Walsh et al., 2006). Challenges to implementing CBT for AN include the ego-syntonicity of the illness and the cognitive rigidity of underweight patients. CBT has also been critiqued for its potentially inadequate involvement of significant others (Bulik, Baucom, Kirby, & Pisetsky, 2011) and its preferential focus on cognitive rather than behavioral strategies despite both being components of the treatment (Steinglass et al., 2010).

Novel Therapies for AN

Catalyzed in part by a 2003 request for applications by the National Institute of Mental Health, several novel therapies for AN have recently been developed, including specialist supportive clinical management, cognitive remediation therapy, uniting couples in the treatment of anorexia nervosa, emotion acceptance behavior therapy, and exposure and response prevention. Although the evidence base is still somewhat limited, clinicians may wish to draw upon techniques from these novel therapies when working with adult patients who have not responded favorably to first-line therapies.

Specialist Supportive Clinical Management (SSCM)

SSCM was originally developed as a comparison therapy for a trial examining the efficacy of CBT versus IPT for adult AN (McIntosh et al., 2005), but the surprising finding that SSCM was comparable to CBT and superior to IPT in promoting weight gain sparked independent clinical interest in SSCM. Although SSCM utilizes some interventions that overlap with CBT (e.g., psychoeducation, self-monitoring), its overarching focus on supportive therapy techniques such as active listening, validation, praise, reassurance, and therapist self-disclosure (McIntosh et al., 2006) suggests that nonspecific therapeutic interventions may have promise in the treatment of AN.

COGNITIVE REMEDIATION THERAPY (CRT) Rather than addressing the content of distorted AN cognitions directly, CRT addresses the hallmark rigidity that characterizes cognitive processing in AN. CRT is a 3-session (Lopez, Roberts, Tchanturia, & Treasure, 2008) to 10-session (Tchanturia, Davies, & Campbell, 2007) adjunctive treatment to standard care and includes a neuropsychological battery designed to identify deficits in set-shifting and central coherence, feedback on how neuropsychological deficits impact both eating and noneating-related life domains, and exercises designed to increase cognitive flexibility. Although CRT has yet to be tested in a randomized controlled trial, several case studies and patient series suggest that CRT is acceptable to patients and is associated with improvements in set-shifting abilities (Davies & Tchanturia, 2005; Lopez et al., 2008; Tchanturia, Whitney, & Treasure, 2006; Tchanturia et al., 2007). Because it directly targets maladaptive thinking styles, CRT is designed to augment rather than replace therapies that focus on normalizing eating and restoring weight.

UNITING COUPLES IN THE TREATMENT OF ANOREXIA NERVOSA (UCAN) The success of family therapy with adolescent AN has inspired the recent application of couples therapy to adult AN (Bulik, Baucom, Kirby, & Pisetsky, 2011). UCAN provides the AN patient and his or her partner with psychoeducation on illness and recovery, teaches the couple effective communication skills, addresses interpersonal conflicts that arise from AN symptoms (e.g., secrecy, restricting, purging),

and facilitates the development of a relapse prevention plan (Bulik et al., 2011). A controlled trial testing the efficacy of UCAN is still underway, <http://www.med.unc.edu/psych/eatingdisorders/patient-care-1/clinical-trials/ucan-uniting-couples-in-the-treatment-of-anorexia-nervosa>.

EMOTION ACCEPTANCE BEHAVIOR THERAPY (EABT) Individuals with AN endorse high levels of emotional avoidance (Wildes, Ringham, & Marcus, 2010). Therefore, Wildes and Marcus (2011) developed EABT in order educate patients about the role of AN symptoms in facilitating emotion avoidance, to encourage greater awareness of emotions, and to facilitate a return to valued (albeit anxiety-provoking) life activities. In an uncontrolled case series of five patients, three showed modest weight gain, highlighting the potential promise of conducting larger-scale trials of EABT.

Exposure and Response Prevention (ERP)

Based on the overlap between eating and anxiety disorders, Steinglass and colleagues (2010) have developed an ERP intervention in which AN patients are repeatedly exposed to specific fear foods (e.g., pizza) and prevented from engaging in safety or avoidance behaviors (e.g., blotting with a napkin, looking away while eating). In a small, randomized controlled trial, AN patients who received ERP consumed more calories at a posttreatment test meal in comparison to those who received treatment as usual without ERP (Steinglass et al., 2007).

Pharmacological Interventions for AN

Psychotropic medication has a relatively limited role in the treatment of acute AN. The main “pharmacological” intervention is nutrition. To date, there are no FDA-approved medications for the treatment of AN, though numerous medications in nearly all psychotropic classes have been studied. The evidence base is significantly limited, as there are few randomized controlled trials (RCTs) and most studies are not blinded or are case reports or series. Among controlled trials, results are mixed but mostly negative. Outcomes are typically rate of weight gain during the acute treatment phase, maintaining stability once weight is restored, and the cognitive and behavioral aspects of the disorder. Few medications are significantly effective when patients are underweight, even when nutritional supplements are taken (Barbarich et al., 2004).

Given the typically undesirable weight gain associated with olanzapine in other patient populations, it has been studied as a weight-promoting agent in patients with AN. One RCT involved a 10-week flexible dose trial where 34 patients were randomized to olanzapine plus hospital day treatment or placebo plus hospital day treatment (Bissada, Tasca, Barber, & Bradwejn, 2008). The dose range was 2.5 mg to 10 mg per day with a mean dose of 6.61 mg per day. Although differences were not large between the control and placebo group, patients randomized to olanzapine did demonstrate more rapid weight gain, reached target BMI sooner, and had a greater decrease in obsessive thoughts. Underscoring the difficulty in conducting large studies in patients with AN, over half the patients approached refused to participate. Other small, controlled trials have

demonstrated potential benefit of low-dose olanzapine (2.5–5 mg) in reducing psychopathological aspects of AN and promoting weight stability (Brambilla et al., 2007; Mondraty et al., 2005). Given that olanzapine can prolong QTc, and patients with AN are prone to QTc prolongation, patients should have an electrocardiogram to ensure that the baseline QTc is less than 450 msec. Additionally, hypomagnesemia and hypokalemia contribute to the risk of cardiac arrhythmias. Because patients with AN frequently have electrolyte disturbances, magnesium and potassium should be monitored closely.

Although an earlier, smaller RCT demonstrated some preliminary evidence that fluoxetine may improve outcomes following inpatient treatment for weight restoration (Kaye et al., 2001), a later, larger RCT with improved completion rates was negative. The latter study sought to evaluate whether fluoxetine promotes maintenance of recovery in weight-restored anorexic patients; fluoxetine did not demonstrate any significant benefit compared to placebo (Walsh et al., 2006). All patients in this study received outpatient individual cognitive behavioral therapy for the duration of the 1-year study.

Despite the lackluster results of medications in trials and lack of FDA-approved psychopharmacological treatments, when patients are significantly underweight and psychopathological symptoms are severe, as long as there are no significant contraindications we support a trial of low-dose olanzapine during the acute recovery to promote weight gain and reduce psychopathological symptoms. Of note: although there is no empirical evidence to guide treatment duration with olanzapine, given the known long-term morbidity associated with its use we caution against long-term treatment. Additionally, as previously stated, QTc, potassium, and magnesium must be carefully monitored during treatment with olanzapine to minimize the risk of cardiac arrhythmias. Similarly, we support a trial of fluoxetine up to 60 mg daily to treat psychopathological symptoms and promote weight maintenance during the acute and long-term recovery.

BULIMIA NERVOSA

Psychological Treatments for Bulimia Nervosa

Cognitive Behavioral Therapy–Enhanced

CBT is the gold standard for the treatment of adult BN. More specifically, cognitive behavioral therapy–enhanced (CBT-E; Fairburn, 2008) is an updated and enhanced version of the original form of CBT for BN (Fairburn et al., 1993). CBT-E is a 4-stage individualized treatment that focuses on creating a personalized formulation for each patient. Throughout therapy, the therapist works with the patient to identify binge triggers and address negative body image and rigid dieting behaviors. CBT-E emphasizes self-monitoring, which allows the patient to pay attention to his or her behaviors and urges in real time. This self-monitoring may also highlight the frequent use of body checking and avoidance, a result of the patient’s overvaluation of weight and shape. Throughout treatment the therapist may encourage the patient to complete behavioral experiments that challenge the rigid food rules often present

in EDs. For example, a patient may believe that eating refined carbohydrates will cause rapid weight gain. This patient would be asked to weigh herself one day, eat the feared food, and then weigh herself again the next day. CBT-E also encourages patients to problem-solve for themselves and to replace binge episodes with healthy, pleasurable activities such as knitting, going for a walk, or socializing with others. While there is a set structure to CBT-E, it has the added advantage of being personalized to the unique maintaining mechanisms of each patient's ED. Specifically, the therapist can implement specific interventions designed to address perfectionism, core self-esteem, mood intolerance, and/or interpersonal difficulties if desired. However, these added modules have not been shown to improve treatment outcomes when added to standard CBT-E (Fairburn et al., 2009). Toward the end of treatment the focus shifts to relapse prevention and the importance of maintaining the positive skills previously set in place. Treatment goals and strategies are reassessed at each stage depending on the efficacy of the prior stage (Fairburn, 2008).

In a randomized controlled study, CBT-E produced positive results when compared to an 8-week treatment delay; patients receiving CBT-E showed substantial symptom reduction at the end of treatment, and roughly half of patients exhibited ED features within one standard deviation of community norms (Fairburn et al., 2009). Even more strikingly, in a randomized controlled trial comparing CBT-E to psychoanalytic psychotherapy for BN, 42% of patients in CBT-E but just 6% of patients in psychoanalytic therapy had stopped bingeing and purging after 5 months of treatment (Poulsen et al., 2014). At 2 years, BN remission rates were nearly half (44%) for CBT-E but just 15% for psychoanalytic therapy, suggesting that CBT-E should be considered the first-line treatment for adults with BN.

Interpersonal Psychotherapy

Although approximately half of individuals with BN respond positively to CBT, the corollary is that the other half will remain symptomatic at the end of treatment, highlighting the need for alternative modalities. Interpersonal psychotherapy (IPT) for BN is a short-term supportive therapy that focuses on the interpersonal difficulties that serve as a backdrop to ED symptoms (Agras et al., 2000). More specifically, patients select one of four possible interpersonal problems on which to focus the therapy: interpersonal deficits, interpersonal role disputes, role transitions, or grief (Grilo & Mitchell, 2010). A randomized trial comparing IPT to CBT provides support for the potential efficacy of IPT for treating BN. CBT was superior to IPT at end of treatment in promoting recovery (defined as having no binge or purge behaviors in the previous 28 days Agras et al., 2000); however, no significant difference was observed between CBT and IPT at the 1-year follow-up (Agras et al., 2000). Thus IPT shows promise for BN, although it may not work as quickly as CBT, and more evidence is needed to better understand its efficacy.

Novel Treatments

Nearly half (47.3%) of individuals with BN are not recovered at the completion of CBT-E (Fairburn et al., 2009). For that

reason, several novel psychosocial treatments are under study including dialectical behavioral therapy, family based treatment, and integrative cognitive affective therapy.

Dialectical Behavioral Therapy (DBT)

DBT was originally developed for the treatment of borderline personality disorder and has since been adapted to fit other populations, giving it the added benefit of being transdiagnostic across ED diagnoses. The main treatment foci of DBT are emotion regulation, distress tolerance, interpersonal effectiveness, and mindfulness (Chen & Safer, 2010). In a study examining the effectiveness of DBT for patients with borderline personality disorder and either AN or BN, participants in both categories demonstrated a benefit from DBT at follow-up. Specifically, AN participants showed a significant weight increase, and BN participants showed a reduction in binge frequency (Kroger et al., 2010). However, the low remission rates and lack of change in ED psychopathology demonstrated a need for further research. Another DBT treatment called *appetite-focused DBT* (DBT-AF) is in the early phases of testing (Hill, Craighead, Safer, 2010). This therapy is a combination of appetite awareness training and DBT and combines awareness of internal appetite cues with awareness of emotional state. At the conclusion of a treatment development study, DBT-AF participants reported fewer BN symptoms than participants in the delayed treatment control group (Hill et al., 2010). Given the impulsive nature of BN, it may be beneficial to collect more evidence on both forms of DBT.

Family Based Treatment (FBT)

FBT has shown previous success for adolescent AN (Lock et al., 2010) and may also be a viable option for the treatment of adolescent BN. In a randomized controlled comparison of FBT and supportive therapy, FBT demonstrated an advantage over supportive therapy in the reduction of core bulimic symptoms at end of treatment and follow-up. Furthermore, compared to supportive therapy, FBT appears to achieve therapeutic results at a more rapid rate (le Grange, Crosby, Rathouz, & Leventhal, 2007).

Integrative Cognitive Affective Therapy (ICAT)

ICAT targets BN by exploring the relationship between self-discrepancies (i.e., differences between actual and ideal self) and self-directed coping mechanisms (Wonderlich et al., 2008). For example, patients with BN may use self-directed behaviors (i.e., dieting, purging, over-exercising) as an attempt to distract from or minimize self-discrepancies. In an assessment-only study comparing individuals with BN and a non-ED control group, BN participants showed higher levels of self-discrepancy. Higher levels of self-discrepancy were also associated with more negative self-directed styles in both the BN and control groups (Wonderlich et al., 2008). The first randomized controlled trial comparing ICAT to CBT-E—the current gold-standard treatment for BN—identified no differences in treatment outcome (Wonderlich et al., 2013), highlighting the potential promise of ICAT as a novel treatment modality.

Pharmacological Therapies for BN

Similar to AN, psychosocial therapies are the main and most effective treatments for BN. However, different from AN, some medications have demonstrated consistent efficacy in reducing the psychopathological and behavioral symptoms of BN. The best studied medication (and also the only one with an FDA approval for treatment of BN) is fluoxetine (60 mg daily). It has been shown in reasonably sized RCTs to reduce the frequency of bingeing and purging behaviors and to improve depression, pathological attitudes about eating, and carbohydrate craving ("Fluoxetine in the Treatment", 1992; Goldbloom & Olmsted, 1993; Goldstein, Wilson, Thompson, Potvin, & Rampey, 1995). Studies demonstrate efficacy of fluoxetine as an adjunctive treatment to psychotherapy (Goldbloom & Olmsted, 1997), particularly if patients are responding poorly to psychotherapy alone (Walsh et al., 2000). Additionally, fluoxetine has been shown to improve long-term outcomes and decrease likelihood of relapse (Romano, Halmi, Sarkar, Koke, & Lee, 2002). Other selective serotonin reuptake inhibitors (SSRIs), including sertraline and citalopram, have demonstrated efficacy in trials, suggesting that SSRIs as a class are likely moderately effective in reducing symptoms of BN (Sloan, Mizes, Helbok, & Muck, 2004; Milano, Petrella, Sabatino, & Capasso, 2004; Leombruni et al., 2006). Similar to the SSRIs, several tricyclic antidepressants have been studied and found to be effective in patients with BN, but they are quite limited by unpleasant side effect profiles and rarely used as first-line treatment (Pope, Hudson, & Jonas, 1983).

Although the SSRIs have been studied the most, other medications demonstrate effectiveness in reducing symptoms of BN. Several RCTs have demonstrated that topiramate (50–400 mg daily) is effective in reducing behaviors and psychopathological features of BN (Hoopes et al., 2003; Hedges et al., 2003; Nickel et al., C). Given the role of endogenous opiates in regulating food ingestion, the opiate antagonist naltrexone has been studied in one small RCT and several non-blinded, non-placebo controlled studies (Marrazzi, Bacon, Kinzie, & Luby, 1995; Marenmani, Castrogiovanni, P., & Deltito, 1996). It is effective in reducing bingeing and purging behaviors; however, risks and benefits in patients with preexisting liver disease should be weighed carefully given the risk of hepatic toxicity.

Bupropion carries a relative contraindication for use in patients with BN due to increased seizure risk. A study of immediate-release bupropion in patients with active bingeing and purging found bupropion to be effective in reducing behaviors; however, 4 of 55 subjects had grand mal seizures (Horne et al., 1998), a rate of seizures much higher than the general population. Three of those four were taking 375 mg immediate-release bupropion daily. Although it is established that the immediate-release formulation and peak concentration is associated with increased risk of seizure, no follow-up studies of sustained-release or extended-release formulations have been done in patients with BN. For patients with serious comorbid depression and prior failed trials of other antidepressants, weighing of all risks and benefits may favor a trial of slow-release formulations of bupropion despite this

early study of immediate-release bupropion and the relative contraindication.

BINGE EATING DISORDER

Psychological Treatments for Binge Eating Disorder

Cognitive Behavioral Therapy

Several therapies have been studied for the treatment of BED, with CBT having the most support to date. Similar to CBT for BN, CBT for BED addresses the mechanisms that maintain disordered eating (Fairburn, 2008). CBT for BED focuses on establishing normalized eating behaviors and editing maladaptive thoughts surrounding weight and shape. An added advantage of CBT for BED is that it can be delivered in therapist-led or self-help versions. Self-led therapy involves limited or no interaction with a clinician. Instead, the individual guides his or her own treatment, usually based on a manual such as *Overcoming Binge Eating* (Fairburn, 2013). Self-led treatment has the benefit of being cost effective and widely disseminable to nonspecialty treatment settings (Grilo & Mitchel, 2010).

In recent studies CBT has shown promising results for the treatment of BED. When compared to treatment as usual, CBTgsh (guided self-help, in which patients read *Overcoming Binge Eating* and met with a therapist for eight 20-minute sessions over a 12-week period) led to greater abstinence from binge episodes and an improvement in restraint, eating, weight and shape concerns, depression, and social adjustment (Striegel-Moore et al., 2010). CBTgsh has also shown to be more effective than behavioral weight loss treatment (BWLTL) for patients who do not rapidly respond to treatment. In this case, rapid response is defined as a 65% or greater reduction in binge symptoms by the fourth week of treatment (Masheb & Grilo, 2007). Nonrapid responders showed a greater reduction in binge episodes after receiving CBTgsh. While this research supports the use of CBTgsh, future research should aim to compare the efficacy of self-help methods versus therapist-led CBT (Sysko & Walsh, 2008). CBT (whether self-led or therapist-led) should currently be considered the first-line treatment for BED.

Interpersonal Psychotherapy

Interpersonal psychotherapy (IPT) has shown comparable results to CBT for the treatment of BED (Wilson et al., 2010). Similar to IPT for BN, IPT for BED examines interpersonal functioning and its relationship to disordered eating. When compared to CBTgsh and BWLTL, IPT and CBTgsh showed greater remission than BWLTL (Wilson et al., 2010). Results suggest that, while CBT is still the best option for the treatment of BED, IPT may be beneficial for BED patients who simultaneously endorse low self-esteem and high ED psychopathology (Wilson et al., 2010).

Behavioral Weight Loss Treatment

Many individuals with BED are obese, putting their physical as well as mental health at risk (Grilo et al., 2005). Although

CBT is highly effective in reducing binge eating among individuals with BED, its impact on body weight is negligible. Behavioral Weight Loss Treatment (BWLT) addresses both binge eating and weight-loss simultaneously by focusing on regulating eating patterns in conjunction with healthy dietary restriction (Grilo et al., 2005). In a study comparing BWLT to CBT, both treatments showed significant improvement from baseline to end of treatment, yet BWLT resulted in a faster and larger reductions in BMI than CBT (Munsch et al., 2007). However, it is important to note that two-year follow-up results show that patients who undergo BWLT actually tend to gain the weight back, bringing into question the long-term efficacy of this therapy (Wilson, Wilfley, Agras, & Bryson, 2010). While BWLT does put an important emphasis on healthy weight control, CBT appears to have an advantage for reducing the binge eating episodes that comprise the core psychopathology of BED (Grilo & Masheb, 2005; Munsch et al., 2007; Wilson et al., 2010).

Pharmacological Interventions

Given successful trials with SSRIs in reducing symptoms of BN, numerous studies of SSRIs in BED have followed suit. Small to moderate sized, short-term (6–24 weeks) RCTs of fluoxetine, citalopram, sertraline, fluvoxamine, and escitalopram have demonstrated that SSRIs as a class may be effective in reducing bingeing frequency, weight, and psychopathological features of the illness (Arnold et al., 2002; McElroy et al., 2003; Guerdjikova et al., 2008; Leombruni et al., 2008). Although sometimes significant when compared to placebo, the amount of weight loss is modest at best and generally unsatisfactory to patients and clinicians. In several placebo-controlled RCTs, topiramate has established efficacy in reducing symptoms of BED (McElroy et al., 2003, 2004, 2007). Atomoxetine, a norepinephrine reuptake inhibitor, was studied in a small 10-week flexible-dose placebo-controlled trial, was found to be effective in reducing symptoms of BED, and was well tolerated (McElroy, 2007).

Although in several RCTs sibutramine demonstrated efficacy in treating BED in obese patients (Wilfley et al., 2008; Milano et al., 2005; Appolinario et al., 2003), it was recently withdrawn from the United States market due to increased cardiovascular events and strokes (James et al., 2010).

OTHER SPECIFIED FEEDING OR EATING DISORDER

Given that a substantial minority of individuals with eating disorders will remain in the residual category (i.e., OSFED or UFED) even after *DSM-5* changes (e.g., Thomas et al., under review), findings from randomized controlled trials based on strict *DSM* diagnoses may not generalize to all patients seen in clinical practice. Fortunately, CBT-E was designed to be transdiagnostic—that is, flexibly based on a patient's individualized formulation rather than a specific ED profile (Fairburn et al., 2009). For example, patients with atypical AN may benefit from CBT-E targeted toward AN-like symptoms, and patients with subthreshold BN or purging disorder

may benefit from CBT-E targeted toward BN-like symptoms. Fortunately, many studies to date have shown the efficacy of disorder-specific therapies for patients with subthreshold classification, and CBT has been the most widely studied therapy in this regard. For example, in a CBT study that included both strict and lenient weight criteria for AN, no significant difference was found between the two subgroups on either symptom severity or therapy outcome (McIntosh et al., 2005). These results were further supported in a long-term efficacy study of CBT for AN and subthreshold AN (s-AN) (Ricca et al., 2010). In this study s-AN participants met all *DSM-IV* diagnostic criteria for AN excluding amenorrhea and underweight. AN and s-AN did not show significant differences on clinical measures at baseline, end of treatment, or follow-up, with both groups demonstrating weight gain and a reduction in ED psychopathology (Ricca et al., 2010). Similarly, in a study using both BN and EDNOS participants, all participants regardless of disorder criterion benefited from CBTgsh for the reduction of binge-eating symptoms (Schmidt et al., 2007).

PATIENTS WHO ARE RELUCTANT TO ACCEPT TREATMENT

It is always frustrating when patients are very ill but still refuse treatment. This is common among patients with ED. In general, when medical and psychiatric problems are not emergent patients reserve the right to refuse treatment. For example, a treatment team may recommend inpatient hospitalization for a young woman with AN who has not made any progress after 3 months in outpatient treatment. However, if she is maintaining a BMI of 17.5 kg/m², has no laboratory abnormalities, and demonstrates cardiovascular stability, she reserves the right to refuse treatment. Mental hygiene laws in most states do not support involuntary treatment in non-emergent situations.

In these situations efforts are best focused on building treatment alliance, clarifying thresholds for increasing the level of care, and enhancing motivation for change. Taking the above situation as an example, we would recommend first stabilizing the treatment alliance by expressing both an empathic understanding of the patient's position and your specific concerns regarding her health and reasons for recommending more intensive treatment. Clearly outline for the patient the requirements to maintain a minimum level of safe care, as well as what is necessary to remain in treatment. Enlist the patient in this problem-solving exercise to increase her sense of ownership and control in treatment. Make the requirements explicit with the patient; it can be helpful to co-create a written contract that the patient and team members co-sign. For this particular patient example, the clinician might require the patient to have weekly visits for weight check-in, laboratory evaluation, and vital signs. It would be reasonable to require inpatient treatment should any of these become unstable (e.g., BMI < 16.0 kg/m², laboratory abnormalities, altered vital signs) and to require increased level of care should the patient make no progress (weight gain) with another 4 weeks

of outpatient treatment. If patients repeatedly fail to follow through, this may be grounds for termination from treatment—although we recommend first consulting with your particular clinic or hospital supervisors given medico-legal issues surrounding termination.

MOTIVATIONAL ENHANCEMENT THERAPY

ED patients are often ambivalent about recovery, which can lead to treatment attrition and relapse. Motivational enhancement therapy (MET) addresses the discrepancy between the patient's motivators and life goals and his or her ED. Although the format is similar to the motivational interviewing originally developed to help patients with substance abuse, the content is specific to the symptoms of ED. Therapy can be applied prior to formal, change-oriented treatment or as an adjunctive or stand-alone treatment. In contrast to CBT and IPT, MET is nondirective, allowing the patient to make his or her own arguments for symptom change. Patients are asked to identify personal goals for the future, such as going to college or having children, and then to critically evaluate how their ED either supports or obstructs these aspirations. Other common interventions include identifying the pros and cons of valued ED symptoms, imagining one's life free from ED, and identifying core life values (e.g., honesty, companionship, spirituality). In a randomized controlled trial comparing MET to treatment as usual, MET patients appeared to show longer-term motivation and engagement in treatment (Dean Touyz, Rieger, & Thornton, 2008). Furthermore, in a two-phase trial study treatment outcomes did not differ whether the patients received MET or CBT in the first phase (Katzman et al., 2010). To date most MET studies have been short or uncontrolled, but, given its attempt to address the ego-syntonic nature of ED, MET appears to be a promising treatment approach.

INVOLUNTARY TREATMENT

Involuntary hospitalization usually occurs when there are emergent psychiatric or medical problems. Psychiatrically this is when patients are suicidal, homicidal, actively engaging in severe self-harm behavior, or suffering severe comorbid illness such as depression, mania, or psychosis. For example, a patient with BN who gains 20 pounds, develops suicidal thoughts, and buys a bottle of acetaminophen with the intention to overdose would be hospitalized involuntarily on a psychiatric unit.

Medically, patients may be hospitalized and treated against their will when two conditions are met: (1) when emergent medical conditions related to the ED arise, and (2) when patients fail to demonstrate adequate decision-making capacity. In these situations clinicians must make a determination of whether the patient maintains decision-making capacity to refuse treatment, similar to any other situation in medicine when patients refuse treatment. An example would be a young woman with AN with a BMI of 14.0 kg/m², heart rate of 40 beats per minute, low potassium, and complete food and water refusal. She refuses to be hospitalized for refeeding despite

a thorough explanation of the risks of refusing treatment because she believes she is fat and does not believe the cardiac risks actually apply to her. She is both in an emergent medical situation and fails to demonstrate adequate decision-making capacity. She would be hospitalized and treated despite her preference to leave against advice.

A full discussion of decision-making capacity is beyond the scope of this chapter. This clinical dilemma is not an uncommon challenge when treating patients with severe EDs and acute AN in particular. Often patients are able to recite verbatim the risks of refusing treatment, yet are unable to appreciate how these risks apply to themselves (i.e., they are in denial of their ill status); their thought styles are overly rigid, and they display poor reasoning skills. In situations where a patient fails to demonstrate decision-making capacity in an emergent situation, treatment is generally instituted while ongoing efforts are made to restore the patient's decision-making capacity. In rare situations a legal guardian may be appointed to help make treatment decisions.

Needless to say, it is difficult for both patients and clinicians when involuntary hospitalization occurs. Clinicians face the dilemma of delicately balancing patients' rights, the treatment alliance, and medical and psychiatric safety. On the one hand, unless there is an associated grave risk of not being hospitalized the long-term utility of involuntary hospitalizations is unclear and may alienate patients from treatment. On the other hand, a study of inpatients with EDs found that nearly half of the patients who felt they did not need inpatient treatment at the time of admission had acknowledged that they indeed did need inpatient treatment at 2-week follow-up (Guarda et al., 2007) suggesting that once in treatment (and perhaps feeling better) they are able to accept the help they need.

SUMMARY

In summary, EDs are common psychiatric illnesses that are associated with substantial medical and psychiatric morbidity. As most patients with ED first present in the medical setting, medical clinicians are uniquely poised to make the first diagnosis of a previously covert ED. Patients with EDs often require multidisciplinary teams composed of a medical clinician, therapist, and sometimes a dietitian and/or psychiatrist. With treatment, most patients achieve significant improvement and many fully remit. Although treatment can be challenging for both patients and clinicians, it can be rewarding as well. Increasingly there are empirically supported psychosocial and pharmacologic treatments for EDs. Although nutritional stabilization and psychosocial therapies remain mainstays of treatment, some pharmacological interventions, particularly fluoxetine in BN, have demonstrated efficacy. The main supported treatments currently are FBT for AN; CBT and fluoxetine for BN; and CBT (including a guided self-help format) for BED. Research into promising novel therapies is needed and is ongoing.

CLINICAL PEARLS

- Early identification and treatment can help prevent the associated morbidity and mortality of eating disorders.
- Patients with eating disorders present most often in medical settings, but rarely with a chief complaint of disordered eating (e.g., restricting food, purging, using laxatives). Rather, they present with nonspecific physical or emotional complaints. For example, patients with AN may report lightheadedness or constipation; patients with BN may present with acid reflux or other gastrointestinal complaints; and patients with BED may present with obesity or depression.
- Traits common to AN and BN include perfectionism and dysphoric mood.
- Anxiety, mood, and substance use disorders are highly comorbid with EDs. AN has among the highest mortality rates of any psychiatric disorder, with the majority of deaths attributable to medical complications related to severe malnutrition and suicide (Harris & Barraclough, 1998; Papadopoulos et al., 2009).
- A higher percentage of patients with BN make suicide attempts: 3%–20% in AN and 25%–35% in BN.
- Overall, outcomes for individuals with BN are better than for AN.
- Many patients with ED, particularly AN and BN, present with medical complaints that are atypical or more severe than would be expected given their demographics and otherwise healthy status.
- Interestingly, there is a subset of patients who meet all the criteria for AN except for not endorsing fear of weight gain. Such patients are especially common in culturally non-Western and youth populations (Becker et al., 2009).
- During the initial evaluation we suggest asking patients specifically what they ate and drank for all meals and snacks on the day prior to evaluation.
- It can be helpful to ask in a way that decreases shame; for example, “Some patients who are struggling with controlling their eating and weight induce vomiting or use laxatives. Have you found yourself doing this?”
- To assess exercise, it is helpful to specifically ask how much of the day is spent active (e.g., not sitting down).
- For an empathic but firm approach, the following statement may be used to ease the anguish about getting weighed: “I realize getting weighed may be difficult for you. In order for me to provide you with good and safe care, I will have to weigh you at each visit. It is likely to be more difficult in the beginning and get easier with time. Let’s go ahead and get it out of the way for today’s visit.”
- The American Dental Association (ADA) currently recommends that patients not brush their teeth immediately

after vomiting but rather rinse with baking soda, which helps to neutralize the destructive effects of the stomach acid (<http://www.mouthhealthy.org/en/az-topics/e/eating-disorders>).

- Approximately 30% of ED patients do not meet full criteria for AN, BN, or BED, and will fall into the residual category of Other Specified Feeding or Eating Disorder (Thomas et al., under review).

DISCLOSURES

Dr. Brennan and Ms. Nevins have no conflicts of interest to disclose. Dr. Thomas receives royalties from Hazelden and Harvard Health Publications for the sale of her book, *Almost Anorexic: Is My (Or My Loved One’s) Relationship with Food a Problem?*.

PRIMARY SLEEP DISORDERS IN MEDICAL AND NEUROLOGICAL PATIENTS

Amit Chopra and Jarrett W. Richardson

INTRODUCTION

The consulting psychiatrist may be called on to help manage variety of psychiatric issues that arise during hospitalization in a medical or surgical setting, including intensive care settings. Sleep disturbances and their consequences are amongst the most common reasons for consultation. Assessment of sleep is a critical component of the psychiatric evaluation in medically ill patients due to multi-factorial etiology of sleep complaints in this population. Comorbid psychiatric disorders, iatrogenic causes, or an undiagnosed primary sleep disorder associated with medical/neurological disorders may lead to sleep complaints in hospitalized patients. This chapter reviews the spectrum of the primary sleep disorders commonly encountered in medical, neurological and ICU patients. This chapter also covers the effects on sleep of medications and environmental factors in hospital settings.

PRIMARY SLEEP DISORDERS IN MEDICAL PATIENTS

ENDOCRINE DISORDERS

Hypothyroidism

Patients with hypothyroidism may present with excessive sleepiness and fatigue. Polysomnography changes in sleep in hypothyroid patients include decreased slow wave sleep (SWS), which tends to normalize after thyroid replacement. A higher incidence of obstructive sleep apnea (OSA) has been noted in patients with untreated hypothyroidism. Factors such as obesity, myopathy, and upper airway edema may contribute to increased incidence of OSA in patients with hypothyroidism.

Acromegaly

Acromegaly is characterized by hypersecretion of growth hormone, usually secondary to pituitary adenoma. Approximately 60%–80% of the patients with acromegaly complain of sleep apnea which is primarily obstructive in nature, although,

central apnea is noted in one-third of the patients. Orofacial anatomic abnormalities secondary to excess growth hormone secretion may lead to development of sleep apnea in patients with acromegaly. Sleep evaluation should be considered in patients with suspected apnea syndromes. Neurosurgical treatment of pituitary adenoma and medication treatments including bromocriptine and octreotide may improve sleep apnea. Patients with persistent apneic episodes despite surgical and medical treatments may benefit from positive airway pressure therapy.

Cushing Syndrome

Patients with Cushing syndrome have an excess of adrenocorticosteroid hormones. Sleep complaints, including insomnia and OSA, are common. Fat accumulation in the parapharyngeal area may play an important role in pathogenesis of OSA. Polysomnography findings include changes in sleep architecture, decreased sleep efficiency, increased sleep fragmentation, decreased slow wave sleep, decreased REM latency, and increased REM density.

Diabetes Mellitus

Type 2 diabetes is a major public health concern with high morbidity, mortality, and health-care costs. Increased prevalence of sleep problems including difficulty initiating sleep, difficulty maintaining sleep, excessive daytime drowsiness, and sleep-disordered breathing have been reported in patients with type 2 diabetes mellitus.

A growing number of epidemiologic studies, originating from various geographic regions and involving diverse study populations, have suggested the existence of an independent link between markers of severity of OSA and an increased risk of type 2 diabetes. Numerous studies have examined the effects of continuous positive airway pressure (CPAP) treatment on glucose metabolism both in diabetic and nondiabetic populations. There is accumulating evidence suggesting that metabolic abnormalities can be partially corrected by CPAP treatment, which supports the concept of a causal link between OSA and altered glucose control.

The pathophysiological mechanisms leading to alterations in glucose metabolism in OSA patients are likely to be

multiple. High sympathetic nervous system activity, intermittent hypoxia, sleep fragmentation and sleep loss, dysregulation of the hypothalamic-pituitary axis, endothelial dysfunction, and alterations in cytokine and adipokine release have all been proposed as potential mechanisms for abnormal glucose metabolism in OSA patients.

Obesity

Obesity is a serious medical disorder resulting in increased risk of morbidity and mortality due to both acute and chronic medical conditions. Sleep disorders including sleep-disordered breathing (SDB), excessive daytime somnolence, night eating syndrome, and sleep-related eating disorders have been noted in obese patients.

Increased incidence of SDB, including OSA and obesity hypoventilation syndrome, has been noted in obese patients. For every 10 kg increment in weight, the risk for OSA increases by more than twofold, while an increase in the body mass index (BMI) by one standard deviation is associated with a fourfold increase in the prevalence of OSA. The possible etiological factors may include gender (OSA more common in obese males), anatomical and neuromuscular factors, and hormonal and genetic factors.

Obesity hypoventilation syndrome is defined as a combination of obesity, chronic daytime hypercapnia ($\text{PaCO}_2 > 45$ mm Hg), and a SDB in the absence of other known causes of hypercapnia. The prevalence of OHS in sleep apnea syndrome is 8%–10% when BMI is between 30–34 kg/m² and 18%–25% when BMI is >40 kg/m². Conversely, not all patients with OHS have sleep apnea syndrome. In approximately 90% of patients with OHS the SDB consists of OSA. The remaining 10% of patients with OHS have an apnea–hypopnea index less than 5. The pathophysiology of OHS results from complex interactions, among which are increased work of breathing related to obesity, abnormal load responsiveness, and repeated airway occlusion during sleep.

The most important therapy for OSA in obese patients is weight loss. Weight loss changes pharyngeal anatomy and decreases airway collapsibility by increasing the pharyngeal closing pressure. A longitudinal study with a 4-year polysomnogram follow-up showed that a 3% change in AHI was noted with each percent change in weight. In one controlled study, 23 obese patients were assigned to receive either dietary counseling or no intervention. Those who experienced weight loss of 10 kg or more had significant reduction in apnea index (AI), improvement in daytime sleepiness, and oxyhemoglobin saturation. The most impressive results of AHI improvement are derived from those morbidly obese patients who underwent bariatric surgery. One of the studies noted a 72% reduction in the mean AHI of 47 morbidly obese patients after 1 year of undergoing Roux-en-Y gastric surgery. However, at 7-year follow-up, 47% had regained considerable weight and were diagnosed with severe OSA. Alternative treatment options for OSA and OHS in obese patients include CPAP and bilevel positive airway pressure (BPAP) devices.

PULMONARY DISORDERS

More than 50% of the patients with COPD experience difficulty initiating and maintaining sleep. Sleep is interrupted in COPD patients due to production of secretions, coughing, and dyspnea related to airway constriction. Patients complain of multiple awakenings during night, daytime fatigue and somnolence. COPD is associated with nocturnal hypoxemia, especially during REM sleep, due to loss of muscle tone of the accessory muscles of respiration during REM sleep. Coexistence of obstructive sleep apnea (OSA) and COPD is termed *overlap syndrome*, and its prevalence has been estimated at 29% according to one study. Patients with overlap syndrome are at greater risk of prolonged oxygen desaturations at night as compared to those with OSA alone, and it appears to be associated with increased morbidity and mortality in these patients. Treatment of OSA with CPAP therapy has been associated with improved outcomes and decreased mortality in patients with overlap syndrome.

Patients with restrictive lung disorders and chest wall abnormalities (kyphoscoliosis) are at risk of sleep related hypoventilation/hypoxemia. Polysomnography findings include frequent arousals, increased wakefulness after sleep onset, and nocturnal hypoxemia. Other consequences of nocturnal hypoxemia include pulmonary hypertension, *cor pulmonale*, and neurocognitive dysfunction. These patients likely require BPAP for treatment of sleep-related hypoventilation/hypoxemia.

CARDIOVASCULAR DISORDERS

Consistent data suggest strong associations between sleep-disordered breathing and hypertension, coronary artery disease, congestive heart failure, and cardiac arrhythmias. Potential mechanisms of increased of cardiovascular events in patients with OSA include increased sympathetic activity during sleep, inflammation due to increased proinflammatory cytokines in OSA, hypercoagulability, endothelial dysfunction, oxidative stress, and insulin resistance.

OSA has been implicated as a cause of nocturnal ST depression and angina pectoris. Higher incidence of fatal and non-fatal cardiovascular events has been reported in patients with severe OSA. Nocturnal arrhythmias may contribute to higher night time prevalence of sudden death in patients with OSA. Early recognition and treatment of sleep-disordered breathing with positive airway pressure therapy in patients with cardiovascular disorders has been associated with improved morbidity and mortality.

Patients with congestive heart failure (CHF) may develop both OSA and central sleep apnea (CSA). CHF patients CSA may develop Cheyne Stokes respiration (CSR) with periodic crescendo-decrescendo breathing accompanied with apneas predominantly during NREM stages 1 and 2. The risk factors for CSA-CSR pattern include old age, male gender, $\text{PaCO}_2 < 38$ mm Hg, atrial fibrillation, and left ventricular ejection fraction $< 40\%$. CHF patients with CSA-CSR pattern have a greater mortality risk as compared to those without CSR pattern. Therapy for CSA-CSR pattern begins with

optimization of medical treatment of heart failure. Treatment with CPAP, adaptive servoventilation device, and supplemental O₂ should be considered for CSA-CSR.

RENAL DISORDERS

Sleep apnea is prevalent in over 50% of the patients with chronic kidney disease (CKD) and end stage renal disease (ESRD). Factors including fluid overload and altered control of breathing have been proposed as causative factors for sleep apnea in ESRD patients.

Presence of untreated sleep apnea in CKD and ESRD patients may have detrimental effect on renal function as sleep apnea has been associated with nocturnal hypoxemia, increased systemic blood pressure, inflammatory cytokines, and increased sympathetic activity. In addition, sleep apnea can lead to disturbed night sleep, daytime sleepiness, and diminished quality of life in these patients. Use of positive airway pressure therapy, nocturnal hemodialysis, and renal transplant have been found to be effective in treatment of sleep apnea in CKD and ESRD.

Patients with CKD and ESRD also have increased prevalence (20%–80%) of restless legs syndrome and periodic limb movement disorder leading to sleep disruption. Increased periodic limb movement index may adversely affect sleep continuity and lead to cyclical apneas due to ventilatory instability. Periodic limb movement disorder has been shown to be better predictor of mortality than serum albumin and other parameters monitored in dialysis patients. Treatment with dopamine agonists and gabapentin (adjusted dose due to renal elimination) may be helpful in these patients. Iron supplementation and erythropoietin for correction of anemia may be considered as well.

GASTROINTESTINAL DISORDERS

Nocturnal gastroesophageal reflux disease (GERD) appears to be common in patients with OSA. In one study, approximately 50% of the episodes of GERD occurring in patients with OSA were related to apneas or hypopneas. Polysomnography findings in patients with GERD include repeated arousals followed by swallowing as represented by an increase in chin EMG activity. GERD episodes may be related to sleep-related laryngospasm which is characterized by sudden awakening accompanied with sensation of suffocation and apnea lasting from 5–45 seconds followed by stridor.

Therapy may involve elevating the head of the bed, pharmacotherapy (proton pump inhibitors), or antireflux surgery. CPAP therapy has been shown to decrease the frequency of nocturnal GERD symptoms both in patients with and without OSA. This antireflux activity may be attributed to elevation of intraesophageal pressure as well as to constriction of lower esophageal sphincter.

RHEUMATOLOGICAL DISORDERS

Arthritis is the leading cause of chronic illness in the United States.

Seventy-two percent of the adults aged 55 years and older with arthritis report sleep difficulties.

Sleep complaints and related daytime symptoms occur in 54%–70% of adult Rheumatoid arthritis (RA) patients, including difficulty falling asleep, poor quality sleep, non-restorative sleep, numerous awakenings during the night, early morning awakening, excessive daytime sleepiness, and fatigue. Sleep architecture—total sleep time, rapid eye movement (REM) sleep latency, non-REM (NREM) sleep stages, REM sleep, and number of sleep cycles—in RA patients is usually normal. NREM sleep latency is usually normal but may be prolonged during disease flare.

Improvement in sleep parameters, including an increase in SWS together with a decrease in REM sleep, correlated with a decrease in pain and morning stiffness; a decrease in wake stage was followed by a decrease in pain level and morning stiffness in RA. Associated primary sleep disorders, including sleep apnea and periodic leg movements of sleep can impair sleep. Sleep apnea affects 7.5%–30.8% in RA subjects and can result from temporomandibular joint destruction narrowing the posterior airspace or compromised position of the head and neck, limited mouth opening, and distorted anatomy with reduced upper airway tone. Depressive symptoms are present in 13%–20% of RA patients. Data from studies in RA patients suggest that pain exacerbates sleep complaints in RA patients and that both pain and sleep disturbances may contribute to depression.

Systemic lupus erythematosus (SLE) is associated with complaints of poor sleep quality, fatigue, pain, and depression. Polysomnographic findings associated with increased disease activity include reduced sleep efficiency, reduced delta sleep, sleep fragmentation, increased arousals, and alpha intrusions. Associated primary sleep disorders include sleep apnea, periodic leg movements of sleep, and narcolepsy with cataplexy. Pain, depression, and insomnia are common complaints associated with osteoarthritis. Polysomnography demonstrates increased Stage 1 NREM sleep, reduced Stage 2 NREM sleep, and increased sleep fragmentation.

Adequate treatment of arthritic pain, use of cognitive behavioral therapy for insomnia (CBT-I), and/or judicious use of hypnotic/sedative medications along with assessment of comorbid depressive symptoms should be considered for insomnia related to rheumatological disorders. Associated sleep disorders include sleep apnea, narcolepsy, and periodic limb movements of sleep; these should be adequately treated to improve outcomes.

CHRONIC FATIGUE AND FIBROMYALGIA SYNDROMES

Sleep disorders—including insomnia, restless legs syndrome, periodic leg movements of sleep, and sleep-disordered breathing—are common in chronic fatigue and fibromyalgia syndromes. PSG findings in fibromyalgia patients include poor sleep efficiency, slightly longer sleep latency with increased wakefulness in the first half of the night. In CFS, longer sleep latency (including REM sleep latency) with reduced REM sleep have been noted. Non-restorative sleep has been linked to alpha activity in

NREM sleep in fibromyalgia patients, although this may be a nonspecific finding and has not been correlated with symptom severity. Fibromyalgia patients have been shown to consistently demonstrate fewer sleep spindles during stage 2 of sleep.

PAIN SYNDROMES (ACUTE AND CHRONIC)

Sleep and pain appear to have bidirectional interaction as pain can lead to sleep interruption, and, conversely, poor sleep can magnify perception of pain intensity. Patients with acute post-operative pain demonstrate shortened and fragmented sleep reduced amount of slow wave and REM sleep as demonstrated in polysomnography studies. The sleep architecture tends to normalize after resolution of acute pain.

Patients with chronic pain often complain of insomnia and daytime somnolence and inactivity, which further exacerbate insomnia. Iatrogenic sleep disturbances due to medications, especially opiates, may further worsen symptoms of daytime drowsiness and fatigue. Patients on chronic opiate therapy, especially at higher doses, are at greater risk of development of central sleep apnea syndromes. Development of depression in patients with chronic pain may further lead to sleep disturbances.

Treatment of sleep disturbances in patients with pain syndromes involves adequate management of pain with judicious use of painkiller medications, adequate sleep hygiene, physical exercise, and treatment of comorbid psychiatric disorders such as depression. Patients with chronic pain refractory to pain medications should be considered for referral to chronic pain management programs. Use of medications such as benzodiazepines in patients on chronic opiate treatment is a concern due to risk of respiratory depression, worsening of sleep apnea syndromes, and increased daytime sedation. Nonmedication therapies such as CBT for insomnia may as well be considered in these patients.

MALIGNANCY

Cancer patients frequently report disturbed sleep and daytime fatigue as distressing symptoms; sleep disturbances may be prevalent in 40%–50% of cancer patients. Prevalence of sleep disturbance may be relatively higher in younger patients (54%), and it may be attributed to higher rates of anxiety and depression in younger patients. Pain, depression, and anxiety are among the common etiologic factors for sleep disturbances—although other factors, including delirium in the later stages of malignant illness, medications (steroids, bronchodilators, chemotherapeutic agents), and environmental factors in institutionalized patients may also be implicated. Adequate treatment of pain has been associated with increases in total sleep time and sleep quality in cancer patients. Recognition and treatment of depression and anxiety can be associated with improved sleep outcomes in cancer patients.

HIV/AIDS

Insomnia has been reported in 73% of the patients meeting criteria for HIV/AIDS and risk factors for insomnia include anxiety, depression, and cognitive impairment. Somatic symptoms associated with sleep disturbance in HIV/AIDS

patients include night sweats, chills, headache, and diarrhea. Polysomnography studies show increased slow-wave sleep in patients with early asymptomatic HIV infection. These findings have been linked to release of cytokines (sleep inducing effect), which are also associated with fatigue and subjective sleepiness. Slow wave sleep has been reported to be decreased in patients with advanced AIDS.

Addressing sleep complaints in HIV/AIDS patients involves comprehensive assessment and treatment of factors such as aggressive management of CNS involvement (CNS metastases, delirium, AIDS-related complex), adequate management of pain, amelioration of medical symptoms (including cough, dyspnea, headaches and diarrhea), and adequate treatment of anxiety and depression. In addition, other measures including sleep hygiene, progressive muscle relaxation, biofeedback, and guided imagery may be helpful.

PRIMARY SLEEP DISORDERS IN NEUROLOGICAL PATIENTS

ALZHEIMER'S DEMENTIA

Sleep disorders in Alzheimer's dementia (AD) are frequently correlated with severity of disease progression. Sleep disorders may range from insomnia, hypersomnia, SDB, parasomnias, sleep-related movement disorders, and circadian rhythm sleep disorders. Polysomnography findings in AD patients include reduced sleep efficiency, reduced sleep time, reduction in spindles and K complexes, reduced REM sleep, and increased arousals. Sleep fragmentation is associated with insomnia, nocturnal wandering, daytime sleepiness and cognitive impairment. Degeneration of specific nuclei in the brain including cholinergic neurons in the nucleus basalis of Meynert, pedunculopontine nucleus, and laterodorsal tegmental nuclei may be implicated in decreased REM sleep in AD patients. Degeneration of suprachiasmatic nucleus is thought to be primarily responsible for circadian rhythm disorders in AD.

Nonpharmacological interventions for sleep disorders include behavioral, environmental, psychosocial management (CBT), and support and education for families have been associated with improved outcomes in AD patients. Treatable causes of sleep disruption including anxiety, depression, and sleep apnea should be addressed. Phototherapy may be helpful in AD patients with circadian rhythm disorders. Medications such as sedatives-hypnotics should be used cautiously due to risk of falls, cognitive impairment, and worsening of preexisting SDB. Medications may be used in AD patients with severe nocturnal agitation and agents such as trazodone and low dose antipsychotics can be considered for specific target symptoms. The use of these medications should be carefully and regularly reviewed due to potential drug-associated adverse effects.

PARKINSON'S DISEASE

Sleep complaints are common non-motor symptoms of Parkinson's disease and related syndromes with prevalence in 60%–90% of the patients. Sleep disorders can range from

insomnia, sleep fragmentation, early morning awakenings, restless legs syndrome, REM sleep behavior disorder, excessive daytime drowsiness, and sleep attacks. Polysomnographic findings in PD patients include decreased total sleep time, poor sleep efficiency, reduced SWS, reduced REM sleep, and REM sleep without atonia. The etiology of sleep problems in PD is multifactorial including motor symptoms of PD (difficulty turning in bed, dyskinesias) interrupting sleep, comorbid psychiatric disorders (depression and anxiety), and medication effects. Sleep disturbance, depression, and lack of independence are the primary determinants of poor quality of life.

Improved sleep hygiene plays an important role in treatment of insomnia in PD patients. Use of dopaminergic agents to treat motor symptoms of PD is the mainstay of treatment. Preliminary evidence suggests that deep brain stimulation for treatment of advanced PD may improve sleep architecture, restless legs syndrome, and daytime sleepiness, although deep brain stimulation has no impact on REM sleep behavior disorder (RBD). Treatment of restless legs syndrome with dopamine agonists (pramipexole/ropinirole) should be considered, as L-dopa treatment may be associated with increased rates of augmentation as compared to dopamine agonists. RBD symptoms may respond to treatment with low-dose clonazepam and melatonin. Comorbid psychiatric disorders such as anxiety and depression should be adequately treated using medication and psychological therapies. Close monitoring of side effects of anti-parkinsonian medications including excessive daytime drowsiness and hallucinations is essential. Adjustment in medication dosages under the supervision of neurologists and use of low dose atypical antipsychotics (quetiapine, clozapine) may be effective in treatment of dopaminergic-induced hallucinations.

EPILEPSY

The interactions between sleep and epilepsy are complex and multidimensional. Sleep deprivation can activate epileptiform activity and interfere with seizure control whereas seizures can disrupt sleep, especially nocturnal epilepsy syndromes, and lead to excessive daytime drowsiness, as do anticonvulsant medications. NREM sleep has been associated with greater tendency for propagation of epileptiform discharges when compared to REM sleep due to excessive diffuse cortical synchronization. Polysomnography findings in epilepsy patients include increase in sleep latency, increase wake time after sleep onset, increased N1 and N2 sleep, and decreased slow wave and REM sleep.

Certain seizure disorders occur predominantly or exclusively during sleep and these may include nocturnal frontal lobe epilepsy (NFLE), benign rolandic epilepsy of childhood with centrotemporal spikes, and juvenile myoclonic epilepsy. Clinical features of sleep-related seizures include abrupt awakenings, abnormal motor activity (automatisms, focal or generalized tonic clonic movements, tongue biting), and urinary incontinence. Postictal confusion may be evident after nocturnal seizures. Abnormal sleep related behaviors such as parasomnias and pseudo-seizures need to be considered in differential diagnosis of nocturnal epilepsy syndromes.

Obstructive sleep apnea (OSA) may have detrimental effects on various aspects of epilepsy: seizure control, mood disorders, cognitive dysfunction, and quality of life. Higher prevalence (up to 30%) of OSA has been reported in drug-resistant epilepsy patients (Malow, Levy, Maturen, & Bowes, 2000), while older epilepsy patients with OSA have been found to show poor seizure control compared with age-matched epilepsy patients not affected by OSA (Chihorek, Abou-Khalil, & Malow, 2007). Continuous positive airway pressure treatment (CPAP) of patients with epilepsy and OSA was found to reduce EEG interictal epileptiform activity (Oliveira, Zamagni, Dolso, Bassetti, & Gigli, 2000) and improved seizure control after CPAP in epilepsy patients with coexisting OSA has also been reported. In a pilot study of patients with drug-resistant epilepsy plus OSA, randomized to receive therapeutic or sham continuous CPAP, seizures were reduced by 50% or more (compared with the baseline period) in 28% of the patients undergoing therapeutic CPAP versus 15% of those receiving sham CPAP (Malow, Foldvary-Schaefer, Vaughn, Selwa, Chervin, et al., 2008).

Several factors can contribute to insomnia in epilepsy patients. These include the fragmentation of sleep due to recurrent seizures; the effects of some antiepileptic drugs (AEDs) such as lamotrigine, felbamate and levetiracetam; and the effects of comorbid anxiety and depression. Sleep fragmentation is frequently reported in nocturnal frontal lobe epilepsy (NFLE) and also in temporal lobe epilepsy (TLE), in which the frequent association with depression may also play an important role in inducing insomnia. Epileptic patients with sleep disturbance, mainly those with insomnia, were reported to have quality of life scores lower than patients without sleep complaints (Piperidou, Karlovasitou, Triantafyllou, Terzoudi, Constantinidis, et al., 2008a; Piperidou, Karlovasitou, Triantafyllou, Dimitrakoudi, Terzoudi, et al., 2008b).

Epilepsy patients frequently experience excessive daytime sleepiness (EDS), a complaint of multifactorial origin. Factors associated with EDS in epilepsy patients include poor or insufficient sleep, nocturnal seizures, AEDs, depression, and sleep disorders such as OSA (Manni & Tartara, 2000).

STROKE

Patients with deep hemispheric lesions may present with increased yawning and hypersomnia, while patients with thalamic, subcortical, and pontine strokes are likely to suffer from insomnia. Comorbid depression may further contribute to sleep disturbances in stroke patients.

Higher prevalence of OSA (up to 60%) has been noted in patients with cerebrovascular events. OSA is the most common form of SDB in these patients, whereas CSA and Cheyne stokes breathing pattern may be present in 30%–40% of the patients. OSA is known to increase the risk of cerebrovascular disease, with obstructive apneas being associated with cerebral hypoperfusion. Other factors such as altered cerebral autoregulation, impaired endothelial function, and accelerated proinflammatory states may play a role as well.

Restless legs syndrome has been noted in patients with pontine, thalamic, basal ganglia and corona radiata infarcts. Pontine

tegmental strokes can lead to RBD, where patients can act out violent dreams with evidence of REM sleep without atonia on polysomnography studies. Sleep-disordered breathing and sleep-wake disturbances negatively affect short and long-term stroke outcomes, length of hospitalization, and stroke recurrence risk.

CPAP therapy is the treatment of choice for obstructive sleep apnea (OSA) and this treatment has potential to reverse vascular risk in stroke patients. An adaptive servoventilation device should be considered for treatment of central sleep apnea syndromes. Hypnotics and sedative antidepressants may aggravate SDB and neurologic recovery and should be used with caution. Modafinil or activating antidepressants may be considered for management of hypersomnia. Poststroke sleep-related movement disorders can be treated with dopaminergic drugs (pramipexole/ropinirole); REM sleep behavior disorder can be treated with clonazepam or melatonin (Hermann & Bassetti, 2009).

TRAUMATIC BRAIN INJURY

Approximately 30%–70% of the patients with TBI experience sleep disturbances which often exacerbate TBI symptoms and impede both rehabilitation process and ability to return to work. Insomnia is one of the most common and well-documented syndromes seen in patients with TBI. Risk factors associated with insomnia include mild TBI, higher levels of fatigue, depression, and pain. Insomnia not only represents a problem immediately following injury but also appears to persist for months and years after a TBI. Insomnia is often associated with daytime fatigue and drowsiness in TBI patients.

Higher incidence of other sleep disorders including OSA, periodic limb movements, and narcolepsy has been noted in TBI patients. Among circadian rhythm disorders, delayed sleep phase syndrome is the most common and is often misinterpreted as insomnia by patients and clinicians alike (Orff, Ayalon, & Drummond, 2009).

Cognitive behavioral therapy for insomnia (CBT-I) holds promise for treatment of insomnia in general but the use of this therapy is not extensively studied in these patients. Use of hypnotic medications should be carefully considered due to potential side effects including daytime drowsiness, dizziness or lightheadedness, and cognitive and psychomotor impairments, all of which are likely to be particularly detrimental for TBI patients. Treatment of delayed sleep phase syndrome in TBI patients can be considered with use of bright light therapy in the morning and use of low-dose melatonin in the evening time. TBI patients with suspected SDB should undergo polysomnography evaluation and use of CPAP for treatment of OSA should be considered. Daytime hypersomnia may respond to use of modafinil or stimulant medications.

PRIMARY SLEEP DISORDERS IN CRITICALLY ILL PATIENTS (ICU SETTING)

Sleep disruption and deprivation with resultant daytime sleepiness are common phenomenon in ICU patients and

are result of multitude of factors including acute illness, iatrogenic factors (medications, medical interventions), pain, environmental (sound and light exposure), and psychosocial factors. Polysomnography studies in ICU patients have shown prolonged sleep latency, decreased sleep efficiency, predominance of stage 1 and 2 NREM sleep, decreased or absent stage 3 NREM and REM sleep, and sleep fragmentation associated with frequent arousals. Those factors endorsed by patients to be most stressful in the ICU setting are the presence of endotracheal tubes, being injected with needles, experiencing pain, and being physically disturbed (Cochran & Ganong, 1989). According to nursing literature in the ICU setting, being restrained and experiencing loss of personal control have the most distressing effect on patients.

Parasomnias are common problems for patients with significant medical disorders. Of the injurious sleep-related behavior that occurs in hospitalized patients, REM sleep behavior disorder is the most common (85%) in the ICU, and night terrors and sleepwalking accounting for the remainder (Schenck & Mahowald, 1991). Parasomnias associated with ICU situations include (1) parasomnias originating in the ICU (e.g., stroke-induced); (2) admission to ICUs resulting from parasomnia-induced injuries; and (3) parasomnias in patients admitted to ICU for other medical problems. Parasomnias including REM sleep behavior disorder, night terrors, somnambulism, and confusional arousals in hospitalized patients, particularly those with known CNS disorders (dementia syndromes, Parkinson's disease, CVAs, and toxic/metabolic states), are important in the differential diagnosis of patients with nocturnal injurious behavior.

Changes in behavior and cognition have been associated with sleep deprivation in ICU patients and these include fatigue, mood changes, irritability, disorientation, short-term memory impairment, perceptual disturbances and visual hallucinations. Sleep deprivation has been considered as an important contributor to the development of ICU syndrome which is noted in up to 40% of the patients admitted to the ICU. Delirium with sleep-wake irregularities is integral to the ICU syndrome. The symptoms of ICU syndrome are rapid in onset and include disorientation, fluctuating levels of consciousness, delusions, hallucinations, and behavioral symptoms including aggression, lasting generally for 24–48 hours.

Daytime sleepiness and cognitive impairment associated with sleep disturbance can compromise the ability of ICU patients to engage in complex tasks such as respiratory muscle training, coughing, and deep breathing that are required to facilitate weaning from mechanical ventilation. Sleep disturbance in the ICU has been associated with increased morbidity and mortality, which is at least partly due to the impaired cellular function and immunity that results from sleep disturbance (Krachman, S'Alonzo, & Criner, 1995). Sleep disturbance in the ICU that persists after hospitalization has been associated with poor outcomes (Hurel, Loirat, Saulnier, Nicolas, & Brivet, 1997).

Interventions used in ICU settings to improve sleep and behavioral symptoms vary from supportive care to aggressive pharmacological management. These interventions may

include providing psychological support, minimizing environmental noise and light exposure during night, optimizing pain treatment, avoidance of medications disrupting sleep architecture, orientation to day/night patterns, and judicious use of sedative/hypnotic medications. Medications including benzodiazepines and opiates may be associated with respiratory depression and worsening of SDB in patients, and therefore should be used carefully. Medical management of severely disrupted sleep/wake patterns may include aggressive pharmacologic overnight sedation with intravenous midazolam or propofol in the ICU, which has been shown to benefit sleep but not necessarily reduce anxiety or depression (Treggiari-Venzi, Borgeat, Fuchs-Buder, Gachoud, & Suter, 1996; Krachman, S'Alonzo, & Criner, 1995).

EFFECT OF MEDICATIONS

In addition to the effects of the primary illness, pain, environmental disturbances, and caregiver influences, many of the medications that are used to treat medically ill patients have significant effects on sleep. As a rule, any drug that crosses the blood–brain barrier is likely to have an effect on receptors that affect sleep. Sleep is known to be affected by the action of drugs on many receptors, as seen in Table 33.1 (Pascue, 1994). Essentially all centrally acting substances that have been studied have been found to have effects on sleep. Some agents affect primarily the circadian pacemaker

Table 33.1 RELATIONSHIP OF NEURO-TRANSMITTERS TO SLEEP

5HT	(agonist—normal activity helps with sleep maintenance, excessive 5HT activity leads to increased number of awakenings, more stage one and less stage REM sleep)
NE	(agonist—normal activity helps with sustained alertness, excessive NE activity leads to sleep disruption) (antagonist—leads to sedation)
DA	(agonist—excessive activity leads to increased wakefulness) (antagonist—leads to sedation)
Ach	(agonist—activity higher in REM than non-REM sleep, and increased in daytime arousal; excessive activity leads to excessive arousal) (antagonist—anticholinergic activity decreases REM-related phenomena)
H1	(antagonists—produce increased daytime drowsiness but little effect on Wake After Sleep Onset) (agonists—lead to increased wakefulness)
H2	(antagonists—little effect on daytime or sleep but have been reported to cause confusion)
H3	(regulates histamine release—agonist produces deeper sleep in rats) Adenosine (neuromodulator—inhibits release of Ach, NE, DA, 5HT, GABA) (antagonism by methylxanthines is excitatory)

system—arginine-vasopressin, GABA, melatonin, gastrin-releasing peptide, neuropeptide-Y, peptide histidine isoleucine, vasoactive intestinal peptide, glutamate, pancreatic polypeptide, and corticosteroids (Dawson & Armstrong, 1996).

Other substances and medications affect various sleep components such as initial sleep latency, number of awakenings, number of sleep stage shifts, percent stage one, percent stage two, percent REM sleep, REM sleep density, REM sleep latency, slow wave sleep, and the number of arousals or discontinuities in sleep as well as evidences of sleep interruptions manifest by alpha rhythm intrusion or K-complexes. Many medications have sedating effects during the daytime that adversely affect subjective or objective functioning, and drugs that disturb sleep may lead to similar daytime problems (Dietrich, 1997; Liborio & Terzano, 1996; Nicholson, Bradley, & Pascoe, 1994; Novak & Shapiro, 1997; Obermeyer & Benca, 1996). See Table 33.2 and chapters 30 and 31.

Very few drugs have a beneficial effect on sleep, and drugs may have different effects on normal subjects than on patients with an illness. Drugs generally decrease slow wave sleep and decrease REM sleep unless proven otherwise. The exceptions are few and seldom helpful enough to compensate for other adverse effects on sleep properties. Alcohol in healthy young adults, lithium, clonidine (α_2 agonist), some TCAs, and chlorpromazine have been reported in some limited situations to increase slow wave sleep. Reserpine, yohimbine (α_2 antagonist), physostigmine (cholinomimetic), and steroids under certain circumstances increase REM sleep. Some drugs that may initially increase a particular sleep component over time will decrease this stage of sleep if administration is continued. If the drug improves some underlying disorder with secondary improvement in sleep, only then is it likely to have long-term benefit.

Rather than assume that these various factors are too complex to be useful in the psychiatric care of the medically ill patient, the medical psychiatrist can learn the few basic groups of drugs that have demonstrated empirically significant effects on sleep, and use knowledge of sleep physiology to logically infer the effects of most other drugs on sleep. Another way to organize an understanding of effects of drugs on sleep is to group drugs according to their most likely adverse effects on sleep/wake behavior (Novak & Shapiro, 1997). Drugs most likely to cause insomnia are those that are CNS stimulants such as ephedrine, caffeine, anorectics, amphetamines, and methylphenidate. Drugs that disturb REM sleep may produce nightmares and other sleep disturbance (e.g., opioids, corticosteroids) that also commonly lead to increased wake after sleep onset, and increased number of awakenings.

Drugs that most commonly cause parasomnias include TCAs, which lead to an increased incidence of periodic limb movements (PLMS), and drugs that are most commonly associated with nightmares such as corticosteroids, certain antineoplastic agents, MAOIs, L-dopa, and certain anti-hypertensive agents (particularly α_2 antagonists, lipophilic beta blockers such as propranolol, and reserpine). Abrupt withdrawal from agents that suppress REM sleep can also produce nightmares. In particular, withdrawal from sedative/hypnotics, TCAs, MAOIs, and venlafaxine commonly

(1) = that the drug is known to produce an increase in the sleep parameter or phenomenon; (–) = that the drug is known to produce a decrease in the sleep parameter or phenomenon; (6) = that the drug is known to produce variable effect on the sleep parameter or phenomenon; (blank) = indicates that there are no reliable data on the effect of this drug on sleep parameters; (11) or (111) = degree of the effect; (NO) = zero effect; TST = total sleep time; #A = number of arousals; SL = sleep latency; %II = percentage stage II sleep; %SWS = percent slow wave sleep; %REM = percent rapid eye movement sleep; REML = REM sleep latency.

produce REM sleep rebound and often nightmares, though withdrawal from other antidepressants can, less commonly, cause sleep disturbance.

Excessive daytime sleepiness is associated with drugs that cause sleep loss or sleep disruption as well as withdrawal from chronic CNS stimulants and direct effects of opioids, antihistamines, certain beta blockers, and many dopamine antagonists including antiemetics. Hypnotics such as flurazepam, with long half-lives or active metabolites that have long half-lives, commonly produce daytime “hangovers” and sedation.

Neuroleptics, commonly used in medical patients for psychosis, delirium, and behavior dyscontrol, may produce akathisia that may be manifest as disturbances in nocturnal sleep/wake behavior. Typical neuroleptics may worsen sleep by exacerbating an underlying restless legs syndrome and periodic movements in sleep. The differential diagnosis between these two phenomena is often difficult. Distinguishing features are that akathisia is not characteristically predominant in the evening and at bedtime as is the syndrome of restless legs. Restless legs are not commonly manifest in the morning or midday hours, except in advanced cases. The differential diagnosis is important because of significant differences in recommended treatment. Treatment for akathisia is reduction of the neuroleptic (or rarely an SSRI), introduction of anticholinergic agents, or low-dose propranolol. Appropriate treatment of restless legs syndrome is reduction of the exacerbating agent, the addition of dopaminergic agents or clonazepam, or, in severe cases, narcotics.

Another source of complexity in evaluating the sleep in medical patients is the increasingly common use of unregulated over-the-counter herbal preparations. Aside from the likelihood that these preparations may be contaminated with unknown substances (antiinflammatory agents, steroids, diuretics, antihistamines, tranquilizers, hormones, and heavy

metals), there is more information becoming available about potential adverse effects of herbal preparations taken as sleep aids, daytime stimulants, or for other purposes. Table 33.3 indicates toxicity described from the use of herbal substances for sedative or stimulant purposes as abstracted from a review of the use of herbal medications among consultation populations (Crone & Wise, 1998).

HOSPITAL ENVIRONMENTAL FACTORS

Hospitalization is in itself anxiety provoking, with the presence of the significant illness that led to admission amplified by a strange environment and the attendant procedures, many of which are painful and require preparation that may be uncomfortable at least. In addition, care routines seldom conform to the patient’s home schedule, and new nursing personnel appear at least three times a day. The cadre of laboratory workers, medical students, residents, fellows and attendings, and consulting services have a schedule of their own that keep days very active and often allow little time for rest and recuperation from the previous tests or procedures.

The hospital day usually begins very early, as the patient is awakened from (usually) a restless night’s sleep in a strange room with a strange bed. The first experience in the morning is often a needle stick for blood work, an opportunity for a hurried bath, and preparations for tests that may include enemas and missed meals. The familiar bed partner’s absence and changes in ambient noises and temperatures also contribute to unsettled sleep patterns and sleep depth, resulting in fragmented sleep and disturbed circadian rhythms. The many circadian, hormonal, and behavioral factors that contribute to stable state of well-being are disrupted, and there is seldom any exposure to ambient light of the right frequency, strength, and duration to reset the important internal sleep–wake cycle

Table 33.3 HERBAL MEDICATIONS WITH SLEEP/WAKE TOXICITY

HERBAL MEDICATIONS	TOXICITY
<i>Preparations used as sedatives</i>	
Broom (<i>Cystisus scoparius</i>)	vomiting, uterine contractions, bradycardia
Kava Kava (<i>Piper methysticum</i>)	dermatitis, hallucinations, shortness of breath
Passion flower (<i>Passiflora caerulea</i>)	seizures, hypotension, hallucinations
Valerian (<i>Valeriana officinalis</i>)	dystonic reactions, hepatotoxicity
<i>Preparations with excessive stimulation and insomnia as side/toxic effects</i>	
Echinacea (<i>Echinacea augustifolia</i> or <i>E. purpurea</i>)	central nervous system stimulant, dermatitis, anaphylaxis
Ginseng (<i>Panax ginseng</i>)	hypertension, mastalgia, agitation, anxiety, depression, insomnia
Golden seal (<i>Hydrastis canadensis</i>)	nausea and vomiting, central nervous system stimulant, paralysis/paresthesia, respiratory failure
Ma huang (<i>Ephedra sinica</i>)	mania/psychosis, hypertension, tachycardia
Yohimbine bark (<i>Pausinystalia yohimbine</i> or <i>Corynanthe yohimbe</i>)	hallucinogen/anxiety, hypertension/tachycardia, nausea/vomiting

pacemakers. Medications may be changed or administered at unfamiliar times, and any over-the-counter pain or sleeping medications that patients have been taking are often omitted.

In addition to these changes in the patient's experience, the staff working with the patient may be either sleep-deprived or functioning on a poorly organized shift-work schedule so that suboptimal emotional and intellectual functioning is the norm rather than the exception in many hospitals. In a setting where extra patience and sensitivity is needed by the patient, staff—particularly junior medical and nursing staff—are themselves anxious and under a great deal of pressure, something that patients often perceive and that adds to their own anxiety.

The minimal effect of all these factors is a tired patient who has some difficulty cooperating maximally with needed care and tests/procedures. Often the patient is also irritable or hypersensitive to perceived slowness of response to calls for help, and interpersonal conflicts with caregivers may arise over otherwise relatively insignificant issues. This phenomenon may lead to changes in the caregivers' approach to the patient, which escalates rather than diffuses things. By the time a psychiatry consult is called, psychological concerns may have been greatly amplified.

While sleep-related problems in the hospital have been noted for many years as being important, formal studies have only been done in recent decades. In the early 1980s the negative effects on sleep of noise in a children's hospital ward in Australia were described by Keipert (1985). Both the ambient and the peak noise levels on the ward were greater than those recommended for hospitals, and at times were even greater than those recommended for outdoor activities. Ward staff were most concerned about the noise of cleaning machines and the sound of crying infants. Noise of staff conversations and staff activity has been documented to be disturbing to patients (Cochran & Ganong, 1989).

Recommended changes in nursing practices include (1) efforts to reduce nighttime noise and unnecessary patient interaction; (2) attention to environmental noise in the form of cleaning machines; (3) decreasing noise of technologic monitoring devices; (4) minimizing staff conversation; (5) timing "morning chores" (such as very early morning baths) and morning laboratory interruptions (such as very early visits from the phlebotomy staff) to the sleep cycle of the patient; (6) attending to the need for reduced light at night; (7) optimal light exposure in the daytime; (8) some semblance of regularity of meals, plus exercise when at all possible; and (9) definite rest periods during the daytime without long periods of daytime sleep.

CLINICAL PEARLS

- Sleep apnea is common in hypothyroid patients and patients with acromegaly.
- There is accumulating evidence suggesting that metabolic abnormalities in diabetics can be partially corrected by CPAP treatment, which supports the concept of a causal link between OSA and altered glucose control.

- For every 10 kg increment in weight the risk for OSA increases by more than twofold.
- The most important therapy for OSA in obese patients is weight loss.
- More than 50% of the patients with COPD experience difficulty initiating and maintaining sleep.
- COPD is associated with nocturnal hypoxemia, especially during REM sleep, due to loss of muscle tone of the accessory muscles of respiration during REM sleep.
- Patients with restrictive lung disorders and chest wall abnormalities (kyphoscoliosis) are at risk of sleep-related hypoventilation/hypoxemia. Polysomnography findings include frequent arousals, increased wakefulness after sleep onset, and nocturnal hypoxemia. Other consequences of nocturnal hypoxemia include pulmonary hypertension, *cor pulmonale*, and neurocognitive dysfunction.
- Periodic limb movement disorder has been shown to be a better predictor of mortality than serum albumin and other parameters monitored in dialysis patients. Treatment with dopamine agonists and gabapentin (adjusted dose due to renal elimination) may be helpful.
- Phototherapy may be helpful in Alzheimer's disease patients with circadian rhythm disorders.
- Certain seizure disorders occur predominantly or exclusively during sleep: nocturnal frontal lobe epilepsy (NFLE), benign rolandic epilepsy of childhood with centrotemporal spikes, and juvenile myoclonic epilepsy.
- CPAP treating obstructive sleep apnea in patients with epilepsy has improved seizure control.
- Patients with deep hemispheric lesions may present with increased yawning and hypersomnia, while patients with thalamic, subcortical, and pontine strokes are likely to suffer from insomnia.
- Restless legs syndrome has been noted in patients with pontine, thalamic, basal ganglia, and corona radiata infarcts.
- Adaptive servoventilation devices should be considered for treatment of central sleep apnea syndromes in stroke patients.
- Insomnia is one of the most common and well documented syndromes seen in patients with traumatic brain injury.
- Among circadian rhythm disorders, delayed sleep phase syndrome is the most common in traumatic brain injury patients and is often misinterpreted as insomnia.
- Drugs generally decrease slow wave sleep and decrease REM sleep unless proven otherwise.
- Withdrawal from sedative/hypnotics, TCAs, MAOIs, and venlafaxine commonly produce REM sleep rebound and often nightmares.

- Akathisia is not characteristically predominant in the evening and at bedtime, as is the syndrome of restless legs.
- Among many changes in hospital that challenge sleep, medications may be changed or administered at unfamiliar times, and any over-the-counter pain or sleeping medications that patients have been taking are often omitted.

INTRODUCTION

Of every five patients seeking medical care, one complains of fatigue; this accounts for more than 7 million office visits per year (Epstein, 1995). Frequently no treatable cause is found. Over 800 research articles reflect the scientific and medical community's vigorous efforts to uncover the etiology and cure for a spectrum of complaints characterized globally as chronic fatigue syndrome (CFS).

CFS denotes a syndrome of severe disabling physical and mental fatigue lasting at least 6 months that substantially impairs functioning, is exacerbated by minimal exertion, and is unexplained by a conventional biomedical diagnosis (Fukuda et al., 1994; Sharpe et al., 1997). It is typically accompanied by other symptoms such as myalgias, sleep disturbances, and mood disorders. There is a high prevalence of comorbid psychiatric illness (Katon et al., 1991; Manu, Matthews, & Lane, 1988) and comorbid fibromyalgia (Bombardier & Buchwald, 1996).

To date, an identifiable etiology for CFS has not been reproducible. Physicians have very few proven treatments to offer. Obviously, it is difficult to treat a syndrome of symptoms effectively if the etiology is unknown.

Patients become disillusioned and angry if they perceive that the authenticity of their suffering is questioned in light of repeated negative findings. Many patients become dissatisfied with their physicians and seek alternative, nontraditional, and nonscientific sources of care (Denz-Penhey & Murdoch, 1993; Murdoch, unpublished). This chapter is a guide for psychiatrists who are evaluating and managing chronically fatigued patients.

DESCRIPTION OF CHRONIC FATIGUE SYNDROME

Chronic fatigue syndrome is a clinically defined condition characterized by severe disabling fatigue and a combination of symptoms that prominently feature self-reported impairments in concentration and short-term memory, sleep disturbances, and musculoskeletal pain. The diagnosis of CFS can be made only after medical and psychiatric causes of chronic fatiguing illness have been excluded (Fukuda et al., 1994).

DIAGNOSTIC CRITERIA

The earliest three operationally qualified working definitions for chronic fatigue syndrome are the CDC version (Fukuda et al., 1994), the British version, and the Australian version (Bates et al., 1994; Wessely, 1995). The CDC version remains the most cited and the best validated although at least five others have been added (Brurberg et al. [2014]; Johnston et al. [2013]). These criteria were designed as a basis for research into CFS to insure uniformity in patient selection. The CDC criteria differ by requiring multiple minor signs and symptoms. The British criteria require a definite onset of the illness, and the Australian criteria require the presence of post-exertional fatigue (Bates et al., 1994).

The CDC guidelines describe the symptom of fatigue as "severe mental and physical exhaustion." It is not somnolence or lack of motivation and cannot be attributed to exertion or diagnosable disease (Fukuda et al., 1994).

Definitions for and clinical evaluation of prolonged fatigue and chronic fatigue according to the current CDC guidelines are as follows: prolonged fatigue is self-reported persistent fatigue lasting 1 month or longer; chronic fatigue is self-reported persistent or relapsing fatigue lasting 6 or more consecutive months. Figure 34.1 describes the evaluation and classification of unexplained chronic fatigue (Fukuda et al., 1994).

Prolonged or chronic fatigue mandates a thorough clinical evaluation to identify potentially treatable underlying or contributing conditions. CFS as defined by the CDC cannot be diagnosed without such an evaluation. This clinical evaluation should include the following:

1. A thorough history to evaluate the following:
 - a. the medical and psychosocial circumstances at the onset of fatigue
 - b. -past medical history (including history of thyroid disease, anemia, etc.)
 - c. the presence or history of depressive or other psychiatric disorders
 - d. any previous episodes of medically unexplained symptoms
 - e. alcohol or other substance abuse
 - f. current use of prescription and over-the-counter medications and/or food supplements.

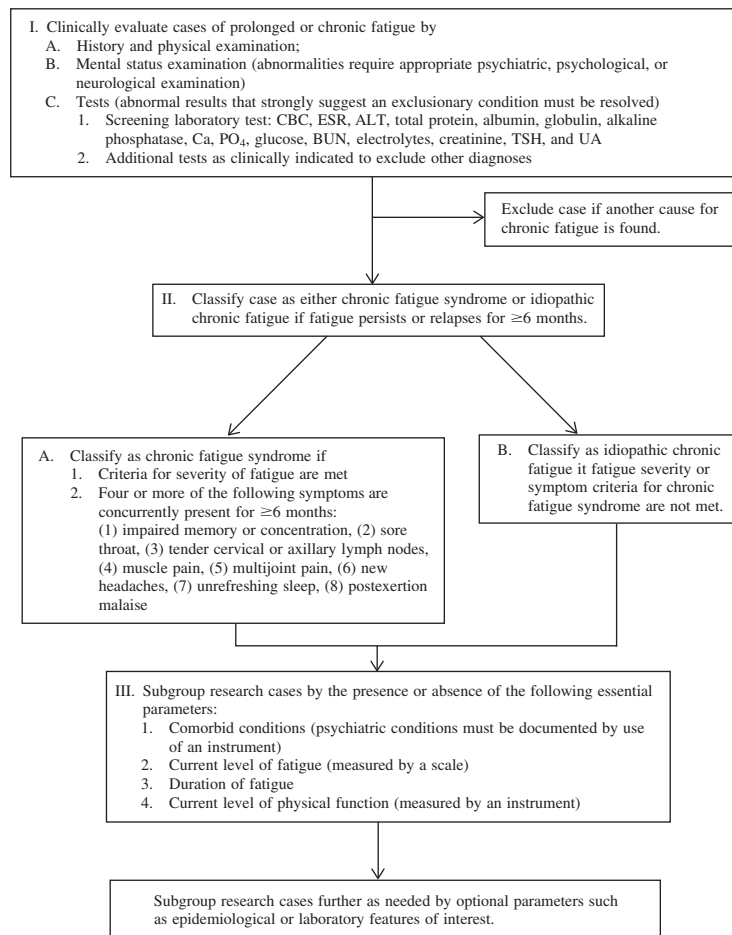

Figure 34.1 Evaluation and classification of unexplained chronic fatigue. ALT = alanine aminotransferase; BUN = blood urea nitrogen; CBC = complete blood counts; ESR = erythrocyte sedimentation rate; PO₄ = phosphorus; TSH = thyroid-stimulating hormone; UA = urinalysis. *Source:* Adapted from Fukuda, Straus Hickie, et al. (1994). The chronic fatigue syndrome: a comprehensive approach to its definition and study. *Annals of Internal Medicine*, 121, 953–959. Used with permission.

2. A mental status examination should be performed, searching for abnormalities in mood, intellectual function, memory, and/or personality. Particular attention should be directed toward current symptoms of depression or anxiety, self-destructive thoughts, and observable signs such as psychomotor retardation. Evidence of a psychiatric or neurologic disorder requires an appropriate psychiatric, psychological, or neurologic evaluation.
3. A thorough physical examination.
4. A minimum battery of laboratory screening tests including complete blood count with leukocyte differential; erythrocyte sedimentation rate; serum levels of alanine aminotransferase, total protein, albumin, globulin, alkaline phosphatase, calcium, phosphorus, glucose, blood urea nitrogen, electrolytes, and creatinine; determination of thyroid-stimulating hormone (TSH); and urinalysis (Fukuda et al., 1994). Further tests should be judiciously included as warranted by suggestive findings in the comprehensive history and physical—for example, human immunodeficiency virus (HIV), Epstein-Barr Virus (EBV) viral capsid antigen immunoglobulin M (EBV VCA IgM) to consider acute mononucleosis -,

enzyme-linked immunosorbent assay (ELISA) and Western blot for *Borrelia burgdorferi*, treponemal (fluorescent treponemal antibody absorption [FTA-Abs]) or non-treponemal tests (VDRL or rapid plasma reagin [RPR] test for syphilis), sleep studies (polysomnography by a certified sleep laboratory), and reproductive/endocrine workup).

Conditions that potentially explain chronic fatigue symptoms include the following:

1. Any active medical condition that may explain the presence of chronic fatigue (Kroenke, 1989), such as untreated hypothyroidism, cancer, sleep apnea, narcolepsy, and iatrogenic conditions such as side effects of medication(s). Unfortunately, much of the research describing CFS patients has included samples of patients with these comorbid conditions.
2. Any previously diagnosed medical condition whose resolution has not been documented beyond reasonable clinical doubt and whose continued activity may explain the chronic fatiguing illness.

3. Any past or current diagnosis of a major depressive disorder with psychotic or melancholic features as well as bipolar mood disorder, schizophrenia of any subtype, delusional disorders of any subtype, dementias of any subtype, anorexia nervosa, or bulimia nervosa.
4. Alcohol or other substance abuse within 2 years of the onset of the chronic fatigue and any time thereafter.
5. Severe obesity as defined by a body mass index (body mass index = weight in kilograms/(height in meters)²) >45.

Any unexplained physical examination finding or laboratory/ imaging test abnormality that suggests the presence of an exclusionary condition must be resolved before further classification.

Conditions that by definition do not adequately explain chronic fatigue or exclude them from the diagnosis of unexplained chronic fatigue include the following:

1. Any condition defined primarily by symptoms that cannot be confirmed by diagnostic laboratory tests, including fibromyalgia, anxiety disorders, somatic symptom disorders, nonpsychotic or nonmelancholic depression, “neurasthenia,” and /or multiple chemical sensitivity syndrome.
2. Any condition under specific treatment sufficient to alleviate all symptoms related to that condition for which the adequacy of treatment has been documented. Such conditions include hypothyroidism for which the adequacy of replacement hormone has been verified by normal TSH levels or asthma in which the adequacy of treatment has been determined by pulmonary function and other testing.
3. Any condition, such as Lyme disease or syphilis, treated with definitive therapy prior to the development of chronic symptomatic sequelae.
4. Any isolated/unexplained physical examination finding or an abnormal laboratory or imaging test insufficient to confirm the existence of an exclusionary condition. For example, an elevated antinuclear antibody titer (ANA) without other laboratory or clinical evidence to support the diagnosis of a discrete connective tissue disorder.

Major Classification Categories

Clinically evaluated, unexplained cases of chronic fatigue can be separated into either the chronic fatigue syndrome or idiopathic chronic fatigue on the basis of the following criteria:

1. Clinically evaluated, unexplained, persistent, or relapsing chronic fatigue that
 - a. is of new or definite onset (has not been lifelong); is not the result of ongoing exertion; is not substantially alleviated by rest
 - b. results in substantial reduction in previous levels of occupational, educational, social, or personal activities

2. The concurrence of four or more of the following symptoms, all of which must have persisted or recurred during 6 or more consecutive months of illness and must not have predated the fatigue:
 - c. self-reported impairment in short-term memory or concentration severe enough to cause substantial reduction in previous levels of occupational, educational, social, or personal activities
 - d. sore throat
 - e. tender cervical or axillary lymph nodes
 - f. muscle pain, multi-joint pain without joint swelling or redness
 - g. headaches of a new type, pattern, or severity
 - h. unrefreshing sleep
 - i. post-exertional malaise lasting more than 24 hours.

A case of idiopathic chronic fatigue is defined as clinically evaluated, unexplained chronic fatigue that fails to meet full, operationally defined criteria for the chronic fatigue syndrome. The reasons for failing to meet the criteria should be specified.

PREVALENCE

In the United States, 24% of the general adult population has had fatigue lasting 2 weeks or longer; 59% to 64% of these persons report that their fatigue has no medical cause (Price et al., 1992; Walker, Katon, & Jemelka, 1993). In one study, 24% of patients in primary care clinics reported having had prolonged fatigue for a month or more (Kroenke et al., 1988). In a community setting study, Buchwald et al. found a point prevalence of 98 to 267 per 100,000 for CFS and 2316 to 6321 per 100,000 for idiopathic chronic fatigue (Bombardier & Buchwald, 1996). More recent studies have reported prevalence rates of 0.24% to 2.6% (Vincent et al., 2012).

COMORBIDITY WITH OTHER CONDITIONS

Approximately 50% of patients meeting criteria for CFS have comorbid mood disorders. Another 25% have other psychiatric disorders such as anxiety disorders or somatic symptom disorders. The remaining 25%–33% of patients with CFS do not have an identifiable psychiatric diagnosis. The overlap between psychological disorders and CFS is not surprising. One of the most robust findings in psychiatric epidemiology is a positive correlation between the number of somatic symptoms and the risk of psychiatric disorder (Goldberg & Huxley, 1992; Simon & VonKorff, 1991). Similarly, the greater the number of pain symptoms, the greater risk of depression (Dworkin, VonKorff, & LeResche, 1990). Fatigue itself may be a feature which augments severity or presence of “caseness” in psychiatric diagnoses (Hickie, Hadzi-Pavlovic, & Ricci, 1997).

An interesting study, prospectively following nearly 3,000 patients without chronic fatigue or psychiatric disorder from age 36, showed that 7% had developed fatigue at age 43. Neuroticism and being female were risk factors for fatigue with or without psychiatric disorder. Of those who reported fatigue at age 43 (with a duration of more than 1 month or fatigue that was present for 12 months on at least 2 days each week), 45% had a comorbid psychiatric disorder. For those who had fatigue and a psychiatric disorder, predictors were family history of psychiatric illness and negative life events. Those with mild and moderate fatigue without psychiatric disorder had increased risk of psychiatric disorders at age 53. The predictors of fatigue without psychiatric disorder were excessive childhood energy reported by teachers at age 13 or being overweight as an adult. These distinct risk factors may suggest a path to a diagnosis of neurasthenia (Harvey et al., 2009).

In the *International Classification of Diseases* [Tenth Edition (ICD-10)] the psychiatric diagnosis of *neurasthenia* would identify almost all subjects with CDC-defined CFS (Farmer et al., 1995). The *DSM-IV* or *V* did not include neurasthenia as a diagnostic category (Sharpe, 1996; DSM-V, 2013). In an international study of mental illness in general health care Ustun and Sartorius (1995) report a 5.4% prevalence of neurasthenia, with two-thirds of those afflicted also having disorders of comorbid anxiety and depression. Merikangas has suggested that neurasthenia in adolescents may be a prodrome of bipolar disorder (Merikangas & Angst, 1994). In adults about one-fourth may have associated hypomanic symptoms (Gastpar & Kielholz, 1991).

Fibromyalgia is a syndrome with prominent muscle pain and specific trigger points (bilateral, above and below the diaphragm) that is often associated with fatigue, insomnia, and anxiety (see chapter 61). The presence of fibromyalgia does not preclude the diagnosis of CFS. Fibromyalgia is also associated with depression and irritable bowel syndrome. Low doses of sedating tricyclic antidepressants have been useful in treating this syndrome (Carrette, Bell & Reynolds, 1994). One theory of fibromyalgia is that symptoms result from a nonspecific sleep disorder, sometimes characterized by “intrusive” alpha waves into deeper levels of sleep; hence, tricyclic antidepressants may be treating a sleep disorder or a moderate mood disorder. Many psychiatrists regard fibromyalgia as somatized depression. Both CFS and fibromyalgia have been seen as conditions of central sensitization, with several top-down and bottom-up mechanisms contributing to the hyperresponsiveness of the CNS to a variety of inputs (Nijs et al., 2012; Clauw et al., 2011).

Vincent and colleagues reviewed the medical records of potential cases of CFS identified from 1998–2002 in the Rochester MN Epidemiology Project, a population-based database. Of those 482 patients who met criteria for CFS, the most common comorbid medical conditions were irritable bowel syndrome (46%), fibromyalgia (38%), and hypertension (30%). Insomnia occurred in 59%, depression in 70%, anxiety in 51%, somatoform disorder in 5%, and dysthymic disorder in 22%. The most common exclusionary

conditions were obstructive sleep apnea (33%), restless legs syndrome (12%), and substance abuse (10%), all treatable conditions. Other exclusionary conditions were chronic obstructive pulmonary disease, heart failure, bipolar disorder, recent pregnancy, cancer within 5 years, dementia, rheumatoid arthritis, hepatitis B or C, stroke without full recovery, epilepsy, schizophrenia, Parkinson’s disease, insulin-dependent diabetes, narcolepsy, depression with psychotic features, and systemic lupus erythematosus. In addition, there were a few cases of melancholic depression, eating disorder within 5 years, multiple sclerosis, cirrhosis, current chemotherapy, organ transplant, morbid obesity, and polymyalgia rheumatica. These serve as guides to diagnoses that should be part of a complete evaluation. They highlight the need to consider whether fatigue or other symptoms should be attributed to exclusionary or comorbid conditions. Careful attribution to the correct underlying condition will ensure disease-specific care.

ETIOLOGY OF CFS

The standardized criteria for CFS have been the basis of research and have defined the syndrome for the public mind, but unfortunately they define a very heterogeneous group of patients with a probable broad spectrum of triggers (Komaroff, 1997). Despite considerable research effort, no pathophysiologic mechanism has yet been established for CFS, and the symptoms remain largely unexplained (Sharpe, 1996; Taerk & Gnam, 1994). There are several hypotheses as to the etiology and pathology of CFS (Gonzalez, Cousins, & Doraiswamy, 1996).

HYPOTHALAMIC-PITUITARY-ADRENAL (HPA) AXIS/CNS ABNORMALITY

Demitrack et al. proposed that the biologic as well as behavioral features of CFS may be linked to an endocrine dysfunction of the HPA axis (Demitrack, 1994b). Dinan and associates reported a blunted serotonergic activation of the HPA axis in CFS (Dinan, 1997). The prominent fatigue associated with adrenal insufficiency has led several researchers to hypothesize that adrenal function is also impaired in patients with CFS (Poteliakhoff, 1981; Sharpe, 1996). Poteliakhoff (1981) showed that individuals with either chronic or acute fatigue had a clear reduction in diurnal levels of cortisol in comparison to nonfatigued controls. Demitrack studied the HPA axis of 30 patients with CFS compared to 72 healthy controls and reported a significant reduction in both plasma and urinary glucocorticoid levels, accompanied by an impairment in the stimulated activity of the axis for the patients with CFS (Demitrack, 1994a; 1997; Demitrack et al., 1991). There is evidence that some patients with CFS have both low levels of cortisol and an abnormal adrenal response to stress and exertion (Sharpe, 1996). Tak et al. (2011) did find evidence in a meta-analysis of 85 studies of statistically significant basal hypocortisolism in CFS subjects compared to controls but not in patients with fibromyalgia or irritable bowel syndrome.

This finding is by no means universal in this patient population. Evidence of hypocortisolism has also been associated with CFS in adolescents with normalization with treatment success (Nijhof, et al., 2014).

Low-dose hydrocortisone (i.e., 20–30 mg q8AM and 5 mg q2PM for 12 weeks) administered to CFS patients in a randomized, placebo-controlled, double-blind therapeutic trial, between 1992 and 1996 resulted in slight (not statistically significant), apparently mild but consistent improvement on a global wellness rating scale, compared to placebo-treated controls. Other self-reported rating scales did not reflect an improvement. Predictably, patients receiving hydrocortisone developed statistically significant adrenal suppression. The most frequent milder side effects of the steroid included insomnia, weight gain, and acne. The final conclusion from this study was that the slight improvement that might be attributable to hydrocortisone treatment was achieved at the expense of significant adrenal suppression precluding its practical use for CFS. Hydrocortisone itself, at these dose levels, has mood-elevating effects (McKenzie et al., 1998).

Of note, a variety of other stress-associated clinical syndromes also manifest disruptions in the integrity of the HPA axis, such as posttraumatic stress disorder (Yehuda et al., 1993) and athletes suffering from “overtraining syndrome” (Barron et al., 1985). How all of these clinical syndromes arrive at the common biochemical disturbance of reduced glucocorticoid output is unclear and may require an integrated, multidimensional model of disease pathogenesis (Demitrack, 1997).

Regardless of the specific hypothesis, the occurrence of neurologic (Komaroff & Buchwald, 1991), affective (Krupp et al., 1994), neuroendocrine (Demitrack et al., 1991), as well as cognitive (DeLuca et al., 1995) abnormalities suggest that the CFS disease process affects the brain (Bell, 1994). It remains to be conclusively shown whether the brain abnormalities are the cause, result, or mediator of the CFS patient’s symptoms and how much brain involvement might influence the outcome or prognosis of CFS (Gonzalez et al., 1996).

Another hypothesis focuses on CFS as a primary mood spectrum disorder, in particular, a type of chronic depression (Demitrack & Engleberg, 1994). Some authors have attempted to integrate the psychiatric and physiologic aspects of the illness (Taerk & Gnam, 1994; Taerk et al., 1987; Salit, 1985, 1987) and propose that CFS reflects the interplay between physical and psychological factors in psychologically vulnerable individuals with a depressive diathesis. They point to the biologic changes in both the hypothalamic-pituitary-adrenal axis and the immune system of individuals who have experienced early traumatic events or losses (Coe et al., 1992; Gunnar, 1992; Laudenslager, Dapitanio & Reite, 1985) and hypothesize a relationship between these changes and CFS (Taerk & Gnam, 1994). Figure 31.2 is the explanatory model for disease susceptibility applied to CFS (Taerk & Gnam, 1994).

It has been suggested that CFS and mood-related psychiatric disorders share a common origin in both neurobiologic and psychosocial dysfunction (Wessely, 1996). The risk of CFS is increased in patients with a history of depression. Rates of comorbid psychiatric syndromes are high—higher than would be expected if the medical dimension of CFS led to psychological consequences (Holgate et al., 2011).

Formal disorders of intellect and memory cannot be confirmed in CFS, despite the severity of the subjective complaints, but a disorder of sustained attention seems probable. Patients with CFS have scored lower on tests in which motor and cognitive processing speeds were a critical factor: tasks of reaction time and tasks of working memory (Christley et al., 2013). However, the cognitive status of patients with CFS did not differ from patients with a history of dysthymia or depression matched for age and intelligence quotient (Marshall et al., 1997). These neuropsychological findings are typical of those found in depressed patients.

Cerebral perfusion studies have shown decreased perfusion to the brain stem in CFS patients (Costa, Tannock, & Brostoff, 1995), although similar if not identical abnormalities have been noted in patients with depression (Sharpe,

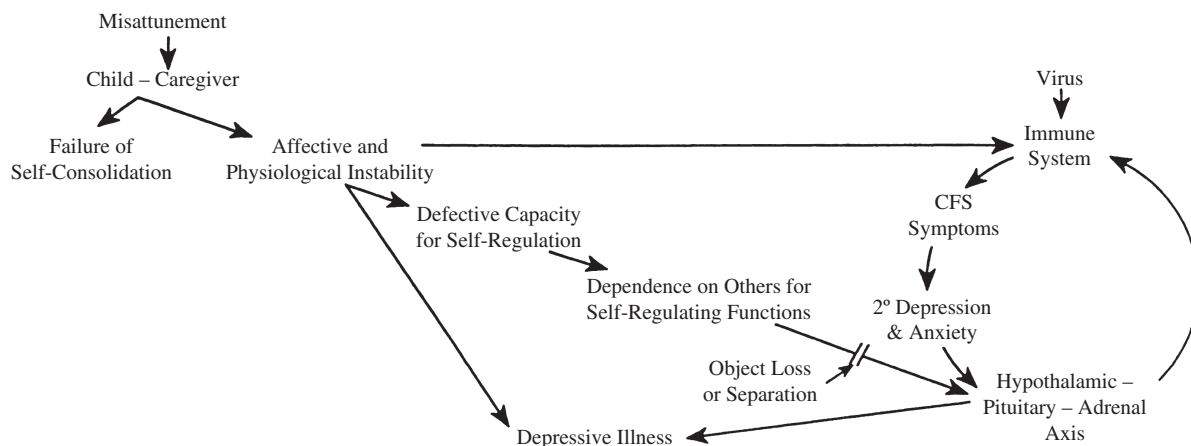

Figure 34.2 One explanatory model of chronic fatigue syndrome.

1996). These studies have not been replicated to our knowledge under controlled conditions with blinded raters of the diagnosis during scan assessment.

EEG spectral coherence data have been able to distinguish unmedicated patients who meet criteria for CFS from those depressed or healthy controls (Duffy et al., 2011). Review of other studies of central nervous system changes in CFS patients show abnormalities but no alterations in specific regions associated with CFS (Nater, Heim, & Raison, 2012).

SLEEP ABNORMALITIES

Unrefreshing sleep is an almost ubiquitous complaint of people suffering from CFS (Sharpe et al., 1992). Morriss reported that 87% of CFS patients surveyed experience sleep disorders such as poor sleep hygiene, restless legs syndrome, and more daytime sleepiness and napping than depressed patients or controls (Morriss, Wearden, & Battersby, 1997). As noted earlier, simple disruption of (deep) slow-wave sleep where alpha waves (associated with relaxed wakefulness with closed eyes) intrude into the sleep pattern is an observation in some with CFS (Morriss et al., 1993; Sharpe, 1996) and may lead to a sensation of low energy. This type of sleep pattern is seen in about one-third of patients with fibromyalgia. Some patients describe their sleep to feel as though they “skim just below the surface of sleep,” feeling as if they are awake during sleep, and completely misjudging the duration before sleep onset and the total duration of sleep (Shapiro, Devins, & Hussain, 1993). As noted above, similar complaints of disrupted sleep are found in fibromyalgia (classically associated with nonrestorative sleep) and in symptomatic perimenopausal women, who report longer and more numerous arousals than nonperimenopausal women (Baker, Simpson, & Dawson, 1997). Although inefficient sleep could contribute to daytime fatigue, its etiologic role and specificity in CFS remain uncertain (Sharpe, 1996). Experimental sleep deprivation can reproduce both the symptoms and neuroendocrine profiles of CFS (Leese et al., 1996; Moldofsky & Scarisbrick, 1976). A study by Sharpley et al. (1997) found that patients with CFS had more abnormalities in sleep continuity than the control group but no significant difference in the actual time spent in individual sleep stages. CFS patients spent significantly longer in bed trying to sleep, reflecting an inefficient sleep pattern, but that did not appear to be a major cause of daytime fatigue. A study of sleep in monozygotic twins discordant for CFS found that the percentage of Stage 3 and REM sleep were greater among the CFS twins than their healthy twins, but no other differences in sleep architecture were noted. The study did not provide strong evidence for a major role of sleep architecture abnormality in CFS. (Bali et al., 2004).

AUTONOMIC NERVOUS SYSTEM DYSFUNCTION

It has been proposed that CFS is a variant (or “6th form”) of neurocirculatory asthenia (van Waveren, 1996) and is due to a dysfunction of the autonomic nervous system, particularly the

sympathetic system, with the predominant symptom being that of fatigue (Martinez-Martinez et al., 2014). (Theories and hypotheses for CFS are in no short supply; proof of their validity is).

Postural hypotension has been noted in patients with CFS (Bou-Holaigah et al., 1995; Van Cauwenbergh et al., 2014), but this may be a consequence of inactivity (Sharpe, 1996).

POSTINFECTIOUS ETIOLOGIES

Epidemiologic data do not confirm a link between CFS and the common infective agents encountered in everyday life. In a controlled prospective study of the outcome of over 1000 symptomatic infective episodes seen in British primary care patients, researchers were unable to demonstrate any link between clinical viral infection and subsequent chronic fatigue or CFS (Wessely, 1995). In contrast, a distinct fatigue syndrome that persisted for the 6-month duration of a single prospective longitudinal primary care study was identified following acute mononucleosis (glandular fever), aseptic meningitis, and hepatitis (White et al., 1995). This fatigue syndrome differed from that seen in CFS, as it was associated with hypersomnia in contrast to the insomnia generally seen in CFS (White et al., 1995).

Although CFS was at one time thought to be due to chronic EBV, attribution of chronic fatigue to EBV infection would now rest on the recognition of recent acute mononucleosis, typically acute pharyngitis, lymphadenopathy, and hepatosplenomegaly. IgM to viral capsid antigen (VCA-IgM) titers may be elevated for 4–8 weeks. Elevated IgG antibodies may persist in some patients, so their presence does not indicate recent infection or symptomatic chronic infection. In adolescents with acute mononucleosis, baseline autonomic symptoms and days spent in bed since diagnosis, proxies of severity of illness, were the only significant predictors of those who met CFS criteria at 6 months. (Jason et al., 2014). An Australian prospective study of patients with EBV, Q fever, or epidemic polyarthritis (Ross River virus) found that 11% of 253 patients met criteria for CFS at the end of 6 months, and this was predicted also primarily by severity of illness (Hickie et al., 2006). This then could be a post-infectious pathway that could trigger CFS but not fully explain it (Holgate, 2011). Coxiella burnetii, parvovirus B19, human herpesvirus-6, and enteroviruses have also been studied as triggers (Duffy, 2011).

Chronic Lyme disease due to infection by the spirochete *Borrelia burgdorferi* had also been linked to chronic fatigue in some cases (Ellenbogen, 1997), but it is extremely unlikely that fatigue would be the only sign of Lyme disease (Dawson & Sabin, 1993). The presence of neurologic findings or arthritic complaints of the knee, hip, or shoulders suggestive of the clinical characteristics of Lyme disease would be an indication for an ELISA test and a Western blot test for *Borrelia burgdorferi*. Typically, non-specific symptoms improve over 6 months following diagnosis and treatment.

Post-Lyme disease syndrome, a syndrome subjectively similar to CFS, was defined to describe documented cases of

early or late Lyme disease treated with a generally accepted antibiotic treatment regimen with objective resolution or stabilization of objective manifestations of Lyme disease, who within 6 months of diagnosis then develop fatigue, widespread musculoskeletal pain, or complaints of cognitive difficulties. Patients were excluded if before the diagnosis of Lyme they had fibromyalgia, unexplained somatic complaints like fatigue or musculoskeletal symptoms or chronic fatigue syndrome. Patients with objective abnormalities on neuropsychologic testing that may explain the patient's complaints were also excluded (Wormser et al., 2006). Very few patients meet these criteria, and antibiotics have not shown benefit for persistent non-specific symptoms. In fact, chronic Lyme disease is now seen as a misnomer (Feder et al., 2007; Baker, 2008).

IMMUNE DYSFUNCTION

Another theory proposes that CFS is a persistent immune dysfunction initiated by some infectious process, such as an unknown virus (Zubietta et al., 1994). It is recognized that fatigue is a prominent symptom in HIV. Research has claimed alterations in immune functioning in some CSF patients, the most consistent finding reported within T-cell subsets (Buchwald & Komaroff, 1991). Unfortunately these abnormalities have not been placed in an epidemiologic context (Wessely, 1995), and the findings have not been consistently replicated. The possibility that any changes might be secondary to confounders such as neurohormonal variables, sleep disorder, or psychological distress has been insufficiently addressed. The presence of immunologic dysfunction has not been associated with clinical status or clinical outcome (Wessely, 1996).

MUSCLE DYSFUNCTION

There is no consistent evidence of a primary disorder of muscle in most studies, nor is there evidence of any change in muscle structure that could not be explained by the consequence of illness (Wessely, 1996).

SJÖGREN'S SYNDROME

Sjögren's syndrome (SS) is a rheumatologic disease of unknown etiology that is characterized by a classic triad of dryness of eyes and mouth accompanied by symptoms of joint inflammation. It is often associated with an enhanced immunologic reactivity (SS-B antibodies, presence of rheumatoid factor, elevated ESR, and occasional proteinuria reflective of interstitial nephritis). Diagnostic procedures such as the Schirmer test (measuring the quantity of tears secreted in 5 minutes to irritation from a filter paper strip placed under a lower eyelid moistening less than 5 mm/5 min), the ocular staining test, tear breakup time, tear lysozyme concentration, and slit-lamp examination are useful. Subjective manifestations of SS such as neurocognitive dysfunction and fatigue have been stressed by some observers. It has been suggested that SS may represent a common and frequently overlooked clinical subset of CFS (Calabrese, Davis, & Wilke, 1994).

CONFOUNDING VARIABLES TO RESEARCH

Unfortunately, most studies of CFS have suffered from methodologic shortcomings (Schluederberg et al., 1992; Sharpe, 1996). The principal shortcoming has been in patient selection. Most etiologic studies recruit their CFS patients from tertiary care clinics and self-help groups. Diagnostic criteria have been both modified capriciously and applied inconsistently (Schluederberg et al., 1992) in this often disabled population of patients, many of whom are completely confined to bed (Wessely, 1995). Numerous studies have reported abnormalities that could be a result of chronic inactivity, which is known to have profound effects on muscle function and chemistry, cardiac function, immune function, and psychological status (Wessely, 1995).

PROGNOSIS OF CFS

There is a paucity of information on the prognosis of patients with CFS (Salit, 1996), especially regarding the natural history of CFS in the community or primary care (Wessely, 1996). Studies in tertiary care settings give both guarded and pessimistic views. Salit recommends that patients with CFS be reassured about the generally positive outcome, stating that most individuals will improve over the first several years after diagnosis, but that the long term prognosis is unknown (Salit, 1996). He indicates that while many patients do improve, few report complete recovery at 2 to 3 years after diagnosis and only a minority of patients show significant deterioration over time. He adds that "CFS is not fatal, although some patients do commit suicide" (Salit, 1996). Komaroff reports that 12% of individuals with CFS return to normal health but half of these relapse. He found the typical course to be very difficult the first 6 months with a gradual improvement thereafter—either because of overall improvement or because patients adjusted their expectations (Komaroff, 1997).

In a small study of patients undergoing cognitive-behavioral therapy (Deale et al., 1997), poor outcome was associated with taking medical retirement or making a new claim for a disability-related benefit during treatment.

The majority of children who are diagnosed with CFS have been reported to recover (Joyce, Hotopf, & Wessely, 1997; Nijhof et al., 2013).

Overall, the greater fatigue severity, the more likely the prognosis will be worse (Vincent, 2012; Taylor et al., 2002; Jason et al., 2011). Consistent risk factors for poor prognosis include duration of disease, lifetime dysthymia (Clark et al., 1993), the strength of belief in a physical cause for symptoms, untreated psychological distress, and the use of avoidant coping strategies such as reducing activity and imposing dietary, social, and other restrictions (Wessely, 1996; Joyce et al., 1997).

EPIDEMIOLOGY

PREMORBID PERSONALITY CHARACTERISTICS

While the criteria define a syndrome with symptoms that may be alleviated, the underlying lifetime vulnerability of patients may be more relevant (Hickie et al., 1997). Baseline fatigue scores are a predictor of chronic fatigue in the general population. Severity and chronicity of fatigue fluctuates over time with intermittent fulfillment of the criteria for CFS. Stressors and constitution then interact with distress as an independent factor (Lawrie et al., 1997). Both research studies and clinical experience suggest that many persons with CFS have a tendency toward hard-driving, perfectionistic, or obsessive compulsive personalities and an overactive premorbid lifestyle (Fry & Martin, 1996; Sharpe, 1996). Loneliness is a predictor of chronic fatigue (Kellner, 1991). Studying a population in Georgia, Nater et al. (2010) found a greater prevalence of CFS patients had a personality disorder compared to well controls.

Many children attending specialist centers in the United Kingdom who have a diagnosis of CFS are described to be high achievers and often “have anxieties about their school performance, which cause them to work excessively hard to achieve at the limits of their ability” (Wessely, 1996; Lievesley, Rimes, & Chalder, 2014). In addition, psychological factors contribute to CFS in children including a complex family dynamic of involvement, high expectations, limited communication regarding emotional issues, and previous experience of illness (Wessely, 1996).

GENDER

Women with CFS are overrepresented in specialty clinics. The relative risk for women to develop CFS in community samples has been reported to be 1.3–1.7. The relative risk for women increases as the diagnostic criteria used for CFS become increasingly stringent (e.g., duration, percentage of time the patient was fatigued, presence of myalgias; see Wessely, 1995).

SOCIAL CLASS

There is no clear link to social class or occupational group; these associations relate to attendance at tertiary center clinics, not to prevalence in the general population (Wessely, 1996). There is no evidence that ethnic minorities are at less risk (Wessely, 1995).

DIFFERENTIAL DIAGNOSES

CANCER-RELATED FATIGUE

In order to study the syndromes of fatigue related to cancer, the syndrome has been defined as a distressing, persistent, and subjective sense of physical, emotional, and/or cognitive tiredness or exhaustion related to cancer or cancer treatment that is not proportional to recent activity and that interferes

with usual functioning (Berger et al., 2010). Patients who have had chemotherapy experience a syndrome of fatigue following treatment that may be related in part to regulation of inflammation (Bower et al., 2011). Radiation treatment is also associated with a fatigue syndrome. Both are typically time-limited and related to intensity of treatment. This syndrome is often embedded with other side effects of treatment like menopausal symptoms, sleep dysfunction, depression or the presence of persistent tumor like lymphoma. In controlled studies stimulants have had mixed results. Methylphenidate led to positive results in one trial, and modafinil has been useful for more severe fatigue. Exercise programs have reduced cancer-related fatigue with effect sizes ranging from 0.18 to 0.37 in a meta-analysis (Cramp & Daniel, 2008). Energy conservation or activity management, teaching self-care or coping techniques, and education about fatigue have been helpful (Pachman et al., 2012; Goedendorp et al., 2009).

APATHY OR DIMINISHED MOTIVATION

Diminished motivation or apathy without dysphoria may present as chronic fatigue without defined somatic symptoms and may be more effectively reexamined with a neuropsychiatric differential diagnosis. Apathy is seen in dementia and is a common symptom in first episode psychosis cohort 10 years after illness debut. Its presence in psychotic patients relates to impaired functioning and poorer subjective quality of life (Evensen, Rossberg, & Barder, 2012).
