They are beautiful, these flowers. Large vibrant pink blooms, decorating trees with no leaves, as if flowers always grew in the wintertime. When I first saw them, I loved them. *This isn't possible!* I thought. It was autumn; there were leaves on the ground. We were on the train to Toronto. I watched these flowers for a while, then I turned to my friend Barbara and told her what I was seeing. I remember being quite enthusiastic, although I wasn't sure I should be saying so much. She just sort of stared at me. Then I made the mistake of telling her about the chain-link fences. I had been seeing chain-link fences everywhere. Well, many places they shouldn't be. There were okay. But the pink flowers were beautiful. Barbara just stared at me even harder. Then she asked me a few questions about how long I had been seeing fences and flowers, and where they appeared. She didn't seem any more comfortable with my answers. For some reason, though, I didn't really care. I just stopped telling people about them. You have to be careful what you say.

MARY FLANNERY'S ELIZABETHAN DINNER PARTY

I was born in Belfast in 1928. My parents died just before the war, so I went to live in Boston with my Uncle Liam. My mother, of course, never liked the British. But I always loved the theater and I loved Shakespeare. I used to dress up in my aunt's old dresses and pretend I was Juliet and Romeo was on his way over to the house. I don't think that has anything to do with my Elizabethan dinner party though. That's what I call it. I see these very formal, earnest people sitting around my dining room table in full Elizabethan dress. Their outfits are made of bright, jeweled fabrics, with lots of lace, high collars, and pinched, V-shaped waists. They look like they belong on stage or in the queen's court. They're not talkative; they don't seem hungry, and they don't seem upset. Actually, they appear to think it's perfectly natural to sit around my dining room table. They irritate me sometimes, but I think my mother would probably roll over in her grave.

Although the syndrome can occur in individuals of any age and in patients with a range of eye disease, including both central and peripheral loss, the syndrome is much more common in the elderly, and this is considered to be because eye disease disproportionately affects the geriatric population. The reported prevalence of the CBS varies widely, depending on the population studied, the specificity of the hallucinations included in the diagnosis, and the methods used to elicit the symptom (Menon, Rahman, et al., 2003; Jackson, Bassett, et al., 2007; Gilmour, Schreiber, et al., 2009). Prevalence of 8.3% was found in a cohort of 300 consecutive Danish patients with neovascular age-related macular degeneration (Singh & Sorensen, 2010). A very low prevalence of 0.4% was reported on a series of patients in Singapore (Tan, Lim, et al., 2004). The prevalence in patients presenting for vision rehabilitation has been found to be approximately one-third in several series (Crane, Fletcher, et al., 1994; Jackson, Bassett, et al., 2007).

Menon prospectively considered two groups of elderly subjects; those with better acuity than 20/40 and those with very poor visual acuity of less than 20/400 (Menon, 2005). He reported a high prevalence of 63% hallucinations in those with the poorer visual acuity, and no hallucinations in the comparison cohort. The risk of experiencing the hallucination is not consistently correlated with the degree of vision loss, although both visual acuity and contrast sensitivity have been correlated with the symptom (Jackson, Bassett, et al., 2007; Singh & Sorensen, 2010).

The hallucinations are considered to be comparable to phantom limb sensations, and it is posited that the hallucinations arise because areas of cortex are not receiving visual afferent information. Neuro-imaging has shown correlation of the type of image seen during the hallucination and the area of brain activity. Patients who experienced hallucinations in color have had activity documented in the fusiform gyrus, an area corresponding to the V4 color center (Kazui, Ishii, et al., 2009); deafferentation and hypermetabolism of the thalamocortical visual pathway have also been suggested (Jang, Youn, et al., 2011).

Other diagnoses are always considered when patients do not have insight into the unreal nature of what they see or have other neurological or psychiatric symptoms. Visual hallucinations can also occur in sleep-wake transitions, during bereavement, and as side effect of medications. Hallucinations also occur in diseases such as Parkinson's, Alzheimer's, and Lewy body dementia. Up to one-third of patients with Parkinson's report hallucinations, and these have been reported to occur prior to pharmacological treatment of the Parkinson's disease (Biousse, Skibell, et al., 2004). A series of 30 subjects with untreated Parkinson's disease (PD) with normal cognitive function and full insight reported that 25% had hallucinations. None of these subjects developed dementia over the subsequent two years. Approximately 20–25% of Alzheimer's disease (AD) patients also experience hallucinations (Bassiony & Lyketsos, 2003). Authors have suggested that there is associated visual pathology in patients with PD and AD who report hallucinations (Diederich, Goetz, et al., 1998; Chapman, Dickinson, et al., 1999). Patients with Lewy body dementia have a clinical triad of visual hallucinations, fluctuating mental status, and Parkinsonism.

A patient with known eye disease, recurrent visual hallucinations, insight into the unreal nature of the images, and no other psychiatric or neurological disease to explain the hallucinations can be considered to have CBS. Most patients appreciate an explanation as to why they are experiencing these peculiar visions. A prospective study of patients seen in a vision rehabilitation clinic found that 25% of those who reported hallucinations at enrollment, reported that the hallucinations had stopped at one year (Jackson & Bassett, 2010). Only a small number of patients are so bothered that pharmacological management needs to be considered. Case reports of successful treatment with a number of medications in different classes have been published, although consensus or evidence base for optimal medication are lacking (Lang, Stogowski, et al., 2007; Segers, 2009). To avoid misdiagnosis and unnecessary investigation, it is important that physicians be aware

of the syndrome and consider it in the differential of patients presenting with visual hallucinations. In addition, patients with recent onset or progression of visual loss should be asked about visual hallucinations, offering an explanation that these sometimes occur with visual loss and are not a sign of mental illness. Often patients will not volunteer a complaint of visual hallucinations unless they are asked about them.

OCULAR ISSUES IN DEMENTIA

ALZHEIMER'S DISEASE

It is estimated that globally, approximately 44.4 million people live with some form of dementia, with AD being the most prevalent form (2013). Vision loss can worsen dementia and is a risk factor for dementia (Lee, 2009). Although AD is primarily a disease of dementia, visual complaints can be primary in a subset of AD patients (Holroyd & Shepherd, 2001; Lee & Martin, 2004). Symptoms can include blurred vision, difficulty reading, and difficulty seeing low-contrast targets. The symptoms are attributed to abnormalities in the central visual pathways. Clinical findings include decreased contrast sensitivity and ocular motor abnormalities such as hypometric saccades, saccadic latency prolongation, fixation instability, and saccadic intrusions during smooth-pursuit eye movements. Higher cortical function abnormalities such as visual agnosia may be present. Referral to a neuro-ophthalmologist is recommended.

WERNICKE'S ENCEPHALOPATHY

Rarely, the diagnosis of disordered consciousness is made by the ophthalmologist. Wernicke's encephalopathy (Wernicke, 1968) is a clinical triad of ocular motility disturbance, ataxia, and altered consciousness, often with memory disturbances, due to vitamin B1 deficiency (Rufa, Rosini, et al., 2011). Although most commonly seen in patients afflicted with chronic alcohol consumption, it can be seen in the settings of malnutrition from other causes. The ocular findings can include nystagmus or paralysis of ocular muscles, particularly of the lateral rectus muscle, producing horizontal diplopia. When treated early with intravenous thiamine, recovery usually is rapid and complete. Left untreated, Wernicke's encephalopathy can lead to Korsakoff syndrome, long-term institutionalization, or death (Harper, Giles, et al., 1986; Day, Bentham, et al., 2004; Kopelman, Thomson, et al., 2009).

PSYCHIATRIC ISSUES AND VISION LOSS—FUNCTIONAL VISION LOSS

Occasionally clinicians are confronted with patients who report vision loss in whom no organic etiology is apparent on clinical evaluation, thus raising the differential diagnosis of non-organic or "functional" vision loss. These patients present a challenge to the clinician (Miller, 2005).

Such patients are often referred for neuro-ophthalmologic and retinal evaluation, as the diseases that are not apparent

on clinical evaluation typically fall under these domains. Neuro-ophthalmologic evaluation may include electrophysiological testing, such as measurement of visual evoked potentials. Patients may be malingering and have willful intent to present symptoms for some secondary gain, or may have functional neurological symptoms or conversion and be unaware of the non-organic source of symptoms. These patients take more time for evaluation. A detailed past history, review of symptoms of dissociation, and an understanding of what the patient thinks is happening will be helpful. *Every aspect of the clinical encounter is important to illuminate visual abilities, from how patients walk into the examination room to whether they shake the clinician's hand.*

Pupil testing is important; however, a malingerer can also simulate pupil abnormalities by self-administration of topical medication. In this situation, the pupil will not constrict with pilocarpine drops.

Optokinetic nystagmus can be elicited by a drum or tape, and a positive test indicates visual acuity of 20/200 (6/60) or better (Beatty, 1999). Malingerers tend to feign not being able to sign their name, although a blind person would not find this difficult; malingerers do not look at their own hands during a manual task. Tests of proprioception can be done by a patient who is truly blind, but malingerers may pretend the task is difficult. A malingerer may not be able to bring together the index fingers in front of their eyes, something a blind person can do. For tests of one eye, the other eye should be covered. Most people feigning blindness would be able to walk smoothly into the examining room; and would flinch to threat or flinch to a bright light aimed at the eyes.

For monocular visual loss, the Fogging Test is the process of placing a series of plus lenses of progressively increasing power in front of the unaffected eye while the vision is tested. Neither eye is occluded. As the vision in the unaffected eye becomes more and more blurred, it becomes clear that the patient is seeing with the affected eye. Further tests are noted in Beatty (Beatty, 1999).

Patients with visual loss without obvious cause can be evaluated with electroretinography, pattern electroretinography, and pattern appearance visually evoked cortical potentials (VECPs). VECPs evaluate the integrity of the retinogeniculostriate pathway. Nearly normal VECPs do not rule out central visual loss due to impaired function of the visual association areas in the occipital and parietal lobes. Patients gaming the test can purposely not focus on the test stimulus and thereby lower the amplitude of the electrical response.

A normal-pattern electroretinogram depends on the functional integrity of the retina and optic nerve. It will detect photoreceptor dysfunction syndromes when signs on fundi are subtle, and it will require good focus and adequate fixation. Simultaneous VECP testing and pattern electroretinogram can thus improve on one of the weaknesses of the electroretinogram alone. Color vision testing may be necessary to rule out cone dysfunction syndromes.

Visual field testing can be misleading, as patients can easily falsify results, and there are no characteristic changes to confirm the suspicion of a non-organic deficit (Stewart, 1995).

Tubular fields are the most common abnormal visual field associated with conversion disorder. True fields expand with increasing test distance. When the field does not expand, it is called "tubular." The visual field must be tested at two distances to define the tubular field, as the normal visual field will be larger at a greater distance (Stone, Carson, et al., 2005).

Diseases that are most typically misdiagnosed as malinger include pituitary tumors with early compression, Leber's hereditary optic neuropathy, early cone or Stargardt's retinal dystrophy, retrobulbar optic neuropathy, small occipital infarcts, or cancer- or melanoma-associated retinopathy. Patients can complain of loss of vision when they have visual agnosia or alexia, and such organic disease should be kept in mind.

The treatment of conversion blindness or non-organic visual loss is reassurance by a concerned physician. Improvement should be documented in a follow-up visit. If the patient is young and has no other psychiatric disorder, then the prognosis is generally good (Beatty, 1999). These patients typically do not require psychiatric referral. Family or school stress or sexual or physical abuse can be predisposing factors (Catalano, Simon, et al., 1986). Patients with non-organic disease can often be encouraged that they do not have underlying disease and that their prognosis for improvement is positive. Combined organic and non-organic complaints do occur, and the possibility that a patient with non-organic complaints can develop organic disease needs to be kept in mind (Scott & Egan, 2003).

Shedding light on the neural signature of conversion blindness, functional magnetic resonance imaging (fMRI) has noted altered but not absent visual cortex responses in patients with conversion blindness. Becker et al. (2013) reported a 25-year-old man with visual pseudo-hallucinations of his deceased friend's face grimacing with agony (Becker, Scheele, et al., 2013). They found normal basic visual cortex responses to checkerboard stimulation during the blindness. In contrast, when they asked the patient to perform a social-emotional perception task, they found hypofunction in the occipital cortex and hyperfunction in the post-central gyrus bilaterally and the right superior temporal gyrus. Extracting this emotion-specific activity, they found increased responses in the angular gyrus bilaterally, the left medial frontal gyrus, and the left anterior cingulate cortex, areas implicated in emotional regulation and moral reasoning. They reported enhanced functional coupling of this network with downregulated visual areas. They concluded that symptom-related functional association of overactivity in fronto-parietal regions and suppressed responses in interconnected visual areas add to the neurocircuitry model of visual conversion disorder.

Another case suggested that event-related potentials (ERPs) could serve as an electrophysiological measure combined with fMRI, a hemodynamic measure, to track the progress of a conversion visual symptom and to track success of treatment (Schoenfeld, Hassa, et al., 2011). In a patient with blindness limited to the left upper and right lower visual quadrant, the fMRI activations were normal for visual stimulation, but the electrophysiological indices of visual processing

were modulated. Unseen parts of the patient's visual field elicited smaller amplitudes of N1 component of the event-related potential at diagnosis. This modulation was absent after treatment when the vision returned to normal. The implication is that functional blindness does have a neurophysiological correlate.

Anxiety or conversion reaction can cause spasm of the near reflex characterized by episodes of a small pupil or miosis, convergence, and accommodation (Bradley, 2004). A constricted pupil would confirm this diagnosis (Kline, 2010).

PSYCHIATRIC ISSUES AND EYE TRAUMA

The psychiatrist may become aware of eye trauma in his patient that can signal the need for concurrent ophthalmology and psychiatric evaluation. Additionally, issues of eye trauma may be brought to the psychiatrist's attention by physicians conducting eye exams who suspect social or psychiatric issues. Child abuse, the "shaken-baby syndrome," spousal or elder abuse can each manifest as any finding of ocular trauma, including retinal detachment, retinal hemorrhages, vitreous hemorrhages, blood in the anterior chamber of the eye (hyphema), eyelid bruising (ecchymosis), eyelid swelling, or lens dislocation. The shaken-baby syndrome typically involves ocular trauma in addition to intracranial pathology such as subdural hematoma or cerebral edema. External eye trauma is not often present (Emerson, Pieramici, et al., 2001; Bhardwaj, Chowdhury, et al., 2010). Sadly, mortality is high (29%) for infants with shaken-baby syndrome (McCabe & Donahue, 2000). Referral for detailed eye examination is important for both documentation and treatment. The differential diagnosis of other sources of trauma or blood dyscrasias must be considered.

Elder abuse is often subtle, despite a national prevalence between 2% and 10% when various forms of abuse are considered (Lachs & Pillemer, 2004). Risk factors include marital, financial, and legal stresses, mental illness, and substance abuse. The clinician should be mindful of the possibility of maltreatment of elderly patients leading to ocular trauma that can occur in private homes, assisted living or nursing homes. Signs may include black eyes, orbital fractures, broken spectacles, misleading histories accounting for clinical findings, or delay in seeking treatment of ocular injuries.

Unfortunately, ocular trauma can ensue from suicide attempts with guns. Requirement for ocular reconstruction is obvious. Autoenucleation or traumatic enucleation by another person is a severe form of trauma, often involving the ophthalmologist for orbit reconstruction (Patton, 2004). Such clinical events are evidence of severe mental pathology requiring psychiatric and ophthalmic co-management.

Autoenucleation is a rare form of major self-mutilation seen especially in first-episode schizophrenia (Large, Andrews, et al., 2008). It is also seen in patients abusing hallucinogenic drugs. Some patients report the need to expiate guilt by removing an evil organ that conveys evil images from an evil world (Jones, 1990). Patients are at risk of further mutilation or suicide.

Patients losing one eye are aware of deficits of peripheral field and binocularity during the ensuing initial few months; however, most adapt spontaneously over time and require no rehabilitation intervention. Some patients experience grieving after monocular vision loss, which, as with grieving of any loss, can infrequently be prolonged and maladaptive. Such patients typically benefit from referral to both vision rehabilitation and counseling.

MEDICATIONS AND VISION

OCULAR MEDICATIONS AND PSYCHIATRIC SYMPTOMS

It is often overlooked that ocular medications can have systemic side effects (Rhee, Colby, et al., 2011). Most systemic effects are due to absorption via the mucous membranes of the eye and nasopharynx. In addition, there can be an additive effect of topical and concurrent oral medications. Systemic absorption after topical administration can be reduced by having patients close their eyes or put digital pressure on the nasolacrimal duct when administering their eye drops. The majority of patients requiring eye medication are elderly, who are, in general, at greater risk of systemic toxicities. In addition, errors in self-administration of ocular medications may be higher than in the general population, as patients with vision loss have difficulty reading labels and instructions (Drummond, Drummond, et al., 2004; 2008).

β -adrenergic antagonists, or β -blockers, are used in glaucoma management as they lower intraocular pressure by reducing aqueous humor production. Depression, lethargy, decreased libido, hallucinations, and sleep disturbance in patients with topical β -blocker medication use for glaucoma are reported (Rhee, Colby, et al., 2011). Alternate medications or management options can be considered. The psychiatrist can assist patients by advising the treating ophthalmologist when such symptoms are detected. Oral acetazolamide is used to treat glaucoma infrequently but can have side effects, including depression, restlessness, fatigue, and diminished libido (Rhee, Colby, et al., 2011).

Topical medications are routinely used in eye examinations to dilate pupils. Dose-related side effects include drowsiness, delirium, hallucinations, or agitation, particularly in children or elderly patients. Severe cases are treated with intravenous physostigmine. A cyclopentolate-induced acute psychosis has been reported, occurring 20–60 minutes after administration of the anti-muscarinic agent to dilate pupils. Symptoms and signs include disorientation, dysarthria, ataxia, hallucinations, and amnesia (Fraunfelder, Fraunfelder, et al., 2001).

OCULAR COMPLICATION OF PSYCHOTROPIC MEDICATIONS

Although infrequent, ocular complications due to psychotropic medications do occur, most frequently with typical antipsychotics, tricyclic antidepressants, lithium, benzodiazepines, carbamazepine, topiramate, and selective serotonin-reuptake inhibitors

(SSRIs) (Richa & Yazbek, 2010). Patients taking medication with anticholinergic effect may report ocular side effects such as dry eye or accommodative changes causing blurred vision (Fraunfelder, Fraunfelder, et al., 2001). Medications with anticholinergic effect can also induce acute or subacute angle-closure glaucoma requiring, typically, both pharmacological management and a laser surgical outpatient procedure (laser iridotomy). Symptoms include eye pain and redness in most patients, but less frequently, patients are not acutely symptomatic or can present with gastrointestinal symptoms such as abdominal pain or nausea. Elderly, Inuit, and Chinese and other Asian populations are at highest risk (Rhee, Colby, et al., 2011).

Uncommonly, patients taking SSRIs report changes in vision, and younger patients may also report “tracking” difficulties, which resolve when the medication is discontinued (Purdy, Bolling, et al., 2010). Topiramate can cause acquired myopia and also angle-closure glaucoma due to displacement of the lens and ciliary body. Induced myopia and angle-closure glaucoma can occur secondary to topiramate. Topiramate is a sulpha-based anti-epileptic drug that interferes with ionic concentrations of sodium and chloride in tissues, including the lens. Such ionic changes may produce uveal tract swelling, causing induced myopia. Significant further damage to the lens-iris complex may lead to angle-closure glaucoma (Abtahi, Abtahi, et al., 2012; Liu & Rhee, 2013).

First-generation antipsychotics, with primarily dopamine receptor blockade, are less well tolerated than second-generation antipsychotics, which have an inhibitory effect on serotonin receptors in addition to dopamine-blocking activity (Purdy, Bolling, et al., 2010). Ophthalmic side effects of first-generation medications include corneal pigment deposition, lens pigmentation, eyelid pigmentation, and retinal pigmentary degeneration, which is associated with vision loss. These side effects occur most commonly with long-term use of thioridazine, typically at doses greater than 800 mg/day (Fraunfelder, Fraunfelder, et al., 2001). Antipsychotics, including second-generation agents, can be associated with tardive dyskinesia. Blepharospasm and other eye movement disorders can occur.

Both lithium and phenothiazines are reported to cause eye irritation and blurred vision, which may be self-limiting. Persisting reports of blurred vision require evaluation to rule out other causes such as pseudotumor cerebri, a rare side effect of lithium. Lithium can cause nystagmus and saccadic eye movement disorders (Richa & Yazbek, 2010). Although some nystagmus can resolve with lower doses or drug cessation, the more severe downbeating nystagmus can be permanent. Thyroid-related eye disease in patients taking lithium is secondary to hyperthyroidism or hypothyroidism (Fraunfelder, Fraunfelder, et al., 2001).

SUMMARY

Since the text *Psychiatric Problems in Ophthalmology* was written in 1977 (Blodi, 1977), much has changed, yet still, the primary psychiatric difficulties in ophthalmology remain the same: reactions to losing vision, functional ocular complaints without organic basis, and side effects of

medications. Although an infrequent referral—an ophthalmology patient to a psychiatrist or a psychiatric patient to an ophthalmologist—the overlap of the domains warrants review by each specialty respectively.

CLINICAL PEARLS

- The most common cause of vision loss in adults in developed countries is age-related macular degeneration, which causes loss of central vision, but typically allows preserved peripheral vision (Klein, Chou, et al., 2011).
- Glaucoma typically affects peripheral vision, and diabetic retinopathy can affect both peripheral and central vision.
- Legal blindness is determined in the United States as visual acuity with corrective lenses if needed, that is equal to or less than 20/200 or a visual field less than 20 degrees in diameter.
- A guideline outlining how vision rehabilitation can be incorporated into ophthalmic care is available (<http://one.aao.org/mart-sight-low-vision>) with patient information and resources for audio digital books, large-print books or newspapers, computer accessibility information, and other resources.
- A directory of vision rehabilitation services is maintained online (see visionaware.org).
- Four criteria have been proposed for Charles Bonnet syndrome: (1) the patient reports vivid, recurrent visual hallucinations; (2) there is some degree of vision loss; (3) the patient has insight into the unreal nature of what they see; and (4) there is no other neurological or psychiatric diagnosis to explain the hallucinations (Jackson & Ferencz, 2009).
- Visual hallucinations can also occur in sleep–wake transitions, during bereavement, and as side effect of medications. They are also seen in Parkinson's, Alzheimer's, and Lewy body dementia.

DISCLOSURES

Dr. Jackson currently serves on the National Board of the Canadian National Institute for the Blind (CNIB) and the Planning Committee for the National Eye Health Education Program (NEHEP). She does not receive salary support for these activities. She also is on the Scientific Advisory for VISUS Technologies and a consultant to Ocata Therapeutics.

Dr. Wallis has no conflicts of interest to disclose.

OTOLARYNGOLOGY

Harold Bronheim

INTRODUCTION

Ear, nose, and throat (ENT) disorders are common, and surgery for them is performed in-hospital and outpatient settings throughout the country. The appropriate psychiatric evaluation and treatment of this patient population have been limited, in part, because of the difficulties in communication encountered in those patients with laryngectomy or tracheostomy. Although otolaryngology patients undergo extreme stress, it unfortunately occurs just at the time that they are least able to verbalize and communicate their basic needs. Therefore, because of the limitations in communication that occur postoperatively, it is important that basic aspects of the psychiatric evaluation be done as much as possible prior to surgery. Pre-operative depression, or premorbid personality disorders have been determined to be predictors of postoperative depression, coping, and quality of life (Fingeret et al., 2013; Aarstad et al., 2008). Head and neck surgeons fail to identify the patients most in need of psychosocial intervention, and screening tools are not widely disseminated (Sollner et al., 2001; Piril et al., 2007).

Psychiatric consultants will confront two important dilemmas in the approach to this patient group: one, diagnostic; and the other, therapeutic. Diagnostically, consultants will need to delineate the overlapping boundaries between normal adaptation and psychiatric morbidity, and therapeutically they will be challenged by the severe limitations of verbal communication (Bronheim et al., 1991a, 1991b; Callahan, 2004).

SPECIAL CLINICAL ISSUES IN OTOLARYNGOLOGY

The extensive head and neck surgery currently performed leads to longer postoperative courses and extended rehabilitation involving alterations in basic physical functions such as breathing, swallowing, speaking, hearing, and vision. Facial contours may be deformed and occlusive relationships disrupted. Chewing and swallowing may be grossly distorted. Oral-pharyngeal surgery usually involves tracheostomy, which may be permanent if the patient undergoes total laryngectomy or suffers from extensive tracheal stenosis. Postoperatively, the patient must not only come to terms with cancer and surgery, but also must live with a changed,

disfigured self with marked impairments in speech (O'Hara et al., 1989; Lucente et al., 1987; Strain, 1985; Surman, 1986; Shapiro & Kornfeld, 1987; Bronheim et al., 1989). Repeated studies have delineated long-term effects on quality of life for the both the patient and partner that necessitate problem-focused interventions (Hammerlid et al., 1999; Gotay et al., 1998; De Boer et al., 1999; Semple et al., 2004; Derks et al., 2005).

In the approach to this patient population, the psychiatrist must be prepared to deal cohesively with the issues of (1) cancer, surgery, and life-threatening illness; (2) disfigurement; (3) difficulties with swallowing, speech, or hearing; and (4) long-term physical and psychological adaptation.

The collected stressors affecting the otolaryngology surgical patient easily reach extreme and catastrophic levels, and vulnerable individuals manifest a variety of symptoms that may persist for an extended period of time (National Comprehensive Cancer Network, 1999). Despite the intensity of the stress, not all individuals become symptomatic, as individual vulnerability is an important component of the stress response. The differentiation between adjustment disorder and depression is sometimes difficult. Nonetheless, when psychiatric symptoms disrupt physical rehabilitation or significantly affect social or psychological functioning, then depression is the more appropriate diagnosis to make, and more intensive psychiatric intervention is necessary. Consideration must be given to the possibility that the patient may have had a preexisting major depression, or a minor depression due to physical disease or medications. The patient must be followed because a seemingly milder adjustment disorder may evolve into a major depression over time.

SURGERY PLUS RADIATION IN THE SETTING OF CANCER TREATMENT

Although ENT cancers are approximately 5% of all cancers (American Cancer Society, 2008), patients with head and neck disease undergo an onslaught of frightening changes that go well beyond those experienced by most other surgical patients. The multiple organs and functions encompassed within the relatively small region of the face and neck give rise to an enormous variety of physical diseases, pathologies, and dysfunctions. The most common cancer, however, is squamous cell carcinoma, and it usually requires, in addition to

surgery, adjunctive treatment with radiation and/or chemotherapy (Urken & Biller, 1988).

Multiple stressors face the otolaryngology patient with cancer, including the fear of death, mutilation, and pain. However, because of its location on the face, or in the head and neck, the mutilation resulting from cancer surgery is often experienced as an assault on the total self (Greenacre, 1958). It is harder for ENT patients to isolate the self from the disease and distance themselves psychologically; especially when there are multiple overwhelming alterations in sensory and motor functions. Anxiety persists as patients' concerns remain focused on the new, significant functional changes and physical disfigurement.

Advances in otolaryngology technique have permitted more extensive resections of cancer surgically, as well ablation by radiation therapy. However, the surgical reconstructions that are necessarily simultaneously performed create additional stressors on the patient by increasing postoperative morbidity, disability, and pain. Some patients require multiple surgical revisions, which can "stress" even healthy, well adapted individuals beyond endurable emotional limits (Bronheim et al., 1989). Accumulating postsurgical quality-of-life studies have indicated persistent serious problems with acute airway management and chronic dysphagia. These complications also lead to caretaker burnout and serious stress on partners and family (Kim et al., 2008; Miziara et al., 2009; Vickery et al., 2003). Radiation therapy combined with more intensive chemotherapy has been administered, which has increased the severity of mucositis, with serious and intractable oral-facial pain. Although nonsurgical treatments of head and neck cancers have become more aggressive and surgical technique has been limited to enable preservation of function, the impact on quality of life has nevertheless been enormous (El-Diery et al., 2005).

DISFIGUREMENT AND RECONSTRUCTION

Head and neck surgery remains the most disfiguring of all surgery, with oral-mandibular surgery considered to be the most stressful (Dropkin et al., 1983). Disfigurement is highly associated with depression (Valente, 2004). Disfigurement may involve the loss of an eye, the shifting of the nose across the midline, facial and jaw asymmetry, a new orifice for the tracheostomy site, asymmetry of the neck by either surgical dissection or skin and muscle grafts, and multiple scars and blemishes. Some patients will complain of having their "throats cut," or an inability to recognize themselves. They may have difficulty looking at their reflection in the mirror or being seen by the public. They may feel like a grotesque monster and notice people staring at them or abruptly turning away. Head and neck patients may hide in their rooms and withdraw from the public view. Disfigurement has an extraordinary, involuntary impact on all visitors who are unfamiliar with the otolaryngology hospital setting, including medical staff or consultants. Even a minimally perceptible frightened reaction by the psychiatric consultant to the patient's

appearance can have a profound effect on the therapeutic relationship. Facial disfigurement also has serious impact on family and other caretakers (Vickery et al., 2003).

Reconstructive surgery is undertaken mainly for the purpose of rapidly restoring fundamental functions such as chewing, swallowing, and breathing, or simply covering an open surgical wound. From a psychiatric standpoint, the main issues revolve around the patient's realistic preparedness for surgery and the possible consequences of further disfigurement or surgical complications. A common postoperative complication involves dysphagia and/or aspiration. Because of the significant morbidity associated with these conditions, more clinical trials are being conducted and new surgical techniques are being incorporated to improve functional outcomes (Logemann, 2006; Crary et al., 2004).

Because of its extraordinary social importance, deliberate efforts are made to preserve speech; even at the risk of increasing the difficulty of swallowing, and the risk of aspiration. Some patients who are non-adherent and who cannot abstain from eating even if adequately nourished with gastric tube feedings may undergo further surgery to physically separate the airway from the oral/hypo-pharyngeal space. In so doing, speech is sacrificed in order to preserve swallowing without aspiration. A psychiatric assessment of such individuals usually reveals either cognitive impairment with poor impulse control, or socially isolated alcoholics who would rather continue to imbibe than communicate.

Reconstructive surgery may also be undertaken either to repair a preexisting physical deformity, or to achieve enhanced cosmetic appearance. Reconstructive surgery in obviously deformed young children generally leads to an improvement in their interpersonal behavior and cognitive development (Kalick, 1982; Belfer et al., 1982). Individuals who seek surgery for purely cosmetic reasons are found to be more anxious as a group and tend to suffer from a poor self-image that they hope surgery will improve. Nevertheless, for many, cosmetic surgery leads to an enhanced sense of well-being with a corresponding increase in social activity (Marcus, 1984).

Psychiatric evaluation of individuals undergoing cosmetic or reconstructive surgery therefore must focus on the nature of their body image and their expectations about how they will be affected by the change. Unrealistic expectations are more likely to lead to postoperative disappointment and maladjustment. Individuals at risk include: those who insist on undergoing extensive or life-threatening surgical interventions for relatively benign deformities, or those who undergo surgery on features with prominent psychological meaning; and those with deformities which have existed for many years. More favorable outcomes are achieved in cosmetic surgery performed on females, especially on those features that have rapidly changed due to aging and have outpaced the changes in their inner body image (Goin & Goin, 1981). "Refreshing" the face or neck of a woman age 60 who feels that she is looking old and unattractive is seldom as complicated psychologically as, for example, doing a rhinoplasty on a young man who feels his lack of success professionally or socially is due mainly to a slightly prominent, non-ideal, nose. Nevertheless, once they have begun, some patients undergo repeated cosmetic

procedures to relieve psychological distress inherent to characters with Body Dysmorphic Disorder.

SPEECH

Speech is the most powerful, immediate, and versatile means of communication and is especially important during periods of acute distress. Speech, autonomy, and personal identity are closely linked. The inability to adequately regulate speech, which occurs as a result of laryngeal and oral-maxillary, pharyngeal surgery or tracheostomy, leads to a sense of urgency, increases in tension and frustration, followed by helplessness and withdrawal (Hagglund & Heikki, 1980). Because of difficulties in comprehensible speech and articulation, verbalization is limited in both quantity and quality. Therefore, whenever speech is attempted, it is markedly limited, and of necessity is focused on the immediate issues of physical needs. Social intercourse, personal communication, and the expression of inner feelings are subtler and more complex, require greater vocal capability and time to fully communicate, and are substantially compromised by such surgery.

Otolaryngology patients are unable to verbalize sufficiently to adequately relate emotions such as anxiety, frustration, sadness, or anger. They are unable to communicate feelings of hopelessness or wishes to end their current suffering one way or another. As a result, they may “act out” on the unit when they become frustrated and are more likely to throw objects and be physically aggressive to staff (Edgecombe, 1984). The psychiatrist, by initiating the process of verbalization, facilitates the process of integrating the new body image and personal identity. It also initiates the important discharge of affect with its concomitant reduction in stress. In the section below, the subject of psychotherapy will be discussed in the context of deficits in communication. The need to facilitate speech and the advantages of new communication technologies will also be reviewed below (Kluin, 1984; Hess, 2005).

ADAPTATION AND PSYCHIATRIC SYNDROMES

Although the majority of otolaryngology patients manage a successful adaptation, they may undergo a stormy, prolonged, and difficult course (West, 1974, 1977). The postoperative period is complicated by alterations that may persist after discharge from the hospital, even with rehabilitation. A number of psychosocial factors have been reported to be correlated with long-term postoperative adaptation (West, 1974; Natvig, 1983a; Anderson, 1987; Meyers et al., 1980; Mumford et al., 1982; Schleifer et al., 1989), and a variety of overlapping psychosomatic disorders (Marek, 2009). Preoperatively, the more patients are informed of what physical alterations they can expect immediately after surgery, the more rapidly they are likely to engage in physical rehabilitation (Natvig, 1983a). The unprepared patient will almost certainly require more time and attention to cope with the trauma of new physical alterations. Postoperatively, physical rehabilitation and

speech therapy have been found to improve long-term outcome as well as quality of life (Frans, 2007). Active coping strategies, more commonly observed in younger patients, lead to better outcomes; at least initially, nevertheless, patients with persistent major defects may suffer from long-term interpersonal disturbances with depression and social withdrawal, especially if the defect involves speech (West, 1974; El-Deiry et al., 2005).

Individuals with personality disorders with limited coping mechanisms, or those with cognitive dysfunction, or both, are particularly vulnerable. Otolaryngology patients have very high rates of alcohol abuse and or nicotine dependence (Baile, 2008; Prout et al., 1997). In addition, individuals with poor family, social, or religious supports are also at risk for psychological dysfunction (Natvig, 1983a; Dhooper, 1985). Early psychiatric examination and intervention can improve long-term adaptation, through the treatment of existing comorbid psychiatric disorders and relief of psychological dysfunction (Buckman, 2008). Optimal long-term rehabilitation, which includes modulation of mood, recovery of physical function, and improved social and work relationships, strongly depends on efforts initiated immediately postoperatively (Anderson, 1987; Mumford et al., 1982). Nevertheless, the distinction between normal and abnormal adaptation as well as the delineation of specific psychiatric syndromes postoperatively remains problematic for the psychiatric diagnostician.

Although some patients make good physical adaptations to the tracheostomy from the standpoint of speech, breathing, and physical endurance, psychologically they may not be as successful. Patients may become more withdrawn and less active than prior to surgery. They may be embarrassed and feel “disgusting” because of bronchial secretions or drooling. The sexual life of these patients may be completely devastated.

When initially examined, there may be no formal, overt psychiatric disorder. Although psychological symptoms may be sub-threshold in magnitude during the initial psychiatric evaluation, with recurrent disease the patient is at substantial risk for developing more fulminant psychiatric syndromes, such as depression, anxiety, or other behavioral disturbances. Substance abuse is a frequent diagnosis in this very high-risk population whose disease may well have been caused by alcohol or nicotine dependency. Major psychological distress is found in head and neck cancer patients (Kirsten, 2008). Only a small portion of patients receive psychological support (Singer et al., 2005; Buckman, 2008), even though practice guidelines have been delineated (National Comprehensive Cancer Network, NCCN, 1999).

Psychiatric syndromes and disorders observed in studies of otolaryngology patients differ by the site of observation. Those examined in a liaison setting on an inpatient head-and-neck surgical service in the United States (Bronheim et al., 1991a) are listed in Table 72.1. Adjustment disorders were the most common Axis I disorder. Substance abuse and cognitive-impairment disorders were also frequently diagnosed. Major mood disorders and anxiety were also commonly observed. A significant portion of patients had definite Axis II disorders. A retrospective review of 189 laryngectomy

**Table 72.1 PSYCHIATRIC DIAGNOSES
AMONG OTOLARYNGOLOGY INPATIENTS
PERIOPERATIVELY***

AXIS I (N = 143)		
No disorder	23.0%	32
Major mood disorder	10.1%	14
Anxiety disorder	1.4%	2
Somatoform/factitious	0.0%	0
Psychotic disorder	1.4%	2
Organic disorder	12.9%	18
Substance abuse disorder	18.0%	25
Adjustment disorders	36.0%	50
AXIS II-PERSONALITY DISORDERS (N = 139)		
No disorder	54.0%	75
Definite personality disorder	18.0%	25
Deferred or unknown diagnosis	28.1%	39

*The patients were consulted in the context of a liaison intervention at the Mount Sinai Hospital from, 1980–1986. The cohort represents a mix of standard consultations plus others identified by or to the liaison psychiatrist. The cohort does not represent a screening sample (Bronheim et al., 1991a).

patients in clinic settings in Germany revealed high rates of alcohol dependency and mood disorder (Herrman et al., 2005). High levels of anxiety and depression were also found in patients with chronic sinusitis, and demonstrate the unusually stressful impact of these chronic conditions and their repeated treatment (Bhattacharyya & Wasan, 2008). In a survey of 106 patients in British outpatient ENT clinics, 39% had an anxiety disorder, and 27% had depression (Veer et al., 2010).

MAJOR MOOD DISORDERS

Given the extreme-to-catastrophic nature of the stressors in the otolaryngology setting, it is not surprising that the most common psychiatric diagnosis encountered was adjustment disorder; either depressed or anxious. Although patients may suffer distress that may warrant consultation, the magnitude of psychological impairment may nonetheless remain at a sub-threshold level of a major mood or panic disorder. Most patients with adjustment disorder do go on, however, to make slow but adequate psychological adaptation over time, with the advent of physical recuperation and social reintegration. Although studies have demonstrated the significant impact of a variety of medical disorders on clinical outcomes (Lesperance et al., 1996; Von Korf et al., 1992), the diagnosis of depression is often complicated by problems of definition and measurement (House, 1988; Kathol et al., 1990a; Mason & Frosch, 1989). Diagnosis of depression in the medically ill

differed by as much as 13%, depending on the diagnostic system, and frequently was falsely positive (Kathol et al., 1990b). The Hamilton Rating Scale for depression depends heavily upon somatic symptoms for the diagnosis and is likely to be over-inclusive of physically ill patients (Rapp & Vrana, 1989; Hamilton, 1960). The Beck Depression Inventory, which depends heavily on cognitive factors, yields false-positive results in patients with transient delirium, which is also common in medically ill populations (Endicott, 1984; Beck et al., 1961). Furthermore, psychological cognitive and vegetative symptoms commonly remit with the alleviation of the medical illness, pain treatment, or improvement postoperatively (Kathol et al., 1990a), which further complicates the reliability of the diagnosis.

The diagnosis of major depression is especially difficult to ascertain in this patient population. Derangements in speech, appetite, swallowing, breathing, and sleeping, and the direct effects of cancer, may all obscure the diagnosis (Holland et al., 1977). Somatic symptoms are often unreliable in establishing a diagnosis and need to be replaced with another symptom domain that is *ideational* or *behavioral* and less liable to distortion by physical illness. Nevertheless, when in addition to being in a depressed mood, the patient becomes extremely needy, pessimistic, angry, brooding, or hopeless over a sustained period of time, the diagnosis of major depression should be made and treatment with antidepressants initiated (Endicott, 1984). Hopeless despair and anhedonia are primary markers for major depression. Hopelessness in particular is a major risk factor for suicide.

ANXIETY AND PANIC

The vulnerable patient who is unprepared and subjected to the trauma of multiple surgeries or complications may develop a sustained anxiety state with intermittent panic and hyperarousal, alternating with numbness and emotional exhaustion. This mental traumatization may evolve to a fully realized syndrome of post-traumatic stress disorder (PTSD) (Marek, 2009). On the other hand, the patient with a tracheostomy who appears to be acutely panicked may be suffering discomfort due to intermittent airway obstruction, bronchospasm, and hypoxemia. Before making a diagnosis of general anxiety or panic disorder, careful consideration to the adequacy of the patient's airway and blood gases should be given (Basawaraj et al., 1990).

SUBSTANCE DEPENDENCY AND AGITATION

Because head and neck tumors are associated with long-term alcohol and tobacco use, a large proportion of otolaryngology patients are male and many have alcohol-related dementias or other cognitive-impairment disorders related to alcohol abuse. In the head and neck surgical setting, the postoperative course is commonly complicated by agitation due to alcohol and nicotine withdrawal—both of which can also mimic

panic disorder. Because of the effects of alcohol use, underlying dementia may first present itself on the ENT service in the context of a postoperative delirium. Individuals with compromised cognitive capacity due to cerebral atrophy are more susceptible to delirium occurring as a result of anesthesia, infection, anemia, hypoxemia, or other metabolic factors.

Alcohol and nicotine use are common in head and neck patients, and alcohol withdrawal must be considered in every patient with postoperative delirium. When patients undergo long reconstructive surgery, the operative report should be reviewed for episodes of hypotension or an unrecognized drop in hematocrit. A neurological exam needs to be performed to rule out a cerebral ischemia. Delirium may be caused by aspiration of contaminated secretions from the oral/pharyngeal/laryngeal surgical wound into the lungs. Medications need to be carefully reviewed in a patient whose delirium persists over an extended period of time.

The assessment of dementia on the ENT service is particularly difficult when the patient has a tracheostomy (Strain et al., 1988). Patients with delirium will “mouth” long responses even when they cannot be understood, and may refuse to write responses to direct requests to do so. They are also unable to simply cover the tracheostomy tube opening with their finger in order to phonate. These are maneuvers that cognitively intact individuals attempt to learn to provide as much comprehensible communication as possible. Patients with delirium cannot learn these basic maneuvers, nor can they recognize that they cannot be understood by others, and consequently they persist in their ineffectual attempts.

This patient population with alcohol and nicotine addictions, delirium, and suicidal and violent behaviors captures many of the principal clinical problems encountered in medical psychiatry.

THERAPEUTIC APPROACH

The treatment of head and neck patients to some extent poses an even greater challenge to the consulting psychiatrist than the diagnostic dilemmas that are presented. Treatment, as elsewhere in the medical-surgical setting, is tailored to the individual needs of the patient, such as antidepressants for major depressions and supportive therapy for adjustment reactions. All too often, however, psychiatric consultants unfamiliar with the otolaryngology setting overprescribe medication when supportive psychotherapy might be the better treatment of choice. Combination therapy or the sequential application of a variety of therapies is often necessary. Following is a brief discussion of the most common therapeutic modalities and how they may be specially modified in the head and neck setting.

PSYCHOTHERAPY

The intensity of the stressors makes psychosocial intervention necessary in the head and neck surgical service, especially problem-focused supportive psychotherapy (Doering, 2009;

Semple, et al., 2009, 2014; Marek, 2009). Because of the profound patient disfigurement, the first reaction of many psychiatrists is to politely retreat from the ENT setting as soon as possible (Spikes & Holland, 1975; Buckley, 1986). Patients, however, are intensely sensitive, if not overly so, to the effects of their appearance on others and respond to the psychiatrist's behavior in kind. Patients will observe from the beginning whether the consulting psychiatrist is sufficiently comfortable to enter into a meaningful, ongoing therapeutic relationship. Poor doctor–patient communication has a negative impact on the patient's physical and psychological recovery (Lehmann et al., 2009).

By practice and history, psychiatry has adopted a receptive role in examining patients, trying to listen empathically while encouraging the patient to speak. Obviously, this will not proceed smoothly on the ENT service, and psychiatrists must be prepared to assist a patient in communication through an active participation (Bronheim, 1994). For the purposes of efficiency, psychiatrists must supply their own phrases to fill in the gap of feelings probably intended to be, but not fully expressed among the patient's short written phrases and facial and hand gestures. Psychiatrists must try to express for patients what the patients are unable to express for themselves.

The face is the most highly cathectic part of the body image, and we all retain primitive, repressed fears of grotesque distortion of body parts. Few experiences in life prepare one for the dramatic disfigurement that occurs as a result of maxillofacial surgery. As a result, the reflection that patients confront with their first look in the mirror can be so horrifying as to significantly traumatize them and delay their psychological and physical recovery. Psychotherapy requires a sensitive but firm exploration of this charged issue of disfigurement. Direct inquiries should be made about a patient's changed appearance and the attendant feelings; as well as the frustration of not being able to speak for themselves.

Supportive psychotherapy involves deliberate efforts to reduce patient stress and anxiety. The more consulting psychiatrists know about the expected course of medical/surgical treatment of the patient, the more helpful they can be to the patient in alleviating their anxiety. Otolaryngology patients have only infrequent discussions with anybody who is knowledgeable about their condition and therefore are motivated to discuss the course of treatment, including a review of the events and emotions leading up to the present state. The psychiatrist may be the only one who enters into a deep exploration of the patient's fears and thoughts and is therefore uniquely positioned to correct cognitive distortions and unfounded fantasies. In this active participatory manner, psychiatrists may build a narrative of affect that communicates their understanding to the patient, and in some instances the psychiatrist literally speaks for the patient. As a result, therapeutic interviews tend to be of shorter duration, and more frequent contacts are necessary (Groves & Kucharski, 1986).

Over the past decade, cognitive behavioral therapy (CBT) has been the type of psychotherapy most often discussed in the medical setting. In Meniere's disease, for example, “intolerance of anxiety” has been identified as the underlying abnormal cognition (Kirby & Yardley, 2009). CBT

involves the identification of abnormal cognitive concerns and behavioral preoccupations; the setting of here-and-now goals in treatment; repeated exposure to the causes of anxiety; confrontation of non-adherence to healthy new behaviors; and supporting the participation in relaxation exercises. Nonetheless, a review of CBT studies in ENT found that it has not demonstrated significant advantage over other stress reduction techniques (Martinez-Devesa et al., 2010). Many of the particular techniques currently considered in CBT have been taught as part of supportive psychotherapy in the clinical literature of the past. Therefore, psychotherapy with this patient population must be eclectic, with the psychiatrists' being flexible in their ability to adapt the psychotherapeutic approach to the needs of the patient at any given time.

DRUG THERAPY

Pharmacological therapy is frequently necessary and is the treatment of choice in a number of situations. In general, oral administration of medications is partially or completely well tolerated. However, patients who have undergone oral-pharyngeal-laryngeal surgery may for a time have profound deficits in swallowing and an inability to ingest medications without coughing or aspiration. Since the remainder of the gastrointestinal system is intact and functional, the consulting psychiatrist in this setting may need to recommend the placement of a feeding tube to facilitate access for the timely administration of medication as well as food and water. The psychiatrist may be the only physician to witness the patient's difficulty with swallowing. When necessary, the parental administration of psychotropics should be considered.

The diagnosis of depression in the medical setting is problematic, but, when made, depression should be treated promptly and adequately with the addition of antidepressants. Selective serotonin reuptake inhibitors (SSRIs) such as sertraline, citalopram, escitalopram, or fluoxetine, as well as combination agents such as duloxetine, mirtazapine, and venlafaxine, are now generally preferred for initial pharmacotherapy. Bupropion should be avoided because of the risk of seizure disorder in this patient population. Although many individuals diagnosed with depression may remit with improvement in their physical condition, some studies of depression in medical-surgical settings indicate that pre-surgical antidepressant treatment is superior for decreasing postoperative depression in select patients and that antidepressant use improves post-op rehabilitation and facilitates the return to work (Lydiatt et al., 2008; Schleifer et al., 1989; Rifkin et al., 1985). Lydiatt et al. (2013) found in a randomized, double-blind, placebo-controlled clinical trial that prophylactic escitalopram (10–20 mg for 16 weeks) given to non-depressed patients about to undergo upfront treatment for head and neck cancer reduced the risk of depression by more than 50%, and the benefit for quality of life continued for three months after the medication was stopped.

The acute control of mania is seldom encountered in this setting, but, if necessary, all major antimanic agents such as lithium carbonate, carbamazepine, and valproate may be used. However, because of blood loss and volume shifts that

may occur in extended surgical reconstructive cases, serum levels of antimanic agents and anticonvulsants should be checked postoperatively. Dosages should then be adjusted to ensure that therapeutic levels are maintained while simultaneously avoiding acute toxicity.

Grave's disease is a medical condition often diagnosed by ENT physicians, and diagnosis and treatment protocols can be found in most medical textbooks. A fifteen-year follow-up of 150 lithium-treated patients yielded an annual rate of hypothyroidism of 1.5%, leading to three thyroidectomies; the equivalent of a 2% incidence rate (Boachetta et al., 2007).

Because of the intense stress of otolaryngology surgery, panic attacks and general anxiety are common in this group. Lorazepam is the preferred medication. Buspirone and SSRIs are not used acutely perioperatively because of the long lag time necessary to obtain anxiolysis. However, they may be used in the outpatient setting postoperatively if chronic panic and anxiety persist, especially in patients with unresectable malignancies and those with a history of chemical and alcohol dependency.

In general, alcohol withdrawal is best managed with long-acting benzodiazepines such as diazepam or chlordiazepoxide hydrochloride. Because of the high incidence of alcoholism and high rates of hepatitis, cirrhosis, and alcohol-related brain atrophy in this patient population, lorazepam, by virtue of its renal excretion and intermediate half-life, as well as its administration by parenteral and sublingual routes, is advantageous for regular use in this setting. Because of the increased prevalence of mild dementia and other cognitive deficits in this patient population, drug-induced delirium occurs frequently, and benzodiazepines should be tapered rapidly. Very short-acting benzodiazepines such as triazolam should be avoided, as well as zolpidem, because of the problems of rebound anxiety, rebound insomnia, and the greater likelihood of nighttime confusion or amnesia. When alcohol withdrawal is thought to predominate (by history or physical exam), then more benzodiazepines such as lorazepam should be given, up to approximately 24 mg/day. Alcohol detox can be accomplished using alternative medications such as chlordiazepoxide and diazepam. In the intensive care unit (ICU), if in addition to anxiety the patient appears more discomforted by the endotracheal or tracheostomy tube, then narcotics should be added and titrated up until the patient is comfortably sedated. The decision about which combination of medications to be used and in what dosage is usually made on an empirical clinical basis.

Because of alcohol and nicotine withdrawal, as well as postoperative intermittent airway obstructions, panic-like states erupt postoperatively. Although serious attention must be given to airway suctioning, benzodiazepines should be employed in adequate doses to increase the patient's comfort and tolerance of the tracheostomy, as well as to block agitation due to withdrawal. Respiratory depression is seldom a problem and in general does not represent an impediment to adequate treatment.

In head and neck tumors, there is a significant effect on disease recurrence with recurrent alcohol abuse. Special efforts should be made for all patients who smoke or use alcohol to

encourage smoking cessation and alcohol detoxification and abstinence. Alcohol cessation is a very important objective of psychosocial intervention. Alcoholism is a life-threatening illness that requires psychiatric support as well as a strong patient commitment. Alcoholics are not uncommonly treated with harshness by the medical-surgical staff because of their persistent self-destructive behavior that engenders feelings of hopelessness on the part of the medical staff. Alcoholism is an increasingly treatable disease incorporating individual psychotherapy, participation in support groups such as Alcoholics Anonymous (AA), and the utilization of prophylactic medications such as naltrexone, acamprosate, disulfiram, and others.

Smoking cessation is also important in head and neck surgery and in all other otolaryngology patients (Prout et al., 1997). Various modalities have been demonstrated to be beneficial for use in this manner. When patients try to stop alone, success rates at one year are 5%. With behavioral intervention, they are up to 16%. With prophylactic medication, the success rates rises to as high as 24% (Laniado-Laborin, 2010). The medications include nicotine-replacement therapy, bupropion, and varenicline (Mechatje, 1998; Evins et al., 2008; Garrison & Dugan, 2009; Schnoll et al., 2005; Webb et al., 2010; Stead et al., 2008). As of yet, which is the most advantageous medication is not clear (Doggrell, 2007).

Pain is seldom psychogenic in nature in otolaryngology and when present, usually reflects pathology, infection, or invasive tumor. Treatment with adequate dosage and frequency of narcotic analgesics relieves pain and lessens the overall quantity of narcotics requested and consumed; substance dependence as a result seldom, if ever, develops. More typically, patients suffer unnecessarily because, all too often, their pain is insufficiently managed with low doses of short-acting narcotics. The occasional substance-abusing patient who stridently demands narcotics at all times can be managed with methadone or other long-acting narcotics, OxyContin, opana, and so on, in fixed doses, which can be slowly tapered over seven to ten days. Patients should be observed for drug accumulation, mental obtundation, and respiratory depression due to the long half-life of the narcotics used.

BEHAVIORAL TEAM APPROACH

The multidisciplinary team has been found to be particularly helpful in supporting families with acute crises as well as chronic long-term conditions; not the least of which is merely smoking cessation (Baile, 2008). Multiple functional disabilities occur in otolaryngology as a direct consequence of the surgery for the underlying disease. As a result, many individuals are overwhelmed and withdrawn in the immediate postoperative period. A behaviorally oriented team comprising the surgeon; occupational, speech, and physical therapists; nursing staff; and a psychiatrist work in conjunction to identify the patients at risk. The team creates a therapeutic milieu that is behaviorally active, rewarding the patient for progressive behaviors instead of passive acceptance or avoidance of somatic preoccupation and regression. In so doing, the team actively prepares the patient for a resumption of life

postoperatively and the transition from the hospital to the home environment (Natvig, 1983b; Dropkin, 1989; Petrucci & Harwick, 1984).

Family members are directly affected by disfigurement and other bodily alterations in the head and neck surgery patients. The negative impact of disfigurement, cancer, surgical wounds, ostomies, and secretions can be severe (Kim et al., 2008). Therapy in the form of family groups is beneficial in supporting both the patient and family members who are overwhelmed. Couple and family groups can be used to correct inappropriate behaviors and facilitate in-hospital teaching of tracheostomy care (Dhooper, 1985; Vogtsberger et al., 1985; Fiegenbaum, 1981). Just as families benefit from support groups and family therapy, effective drug and alcohol rehabilitation almost always requires group participation. Unfortunately, despite observed benefits, up to 80% of families decline to participate in multi-family group-support programs (Ostroff et al., 2004). Long-term benefits and improvements in quality of life have been observed in patients who participate in group psychotherapy (Hammerlid et al., 1999). Patients with pain disorders, disabling dizziness, or vertigo also benefit from involvement with similarly affected individuals in Group Psychotherapy (Miziara et al., 2009). Visitations in the hospital by carefully selected volunteers can be profoundly helpful to patients who are traumatized by head and neck surgery and disfigurement. The psychiatrist can play a central role in formulating a treatment plan for the otolaryngology patient by being the one clinician sufficiently informed enough by all parties to integrate all the biopsychosocial factors involved in the patient's illness and rehabilitation.

SPECIAL TOPICS

AIDS TO COMMUNICATION

In order to communicate effectively with head and neck surgical patients, especially those with laryngectomies, the psychiatrist must effect a close relationship despite all the physical obstacles to normal communication. At first, the nonverbal efforts by the psychiatrist communicate to patients a willingness to search for deeper thoughts and feelings. Helping to arrange the patients so they can write more comfortably and then adopting a receptive pose allows the patients to more fully express their feelings. When unable to write, letter boards and other devices may be used in situations where the patient is too ill or in the ICU.

The presence of a tracheostomy does not necessarily imply the inability to communicate. In many cases it does not even mean the absence of the larynx or vocal cords. Tracheostomy may be necessary either temporarily postoperatively or in situations of chronic airway narrowing or obstruction. Simple adjustments of the size of the cuffed tracheostomy can lead to significant changes in the patient's acceptance of the tube (Kluin et al., 1984). Less physical inspiratory effort is required to quickly suck in sufficient air in a larger bore tracheostomy tube. Speech can then be produced by covering the

tracheostomy opening with one's finger and forcing air up and through the vocal cords—producing sound. It may become necessary to repeatedly refocus the patient on the best respiratory efforts to produce audible, comprehensible language. In-depth communication with a patient on a ventilator is facilitated by the use of a one valve on a tracheostomy tube (Hess, 2005). The consultant psychiatrist who is aware of the alternatives can advise the respiratory care team to consider exchanging the tracheostomy for one of several special tubes with one-way speaking valves (Cazolli, 1999).

Speech restoration following laryngectomy and the removal of the vocal cords has always been an important goal for head and neck surgeons. Speech can be produced by creating a vibrating column of air that is funneled through other tissue spaces and then to the oral pharynx to produce sound. The most common surgical procedure to restore speech in this manner is the tracheo-esophageal puncture (TEP) (Hamaker et al., 1985; Halvorson & Kuhn, 1997). Some patients who are overwhelmed or unmotivated to make an active effort to do so, fail to communicate effectively; thus becoming depressed and withdrawn.

For those who cannot tolerate surgery, rehabilitation with a speech therapist utilizing mechanical and electronic devices is necessary. In them, sound is produced by creating the voice artificially. The most commonly employed communication aids involve trans-cervical sound production, which may be generated by positioning the device carefully in the neck (an electronic larynx). Vibration is transmitted from the vocal tract through the neck and then converted to synthetic speech. Although easy to use, these devices produce a voice that sounds artificial. With newer computer technology and voice reproduction programming, signal recognition and amplification is being converted to more natural-sounding voice production. Visits to the bedside by a former patient who has suffered through similar surgery and rehabilitation are particularly helpful in demonstrating mechanical devices and speech for a patient who is anxious about the future.

Group therapy is of invaluable benefit for the laryngectomy patient and family. A network of self-help groups exists for similarly afflicted patients. For those unable to attend groups, individual online groups' internet postings are of unique benefit to individuals with speech deficits. Although online discussion can be recommended, it should not take the place of psychosocial rehabilitation, human contact, and re-socialization efforts.

HEARING LOSS AND DEAFNESS

Approximately 6% of the population has significant bilateral hearing impairment, approximately 45% of whom are over age 65 (Bailey et al., 1976). Twenty-five percent of people between ages 65 and 74 and 50% of those 75 years and older experience hearing difficulties (Anderson & Meyerhoff, 1986). Although there is no basis for an association with psychotic states, in the elderly, the "hard of hearing" are over-represented in cohorts of paranoid disorders (Cooper, 1976; Savoy et al., 1991; Eastwood et al., 1985). Because of communication deficits and social isolation, the hard of hearing are also more commonly

afflicted with depressive disorders (Yovell et al., 1995; Lee & Gomez-Marin, 1997).

Deafness is also a major cause of speech retardation and associated behavioral impairments in children (Kaplan & Sadock, 1985). In children referred for a wide variety of school problems, 8% have abnormal hearing, 30% have abnormal speech discrimination in noise, and approximately 60% have abnormal auditory memory (Oberklaid et al., 1989). Therefore, a complete audiology assessment is warranted as part of the evaluation of all children with learning difficulties or developmental language disorders. Evaluation of hearing includes otoscopic examination of the ear canals and tympanic membrane, pure-tone and speech audiometry, stapedius reflex, and vestibular testing with nystagmography to distinguish between conductive and sensorineural deficits. Hearing sensitivity is measured for frequencies of 250–18000 cycles/sec (Hertz). A hearing threshold of 15 decibels (db) or less is considered normal, and an average hearing threshold of 30 db or less in the 500–3000 Hz zone is sufficient for ordinary needs. Amplification may be necessary if school or social activities require even better hearing. Although pure-tone measurements provide significant information, speech discrimination is equally important for the assessment of hearing deficits. Monosyllabic words can be presented at loud levels, and the percentage of words correctly identified is noted. Scores lower than 70%–80% indicate significant difficulties in understanding speech (Anderson & Meyerhoff, 1986). A functional prosthetic hearing aid is indicated for deafness, and individual fitting of a device should be performed by an audiologist. Complete deafness is very rare, and those with almost total deafness usually have remnants that can be utilized by high-performance hearing aids. Only in acoustic agnosia (sensory aphasia) is a functional hearing-aid prosthesis completely useless (Becher et al., 1989). Very young children can be tested with electric impedance-response audiometry (Becher et al., 1989).

Deaf children until recently were ordinarily educated in separate schools where sign language is taught (Becher et al., 1989). Recently, in select cases of children as well as adults, implantation of electrodes into the inner ear (the cochlear implant) has led to remarkable enhancement of acoustic perception. Although the device may lead to greater awareness of auditory stimuli, such as traffic sounds, loud speech, and syllabic vowels, not all patients will necessarily obtain the fine auditory discrimination necessary to decode all speech. As a result of the implant, therefore, individuals may develop enhanced communication and lip- and or sign-reading skills. Tensions over this issue pit advocates for cochlear implantation and potential "mainstreaming" of children against those in favor of "separate but equal" education and support for sign language and "deaf culture" (Davey, 2011).

The fastest growing cohort of beneficiaries of cochlear implantation has been the elderly with presbycusis. The surgery is relatively uncomplicated (Berke, 2011). Review studies indicate that the elderly benefit from the surgery as much as the young (Sahli et al., 2009), and that for those who are severely hard of hearing and successfully treated, a significant improvement in depression, loneliness, and quality of life

has been achieved—equal to that seen in adolescents; even more than anticipated (Poissant, 2008; Sprinzel et al., 2010). The combination of implantation in one ear with hearing-aid amplification in the other can lead to significant improvement in speech recognition (especially high frequency) without loss to background noise (low frequency) (Olson & Shinn, 2008). As a group, individuals who undergo cochlear implantation experience an improvement in the quality of their lives with decreases in depression, anxiety, loneliness, and suspiciousness, even if up to a quarter of those patients are affected by mild to moderate tinnitus postoperatively (Anderson et al., 2009; Knutson et al., 1991; Harris et al., 1995). The psychiatrist's role, in addition to identifying the patients who are unmotivated or suffering from overt psychiatric syndromes, is to help patients and family cope with partial or limited results (McKenna, 1986; Tiber, 1985).

The management of the hearing impaired requires continuous attention directed at achieving optimum communication. The psychiatrist must remember to speak loudly, slowly, and clearly, preferably with the patient facing the lips and face of the consultant. Augmenting speech with physical, facial, and hand gestures adds to their overall comprehension and communication. Where the patient is severely deaf, sight must substitute for sound by writing, lip reading, or sign language. However, full rehabilitation requires patient, repetitive explanation and training in the use of a hearing aid (Anderson & Meyerhoff, 1986; Becher & Cohn, 1982). In general, individuals who are highly motivated, physically and socially active, and sensitive to the feelings of others, accept and adapt to the use of a hearing aid early.

Many patients who might potentially benefit from the adoption of a hearing aid give up too quickly. Resistance to the use of hearing aids is common, and not well understood. Resistance may involve physical factors, including discomfort due to poor fit of ear molds, ear canal infection, skin erosion, pain, and wax collection. Other individuals are sensitive to noise and find amplification painful (Becher & Cohn, 1982). Others who are unmotivated, socially inactive, physically immobile, depressed, or isolated will not make the necessary effort. Patients with chronic neurological disorders and dementia simply confuse the proper use of the device, such as remembering to put it in, turn it on, or change the batteries. Still others, as a result of growing dependency and interpersonal rigidity with aging, resist using a hearing aid as a means to engage in a power struggle or to avoid communication with those upon whom they depend (Savoy et al., 1991). Some individuals stubbornly resist all efforts to make communication with them easier for all those who would care to try. Behavioral approaches may be attempted, and may be beneficial in some situations.

TINNITUS AND DIZZINESS

A disorder closely related to hearing loss is tinnitus. Both hearing loss and tinnitus increase with age, and as the threshold for hearing increases, so does the severity of tinnitus. Approximately 2% of the population report significant tinnitus resulting in some disability (Coles et al., 1985). The

etiology of tinnitus is unclear and may involve a combination of factors, including spontaneous firing of the auditory nerve, denervation hypersensitivity with neural loss, or central excitation as in phantom limb pain (Slater & Terry, 1987). Tinnitus may be tested by brain stem evoked potentials. Patients who suffer from tinnitus may be extremely sensitive to noise, as was Beethoven, who suffered recurrent bouts that worsened every winter (Slater & Terry, 1987). A host of medical conditions are associated with tinnitus, such as diabetes, thyroid disorders, and anemia; as well as drugs, particularly caffeine, nicotine, aspirin, non-steroidal antiinflammatory drugs (NSAIDs), antibiotics, monoamine oxidase inhibitors, SSRIs, tricyclic antidepressants, buspirone, morphine, benzodiazepine, and many others (Slater & Terry, 1987; Seligmann et al., 1996). When tinnitus is accompanied by vertigo and deafness, Meniere's disease needs be considered. Where in addition to deafness there are symptoms of tinnitus, dizziness, and a disorder of balance, labyrinthine disease or acoustic neuroma (a surgically and focused-beam-radiation treatable condition) should be considered with further investigation by computerized tomography scan (CTS) with contrast or magnetic resonance imaging (MRI).

A significantly higher prevalence of psychiatric conditions is found in tinnitus sufferers. There is both a higher premorbid past history of depression as well as a higher comorbid incidence of major depression, with a lifetime prevalence as high as 78% (Sullivan et al., 1988). Anxiety is most associated with Meniere's disease (Kirby & Yardley, 2009). The patients most disabled by tinnitus are more likely to manifest behaviors associated with depression such as sleep disorders, poor concentration, and social withdrawal.

The treatment of tinnitus patients is multimodal. Hearing aids that amplify external sounds or produce sounds of a specific tone are commonly prescribed. Clearly, antidepressants are indicated in individuals with associated major depression. Although the underlying condition may not be eliminated by antidepressant treatment, the degree of disability and perceived suffering can be markedly improved. In addition, some patients have a robust response to even low doses of tricyclic antidepressants and fluoxetine (Shemen, 1998), perhaps because of their anxiolytic and sedating effects. Vertigo is treated with antihistamines and calcium channel blockers (Albera et al., 2003). Tinnitus is often most tormenting at nighttime, and the use of background music or white noise for masking the sensation, as well as anti-histamine medications, have been found helpful. Biofeedback and relaxation training have also been beneficially employed (Slater & Terry, 1987).

In very severe cases of tinnitus, sectioning of the vestibular nerve may be done, which ordinarily leads to dizziness due to asymmetrical input to the brain from the semicircular canals. However, in the otherwise healthy patient, rapid neurological accommodation leads to gradual improvement over time (Staffel & Pillsbury, 1993). Dizziness should always be distinguished from syncope. Syncope has multiple etiologies, including cardiac arrhythmias, orthostatic hypertension, cerebral vascular disease, or seizure disorder.

Unexplained dizziness, on the other hand, is a very common complaint in the outpatient medical setting, as well as the second most frequently reported symptom in panic disorder. Patients referred to otolaryngology clinics with complaints of dizziness have a high incidence of panic disorder: 15–20% (Clark et al., 1994; Stein et al., 1994). Other patients with unexplained vertigo demonstrate high rates of depression, anxiety, somatization, and sexual abuse (Jantos & White, 1997; Eckhardt-Henn et al., 2008). Clearly, there is a need for psychiatric consultation in the management of this difficult patient population.

In addition to examination for physical conditions discussed above, or anxiety and depression, special care should be given to obtaining a history of neglect and sexual or physical abuse. These individuals frequent multiple physicians and undergo much medical testing. Efforts should be made to limit redundant testing, and treatment should be initiated with appropriate pharmacotherapy and psychotherapy. For individuals reluctant to seek psychiatric care, support groups for a large variety of disorders exist that may be recommended, including for those suffering from chronic dizziness, tinnitus, or vertigo; and may be located on the internet at <http://www.support-group.com>.

SINUSITIS

Sinusitis affects approximately 15% of the population. Acute sinusitis is generally caused by *H. influenzae* or *S. pneumoniae* and may be satisfactorily treated with a short course of antibiotics (Kankam & Sallis, 1997). Persistent symptoms of sinusitis, including nasal congestion, rhinorrhea, facial pressure, and postnasal drip, can in most cases (85%) be treated with an extended course of antibiotics (4 weeks), nasal lavage, nasal corticosteroids, and topical decongestants. Fewer than 10% of chronic sinus sufferers will require surgery (McNally et al., 1997). The past decade has witnessed a clinical shift to endoscopic (and even robotic) techniques to virtually all surgical subspecialties. Endoscopic surgery has been particularly adapted to sinus surgery. Undiagnosed sinusitis is a common cause of intracranial pressure and pain, which often present as headache. MRI of a cohort of patients who presented to a neurology clinic with headache complaints revealed a 60% incidence of sinus disorders, two-thirds of whom had chronic sinusitis (Gordts et al., 1996).

High levels of anxiety and depression are associated with chronic sinusitis, but most of it goes undetected or untreated (Wasan et al., 2007; Bhattacharyya & Wasan, 2008; Macdonald et al., 2009). Depression is associated with poorer postoperative quality of life and chronic head pain (Chester, 2009; Mace et al., 2009; Chester et al., 2008). Conversely, depression was relieved by surgery that was successful in ameliorating chronic inflammation and facial pain (Litvack et al., 2011).

Migraine and chronic headaches are commonly seen in psychiatric practice and share overlapping symptoms of fatigue, depression, anxiety, and dizziness, which are associated with other common psychiatric disorders. Therefore, in

patients with frequent headaches that are not classic in form, or in patients with a history of recurrent or allergic sinusitis, sinus evaluation by X-ray or CT to rule out air-fluid levels, polyps, and/or inflammation should be considered. Occult sinusitis is a frequent unrecognized diagnosis in both medical and psychiatric presentations.

SPECIAL ENT DISORDERS

Spastic dysphonia, pharyngeal spasm, atypical facial pain syndrome, temporomandibular joint disorder (TMJ), laryngitis due to unresponsive gastroesophageal reflux disease (GERD), and burning tongue syndrome are disorders that can mystify the general practitioner. These disorders, which all involve the face and mouth, are consulted upon by several subspecialists before eventual referral to a psychiatrist. Usually no explanatory organic etiology can be found, and psychological explanations are sought. Although these syndromes are associated with elevated rates of anxiety and depression, clinical experience suggests that, in addition to chronic somatization and depression, these disorders might involve dysfunction of the cranial nerves' nuclei and their interconnection through the ascending tracts of the fifth nerve. Clonazepam has been used successfully in pharyngeal spasm, chronic reflux esophagitis, and TMJ. Burning tongue syndrome frequently responds to antidepressants and smoking cessation, or supportive psychotherapy (Gao et al., 2009; Miziaria et al., 2009). Spastic dysphonia is treated surgically by methods that lead to vocal cord fixation. In these patients with atypical conditions, when the pain is successfully relieved, there is usually a return to baseline psychosocial function.

Patients with atypical facial pain syndromes are usually referred to neurologists to rule out trigeminal neuralgia. Although chronic pain patients manifest high rates of somatization, optimal management involves the combination of psychosocial treatment and pain management. Temporal mandibular joint (TMJ) pain disorder is normally managed in dental practices where mal-aligned bites are manipulated. There is a high incidence of recurrence of the disorder when patients are under stress. Clonazepam is prescribed at bedtime. Spastic dysphonia was for many years considered a conversion disorder. Although anxiety was known to exacerbate this disorder of speech, psychological studies of these patients failed to reveal either somatization or conversion disorder (Ginsberg et al., 1988). Nowadays, spastic dysphonia is considered a disorder of neurological origin with features that overlap with dystonia; thought to be caused by basal ganglia, or related dysfunction within the brainstem nuclei. Electromyographically guided injections of botulin toxin administered by the otolaryngologist achieve relaxation and approximation of the vocal cords to the midline. Botulin toxin injection has also been used in palatal and pharyngeal dystonia (Jankovic et al., 1991). In all these various facial pain and dystonic syndromes, chronically recurrent depression is invariably associated.

SUMMARY

The head and neck surgical service is a unique setting for psychiatrists to apply their skills. Psychiatrists will encounter emotional threats that affect the patient directly and possibly the psychiatrists' countertransference as well. Psychiatrists will need to participate actively with the patient, sometimes in unpleasant surroundings, and will need to be familiar with surgical techniques, tracheostomy, communication, and hearing devices, as well as other prosthetic and cosmetic options. The psychiatrists will need to rely on a variety of skills and diagnostic capabilities, as well as biological and psychosocial treatment techniques to facilitate the best adaptation of the otolaryngology patient to the overwhelmingly traumatic effects of surgery.

Because of the frequent alterations in speech, detection of patients at risk is normally quite limited. Therefore, even more than is indicated in other medical-surgical settings, a liaison psychiatric approach in screening for patients at risk is most successful. The continuous presence of a psychiatrist and the enhanced awareness of the surgical staff can lead to the identification and referral of vulnerable or subclinically symptomatic patients.

Lastly, a review of the psychiatric literature in otolaryngology reveals a lack of controlled studies that may reflect psychiatric discomfort in dealing with this patient population. More rigorous study of diagnosis, interventions, and outcomes is necessary to determine the most effective psychosocial care for these patients.

CLINICAL PEARLS

- It is harder for ENT patients to isolate the self from the disease and distance themselves psychologically; especially when there are multiple overwhelming alterations in sensory and motor functions.
- Disfigurement is highly associated with depression (Valente, 2004).
- Even a minimally perceptible frightened reaction by the psychiatric consultant to the patient's appearance can have a profound effect on the therapeutic relationship.
- From a psychiatric standpoint, the main issues revolve around the patient's realistic preparedness for surgery and the possible consequences of further disfigurement or surgical complications.
- Head and neck cancer patients have very high rates of alcohol abuse and or nicotine dependence (Baile, 2008; Prout et al., 1997).
- Patients after ENT surgery with delirium will "mouth" long responses even when they cannot be understood, and may refuse to write responses to direct requests to do so. They are also unable to simply cover the tracheostomy tube opening with their finger in order to phonate. They can neither learn basic communication maneuvers nor

can they recognize that they cannot be understood by others, and consequently they may persist in their ineffectual attempts.

- For the purposes of efficiency, psychiatrists must supply their own phrases to fill in the gap of feelings probably intended, but not fully expressed, among the patient's short written phrases and facial and hand gestures. Psychiatrists must try to express for patients what the patients are unable to express for themselves.
- The reflection that patients confront with their first look in the mirror can be so horrifying as to significantly traumatize them and delay their psychological and physical recovery.
- The psychiatrist may be the only one who enters into a deep exploration of the patient's fears and thoughts and be uniquely positioned to correct cognitive distortions and unfounded fantasies.
- Lydiatt et al. (2013) found in a randomized, double-blind, placebo-controlled clinical trial, that prophylactic escitalopram (10–20 mg for 16 weeks) given to non-depressed patients about to undergo upfront treatment for head and neck cancer reduced the risk of depression by more than 50%, and the benefit for quality of life continued for three months after the medication was stopped.
- The fastest growing cohort of beneficiaries of cochlear implantation has been the elderly with presbycusis.
- When there are symptoms in addition to deafness of tinnitus, dizziness, and a disorder of balance, labyrinthine disease or acoustic neuroma (a surgically and focused-beam-radiation treatable condition) should be considered with further investigation by CT scan with contrast or MRI.
- Tinnitus is often most tormenting at nighttime, and the use of background music or white noise for masking the sensation, as well as anti-histamine medications, have been found helpful.

AESTHETIC SURGERY

David B. Sarwer and Jacqueline C. Spitzer

INTRODUCTION

According to the American Society of Plastic Surgeons (ASPS), approximately 15.1 million surgical and nonsurgical cosmetic treatments were performed in the United States in 2013 (ASPS, 2014). Of these, approximately 1.6 million were surgical procedures (e.g., rhinoplasty, breast augmentation), and over 13.5 million treatments were minimally invasive nonsurgical treatments (e.g., facial injectables, laser treatments). These numbers often are surprising to laypersons who have not considered the number of Americans who turn to plastic surgeons and other physicians to improve their appearance with medical treatments.

In recent years, numerous studies have investigated the changing attitudes of the public about cosmetic surgery. The results reveal a growing acceptance of both cosmetic surgical and noninvasive procedures to improve appearance. In 2010, for example, the American Society for Aesthetic and Plastic Surgery (ASAPS) surveyed Americans' attitudes about cosmetic surgery. The small majority of women (53%) and 49% of men surveyed said that they approve of cosmetic surgery (ASAPS, 2011). More than 60% of individuals surveyed, from young adults to those over 65 years of age, indicated that they would not be embarrassed if friends and family knew that they had had cosmetic surgery (ASAPS, 2011). One of now several independent studies of college-age women found that 45% approved of people's surgically changing their appearance to feel better about themselves (Sarwer et al., 2005). In both the ASAPS survey and other studies, women are more likely than men to consider cosmetic surgery (Swami et al., 2008).

The growth in popularity of the use of medical science to improve one's appearance can probably be attributed to a number of factors. Technological advances in medicine have made many surgical and treatments safer and have led to shorter postoperative recovery periods. Minimally invasive treatments have even less risk and recovery time associated with them, and the decreased cost of these treatments has also facilitated their rapid growth.

Along with these medical advances, the mass media and entertainment industries have contributed to the growth of cosmetic surgery. A large number and variety of television programs have covered the topic of cosmetic surgery over the past decade, ranging from educational health programs to reality-based, patient- and surgeon-focused shows, to a

fictional program set in a cosmetic surgery practice. While these shows may be "guilty pleasures" for many viewers, a recent study found a positive relationship between exposure to cosmetic "reality" television shows, more positive attitudes toward cosmetic surgery, and a feeling of increased pressure to undergo cosmetic surgery (Sperry et al., 2009). At the same time, an increasing number of celebrities have spoken publicly about their experience with cosmetic surgery, implicitly endorsing the procedures. A handful of others have served as spokespersons for specific products.

Considering the medical advances in cosmetic medicine, coupled with the mass media's continued fascination with the medical specialty, the increased popularity does not seem so surprising. The growth of these procedures has been accompanied the development of a body of research that has investigated the psychological characteristics of the persons interested in these procedures and the psychological changes they experience postoperatively.

This chapter provides an overview of this body of research. We begin with a brief review of the relationship between *preoperative characteristics and interest in surgery*, with a specific focus on the body-image concerns of patients. Given the central role of body image in this literature, the *relationship between cosmetic procedures and body dysmorphic disorder as well as eating disorders* is discussed. In addition, the surprising relationship between *cosmetic breast augmentation and suicide* is reviewed. The chapter closes with a description of the preoperative psychological screening of cosmetic surgery patients that mental health professionals may be asked to conduct.

EARLY PSYCHOLOGICAL RESEARCH ON COSMETIC SURGERY PATIENTS

Over the past 50 years, a surprisingly large number of studies have investigated the psychological characteristics of patients who present for cosmetic procedures, as well as the psychological changes they report after these treatments. This field has particularly blossomed in the past 20 years, with a specific focus on the relationship between body image and cosmetic treatments. This entire literature is reviewed in extensive detail elsewhere (Crerand, Franklin, & Sarwer, 2006, 2008; Sarwer & Crerand, 2008; Sarwer et al., 1998a). A brief overview is provided here.

Early research in this area, conducted decades ago, focused on preoperative psychopathology and relied heavily on the use of clinical interviews, often conducted by psychoanalytically trained psychiatrists, of cosmetic surgical patients. The results of these early studies indicated that cosmetic surgery patients had high rates of psychopathology, ranging from mood and anxiety disorders to personality disorders (e.g., Edgerton & McClary, 1958; Edgerton, Meyer, & Jacobson, 1961; Baker, Kolin, & Bartlett, 1974). This preoperative psychopathology was believed to be associated with poor psychosocial adjustment postoperatively.

Beginning in the 1970s, studies began to include validated psychometric measures, either alone in or combination with clinical interviews, to assess patients' symptoms of psychopathology (e.g., Wright & Wright, 1975; Goin, Burgoyne, Goin, & Staples, 1980). These studies reported far less psychopathology in candidates for surgery compared to the first studies in this area. The studies of this era also reported more positive psychological outcomes. Unfortunately, both sets of studies suffered from numerous methodological problems, making interpretation of the entire body of results difficult.

PHYSICAL APPEARANCE, BODY IMAGE, AND COSMETIC SURGERY

In addition to the contributions to the growth of cosmetic surgery described earlier in this chapter, social-psychological research can also be used to understand the growth of cosmetic surgery witnessed over the past two decades. This body of research, which can trace its origins to seminal studies of the early 1970s, has suggested that individuals who are more physically attractive are believed to have a number of more positive personality traits. Furthermore, more attractive individuals also receive preferential treatment in a range of social situations across the lifespan (Jonzon, 2009; Sarwer & Magee, 2006). With this literature in mind, an investment in or focus on one's appearance through the pursuit of cosmetic surgery may be likened to other self-improvement strategies, such as eating a healthy diet and exercising regularly, and not necessarily be a symptom of psychopathology (Sarwer et al., 1998a).

In the area of cosmetic medicine, interest in one's appearance has been studied from the perspective of the psychological construct of *body image*—a multidimensional construct, defined as an individual's internal experience of his or her appearance (Cash & Smolak, 2011). Dissatisfaction with one's body image is considered to be a primary motivating factor in the pursuit of cosmetic surgery. Several studies suggest that patients report heightened body-image dissatisfaction, particularly dissatisfaction with the specific feature being considered for surgery, preoperatively (Sarwer et al., 1998b; Sarwer, LaRossa, Bartlett, et al., 2003). Following cosmetic surgery, many studies have found that the vast majority of patients report satisfaction with the changes in their appearance as well as improvements in their body image (Banbury et al., 2004; Bolton, Pruzinsky, Cash, & Persing, 2003; Dunofsky,

1997; Murphy, Beckstrand, & Sarwer, 2009; Sarwer et al., 2008; von Soest et al., 2011). The impact of cosmetic surgery on other areas of psychological functioning, however, is less clear. While some studies have reported improvements in constructs such as self-esteem and quality of life, other studies have reported no significant improvements, or worsening of these areas of psychosocial functioning (Crerand et al., 2009; Murphy et al., 2009; Sarwer et al., 1998b; von Soest et al., 2011).

COSMETIC SURGERY AND PSYCHOPATHOLOGY

The extant research to date suggests that most cosmetic surgical patients are psychologically healthy when they present for surgery, and report satisfaction with their surgical outcome and improvements in body image postoperatively. However, three psychological disorders—body dysmorphic disorder (BDD), eating disorders, and depression—are believed to occur with frequency among candidates for cosmetic surgery and may be associated with poor postoperative outcomes.

BODY DYSMORPHIC DISORDER

BDD is defined as a preoccupation with a slight or imagined defect in appearance that leads to substantial distress or impairment in functioning (American Psychiatric Association, 2013). The most common focus of this preoccupation is the skin, hair, or nose; however, any part of the body can be the focus of the disorder (Veale, De Haro, & Lambrou, 2003). In the general population, the incidence of BDD is estimated to be less than 1–3% (Bienvenu et al., 2000; Faravelli et al., 1997; Otto, Wilhelm, Cohen, & Harlow, 2001; Rief, Buhlmann, Wilhelm, Borkenhagen, & Brahler, 2006). The incidence of BDD in patients seeking cosmetic surgery is much higher than in the general population. In studies of cosmetic surgery patients around the world, BDD ranges from 3–17% (Aouizerate et al., 2003; Vulink et al., 2006). In the United States, studies have found the incidence rate to be between 7% and 8% (Crerand et al., 2004; Sarwer, Wadden, Pertschuk, & Whitaker, 1998b).

In addition to compulsive behaviors to reduce appearance-related distress, such as repeated checking of one's appearance in mirrors or reflective surfaces, one way patients suffering from BDD seek to improve their perceived defects is through cosmetic treatments. In a study of 250 BDD patients, 76% of the patients sought and 66% received treatment (Crerand et al., 2005). Unlike most cosmetic surgery patients, patients with BDD who undergo cosmetic surgery are often dissatisfied and may, in fact, experience a worsening of their BDD symptoms. Two studies found that over 90% of patients with BDD report that their symptoms have remained the same or that they have worsened following cosmetic surgery (Crerand et al., 2005; Crerand, Menard, & Phillips, 2010). Patients may also engage in a range of ineffective treatments, “do-it-yourself surgery” or other self-harming behaviors

(Veale, 2000). Persons with BDD, regardless of their interest in cosmetic surgery, also have high rates of suicidal ideation or suicide attempts (Phillips & Menard, 2006). Finally, patients who pursue cosmetic procedures and are dissatisfied with the cosmetic outcome and/or the lack of impact on their BDD symptoms, may threaten or pursue legal action or violence against their surgeons (Sarwer, 2002). For all of these reasons, BDD is often considered a contraindication for cosmetic procedures (Crerand, Franklin, & Sarwer, 2008; Crerand & Sarwer, 2010).

EATING DISORDERS

The major eating disorders, anorexia nervosa and bulimia nervosa, are characterized by extreme body-image dissatisfaction, specifically with one's weight and shape (APA, 2013). The amount of concern that these patients feel about their appearance would intuitively suggest that both disorders may appear with some frequency among those seeking cosmetic surgery. Somewhat surprisingly, the relationship between eating disorders and cosmetic surgery has received little empirical study to date. Studies of women presenting for cosmetic breast augmentation suggests that many are of below-average weight and report greater levels of exercise compared to women not seeking breast augmentation (Brinton et al., 2000; Cook et al., 1997; Fryzek et al., 2000; Kjoller et al., 2003). Both of these characteristics may be suggestive of eating pathology. Similarly, individuals with eating disorders interested in other body-contouring procedures, such as liposuction or abdominoplasty, may erroneously believe that these procedures can "improve" their body shape in ways that inappropriate eating behavior and compensatory behaviors cannot.

A limited number of case reports have described the postoperative course of individuals with eating disorders who have undergone plastic surgical procedures. Case studies of patients with eating disorders have described patients whose eating disorder symptomatology has deteriorated following cosmetic surgery, specifically following breast augmentation, lipoplasty, rhinoplasty, and chin augmentation (McIntosh, Britt, & Bulik, 1994; Willard, McDermott, & Woodhouse, 1996; Yates, Shisslak, Allender, & Wolman, 1988). In contrast, a study of five breast-reduction patients with bulimia found that four of the women experienced an improvement of their symptoms and a reduction in emotional distress. These improvements were maintained for ten years postoperatively (Losee et al., 1997, 2004). In these cases, the excessive breast tissue may have contributed to the initial body-image disturbance and may have been an etiological factor in the development of the eating disorder. By having this excess breast tissue removed surgically, the patients' body dissatisfaction appears to have been lessened, although this was not objectively studied.

DEPRESSION

The presence of mood disorders, specifically depression, in cosmetic surgery patients also warrants specific attention.

Approximately 20% of all cosmetic surgery patients are engaged in mental health treatment, typically with the use of an antidepressant or other psychiatric medications (Sarwer, Zanville, et al., 2004). The most common treatment was the use of antidepressant medications. Compared to women in the general population, women seeking breast implants also were found to have a higher rate of outpatient psychotherapy (Sarwer, LaRossa, et al., 2004) and psychiatric hospitalizations (Jacobsen, et al., 2004). Though these studies suggest that cosmetic surgery patients, and cosmetic breast-augmentation patients in particular, may have higher rates of depression or mood disorders, the specific psychiatric diagnoses of these women were not described.

Other studies of cosmetic breast augmentation patients have suggested that these women frequently present for surgery with a number of unique personality characteristics and life experiences (see Sarwer, Brown, & Evans, 2007, for a detailed review). They are more likely to have more sexual partners over their lifetimes, report a greater use of oral contraceptives, be younger at their first pregnancy, and have a history of terminated pregnancies. They are more frequent users of alcohol and tobacco and have a higher rate of dissolved marriages. All of these characteristics may be associated with mood disorders or other forms of psychopathology.

Furthermore, studies over the past decade have revealed a surprising relationship between cosmetic breast augmentation and postoperative suicides. Seven epidemiological studies that investigated silicone gel-filled breast implants (used for cosmetic purposes) and all-cause mortality, found the rate of suicide among women with breast implants is two to three times higher than the estimated suicide rates in the general population or as compared to women interested in other plastic surgical procedures. There are a number of potential explanations for these findings; most have focused on the preoperative psychosocial status and functioning of the women (McLaughlin, Wise, & Lipworth, 2004; Sarwer, 2003; Sarwer et al., 2007). That is, the unique personality characteristics and life experiences of these women described above are, in and of themselves, associated with psychopathology as well as an increased risk of suicide, and they, rather than something related to the surgical procedure or implants themselves, are the most parsimonious explanation for the subsequent suicides. Unfortunately, of the seven epidemiological studies, only one provided information on the psychiatric history of the women studied. Jacobsen and colleagues (2004) found that women who received cosmetic breast implants had a higher rate of previous psychiatric hospitalizations compared with women who received other cosmetic procedures or underwent breast reduction surgery. A history of psychiatric hospitalizations is one of the strongest predictors of suicide among women in the general population (Qin, Agerbo, & Mortensen, 2003). Unfortunately, Jacobsen and colleagues (2004) did not report information on diagnosis, history of illness, or other psychiatric treatments for the women in the sample.

MENTAL HEALTH EVALUATIONS OF COSMETIC SURGERY PATIENTS

The mental health issues detailed above are believed to impact a small, yet not inconsequential, number of cosmetic surgery patients. Most individuals interested in cosmetic surgery are probably more similar to than different from those who do not present for surgery, in that they have a number of psychological strengths but also psychological issues—many of which may be completely unrelated to their pursuit of cosmetic surgery. Most patients present to the surgeon with specific appearance concerns, internal motivations, and realistic postoperative expectations. After surgery, the vast majority of patients report satisfaction with their postoperative outcomes and improvements in body image. The impacts on other areas of psychological functioning are less well established.

For these reasons, cosmetic surgeons do not require that patients undergo a mental health evaluation prior to cosmetic surgery. Given the lack of current evidence suggesting a relationship between preoperative psychosocial status and postoperative outcomes, recommendations for such routine evaluations are not warranted. Rather, cosmetic surgeons, like all medical professionals, should assess and screen for the presence of psychopathology as part of taking a medical history and completing a physical examination. Unfortunately, most surgeons (or their delegates) are likely to skip this part of the assessment and, as a result, fail to identify patients who may exhibit symptoms of psychopathology.

Patients who display symptoms of psychopathology during their initial consultation with the plastic surgeon, as well as those with a history of psychopathology, are the ones who probably should be referred for a mental health consultation prior to a cosmetic procedure (Sarwer, 2006). Many of the early descriptions of cosmetic surgery patients are complete with elaborate interpretations of the role of unconscious conflicts and poor parental relationships in the decision to seek surgery. There is no evidence, however, to suggest that such interpretations are necessarily valid or useful in determining patients' appropriateness for surgery. Thus, a detailed assessment of patients' parental relationships and decades-old historical experiences is unlikely to provide useful information to either the mental health professional or the referring surgeon in determining appropriateness for surgery. A more straightforward evaluation of patients' current functioning, as found in the more general cognitive-behavioral assessment, is recommended (Sarwer, 2006).

The cognitive-behavioral assessment of the cosmetic medicine patient should focus on the thoughts, behaviors, and experiences that have contributed to their dissatisfaction with their appearance as well as the decision to seek surgery. This involves the assessment of the "ABCs" of patients' interest in surgery (Sarwer, 2006)—the antecedents ("A") to the decision to seek a cosmetic treatment, the behavioral responses ("B") to their concerns about their appearance, and consequences ("C") of their decision to seek surgery. The evaluation also should determine if the patients' thoughts and behaviors are maladaptive to the point that they reflect some form of psychopathology that would contraindicate surgery. Finally, the

assessment should focus on the patients' psychiatric status and history, their appearance and body-image concerns, as well as their motivations for surgery and expectations regarding the postoperative result and its impact on daily functioning.

PSYCHIATRIC HISTORY AND STATUS

The assessment of the patients' psychiatric history and current status, as done in any mental health consultation, is a central part of the evaluation. With the exception of BDD, there currently are no conclusive data on the prevalence of psychiatric diagnoses among persons who seek or undergo cosmetic surgery. Given the number of individuals who now seek cosmetic surgery and minimally invasive treatments, it is likely that all of the major psychiatric diagnoses can be found in the patient population. The consulting mental health professional should pay particular attention to disorders with a body-image component, such as eating disorders and somatoform disorders, as well as mood and anxiety disorders. The presence of these disorders, however, may not be an absolute contraindication for cosmetic surgery. In the absence of specific data on the relationship between psychopathology and surgical outcome, appropriateness for surgery should be made on a case-by-case basis.

As noted above, approximately 20% of patients who seek cosmetic medical treatment report using a psychiatric medication at the time of treatment (Sarwer, Zanzville, et al., 2004). Patients who receive these medications from a primary care physician often do not experience complete relief from their symptoms. Thus, a psychopharmacological evaluation should be considered if symptoms do not appear to be well controlled. If patients are in treatment with another psychiatrist or psychologist, the consultant should contact the treating clinician and, as appropriate, discuss patients' appropriateness for cosmetic treatment.

PHYSICAL APPEARANCE AND BODY IMAGE

Pruzinsky (1996) suggested the use of Lazarus's BASIC ID (1993)—Behavior, Affect, Sensation, Imagery, Cognition, Interpersonal, and Drugs—as a template to assess the body-image concerns of patients interested in cosmetic surgery. In addition, Cash's (2002) model of the historical and proximal influences on body image can provide an additional framework for this part of the assessment. The medical psychiatrist or psychologist also may want to consider the use of more specific body-image measures to assist with providing a more comprehensive assessment. Valid and reliable measures such as the Multidimensional Body Self Relations Questionnaire (Brown, Cash, & Mikulka, 1990) or the Derriford Appearance Scale (Carr, Harris, & James, 2000) can provide the mental health professional with detailed information on any symptoms of body-image dissatisfaction or BDD.

Prospective patients should be able to articulate specific concerns about their appearance that should be visible with little effort. Patients who are markedly distressed about slight defects that are not readily visible may be suffering from BDD. Some of the appearance concerns may be difficult to

assess, as the context of the consultation may prohibit medical psychiatrists or psychologists from asking patients to remove articles of clothing. Furthermore, the judgement of an appearance defect as “slight or imagined” is highly subjective. What a medical psychiatrist or psychologist judges to be a slight defect well within the range of normal may be a defect that a cosmetic surgeon judges to be appropriate for treatment. As a result, the degree of emotional distress and impairment, rather than the specific nature of the defect, may be more accurate indicators of BDD in these patients (Crerand, Sarwer, & Franklin, 2006, 2008; Sarwer, 2006; Sarwer & Crerand, 2008).

The degree of dissatisfaction and any psychosocial consequences of dissatisfaction also should be assessed. Asking about the amount of time spent thinking about a feature or the activities missed or avoided on its account may indicate the degree of distress and impairment a person is experiencing and may help determine the presence of BDD. Self-report measures of BDD symptoms, such as the Body Dysmorphic Disorder Questionnaire, also may be helpful in this regard.

MOTIVATIONS AND EXPECTATIONS

The consultant also should inquire about patients’ motivations for surgery. Specific questions about what a patient hopes to accomplish by having surgery can provide essential details about motivations. Patients who are motivated by internal factors, such as improvements in body image, are believed to have better postoperative outcomes than those motivated by external factors, such as pleasing a romantic partner (Honigman et al., 2004).

To assess motivations for surgery, the first question to begin the discussion may be “When did you first think about changing your appearance?” In addition to providing important clinical information, a thorough discussion of the issue may reveal the presence of some obsessive or delusional thinking, as well as bizarre or compulsive behaviors, related to physical appearance. Patients also should be asked how romantic partners, family members, and close friends feel about their decision to change a physical feature. Thus, the clinician should inquire about patients’ general expectations about how the change in appearance, which may be rather subtle and potentially unnoticed by others, will influence their lives. There is no current evidence suggesting that cosmetic procedures directly affect interpersonal relationships. Therefore, patients should be reminded that it is impossible to predict how others will respond to their changed appearance. Some patients may find that few people notice the change in their appearance, while others may have the experience that everyone seems to notice them. While some patients may find this attention pleasurable, others may find it uncomfortable. To assess this issue, patients should be asked how they anticipate their lives will be different following surgery. The experience of unmet postoperative expectations is another possible explanation of the relationship between cosmetic breast augmentation and suicide (Sarwer, Brown, & Evans, 2007).

CONCLUDING THE EVALUATION

At the conclusion of the evaluation, the consultant should share the clinical impressions with the patient, as well as the ultimate recommendation to the referring physician about the appropriateness for surgery. The results of the evaluation should be communicated to the surgeon in a letter summarizing the assessment and recommendations. Obviously, the referring physician will make the ultimate decision about the decision to go forward with a given treatment.

POSTOPERATIVE CONSULTATIONS

Medical psychiatrists and psychologists also may be asked to consult with cosmetic surgery patients postoperatively. This typically occurs in one of two scenarios—the patient is dissatisfied with a technically successful procedure, or the patient is experiencing an exacerbation of psychopathology that was not detected preoperatively. Patients in each of these examples typically warrant psychotherapeutic care. Cognitive-behavioral models of body-image therapy are often useful with these individuals, although more diagnosis-specific treatments also may be necessary (e.g., for depression, social or generalized anxiety, etc.).

SUMMARY

Over 15 million cosmetic surgical and minimally invasive treatments designed to improve one’s physical appearance are performed each year in the United States. As the number of these procedures has increased, so has the interest in the psychosocial functioning of individuals who present for surgery, as well as the psychological changes that they experience postoperatively. The current body of evidence suggests that the vast majority of patients are psychologically healthy and that most patients will be satisfied with the outcome of their treatments and experience improvements in body image. The impact on other areas of psychological functioning, such as self-esteem and quality of life, are less clear. At the same time, a minority of patients may be suffering from significant psychopathology that may decrease the likelihood that these individuals would experience psychological benefits from these procedures. The literature suggests that BDD occurs with greater frequency among cosmetic surgery patients, compared to the general population, and probably contraindicates cosmetic surgery. Depression and suicidality also appear to be of concern, particularly among women who present for cosmetic breast augmentation. Given the relationship with body-image dissatisfaction, eating disorders also may be prevalent among persons who present for cosmetic surgery, but this area of research awaits further study.

With the increasing popularity of cosmetic surgery, it is likely that most medical psychiatrists will encounter patients interested in changing their bodies through cosmetic surgery. They may be asked to consult with patients interested in surgery to assess their psychological appropriateness for certain procedures. In addition to utilizing

the basic principles of cognitive-behavioral assessment, preoperative assessments should focus on psychiatric status and history, body-image concerns, and motivations and expectations for surgery. Successful collaboration with the cosmetic surgeon can increase the likelihood that most patients are psychologically appropriate for surgery or will receive mental health treatment to address their appearance concerns.

CLINICAL PEARLS

- In the area of cosmetic medicine, interest in one's appearance has been studied from the perspective of the psychological construct of "body image"—a multidimensional construct, defined as an individual's internal experience of his or her appearance (Cash & Smolak, 2011).
- Following cosmetic surgery, many studies have found that the vast majority of patients report satisfaction with the changes in their appearance as well as improvements in body image (Banbury et al., 2004; Bolton, Pruzinsky, Cash, & Persing, 2003; Dunofsky, 1997; Murphy, Beckstrand, & Sarwer, 2009; Sarwer et al., 2008; von Soest et al., 2011).
- Three psychological disorders—body dysmorphic disorder (BDD), eating disorders, and depression—are believed to occur with frequency among candidates for cosmetic surgery and may be associated with poor postoperative outcomes.
- In the United States, studies have found the incidence rate of BDD to be between 7% and 8% (Crerand et al., 2004; Sarwer, Wadden, Pertschuk, & Whitaker, 1998b).
- Unlike most cosmetic surgery patients, patients with BDD who undergo cosmetic surgery are often dissatisfied and may, in fact, experience a worsening in their BDD symptoms.
- Persons with BDD, regardless of their interest in cosmetic surgery, also have high rates of suicidal ideation or suicide attempts (Phillips & Menard, 2006).
- Studies of women presenting for cosmetic breast augmentation suggest that many are of below-average weight and report greater levels of exercise compared to women not seeking breast augmentation (Brinton et al., 2000; Cook et al., 1997; Fryzek et al., 2000; Kjoller et al., 2000).
- Approximately 20% of all cosmetic surgery patients are engaged in mental health treatment, typically with the use of an antidepressant or other psychiatric medications (Sarwer, Zanzville, et al., 2004).
- Seven epidemiological studies that investigated silicone gel-filled breast implants (used for cosmetic purposes) and all-cause mortality, found the rate of suicide among women with breast implants is two to three times higher than the estimated suicide rates in the general population

or as compared to women interested in other plastic surgical procedures.

- The cognitive-behavioral assessment of the cosmetic medicine patient should focus on the thoughts, behaviors, and experiences that have contributed to their dissatisfaction with their appearance as well as their decision to seek surgery. This involves the assessment of the "ABCs" of patients' interest in surgery (Sarwer, 2006)—the antecedents ("A") to the decision to seek a cosmetic treatment, the behavioral responses ("B") to their concerns about their appearance, and consequences ("C") of their decision to seek surgery.
- Asking about the amount of time spent thinking about a feature or the activities missed or avoided may indicate the degree of distress and impairment a person is experiencing and may help determine the presence of BDD.

DISCLOSURE STATEMENTS

Dr. Sarwer has consulting relationships with the following companies: BARONova, EnteroMedics, Ethicon, and Kythera.

Ms. Spitzer reports no disclosures.

TRANSPLANTATION

Thomas W. Heinrich, Michael Marcangelo, and Heidi Christianson

INTRODUCTION

Perhaps nowhere in medicine have science, technology, and clinical care become as closely interlinked as in the field of transplant medicine. Science, in the form of effective immunosuppressant agents, has provided clinicians with the means of overcoming the expected immunological reaction that results when the tissue from a genetically dissimilar individual is transplanted into another individual. Technology, in the form of advancement of surgical technique, has led to better surgical outcomes following solid organ transplantation. Medical science has allowed organ transplantation to advance from an experimental concept less than 70 years ago to a well-established treatment modality for a wide variety of illnesses and end-organ failure. As a result, transplantation of solid organs (kidney, liver, pancreas, intestine, heart, and lung) along with hematopoietic stem cell transplants (HCTs) has become common practice in medical centers all over the world.

TYPES OF TRANSPLANTATION

Transplantation describes the act of transferring an organ, tissue, or cell from one individual to another. Transplants are broadly defined by the genetic similarities between donor and recipient. *Autotransplants* involve the transfer of an organ, tissue, or cell from one part of an individual to another part of that same individual. Because both the donor and recipient are the same person, there is no genetic difference recognized by the recipient's immune system, and no immunosuppression is required to prevent rejection. *Allotransplants* involve the transfer of an organ, tissue, or cell from one individual to a different individual. Unless this transfer occurs between genetically identical twins, some form of suppression of the recipient's immune system will be required to prevent rejection of the graft. Although some generalities exist among transplant patients, organ-specific considerations are important and guide many aspects of assessment and management.

DECEASED DONOR TRANSPLANTS

Most donated solid organs are from deceased individuals (Organ Procurement and Transplantation Network/The Scientific Registry of Transplant Recipients [OPTN/SRTR], 2009). These donors meet the criteria for brain death, but

their organs are maintained by life-support measures until informed consent can be obtained from family for donation and the organ procured by the transplant team. The concept of "brain death" means that all brain and brain stem functions have irreversibly ceased activity. Medication effects, hypothermia, and other potentially reversible causes for brain failure must be excluded prior to the final determination and declaration of brain death. The withdrawal of life support from the donor and actual organ donation always occurs with the consent and understanding of the family of the donor.

LIVING DONORS

Potential organ recipients often die awaiting the donation of a compatible organ from a deceased donor (OPTN/SRTR, 2009). The use of organs provided by living donors has greatly increased the supply of certain organs available for transplantation. As a consequence, living-donor donation has become fundamental to the modern practice of transplantation medicine. The concept of living-donation, however, presents its own set of medical and ethical challenges (Ventura, 2010). It is fortunate, however, that the potential disadvantages of living-donor transplants to the donor appear fairly minimal. Adverse donor outcomes usually are related to the surgical procedure being performed, as some organ procurement procedures are technically complex, resulting in an increased incidence of surgical complications, morbidity, and mortality.

Some individuals in need of organ transplantation have family and friends interested in donation, but often these potential donors are unable to donate secondary to genetic incompatibility. In an effort to help these patients receive the potentially life-saving organs, transplant programs have begun arranging paired living-donor transplants (Wallis, Samy, Roth, & Rees, 2011). In these cases, two or more pairs of living donors and matched recipients participate in a paired exchange of organs. In other words, donor/recipient pairs with willing but incompatible donors are matched with another donor/recipient pair who have the same incompatibility problem.

KIDNEY TRANSPLANTATION

As a result of effective immunosuppression, kidney transplantation now is the treatment of choice for many patients with end-stage renal disease (ESRD). Almost all renal diseases

responsible for renal failure can be treated by transplantation, and most patients with chronic renal failure should be considered for possible renal transplantation. Transplantation often offers the greatest potential for restoring the patient to a healthy and productive life. Renal transplantation, when compared with dialysis, has been associated with improved patient survival, superior health-related quality of life, and lower overall health costs (Fujisawa et al., 2000; Wolfe et al., 1999). Results for patients who receive a kidney transplant prior to the initiation of dialysis show an improved rate of graft survival compared to that of patients who had had long-term dialysis prior to transplantation (Papalois et al., 2000). It is therefore important for the treatment team to consider patients for renal transplantation as soon as the need for renal replacement therapy appears imminent.

The two sources of kidneys for renal transplantation are living and deceased donors. Living kidney donations are now as common as deceased donation; although the total number of kidneys from deceased donors still exceeds that obtained from living donors, as each deceased donor can donate two kidneys (Figure 74.1).

The graft survival rate for living-donor kidney transplants has been reported to be 96% at one year, 81% at five years, and almost 60% at ten years (OPTN/SRTR, 2009). The donor's remaining kidney compensates for the loss of the donated kidney. Unfortunately, as noted previously, most candidates for a kidney transplant do not have a suitable identified living donor. These patients are placed on a waiting list for a kidney from a deceased donor. Because of the clinical success of the procedure and the limited amount of available organs, this waiting list has grown dramatically over the years. Currently, there are over 100,000 patients in the United States awaiting a kidney transplant (OPTN: Organ Procurement and Transplantation Network, <http://optn.transplant.hrsa.gov/>).

Figure 74.1 Kidney and kidney-pancreas transplants. U.S. Department of Health and Human Services, Health Resources and Services Administration (2010). 2009 Annual Report of the U.S. Organ Procurement and Transplantation Network and the Scientific Registry of Transplant Recipients: Transplant Data 1999–2008. Rockville, MD: Healthcare Systems Bureau, Division of Transplantation.

Following kidney transplantation, patients are monitored for organ rejection by serial measurements of renal function. When the transplanted kidney begins to function, the serum creatinine will gradually fall over a period of several days to reach a new functional baseline. Any significant decrease in renal function below the newly established baseline should prompt an evaluation to determine the etiology. Potential causes include dehydration, obstruction, infection, and graft rejection. Rejection of the transplanted kidney is diagnosed by renal biopsy. Aggressive immunosuppressant therapy is effective in reversing more than 90% of the cases of acute kidney rejection (Midtvedt et al., 2003).

PANCREAS TRANSPLANTATION

A successful pancreas transplantation can lead to normalization of glycemic control in previously diabetic patients without the need for glucose monitoring or insulin administration. Through maintenance of a euglycemic state, the successful pancreas transplant may halt the progression of complications of hyperglycemia, which are associated with significant morbidity and mortality. Pancreatic transplants may also improve the recipient's quality of life, although pre-morbid psychiatric illness may temper this benefit (Smith, Trauer, Kerr, & Chadban, 2010). Pancreas transplants are now most commonly performed in diabetic patients with concurrent ESRD who are also candidates for a kidney transplant. Pancreas transplant alone, however, may be considered appropriate in the adherent diabetic patient without ESRD who is experiencing an impaired quality of life secondary to the sequelae of difficult-to-control diabetes.

LIVER TRANSPLANTATION

Liver transplant outcomes were generally quite poor until the introduction of the immunosuppressant cyclosporine in the 1980s. Since that time, survival rates have improved dramatically, with one-year patient survival rates hovering around 90% in 2007 (OPTN/SRTR, 2009). Improved outcomes have led to an expanding list of potential indications and a diminishing list of contraindications to liver transplantation. As a result, nearly 6,000 liver transplantations were performed in the United States in 2007 (OPTN/SRTR, 2009) (Figure 74.2).

The list of illnesses that may be addressed through a liver transplantation may be divided into acute hepatic insults and chronic liver disease states. The chronic disease states, specifically cirrhosis, account for the majority of liver transplants today. Cirrhosis is most commonly secondary to chronic hepatitis C infection, but cirrhosis may also be caused by hepatitis B infection, sclerosing cholangitis, fatty liver disease, autoimmune hepatitis, or primary biliary cirrhosis. Alcohol may contribute to the development of end-stage liver disease and cirrhosis, alone or in combination with viral hepatitis infection. Fulminant hepatic failure, or acute liver disease, is defined as the development of coagulopathy and hepatic encephalopathy

Figure 74.2 Liver, heart, and lung transplants. U.S. Department of Health and Human Services, Health Resources and Services Administration (2010). 2009 Annual Report of the U.S. Organ Procurement and Transplantation Network and the Scientific Registry of Transplant Recipients: Transplant Data 1999–2008. Rockville, MD: Healthcare Systems Bureau, Division of Transplantation.

in a patient shortly after the onset of other symptoms of liver disease. There are many causes of acute liver failure. One of the most common etiologies of acute liver failure encountered by the psychiatrist is acetaminophen overdose.

The Model for End-stage Liver Disease (MELD) score has been utilized to help predict the severity of illness and associated mortality of patients awaiting a liver transplant (Kamath et al., 2001).

A higher MELD score suggests a more severe level of illness and associated elevated risk of mortality (Box 74.1). Patients on the waiting list are listed by MELD score, with the highest scores being at the top of each blood group. This differs from kidney transplants, where patients are listed simply by the amount of time they have been waiting for a transplant. The goal is to direct the donated liver to the individual in greatest need based on their predicted mortality. It is important to note that the MELD system does not account for all illness parameters, and unique patient-specific circumstances must often be taken into account to ensure the best use of donated livers.

Living-donor liver transplantation is an option for some candidates, but the risk to the proposed donor and the benefit to the potential organ recipient must be carefully balanced. Donation of the left lateral segment or lobe of the liver, which is used primarily in pediatric liver transplantation, and right lobe liver donation, which is used in adult liver transplantation, are both associated with the potential for donor morbidity and mortality. Middleton et al. (2006) reported an overall donor mortality of approximately 0.2%, with a slightly higher rate of approximately 0.4% in right lobe donation. The most common complications reported in this study were infections and biliary leaks. A study that looked at the psychosocial outcomes of liver donors found that approximately 96% returned to their previous employment at 2.4 months,

Box 74.1 MODEL FOR END-STAGE LIVER DISEASE (MELD)

$$\text{MELD score} = 3.8 \times \log(e)(\text{bilirubin mg/dL}) + 11.2 \times \log(e)(\text{INR}) + 9.6 \log(e) \text{ creatinine mg/dL}$$

Source: Kamath, P. S., Wiesner, R. H., Malinchoc, M., Kremers, W., Therneau, T. M., Kosberg, C. L., et al. (2001). A model to predict survival in patients with end stage liver disease. *Hepatology*, 33(2), 464–470.

but a significant minority (42%) reported a change in bodily images, and a majority (71%) reported ongoing mild physical symptoms. The out-of-pocket cost associated with the donation averaged over \$3,500. Importantly, each of the 24 individuals surveyed reported that they would donate again (Trotter et al., 2001).

When compared to other transplanted organs, the transplanted liver appears to require less immunosuppression maintenance therapy. Corticosteroids may be gradually discontinued once the graft is established. Monotherapy with a calcineurin inhibitor is often all that is required to suppress rejection long-term. In fact, immune tolerance with normal graft function in the absence of immunosuppressant medications has been reported to occur in approximately 10–20% of liver transplant recipients (Lerut & Sanchez-Fueyo, 2006).

HEART TRANSPLANTATION

Over 2,000 heart transplants were performed in 2007, with a one-year survival rate of just less than 90% (OPTN/SRTR, 2009). Donor hearts must be ABO-compatible and preferably free of preexisting heart disease. In addition, the donor should be within 20% of the recipient's ideal body weight in an effort to match historic and potential cardiac work load. The most common medical conditions treated with cardiac transplantation include idiopathic dilated or ischemic cardiomyopathy. Candidates for transplantation should have failed optimal medical therapy for their end-stage heart failure and have exhausted all other surgical options.

As the transplanted heart is both afferent and efferent denervated, allograft pathology is difficult to diagnosis clinically. Therefore, in asymptomatic individuals, regular post-transplant monitoring for rejection is warranted. The 2010 consensus statement by the International Society for Heart and Lung Transplantation indicates that routine coronary angiography is the accepted standard for surveillance for rejection following heart transplantation (Mehra et al., 2010). Noninvasive techniques have yet to be shown to be sensitive enough to replace invasive coronary angiography within the first five years following transplantation. If the noninvasive studies, such as dobutamine stress echocardiography or computed tomography (CT) angiography, are abnormal, the patient will require evaluation by invasive coronary angiography. In addition, if the patient presents with symptoms and signs of left ventricular dysfunction, invasive coronary

angiography and endometrial biopsy are necessary to diagnosis rejection. Acute rejection in cardiac graft recipients is identified based on the results of an endomyocardial biopsy. Transplant centers often follow a regular predetermined schedule of biopsies after transplantation.

Chronic rejection is believed to be manifested through accelerated coronary atherosclerosis, or allograft vasculopathy, in the engrafted heart. Chronic graft rejection has been documented to occur in 30–40% of patients within five years after transplantation (Syeda, Roedler, Schukro, Yahya, Zuckermann, & Glogar, 2005). Registry data indicate that about 33% of deaths up to ten years following transplantation are secondary to cardiac allograft vasculopathy and resulting graft failure (Taylor et al., 2009). Fortunately, cardiac allograft vasculopathy is a slowly progressive disease, and clinical outcome appears related to severity of the coronary disease (Costanzo et al., 1998). Unfortunately, there is no known effective therapy for this progressive condition except retransplantation with another heart.

Patients with failing hearts awaiting cardiac transplant may be bridged to transplantation using mechanical ventricular assist devices (VADs). These cardiac assist devices are driven by external power sources and have been shown to improve survival to transplantation (Frazier et al., 2001). Individuals being bridged to transplant with a VAD must meet criteria for transplantation and must have failed all other pharmacological therapies for severe heart failure, including oral medications and intravenous inotropic support. VAD placement stabilizes the patient's hemodynamic status while awaiting transplantation (Haft et al., 2007). As a result, the end-organ effects of severe congestive heart failure, such as renal failure, hepatic dysfunction, and delirium, can be dramatically reduced. These devices can sustain the patient over weeks, months, or even years until a cardiac transplant is obtained for the patient. Post-transplant survival for patients bridged to cardiac transplant with VADs has been shown to be comparable to those not requiring treatment with VAD (Shuhaiber, Hur, & Gibbons, 2010). The use of VADs is not without associated psychiatric comorbidity (Tigges-Limmer, Schönbrodt, Roefe, Arusoglu, Morshuis, & Gummert, 2010). Memory problems and risk of stroke have been concerns, but the technology is improving.

LUNG TRANSPLANTATION

Over the last decade, lung transplantation has become an established intervention in the management of patients with irreversible end-stage pulmonary disease. Patients must be oxygen-dependent, and they typically have a life expectancy of 12–18 months without successful lung transplantation. Pulmonary diseases that can lead to transplantation include chronic obstructive pulmonary disease (COPD), cystic fibrosis, interstitial lung disease, α_1 -antitrypsin deficiency, and primary pulmonary hypertension. Patients with different lung pathologies may derive varying levels of clinical benefit from transplant. In a study of United Kingdom lung transplants, Titman et al.

(2009) found transplantation appeared to improve survival for all groups studied, but cystic fibrosis patients fared the best post-transplant, while patients with COPD had the greatest risk of death following transplant. There are approximately 1,300 lung transplants performed annually in the United States (OPTN/SRTR, 2009). Lung transplant patient survival rates, overall, in the United States have been reported to be 84% at one year, 54% at five years, and 27% at ten years (OPTN/SRTR 2009).

A major long-term complication of lung transplantation is the development of the bronchiolitis obliterans syndrome (BOS). BOS is characterized clinically by airflow limitation and pathologically by partial or complete occlusion of the lumens of terminal bronchioles by inflammation and fibrous tissue. Over 50% of lung transplant recipients surviving to five years will develop BOS (Christie et al., 2008). BOS is thought to be a manifestation of chronic rejection. Episodes of acute rejection of the lung graft have been identified as a risk factor for the future development of chronic rejection and BOS (Todd & Palmer, 2011). There is currently no effective therapy for BOS, although the development of aerosolized immunosuppression provides hope for directed and enhanced pulmonary immunosuppression.

INTESTINAL TRANSPLANTATION

Intestinal transplantation may be offered to patients with irreversible intestinal failure resulting in impaired absorption and associated malnutrition. Intestinal failure is most often due to short-bowel syndrome. Crohn's disease, trauma, and surgical complications are common causes of short-bowel syndrome in the United States. Total parental nutrition (TPN), the standard treatment for impaired intestinal absorption, has significant associated morbidity and mortality. Intestinal transplantation was developed in an attempt to avoid the potential complications of long-term TPN. Controversy exists about which patients should continue to receive TPN and which should receive an intestinal transplant (Fishbein, 2009). As a result, intestinal transplants represent one of the least frequently performed organ transplants, with only 162 intestinal transplantations performed in the United States in 2007 (OPTN/SRTR 2009).

Intestinal transplants are associated with some of the highest rates of rejection in solid organ transplantation. The high rates of rejection are probably due to the fact that the intestine is a very complex organ immunologically (Newell, 2003). Transplantation is further complicated by the fact that identification of graft rejection is a clinical challenge, since the most common symptom of graft dysfunction is the very nonspecific complaint of diarrhea. It is also very difficult to biochemically monitor for rejection, as no laboratory screening tests have been developed that reliably indicate the presence of acute rejection of the intestinal graft. Infection is another common complication after intestinal transplantation, as shown in a study of 13 patients that found that bacterial infections (primarily gram-negative organisms) were the most common type of infection encountered postoperatively,

followed by viral (primarily CMV) and fungal infections (Guaraldi et al., 2005).

COMPOSITE TISSUE TRANSPLANTATION

Composite tissue transplantation is a developing area of reconstructive transplant surgery. Such composite tissue transplantation may lead to improved outcomes for patients who have suffered devastating facial or upper extremity injuries. Quality of life has been reported to improve following composite tissue transplantation (Coffman, Gordon, & Siemionow, 2010). The most important determinants of successful composite tissue transplantation appear to be patient selection, adherence, intense rehabilitation, and a dedicated, experienced, multidisciplinary treatment team (Siemionow, Zor, & Gordon, 2010).

A review of 13 cases of facial transplantation was performed between 2005 and 2010 (Siemionow & Ozturk, 2011) in which a majority of facial transplantations were described as “partial facial reconstruction.” For the majority the need resulted from traumatic injury. Two of the 13 patients had died due to transplant-related complications. Functional outcomes differed in each survivor as a result of differences in pre-transplant injury. Because of limited experience with it and the overall complexity of composite tissue transplantation, multiple questions regarding the role of this treatment remain unanswered.

HEMATOPOIETIC STEM CELL TRANSPLANTATION (HCT)

An HCT involves the infusion of hematopoietic stem cells obtained from bone marrow (bone marrow transplantation), peripheral blood, or umbilical cord blood in an effort to treat various hematological, neoplastic, and autoimmune conditions. HCTs may be autologous or allogeneic. In allogeneic stem cell transplants, human leukocyte antigen (HLA)-matched stem cells from a donor are transferred to the recipient. In an autologous stem cell transplants, the patient's own previously harvested stem cells are infused back into the patient following the myeloablative therapy. Autologous HCT is now a more common therapy than allotransplantation (Pasquini & Wang, 2010). The ability to transplant healthy hematopoietic stem cells permits the administration of otherwise lethal chemotherapy with or without associated radiation to a patient. The object of this myeloablative preparation is to eradicate the unwanted cell lines.

Allogeneic transplants are usually considered for patients younger than 60 years of age, due to an increasing incidence of graft-versus-host disease (GVHD) in older recipients (Gale et al., 1987). Patients who do not have an HLA-matched sibling may use stem cells from a partially HLA-matched relative, or the National Marrow Donor Program (NMDP) may identify an unrelated but closely HLA-matched potential donor. In addition, cord blood can be utilized in HCT. Immunosuppression to prevent

graft rejection and GVHD is an important component of allogeneic transplantation. However, lifelong immunosuppression is often not required in allogeneic HCT due to the development of immunological tolerance once engraftment of the transplanted cells is complete. The same immunological activity of the donor cells that contributes to the occurrence of GVHD also provides an important graft-versus-tumor effect, which leads to reduced rates of oncological relapse after allogeneic transplant in patients who develop GVHD (Horowitz et al., 1990). In contrast to allogeneic HCT, autologous transplantation may be safely utilized in older patients because of the absence of GVHD. However, the risk of transplanted autologous stem cells being contaminated with tumor cells, coupled with the loss of a graft-versus-tumor effect, results in patients who are undergoing autologous transplantation having higher cancer relapse rates. If no suitable hematopoietic stem cell donor is found, or if the transplant is urgent, cord blood from related or unrelated donors can be used. Cellular qualities of cord blood may convey less host-targeted activity so that the incidence of GVHD is reduced despite HLA mismatch. One proposed theory is that the cytotoxic T cells in cord blood are naïve with decreased allogeneic reactivity, due to the presence of non-inherited maternal antigens. For many children, cord blood is now transplanted instead of peripheral blood or marrow from unrelated adults. Outcomes of cord blood HCT vary according to the disease being treated, the age of the patient, and the degree of HLA mismatch between the recipient and the transplanted cord blood.

HCTs are associated with the potential for significant morbidity. Infections are a major cause of morbidity due to the effects of myeloablation therapy and, in the case of allogeneic HCT, the immunosuppressive therapy (Wingard, Hsu, & Hiemenz, 2010). Mucositis is a common complication of the pre-transplant myeloablative preparative regimens. When mucositis affects the gastrointestinal tract, it may cause nausea, cramping, and diarrhea, and can be so severe as to require parenteral nutrition. Oropharyngeal mucositis is very painful and can lead to poor oral intake. Another acute adverse effect of HCT is veno-occlusive disease of the liver. This syndrome consists of painful hepatomegaly, jaundice, ascites, and weight gain. Veno-occlusive disease is potentially fatal.

THE PRE-TRANSPLANTATION ASSESSMENT

One of the key roles that the medical psychiatrist or psychologist plays on a transplant team is performing the pre-transplantation assessment of patients who are being considered for transplantation. This evaluation plays an important role in determining which patients will be listed for transplantation and eligible for the scarce organs that make up the transplant pool. Pre-transplant assessment should address substance abuse, social support, adherence, major mental disorders, and cognitive impairment. As a whole, pre-transplant assessment can be used to assess the patient's

ability to cope with the intervention and the post-transplant recovery period, in order to inform the team whether an individual would be able to psychologically handle transplant. It also allows for treatment planning to monitor and manage high-risk patients.

THE MULTIDISCIPLINARY TEAM

Organ transplantation involves professionals from many disciplines. In order to achieve clinical and administrative success, this team must work together effectively to serve patients. While teams vary in composition from transplant center to transplant center and from organ to organ within centers, a number of disciplines are typically represented. Sub-specialist internists, such as cardiologists or hepatologists, often play central roles in the management of the patients and frequently serve as the referral source for the team. Transplant surgeons perform the operations and play leading roles in organ procurement and post-operative management. Nurses often serve as coordinators for the patients and become the people whom patients turn to with questions about nuances of their medical regimen as they navigate their way through the process of transplantation. The assessment team includes, usually, a psychiatrist or a psychologist and a social worker. Sometimes, teams have both a psychiatrist and a psychologist. Screening assessments and supportive psychotherapy are performed by any of the three disciplines. In addition, typically, psychiatrists diagnose major mental disorders and prescribe psychotropic drugs; psychologists do diagnostic assessments and deliver cognitive behavioral therapy (CBT); and social workers address family, occupational, financial, and insurance-related problem. The leader of the assessment team is typically either a psychiatrist or a psychologist. Advance-practice nurses function as case managers on many transplant teams, coordinating the biomedical, psychosocial, and practical aspects of patients' care.

Patient selection is a key aspect of transplantation team work, and usually this occurs as a weekly meeting of the selection committee where all disciplines are present. Typically, surgery, the applicable medical subspecialties, and psychiatry are represented. Patient care coordinators, who are usually nurses, often lead the meetings and initiate the presentation of the patient's case.

LIVING-DONOR ASSESSMENT

Living donation for kidney and liver transplantation is performed at many transplant centers. Transplant centers should have a special team dedicated to evaluating prospective donors. The donor's motivation for donation is a key aspect of the evaluation. "True informed consent" is a challenging concept in the face of family pressure and a life-or-death situation. If the donor knows the recipient, which is by the far the most common scenario, there must be discussion of their relationship and the donor's hopes for life after the transplant. A basic psychiatric evaluation should also take place to ensure that the patient's decision is not unduly influenced by an

active mental disorder. Financial incentives for donation are strictly prohibited in the United States, and efforts should be made to ensure that the recipient is not paying for the organ. This concern increases with donor-recipient pairs who are distantly related or even strangers, and where the recipient has financial means.

BIOPSYCHOSOCIAL ASSESSMENT

The assessment of potential transplant recipients includes many of the professionals outlined above. Medical and surgical assessment is central to establishing that a patient is likely to survive transplant and is suitable from a technical perspective. Additionally, psychosocial assessment is essential and covers a number of key areas, including his or her psychiatric history, coping style, and level of social support.

When patients consent to a psychiatric evaluation as part of their transplant assessment, the psychiatrist has two duties, which are sometimes in conflict. One duty, akin to that of a typical psychiatric evaluation, is to assess the patient's safety and overall mental health and provide treatment as indicated. The other duty is to provide information to the team that will inform the team's decision about how to proceed with the patient's medical care, including what priority to assign to the patient on a waiting list. This part of the work, akin to forensic evaluation, is intended to maximize overall social benefit and may not always serve the best interests of the patient being evaluated. Juggling these responsibilities is one of the primary challenges facing psychiatrists and psychologists working in transplant. At the outset of the evaluation, the psychiatrist can explain that the purpose of the evaluation is to determine if the patient is a suitable candidate for transplantation and to provide treatment recommendations for any psychiatric conditions that are diagnosed during the evaluation.

SOCIAL SUPPORT

A major element of the evaluation is assessment of a patient's social support. Often, the social worker on the team will perform a detailed assessment of a patient's living situation, family structure, and financial status. The psychiatrist should review these with the patient and assess the stability and constancy of the patient's support network. After transplant, patients require assistance with many aspects of their lives, including nutrition, transportation, and finances. There is evidence that transplant patients who live with at least one other person have better medical and psychiatric outcomes than those who live alone (Tsunoda et al., 2010; Spaderna et al., 2010). Patients with poor social support have lower rates of adherence after transplant (Dobbels et al., 2009; Stille et al., 2010). The emotional support provided by family and friends also assists patients with the often difficult recovery after transplant. For patients with limited support, involving those closest to them in the process and developing a plan for the post-transplant period can often improve their candidacies significantly.

INFORMED CONSENT

Organ transplantation is among the most invasive and life-altering surgeries a person can undergo, and, as such, the patient's capacity to consent should be assessed carefully. In the face of end-stage organ disease, patients face the prospect of death without transplant, and they often quickly agree to the procedure before they understand the impact it will have on their life. The pre-transplant evaluation should assess a patient's consent for transplant. By reviewing their medical problem, their options, and their choice, a patient can demonstrate that they have the capacity to make an informed decision (Appelbaum, 2007). A patient's knowledge of the illness does not have to be complete, but basic facts, like which organ needs to be transplanted and the likely outcomes with or without transplant, should be confirmed. A bedside cognitive evaluation should also be performed to help to assess the patient's capacity to consent. When the chronic mental status waxes and wanes as it might pre-liver transplant, the assessments are made when the patient is at his best.

ADHERENCE

The medication regimen that patients are prescribed after transplant is often complex and daunting to follow, even by the standards of patients who have had long-standing medical problems. The threat of organ rejection and the need for powerful immunosuppressants mean that patients must be able to take their medications as prescribed in order to maintain their health. During the pre-transplant assessment, a patient's ability to adhere to complex medical regimens should be investigated as thoroughly as possible. Predicting a patient's behavior months or years after an evaluation is impossible, but if patients have a clear history of non-adherence with past treatment, they are at risk for non-adherence after transplant. More than 60% of American liver transplant programs reported that they would not list for transplantation a patient with a history of non-adherence (Kroeker et al., 2008). Risk factors for non-adherence in kidney transplantation include depression, younger age, and fewer than 12 years of education (Jindal et al., 2009), and it is reasonable to believe that these risk factors apply to other organs as well. Hemodialysis attendance for patients with renal failure is probably the most straightforward way to assess adherence in pre-transplant patients; if patients have struggled to attend dialysis sessions regularly, they are likely to struggle with the post-transplant regimen of medications and appointments.

When assessing adherence, both patients and their medical record should be consulted. Patients should be asked about their understanding of post-transplant management and expectations. Patients may be surprised after transplant by the complexity of their situation and voice regret about having agreed to take on the major responsibility of managing their medications and appointments. A detailed discussion before transplant can often clear up some of this misunderstanding. Patients should also review their current medications, including their indications, dosages, and timing. The amount of

assistance the patient requires to take his or her medications as well as their level of organization (e.g., weekly pillboxes) can provide hints of how much effort a patient puts into their medical care. Records can indicate how often patients miss scheduled appointments and reveal their physician's assessment of past adherence.

In addition to medications, patients have to change their lifestyles after transplant. A post-transplant patient has to be a "professional patient" in the sense that they will be having regular physician visits, medical tests, and blood work for the rest of their lives. Additionally, patients must adhere to lifestyle changes, such as changes in diet, exercise, or mobility, following transplant that may significantly alter the way they live their lives. During the assessment, patients should be informed of these expectations and discuss their attitudes towards the patient role and significant life-adaptation. If patients indicate that they are going to struggle to incorporate the self-concept of "patient" into their post-transplant lives, they should be encouraged to think further about their choice and decide if transplant is right for them.

PSYCHIATRIC DISORDERS

Assessment of psychopathology is a primary goal of the pre-transplant assessment. The evaluation is similar to that of routine psychiatric exams, although with the absence of an obvious chief complaint. Common psychiatric disorders, such as major depressive disorder and generalized anxiety disorder, and major psychiatric symptoms, such as suicidal ideation or auditory hallucinations, should be investigated during the exam. If the patient shows signs of having impaired cognition, deciding between delirium and dementia is vital to helping the team make a decision about transplant. Hepatic encephalopathy, uremia from kidney failure, advanced heart failure with poor forward flow, or hypoxia from lung disease can all cause delirium in the context of end-stage organ disease. In these clinical situations, it is essential to gather collateral history from the patient's designated healthcare power of attorney as well as other family and friends to confirm that the cognitive changes are new and to use their substituted decision on behalf of the patient if death is imminent and listing for transplant urgent. Neuropsychological testing can be utilized to distinguish between different types of cognitive disorders and provide guidance on interventions. If the cognitive evaluation reveals significant deficits that are determined to be long-standing and consistent with dementia, the team will usually not offer transplantation.

A detailed psychiatric history, including history of hospitalizations, suicide attempts, psychotropic medications, and past diagnoses, should be obtained. As with other types of patients, transplant patients who have historically been accepting of psychiatric care are more likely to accept care in the future when it is necessary. A family history of psychiatric disorders can point towards a genetic diathesis towards affective or anxiety disorders that may emerge due to the stress of transplant.

Substance Use Disorders

Patients who receive organ transplants can have significant histories of alcoholism or substance abuse. The two most common indications for liver transplantation are hepatitis C, which commonly is contracted through intravenous drug use, and alcohol-related liver disease (Varma et al., 2010). Patients with end-stage heart failure may have ischemic cardiomyopathy with smoking as a contributing factor, or alcohol-related cardiomyopathy. Finally, COPD, most commonly caused by smoking, is one of the leading indications for lung transplantation. A detailed history of substance use, including age of onset, patterns of use, consequences of use, and most recent use, should be elicited. Each substance that the patient has used should be discussed in this fashion, and some patients will have a history of polysubstance dependence. Patients with a history of polysubstance dependence do not appear to have higher rates of alcohol and drug use after liver transplantation than those with only alcohol dependence (Coffman et al., 1997).

Another aspect of substance use that should be investigated is the patient's history of rehabilitation attempts. Both formal rehabilitation programs and attendance at Alcoholics Anonymous (AA) should be documented. Many programs require patients to either join a Twelve Step program such as AA or go into rehabilitation, although the evidence in favor of this is limited. Motivational enhancement therapy may decrease the amount and frequency of drinking in pre-transplant patients compared with usual Twelve Step-based treatments (Weinrieb et al., 2011). Risk factors for relapse that have been identified include psychiatric comorbidities, duration of abstinence of less than six months, and a high score on the High-Risk Alcoholism Relapse scale (which includes number of attempts at rehabilitation, duration of drinking, and amount of alcohol consumed each day) (De Gottardi et al., 2007). A comprehensive meta-analysis identified poor social support, a family history of alcoholism, and duration of abstinence less than six months as the major risk factors for relapse to alcohol use after liver transplant (Dew et al., 2008). It is reasonable to think that similar risk factors apply to other substances of abuse and organs.

Programs have a wide range of guidelines in regard to substance use prior to and after transplant. For heart and lung transplant programs, it is standard practice that patients abstain from smoking cigarettes for at least six months prior to transplant, and for the patient to be expected to remain abstinent for the rest of their lives. On the other hand, thoracic transplant programs often do not have a formal policy on alcohol use and, while they would expect patients with alcohol dependence to receive treatment and abstain, they tolerate moderate use of alcohol. The situation is reversed for liver transplant candidates. These patients are expected to abstain for a period of time prior to transplant, usually six months, and to remain abstinent afterwards. However, many liver and kidney transplant programs do not have formal smoking guidelines, and some programs tolerate cannabis use by transplant patients. The six-month guideline that programs have adopted has limited supporting evidence, but it does appear

that the longer a patient has been abstinent prior to transplant, the more likely they are to remain abstinent after transplant (DiMartini et al., 2010; Karim et al., 2010). Reports of successful liver transplantation in carefully selected patients with acute alcoholic hepatitis who have not achieved abstinence for any significant amount of time may lead to a change in approach for these patients, who face high mortality without transplantation (Mathurin et al., 2011).

Patients who are dependent on heroin or other opioids have high rates of hepatitis C and may develop cirrhosis and require liver transplant. Methadone maintenance therapy has been used successfully in patients undergoing transplantation, and it appears the highest rates of success are seen in patients who remain on methadone rather than transitioning off after transplant (Jiao et al., 2010). These patients often require higher doses of pain medication after transplant and often need additional methadone for an extended period post-transplant (Weinrieb et al., 2004). Other factors related to their candidacy, including levels of social support and comorbid psychiatric conditions, should be closely investigated, but if a patient is otherwise a good candidate, he or she can be successfully transplanted while on methadone. Experience with buprenorphine is limited, but it may prove to be as efficacious as methadone.

Personality Disorders

Personality disorders are a complex issue in transplantation. Personality disorders do not appear to be more prevalent in transplant populations (Dobbels et al., 2000), but patients with personality disorders can cause significant problems for transplant teams. Many programs cite major personality disorders, such as antisocial personality disorder or borderline personality disorder, as relative contraindications to transplant (Levenson & Olbrisch, 1993). Personality disorders can lead to increased rates of mood disorders after transplant, impulsive behavior such as suicidal ideation or attempts, and conflicted relationships with the transplant team. Patients with obsessive personality traits are often very adherent, but they can struggle with the loss of control that occurs during the transplant process and develop depressive disorders or adjustment disorders with disturbance of behavior in which they refuse to comply due to anger. Part of the pre-transplant evaluation should assess the patient's underlying personality traits and whether they can work successfully with the team. If the patient can, suggestions about ways in which the team can accommodate the patient (e.g., giving an obsessive patient choices to increase their sense of control when possible) help both the patient and the team work together successfully. Often, it is helpful to identify one team member to work exclusively with the patient to avoid "splitting." If the patient's personality is assessed as being prohibitive for transplant, explaining this to the team in clear language that avoids psychiatric jargon will help everyone to understand why the patient presents an unacceptable risk.

A common indication for liver transplantation is acute acetaminophen toxicity leading to fulminant hepatic failure. A large series found that 44% of these cases were related to

a suicide attempt (Larson et al., 2005). In the United States, if a patient with fulminant hepatic failure is listed, they essentially go right to the top of the list because their risk of death if there is delay quickly approaches 100%, so obtaining an accurate history quickly is essential. The patient is at risk for developing hepatic coma as their liver injury progresses, so rapid evaluation is essential. Even if the patient is awake, efforts at piecing together what happened prior to the suicide attempt can be thwarted by the patient's psychiatric disorder or their unwillingness to discuss their attempt. Family and friends may minimize risk in order to improve the patient's candidacy. While the evaluation is complex and the whole picture should be examined, the number of past attempts and the social stability of the patient are two key factors in determining if the patient is a candidate for transplant. If a patient voices a willingness to undergo transplant and has a relatively stable personal and psychiatric history, he or she can be a successful transplant recipient. In the United Kingdom, patients who underwent liver transplantation following a suicide attempt had similar outcomes as other candidates, although 6% had post-transplant suicide attempts (Karvellas et al., 2010). Ongoing suicidal ideation during the evaluation should preclude the patient from being a candidate.

Psychotic Disorders

Patients with schizophrenia present challenges to a transplant team. Their illness may be marked by non-adherence and poor social support, two common findings in a poor candidate for transplant. However, if a patient with a long-standing psychotic illness has other findings consistent with being a good candidate, including family or social support and good adherence with medications, he or she can have success with transplant. The transplant psychiatrist is likely to play an active role in the care of the patient, but if the patient has a strong established relationship with his or her psychiatrist, that person should continue to care for the patient. While outcomes have been mixed both medically and psychiatrically (Coffman & Crone, 2002), psychotic disorders should not be an absolute contraindication to transplant.

PSYCHOLOGICAL ASSESSMENT TOOLS FOR PRE-TRANSPLANT EVALUATION

Brief psychological assessment instruments used to determine readiness for transplant are the Psychosocial Assessment of Candidates for Transplantation (PACT; Olbrisch, Levenson, & Hamer, 1989), the Transplant Evaluation Rating Scale (TERS; Twillman, Manetto, Wellisch, & Wolcott, 1993), and the Millon Behavioral Medicine Diagnostic (MBMD; Millon, Antoni, Millon, Meagher, & Grossman, 2001). The former two assessment tools are rating scales that are derived from a clinical interview, while the MBMD is a validated measure that provides information in a self-report questionnaire format. The most recently developed structured transplant assessment tool, the Stanford Integrated Psychosocial Assessment for Transplantation, or SIPAT, produces a single score from a clinical interview that estimates

the patient's risks of a poor psychosocial outcome after transplant (Maldonado et al., 2012).

The items of the PACT include support stability, support availability, personality psychopathology, psychopathology risk, healthy lifestyle, drug and alcohol use, compliance, and transplant knowledge. The TERS is completed from data derived from a clinical interview and includes substance abuse, health behavior, compliance, coping history, *Diagnostic and Statistical Manual of Mental Disorders-IV* (DSM-IV) Axis I disorder, DSM-IV Axis II disorder, affect quality, mental status, family support, and disease coping. The MBMD (Millon et al., 2004) is a health psychology test that assesses selected psychiatric symptomatology, dominant coping strategies, stress moderators, and behaviors and attitudes that either complicate or enhance treatment efficacy. It has been standardized in patients with general medical conditions as well as patients seeking bariatric surgery. Farrell et al. (2011) found that the Medication Abuse subscale of the MBMD predicted medication non-adherence in heart transplant patients and accounted for the relationship between depression and non-adherence. The MBMD can also be used to identify coping strengths, such as social support, religious beliefs, and informational comfort about one's disease and treatment. As such, use of this tool can be particularly helpful when considering patient's strengths and developing treatment plans to address patients' psychiatric problems during their hospitalization and post-transplant recovery period.

Given the comorbidity of cognitive deficits in medically complicated patients undergoing transplant, neuropsychological testing may be necessary to determine their cognitive capacity to make decisions about transplant as well as to engage in appropriate self-care following treatment. Routine mental status examinations such as the Mini Mental Status Exam (Folstein, Folstein, & McHugh, 1975), St. Louis University Mental Status (SLUMS; Tariq, Tumosa, Chibnall, Perry, & Morley, 2006), or Montreal Cognitive Assessment (MoCA; Nasreddine, Phillips, Beédirian, et al., 2005) provide clinicians with a gross estimate of cognition and information about whether formal neuropsychological testing is indicated.

Assessment of psychiatric symptomatology as well as personality functioning may also be useful in the context of pre-transplant assessment; however, application of these measures must be done with caution, considering potential ethical conflicts. Personality tests were created and normalized for psychiatric populations and may be inappropriately interpreted when applied to a non-psychiatric population. Popular measures of psychological distress as well as personality include the Minnesota Multiphasic Personality Inventory-2 (MMPI-2) (Butcher et al., 2001) and Millon Clinical Multiaxial Inventory-III (MCMI-III) (Millon, 1994). Assessment of personality functioning may be helpful if preexisting personality disorder is suspected. However, as a routine part of pre-transplant evaluation, personality testing is likely to be inappropriate.

Overall, the measures needed for pre-transplant evaluation consist of a measure of transplant-related coping and behavior, a screen of cognitive function, and a measure of psychiatric symptomatology. Additional measures of major psychopathology

or personality dysfunction should be added where they are clinically warranted; for instance, if the patient is displaying inappropriate behaviors prior to transplant, or if the patient is suspected to have long-standing maladaptive coping strategies.

PRE-TRANSPLANT PERIOD: THE WAITING PERIOD

Once an individual has been placed on the waiting list, they typically wait a significant period of time prior to undergoing transplant, given the limited number of available organs. This time can be several months to years, depending on age, blood type, and other medical factors (Table 74.1).

Research suggests patients on a waiting list for an extended period of time tend to lose a sense of self and define themselves by test results and medical information (Brown, Sorrell, McClaren, & Creswell, 2006). The experience of being on call for an organ limits an individual, as he/she must restrain relationships, job decisions, and travel in order to be ready for an organ when it arrives. This situation of “arrested development” adversely affects their quality of life. In addition, patients often have mixed feelings about the waitlist process and may question its fairness (Brown, Sorrell, McClaren, & Creswell, 2006). Apart from concerns related to the wait itself, it is common for patients awaiting transplant to feel anxiety and apprehension about the procedure, with fears of pain, of invasive medical procedures, and of having foreign tissue in their bodies (Tringali et al., 1994).

POSTOPERATIVE PERIOD

GRAFT REJECTION

Graft rejection is triggered when the T and B lymphocytes of the transplant recipient’s immune system recognize antigens

present on the graft. The main antigens involved in triggering organ rejection are coded for by a group of genes known as the HLA system. Multiple components of the immune system are then activated, leading to inflammation, tissue injury, and graft damage (Cuturi, Blanche, Josien, & Souillou, 1994). Rejection of transplanted organs can be classified into three types, based on the timing and mechanism of injury: hyperacute, acute, and chronic.

Hyperacute Organ Rejection

Hyperacute rejection, which usually occurs within minutes after the transplanted organ is re-perfused, is due to the presence in the recipient, prior to the transplant procedure, of antibodies directed against antigens on the donated organ. These antibodies bind to the vascular endothelium in the graft and lead to intravascular coagulation. The result is an edematous graft that undergoes ischemic necrosis within as little as 24 hours. This type of rejection generally is irreversible, and replacement of the transplant with one from a different donor is the only therapeutic option. Fortunately, pre-transplant cross-matching has essentially eliminated this type of organ rejection.

Acute Organ Rejection

Acute rejection can occur in the months following transplantation. The mechanism is primarily cell-mediated, mainly by lymphocytes. In acute organ rejection, the patient is usually asymptomatic, and the diagnosis is suspected based on a pattern of results on serial laboratory measures, such as a rising creatinine levels in kidney transplant recipients. In severe cases, systemic symptoms can emerge as a consequence of graft failure. Acute graft rejection is most often treated with high-dose pulse steroid therapy. Polyclonal anti-T-cell antibodies, such as antithymocyte globulin, along with monoclonal antibodies, such as the anti-CD52 antibody alemtuzumab and the anti-CD20 antibody rituximab may be utilized to treat acute rejection not responsive to other means of treatment.

Chronic Organ Rejection

Chronic rejection is a late cause of graft deterioration. The improvement in short-term graft survival has resulted in chronic rejection’s becoming an increasingly common complication of organ transplantation. The exact mechanism of chronic rejection is complex, but inflammation, atrophy, and fibrosis are the histological hallmarks of this process. It is most often diagnosed by the gradual deterioration in the functional capacity of the transplanted organ. Manifestations of chronic rejection are organ-specific. In liver transplant recipients, it is characterized by “vanishing-bile-duct syndrome.” Bronchiolitis obliterans is an expression of chronic rejection in lung transplant recipients. Atherosclerosis of the coronary arteries characterizes chronic rejection in the transplanted heart. Kidney transplant patients with chronic rejection develop proteinuria and hypertension. Chronic rejection

Table 74.1 WAITING TIME UNTIL TRANSPLANTATION

MEDIAN WAITING TIME UNTIL TRANSPLANT (2003–2004 DATA)				
Organ	Age range: 18–34	Age range: 35–49	Age range: 50–64	Age range: 65+
Heart	170 days	169	169	86
Intestine	149	109	109	–
Kidney	1813	1806	1627	1416
Liver	169	450	417	294
Lung	808	1059	511	186
Pancreas	561	510	747	–

NOTE: Data from Organ Procurement and Transplantation Network, years 1999–2004. See OPTN: Organ Procurement and Transplantation Network, <http://optn.transplant.hrsa.gov/latestData/rptStrat.Asp>.

is resistant to all known methods of therapy, and graft loss will eventually occur, though perhaps not for several years after function begins to deteriorate.

GRAFT-VERSUS-HOST DISEASE (GVHD)

GVHD is one of the most important complications of allogeneic stem cell transplantation. GVHD occurs in both acute and chronic forms. GVHD occurs when donor T cells initiate an immunological reaction towards genetically different proteins on host cells. The principal risk factor for GVHD is HLA mismatch, and the incidence of acute GVHD is directly related to the degree of mismatch. Prophylactic immunosuppression following allogeneic HCT is necessary to prevent GVHD (Sullivan et al., 1986).

Acute GVHD occurs within 100 days of the transplant and is manifested by symptoms and signs of skin, gastrointestinal, and liver dysfunction. Martin et al. (1990) reported that, at the onset of acute GVHD, 81% of patients had skin involvement, 54% had gastrointestinal involvement, and 50% had liver involvement. The skin manifestations include a pruritic rash that occurs initially on the palms, soles, or face. The rash may generalize over the entire body and lead to significant desquamation. Nausea, vomiting, anorexia, abdominal pain, diarrhea, and bloody stool can occur when GVHD affects the gastrointestinal system. GVHD affecting the liver can present with jaundice and can be difficult to differentiate from other post-transplant causes of liver dysfunction. Treatment of acute GVHD involves increasing the level of immunosuppression.

The chronic form of GVHD affects patients 100 or more days after transplantation. Chronic GVHD is most likely to occur in older patients and in patients who have already suffered acute GVHD. The manifestations of chronic GVHD are variable and can include bronchiolitis, esophageal stricture, malabsorption, and cholestasis. Chronic GVHD may be lethal and is a major cause of death following HCT (Lee et al., 2002). Treatment of chronic GVHD includes certain immunosuppressant agents, thalidomide, and ultraviolet light.

MALIGNANCIES

Transplant recipients are at increased risk for developing specific types of cancers. The incidence of malignancy has been estimated at 20% after ten years (Buell, Gross, & Woodle, 2005). The most common malignancies in transplant recipients are various types of skin cancers (Euvrard, Kanitakis, & Claudy, 2003). Lymphoproliferative conditions, urological cancers, and Kaposi's sarcoma also have higher incidence in transplant patients. The etiology of the increased rates of post-transplant malignancy is thought to be multifactorial and linked to suppression both of immunosurveillance of malignant cells and of immunity to viral infection.

IMMUNOSUPPRESSANT AGENTS

Many drugs are available today to induce immunosuppression in the post-transplant patient, with the goal of preventing the

acute rejection of the allograft. Most immunosuppression regimens involve the use of multiple agents that have different mechanisms of action. This is especially true in the acute post-transplant period when the risk of rejection is highest. Theoretically, the use of multiple immunosuppressive agents with different mechanisms of action reduces the risk of toxicity from any individual agent, as lower doses of each drug are used to induce the same level of clinical immunosuppression. The management of immunosuppression following transplant involves a careful balance between the suppression of immunological reactivity that results in graft rejection and the maintenance of enough immune activity to prevent most infectious diseases. The prescribing clinician must also be aware of the potential for pharmacokinetic drug interactions with certain immunosuppressants, as many of these medications are both substrates and inhibitors of the 3A4 isoenzyme of the P450 system (Table 74.2).

Immunosuppressive therapy in transplant medicine can be divided into three phases of treatment: induction immunosuppression, maintenance immunosuppression, and the treatment of acute graft rejection. The induction phase usually is continued for two to four weeks following transplant. Most induction regimens include the use of systemic corticosteroids, a calcineurin inhibitor, and an antimetabolite. The second phase of immune modulation, maintenance immunosuppression, usually represents a reduction in the intensity of immunosuppression and enables the suppression of rejection over a prolonged period of time. Most patients will be maintained on either prednisone and cyclosporine or tacrolimus. However, it now appears that some patients taking tacrolimus for maintenance therapy may have the corticosteroid component discontinued entirely (Eason, Nair, Cohen, Blazek, & Loss, 2003). The final phase of immunosuppression is not planned, but rather represents the attempt to treat an occurrence of acute graft rejection. Early recognition and prompt treatment of acute rejection are essential to ensure long-term graft function. The treatment of acute rejection most often involves the use of high-dose steroids, polyclonal or monoclonal antibodies, and increased doses of the other immunosuppressive agents in an effort to escalate the level of clinical immunosuppression.

Table 74.2 P450 ENZYMES INVOLVED IN DRUG METABOLISM

	SUBSTRATE OF:	INHIBITS:	INDUCES:
Immunosuppressants			
Prednisone	3A4	None	None
Cyclosporine	3A4	3A4	None
Tacrolimus	3A4	3A4	None
Sirolimus	3A4	None	None
Mycophenolate Mofetil	None	None	None

CORTICOSTEROIDS

Corticosteroids have been a significant component of post-transplant immunosuppressive protocols for approximately a half century, and they remain integral to most acute and chronic immunosuppressant regimens. Corticosteroids display complex and varied mechanisms of action. They are both anti-inflammatory and immunosuppressive agents. Corticosteroids are associated with a wide variety of side effects. These adverse effects may contribute significantly to the morbidity experienced by transplant recipients (Fryer et al., 1994). These include infection, weight gain, hyperglycemia, hypertension, acne, hyperlipidemia, neuropsychiatric symptoms, impaired wound healing, and Cushing's syndrome. The neuropsychiatric adverse effects of corticosteroids are common and wide-ranging. Psychiatric symptoms attributable to steroids include anxiety, agitation, psychosis, mood disturbance, apathy, memory loss, and suicidal ideation. The Boston Collaborative Drug Surveillance Program (1972) suggested a dose-response relationship between steroids and psychiatric adverse effects. This study found that psychiatric reactions occurred in 1.3% of hospitalized patients receiving 40 mg or less of prednisone per day, in 4.6% of individuals receiving 41 to 80 mg/day, and in 18.4% of patients receiving more than 80 mg/day. The neuropsychiatric side effects of steroids are generally treated by reducing or discontinuing the steroids if possible. If discontinuation or dose reduction is not possible, then psychotropic medications are prescribed to treat the offending psychiatric symptoms (i.e., antipsychotics to treat steroid-induced psychosis). The individual patient's susceptibility to these side effects varies remarkably. In addition, if a patient is chronically administered steroids, the possibility of adrenal suppression and the resulting potential for adrenal insufficiency if steroids are abruptly discontinued must be considered.

The steroids most commonly utilized in transplantation medicine are metabolized by the cytochrome P450 3A4. This includes prednisolone, the active metabolite of prednisone. Medications that are known 3A4 inhibitors, such as fluvoxamine, may therefore increase serum concentrations and the associated risk of toxicity. Inducers of 3A4 lead to the reduction of circulating corticosteroid concentrations and the potential for adrenal insufficiency or graft rejection.

CALCINEURIN INHIBITORS (CYCLOSPORINE AND TACROLIMUS)

The introduction of the first calcineurin inhibitor, cyclosporine, in the 1980s revolutionized organ transplantation. The development of tacrolimus, another calcineurin inhibitor, followed in 1994. All calcineurin inhibitors provide immunosuppression through their propensity to inhibit T-cell activation and proliferation, although they differ in their mechanism of calcineurin inhibition. These drugs are important components of most immunosuppressive regimens. Serum drug concentrations are used to guide therapy and prevent toxicity.

It is important to recognize the acute and chronic sequelae associated with the use of cyclosporine and tacrolimus. The

most frequently encountered of these is nephrotoxicity. Nephrotoxicity may be secondary to acute toxicity, but it has also been associated with prolonged use of calcineurin inhibitors unrelated to toxic levels (Chapman, Griffiths, Harding, & Morris, 1985; Ojo et al., 2003). The clinical course is characterized by a gradual decline in renal function that may eventually lead to ESRD. In contrast to the acute form, chronic calcineurin inhibitor-induced renal insufficiency improves little after dose reduction or cessation of the punitive agent. The pathogenesis of nephrotoxicity is poorly understood with possible etiologies as diverse as ischemia and/or direct toxic effects of calcineurin-inhibitor on the renal tubules (Naesens, Kuypers, & Sarwal, 2009). Neurological complications are also encountered in patients being treated with calcineurin inhibitors, including restlessness, tremor, paresthesias, delirium, seizures, headache, and even coma. Calcineurin inhibitor neurotoxicity may also lead to the development of posterior reversible encephalopathy syndrome (PRES) (Bartynski, Tan, Boardman, Shapiro, & Marsh, 2008). The clinical presentation of PRES is often varied, but symptoms include headache, visual disturbances, delirium, possible seizures, and the potential for coma.

When working with transplant patients who may be emotionally labile, the potential consequences of intentional overdose need to be considered by the prescribing clinician. Cyclosporine overdose has been associated with significant neurotoxicity (Nghiem, 2002). Tacrolimus overdose, however, has been reported to result in minimal toxicity (Mrvos, Hodgman, & Krenzelok, 1997). Other complications of calcineurin inhibitors include hypertension, impaired glucose tolerance, hyperlipidemia, hyperkalemia, and hyperuricemia. The incidence of hyperglycemia appears higher with tacrolimus than with cyclosporine (Heisel, Heisel, Balshaw, & Keown, 2004). The hirsutism and gingival hyperplasia commonly experienced by patients taking cyclosporine do not appear to occur with tacrolimus.

Calcineurin inhibitors are metabolized via the P-450 system, specifically cytochrome 3A4. Inhibitors of cytochrome 3A4 may potentiate serum levels of these agents, whereas inducers of these enzymes will decrease the serum levels. Elevated levels of calcineurin inhibitors may lead to significant neurotoxicity and nephrotoxicity, whereas subtherapeutic levels of immunosuppression may lead to rejection of the transplanted organ. Cyclosporine and tacrolimus have also been identified as inhibitors of 3A4 and may, therefore, affect the levels of medications metabolized by isoenzyme 3A4.

SIROLIMUS

Sirolimus was introduced clinically in 1999. Sirolimus, like tacrolimus, binds to FK506-binding proteins, but it does not inhibit calcineurin activity. Sirolimus, instead, blocks signal transduction from interleukin-2 (IL-2), thereby inhibiting T and B cell proliferation. It is commonly used in combination with a calcineurin inhibitor. In this combination, sirolimus is often utilized in an attempt to minimize the use of steroids, with the goal of avoiding the potential negative effects of corticosteroids. Adverse side effects of sirolimus

include hyperlipidemia, thrombocytopenia, neutropenia, and impaired wound healing. Compared to the calcineurin inhibitors, sirolimus does not appear to cause the same degree of nephrotoxicity or neurotoxicity. Sirolimus is metabolized as a substrate of 3A4, but there are few reports of significant drug–drug interactions involving sirolimus (Fireman, DiMartini, Armstrong, & Cozza, 2004).

ANTIMETABOLITE DRUGS (MYCOPHENOLATE AND AZATHIOPRINE)

The antimetabolite azathioprine was one of the first immunosuppressant agents introduced in the 1960s. It was an integral component of most immunosuppressant regimens, along with corticosteroids, until the introduction of cyclosporine in the 1980s. Mycophenolic acid is an antimetabolite available as an ester prodrug, mycophenolate mofetil; or as its sodium salt, sodium mycophenolate. Mycophenolate mofetil was approved by the Food and Drug Administration (FDA) in the mid-1990s, and by now, mycophenolate has largely replaced azathioprine as the antimetabolite of choice for use in combination with calcineurin inhibitors and/or corticosteroids in post-transplant immunosuppressant regimens.

The most important side effects of mycophenolate include bone marrow suppression, specifically leukopenia and thrombocytopenia. Leukopenia has been reported to affect almost a quarter of recipients treated with mycophenolate (Jacobson et al., 2011). Temporary discontinuation or dose reduction is usually sufficient to raise the leukocyte count. Other common side effects of mycophenolate include gastrointestinal disturbances such as diarrhea, gastritis, nausea, and vomiting. Less frequent adverse effects include esophagitis and gastrointestinal bleeding. Fortunately, mycophenolate appears to have few neuropsychiatric adverse effects. Mycophenolic acid is metabolized via glucuronidation, and de-esterification of mycophenolate mofetil is not dependent upon the liver. As a consequence, there appears to be little risk of pharmacokinetic interactions between either mycophenolate formulation and other drugs.

POLYCLONAL AND MONOCLONAL ANTIBODIES

Polyclonal and monoclonal antibodies represent a fairly new class of immunosuppressant agents. As the names imply, polyclonal antibodies are active against a wide range of target antigens, whereas monoclonal antibodies are antibodies active against only a single target antigen, thereby selectively depleting or inhibiting specific subsets of cells involved in the immune response. This class of immunosuppressants appears to be effective in the treatment of acute rejection in transplant recipients (Midtvedt et al., 2003). However, when antibodies are given to a patient on more than one occasion, the patient may develop antibodies directed against the preparation that may limit the clinical efficacy of future administration of these agents.

Polyclonal anti-T-cell antibodies, such as anti-thymocyte globulin, have been used for years to treat allograft rejection.

Unfortunately, polyclonal antibodies are plagued by significant adverse events, due to their action on diffuse cellular targets. These side effects vary from thrombocytopenia and leukopenia to serum sickness.

The monoclonal antibodies, by definition, are specific in their molecular target. These targeted immunosuppressants have varied uses in transplant medicine (van den Hoogen & Hilbrands, 2011). Alemtuzumab (anti-CD52 antibody) and rituximab (anti-CD20 antibody) are utilized to treat acute rejection, whereas basiliximab (the anti-CD25 antibody) is used in immunosuppression-induction therapy. The specific nature of these newer agents may also make them more tolerable than the polyclonal antibodies or the older monoclonal anti-CD3 antibody muromonab. Alemtuzumab has been associated with some anxiety and insomnia as the primary neuropsychiatric side effects. Rituximab has been associated with PRES and progressive multifocal leukoencephalopathy (PML) as well as an acute cytokine release syndrome after administration.

The monoclonal antibody preparations have the potential for multiple non-neuropsychiatric side effects, which at times may be quite severe. Like the polyclonal antibodies, the monoclonal antibodies may also cause a systemic, febrile inflammatory response immediately after administration, which can mask the fever of an opportunistic infection. This usually responds to a combination of corticosteroids, antihistamines, and acetaminophen (Chatenoud, Ferran, & Bach, 1991).

PERIOPERATIVE PSYCHIATRIC COMPLICATIONS

Psychiatric disorders often emerge in the immediate post-transplant period. Many of these are similar to those found in hospitalized patients with other acute medical problems, but due to the special nature of transplantation, there are some unusual diagnostic considerations.

If patients emerge from transplant with an acute onset of depression, the issue of survivor guilt should be explored during the diagnostic interview. Patient's guilt can sometimes be relieved by exploration of the reasons that underlie the guilt in their specific case, and discussion of what might have happened to the organ had the patient not received it.

Altered mental status is common after transplant. Usually, the post-operative delirium shows clear signs of improvement within five to seven days after transplant, but if cognitive problems persist past that point, an investigation of the cause should occur. The usual culprits, such as electrolyte disturbance or infection, should be obvious, but causes related directly to transplant are also possible. Delirium may indicate graft dysfunction or an adverse medication effect. Prednisone and other corticosteroids are often given at high doses at the time of transplant and can lead to a variety of affective and psychotic symptoms, including delirium. Calcineurin inhibitors, such as cyclosporine and tacrolimus, can cause delirium, most seriously through the PRES. Patients usually will have to be transitioned to other immunosuppressants if they develop PRES and need to be monitored closely for rejection.

POST-TRANSPLANT RECOVERY PERIOD

Many patients believe that transplantation will act as a means to reestablish a sense of normalcy following significant medical illness. However, the post-transplant recovery period can include challenges to significant relationships, difficulty adjusting to a “new normal,” and accepting an altered quality of life.

QUALITY OF LIFE AND ADJUSTMENT TO TRANSPLANT

The term *quality of life* is used to describe the extent to which an individual is able to live a fulfilling existence across different domains of life (i.e., physical, emotional, social, etc.). Empirical review of the transplant literature suggests that quality of life improves with transplant, but the amount and domain of improvement varies, depending on the transplant type (Dew et al., 1997). Body image is a common concern among transplant patients (Engel, 2001). After the procedure, patients may be left with scarring, weight gain, and physical changes associated with long-term steroid medication. Adjusting to life following a transplant involves tempering one's expectations of a cure and absolute health with realistic expectations about living with a different set of chronic health concerns.

Transplant patients must also be alert for organ rejection post-transplant. Coping with the chronic threat of organ rejection, worsening health, and possible death is an expected element of post-transplant recovery (De Vito et al., 2004). A proposed model suggests that patients undergo a transformative process beginning with naïvely believing a transplant will be a health panacea and ending with insight into and acceptance of their role in their health maintenance as a result of the chronic threat of losing their graft (De Vito et al., 2004). As such, the anxiety and depression associated with uncertainty about the quality and length of one's life changes over the course of the post-transplant recovery period. Patients must negotiate the challenging balance between engaging in appropriate behavior to care for their allograft while also accepting ambiguity around the potential failure of that graft.

FAMILY STRESS POST-TRANSPLANT

Family members undergo significant stress during the post-transplant recovery period as well. Transplant centers are often far from people's homes, and loved ones have to make a difficult decision about whether to stay with the transplant recipient or stay at home and tend to their usual life activities (Olbrisch, Benedict, Ashe, & Levenson, 2002). Family members also provide a significant amount of instrumental social support such as caring for the patient's responsibilities around the home, helping with medical regimens, and assisting with finances. This caregiving role can conflict with other roles in a spousal or other family relationship (Montgomery & Kosloski, 2000).

POST-OPERATIVE ADHERENCE

By definition, “non-adherence” refers to failing to adapt one's behaviors or actions to those prescribed by a physician (Morrissey, Flynn, & Lin, 2007). In transplant, it refers to the patient's inability to appropriately take medications as prescribed after transplant, engage in appropriate health-related behaviors, and follow through with medical appointments. Non-adherence is an appreciable problem in the post-transplant recovery period. In a comprehensive meta-analytic review of the renal transplant literature, Butler et al. (2004) found between 15% and 22.3% of patients had been non-adherent following kidney transplant, with 36% of patients missing four or more consecutive doses of an anti-rejection drug, and 16% missing at least ten consecutive doses. In heart transplant patients, Dew, Roth, Thompson, et al. (1996) found that nearly one-third of heart patients were consistently non-adherent with regard to exercise and blood pressure monitoring post-transplant, and approximately one-fifth of patients were non-adherent with regard to medications, smoking, and diet.

Although the definition of non-adherence differs greatly across studies, it is particularly dangerous in the post-transplant population, as the impact on graft failure is well documented. Non-adherence to medication regimens has been found to contribute to graft rejection and increased mortality across transplant populations (Dew, Kormos, Roth, Murali, DeMartini, & Griffith, 1999). Non-adherence accounted for the greatest proportion of graft failures among patients who died without a functioning renal graft (Butler et al., 2004); the odds of rejecting a graft increased seven-fold when comparing non-adherent to adherent patients. Kidney transplant recipients, who have been found to have the highest rates of non-adherence (Denhaerynck, Dobbels, Cleemput, et al., 2005), had a median of 36.4% of graft losses associated with non-adherence; the risk of kidney transplant rejection with non-adherence had a median odds increase of 4.8% (Butler, Roderick, Mullee, Mason, & Peveler, 2004). For heart transplant patients, the rate of rejection was 4.7 times higher for patients who were not adherent to their medication regimen compared to those who took their medications as prescribed (Dew, Kormos, Roth, Murali, DiMartini, & Griffith, 1999). Additionally, the risk of late acute rejection is also greater in non-adherent heart patient populations, with non-compliant patients having a higher rate of late acute rejection (11.8%) compared with compliant patients (2.4%) (Dobbels, De Geest, Van Cleemput, Droogne, & Vanhaecke, 2004). For lung transplant patients, research has suggested that non-adherence to immunosuppression is less than for heart recipient patients, which was demonstrated at several time points over a two-year period to range from 8–20% compared to 11–30% in heart transplant patients (Dew, DiMartini, De Vito Dabbs, et al., 2008). However, lung transplant patients had variably higher rates in other areas of behavioral noncompliance (Dew et al., 2008). For liver transplant patients, late acute rejection is four times more likely in non-compliant patients (21%) compared to compliant patients (5%) (Berlakovich,

Langer, Freundorfer, et al., 2000). Empirical data examining the impact of non-adherence on graft failure are limited in pancreas and intestinal transplant and are applied differently (i.e., GVHD) for stem cell transplantation.

Multiple demographic, personality, and coping variables have been postulated to account for variable adherence post-transplant. Research has shown social support, agreeableness, and planning as a coping behavior to predict post-transplant adherence in liver transplant candidates (Telles-Corrieia, Barbosa, & Mega, 2009). Common factors associated with medication non-adherence in transplant patients include non-adherence prior to transplant, psychiatric illness (depression and anxiety), personality disorders, poor social support, substance abuse, higher education level, increased time since transplant, inadequate follow-up, inadequate pre-transplant education, adverse effects from medications, and a complex medication regimen (Morrissey, Flynn, & Lin, 2007).

Non-adherent behavior can be categorized into *accidental*, *invulnerable*, and *decisive* non-adherence patterns (Greenstein & Siegal, 1998; Siegal & Greenstein, 1999). Accidental non-compliers, who account for approximately half of patients, hold strong beliefs about the efficacy of immunosuppressant medication and taking their medication even when the kidneys are functioning well, but miss doses of medication for circumstantial reasons. Invulnerable non-adherent patients, who account for approximately one-fourth of transplant patients (Greenstein & Siegal, 1998), see themselves as relatively immune to the negative effects of non-adherence. These patients tend to be younger, male, less educated, and have newer grafts. They generally do not believe in the efficacy of immunosuppressant medication or believe that delay in medication administration is not problematic. As such, they are more vulnerable to non-adherent behavior over the long-term course of the post-transplant recovery period, being particularly susceptible to non-adherence once they feel relatively well post-transplant. Finally, decisive non-compliers, who tend to account for approximately 25% of patients, tend to be well-educated, white-collar professionals who are accustomed to making independent decisions and as such may present with non-adherent behavior as an independent choice. Unfortunately, these patients may have a well-thought-out reason for non-adherence, which can be challenging for treatment providers to address.

POST-TRANSPLANT PSYCHIATRIC DISORDERS

In general, across transplant types, psychological distress is typically highest the first few months after transplant and declines gradually during the year following transplant (Fisher et al., 1995; TenVergert et al., 1998). Although transplant can both save lives and improve quality of life from pre-transplant states, the transplant process leaves patients vulnerable to psychiatric disorders. Transplant patients have more psychiatric symptoms (e.g., depression, anxiety, and substance abuse) compared to a non-clinical population (Jowsey et al., 2001).

This can be attributed to psychiatric syndromes that pre-date transplant, develop during transplant, or develop during the post-transplant recovery period and cause significant harm to their quality of life.

Adjustment disorders with depression and/or anxiety are the most prevalent disorders prior to transplant, with depression and anxiety prevalent in clinical and adjustment-related ranges (Olbrisch, Benedict, Ashe, & Levenson, 2002). In a sample of heart, lung, kidney, and liver transplant patients, over 60% met criteria for an Axis I psychiatric disorder, and approximately 32% met criteria for an Axis II disorder with significant implications for both adherence and adjustment (Chacko, Harper, Kunik, & Young, 1996). Across lung, and heart and lung transplant recipients, the proportion experiencing anxiety and depression ranged from 26.5 to 34.7% (Stilley et al., 1999).

The most common disorders found in post-transplant populations include depression, post-traumatic stress disorder (PTSD), and adjustment disorders (Dew et al., 1996). In a review of the transplant literature, Dew, Switzer, and DeMartini (2000) found that rates of psychiatric disorders in the long-term post-transplant period range from 10–58% for depressive disorders and 3–33% for anxiety disorders. The presence of adjustment disorders or adjustment-related symptoms has been well established in transplant patients (Baba et al., 2006; Heilmann et al., 2011). The presence of depression and other concerns about adjustment are one of the major impediments to quality of life in transplant populations (Goetzmann et al., 2008). Recently, a European group found depression was an independent risk factor for death over a seven-year period following renal transplantation (Zelle et al., 2012), further cementing the importance of identification and treatment of mood disorders in the post-transplant period.

The potential for exposure to trauma as a transplant patient is greater than that experienced by the general population. Favaloro et al. (1999) found that 13% of a population of heart transplant patients met criteria for PTSD, and an additional 20% met criteria for PTSD-related symptoms. Transplant patients who experience more stressful and negative life events, either related to or not related to transplant, are more vulnerable to post-traumatic stress (DuHamel et al., 2001). The development of PTSD can be prompted by exposure to medical procedures or threats of death, including more complications after transplant (Jin, Yan, Xiang, et al., 2012) and more invasive treatment. In order to meet criteria for PTSD, one must be exposed to real or imagined death or threat of significant injury to oneself or others. Depending on the type and course of treatment, invasive medical procedures such as transplant may be interpreted as such by patients. Unfortunately, PTSD symptoms, especially intrusive PTSD thoughts about transplant, have been related to problematic adherence behavior (Favaro, Gerosa, Caforio, et al., 2011). Shemesh et al. (Shemesh, Lurie, Stuber, et al., 2000) hypothesized that non-adherence in those with symptomatic memories of trauma may be related to avoidance of disease and treatment-related stimuli. Avoidant coping, which is common in PTSD, can prevail over the need for health-related behaviors and leave patients vulnerable to

graft rejection. Given that cognitive behavioral treatment for PTSD significantly improves avoidant behavior, effective management of PTSD should improve treatment compliance related to avoidance of trauma stimuli.

POST-TRANSPLANT PSYCHIATRIC TREATMENT

The treatment of psychiatric illnesses and neuropsychiatric complications in transplant patients is critical in order to minimize suffering, improve quality of life, and maximize clinical outcomes in this vulnerable patient population. The general principles of treatment of psychiatric disorders experienced by transplant patients are not significantly different than the treatment principles utilized to manage these conditions in patients with other forms of co-occurring medical illness. Transplant patients are usually on a complex medication regimen of immunosuppressants to prevent graft rejection combined with various other medications used to treat other comorbid medical and psychiatric conditions. Drug interactions, both pharmacokinetic and pharmacodynamic, are common. They should be considered systematically in every case, avoided when feasible, and, when unavoidable, managed with dosage adjustments or changes in other aspects of the patient's drug regimen. Treatment must be individualized.

PSYCHOPHARMACOLOGY

Efforts to anticipate, minimize, and mitigate the effects of drug interactions are the characteristic feature of psychopharmacological treatment of transplant patients. Not only do such interactions risk increased neuropsychiatric side effects and compromise the efficacy of the psychiatric treatment, but they also can cause an increased risk of organ rejection—a dire consequence. For this reason, it is critical to maintain an accurate and continually updated list of the patient's medications, and to ascertain whether the patient is actually taking the medications consistently and as prescribed.

Antidepressants

Given the paucity of studies regarding the use of antidepressants in patients following organ transplantation, the recommendations for antidepressants are often based on the concern about drug interactions and the side effect profiles of the various antidepressants (Kim, Phongsamran, & Park, 2004). The selective serotonin receptor inhibitors (SSRIs), particularly sertraline, escitalopram, and citalopram, are often considered first-line agents in the treatment of depression and anxiety in the transplant patient population (Crone & Gabriel, 2004). Dosing strategies should be guided by an appreciation of the inherent differences in pharmacokinetic and pharmacodynamic profiles. The serotonin-norepinephrine reuptake inhibitor (SNRI) class of antidepressants may also be utilized in patients following transplant. Venlafaxine exhibits a limited potential for protein-binding. SNRIs, particularly venlafaxine, may raise blood pressure, leading to clinically significant

hypertension. Drug-induced hypertension is already an important health concern in the transplant population. It has been estimated that more than 90% of kidney transplant recipients being treated with a calcineurin inhibitor experience hypertension (Mangray & Vella, 2011). There have been case reports of co-administration of calcineurin inhibitors and serotonergic antidepressants such as sertraline (Wong, Chan, Sze, & Or, 2002) and venlafaxine (Newey, Khawam, & Coffman, 2011) leading to the development of "serotonin syndrome." This adverse reaction could be secondary to pharmacokinetic and/or pharmacodynamic interactions between the calcineurin inhibitor and the co-administered antidepressant. Little additional information is known about the use of duloxetine and desvenlafaxine in transplant patients.

Mirtazapine is a useful antidepressant in a subset of medically ill patients, including transplant patients. The unique pharmacodynamic profile of mirtazapine may prove beneficial for patients suffering from insomnia, anorexia, and nausea (Fusar-Poli, Matteo, Luca, et al., 2007). It is metabolized by multiple hepatic enzymes and is therefore less susceptible to other drugs' affecting its metabolism. In addition, mirtazapine does not appear to significantly inhibit or induce any hepatic enzymes, so it does not appear to induce pharmacokinetic drug interactions. Bupropion is vulnerable to drug-drug interactions through pharmacokinetic mechanisms, as it is a substrate of 2B6 and a potential inhibitor of 2D6. The potential for electrolyte abnormalities and polypharmacy in post-transplant patients may make bupropion risky, especially given the lowering of seizure threshold that is observed with some immunosuppressants.

Although tricyclic antidepressants (TCA) and monoamine oxidase inhibitors (MAOI) have historically been used for the treatment of depression in the transplant population, they are now reserved for cases resistant to more standard therapies. The TCAs have several pharmacodynamic and pharmacokinetic issues that make them a challenge to use safely in the medically ill. For example, cardiac transplant patients suffering from left ventricular dysfunction, along with those taking diuretics and vasodilators, are at increased risk of drug-induced orthostatic hypotension with TCA administration (Fusar-Poli et al., 2006). In addition, the physiological effects of TCAs on the denervated transplanted human heart remain unclear. Pharmacokinetically, they are substrates of 2D6 and 3A4 and susceptible to the effects of pertinent inhibitors and inducers of these enzymes, which include various immunosuppressant agents. MAOI use is rare due to concerns of dangerous drug and food interactions. The psychostimulants have a long history of successful use in the treatment of neurovegetative symptoms in the medically ill and may be helpful in addressing these symptoms in patients following organ transplantation. Plutchik et al. (1998) found methylphenidate to be efficacious and fairly well tolerated in a retrospective case series of eight patients treated with methylphenidate following liver transplantation. Episodes of intermittent supraventricular tachycardia, however, have been associated with administration of methylphenidate in a heart transplant patient with multiple risk factors for a cardiac arrhythmia (Come & Shapiro, 2005).

Anxiolytics

The benzodiazepines are effective agents in the pharmacological management of anxiety. The use of benzodiazepines in patients following transplant is similar to their use in other medical ill populations. However, their use in patients with active pulmonary disease requires special caution due to benzodiazepines' propensity to blunt CO₂ sensitivity and contribute to respiratory depression. Nevertheless, in patients with significant anxiety that is unresponsive to other measures, benzodiazepines may be beneficial if the patient is carefully monitored for evidence of respiratory compromise. In general, benzodiazepines with shorter half-lives (e.g., alprazolam, lorazepam) are less likely to accumulate than those with longer half-lives (e.g., diazepam, clonazepam) and may therefore be relatively safer in patients with respiratory disease. The longer acting benzodiazepines, however, may be useful as time-limited scheduled agents for patients with anxiety as one waits for the co-administered SSRI to become effective.

The choice of which benzodiazepine to use should also depend on the medication's pharmacokinetic properties (e.g., hepatic metabolism, active metabolites, and elimination half-life). Lorazepam, oxazepam, and temazepam undergo glucuronidation and do not require oxidative metabolism, often making them the benzodiazepines of choice in patients for whom drug interactions are a concern. Benzodiazepines' use should be time-limited to avoid the potential complications of tolerance and dependence, coupled with the risk of withdrawal. These issues may be especially pertinent to the subset of transplant patients with a history of substance use disorders.

The non-benzodiazepine anti-anxiety medication buspirone may be effective in the management of generalized anxiety disorder in the transplant population. It, however, is metabolized by the liver via 3A4 isoenzymes and is susceptible to drug interactions.

Antipsychotics

Typical and atypical antipsychotics have been used safely and effectively in the post-transplant period following both solid organ and HCTs (Siddiqui, Ramaswamy, & Petty, 2005; Michopoulos, Christodoulou, Dervenoulas, Soldatos, & Lykouras, 2010). The indications for their use vary from the management of a preexisting primary psychotic disorder to treatment of delirium or steroid-induced secondary mania. The regular concerns of neurological, metabolic, and cardiac adverse events remain pertinent in the transplant patient population. The metabolic effects of antipsychotics are particularly pertinent. Transplant recipients are already predisposed to obesity and metabolic changes, often secondary to the immunosuppressant regimen, so caution about adding more risk for metabolic syndrome is advisable. Neuroleptic malignant syndrome has been reported in the literature following a bone marrow transplant (Onose et al., 2002).

Lithium

The use of the mood stabilizer lithium presents several problems when used in transplant patients (Fusar-Poli et al., 2006).

Lithium's pharmacokinetics make it difficult to dose in the immediate post-operative period due to the rapid changes in volume status. Lithium levels may also be increased with co-administration of cyclosporine, given the latter's propensity to impair renal function (Vincent, Wenting, & Schalekamp, 1988). It can therefore be a challenge to maintain a therapeutic lithium level in a transplant patient.

Neurostimulation

Electroconvulsive therapy (ECT) is a safe, well tolerated, and very effective nonpharmacological treatment for major depression for patients suffering from a wide variety of acute and chronic medical conditions, including transplant recipients (Jayaram & Casimir, 2005). For most transplant patients, ECT may be considered as an appropriate treatment option following a careful evaluation of the risks and benefits. The heart's response to ECT following cardiac transplant is unusual in that the transplant heart is denervated. As a consequence, the patient does not experience the parasympathetically mediated post-seizure bradycardia that typically follows the induction of a seizure (Kellner, Monroe, Burns, Bernstein, & Crumbley, 1991). The efficacy and safety of the repetitive transcranial magnetic stimulation (rTMS) for the treatment of neuropsychiatric illness following organ transplantation is unreported in the literature at this time.

PSYCHOTHERAPEUTIC TREATMENT

Adjustment to Life Post-Transplant

Psychotherapy for transplant patients is often initiated because a patient wants to return to a sense of normalcy, specifically the sense of what was "normal" prior to transplant. Patients cope with the stressors of chronic illness, living on a waiting list, and undergoing transplant with the belief that they will be able to "return to normal" after the treatment is complete. However, as with any person undergoing major life events, patients often cannot return to the same sense of normalcy they experienced prior to transplant. This can leave patients feeling disconnected and disillusioned, as their expectations for life after transplant and the reality of their situation are incongruent.

Adjustment-related psychotherapy focuses on helping them establish a new sense of normalcy post-transplant (Baines, Joseph, & Jindal, 2002). The adjustment literature suggests that patients who utilize benefit-finding attributions when reviewing their situation in order to cope with traumatic stressors experience personal growth (Sears, Stanton, & Danoff-Burg, 2003). For example, bone marrow transplant survivors have been found to have a greater sense of strength and enhanced interpersonal relationships following treatment (Tallman, Shaw, Schultz, & Altmaier, 2010).

Although post-traumatic growth is thought to occur naturally as a result of coping with trauma related to health concerns, adjustment-related psychotherapy can facilitate the process by helping a patient address the reestablishment of a

sense of stability and normalcy (i.e., the “new normal”) following transplant. Psychotherapy targeted towards helping the patient review attributions from a growth perspective to accept and cope with the persistent changes related to transplantation survival (Baines, Joseph, & Jindal, 2002) facilitates reintegration into a fully functioning life that integrates the new limits and growth related to living with a donated organ.

In addition to psychotherapy, peer-based support approaches such as support groups or peer mentoring can positively impact patient quality of life. Meeting with a transplant patient who has gone through similar experiences with success provides hope and a sense of legitimacy that a professional caregiver who has not undergone transplant cannot provide. Encouraging support-group participation and information gathering from peers who are further along in the transplant process can provide a roadmap and a belief that individuals do survive and thrive for patients moving into an unknown area of life (Jowsey et al., 2001).

Non-Adherence Issues

Psychotherapy can be beneficial to address treatment non-adherence issues in post-transplant populations. Depending on the reason for non-adherence, psycho-education can be used to increase adherence (Greenstein & Siegal, 1998). For accidentally non-adherent patients, providing education on methods to increase medication compliance using behavioral strategies, such as use of a pill box or scheduled administration of medications, may be helpful. For “invulnerable” non-adherent patients, using educational material that is less technically cumbersome yet addresses the need for long-term adherence even when they are feeling physically well may improve their adherence. Finally, for the decisive non-adherent patients, fostering independent decision-making in the direction of adherent behavior should increase compliance (Greenstein & Siegal, 1998). The reasons for non-adherence should be assessed, and psychotherapeutic and educational efforts should be appropriately tailored to increase the likelihood of adherent behavior. Specifically, having patients meet with a psychologist to determine underlying attributions driving non-adherence will help the psychologist more appropriately target interventions (e.g., behavioral strategies, cognitive restructuring of beliefs about the need to engage in adherent behavior, motivational interviewing techniques) to improve non-adherent behavior.

CBT can be used to help alter the expectation that life post-transplant will be the same as life prior to becoming ill, and can thus be used to address non-adherence. Because patients engage in non-adherent behavior for a range of reasons, helping patients identify beliefs they have about their health (e.g., “I have had my transplanted organ for three years; there is no way I will reject it now”) and challenging those beliefs in the context of a supportive therapeutic relationship can help patients achieve a more realistic understanding of their behaviors post-transplant. Additionally, behavioral strategies, such as scheduling medications, using tracking and logging methods, and appropriate

reinforcement can help patients who are non-adherent due to situation, priority, or memory constraints maintain an adaptive health schedule post-transplant. Although adherence-related psychotherapy tends to be more solution-focused, goal-oriented, and monitored, this approach can help provide the structure and support for long-lasting behavioral change.

Psychiatric Symptom Management

Patients who present for treatment may have a history of a psychiatric disorder that was either effectively or ineffectively managed prior to transplant. Given the multiple stressors related to the post-transplant recovery period, as well as the demands of adherence, it is recommended that patients receive psychotherapy in addition to medication management to treat premorbid and persisting psychiatric symptoms. Multiple psychotherapeutic approaches have been advocated for transplant patients. Anxiety management techniques such as progressive muscle relaxation, guided imagery, and self-hypnosis have been suggested for anxiety management during medical procedures (Olbrisch, Benedict, Ashe, & Levenson, 2002). Although the literature on specific therapeutic modalities to treat psychiatric symptoms in transplant patients is sparse, several therapeutic modalities have been empirically validated in more general medical populations, including cognitive behavioral and behavioral therapies, brief psychodynamic therapies, and other varied approaches (Compas, Haaga, Keefe, Leitenberg, & Williams, 1998). As an example, CBT can be particularly useful for treating psychiatric symptoms in the medically ill by focusing on cognitions, appraisals, and coping strategies and how the patient’s life and health impact mood. In CBT, patients are challenged to see how personal expectations and beliefs about their situation exacerbate their psychiatric symptoms. It is important to note that many transplant patients cope with realistically negative stressors, and thus the goals of CBT with transplant patients differ slightly from those for non-medically ill patients. That said, one’s choices with regard to both solution- and emotion-focused coping in the face of major health concerns affect one’s emotional health, and they can be successfully targeted through CBT. CBT can be used to help alleviate psychiatric symptoms, to improve coping strategies (e.g., by relaxation training), and to reexamine one’s expectations and views of the world and oneself (e.g., by cognitive restructuring) in a time-limited manner to improve patient quality of life. Application of a range of psychotherapeutic approaches within the context of transplant-specific stressors is the current recommendation for psychotherapeutically managing symptoms in transplant patients.

CLINICAL PEARLS

- If the donor knows the recipient—the most common scenario—then there must be discussion of their relationship and the donor’s hopes for results after the transplant.

- If patients have struggled to attend dialysis sessions regularly, they are likely to struggle with the post-transplant regimen of medications and appointments.
- If the patient can work with the team, suggestions about ways in which the team can accommodate the patient's personality (e.g., giving an obsessive patient choices to increase his sense of control when possible) can help both the patient and the team work together successfully.
- In the United States, following an acetaminophen overdose, if a patient is listed for transplant due to fulminant hepatic failure, that patient goes right to the top of the list because the risk of death if there is delay quickly approaches 100%, so obtaining an accurate psychiatric history before their mental status is compromised is particularly essential. The patient is at risk for developing hepatic coma as liver injury progresses.
- Cyclosporine overdose has been associated with significant neurotoxicity (Nghiem, 2002); tacrolimus overdose, however, has been reported to result in minimal toxicity (Mrvos, Hodgman, & Krenzelok, 1997).
- Adjusting to life following a transplant involves tempering one's expectations of a "cure" and absolute health with realistic expectations about living with a different set of chronic health concerns.
- A proposed model suggests that patients undergo a transformative process, beginning with naïvely believing a transplant will be a health panacea and ending with insight into and acceptance of their role in their health maintenance as a result of the chronic threat of losing their graft (De Vito Dabbs et al., 2004).
- Non-adherent behavior can be categorized into *accidental*, *invulnerable*, and *decisive* non-adherence patterns (Greenstein & Siegal, 1998; Siegal & Greenstein, 1999).
 - Accidental non-compliers (approximately half of patients) hold strong beliefs about the efficacy of immunosuppressant medication and taking their medication even when the kidney is functioning well, but miss doses of medication for circumstantial reasons.
 - Invulnerable non-adherent patients (approximately one-fourth of transplant patients) (Greenstein & Siegal, 1998), see themselves as relatively immune to the negative effects of non-adherence. These patients tend to be younger, male, less educated, and have newer grafts. They generally do not believe in the efficacy of immunosuppressant medication or believe that delay in medication administration is problematic. As such, they are more vulnerable to non-adherent behavior over the long-term course of the post-transplant recovery period, being particularly susceptible to non-adherence once they feel relatively well post-transplant.
 - Finally, decisive non-compliers (approximately 25% of patients), tend to be well-educated, white-collar professionals who are accustomed to making independent decisions and as such may present with non-adherent behavior as an independent choice. Unfortunately, these patients may have a well-thought-out reason for non-adherence, which can be challenging for treatment providers to address.
- Intrusive PTSD thoughts about transplants have been related to problematic adherence behavior (Favaro et al., 2011). Shemesh et al. (2000) hypothesized PTSD-related non-adherence to be related to avoidance of disease and treatment-related stimuli.
- It is critical to maintain an accurate and continually updated list of the patient's medications and to ascertain whether the patient is actually taking the medications consistently and as prescribed.
- For decisive non-compliers, a psychiatrist or psychologist can determine underlying attributions driving non-adherence to help them more appropriately target interventions (e.g., behavioral strategies, cognitive restructuring of beliefs about need to engage in adherent behavior, motivational interviewing techniques) to improve non-adherent behavior.

BURNS

Shamim H. Nejad, Amelia Dubovsky, Kelly Irwin, Shawn Fagan, and Jeremy Goverman

INTRODUCTION

Since ancient times, burn injuries have been a source of trauma for humans. While historic treatments may have been primitive, today's modern medical and surgical treatment has become increasingly sophisticated, resulting in lower mortality rates, especially from severe burns. However, while burn patients are increasingly likely to survive their injuries, they often carry a lifetime burden from their injury. The impact is greatest on children and young adults, who have most of their lives ahead of them.

Modern psychiatric burn research and treatment began in the mid-1940s during World War II, when the symptoms of stress and grief experienced in burn survivors of the Coconut Grove fire of 1942, in which 491 people died, were described. In what is now considered a classic paper, Erich Lindemann reported for the first time the symptoms and psychotherapeutic management of acute grief (Lindemann, 1944). These studies involved psychiatric treatment and subsequent research on grief that would eventually be applied, not only to other patients and the bereaved, but also to military personnel. Norman Bernstein, a pioneer in the treatment of psychiatric care for children, described hypnosis in the treatment of burn pain and brought attention to the stigma experienced by those with facial injuries (Bernstein, 1976), while Richard Galdston described depression and emotional sequelae of burns in young children of depressed mothers (Galdston, 1972).

As most burn units are closed systems (only certain individuals generally enter and leave the unit), physicians and other medical staff who are new to the unit often experience trepidation when they have to care for a patient following a burn injury. The traditional role of the psychiatric consultant in the care of the burn patient has been to diagnose and treat discrete psychiatric disorders when called upon by the burn physicians. However, a psychiatrist's training and clinical background provide a unique set of skills that may be useful to the burn team in the treatment of every patient. Medical psychiatrists are trained to view patients and their conditions from existential, social, and developmental perspectives in addition to their physiological state. This chapter addresses the medical and psychiatric issues pertinent to patients in the acute, intermediate, and rehabilitative phases of burn injury.

EPIDEMIOLOGY

The United States has one of the highest rates of burn injury in the world. According to the American Burn Association Fact Sheet for 2011, 450,000 patients annually visit emergency rooms with burn-related injuries, and about 45,000 of them are hospitalized (American Burn Association, 2011b). About 55% of the estimated 45,000 acute hospitalizations for burn injury in the United States in recent years were admitted to 125 hospitals with specialized burn centers. The percentage admitted to burn centers has increased steadily in recent decades, with growing recognition of the special needs of burn patients and continuing advances in the technical resources and skills of those who refer, transport, and treat them. An American burn center now averages 200 admissions per year, and their average survival rate exceeds 94%. The other 4,700 American acute care hospitals average fewer than three burn cases per year, and have a greater than 94% survival rate.

The National Burn Repository 2011 report, which compiles burn admission data from 2001 to 2011 from 91 hospitals from 35 states (and the District of Columbia), shows that nearly 70% of burn patients were between age 5 and age 60, with a mean age of 32. Children under five are over-represented among burn patients, accounting for 18% of all burn admissions. Patients aged 60 or older are under-represented, accounting for only 12% of admissions (American Burn Association, 2011a). Seventy percent of patients hospitalized for burns had burns covering less than 10% of their total body surface area (TBSA), with the two most commonly reported etiologies being fire/flame burns and scalding injuries. With regard to circumstance of injury, non-work-related injuries were the most common (67.4%), followed by work-related accidents (15.8%), while assault/abuse accounted for 1.4%, and both self-inflicted injuries and suspected child abuse cases were 1.1%. During the ten-year period from 2001 and 2010, the mortality rate decreased from 4.5% to roughly 3% for males and from 6.8% to 3.6% for females. Deaths from burn injury increased with advancing age and burn size, and presence of inhalation injury. For patients under age 60 and with a burn affecting a TBSA of less than 20%, the presence of inhalation injury increased the likelihood of death by 20 times. Pneumonia was the most frequent clinically related complication and occurred in 5.8% of fire/flame-injured patients. The frequency of pneumonia and

respiratory failure was much greater in patients with four days or more of mechanical ventilation. The incidence of clinically related complications for patients not requiring mechanical ventilation increased with age, plateauing at 20% for those age 80 and over.

RISK FACTORS FOR BURN-RELATED INJURIES (SEE TABLE 75.1)

OCCUPATIONAL

Particular occupations are the greatest risk factors for burns in adults. Those in high-risk occupations include mechanics working with boilers, radiators, or gasoline engines; power plant workers; cooks; truckers and other transport workers; farm workers; and those whose jobs involve the use of caustic chemicals.

ALCOHOL AND SUBSTANCE USE

Premorbid substance use is common among those with burn injuries. In a study conducted by Barillo and Goode, among 727 deaths from fires, a blood alcohol level was positive in approximately 30% of patients, and almost 15% of patients also had positive results for another illicit substance. Seventy-five percent of the drug-positive and 58% of the alcohol-positive fatalities were between the ages of 21 and 50 (Barillo & Goode, 1996).

Among patients who survive their initial burn injuries, several studies have evaluated the prevalence of alcohol intoxication, alcohol abuse, or alcohol dependence. In a study by Jones and colleagues, 27% were intoxicated at the time of their burns, while 90% of these intoxicated patients were also diagnosed with alcohol abuse, compared with 11% in the non-intoxicated burn-injured patients (Jones, Barber, Engrav, & Heimbach, 1991). Other studies have reported the prevalence of alcohol abuse and dependence as being between 6% and 11% (Powers et al., 1994; Tabares & Peck, 1997). Fauerbach and colleagues reported lifetime prevalence rates of alcohol and drug use disorders among 98 adult burn inpatients of 41% and 24% respectively, notably higher than when compared to such rates in the general population (Fauerbach, Lawrence, Haythornthwaite, McGuire, & Munster, 1996).

Burns associated with methamphetamine represent a relatively new problem, mainly affecting certain geographic regions of the United States where its use is more prevalent. In some studies, up to 10% of injured patients with burn injuries were under the influence of methamphetamine. Not only does methamphetamine intoxication predispose to burn injury, but, its production involves highly volatile chemical compounds that can cause both thermal and chemical burns.

PREMORBID PSYCHIATRIC ILLNESS

Burn patients have higher rates of pre-injury psychiatric illness compared to the general population (Powers, Cruse, &

Boyd, 2000; Rockwell, Dimsdale, Carroll, & Hansbrough, 1988). Burn patients with pre-burn psychiatric illness are more likely to have had potentially preventable burn injuries (Powers et al., 2000). They have longer lengths of hospitalization (Tarrier, Gregg, Edwards, & Dunn, 2005; van der Does, Hinderink, Vloemans, & Spinhoven, 1997), and have more complicated post-burn adjustment (Dyster-Aas, Willebrand, Wikehult, Gerdin, & Ekselius, 2008; Fauerbach et al., 1996; Tarrier et al., 2005; van der Does et al., 1997). In two studies using criteria from the *Diagnostic and Statistical Manual of Mental Disorders* (DSM), lifetime mood disorders were identified in 31% and 42% of burn patients (Dyster-Aas et al., 2008; Fauerbach et al., 1997). In both studies, major depression was the most common disorder (27% and 41%), with these figures being significantly higher compared with those in the general population (Kessler, Chiu, Demler, Merikangas, & Walters, 2005; Kessler et al., 1994; Kringlen, Torgersen, & Cramer, 2001, 2006). In addition, those who had a lifetime mood disorder had worse functional status at discharge (Fauerbach et al., 1996). In the same studies, the lifetime anxiety was found to be 10% and 37%. In one study, the prevalence of pre-burn post-traumatic stress disorder (PTSD) was 2% (Fauerbach et al., 1996); in the other it was 10% (Dyster-Aas et al., 2008). Dyster-Aas and colleagues have reported that 4% of burn patients assessed had lifetime psychotic disorders; however, this number may be as high as 12% in patients with self-inflicted burns (Dyster-Aas et al., 2008).

SELF-INFLECTED BURN INJURY AND SELF-IMMOLATION

The act of self-immolation is rare in Western countries, with prevalence rates between 1% to 9% of all burn-injured patients, while in other parts of the world such as the Middle East, Africa, and South Asia, prevalence rates may be as high as 28% of burn-injured patients (Ahmadi, 2007; Krummen, James, & Klein, 1998; Palmu et al., 2004; Scully & Hutcherson, 1983; Squyres, Law, & Still, 1993).

In Western countries, the data on gender and self-immolation are conflicting, with some studies showing it to be more common in men, while others show a greater incidence in women (Krummen et al., 1998; Swenson & Dimsdale, 1990). Risk factors include marital or relationship difficulties (Squyres et al., 1993) and unemployment (Palmu et al., 2004). Studies consistently show the association of self-immolation with alcohol and other substance use disorders (Pham, King, Palmieri, & Greenhalgh, 2003; Thombs, Singh, Halonen, Diallo, & Milner, 2007), as well as mood and psychotic disorders (Palmu et al., 2004; Thombs et al., 2007).

The prevalence of self-immolation as well as mortality following self-immolation is greater in developing countries, probably reflecting limited overall access to health care and less availability of burn-specific treatment. Risk factors associated with self-immolation in developing countries include younger age, female gender, low socioeconomic status, decreased literacy, limited access to mental health services,

and marital and familial conflict (Ahmadi et al., 2009; Ahmadi & Ytterstad, 2007).

Self-inflicted burn injuries are quite often associated with underlying personality disorders; namely, borderline personality disorder. While many studies have looked at self-immolation, few studies have examined the subset of patients who intentionally burn themselves but do not intend their injury to be fatal. Providing inpatient burn care to a patient with borderline personality disorder can be markedly challenging, as these patients generally exhibit interpersonal difficulties that can interfere with the patient–healthcare professional relationship, complicating the delivery of necessary care. Ideally, all patients with suspected self-inflicted burn injury should be evaluated by a psychiatrist; and in cases of borderline personality disorder, behavioral plans, centralization of care with consistent nursing staff, and education of burn staff regarding “splitting” behavior and behavioral limit-setting should be employed.

CHILDREN AND ADOLESCENTS

Environmental, developmental, and familial factors contribute to the risk of burn-related injuries in children (Stoddard & Fricchione, 2004). Risks include low socioeconomic status, poor social supports, access to inflammatory and caustic agents, along with risk-taking behavior. In addition, parental psychopathology, neglect, childhood depression, learning disabilities, developmental delay, conduct disorder, attention-deficit hyperactivity disorder (ADHD), bipolar mood disorder, and substance abuse have also been shown to be associated with burn-related injuries.

Table 75.1 RISK FACTORS FOR BURN INJURY

BURNS IN ADULTS	BURNS IN CHILDREN AND ADOLESCENTS
Occupational hazards	Learning disabilities
Alcohol or substance abuse	Abuse
Dementia	Risk-taking behavior
Self-harming behavior	Fire-setting
Chronic medical illness	Neglect
Mood disorder	
Suicide attempt	
Psychotic disorder	

TYPES OF BURN INJURIES

Burn injuries are generally classified by the depth of the injury, ranging from first-degree to fourth-degree with regard to severity (see Table 75.2). First-degree burns are characterized by intact epithelium and usually do not require specific care. Second-degree burns are wet, pink to red in color, and with edema present. They are further categorized into “superficial” and “deep.” Second-degree burns must be monitored closely for progression of injury and for infection. Third-degree burns involve the full thickness of the skin, with damage to sensory nerves and to blood vessels beneath. They are dry and leathery. Because of nerve damage, they may be less painful than second-degree burns. Their treatment requires excision and grafting. Fourth-degree burns are the severest

Table 75.2 SEVERITY OF BURN INJURIES: APPEARANCE, SENSATION, AND COMPLICATIONS

INJURY	LAYER	APPEARANCE	TEXTURE	SENSATION	TIME TO HEALING	COMPLICATIONS
1 st -degree	Epidermis	Redness (erythema)	Dry	Painful	7 days or less	None
2 nd -degree (superficial partial thickness)	Extends into superficial dermis	Red with clear blisters; blanches with pressure	Moist	Painful	2–3wks	Local infection/ cellulitis
2 nd -degree (deep partial thickness)	Extends into deep dermis	Red-and-white with bloody blisters. Less blanching	Moist	Painful	Weeks—may progress to third-degree	Scarring, contractures (may require excision and skin grafting)
3 rd -degree (full thickness)	Extends through entire dermis	Stiff and white/brown	Dry, leathery	Painless due to loss of nerve fibers (extensive peripheral pain where 2nd-degree burns lie)	Requires excision	Scarring, contractures, amputation
4 th -degree	Extends through skin, subcutaneous tissue, and into underlying muscle and bone	Black; charred with eschar	Dry	Painless (painful at periphery)	Requires excision	Amputation, significant functional impairment

Table 75.3 DEGREE OF BURN INJURY WITH USUAL ASSOCIATED PAIN SENSATIONS AND COMPLICATIONS. COMMON DRESSINGS USED IN BURN INJURIES

DRESSING	WHAT IT IS	TYPE OF INJURY	HOW APPLIED	NOTES
Silver Nitrate Solution	<ul style="list-style-type: none"> • 0.5% hypotonic solution • Offers broad-spectrum antimicrobial and fungal coverage 	Deep partial thickness wounds	<ul style="list-style-type: none"> • Dressing changed daily • 8 layers of nitrate-saturated dressings • Requires soaking with nitrate q6H & PRN° 	<ul style="list-style-type: none"> • Leaches electrolytes (especially sodium) from the wound surface—can result in hyponatremia and hypokalemia (incidence is directly proportional to size of the area involved)
Silver Sulfadiazene (Silvadene)	<ul style="list-style-type: none"> • 1% water soluble cream • Offers broad spectrum antimicrobial activity 	Partial thickness wounds	<ul style="list-style-type: none"> • Dressing changed BID • Area cleansed with soap and water 	<ul style="list-style-type: none"> • May result in a self-resolving agranulocytosis, evidenced after several days of use <p>Contraindicated in patients with allergies to sulfa</p>
Mafenide Acetate (Sulfamylon) Solution	<ul style="list-style-type: none"> • 5% bacterostatic solution for gram (+) and gram (–) organisms 	Full-thickness wounds with eschar	<ul style="list-style-type: none"> • Dressing changed daily • Area cleansed with Hibiclens and water 	<ul style="list-style-type: none"> • Carbonic anhydrase inhibition may result in lactic acidosis depending, upon the size of the area involved and length of time used • May be painful, and some patients do not tolerate • Sulfamylon is the only agent to penetrate eschar
Mafenide Acetate (Sulfamylon) Cream	<ul style="list-style-type: none"> • 11.1% Cream • Bacterostatic for gram (+) and gram (–) organisms 	Wounds with exposed cartilage (i.e., nose, ears)	<ul style="list-style-type: none"> • Dressing changed BID • Area cleansed with Hibiclens and water • Applied directly to the wound and covered with dressing 	<ul style="list-style-type: none"> • Can be painful if used on areas other than ears and nose
Acticoat (Silver-coated antimicrobial barrier)	<ul style="list-style-type: none"> • Broad spectrum antimicrobial agent • Based on ability to dissolve pure silver in water • Activated with moisture (sterile water or exudate) <p>Constant concentration of silver is delivered to the wound</p>	Partial-thickness wounds	<ul style="list-style-type: none"> • Dressing changed every 3 days • Area cleansed with soap and water 	<ul style="list-style-type: none"> • Sustained release of silver lowers frequency of dressing changes • Comes in 3-day or 7-day formulations (usually 3 days for acute injury)
Aquacel Ag	<ul style="list-style-type: none"> • Ionic silver in the Hydrofiber technology of Aquacel • Offers broad spectrum of wound coverage 	Partial thickness wounds (May also be used for donor sites)	<ul style="list-style-type: none"> • Dressing not changed unless it is not adhering to the wound after 2–3 days • Dressing applied dry 	<ul style="list-style-type: none"> • May be left in place up to 14 days • When used for donor sites, the ABD pads directly over the Aquacel are removed on POD #1; the stretch net is left in place until POD #2 • The Aquacel is left in place until donor site is healed, ~10–14 days (generally removed in clinic)

Bacitracin	<ul style="list-style-type: none"> • Topical antibiotic ointment 	Partial-thickness wounds	<ul style="list-style-type: none"> • Dressing changed BID • Area cleansed with soap and water and applied directly to the wound • Covered with non-stick dressing (preferably Adaptic) 	<ul style="list-style-type: none"> • ~10% of patients can develop reactions to Bacitracin evidenced by an itchy, maculopapular rash
Mupircin (Bactroban)	Topical antibiotic ointment/cream	Partial-thickness wounds	<ul style="list-style-type: none"> • Dressing changed BID • Area cleansed with soap and water • Covered with non-stick dressing (preferably Adaptic) 	<ul style="list-style-type: none"> • Preferable when patient is positive for MRSA if choosing between Bacitracin and Bactroban
Collagenase (Santyl)	<ul style="list-style-type: none"> • Enzymatic debriding agent 	Adherent eschar or debris	<ul style="list-style-type: none"> • Area cleansed with soap and water • Applied directly to the wound 	<ul style="list-style-type: none"> • Drainage from the wound may increase as the eschar sloughs
Xeroform	<ul style="list-style-type: none"> • Petrolatum dressing 	Usually used for donor sites	<ul style="list-style-type: none"> • The dressing is not changed 	<ul style="list-style-type: none"> • On POD #1, the outer wrap is removed and the Xeroform is allowed to dry
Xenograft	<ul style="list-style-type: none"> • Biological dressing made of porcine 	Partial thickness wounds	<ul style="list-style-type: none"> • Xenograft is not changed • It is applied to a clean, debrided wound, usually in the OR • The outer wrap is removed on POD #1 and the Xenograft examined for adherence. If adhered, the wound is left open to air 	<ul style="list-style-type: none"> • Joints are immobilized for 4 days to allow for adherence to the wound bed

type of burn injury. They extend through the subcutaneous tissue into tendons, muscles, and bones. They require complex surgical reconstruction and treatment, usually with multiple trips to the operating theater.

Surgical treatment of severe burns involves wound debridement, escharotomy (excision of burned skin), and at times release of the fascial layer (fasciotomy) to prevent compartment syndrome, particularly with circumferential burn injuries. In addition to surgical treatment, burn patients require frequent dressing changes, and they are frequently treated with systemic antimicrobial agents (see Table 75.3).

BURNS AND THE SYSTEMIC INFLAMMATORY RESPONSE

PATHOPHYSIOLOGY OF BURN SHOCK

Cutaneous thermal injury to greater than one-third of the TBSA often results in a severe derangement of cardiovascular function called *burn shock*. Shock is an abnormal physiological state in which tissue perfusion is insufficient to maintain adequate delivery of oxygen and nutrients and the removal of cellular waste products. Burn shock is a unique type of cardiovascular dysfunction that is not easily or fully reversed by fluid resuscitation. Severe burn injury results in significant hypovolemic shock and the release of local and systemic mediators of inflammation. Burn shock results from the interplay of hypovolemia and multiple mediators of inflammation which affect the microcirculation as well as the heart, large vessels, and lungs. These inflammatory mediators include histamine, serotonin, bradykinin, nitric oxide, free radicals, prostaglandin, thromboxane, tumor necrosis factor (TNF), and interleukins. Additionally, hormones and mediators of cardiovascular function elevated after burn injury include epinephrine, norepinephrine, vasopressin, angiotensin II, and neuropeptide-Y. The hypovolemic nature of burn shock results from the massive extravasation of plasma into the burn wound and the surrounding tissues as a result of these local and systemic inflammatory mediators altering Starling forces in vessels (Kramer, Lund, Tjostolv, & Beckum, 2002). Fluid resuscitation is both necessary and complex.

SEPSIS AND THE SYSTEMIC INFLAMMATORY RESPONSE SYNDROME

Burn patients commonly exhibit a clinical picture that is predominantly produced by systemic inflammation involving multiple organ systems, including the central nervous system. Symptoms associated with systemic inflammatory response syndrome (SIRS) include tachycardia, tachypnea, fever, leukocytosis, refractory hypotension, and in its severest form, multiple organ-system dysfunction. In thermally injured patients, the most common cause of SIRS is the burn itself. Sepsis, defined as SIRS in the presence of an infection, is also a common cause. Since virtually all patients with severe burns demonstrate signs of SIRS, the American Burn Association (ABA) has come up with specific guidelines for the definition

of sepsis in patients with burns, particularly because the hypermetabolic state may persist for months after the burn wound has healed. As a sign of the hypermetabolic state, patients with large burns may have a baseline temperature to 38.5°C. The change in the burn patient that triggers the concern for infection includes temperature higher than 39° or lower than 36.5°C; progressive tachycardia higher than 100 bpm in adults; progressive tachypnea greater than 25 in an adult not ventilated, thrombocytopenia less than 100,000/mcl three or more days after resuscitation, hyperglycemia if not diabetic, and inability to continue enteral feedings for 24 hours. The finding of a documented infection defines sepsis (Greenhalgh et al., 2007). The most commonly used markers of inflammation and infection include C-reactive protein (CRP), erythrocyte sedimentation rate (ESR), and white blood cell (WBC) count. These are elevated early and taper with time (Chipp, Milner, & Blackburn, 2010) (see Box 75.1).

Box 75.1 AMERICAN BURN ASSOCIATION CONSENSUS ON DEFINITIONS OF SIRS, SEPSIS, AND MULTIPLE ORGAN DYSFUNCTION SYNDROME

Systemic Inflammatory Response Syndrome (SIRS)

At least two or more of the following:

- Temperature above 38°C or below 36°C
- Heart rate >90 beats per minute (bpm)
- Respiratory rate >20/min or maintenance of PaCO₂ <32mm Hg
- WBC count >12,000/mm³ or <4000/mm³, or left shift defined as >10% bands.

Sepsis

Sepsis is a change in the burn patient that triggers the concern for infection.

Trigger includes at least three of the following:

- I. Temperature >39° or <36.5°C
- II. Progressive tachycardia:
 - a. Adults >110 bpm
 - b. Children >2 standard deviations (SD) above age-specific norms (85% age-adjusted maximum heart rate)
- III. Progressive tachypnea:
 - a. Adults >25 bpm not ventilated
 - i. Minutes of ventilation >121/min ventilated
 - b. Children >2 SD above age-specific norms (85% age-adjusted max respiratory rate)
- IV. Thrombocytopenia (will not apply until 3 days after initial resuscitation):
 - a. Adults <100,000/mc.l

- b. Children <2 SD below age-specific norms
- V. Hyperglycemia (in the absence of preexisting diabetes mellitus):
 - a. Untreated plasma glucose >200 mg/dl or equivalent mM/L
 - b. Insulin resistance—examples include:
 - i. >7 units of insulin/hr intravenous drip (adults)
 - ii. Significant resistance to insulin (>25% increase in insulin requirements over 24 hours)

VI. Inability to continue enteral feedings >24 hours:

- a. Abdominal distension
- b. Enteral feeding intolerance (residual >150ml/hr in children or two times feeding rate in adults)
- c. Uncontrollable diarrhea (>2500 ml/d for adults or >400 ml/d in children)

In addition, it is required that a documented infection be identified by positive culture, pathological tissue sourced, or clinical response to antimicrobials.

Multiple Organ Dysfunction Syndrome

Cardiovascular heart rate >120
 Respiratory, pO_2/FIO_2 <300
 Renal (creatinine mmol/L) >100
 Central nervous system (Glasgow coma scale score) >15
 Hepatic (total bilirubin, mmol/L) >20
 Hematologic (platelet count $\times 1000$) <120

From Greenhalgh, D. G., et al. (2007). American Burn Association Consensus Conference to define sepsis and infection in burns. *Journal of Burn Care & Research*, 28, 776–790.

The pathogenesis of SIRS starts with tissue injury, which results in the acute release of pro-inflammatory cytokines such as $\text{TNF}\alpha$ and interleukins IL-1 and IL-6. If the thermal injury is extensive enough, a profound release of cytokines occurs. $\text{TNF}\alpha$ is released by macrophages during the first minutes of local or systemic injury. Macrophage dysfunction has been found to be one of the key components of burn-related inflammatory dysregulation (Schwacha, 2003). At the local site of injury, $\text{TNF}\alpha$ initiates an immune response and activates neutrophils and mononuclear phagocytes. It is also a growth factor for fibroblasts and an angiogenesis factor. At the local site, $\text{TNF}\alpha$ will eventually result in tissue repair. However, systemic release of $\text{TNF}\alpha$ can induce fever, stimulation of acute-phase protein secretion by the liver, activation of the coagulation cascade, myocardial suppression, induction of systemic vasodilators with resultant hypotension, catabolism, and hypoglycemia. It also stimulates the release of IL-1 and IL-6, which potentiate the effects of $\text{TNF}\alpha$.

Brain dysfunction is often one of the first visible symptoms in sepsis, as the brain can be affected by multiple

factors such as hypotension, hypoxemia, hyperglycemia, hypoglycemia, and organ dysfunction (such as increased levels of ammonia in liver dysfunction, or urea in kidney dysfunction). In addition to these factors, inflammation can affect the brain directly. The blood–brain barrier permeability is increased, and significant changes in regulation of cerebral perfusion can occur (Burkhart, Siegemund, & Steiner, 2010).

The presence of SIRS, especially in the setting of multi-organ dysfunction syndrome (MODS) is a predictor of poor outcome. The presence of more than two of the SIRS criteria has been correlated with increased morbidity and mortality (Rangel-Frausto et al., 1995). Three factors seem to determine the effect of SIRS on a patient: First, the severity of the initial inflammatory response, which is proportional to the severity of the injury. Specifically, the presence of shock or MODS within the first 24 hours predicts poor prognosis. The second factor is the persistence of SIRS beyond the second day of injury. The third factor is the adaptive capability of the patient. Extremes of age and coexisting disease predict a worse outcome (Sherwood & Traber, 2002).

Treatment of SIRS is largely supportive. Sheridan and colleagues found that the majority of MODS deaths on their unit were clinically free from infection at the time of death, highlighting the overwhelming inflammatory response to thermal injury (Sheridan, Ryan, Yin, Hurley, & Tompkins, 1998). The progression of SIRS to MODS is often more dependent on the inflammatory response than on the actual presence of invasive microorganisms.

PSYCHIATRIC ASSESSMENT AND MANAGEMENT OF PATIENTS WITH BURNS

ACUTE PHASE

The acute phase is the time from initial injury to the time when the patient cognitively and emotionally is convinced that survival is possible, when pain (physical and procedural) becomes controlled, and the patient begins assisting in the recovery and resumes basic autonomous functioning.

Initial assessment and treatment begin from the time of admission or at the time of evaluation, which may occur in the emergency room, particularly for patients with self-inflicted burn injuries. Assessment may be complicated by an intubated or obtunded state. However, cognitive state should be assessed even in the intubated patient, and history should be obtained from collateral sources if possible. A narrative of how the burn occurred and how the patient got to the hospital should be put together.

Laboratory data such as blood chemistries, electrolytes, liver function tests, urine and serum toxicology screens, and carbon monoxide levels (if pertinent) are vital, particularly in intubated or comatose patients. Special studies such as neuroimaging (when there are concerns for head injury, stroke, or hypoxic/anoxic injury), and electroencephalography (EEG) may be indicated, depending on the clinical case.

Encephalopathy

Encephalopathy (delirium) is common in burn centers (see Table 75.4). The prevalence of delirium has ranged from 10–30% of overall burn patients and up to 80% of burn patients in the critical care setting. Specifically, one prospective study of burn intensive care unit (ICU) patients demonstrated delirium in 77% of ventilated burn patients. The majority of patients were identified to have hypoactive delirium (Agarwal et al., 2010).

In trauma patients, age, male gender, intoxication with alcohol on admission, and lack of insurance have been associated with delirium (Blondell et al., 2004; Branco et al., 2011). In the ICU setting, cigarette smoking has also been independently associated with delirium (Van Rompacy et al., 2009). Many of these factors—premorbid psychiatric illness, substance dependence, advanced age, dementia, and smoking—also predispose to the development of burns. However, risk factors for delirium in the ICU and particularly for mechanically ventilated patients are different (Dubois et al., 2001). One prospective observational trial of delirium with mechanically ventilated burn patients found that patients tended to be younger and to have lower rates of cognitive impairment compared to the general hospital population. Nearly 80% of patients developed delirium measured by the Confusion Assessment Method for the intensive care unit (CAM-ICU). Risk was not associated with advanced age, cognitive impairment, substance dependence, burn type or severity, or presence of an inhalation injury. Instead, delirium was independently associated with medications used to target anxiety and pain control. Specifically, benzodiazepine exposure independently predicted the development of delirium (odds ratio [OR] 6.8, $p < .001$). In contrast, receiving higher doses of intravenous (IV) fentanyl and higher doses of methadone were

both associated with half the risk of delirium (Agarwal et al., 2010).

In patients with burn trauma, a high burden of local injury triggers a strong systemic hypermetabolic and inflammatory response. This response is necessary for wound healing and recovery but also has downstream effects on the central nervous system that can predispose to delirium. Since the 1970s, clinicians have observed a high prevalence of delirium in both adults and children who have experienced severe burns and have postulated the existence of a burn-related toxin (Antoon, Volpe, & Crawford, 1972). Although no specific “burn toxin” has been identified, the inflammatory response syndrome impacts the brain through both hormonal and neuronal mechanisms. Local tissue injury causes a pro-inflammatory cytokine cascade that leads to the production of neurotoxins and excessive cortisol. In addition, oxidative stress alters neuronal activity (particularly in areas of the brain more sensitive to hypoxia, such as the hippocampus and subcortical gray matter), and affects the levels of neurotransmitters. For example, cholinergic neurons are uniquely sensitive to oxygen deprivation, resulting in decreased synthesis and release of acetylcholine (Fricchione et al., 2008).

Metabolic Abnormalities and Risk for Infection

In addition to being exposed to a pro-inflammatory state, burn patients, given large areas of exposed surface area, open wounds, administration of various antimicrobial dressings, and high caloric demands, are vulnerable to hyperglycemia, and fluid and electrolyte abnormalities, including hyponatremia, that have been associated with delirium. The systemic inflammatory response may evolve into sepsis and multi-organ failure.

Table 75.4 RISK FACTORS FOR DELIRIUM IN THE BURN PATIENT.

<i>Demographic and Predisposing Factors</i>	<i>Potentially Modifiable Factors: Focus on ICU Patients</i> <i>Note: Demographic Factors Less Robust in the Critically Ill Population</i>
<i>General Medical and Surgical Patients:</i> <ul style="list-style-type: none">• Advanced Age• Cognitive Impairment• Hypertension• Depression• Substance dependence: Alcohol, Illicit drugs, nicotine	<ul style="list-style-type: none">• Need for frequent procedures• Electrolyte imbalances• Pro-inflammatory state and risk of infection• Disruptions of sleep-wake cycle• Pain control• Assessing for alcohol/substance withdrawal• Medications: Sedative-hypnotics, unnecessary administration of narcotics
<i>Trauma Patients</i> <ul style="list-style-type: none">• Age >45 years• Alcohol dependence: Elevated mean corpuscular volume and + blood alcohol level on admission• Type of injury: Burns, falls• Male gender• Lack of insurance	<i>Decreased risk for delirium</i> <ul style="list-style-type: none">• Appropriate use of opiates to treat background and procedural pain• Drug holidays, individualized sedation protocols
<i>Burn Patients</i> <ul style="list-style-type: none">• TBSA >30%• Inhalation injury• Charcoal/gas stove: Carbon monoxide exposure	<i>Increased risk for delirium</i> <ul style="list-style-type: none">• Benzodiazepines: Larger doses; use of longer acting agents• Use of opiates to target agitation• Anticholinergic agents

Carbon Monoxide Exposure and Hypoxia

The circumstances of the burn, and particular toxins involved, may also heighten the risk of delirium. Patients who have experienced burns related to charcoal, gas stoves, or inhalation injuries may also have been exposed to carbon monoxide. In the acute setting, carbon monoxide exposure causes non-specific symptoms; especially, headache, disturbance of consciousness, nausea and vomiting, dizziness, confusion, fatigue, chest pain, and dyspnea. The diagnosis of carbon monoxide (CO) poisoning is clinical, requiring a history of recent CO exposure, the presence of symptoms consistent with CO poisoning, and demonstration of an elevated carboxyhemoglobin level. No particular symptoms correlate with the CO level. High-flow oxygen by mask or endotracheal tube is the front-line treatment (Hampson et al., 2012). Through both the impact of hypoxia and oxidative stress resulting from carboxyhemoglobin, patients can also develop persistent neurological sequelae, and after a lucid interval, develop delayed neurological sequelae within a timeframe of a few days to six weeks. The symptoms observed correspond to the sensitivity of brain regions to hypoxia and oxidative stress and can include: deficits in memory due to insults to the hippocampus; impaired attention and executive function and personality change linked to the thalamus and subcortical white matter; and symptoms of Parkinsonism, chorea, dystonia, and psychosis due to impact on the basal ganglia and dopaminergic neurons (Weaver, 2009). There is mixed evidence that treatment with hyperbaric oxygen decreases the risk of the development of delayed neurological sequelae (Buckley et al., 2011); however, hyperbaric oxygen should at least be considered in all cases of serious acute CO poisoning and normobaric 100% oxygen continued until the time of hyperbaric oxygen administration (Jurrlink et al., 2005). The goal of hyperbaric oxygen treatment would be to prevent later neurological sequelae. There is a risk of long-term cognitive deficits and the development of anxiety and depression not necessarily associated with the severity of carbon monoxide exposure. Treatment decisions in the mildly poisoned patient are difficult and controversial even among experts (Weaver, 2009). More broadly, inhalation injury and exposure to smoke may also predispose to the development of delirium due to hypoxia and poor CNS perfusion. Those who are accidentally exposed to carbon monoxide should be seen one to two months later, and formal neuropsychiatric testing used to document baseline function or deficits.

Pain Control and Exposure to Medications

For decades, pain was under-treated in the burn population, in part due to concern of over-sedation and death. Poorly controlled pain has been linked to the development of delirium in postoperative patients (Morrison et al., 2003) and has also been associated with increased long-term risk of PTSD (Moeller-Bertram, Keltner, & Strigo, 2011; Watkins, Cook, May, & Ehleben, 1988). Burn patients experience both a chronic, background level of pain due to tissue damage, and acute procedural pain in the context of daily debridement.

High doses and combinations of medications have been utilized to treat pain, anxiety, and fear. The goal is to treat pain and relieve fear and anxiety, provide adequate sedation for procedures, and enable restful sleep, at the same time trying to avoid precipitating a drug-related delirium.

Sedatives

Trials have been conducted in the critical care setting to help guide the judicious use of sedatives. Specifically, in the ICU, administration of high-dose benzodiazepines has been independently associated with delirium. In mechanically ventilated burn patients, as described above, higher doses of lorazepam were a strong independent predictor of delirium (Agarwal et al., 2010). Additionally, delirium has been more strongly linked to longer acting benzodiazepines (Marcantonio et al., 1994). Alternative agents for sedation are also being studied in the ICU setting. One alternative to benzodiazepines and propofol is dexmedetomidine, an alpha-2-agonist, with approximately 8 times greater affinity for the alpha-2-receptor than clonidine. Compared to patients treated with equally efficacious doses of midazolam equivalents, patients treated with dexmedetomidine had a lower risk of delirium and fewer days of being ventilated; the downside was an increased risk of bradycardia (Riker et al., 2009). A randomized controlled trial of individualized sedation for mechanically ventilated patients demonstrated that, compared to lorazepam, dexmedetomidine was associated with decreased duration of delirium (Pandharipande et al., 2008). Complicating its use in the burn patient population is its potential to cause hypotension; thus proper hydration is critical, and a loading dose should be avoided if possible. Propofol is another alternative sedating agent with a significantly shorter half-life that has been postulated to be less deliriogenic than benzodiazepines. However, in a patient with large-scale burns that would necessitate the use of sedatives and ventilation for an extended duration of time (more than two to three weeks), the use of propofol may not be possible due to the risk of propofol infusion syndrome and resulting lipid and metabolic derangements associated with its use.

Opiates

Evidence regarding the link between exposure to opiates and the risk for delirium is mixed. Meperidine and high doses of morphine have been more consistently associated with delirium than has the use of other opiates. However, studies conducted in the postoperative setting link pain to delirium, suggesting that there is a delirium risk in under-treatment with opiates. In mechanically ventilated burn patients, intravenous opiate exposure and treatment with methadone were both associated with a 50% decreased risk of delirium. Consistent with clinical experience, authors have argued that controlling pain (background and procedural) is protective, but when opiates are used for sedation or control of agitation—usually at higher doses than those needed for adequate pain control—the risk of delirium increases (Agarwal et al., 2010).

Addiction and Withdrawal Syndromes

Chronic alcohol misuse is more common in burn patients (up to 41%), even when compared to psychiatric patients (30%) and neurological patients (19%) (Fauerbach et al., 1997; Spies & Rommelspacher, 1999). Almost half of all trauma beds are occupied by patients who were injured while intoxicated or under the influence of alcohol (Spies & Rommelspacher, 1999). In addition, the rate of morbidity and mortality due to infections, cardiopulmonary insufficiency, or bleeding disorders is two to four times greater in patients who chronically misuse alcohol.

In a study by Soderstrom and colleagues, the rates of point-prevalence of drug dependency in a trauma center were 10.6% for cocaine, 10.0% for opiates, 6.5% for cannabis, 0.4% for hallucinogens, and 0.3% for stimulants (Soderstrom et al., 1997). Their data seem to show that seriously injured trauma center patients manifest severer forms of addiction than the general population with polysubstance dependence.

The incidence of alcohol withdrawal delirium (AWD), commonly referred to as delirium tremens or DTs, in hospitalized patients is significant. Among trauma patients, it is estimated that 40–50% of patients are intoxicated, and 94% of those presenting with intoxication have a substance abuse disorder (Lukan, Reed, Looney, Spain, & Blondell, 2002). The clinician should attempt to identify the patients at high risk for developing AWD, initiate prophylactic treatment in patients at high risk, and provide effective treatment of patients who go on to develop AWD despite prophylaxis, in order to decrease associated morbidity and mortality (Box 75.2).

Management of Encephalopathy

The first step to management of delirium is establishing the safety of the patient and staff. This may require the temporary use of restraints. The next step, if possible, is to identify the underlying etiology or etiologies and correct any reversible causes that may contribute to delirium. In the burn patient

in the critical care unit, this means frequent monitoring and correction of electrolytes, assessing oxygenation and CNS perfusion, monitoring for infection, controlling pain, assessing for use of deliriogenic medications, and monitoring for withdrawal from alcohol, benzodiazepines, and opiates.

As the diagnostic work-up is occurring, antipsychotics can be utilized to target agitation and confusion. Specifically, IV haloperidol is often the most practical choice in the acutely ill burn patient given its relatively low hypotensive and anticholinergic effects. Acute extrapyramidal syndromes are also infrequent with short periods of intravenous haloperidol use. A starting dose of 2–5 mg IV is reasonable and can be titrated up by 5–10 mg every 30 minutes until the patient is calm. Particularly in burn patients who are more vulnerable to electrolyte abnormalities, it is important to monitor and replenish potassium and magnesium to high-normal values and assess the corrected QT interval. Quetiapine has been used in critical care settings for the control of agitation in states of hyperactive delirium and may have benefit in the agitated burn patient. Doses may be started at 25–100 mg to a maximum 800 mg total daily dose—this maximum dose should not be continued for more than 72 hours, due to risk of anticholinergic excess, particularly in dopamine antagonist-naïve patients. Olanzapine and its oral disintegrating formulation (olanzapine—Zydis) may also be considered, although it has limited utility in the severely agitated patient who may require large doses of medication for control of agitation. Doses may be started ranging from 2.5–10 mg, with a maximum of 30 mg in a 24-hour period, due to its potential to create anticholinergic excess.

Management of Alcohol Withdrawal

The diagnosis of alcohol withdrawal is clinical and characterized by the presence of hyperarousal, confusion, hallucinations, hypertension, tachycardia, fever, diaphoresis, and agitated behavior in the setting of acute reduction of or abstinence from alcohol. Once comorbid illnesses have been excluded or adequately addressed or treated, the management of alcohol withdrawal is directed at alleviating symptoms and identifying and correcting metabolic derangements. Supportive care, including administration of intravenous fluids; nutritional supplementation; correction of deficiencies of potassium, magnesium, phosphate, and glucose; along with administration of intravenous thiamine to prevent or treat Wernicke's encephalopathy, should be initiated. Benzodiazepines are generally considered first-line treatment for AWS, and for the prevention of alcohol withdrawal seizures. There is no consensus as to the best benzodiazepine to use; however, longer acting benzodiazepines with active metabolites, such as diazepam, may allow a smoother course of withdrawal, lower the chance of recurrent seizure, and have greater efficacy in the prevention of delirium (Ntais, Pakos, Kyzas, & Ioannidis, 2005). Benzodiazepines with an intermediate half-life, such as lorazepam, may have a safer profile in patients with comorbid hepatic dysfunction. While symptom triggered therapy utilizing the Clinical Institute Withdrawal Assessment for Alcohol Scale (CIWA-Ar) has been shown

Box 75.2 RISK FACTORS FOR ALCOHOL WITHDRAWAL DELIRIUM (DELIRIUM TREMENS)

History of past alcohol withdrawal seizure(s) or delirium tremens
Seizure in the field or in emergency department prior to admission
Acute concurrent medical illness
More days since last drink (two or more days)
Elevated blood alcohol upon admission
Heavier and longer drinking history
Age >40
Race and genetic predisposition
Burn-related injuries
Falls, particularly with long-bone fractures
In one study—motor vehicle accidents had negative predictive value
Elevated MCV, aspartate aminotransferase

to be effective in treating patients in alcohol withdrawal, its applicability in patients with comorbid medical and surgical illness has not (Hecksel, Bostwick, Jaeger, & Cha, 2008). In addition, it relies heavily on the patients' ability to logically respond to questions about their subjective experiences with AWS in seven of its ten items, which is often not possible in patients with AWD or delirious with other comorbid medical and surgical conditions.

Pain

Burn-related injuries are among the most painful types of trauma sustained. The ability to adequately assess and treat the burn patient's pain is aided by the understanding of the types of pain that these patients experience. In the acute phase of injury, there are three types of pain that the clinician should assess and treat accordingly. These include:

1. Continuous background pain from damaged tissue and nerve injury.
2. Acute pain caused by mechanical and chemical irritation of damaged tissue.
3. Procedural pain caused by dressing changes, or increased physical exertion when the patient is being treated by physical and occupational therapists.

If pain symptoms are not adequately controlled, particularly with procedures, the patient may begin to anticipate that pain will be associated with each subsequent intervention, commonly referred to as an *anticipatory pain response*. While many clinicians initially describe this as a form of "anxiety," it is far from it, and more accurately described as a "fear" response, particularly in the immediate period following burn injury. This distinction is more than a matter of nomenclature, as it has direct effects on treatment. Fear is amygdalar in origin and treated with dopamine antagonists, while symptoms of anxiety are treated with use of benzodiazepines. It should be noted that even when pain treatment is optimized, the process of seeing their affected body parts once bandages are removed can be overwhelming and frightening. Co-administration of low-dose IV haloperidol with IV opioids 15 minutes prior to dressing changes can reduce the anticipatory fear response.

Figure 75.1 Relationship between physiological and psychological pain.

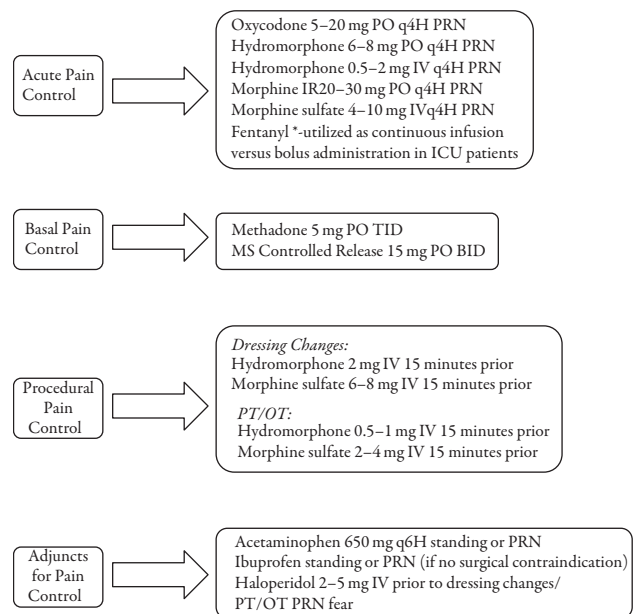

Figure 75.2 Commonly utilized strategies for acute nociceptive pain.

Patients can experience various painful emotions—anger, frustration, depression, anxiety, fear of death, etc.—at any time during their clinical course. These symptoms and their physiological accompaniments will make somatic pain and discomfort more severe and less bearable (see Figure 75.1).

Various pain scales are available to assist in grading pain symptoms in a more objective manner. The 0 to 10 visual analogue scale is often utilized in quantifying the patient's level of perceived pain, and using this scale, the patient is asked to quantify his or her pain when at rest, and before and after dressing changes, debridements, and physical and occupational therapy.

Once a method is in place for tracking the patient's pain, a pharmacological regimen is then designed to meet the patient's needs. In the intubated patient, or the patient with large-scale burns that necessitate frequent trips to the operating theater for excision and grafting (E & G), IV fentanyl is often utilized for basal control of pain, with bolus administration for intermittent pain symptoms. For smaller scale burns or later in the course of a larger scale burn patient, long-acting opiate analgesics such as methadone may be employed for basal pain control, with the short-acting narcotics such as hydromorphone or morphine used for intermittent pain and for procedural pain control (see Figure 75.2).

Pain control in the opioid-dependent patient with burn injury should be mentioned: Generally, patients with active or recent chronic opioid use, whether illicit or iatrogenic, will exhibit physiological tolerance to opioid medications, necessitating increased dosages or frequency of administration. These patients will often respond better to use of a patient-controlled analgesia (PCA) pump for the first 24 to 36 hours, and achieve improved pain control versus nurse- or clinician-administered PRN approaches. Their previous 24 hours short-acting narcotic requirement can then be converted to a long-acting analgesic (e.g., methadone) with the goal of decreasing the amount of short-acting narcotic required by the time of discharge.

PSYCHOLOGICAL ADAPTATIONS AND REACTIONS IN THE ACUTE PHASE

As patients who have experienced severer burns are surviving, there is a greater emphasis on psychological adjustment and the potential impact on the person's long-term functional outcome. PTSD affects a significant population of burn survivors and has been linked to significant morbidity.

In the acute setting, psychiatric consultants can promote psychological adaptation, collaborate with the team to assess and control pain, and diagnose and treat discrete psychiatric disorders (Watkins et al., 1988). The primary goal is to foster psychiatric stabilization so that the patient can engage with medical care and rehabilitation. It is also important to have an understanding of which symptoms are normative and not indicative of increased risk for the development of a psychiatric disorder. For example, the majority of burn survivors experience symptoms of acute stress, including disrupted sleep and re-experiencing of the trauma (Ehde, Patterson, Wiechman, & Wilson, 2000).

Stages of Adaptation—Acute Phase

Burn specialists have identified a series of key psychological stages in adaptation to recovery from severe burns and discussed interventions that teams can provide to support the patient's physical and psychological recovery. This approach provides a practical framework that can heighten understanding of the patient's perspective and promote the patient's engagement in care.

Survival Fear

Immediately following the experience of a severe burn, the patient is focused solely on survival. The patient is hypervigilant and tremulous, and directs his or her energy toward the demands of physical recovery. In this context, the patient is less able to process verbal content. Therefore, the patient will probably benefit from frequent reorientation and repetition of basic information, including a realistic appraisal of his chance of survival, the severity of his injury, the physical phenomena he is experiencing, and the most likely course of recovery (Watkins et al., 1988).

Search for Meaning

Additional psychological stages of adaptation to severe burns include a detailed recounting of the events of the burn and a related search for an explanation that makes sense and can be tolerated emotionally. Patients question why the burn happened and, in particular, why it happened to them. Subsequently, after engagement in rehabilitation, many patients confront feelings of helplessness and work to grieve and accept the losses of appearance and capability. Watkins and colleagues argue that failure to negotiate these stages successfully predisposes them to the development of specific psychiatric disorders, including PTSD and depression.

INTERMEDIATE PHASE

As the burn patients progress from the acute phase of injury to the intermediate phase, their survival is usually assured. Despite this, ongoing physiological stress with regard to

injury, inflammation, frequent dressing changes, repeated trips to the operating room, and active attempts at mobilization may affect adversely affect the individual's ability to cope with the psychological aspects of her injury. In addition, as the patient becomes fully grafted, there is a rapid reduction in altered mental status and delirium, and generally rapid improvement in cognitive function. It is usually during this phase that psychiatric consultation for depression, mood lability, anxiety, insomnia, nightmares, and concerns about acute stress reactions occur.

Acute Psychiatric Disorders After Burn Injury

An additional role of the psychiatrist during the acute phase of recovery is to identify burn patients who are at risk for poor adjustment. As previously described, psychiatric disorders, including substance dependence, mood disorders, and psychosis, are over-represented in the burns population, and pre-burn mental function is associated with post-burn adjustment (Klinge, Chamberlain, Redden, & King, 2009; Wisely, Wilson, Duncan, & Tarrier, 2010). Additional variables that have been postulated to be linked to the development of acute stress disorder and PTSD include exposure to high doses of benzodiazepines in the ICU, poor pain control, and peritraumatic tachycardia. Elevated heart rate in the ambulance following burn injury has been associated with higher rates of acute stress disorder and PTSD at six months (Dyster-Aas et al., 2008; Ehde et al., 2000; Esselman, Thombs, Magyar-Russell, & Fauerbach, 2006; Gould et al., 2011; McKibben, Bresnick, Wiechman, Askay, & Fauerbach, 2008).

Adjustment Disorders with Anxiety or Depressed Mood

Patients who have experienced burns are at increased risk for the development of adjustment disorders with anxiety and depressed mood. As described above, risk may be linked to premorbid psychopathology, coping style, and characteristics of the burn experienced. Symptoms occur within three months of the burn injury and cause clinically significant distress and disturbance in functioning. The recommended treatment of adjustment disorders includes targeting associated symptoms such as insomnia and anxiety, and the use of supportive psychotherapy with an understanding of the person's strengths and coping style.

Acute Stress Disorder

Experiencing some symptoms of acute stress following burn trauma is normal. To diagnose acute stress disorder, the patient must respond to the burn with fear, helplessness, or horror. Additionally, the patient needs to experience symptoms in the same clusters as PTSD, including: three symptoms of dissociation in addition to re-experiencing, avoidance, and hyperarousal, that last for at least two days and occur within four weeks of the traumatic event.

Acute stress disorder (ASD) is not uncommon in burn survivors, occurring in 11–32% of patients (McKibben et al., 2008). Importantly, the diagnosis of ASD is a strong and

stable predictor of PTSD over time, from one month to two years following the burn. This association remains after controlling for the factor of acute psychological distress.

Both pharmacological and psychological interventions have been assessed in the treatment of ASD. Evidence of the effectiveness of particular medications such as beta blockers in ASD is mixed. In the past, some have also suggested having only a single debriefing session after a traumatic event. The evidence shows that debriefing of traumatic events can be linked to adverse outcomes, and is not recommended (Rose, Bisson, Churchill, & Wessely, 2002). In contrast, cognitive behavioral therapy has been shown to be effective in survivors of accidents with ASD, and is likely beneficial when extended to the burn population (Bryant, Sackville, Dang, Moulds, & Guthrie, 1999). Additional potentially modifiable factors include optimization of pain control and anxiety-management in the acute setting.

Stages of Adaptation—Intermediate Phase

Investing in Recovery

As the patient enters the intermediate phase of injury, her focus shifts to getting a better understanding of the details of her treatment, and to optimize her participation in the recovery and resumption of daily life skills (grooming, feeding, communicating, ambulating, etc.). In some instances, as the patient begins to attempt to perform basic autonomous functions, the patient will feel that her ability or progress is inadequate or a disappointment. Feelings of frustration or anger over perceptions of helplessness and dependency on others may be common, as are adjustment reactions with depressive symptoms. Watkins and colleagues describe four staff interventions that can aid the patients during their progression during this phase:

1. Educating the patient about the expected course of recovery specific for the type of injury he sustained.
2. Orienting the patient to the physical phenomena that he will experience during this phase of recuperation (e.g., itching, nociceptive and neuropathic pain, etc.).
3. Creating a program for self-care and activities. Initially, goals should be realistic about the degree of physical impairment sustained by the patient, with gradual progression of goals once the patient begins to derive a sense of pride in his accomplishments.
4. Focusing on returning abilities versus remaining disabilities by verbal acknowledgement and praise of any improvements in autonomous functioning, no matter how small.

Acceptance of Losses

As patients become more actively involved in their recovery and attempt to resume basic autonomous functioning, they begin to cognitively define and emotionally realize the long-term and often permanent losses that they have sustained from their burn injuries. While some losses may be

immediately obvious (e.g., loss of ambulation, function of limbs, loss of limbs, etc.), others may not be as apparent immediately. The loss of some ability to associate with friends and family, or the loss of the opportunity to live life in the manner they were accustomed to may be equally devastating. This initial realization is often expressed as “hurt,” and perceived as feelings of sadness or “depression,” and may be exhibited by social withdrawal, tearfulness, decreased appetite, impaired sleep initiation and/or maintenance, or decreased participation in physical therapy. The patients should be allowed the opportunity to talk about their perceptions regarding these issues and the emotional difficulties they are experiencing, in an effort to legitimize their situation and allow them to ventilate their perceptions and feelings regarding losses (Watkins et al., 1988).

REHABILITATIVE PHASE

In many respects, the rehabilitative phase is an extension of the intermediate phase of injury, with continued pursuit of reintegration, both psychologically and physically. Ongoing psychiatric evaluation, assessment, and treatment may be required during this phase, particularly as struggles with autonomous functioning continue.

Post-Traumatic Stress Disorder

Although estimates vary based on the assessment tool used, PTSD is estimated to occur in 12–42% of burn survivors, and the diagnosis appears relatively stable over the first two years after the burn. For example, PTSD at one month predicts PTSD at one year (Ehde et al., 2000; Fauerbach et al., 1997). PTSD has been reported to be associated with depression and higher utilization of health care, and is linked to longer term functional impairment, lower health-related quality of life, and decreased chances of returning to work (Davydow, Katon, & Zatzick, 2009).

The largest risk factor for the development of PTSD following traumatic injury seems to be a previous history of psychiatric illness. Additional risk factors for the development of PTSD following injury include acute pain symptoms, female gender, and personality characteristics such as externalization of blame, poor coping style, and high neuroticism (McGhee et al., 2011). Characteristics of the burn, including higher percent of the TBSA and location on the face, head, and neck, have also been linked to the development of PTSD (Ehde et al., 2000).

Interventions in the acute setting can focus on potential mediating factors and can foster improved long-term psychological adjustment. Initiation of quetiapine for states of hyperarousal may be helpful, in addition to assisting in treating difficulty with sleep initiation and sleep maintenance, particularly when associated with nightmares. If nightmares persist, a trial of prazosin can be started and titrated to assist in symptomatic control. Cognitive behavioral therapy (CBT) may also be helpful to challenge cognitive distortions or to treat underlying anxiety or depressive symptoms. A formal course of CBT to help patients get

back to work (e.g., exposure-type therapy) following an on-the-job injury may also be helpful in resumption of pre-morbid activities.

Depression

Lifetime mood disorders following burn injuries have been found to be as high as 31% (Fauerbach et al., 1997), with major depression being the most common mood disorder (27%). These figures are higher than in the general population and associated with worse functional status at discharge (Fauerbach et al., 1996), in addition to having an increased chance of developing PTSD (Dyster-Aas et al., 2008; Fauerbach et al., 1997) at one year post-injury.

If there is no surgical contraindication, initiation of a selective serotonin-reuptake inhibitor (SSRI) such as sertraline or citalopram may be initiated to treat underlying symptoms. Use of selective noradrenergic reuptake inhibitors (SNRIs), such as duloxetine, may also be employed, with the potential benefit of also helping to treat underlying neuropathic pain from burn-related injury. For patients with significant underlying apathy or abulia, initiation of a stimulant such as dextroamphetamine or methylphenidate may be indicated and useful.

Chronic Pain

Pain often does not end after the acute phase following burn injuries, with many patients continuing to have chronic pain, even after complete wound healing. Studies have found that about one-third of burn patients from one to nine years out from their initial injuries continue to experience significant and life-disrupting pain symptoms.

In certain patients, it may be sometimes necessary to utilize chronic opioids to maintain a reasonable level of comfort and to assist in optimizing functional abilities. In addition, it may be necessary to add adjuvant pain medicine for the specific treatment of neuropathic pain. Certain antidepressants, such as tricyclic antidepressants (TCAs) and SNRIs, along with anti-epileptic medications, have been used widely for the control of neuropathic pain; however, controlled studies on the effectiveness of these agents on burn pain are lacking. Pain management in patients after severe burns can require the full multidisciplinary, multimodality approach needed for other refractory chronic pain syndromes. Referral to a specialized pain clinic may be necessary.

END-OF-LIFE CARE

Although the mortality rate of severe burns has decreased over the years due to advances made in burn care, burn units still see a significant number of deaths. The major risk factors for mortality include older age (>60), percent-age TBSA (greater than 40%) and the presence of an inhalation injury (Blot & Brusselsaers, 2009; Ryan et al., 1998). Fratianne and Brandt developed a system for determination of futility by convening with the burn team to discuss

Do Not Resuscitate (DNR) orders if patients with age plus percent TBSA burn equal a score of 100 or greater at the time of admission, or later in the course of treatment when at least two major organs are failing (Fratianne & Brandt, 1997). The mortality rate on adult burn units is often higher than on pediatric burn units because of severe medical and psychiatric risk factors and an increased mortality risk associated with older age. The psychiatrist is often consulted to assist in the care of dying patients and their families to minimize pain and suffering and to assist in the process of decision-making at the end of life (Jellinek, Todres, Catlin, Cassem, & Salzman, 1993). It is important to explain to patients and their families that a DNR is not equivalent to a "Do Not Care (DNC) order." The Society of Critical Care Medicine states that for both children and adults, palliative care and intensive care are not mutually exclusive options, but rather should coexist (Truog et al., 2001). For both adults and children, the discussion about end-of-life decisions is often delayed because clinicians are used to preserving life whenever possible and moving forward with care. However, delaying this difficult discussion too long can result in missing the opportunity for good palliative care. When the shift has been made from curative therapy to palliative care, the goal should be the relief of suffering. The burn team, in addition to the psychiatrist, should focus on adequate symptom management, no inappropriate prolongation of dying, a sense of control for patient and family, and a focus on the relationship between patient and family. The concept of having a patient-centered conference including nurses, social workers, residents, and attending surgeons to decide when to forego life-sustaining measures has proved to have high acceptance by both patients and families. It can be very meaningful and reassuring to have the entire team present their recommendation to withdraw life-sustaining measures to the patient (when possible) and to their family (Fratianne, Brandt, Yurko, & Coffee, 1992). By obtaining team consensus, an atmosphere of mutual respect and trust between team members is created, which will result in better patient care and a better work environment.

In children, the shift to palliative care is often later than with adults, and the burn team will often wait until the last hours of the child's life to address limitation of life-sustaining measures such as inotropic agents, cardiopulmonary resuscitation (CPR), and ventilator support (O'Mara, Chapyak, Greenhalgh, & Palmieri, 2006). The decision to withdraw care for younger patients is more commonly based on burn size or severity (Ismail, Long, Moiemmen, & Wilson, 2011). Once pediatric patients are made DNR, the progression to death tends to be very rapid, with the time from a consensus on resuscitation status to death being on average 24 hours or less. O'Mara et al. found that in one pediatric burn unit, the writing of a DNR order occurred on average a few hours before the patient's death (median, 2.75 hours). The authors also found that if a DNR order was written, the family was present 75% of the time at the child's death. However, in only half of the cases in which the patient did not have a

DNR order was the family present at the time of death. This finding shows that either the family was not well prepared for the death of the child, or the death was too sudden to allow for adequate preparation. The psychiatrist can play a role in facilitating these difficult discussions of death earlier rather than later when possible, so as to adequately prepare families.

STAFF SUPPORT, STAFF STRESS, AND BURNOUT PREVENTION

Burn units are often regarded with fear and awe. The staff members in burn units are constantly exposed to traumatic images such as facial burns, massive injuries, and amputations. Functioning effectively in this environment may require unique coping mechanisms. Indeed, exposure to extreme injuries can cause “secondary traumatization” in hospital staff (Fullerton, Ursano, & Wang, 2004). Rapid turnover of staff may occur, especially on understaffed units, after admission of a series of unusually serious burns, and when support for staff is not adequate. Burnout is a syndrome of emotional exhaustion, depersonalization, and reduced personal accomplishment associated with chronic occupational stressors. Psychiatrists can help to prevent such outcomes by encouraging communication, validating attitudes and feelings, providing emotional support and specific psychological interventions, and by mobilizing organizational resources.

Some of the more difficult patients in burn unit are patients with active psychiatric disorders. For example, untreated psychopathology in adolescent self-immolators can induce intense staff hostility and conflict. Encouragement of staff to express their frustration and teaching them ways to avoid power struggles can help them avoid the kinds of interactions that evoke staff counter-transference. The best approach is for surgery and psychiatry to work together in developing a clear treatment plan and initiate long-term psychiatric treatment on the burn unit.

Patients with substance use disorders also evoke adverse reactions in caregivers and staff. Often, staff members are concerned about giving benzodiazepines and opiates to patients with substance use disorders. The psychiatrist can play a role in educating staff about substance use disorders, and stressing that, while patients may become physically dependent on these medications, addiction is almost never *caused* by use of these agents in the context of burns (Stoddard & Fricchione, 2004). In fact, these patients may initially require higher doses of narcotics and benzodiazepines to effectively treat symptoms than do others without similar histories. However, it is important to taper off these medications once it is determined they are no longer required.

Agitated and aggressive delirious patients can be particularly difficult for staff to manage on a burn unit. Behaviors such as aggressiveness towards staff, attempting to leave, pulling out lines, and disrupting the milieu are not uncommon in such patients. The psychiatrist should assess for need for

restraints and medications, as well as help provide increased support to staff. Overall the psychiatrist can serve as an integral part of the burn team and can provide education and reassurance for the staff about the dynamics of a particular case. The psychiatrist can also foster open discussion with the staff about staff members’ feelings, needs, and expectations, thereby reducing feelings of helplessness and the risk of burnout.

CLINICAL PEARLS

- Burn centers now average 200 admissions apiece per year, and their average survival rate exceeds 94%.
- Premorbid psychiatric diagnoses and substance use—alcohol, narcotics, cocaine—are common among those with burn injuries.
- Burns associated with methamphetamine use are a relatively new problem; not only does methamphetamine intoxication predispose to burn injury, but its production involves highly volatile chemical compounds that can cause both thermal and chemical injuries.
- Risk factors associated with self-immolation in developing countries include younger age, female gender, low socioeconomic status, decreased literacy, limited access to mental health services, marital and familial conflict (Ahmadi et al., 2009; Ahmadi & Ytterstad, 2007).
- Because of nerve damage, third-degree burns may be less painful than second-degree burns.
- Symptoms associated with SIRS include tachycardia, tachypnea, fever, leukocytosis, refractory hypotension, and, in its severest form, multiple organ-system dysfunction. In thermally injured patients, the most common cause of SIRS is the burn itself.
- One prospective study of burn ICU patients demonstrated delirium in 77% of ventilated burn patients. The majority of patients were identified to have hypoactive delirium (Agarwal et al., 2010).
- The hypermetabolic state may persist for months after the burn wound has healed.
- Mental status should be assessed even in the intubated patient.
- In the acute phase, pain comes in three types: continuous background pain from damaged tissue and nerve injury; acute pain caused by mechanical and chemical irritation of damaged tissue; procedural pain caused by dressing changes or increased physical exertion when the patient is being treated by physical and occupational therapists.
- Patients who have experienced burns related to charcoal, gas stoves, or inhalation injuries may also have been exposed to carbon monoxide. In the acute setting, carbon monoxide exposure causes non-specific symptoms, especially headache,

disturbance of consciousness, nausea and vomiting, dizziness, confusion, fatigue, chest pain, and dyspnea.

- There is mixed evidence that treatment with hyperbaric oxygen decreases the risk of developing delayed neurological sequelae (Buckley, 2011); however, hyperbaric oxygen should at least be considered in all cases of serious acute CO poisoning. The goal of hyperbaric oxygen treatment would be to prevent later neurological sequelae.

UROLOGY AND ANDROLOGY

Andrew J. Roth, Suzanne R. Karl, and Christian J. Nelson

INTRODUCTION

Benign prostatic hyperplasia (BPH), kidney stones, interstitial cystitis, testosterone deficiency, and urinary incontinence (UI) are non-malignant conditions that can cause significant emotional distress. Urological disorders are common and translate into billions of dollars in healthcare expenditures each year. Incontinence and sexual dysfunction are frustrating problems with emotional consequences. Psychological sequelae range in severity from mild to devastating and may affect the patient's relationships, work, social life, and general morale. Patients may not readily admit to uncomfortable symptoms that they view as private or the distress that comes with them, and in that context, referral to a psychiatrist or psychologist has particular value.

Urological cancers can cause similar symptoms. Though great advances in cancer treatment have been made in recent years, patients still associate a diagnosis of cancer with negative outcomes, and struggle with less-than-optimal quality of life (QOL). This chapter will provide a basic understanding of non-malignant urological disorders and urological cancers and their management, including coping with issues of distress, sexual dysfunction, and relationships that may accompany urological disorder.

PSYCHIATRIC ISSUES IN NON-MALIGNANT CONDITIONS

BENIGN PROSTATIC HYPERPLASIA

According to the National Institutes of Health (NIH), 6.5 million Caucasian men ages 50 to 79 in the United States were going to discuss treatment options for BPH with their physicians, and about \$1.1 billion are spent annually in direct expenditures for this illness. The exact etiology of BPH is unknown, but it is hypothesized that imbalances of estrogen, testosterone, and dihydrotestosterone later in life are contributory (Carson & Rittmaster, 2003). BPH is a natural enlargement of the prostate that happens with age. Men experience two periods of prostate growth in their lives: one at puberty, during which time it doubles in size, and another period of slow growth starting at around age 25. This second stage of growth usually does not cause problems until later in life. The prostate surrounds the urethra; as it enlarges, there is a

clamping effect. Urine flow may decrease, the patient may feel like he cannot entirely empty his bladder, and over time the walls of the bladder thicken and become irritated. This causes more frequent urination because the bladder contracts with even small amounts of urine present. Untreated BPH may progress to urinary tract infections, bladder or kidney damage, bladder stones, and incontinence (Presti, 2008).

Treatment of BPH may not be necessary in the early, mild stages. Some men have improvement or even resolution of symptoms without treatment (Webber, 2005; Presti, 2008). If treatment is indicated, there are pharmacological, minimally invasive, and surgical options available.

The Food and Drug Administration (FDA) has currently approved six medications to treat BPH. Finasteride (Proscar) and dutasteride (Avodart) inhibit production of the hormone dihydrotestosterone, which is involved with prostate enlargement. The use of either of these drugs can either prevent progression of growth of the prostate or actually shrink the prostate in some men. Studies suggest that both these drugs may (rarely) cause depression or sexual dysfunction (Römer & Gass, 2010; Traish et al., 2011).

The medications terazosin (Hytrin), doxazosin (Cardura), tamsulosin (Flomax), and alfuzosin (Uroxatral) are also available for the treatment of BPH. These are alpha blockers, which improve urine flow and reduce bladder outlet obstruction by relaxing the smooth muscle of the prostate and bladder neck. Terazosin and doxazosin were first developed to treat high blood pressure. Tamsulosin and alfuzosin were developed specifically to treat BPH. Finasteride and doxazosin in combination have been shown to be more effective than using either drug alone to relieve symptoms and prevent BPH progression (McConnell et al., 2003), but combination therapy may also lead to greater chance of sexual side effects (Hellstrom, Giuliano, & Rosen, 2009).

Research strongly suggests that patients treated with a surgical procedure transurethral resection of the prostate (TURP) show better outcomes in terms of QOL and urinary symptoms when compared with pharmacological treatment. However, the less invasive nature of medications makes them an attractive option for many men, and in recent years there has been a marked shift from surgical to pharmacological management of BPH. Consequently, BPH is now viewed more as a chronic condition. Many men ultimately need surgery anyway, so there is a debate over how best to handle BPH in its earlier stages (Wei, Calhoun, & Jacobsen, 2005).

Minimally invasive procedures are used when medication proves inadequate but as an alternative to TURP. Minimally invasive procedures include laser ablation, transurethral needle ablation (TUNA), transurethral microwave therapy (TUMT), high-energy focused ultrasound, and hot water thermotherapy (Wei, Calhoun, & Jacobsen, 2005).

The sequelae of BPH and its treatment can have profound effects on the patient's lifestyle. These include problems urinating, bleeding, incontinence, or sexual dysfunction. In these cases, the patient may benefit from psychiatric or psychological consultation to assess for the presence and extent of significant depressive and anxiety symptoms.

Patients may be reluctant to talk about these problems, which they may feel are stigmatizing and isolating. Supportive or cognitive behaviorally oriented therapy may be appreciated by the patient if he is undergoing surgery or dealing with potentially embarrassing side effects.

Psychopharmacologically, it is useful to avoid medications that may exacerbate urinary symptoms or sexual dysfunction that may already be a problem due to the BPH or its treatment. Antidepressants like the tricyclic antidepressants (TCAs) have anticholinergic effects that may slow down the urinary system. However, the TCAs are used much less frequently than other antidepressants today because of their sedative, cardiac, and autonomic side effects. Serotonin specific reuptake inhibitors (SSRIs) and serotonin and norepinephrine reuptake inhibitors (SNRIs) have sexual side effects, but do not impact the urinary system. The heterocyclic antidepressant, trazodone, can (rarely) cause priapism, and this should be discussed with the patient prior to administration of the drug. Bupropion is less likely to have sexual side effects than other antidepressants, but it can cause anxiety and insomnia. It is important to be aware that lower-potency antipsychotics, including chlorpromazine, mesoridazine, thioridazine, and clozapine, have significant alpha1-adrenergic effects just like some of the drugs used to treat BPH. The compounded alpha1-adrenergic effects can lead to orthostatic hypotension and syncope associated with vasodilation (Alpert, Fava, & Rosenbaum, 2004).

Urinary Incontinence

According to the National Association for Continence, one-third of men and women ages 30–70 have experienced loss of bladder control at some point in their adult lives (Muller, 2005). An estimated \$463 million is spent annually for treatment. UI can be caused by pregnancy, childbirth, menopause, neurological injury, birth defects, stroke, multiple sclerosis, and physical problems associated with aging (Brubaker, Meikle, & Steers, 2010). Apart from pregnancy and childbirth, menopause and the makeup of the female urinary tract account for women being affected by UI more often than men. However, women and men alike experience the psychological sequelae of incontinence, which at its best is bothersome and at its worst, embarrassing and isolating.

Treatment for incontinence includes behavioral therapy and medication, primarily antimuscarinics. Behavioral techniques have been shown to be more effective than medication and should be used as a first-line treatment for UI (Burgio

et al., 1998). There are several ways to employ behavioral techniques. Bladder training involves voiding the bladder at timed intervals throughout the day. Over time, the patient extends the amount of time between voids. Pelvic muscle reeducation is a technique used in women. It refers to exercises the patient performs to strengthen her pelvic floor muscles. These exercises are sometimes referred to as “Kegels” (Bo, 2004).

Antimuscarinics have reasonably good success, but side effects are common and can be uncomfortable. Studies have shown varying rates of success using duloxetine (Cymbalta) in the treatment of post-prostatectomy incontinence and stress UI in women (Cornu et al., 2011). This treatment, used in Europe, has yet to be approved to treat incontinence in the United States (Smith et al., 2010). Should behavioral therapy and medications fail to help, artificial urinary sphincter implantation appears to be a durable treatment if needed after prostatectomy or radiation therapy (Lai et al., 2007).

Studies have shown that UI can cause social avoidance, relationship stress, and loss of independence in activities of daily living (Sims et al., 2011; Easton, 2010). Men and women with overactive bladders report higher levels of depression and anxiety, as well as lower levels of health-related QOL and work productivity (Coyne et al., 2011). Men with UI report higher rates of erectile dysfunction and lower frequency and enjoyment of sex (Irwin et al., 2008). These men often worry about, and are embarrassed by, loss of urine during sexual intercourse. A study specific to African-Americans showed a strong positive correlation between UI and symptoms of depression (Malmstrom et al., 2010). Beyond the incontinence itself, patients report stress and anxiety related to frequency and urgency (Elstad et al., 2010).

Although the evidence for drugs specifically causing incontinence is limited, the drug classes proposed to induce stress incontinence include alpha 1 adrenergic receptor antagonists, and antipsychotics like thioridazine, clozapine, risperidone, and olanzapine. (Tsakiris, Oelke, & Michel, 2008). Should the patient require an antidepressant, the best medication will be one that does not exacerbate existing symptoms. Duloxetine has been shown to improve stress incontinence, and a higher rate of UI has been noted with sertraline than with other SSRIs (Movig et al., 2002; Tsakiris, Oelke, & Michel, 2008).

Interstitial Cystitis: Bladder Pain Syndrome

What had been called interstitial cystitis is now thought of as a syndrome of chronic bladder pain. It is presumed to be a heterogeneous, chronic, visceral pain syndrome, characterized by pain with filling and relief by voiding, associated with central sensitization. Males or females with pain, pressure, or discomfort that they perceive to be related to the bladder with at least one urinary symptom, such as frequency not obviously related to high fluid intake, or a persistent urge to void, should be evaluated for possible bladder pain syndrome (Hanno et al., 2010). The disorder may not involve the bladder interstitium, as some patients lack bladder inflammation. Prevalence is much more common in women than men. Symptoms wax and wane with flares. In a population-based sample (Watkins,

2011), one-third had a diagnosis of depression, and 52% reported recent panic attacks. History of sexual abuse is a risk factor (Mayson & Tecihman, 2009). There is an overlap with non-bladder pain syndromes such as fibromyalgia, chronic fatigue syndrome, irritable bowel syndrome, vulvodynia, and voiding dysfunction (Clemens et al., 2008; Warren, van de Merwe, & Nickel, 2011).

Diagnosis is based on history, examination, frequency-volume chart, urinalysis and culture, and if deemed appropriate by the clinician, cystoscopy or urodynamics. Pain sources outside the bladder may become clear from the evaluation. Guidelines emphasize education, diet, stress management, and reevaluation of treatment approaches at regular intervals. Hunner lesions are a specific condition treated with fulguration or steroid injection (Quillin & Erickson, 2012). Treatment is individualized and includes behavioral, physical therapy for the pelvic floor, and medication.

History of previous infection, pelvic operations, pelvic radiation treatment, and autoimmune diseases is relevant. In men, rectal examination and mapping of pain in the scrotal anal region and palpation of the tenderness of bladder, prostate, and levator and adductor muscles of the pelvic floor and scrotal contents are appropriate. In women, physical examination includes vaginal exam with pain mapping of the vulvar region, and palpation for tenderness of the bladder, urethra, levator and adductor muscles of the pelvic floor. Range of motion of hips, kyphosis, scars, and hernias are noted.

TESTOSTERONE DEFICIENCY

Disturbance of normal testosterone levels has been shown to negatively affect QOL, morbidity, and psychological states in men. One way to appreciate the effects of testosterone is to look at men who have testosterone deficiency from various etiologies, including natural aging, congenital causes such as hypogonadism, idiopathic causes, obesity, diabetes, infectious causes such as HIV/AIDS, malignancies, androgen ablation therapy for prostate cancer, hypertension, and medication used for medical comorbidities (Traish et al., 2011; Nelson, Roth, & Mulhall, 2007; Morgentaler, 2011; Raynor et al., 2011). These patients experience a spectrum of disheartening effects, including but not limited to: fatigue and decreased vitality, weight gain, erectile dysfunction, muscle loss, glucose intolerance, osteoporosis, depression and anxiety, memory loss, muscle wasting, loss of libido, and difficulty concentrating (Allan & McLachlan, 2006). Such symptoms put stress on careers, relationships, and other activities of daily living. Patients receiving testosterone replacement therapy experience relief from symptoms, including depression (Traish et al., 2011; Khara et al., 2012); however, this treatment should only occur after a comprehensive discussion between physician and patient about potential consequences. If necessary and appropriate, testosterone replacement may be used indefinitely.

Androgen ablation therapy has long been a mainstay of treatment for men with prostate cancer. Androgen exposure increases the growth rate of malignant prostate cancer cells. Conversely, prostatic atrophy occurs with testosterone

deficiency (Nelson et al., 2007). Up to 50% of patients with prostate cancer are treated using androgen deprivation therapy (ADT), many for up to several years (Timilshina, Breunis, & Alibhai, 2012). Common side effects include those listed above.

Recent research regarding ADT has challenged the idea that normal or high levels of testosterone are detrimental to men with prostate cancer. The studies postulate that low levels of testosterone may stimulate the growth of prostate cancer, but beyond those low levels, saturation occurs and no more stimulation of growth takes place with additional testosterone (Morgentaler, 2011). Such research suggests that administering testosterone to men with prostate cancer may be acceptable; however, since these ideas have only been tested recently, more research is necessary to prove that testosterone is safe for prostate cancer patients (Morris et al., 2009; Rathkopf et al., 2008). Low testosterone is generally associated with depression. There is some literature that refutes evidence of a correlation between low testosterone and depression (Amiaz & Seidman, 2008), but there is also much investigation to back up a relationship between the two. One study showed that testosterone replacement helped alleviate refractory depressive symptoms in older men with low androgen levels who had not responded to SSRIs (Pope et al., 2003). Another concluded that testosterone might have an antidepressant effect on depressed patients, especially those with HIV/AIDS, and elderly subpopulations (Zarrouf et al., 2009).

The HIV/AIDS population may especially benefit from treatment with testosterone. Hypogonadism occurs in about 30% of men in this population, and androgen therapy is used widely to alleviate symptoms. Muscle wasting and body composition are especially important considerations in the HIV/AIDS patient, and anabolic steroids such as oxandrolone are useful to increase both (Catlin, 2006). Studies have also shown an improvement in depressive symptoms in AIDS patients who were prescribed testosterone (Hengge, 2003).

Guidelines for treatment of androgen deficiency syndromes recommend measuring morning total testosterone as the initial diagnostic test and repeating it with a reliable assay. In some patients, a free or bioavailable testosterone level is warranted. Testosterone therapy is recommended for symptomatic men with unequivocally low serum testosterone levels in order to improve sexual function, sense of well-being, muscle mass and strength, and bone mineral density. Urological evaluation would be warranted if there are questions of prostate cancer. Hyperviscosity, untreated obstructive sleep apnea, severe lower urinary tract symptoms, or heart failure are other contraindications. The guidelines recommend not testing for testosterone deficiency in the general population, but to limit testing to those men with disorders that predispose to low testosterone: men with a sellar mass and history of radiation to the sellar region; those chronically treated with glucocorticoids, ketoconazole, or opioids; HIV-associated weight loss; end-stage renal disease; chronic obstructive lung disease; infertility; osteoporosis; or type 2 diabetes mellitus. If treatment is instituted, they recommend aiming for a mid-normal range level of testosterone and monitoring by a standard protocol over time. They warn against a general clinical policy of

offering testosterone therapy to all older men with low testosterone levels because of the uncertainty of adverse side effects (Bhasin et al., 2006). A recent randomized, double-blind, parallel placebo-controlled trial of the effect of testosterone replacement on the response to sildenafil citrate in men with erectile dysfunction did not show that sildenafil plus testosterone was superior to sildenafil with placebo in men with erectile dysfunction and low testosterone levels (Spitzer et al., 2012).

KIDNEY STONES

Kidney stones have been described as causing the worst pain people can experience. Kidney stones occur in 5.2% of adults, occasionally requiring a hospital admission, and cost \$2.07 billion in 2000 for evaluation and treatment.

Studying the psychological effects of kidney stones (also called nephrolithiasis) is somewhat different than studying those of UI and BPH. Kidney stones have rapid onset, relatively fast resolution, and high pain levels, whereas incontinence and BPH are more long-term problems with a tendency to produce less pain and more embarrassment. While the correlation between repeated episodes of pain and psychological distress has been documented, there is less literature on psychological distress due to pain from kidney stones in particular.

Kidney stones have been correlated with depression and anxiety (Diniz, Blay, & Schor, 2007). A case report noted post-traumatic stress disorder (PTSD) as a result of nephrolithiasis (Bilić, & Marcinko, 2010); however, there have been no other published corroborating reports of PTSD from kidney stones.

Hyperparathyroidism has long been linked to both kidney stones and psychological disorders, including depression, anxiety, obsessive-compulsive disorder, and paranoia (McAllion, 1989; Chiba et al., 2007; Wilhelm, Lee, & Prinz, 2004). Regardless of its cause, hyperparathyroidism can lead to cognitive and psychiatric disorders that negatively influence estimates of QOL (Coker, 2005). Concurrent with cognitive disorders, excess calcium can contribute to kidney stones, which compound negative effects on QOL and contribute to psychological distress.

When kidney stones and psychological distress are the result of benign hyperparathyroidism, parathyroidectomy reduces symptoms of major depression, improves the QOL, and can eliminate or reduce the need for antidepressant medication in up to 54% of patients (Wilhelm et al., 2004). Parathyroidectomy decreases the risk of kidney stones in vulnerable patients for about ten years, but after that the risk goes back to baseline (Parmar, 2004).

Some patients experience idiopathic kidney stones; they do not show evidence of hormone imbalance. In patients who are beyond the stage of preventative treatment and are already passing the stones, the goal of the physician is to ease renal colic. Prostaglandin-induced kidney stone pain has been described by patients as severe and unrelenting, and understandably induces significant anxiety. Often, narcotics are used to dampen the pain. However, a double-blind study

in 66 patients with acute renal colic showed that intramuscular injection of a potent prostaglandin-synthetase inhibitor (diclofenac sodium) is more effective and has fewer side effects than a narcotic drug commonly used to treat ureteric colic (Lundstam et al., 1982). Alternatively, one study showed the efficacy of acupuncture in easing renal colic (Lee et al., 1992). Another study found that local active warming of the abdomen and lower back significantly reduced pain and anxiety in kidney stone patients (Kober et al., 2003). Other types of kidney stones (e.g., oxalate) may be nutritionally induced. Recommendation for a nutrition consultation may be helpful for patients with recurrent stones.

As with the other non-malignant urological disorders, psychiatric treatment of distress due to kidney stones may be brief and supportive. This may be truer of patients with kidney stones than of those with UI or BPH, since there is a clear resolution of symptoms once the stone has passed. Some studies indicate that a significant proportion of patients with kidney stones will experience anxiety and depression, especially if they have recurrent stones (Diniz, Blay, & Schor, 2007).

INTERSTITIAL NEPHRITIS

Interstitial nephritis (IN) is an acute or chronic condition that affects the interstitial compartment of the kidney but spares the glomeruli. Acute IN is generally induced by infection or medications such as nonsteroidal anti-inflammatory drugs (NSAIDs)—acetaminophen, penicillin, ampicillin, methicillin, sulfonamide, furosemide, and thiazide diuretics—but it may also be idiopathic. It presents clinically as a sudden decrease in renal function. Signs may include skin rash, fever, and eosinophilia. Lumbar pain is a common symptom. Chronic IN has a variety of etiologies, including sarcoidosis, multiple myeloma, radiation treatments, medications, hypercalcemia, hypokalemia, lead or cadmium poisoning, and urinary tract obstruction. Even in chronic IN, glomeruli remain normal upon viewing with light microscopy, despite functional problems. Only as interstitial injury progresses to later stages might glomerular abnormalities become apparent on visualization (Kelly & Neilson, 2004). Chronic IN patients present due to symptoms of a primary disease or with nonspecific symptoms of renal failure, which include weakness, nocturia, nausea, and/or sleep disturbances (Kelly & Neilson, 2004; Eknayan, 2001).

Treatment of acute IN is removal of the offending irritant or treating the cause, which often resolves the disease. If this is not done in a reasonable time frame, steroids or chemotherapy may have a role in therapy. Similarly, there is no specific treatment indicated for chronic IN (Kelly & Neilson, 2004).

Some psychiatric drugs, such as clozapine and lithium, may in rare cases cause IN. Recommended precautions to identify acute IN before it can have an adverse effect include carefully screening the patient for fever, which may be an early manifestation of a hypersensitivity reaction; monitoring for a rise in eosinophil count; and looking for proteinuria and/or white blood cells in the urine (Kanofsky et al., 2011); as well as monitoring lithium levels, serum creatinine levels, and possibly dosing lithium once a day (Gitlin, 1999).

THE UROLOGICAL CANCERS

The genitourinary cancers are affecting a larger proportion of our population as detection methods are improving. Patients often must cope with changes in lifestyle, sexuality, bladder and bowel function, body image, relationships, fatigue, and pain in the later stages of disease. Discomfort and beliefs about stigma on the part of the patient, the family, and healthcare providers in discussing these issues provide formidable barriers to evaluation and resolution of distress. Although some clinicians fear that acknowledging and addressing psychological issues will open up a Pandora's box of troubles and somehow make the symptoms worse, psychological interventions provide avenues for decreased stress and improved QOL. Not addressing these issues often leads to increased suffering, major psychiatric disorders, despair, demoralization, isolation, hopelessness, and suicidal ideation.

Medical caregivers are encouraged to screen for distress in order to identify who might benefit from further psychiatric assessment. Psychiatrists can assist patients who have anxiety about treatment decisions, facing mortality, coping with complications, fear of recurrent disease, and coping with recurrence of disease. Once they are assessed, management and support (which may initially be provided by the oncology team) can include a spectrum of psychological and psychiatric interventions that includes education, individual and group psychotherapy, couples' therapy, and cognitive and behaviorally oriented interventions. (For a discussion about the prevalence and management of psychiatric disorders in the general cancer patient, see Chapter 57.)

PROSTATE CANCER

EPIDEMIOLOGY AND DIAGNOSIS

An estimated 240,890 new cases of prostate cancer occurred in 2011. Approximately 65% of these new cases occur in men over the age of 65. Death rates in African-Americans remain more than twice as high as those in whites. Over the past 25 years, the five-year relative survival rate for all stages combined has increased from 69% to 99.6%, and according to the most recent data, the 10-year survival is 95%, and 15-year survival is 82% (American Cancer Society, 2011).

This generally older population of men has particular needs influenced by their generational and developmental phase of life. Five to ten percent of all prostate cancers are believed to be of familial predisposition. Some nutritional factors, such as diets high in saturated fat, have been correlated with increased incidence of prostate cancer (Wang et al., 1995).

American Cancer Society guidelines recommend a yearly discussion between patients and physicians about digital rectal examination (DRE) for men 50 years of age and older, along with an annual prostate-specific antigen (PSA) test. Men who are at high risk, such as African-Americans or those with a strong family history of prostate cancer, are advised to begin PSA testing starting at age 45 (American Cancer Society, 2011). Other than

self-examination for testicular cancer, prostate cancer is the only genitourinary cancer that has a reliable tool for early detection.

It is controversial whether early detection by PSA testing and potential treatment of indolent forms of prostate cancer is beneficial when the distress and impairment of QOL from the primary treatments of surgery or radiotherapy are taken into account (Mokulis & Thompson, 1995). These uncertainties have implications for the psychological well-being of men and their families. However at this time, it is difficult to distinguish more lethal from more benign varieties of prostate cancer before men receive primary treatment. In the past, many men would die of another cause, never knowing they had prostate cancer, with detection only occurring at autopsy. Those who were diagnosed with the disease often presented with signs of metastatic disease, such as pain and urinary problems.

A PSA level can be normal even in the presence of cancer. It is also not cancer-specific. False positive results can be seen with prostatitis, benign prostatic hypertrophy, and after manipulation of the prostate, as with transrectal ultrasound and needle biopsies or DRE. Improvement in the specificity of this test has helped rule out many false positives. However, PSA levels may vary with the age of the patient as well as other medical factors.

One of the psychological distresses oncologists have noted in patients is the degree of anxiety surrounding each PSA test, and the anticipation before getting the results. This has been termed "PSA anxiety," "PSA-itis," and "PSA-dynia" (Roth et al., 2005; Lofters et al., 2002; Klotz, 1997). Some men give great significance and worry to each test and even about minuscule changes within the normal range, which they may view as a marker of life or death. Level of worry about a current result may be related to the trend of recent test results—in one study, men with stable PSA levels had less anxiety than those whose scores were either going up or going down (Roth et al., 2006). Men apparently are looking for good news only and "seeking peace of mind," and feel devastated and angry about unwanted or unexpected increases (Dale et al., 2005).

SURGICAL AND MEDICAL MANAGEMENT

As of this writing, there has not been a definitive comparative analysis of the major primary treatment options for prostate cancer. Thus there is still legitimate professional disagreement and controversy about the selection of primary treatments (Wilt et al., 2008). Though overall QOL may not be significantly different with the various primary treatment options, there may be compromises when considering specific treatment side effects and long-term complications (Eton & Lepore, 2002; Sanda et al., 2008). Primary treatment options vary from "watchful waiting," also described as "expectant monitoring," and "active surveillance" to surgery, radiation, and cryotherapy. Watchful waiting (deferred therapy) is often recommended for those with significant comorbid illness, low-grade indolent cancers, and less than ten years' life expectancy. Active surveillance is suggested for younger men with early-stage disease, who get more frequent follow-up and observation. Though active surveillance is promising to prevent unnecessary compromise to QOL

with treatment complications, further study is still needed to observe long-term medical and psychological benefits and complications (Klotz, 2008; Johansson et al., 2009).

The definitive treatment choice in the past was surgery, the open radical prostatectomy. Newer “nerve-sparing” procedures have decreased the rate of complications of impotence and UI somewhat. Many urologists are starting to do laparoscopic and robotic prostatectomies, which are alleged to cause less bleeding, less chance of infection, and less time in the hospital after the procedure (Hakimi, Feder, & Ghavamian, 2007).

Radiation therapy, either conventional intensity-modulated radiation therapy (IMRT) or seed implants, often in combination with external beam radiotherapy, may yield decreased, though delayed incidence of impotence compared to surgery; however, there are increased difficulties with bowel function. Post-radiation treatment PSA levels take a variable amount of time to reach a nadir of undetectable PSA that would indicate probable cure of the cancer; this can lead to prolonged anxiety. Radiation therapy may be given with adjuvant hormonal therapy, which can add to the side-effect burden for men.

For more advanced prostate cancer, hormonal manipulation is used to decrease the synthesis of testosterone or its action on prostate cancer cell growth. This can be done with luteinizing hormone-releasing hormone agonists such as leuprolide, goserelin, or buserelin, which prevent the testicles from producing testosterone; estrogenic substances such as diethylstilbestrol; peripheral anti-androgenic agents, such as flutamide, nilutamide, or bicalutamide; or drugs that prevent the adrenal glands from making androgens, such as ketoconazole and aminoglutethimide. Abiraterone and enzalutamide are new hormonal agents. Abiraterone inhibits Cyp 17 enzymes expressed in testis, adrenals, and prostate tumor tissue, decreasing circulating levels of testosterone. Enzalutamide is an androgen receptor inhibitor. Orchiectomy, or surgical castration, also reduces testosterone production.

Hormonal therapy at this stage of disease is not curative. Equally effective in slowing tumor growth with similar side-effect profiles, medical hormonal therapy may be preferred over orchiectomy by patients because it better preserves patient body image and therefore improved QOL; however, it is an expensive treatment. Side effects of androgen ablation may include erectile dysfunction (ED), loss of libido, hot flashes, gynecomastia, irritability, anxiety, and depression. Pirl and colleagues (2002) found that men most at risk for depression while on hormonal therapy were those who had histories significant for major depression. Standard of care is moving towards giving intermittent hormone therapy (with some time off in between treatment with hormones) since it lessens side effects, reduces health care costs, and has been shown to be as effective as continuous therapy (Organ et al., 2013; Klotz et al., 2011). Further studies are underway to corroborate this evidence. Chemotherapeutic agents are used for more advanced tumors—they, too, are not curative.

MANAGEMENT OF DISTRESS

Uncertainty about choice of treatment options and related outcomes such as potential sexual dysfunction, UI, weakness,

fatigue, pain, and other side effects of the disease or treatment can have profound effects on mood, irritability, and anxiety, especially for men who are used to feeling a strong sense of control over their futures. Many men entertain multiple second opinions regarding their primary therapy. Some spend hours on the Internet and in libraries trying to gather enough information to find the perfect treatment for them. This often leads to anxiety and frustration. Treatment choices and decisions may vary based on the extent of disease, age of the patient, life expectancy, specialty bias of physician, side-effect risk profile acceptable to a patient, expense, and geography (Harlan et al., 1995). Personality factors and coping strategies may influence a man's satisfaction with his treatment (Blank & Bellizzi, 2006). An example of a helpful “take control” attitude that may help improve outcome and tolerance of prostate cancer treatment and overall health is the man who changes his diet to what is thought of as a prostate-friendly diet with low fat, high soy, fish oil, selenium and other nutrients, and begins or continues a regular exercise program, stops smoking tobacco, and limits his alcohol intake. Hormonal therapies can be particularly distressing because of sexual, energy, or concentration side effects.

In general, men with prostate cancer respond to useful information and various types of brief psychotherapy, including supportive, cognitive-behaviorally oriented, and insight-oriented therapies. However, some men are reluctant to participate in therapy, particularly older men who have never done so previously. Allowing a man to enter therapy with his spouse or partner present has facilitated many getting treatment for psychological distress who would not otherwise receive assistance. Support groups are available specifically for men with prostate cancer. Two of the national support groups available to men are “Us Too” and “Man to Man.”

Loss of urinary continence occurs as a complication of surgery and radiation and leads men to shun social engagements. Radical prostatectomy (RP) is the most common cause of stress UI in men. Stress UI rates after RP range from 5–48%. Seventy-seven percent of men will suffer from overactive bladder following RP (Bauer et al., 2011). This UI after surgery has been associated with depression, anger, and a reduced sense of well-being in men after RP (Klotz, 1997). Interestingly, the UI does not have to be severe for men to report significant distress (Roth et al., 2006). Also important to note is that from 20% to 25% of men with UI report some restriction of their everyday activity as a result of this incontinence, which has a significant impact on their general QOL (Roth et al., 2006; Dale et al., 2005). The fear of urine leaking, of smelling of urine, and of having to use diapers feels regressive and humiliating. Urologists and their staffs can work with patients to identify etiologies of incontinence, to educate patients and families about the incontinence, and to offer suggestions to alleviate or reduce symptoms. Psychiatrists and psychologists can help with support-, cognitive-, and behaviorally oriented strategies to cope with incontinence and sometimes with antidepressants or anxiolytics to lower barriers to better coping.

Pain syndromes result from local expansion and inflammation of the prostate gland, from local tumor growth, and from distant long bone, vertebral, and skull metastases. Pain

related to metastatic bone disease can impair mobility and accompany neurological impairments such as cranial nerve deficits, paralysis, incontinence of bowel and bladder, and impotence (Payne, 1993). Patients with pain are significantly more depressed or anxious than patients without pain; these mood changes may not be related to the extent of disease (Heim & Oei, 1993; Kornblith et al., 1994). However, older men are often reluctant to take pain medications or dosages adequate to truly help.

Fatigue and weakness can be caused by the illness, hormonal or radiation therapy, pain medication, steroids, and other factors. These symptoms are particularly upsetting to men who have led active and independent lives and who are now more dependent on family or friends. Helping the patient reorganize his schedule and set realistic goals may result in less distress. A psychostimulant, such as modafinil or methylphenidate, may counter the sedating effects of opioids, increase motivation, enhance appetite, and elevate a patient's mood. Though stimulants can be an effective treatment for fatigue even in older men with prostate cancer, patients should be monitored by their physicians for possible tachycardia and increases in blood pressure (Roth et al., 2010). An activating antidepressant such as bupropion, which will not compromise sexual functioning, or another antidepressant like fluoxetine can be used to increase energy.

Hot flashes in men with prostate cancer are caused by medical and surgical androgen ablation. They are the result of increased vasomotor activity, possibly related to increased noradrenergic activity and decreased serotonergic activity, which leads to diaphoresis, feelings of intense heat and chills, similar to symptoms that women have during menopause. At times, hormonal therapy must be stopped because of drenching sweats and discomfort. Antidepressants like the SSRIs, such as sertraline and paroxetine; SNRIs, such as venlafaxine; and anti-epileptic medications, such as gabapentin, have been reported to reduce the frequency and intensity of hot flashes (Roth et al., 1998; Loprinzi, 2004; Adelson, Loprinzi, & Hershman, 2005). Teaching men to change habits such as decreasing caffeine, alcohol, and hot fluid intake, and even carrying portable fans in warmer weather, may be useful to prevent or decrease the frequency and extent of discomfort from the hot flashes.

SEXUAL DYSFUNCTION

Prostate cancer symptoms run the gamut of possible sexual side effects that could occur in any urological cancer. Each of the urological cancers poses unique challenges to healthy sexual functioning, but an understanding of sexual dysfunction management in prostate cancer provides a strong foundation from which to manage dysfunction in others. (For this reason, a discussion of sexual dysfunction in men will appear here and should be referred to for each of the urological cancers. For a discussion of sexual dysfunction in women, please see Part IV: Women's Health).

Aging, the cancer itself, surgery, radiation, and hormonal therapy can cause difficulties with sexual functioning (Ofman, 1994; Steginga et al., 2000). Hormonal therapy, in particular, eliminates libido, which may decrease distress about ED;

however, decreased desire for any physical intimacy can also be harmful to a relationship. Feelings of being emasculated occur. An honest or realistic assessment of sexual functioning before primary treatment may assist a man in choosing a more acceptable treatment option, regardless of outcome. Therapies to improve ED include phosphodiesterase-5 (PDE-5) inhibitors such as sildenafil, tadalafil, and vardenafil; penile injections; vacuum erection devices; and penile prostheses. However, most men are not initially comfortable with non-pill forms of treatment. Sex therapy with a trained therapist familiar with cancer issues can help men with sexual dysfunction express the feelings engendered by this problem, and also help a couple learn alternative ways of sharing sexual intimacy (McCarthy & Bodnar, 2005).

ED is a significant problem encountered by men with urological cancers and with BPH. Rates of ED after prostate cancer surgery vary; however, most agree that a vast majority of men will have to cope with ED to some degree. In a study of over 1,200 men four years post-treatment, 85% of them reported that ED was a problem (Schover et al., 2002). It is also clear that patients who experience ED after RP report significant distress and bother associated with their ED. Although this bother may be mitigated to some extent as patients focus more on the life-saving nature of treatment (Penson et al., 2003), data suggest that a significant number of men still report being bothered or upset by its impact on erections. Data from 231 men following either surgery or radiation for prostate cancer showed that ED bother significantly increased at three months post-treatment and remained at consistently high levels throughout the follow-up period (i.e., every 3 months, up to 24 months post-treatment) (Nelson et al., 2007). Significant in these data is that even men who returned to "normal" erectile functioning (IIEF-ED domain score >24) reported greater ED bother post-treatment compared to pre-treatment. These data support the clinical observation that even if men's erections return after treatment, the quality of these erections may still be inferior to that of pre-treatment erections, potentially causing significant distress. It is also well established that ED and male sexual dysfunction are associated with higher depressive symptoms (Nelson et al., 2007; Shabsigh et al., 1998; Araujo et al., 1998; Shiri et al., 2007).

Oftentimes it is assumed that as men grow older they will be less concerned with sexual functioning; however, these studies have been conducted in men ranging in age from 40 to 70 years (similar to the age range of men with prostate cancer), and many of these studies controlled for age in their analyses. The bother and distress associated with ED often leads to a loss of intimacy in men's relationships and can potentially lead to significant relationship conflict (Bokhour et al., 2001; Moore et al., 2003).

In addition to the myriad of physiological changes that can disrupt sexual function after cancer diagnosis, it is important to acknowledge the significant interpersonal shifts that may take place and affect their sexuality. For instance, although changes in body image are readily acknowledged and often anticipated when we think about the effects of breast cancer, it is critical to understand that body image does not occur in isolation and that it is an experience that is contextually and

relationally based. Women are sensitive to their partner's perception of their new appearance, and male patients tend to avoid conversations with their wives about their sexual challenges that result from cancer treatment (Boehmer & Clark, 2001) and speculate how their wives feel about their sexual functioning (Rivers et al., 2011). In some situations, patients may feel uncomfortable discussing this aspect of their cancer experience with their partners, out of a fear of rejection. Partners are often afraid to broach the subject, out of fear of causing distress. This interpersonal silence can quickly become the "elephant in the room," and over time, disruptions in intimate functioning can become more difficult to address, with either one or both partners misperceiving each other's feelings and intentions.

Healthcare providers are particularly well positioned to assist couples in communicating more openly about their fears and to answer questions regarding sexual dysfunction, by providing them with available resources on social support and information on cancer treatments that affect sexuality (Couper et al., 2006). Manne and Badr (2008) have proposed an integrative theoretical framework to understanding and addressing the challenges that couples face during and after cancer. By focusing on relationship processes that contribute to intimacy, this framework can help providers facilitate a discussion of the illness as something that happens to the *relationship*, rather than to individual partners. Based on this approach, couples should be encouraged to perform "relationship-enhancing" behaviors such as reciprocal self-disclosure of fears and concerns, partner responsiveness, and relationship engagement, while discouraging "relationship-compromising" behaviors such as avoidance and criticism (Manne & Badr, 2008).

COMMUNICATION ABOUT SEXUAL PROBLEMS

Although the optimal time to initiate discussion about sexual concerns may vary, it is essential that clinicians prepare patients for potential changes that may be encountered and let them know that discussion about sexual health concerns is welcome. It is notable that patients will rarely initiate conversation on this topic for fear of embarrassing their doctor and also out of concern that their symptoms are not treatable. For a majority of men, it is invaluable to receive a brief yet clear message that serves to normalize their symptoms and reassures them that they are not alone and that resources are available. Many patients report that much of their distress often starts with the observation that they were not prepared for changes in sexual function. In the same way that clinicians view a wide range of potential side effects from any course of cancer treatment, knowledge about potential cancer-related sexual side effects needs to be acknowledged. This allows patients to prepare for managing side effects and potentially may help them make better informed decisions about treatment options. It is our belief that clinicians should learn to address this topic as they would any other topic. Practical information should be provided at multiple time points across the continuum of cancer care.

For some patients, it may be valuable and/or necessary to make a referral for more directed sexual therapy. Additional intervention may include counseling with a licensed therapist who specializes in sex therapy and/or couples counseling. Often it can be useful within an oncology practice to identify one clinician—a physician, nurse, social worker, or psychologist—who can serve as the primary resource person for sexual health. Several professional organizations such as the American Psychosocial Oncology Society (APOS), the Society for Sex Therapy and Research (SSTAR), and the American Association of Sexual Educators, Counselors and Therapists (AASECT) all have directories and resources for locating professionals who specialize in working with sexual dysfunction.

TESTICULAR CANCER

EPIDEMIOLOGY AND DIAGNOSIS

Testicular cancer is the most common cancer in American men between the ages of 20 and 40, accounting for 46% of all cancers in this age range, though it accounts for only about 1% of all male cancers. It is considerably more common in Caucasian than African-American men, with intermediate rates for Hispanics, Native Americans, and Asians. Distinct geographical and racial variations suggest both genetic and environmental factors promoting the development of testicular cancer (Dearnaley, Huddart, & Horwich, 2001). One major risk factor is cryptorchidism, the congenital failure of one or both testes to descend into the scrotal sac (Bosl et al., 2008). There is evidence of increased risk in men infected with human immunodeficiency virus/acquired immunodeficiency syndrome (HIV/AIDS) and in those having a prior testicular cancer. At diagnosis, testicular cancer may be localized or spread to regional lymph nodes or metastasized to distant body sites.

Testicular self-examination is the most common form of detection of this cancer, usually with the presence of a small, hard lump in either testicle, an enlarged testicle, a collection of fluid, or unusual pain. However, most patients will first seek medical attention because of development of a painless, swollen testis. In approximately 25% of patients, the first symptoms will be related to metastatic disease, back pain being the most common, from tumor in the retroperitoneum. Pulmonary symptoms such as shortness of breath, chest pain, or hemoptysis occur due to advanced lung metastases (Nichols et al., 2000).

Biopsy is not possible in this disease because the cancer cells may spread during the procedure. Orchiectomy is the standard diagnostic procedure, which prevents further growth of the primary tumor. Ninety percent of testicular cancers are germ cell tumors (GCT), which are subdivided into seminomas and non-seminomas. Lymphoma is the second most common tumor of the testis and should be suspected in men over age 50. The tumor markers α -fetoprotein (AFP), β -human chorionic gonadotropin (β -HCG), and lactate dehydrogenase (LDH) are used for the detection

of small tumors and for comparison over time to evaluate response to treatment. Retroperitoneal lymph node dissection (RPLND) is critical to stage non-seminomatous GCT and must always be performed with curative intent. This procedure is often associated with ejaculatory dysfunction (retrograde ejaculation) and secondary infertility, though newer nerve-sparing procedures may preserve normal ejaculation.

SURGICAL AND MEDICAL MANAGEMENT

Survival in this population has significantly improved owing to improved diagnostic and treatment techniques, with over 95% of patients expected to be cured. Cure rates depend on the stage of disease, approaching 100% for early-stage seminomas and nearly 100% overall survival for stage I non-seminomatous GCT. Approximately 85% of men with advanced testicular cancer will be cured with a combination of chemotherapy and surgery.

The effects on fertility and the possibility of storing sperm should be discussed with all patients undergoing chemotherapy or radiotherapy (Dearnaley et al., 2001). Treatment differs for seminomatous and non-seminomatous tumors, as well as the stage of disease. More advanced disease is treated with orchiectomy and multidrug chemotherapy.

Non-seminomas have often metastasized by the time of clinical presentation. Early and moderate-stage disease can be treated with orchiectomy alone, or followed by either RPLND, observation with frequent follow-ups, or chemotherapy. High-dose chemotherapy with peripheral blood stem-cell transplantation is used for metastatic refractory germ cell cancer and has been found to improve survival for some patients (Kollmannsberger et al., 1999).

MANAGEMENT OF DISTRESS

Testicular and GCTs often occur in young men, when sexuality, fertility, and intimacy are critically important. Although unilateral orchiectomy does not lead to infertility or sexual dysfunction, men are often concerned about their appearance. Artificial testicular implants have been successful in helping men cope with this issue. RPLND can lead to infertility by causing retrograde ejaculation, though sexual desire and the ability to have erections and orgasms are not affected. A pattern of sexual avoidance and decreased sexual interest can develop related to the distress of the cancer treatment in general. Although there is substantial recovery of sexual functioning after treatment (Ozen et al., 1998), a significant number of men will have long-term sexual dysfunction (Heidenreich & Hofmann, 1999). For men with partners or spouses, couples' therapy can address these issues and help the couple gain some perspective on how their relationship has been changed by cancer. Apart from infertility, fears about the effects on sexual functioning need to be addressed, especially before a young man has been involved in a long-term sexual relationship. Thorough sexual histories should include questions about frequency and intensity of sexual activity, including masturbation, desire, erection, orgasm, and satisfaction.

Infertility can be related to surgery, with RPLND posing the greatest threat by interfering with ejaculation. Infertility can also be due to radiotherapy or chemotherapy. Sperm production can be affected by radiation therapy, and infertility from this degree of radiation is temporary in most patients. Many men with testicular cancer have been found to have low sperm counts even before diagnosis, perhaps due to an autoimmune process that is probably confined to the few months before diagnosis. Unfortunately, this can limit the usefulness of sperm-banking at the time of diagnosis. Antegrade ejaculation may return spontaneously over the months or years following surgery, and the administration of sympathomimetic drugs can convert retrograde to antegrade ejaculation. Whether due to acquired infertility or because of decreased desire of having children, paternity rates are 15–30% lower than in the general population (Bertetto et al., 2001).

Chemotherapeutic agents such as cyclophosphamide can also cause infertility, though this may last for a transient period of two to three years after completing chemotherapy. Trask and colleagues (2003) found no significant difference among 16 study subjects in distress and QOL measured before, during, and after chemotherapy. The most disruptive symptoms noted were fatigue and changes in sleep, mood, and appetite.

Approximately 10% of patients will have long-term psychological problems (Heidenreich & Hofmann, 1999). A large study in a Norwegian population reported a greater prevalence of anxiety disorders in long-term testicular cancer survivors when compared to a matched healthy population, with no differences observed in depression measures (Dahl et al., 2005). Surviving patients are concerned with late complications of curative therapy, as is seen in other malignancies, as well as fears of recurrence. For these reasons, it is thought that supportive and educational counseling should be offered before and after cancer treatment. (For a more comprehensive discussion of sexual dysfunction in urological cancer, please see the section on prostate cancer.)

Awareness of potential long-term effects from chemotherapy and other QOL problems can inform a therapist about how to help a young patient cope better with the frustration of side effects: for instance, compromised renal function from cisplatin, Raynaud's phenomenon following combinations of vinblastine and bleomycin, pulmonary toxicity with bleomycin, and neuropathy and ototoxicity attributable to cisplatin and vinblastine leave patients with secondary deficits that challenge their daily living. Short- and long-term consequences for QOL are also seen with the use of radiotherapy, in the form of erectile and ejaculation disorders and radiation-induced tumors (Kollmannsberger et al., 1999).

BLADDER CANCER

EPIDEMIOLOGY AND DIAGNOSIS

There will be an estimated 74,690 new cases of bladder cancer diagnosed in 2014 in the United States (about 56,390 in men and 18,300 in women) (ACS, 2014). The incidence is

greater in whites, who are almost twice as likely to be diagnosed as black men, followed by Hispanics and Asians, who have the lowest incidence. Mortality rates have been stable in men and are decreasing slowly in women (ACS, 2014). The largest known risk factor is tobacco smoking, leading to twice the number of cases relative to those who do not smoke. Risk increases with age, as 70% of cases are diagnosed after age 65. Certain cancer treatments, such as high-dose cyclophosphamide or ifosfamide and radiation treatment to the pelvis, may increase the risk of developing bladder cancer. People at high risk due to exposure or selected bladder birth defects may benefit from screening with urine cytology and cystoscopy. Currently, there are no good tests for early detection and widespread screening of bladder cancer. Most are detected because they cause grossly visible or microscopic hematuria. Over 90% of bladder cancers are transitional cell carcinomas (TCC). Disease stage has been shown to be the single best predictor of outcome for TCC of the bladder (McDougal et al., 2008).

SURGICAL AND MEDICAL MANAGEMENT

If bladder cancer is detected at an early stage (0–I), the five-year survival rate is 85–95%. For more advanced disease (stages II–IV), the survival rates are between 16% and 55%, depending on extent of disease (ACS, 2014). Categorizing cases into *superficial* bladder cancer or *muscle-invasive* bladder cancer is a useful way to describe treatment and the multiple effects on QOL.

Cystoscopy and transurethral resection of the bladder (TURB) are the primary modes for diagnosis of superficial bladder cancer tumors. TURB is also the definitive treatment for low-grade and superficial tumors, with perioperative bladder instillation of chemotherapy recommended for most patients (Barocas & Clark, 2008; Clarke, 2007). Agents for this local treatment are the immune modulator Bacillus Calmette-Guerin (BCG) and chemotherapeutic agents, such as mitomycin and thiotepa, usually given by the intravesical route. Cystitis is often an uncomfortable side effect of these treatments; cutaneous complications from intravesical instillations may be quite severe (Kureshi et al., 2006). Attempts to avoid or postpone cystectomy for localized, superficial bladder cancers may require long-term follow-up with repeated cystoscopies, which can have negative psychological effects. However, for high-risk noninvasive bladder cancers or those not responding to bladder instillation, a cystectomy is recommended by many specialists (Oosterlinck, Witjes, & Sylvester, 2008; Skinner, 2007). It remains to be seen what effect the presence of genetic markers such as the *p53* gene or mutations of the fibroblast growth factor receptor 3 (*FGFR*) will have on treatment options. It is important for medical psychiatrists and psychologists to understand that, despite patients being informed of the good prognosis of their illness, there is a strong negative psychological impact, with most feeling that their lives would be negatively disrupted (Bohle et al., 1996).

Men receiving treatment for early-stage bladder cancer generally do not have sexual dysfunction. However, there have been reports of men developing penile curvature, or Peyronie's disease, after frequent cystoscopy. The overall

impact on sexual activity is independent of age and gender (Mack & Frick, 1996). Complaints of decreased sexual desire, feelings of contamination by the cancer, painful intercourse, and other urethral symptoms are reported.

Radical cystectomy (bladder removal) is the standard procedure for muscle-invasive bladder carcinoma. Surgery, alone or in combination with other treatments, is used in over 90% of cases. Chemotherapy, alone or with radiation before cystectomy, has improved some treatment results for more advanced tumors. Studies suggest a window of opportunity of less than 12 weeks from diagnosis of invasive disease to radical cystectomy to improve prognosis (Fahmy, Mahmud, & Aprikian, 2006).

Compared with cystectomy, radiation treatment provides better short-term QOL in the physical, psychological, and sexual domains, although one study found no difference in the QOL between both treatments after 18 months (Lynch et al., 1992). Frequent symptoms affecting QOL post-radiotherapy include urinary frequency, urgency, nocturia, and reduced bladder capacity. Surrounding organs are frequently affected, and the dose and volume of radiation are correlated with the more unpleasant symptoms of fecal leakage and urgency, and diarrhea with blood and mucus (Henningssohn, 2006). Significant gastrointestinal symptoms may persist two to three years after pelvic radiotherapy, including the development of proctitis (Andreyev et al., 2005). Modern radiation therapy techniques offer the potential to improve cure rates and reduce adverse effects (Milosevic et al., 2007). Radical cystectomy impacts sexual and urinary functioning in men in a fashion similar to RP, as the prostate is often removed with the bladder. A large proportion of men suffer ED, though the incidence is decreasing with nerve-sparing and seminal vesicle-sparing techniques. Testosterone secretion is unimpaired, so sexual desire remains unchanged in the long term. Prostate-sparing cystectomy has yet to show oncological efficacy, despite its functional advantages (Kefer et al., 2007).

With cystectomy, many patients have been helped by the development of internal urinary reservoirs constructed from the bowel (Parekh & Donat, 2007). These can be anastomosed to either the skin or urethra. When attached to the urethra, continence can be maintained. This has permitted the creation of the neobladder, with which almost all patients achieve daytime urinary continence (McDougal et al., 2008). Although complications are higher than with the conduit, these procedures obviate the need for an appliance, and are welcomed psychologically.

MANAGEMENT OF DISTRESS

Urinary tract reconstruction procedures affect overall QOL, mostly in the sexual and urinary spheres. Symptoms vary with the type of reconstruction. Patients with ileal conduits report impaired body image, increased self-consciousness, and decreases in travel and activity level, probably related to urinary leakage, odor, and skin irritation at the stoma site. Those with continent diversion report symptoms related to having to use a catheter, while neobladder patients report nighttime leakage. Almost all populations, regardless of

reconstruction technique, have sexual dysfunction related to negative physical or psychological effects of the procedure (Botteman et al., 2003). A sound strategy to achieve greater QOL after radical cystectomy is thorough and active counseling on the various reconstructive alternatives before the surgery that allows patients a choice of the type of urinary diversion on the basis of patient preference, anatomy, and tumor status, as well as counseling and support post-operatively (Wright & Porter, 2007; Davidsson et al., 2007). Advanced-disease TCC is usually treated with systemic chemotherapy.

Women make a better adjustment to the presence of a urinary diversion than men do; this is perhaps related to their being more independent in their stoma care than men. Radical cystectomy in women also includes hysterectomy and oophorectomy and resection of the anterior wall of the vagina. The major sexual side effect for women is genital pain, particularly during intercourse. Decreased sexual arousal, desire, and loss of sexual attractiveness are frequently reported. Surgical modifications to preserve internal genitalia have been suggested as long as cancer control is not compromised (Miranda-Sousa, 2006). Use of vaginal dilators, lubricants, and estrogen creams can help women become more comfortable during sexual activity by overcoming the consequences of scarring and premature menopause (Ofman, Kingsberg, & Nelson, 2008).

KIDNEY CANCER

EPIDEMIOLOGY AND DIAGNOSIS

Approximately 60,920 patients were diagnosed with kidney cancer in 2011, and more than 13,000 were projected to die of the disease (ACS, 2011). Kidney cancer includes renal cell carcinoma (92%), renal pelvis carcinoma (7%), and Wilms tumor (1%), a childhood cancer. Death rates have been slowly decreasing in women. The one-year survival rate for cancer of the kidney and renal pelvis is 83%, and the five-year survival rate is 69%. The incidence rises with age, as with TCC of the bladder and prostate cancer. Renal cell carcinoma is almost twice as common in men as in women. Often the diagnosis is made incidentally at the time of radiographic procedures such as ultrasonography or a computed tomography (CT) scan for non-urolological problems. There has been some association with cigarette smoking, obesity, and exposure to lead phosphate, dimethyl nitrosamine, and aflatoxins. In addition, exposure to asbestos, cadmium, and trichloroethylene have been implicated in the development of some kidney cancers (Linehan & Schmidt, 2008). A large percentage of these cancers may remain undiagnosed during life, like prostate cancer; however, with renal cancers a significant proportion of those found incidentally at autopsy actually caused death (ACS, 2011). A significant number of new cases have overt metastatic disease at the time of diagnosis. The prognosis for these patients is bleak, with a median survival of less than one year. The increased use of ultrasound has resulted in a higher detection rate of lower stage tumors.

SURGICAL AND MEDICAL MANAGEMENT

Patients' presentations may range from the triad of hematuria, pain, and palpable renal mass, to more obscure paraneoplastic syndromes, fever, anemia, or polycythemia. Diagnosis is made by intravenous pyelography (IVP), ultrasound, renal arteriography, CT scans, and magnetic resonance imaging (MRI). Pathological staging is the most important determinant of prognosis.

The treatment of choice for localized disease is surgical removal of the affected kidney, with regional lymphadenectomy. Five-year survival for stage I disease ranges from 60–75%, and from 40–65% in those with stage II disease. Renal preservation with only partial excision of renal tissue by open surgical or laparoscopic procedures has become more widely accepted, though there is still uncertainty about long-term prognosis. Treatment can provide challenges because of compromised renal function. Most survivors of localized kidney cancer have normal physical and mental health regardless of the type of nephrectomy performed, though QOL is better for patients with more renal parenchyma remaining after surgery (Clarke et al., 2001).

To date, chemotherapeutic agents have not demonstrated sufficient antitumor activity to prolong the survival of patients with metastatic disease. Sorafenib, Sutininib, and Pazopanib are new targeted chemotherapeutic agents that have shown promise in older as well as younger patients (Eisen et al., 2008).

Immunotherapy, autolymphocyte therapy, vaccines, and nonspecific immunomodulators may prolong survival for patients with metastatic renal disease. Interferon and high-dose interleukin-2, used with some success in treating advanced renal cancer, can cause depression and anxiety, which may be mediated through cytokines with physical or somatic side effects such as fatigue and fever. It is possible that patients most at risk of developing significant depression on these drugs are those who have higher baseline depressive symptom scores (Capuron et al., 2004). An important study found that the patients who were to get treated with high-dose interferon alpha and who received prophylactic treatment of an SSRI antidepressant had less depression than those who did not get the antidepressant; and for many, major depression onset was delayed (Musselman et al., 2001). Delirium and cognitive deficits may also be seen as independent effects of interferon and interleukin on the central nervous system.

MANAGEMENT OF DISTRESS

The poor prognosis for this illness is the cause of much psychological distress experienced by many patients and their families after diagnosis and treatment. Later stages of disease are highlighted by metastases to bone, lungs, and brain, and necessitate coping with pain, shortness of breath, concentration deficits, and other cognitive difficulties. Distress is caused by periods when the person is free of disease after surgery but knows that recurrence is likely. The conflict of maintaining hope for successful treatment, in the context of discouraging odds, can be burdensome and can lead to various degrees

of anxiety and depression. As with other GU cancers, many patients with renal cancer report worse sexual functioning than in comparable chronically ill populations (Anastasiadis et al., 2003).

CLINICAL PEARLS

- Lower-potency antipsychotics, including chlorpromazine, mesoridazine, thioridazine, and clozapine, have significant α_1 -adrenergic effects, just like some of the drugs used to treat BPH. The compounded α_1 -adrenergic effects can lead to orthostatic hypotension and syncope associated with vasodilation (Alpert et al., 2004).
- For UI, behavioral techniques have been shown to be more effective than medication and should be used as a first-line treatment (Burgio et al., 1998).
- Studies have shown varying rates of success using duloxetine in the treatment of post-prostatectomy incontinence and stress UI in women (Cornu et al., 2011).
- Side effects of androgen ablation may include ED, loss of libido, hot flashes, gynecomastia, irritability, anxiety, and depression. Men most at risk for depression while on hormonal therapy were those who had histories significant for major depression (Pirl, Siegel, & Good, 2002).
- Guidelines recommend detection of cases of testosterone deficiency not in the general population but in those with certain clinical disorders that predispose them to low testosterone: men with a sellar mass, history of radiation to the sellar region; those chronically treated with glucocorticoids, ketoconazole, or opioids; HIV-associated weight loss; end-stage renal disease; chronic obstructive lung disease; infertility; osteoporosis; or type 2 diabetes mellitus.
- Antidepressants like the SSRIs such as sertraline and paroxetine; SNRIs such as venlafaxine; and anti-epileptic medications such as gabapentin, have been reported to reduce the frequency and intensity of hot flashes in men (Roth et al., 1998; Loprinzi, 2004; Adelson et al., 2005).
- Manne and Badr (2008) have proposed an integrative theoretical framework to understand the challenges that couples face during and after cancer. By focusing on relationship processes that contribute to intimacy, this framework can help providers facilitate a discussion of the illness as something that happens to the relationship rather than to individual partners. Based on this approach, couples should be encouraged to perform “relationship-enhancing” behaviors such as reciprocal self-disclosure of fears and concerns, partner responsiveness, and relationship engagement, while discouraging “relationship-compromising” behaviors such as avoidance and criticism (Manne & Badr, 2008).
- Many patients report feeling distress that they were not prepared for changes in sexual functioning. In the same

way that clinicians present a wide range of potential side effects from any course of cancer treatment, potential cancer-related sexual side effects need to be acknowledged in advance. This allows patients to prepare to manage side effects and may help them make better informed decisions about treatment options. Practical information should be provided at multiple time points across the continuum of cancer care.

- Antegrade ejaculation may return spontaneously over the months or years following surgery, and the administration of sympathomimetic drugs can convert retrograde to antegrade ejaculation.
- Significant gastrointestinal symptoms may persist two to three years after pelvic radiotherapy, including the development of proctitis (Andreyev et al., 2005).
- With cystectomy, many patients have been helped by the development of internal urinary reservoirs constructed from the bowel (Parekh & Donat, 2007). These can be anastomosed to either the skin or urethra. When attached to the urethra, continence can be maintained. This has permitted the creation of the neobladder, with which almost all patients achieve daytime urinary continence (McDougal et al., 2008). Although complications are higher than with the conduit, these procedures obviate the need for an appliance, and are welcomed psychologically.
- Women make a better adjustment to the presence of a urinary diversion than men do; this is perhaps related to their being more independent in their stoma care than men. Radical cystectomy in women also includes hysterectomy and oophorectomy and resection of the anterior wall of the vagina. The major sexual side effect for women is genital pain, particularly during intercourse.

PSYCHOSOCIAL ASPECTS OF UPPER EXTREMITY ILLNESS AND OTHER ORTHOPEDIC PROBLEMS

Ana-Maria Vranceanu, David Ring, and Donna B. Greenberg

INTRODUCTION

This chapter discusses the psychological, sociological and behavioral aspects of orthopedic problems, with particular emphasis on hand and arm illness in orthopedic surgical practices. This chapter emphasizes a biopsychosocial rather than biomedical approach to how pain is conceptualized, assessed, and treated. The biopsychosocial approach specifies the relationship between physical and psychosocial factors in the etiology and maintenance of pain conditions, with an understanding that the relative importance of these factors varies across time and individuals.

The psychosocial aspects of illness usually manifest in the difference between disease, nociception, and impairment on one hand, and illness, pain, and disability on the other hand. Before proceeding, it is important to clarify how we are using several terms: *disease* versus *illness*, *nociception* versus *pain*, and *impairment* versus *disability*.

Disease is defined as an “objective biological event” that involves disruption of specific body structures or organ systems caused by pathological, anatomical, or physiological changes (Mechanic, 1986). Impairment is an “objective loss of function” positively correlated with the magnitude of the biological event. Nociception entails stimulation of nerves that convey information about tissue damage to the brain.

In contrast, illness is defined as a “subjective experience or self-attribution” that a disease is present (Turk, 1999); this leads to physical discomfort, emotional distress, behavioral limitations, and psychosocial disruption. Illness is thus how the sick person as well as the social network and perhaps the society perceive, live with, and respond to physical symptoms. Disability is the effect of this subjective experience. Pain is the subjective perception that results from the modulation of the sensory input filtered through a person’s genetic makeup, prior learning history, and current physiological status, appraisals, expectations, mood and sociocultural factors.

The psychosocial aspects of illness are often considered “all or none” (dichotomous); for instance, a patient might say, “You think it’s all in my head.” The fact is that illness, pain, and disability are not dichotomous, and neither are the psychosocial and behavioral aspects of illness. They occur on a continuum between adaptation, resiliency, and maintained function in spite of substantial impairment on one hand, and

disproportionate complaints and disability with little or no objective impairment on the other. Beyond the underlying pathophysiology or disease, the illness encompasses the complex human reaction to injury and illness. Illness, disability, and pain are always interactive, mind/body events.

DEPRESSION, PAIN CATASTROPHIZING, AND HEALTH ANXIETY

Consistent with findings in patients with chronic pain throughout the body, the most common psychosocial factors that influence reported pain intensity and disability are depression, pain catastrophizing, negative pain thoughts, and heightened illness concerns (Pincus et al., 2002). Previously well-compensated psychosocial factors may become problematic when one is confronted with pain. For instance, a person who tends to worry about minor matters may develop *pain catastrophizing* (a tendency to magnify the pain experience, to feel helpless when thinking about pain, and to ruminate on the pain experience). Someone who has a tendency to worry about his health may start viewing a benign pain condition as a sign of serious pathology, and may have a difficult time internalizing reassurances that his condition is benign (*heightened illness-concern*, *health anxiety*, or *hypochondriasis*). A depressed patient may make internal (“It’s my fault”), global (“Everything is going wrong”), and stable (“I will never get over this”) attributions about the pain conditions. Pain may exacerbate a predisposition toward *depression*, may intensify an already existent depression, or may become a somatic focus for depressive symptoms (Dersch et al., 2007). A tendency toward negative thinking and appraisal of life situations may translate into a similar appraisal of the pain condition. All of this may convert into reports of increased pain and disability.

Several measures have been developed for assessing these aspects of illness, and some are specific for pain. These are Likert-type scales, asking specific questions about the construct assessed. Depression is most often assessed with the Center for the Epidemiologic Study of Depression scale (CESD; Radloff, 1977), the Beck Depression Inventory (BDI; Beck et al., 1961), or the Depression Subscale of the Patient Health Questionnaire (PHQ; Spitzer et al., 1999). These measures inquire about typical symptoms of depression, and

they vary in terms of the relative emphasis on the somatic or cognitive components of depression. While major depression is a discrete, all-or-none diagnosis, these scales measure depressive traits or symptoms along the continuous spectrum on which they actually occur and affect illness behavior.

Pain catastrophizing is assessed with the Pain Catastrophizing Scale (PCS; Sullivan et al., 1985), a 13-item measure with three subscales: magnification (e.g., "I become afraid that pain may get worse"), helplessness (e.g., "It is awful and I feel that it overwhelms me"), and rumination (e.g., "I can't seem to keep it out of my mind"). Pain catastrophizing is one of the strongest predictors of pain intensity and disability across a variety of pain conditions.

Health anxiety can be assessed with the Health Anxiety Inventory (Salkovskis et al., 2002), the Whitley Index (Pilovsky, 1967), and the Somatic Symptoms Inventory (SSI; Barsky et al., 1992). The SSI inquires about the extent to which patients experience certain bodily functions (e.g., nausea and vomiting, hot or cold spells, heart pounding, heavy arms). The Health Anxiety Inventory and Whitley Index comprise questions assessing the extent to which patients endorse cognitive aspects of health anxiety (e.g., "Do you worry about your health?" "Do you often worry about the possibility that you have a serious illness?"). Health anxiety and hypochondriasis are increasingly recognized correlates of pain intensity and disability in chronic pain conditions.

The use of these validated measures may facilitate addressing these sensitive topics. According to the model developed in other fields, these issues may be best addressed within multidisciplinary teams, where the various health providers (surgeons, non-operative providers such as physiatrists, certified hand therapists, and behavioral medicine specialists/psychologists) work as a team with unified treatment goals. Such multidisciplinary treatment teams have been successful in the treatment of several pain conditions (Jensen, 1994). When such teams are not available, it is important to pursue communication among members of patients' care team as means of improving overall care and decreasing confusion.

SECONDARY-GAIN ISSUES

Secondary gain describes external psychological motivating factors for the initiation or perpetuation of painful symptoms. The patient may or may not be consciously aware of these psycho-emotional motivating factors.

Early psychodynamic theories described secondary gain as responsible for the repression of emotional issues and development of psychosomatic pain. More current theories follow a cognitive-behavioral approach and emphasize secondary gain as a social-learning model where environmental external factors are reinforcing chronicity. For example, a doting spouse, escape from a stressful job, or sympathy from family and friends may all reinforce chronicity. Within this new framework, the term "unconscious" means unawareness or a lack of a conscious plan for the gain. The term "unconscious" thus means the patient is unaware that the loss of holding onto the condition is often far greater than the perceived gain.

The patients may or may not realize the benefits of secondary gain, but they do not consciously cause it to be. This is not the same phenomenon as a patient who pretends to be sick or exaggerates a condition on purpose, in order to gain a particular objective (e.g., malingering), though conscious malingering and unconsciously seeking the benefits of illness represent extremes of the continuum of secondary gain.

Fordyce (1976), the founder of the social-learning theory model of pain, believed that pain is behavior designed to protect oneself or solicit aid; as the pain increases, this behavior is strengthened when it is followed by desirable consequences. Fordyce argued that if pain persisted beyond the normal healing time in an environment with secondary gains, the pain would become chronic. He gave as examples of secondary gains, or "desirable consequences" of pain, the following factors: attention and sympathy from family, friends, and physicians; release from task responsibilities at home and at work; narcotic medications; and monetary compensation. Unfortunately, patients are not sufficiently mindful of the undesirable consequences of these behaviors, such as anger and rejection by family and friends when they get tired of having to take on the patient's daily tasks and are exasperated about the failure to get well; frustration with complicated bureaucracy; increased physical suffering due to chronic narcotic use and dependency; unpleasant side effects with medication; and constant bitter battles for disability benefits during which the patient must take on and even exaggerate the sick role. An open discussion of the issues raised by secondary gain and discussion of the long-term consequences can greatly contribute to healing, and can prevent the development of chronic symptoms and disability.

PSYCHOLOGICAL FACTORS FAMILIAR TO PSYCHOLOGISTS AND PSYCHIATRISTS

Psychosocial factors are particularly important when a patient's problem is puzzling (non-characteristic, non-anatomical, or disproportionately symptomatic and disabling) and the examination and diagnostic procedures are inconclusive or contradictory (Ring et al., 2005; Vranceanu et al., 2008).

UPPER EXTREMITY ILLNESS

In this section, we discuss psychiatric diagnoses and puzzling hand and arm conditions—conditions that are instructive of the interrelationship between medical and psychological factors—from factitious disorders, where medical symptoms are consciously produced; to somatic symptom and related disorders, where normal bodily symptoms are amplified via cognitive processes.

Factitious Disorders

Factitious disorders are conditions in which a person acts as if he or she has an illness by deliberately producing, feigning, or exaggerating symptoms. There is a motivation to assume the sick role

and an absence of external incentives (Diagnostic and Statistical Manual of Mental Disorders; DMS-IV, 2000). Patients may lie about or fake symptoms, hurt themselves to bring on symptoms, or even alter diagnostic tests (such as contaminating a urine sample). People might be motivated to perpetrate factitious disorders either as patients or by proxy as caregivers to gain any of a variety of benefits, including attention, nurturance, sympathy, and leniency, that are perceived as otherwise unobtainable (Eisendrath, 1984). Patients with factitious disorders deny responsibility, yet they deliberately injure themselves to fulfill psychological needs, sometimes without regard to economic or social gain (Kasdan et al., 1998; Guziec & Harding, 1994).

Patients with upper-extremity problems rarely meet diagnostic criteria for a factitious disorder. On the other hand, patients can present with elements of a factitious disorder, which can sometimes occur in the context of a clear medical condition. Factitious disorders are on “a spectrum of consciously simulated disease, ranging from occasional falsification of disease—perhaps in the midst of stress—to the repetitive presentation of exaggerated or false symptoms and conscious production of signs.”

Clenched Fist Syndrome

The *clenched fist* is a condition wherein the arm is healthy, but all or one, two, or three fingers are tightly flexed. Often, the index finger and thumb are not involved, thereby allowing the patient useful hand function. The concept of the “clenched fist syndrome” is controversial, with some including it as a factitious disorder, while others see it as a conversion disorder, acknowledging that the motivation and source of this condition may be unconscious (Zeinch, 2008). In the short term, the diagnosis can be confirmed by a hand surgeon by anesthetizing the extremity or the patient and demonstrating the absence of fixed contracture, but in long-standing cases, fixed contracture can develop. A variation on this theme is the stiff index finger that “won’t bend” except under anesthesia.

Factitious Lymphedema and Unexplained Swelling

Unexplained swelling of the hand or arm may be a result of the patient’s surreptitious application of a tourniquet to the extremity. Examples of tight bands that may be used include an Ace bandage, a sphygmomanometer cuff, a rubber band, or a piece of string. Placing the extremity in a plaster cast allows the swelling to subside and prevents further application of the constricting band.

Many conditions may cause edema of the limb. However, with factitious lymphedema caused by intermittent application of a tourniquet, a so-called broken windowpane pattern of collateral lymphatic circulation distal to the site of tourniquet obstruction is seen. Ruptured lymph channels due to recurrent lymph stasis and direct constriction may also be seen. The size and distribution of the lymphatics is normal, however. There is no abnormality of the lymph nodes (Moretta & Cooley, 2002).

Self-Inflicted Wounds and Wound Manipulation

Voluntary, self-inflicted wounds often have an obvious origin. Cigarette burns, stab wounds, subcutaneous injection of feces

and other noxious substances, and even bite wounds are seen in these patients. The clinician must discriminate between the *deliberately* self-inflicted wound and the *accidentally* self-inflicted wound in patients with other types of mental problems, such as the hand that is damaged by accidental intra-arterial injection by a drug addict.

Self-Cutting

Self-cutting is rare but can be quite spectacular, with dozens, sometimes hundreds, of lacerations or scars on the forearms and hands. The lacerations usually involve only the epidermis but occasionally are deeper. The wounds are usually longitudinal or oblique and are most commonly on the dorsum of the hand and forearm. Self-cutting is common in patients with a borderline personality disorder, and is usually conceptualized as means of coping with intense psychological pain as well as the need for attention (DSM, 2000).

Secretan’s Syndrome

Secretan’s syndrome (also known as peritendinous fibrosis, post-traumatic hard edema, and factitious lymphedema) is a condition caused by the patient’s repeatedly striking the dorsum of the hand with a blunt object or against a blunt object, causing diffuse swelling as a result of a peritendinous fibrosis of the extensor tendons. The literature suggests that Secretan’s disease is an injury that is self-inflicted, either for secondary gain or as a conversion reaction, and that it is best treated with conservative care and psychiatric counseling (Moretta & Cooley, 2002).

Munchausen Syndrome

Patients with *Munchausen syndrome* present themselves as sufferers of all sorts of symptoms and ailments involving any and all parts of the body, including the hand. They often have a long history of many illnesses and treatments, including multiple operations. They are often migratory, going from one medical facility after another, giving detailed histories of specific ailments and begging for yet another operation. These people are generally well read in the medical literature and often know more about the ailment they are projecting than does the physician they are consulting. When found out, they simply transfer their medical attentions to another part of the country. The patient who has had multiple carpal tunnel operations may well be a variant of this condition.

SHAFT Syndrome

Patients with *SHAFT syndrome* (sad, hostile, anxious, frustrating, and tenacious) have pain as a typical complaint, usually without objective physical findings that would support a more definitive diagnosis. Patients with the SHAFT syndrome attempt to manipulate the surgeon to perform one or more invasive procedures, despite the lack of objective findings, and without relief of symptoms.

Ten criteria were identified that characterized the medical and psychosocial factors common to patients with SHAFT syndrome: multiple invasive procedures, absence of objective findings, multiple physicians, medications (psychotropic and analgesic), psychiatric treatment, a history of being off work,

disproportionate self-characterization and verbalization of symptoms, history of crying with pain, family history of disability, and history of abuse (emotional, physical, or sexual) (Johnson, 1998).

Somatic Symptom Disorders and Related Disorders

The somatic symptom disorders are conditions wherein the presence of physical symptoms suggests a medical condition, but the symptoms are not fully explained by disease (pathophysiology) or by another mental disorder. Historically, the disorders included in this category were: pain disorder, somatization disorder, conversion disorder, and hypochondriasis (DSM, 2000). These terms still highlight prominent features in the presentation of what has been lumped together as *Somatic symptom disorders* in DSM-V (DSM-V, 2013).

Pain disorder called attention to the patient whose pain, acute or chronic, is the predominant focus of the clinical presentation, when the pain causes substantial disability and distress, and when psychological factors are judged to have an important role in the onset, severity, exacerbation, or maintenance of the pain (DSM, 2000). In DSM-V, the patient would have *Somatic symptom disorder with predominant pain*. Pain disorders had been the most common psychiatric diagnosis in patients with pain, with prevalence rates as high as 97% in some samples of post-injury, chronic low-back pain patients in an inpatient rehabilitation setting.

Somatization disorder was a diagnosis in patients with multiple somatic symptoms—including digestive, sexual, and neurological symptoms in addition to pain—that could not be explained by a physical disorder. While somatization is common among patients with chronic pain, few patients met the full diagnostic criteria for the classification of *Somatization disorder*. The process of somatization is currently conceptualized as involving the focusing of attention on internal stimuli and development of “sensory amplification” (Barsky & Klerman, 1992), along with denial of psychological or interpersonal difficulties (Osteweis et al., 1987), resulting in an increase in somatic symptoms that remain partly or completely unexplained by objective disease processes.

In DSM-V, it is the maladaptive thoughts, feelings, and behaviors that define the somatic symptom disorder and subsume many patients who would have been diagnosed with somatization disorder. It includes the many patients who did not quite meet the old criteria.

Hypochondriasis historically represented a preoccupation with fears of having, or the idea that one has, a serious disease, based on a misinterpretation of bodily symptoms. This preoccupation persists despite appropriate medical evaluation and reassurance.

Only a small number of hand and arm patients met full criteria for hypochondriasis when it was a distinct diagnostic category. However, a larger number present with heightened illness-concern or health anxiety, which are less severe, yet distressing, conditions in which patient’s concern with a medical or perceived medical condition is exaggerated and consuming. It is important to note that most people are affected and concerned by the presence of pain. However, the majority readily

accept reassurance with regard to their pain symptoms, and are able to put their worries at rest if told that their condition is not dangerous or severe. In patients with heightened illness-concern (and its extreme form, hypochondriasis), no amount of reassurance is enough, and patients continue to believe that the doctors “missed” something. Recent research supports the theory that heightened illness-concern is an important mechanism for the development of chronic pain conditions (Hadjistavropoulos & Hadjistavropoulos, 2003). In DSM-V, “hypochondriasis” has been eliminated as a disorder, and those with high illness anxiety without somatic symptoms would receive a diagnosis of *Illness anxiety disorder*.

Conversion disorder or *Functional neurologic symptom disorder* are diagnosed when one or more distressing deficits affecting voluntary or sensory function are internally inconsistent and incompatible with known organic physiology. Psychological factors are judged to be associated with the symptoms or deficits because the initiation or exacerbation of the symptoms or deficits is preceded by conflicts or other stressors. Conversion disorders are rare in pain patients. However, patients may present with symptoms of a conversion disorder, such as the sudden onset of arm weakness, and perhaps the inability to lift their hand, which is found to have no medical explanation.

Puzzling Pain Problems

Many illness constructs used by hand specialists and currently described in the literature as purely medical (based on a biomedical framework) have minimal or no objective, verifiable pathology, and—as research is increasingly demonstrating—strong psychosocial correlates. A biopsychosocial behavioral approach may be more appropriate in conceptualizing and treating these conditions.

Repetitive strain injury—also known as *writer’s cramp*, *cumulative trauma disorder*, *occupational overuse syndrome*, and *work-related upper-limb disorder* among other terms—is an unverifiable diagnosis (essentially, it is a “social illness” construct, which is defined as a term “invented” or “constructed” by our culture and society, which exists because people agree to behave as if it exists) diagnosed on the basis of chronic activity-associated pain, typically in an upper limb. Although the “illness” construct implies injury or damage, an important characteristic of this diagnosis is that there are no objective signs of damage or disease. The illness is entirely subjective, and there are no objective tests to verify the diagnosis.

There are several unverifiable pain conditions that are accepted illness constructs within hand surgery and medicine, including radial tunnel syndrome, pronator syndrome; as well as electrophysiologically normal thoracic outlet, carpal tunnel, and cubital tunnel syndromes; not to mention dynamic scapholunate instability, occult dorsal ganglion, and so forth. These debatable and unverifiable conditions are similar to other non-specific conditions (Szabo & King, 1999) such as fibromyalgia and chronic fatigue syndrome, which are often comorbid.

The nomenclature of these illness constructs is somewhat troubling, as it implies an understanding of the

pathophysiology and a known physical basis where one is, by definition, lacking. It is recognized, but underappreciated, that chronic nonspecific arm pain is comorbid with depression, health anxiety, pain catastrophizing, and somatization, which are perhaps the only clear targets of intervention in the absence of verifiable and treatable objective pathology.

From a biopsychosocial perspective, patients with repetitive strain injury (RSI) can also be conceptualized as presenting with features of conversion disorder, heightened illness-concern, and somatic symptom disorder. There may also be distress in the form of anxiety and depression. Perhaps a biopsychosocial approach that considers both medical and psychological factors should replace the purely medical focus that currently hinders comprehensive management of these illnesses. In this way, unnecessary medical procedures can be avoided, and psychological distress can be addressed, thus increasing patients' quality of life and functioning. While some state that these medical labels serve the patient's need to emphasize the physical rather than the psychosocial or somatoform aspect of their illness (Barsky, 1992; Hadler, 2003), and thus avoid stigmatization, the benefit of these diagnoses is short-lived. In the long run, a focus on a purely medical condition and the administration of numerous tests and medical procedures act to reinforce a sick role, and do not address core issues such as acceptance, adaptation, and resiliency. No matter the advances to come in medicine, illness will always be a part of human existence, and effective coping skills will improve ability, wellness, and peace of mind.

Complex regional pain syndromes (CRPS) represent another puzzling, chronically painful condition (Nelson & Novy, 1996), with little epidemiological information, a lack of understanding of their natural course or basic pathophysiology, and lack of agreement even on definition and diagnostic criteria (Nelson & Novy, 1999). The most up-to-date definition of CRPS currently adopted by the International Association for the Study of Pain (IASP) reflects the evolution of the controversies over the concepts of *reflex sympathetic dystrophy*, *sympathetically maintained pain*, and *sympathetically independent pain*, and attempts to provide a definition focused on a description without any presumption as to underlying mechanisms. The current nomenclature reflects the complexity of this condition, the regional distribution of symptoms (which mostly affect the hands), and the cardinal symptom of pain. Two types of disorders are included in this category: (1) CRPS I, where pain follows injury, and involves continued pain, hypersensitivity, or allodynia, and there is evidence of edema or abnormal sudomotor activity; and (2) CRPS II, which has similar criteria but it implies a known nerve injury, but is, however, not limited to the distribution of the particular nerve (Stanton-Hicks et al., 1995).

These diagnostic criteria have been strongly criticized as being too vague, thereby allowing for over-diagnosis (Galer et al., 2001). Furthermore, the pathogenesis of this disorder is unclear, failing to explain why only a small percent of patients develop CRPS after an injury or well-defined nerve injury while the majority do not, whether there is there a genetic predisposition, and why such a significant variability among the different symptom classes of abnormalities is seen in patients with CRPS.

There is general agreement that many patients with CRPS manifest important and profound behavioral and emotional issues (Lynch, 1992), as well as reports of intense pain and severe disability. There is also some evidence that depression, anxiety, and life stressors (frequently reported as present in CRPS patients) might influence the development of this condition through alpha-adrenaline activity. Van Houdenhove and colleagues (1992) articulated a conceptualization suggesting the role of hyper-arousal due to life stress or other factors preceding, or around the time of, injury or during the subsequent initial period of healing, and having difficulties coping (van Houdenhove et al., 1992). CRPS is seen as overlapping with several conditions, including neuromas and phantom limb pain. The key element in all these conditions is that pain is considered "sympathetically maintained."

Neuromas are chronic pain conditions that, if severe enough, may severely curtail any useful function of the hand. Surgical management of painful neuromas has not been as effective as we might wish.

Phantom limb pain is a clinical condition in which patients experience pain in a limb after amputation. A "phantom limb" is the sensation that an amputated or missing limb (even an organ, like the appendix) is still attached to the body and is moving appropriately with other body parts (Halligan & Berger, 1999; Halligan, 2002; Halbert & Crotty, 2002). Approximately 50–80% of individuals with an amputation experience phantom sensations in their amputated limb, and the majority of the sensations are painful (Melzack, 1992). Phantom limb sensations usually will disappear or decrease over time. When phantom limb pain continues for more than six months, the prognosis for spontaneous improvement is poor, and pain can become disabling and can lead to a lifelong struggle with chronic pain. Research has found that, among other factors, pain and psychiatric distress in the form of depression, anxiety, and somatization are predictors of persistence of phantom limb pain (Tota-Faucette et al., 1993; Turk & Monarch, 1999).

OTHER PSYCHOSOCIAL ASPECTS OF ILLNESS

Cognitive processes, behaviors, affective states, and coping styles, along with sociocultural factors, are as important as or more important than biological factors in management of chronic pain conditions. The role of cognitive processes is predicated upon the evidence that people are not passive responders to physical sensations. Rather, humans are actively seeking to make sense of their experiences. They appraise their conditions by matching sensations to some preexisting implicit cognitive schema and determine whether a particular sensation is a symptom of a particular disorder that requires attention, or can be ignored. In this way, each person functions with a uniquely constructed reality. When information is ambiguous, people rely on general attitudes and beliefs based on experiences, prior learning history, or input from family and friends. These beliefs determine the meaning and significance of the problem, as well as the perceptions of the

appropriate treatment. As such, an understanding of each person's unique beliefs about pain, appraisals, and coping repertoire becomes critical for treatment success. A great body of research shows that patients' attitudes, beliefs, expectations, and coping resources are key in reports of pain intensity and disability (DeGood & Tait, 2001; Jensen et al., 1991).

Beliefs about pain may lead to maladaptive coping, increased suffering, exacerbation of pain, and greater disability. For example, pain that is interpreted as tissue damage rather than viewed as a problem that will improve may lead to more suffering and dysfunction. Also, patients who believe that their pain will last forever may take a fatalistic, passive approach to coping. Beliefs about the implications of diseases are also important. People high in health anxiety may interpret pain as a sign of a serious disease (e.g., a benign cyst is interpreted as cancer despite medical reassurance) and have more disability and more intense pain. People who attribute a pain flare-up to a worsening of tissue damage may experience more pain and disability. Cognitive factors thus affect functioning in two interrelated ways: (1) they influence mood and coping efforts, and (2) they affect physiological activity associated with pain, such as muscle tension (Flor & Turk, 1985) and the production of endogenous chemicals (Bandura et al., 1987).

Self-efficacy, or the belief in one's ability to successfully achieve a desired outcome, is another cognitive factor that strongly predicts success in coping with pain and reducing disability. Greater self-efficacy leads to reduced anxiety and its physiological component, an increased ability to use distraction as a coping strategy, increased determination to go on with planned activity in spite of pain, and avoidance of rumination on the pain.

In addition to specific self-efficacy beliefs, a number of investigators have suggested that a common set of "cognitive errors" affects the perception of pain, affective distress, and disability (Smith et al., 1986, 1990). A *cognitive error* is a negatively distorted belief about oneself or one's situation. The most common cognitive errors in pain patients are catastrophizing (rumination, magnification, and helplessness when faced with pain), overgeneralization (assumption that the impact of an event [negative] will apply to outcomes of future or similar events), personalization (interpreting negative events as reflecting personal meaning or responsibility), and selective abstractions (selectively attending to negative aspects of an experience).

Self-regulation of pain and its impact depend on a person's specific ways of dealing with pain, adjusting to pain, and reducing or minimizing the distress caused by the pain, which represent a set of coping strategies. Studies have found that active coping strategies, such as efforts to function in spite of pain or to distract oneself from pain, or ignoring pain, are associated with adaptive functioning, while passive coping strategies, such as depending on others for help in pain control, or letting pain dictate and restrict activity level, are related to greater pain and depression (Tota-Faucette et al., 1993; Lawson et al., 1990).

The *affective component* of pain includes many different emotions, but they are primarily negative in quality.

Depression is the most common diagnoses associated with pain and it is significantly associated with coping. That is, those who believe that they can continue to function in spite of pain do not become depressed, while those who engage in negative thinking are low in self-efficacy and are high in health anxiety and more likely to become depressed. Anxiety in the form of pain-related fear and concerns about harm-avoidance exacerbate pain symptoms. Anxiety's cognitive (uncertainty, misperceptions of danger) and physiological (bodily changes triggered by the fight-or-flight system) symptoms are common when people experience pain, and they have a strong association with disability and pain intensity (Vluyen et al., 1995). Post-traumatic stress disorder (PTSD) is a subtype of anxiety that can sometimes develop in people with pain triggered by traumatic injuries, and it has a strong relationship with disability and pain chronicity. Anger has also been observed in patients with pain. Anger can take the form of frustrations related to the persistence of symptoms, lack of etiology, treatment failures, worker's compensation, finances, and family relations. Anger may affect pain via biological (increased arousal) mechanisms, and may interfere with pain acceptance and adherence to treatment. As previously discussed, health anxiety and somatization are also commonplace in pain patients.

Common-sense beliefs about illness and healthcare providers are also highly influenced by prior experience and social and cultural transmission of beliefs and expectations across generations. Ethnic group and gender differences influence beliefs about pain and responses to pain. Social factors influence how families and communities respond to and interact with patients. For example, children acquire attitudes about health and health care, perceptions and interpretation of symptoms, and appropriate responses to injury from their parents, cultural stereotypes, and social environment. These influences will determine whether they will ignore or overreact to symptoms.

People's behaviors when experiencing pain (e.g., pain behaviors) are additional factors that affect their experience with pain, pain intensity, disability, and chronicity. Operant conditioning posits that behaviors that are reinforced are maintained, and those that are not reinforced are stopped. The operant view (Fordyce, 1976) proposes that via external contingencies of reinforcement, behaviors such as grimaces to communicate pain, or holding an arm in order to avoid additional pain, are maintained if reinforced by a doting spouse or healthcare provider. They may also be maintained by the escape from noxious stimulation through the use of drugs, rest, or avoidance of undesirable activities like work. Avoiding activities can thus serve as a reinforcer maintaining the pain.

In acute pain, reducing an activity may accelerate the healing process. However, repetitively engaging in avoidance of activity leads to anticipatory anxiety about pain (e.g., muscle tension and other symptoms associated with fight-or-flight or sympathetic activation), which may act as a conditioned stimulus for pain, which may be maintained after healing ends. Over time, more and more activities are perceived as aversive and are avoided. This may lead to deconditioning and more injuries and pain problems as a result.

Persistent avoidance of activities also prevents disconfirmation of the predicted pain. This is a common mechanism in the etiology, maintenance, and generalization of most anxiety disorders, and it has good applications for pain. Pain avoidance succeeds thus in preserving the *belief* that pain will continue when engaging in an activity, and would prevent a corrective *experience* that pain will eventually subside with activity.

There are also more subtle, yet potent factors that impact the pain experience. Internet and media shape patient's beliefs about pain and medical treatments. Television advertisements about cures for pain conditions via miracle drugs or intervention, without data to back up their efficacy; advertisements about avoiding aging that reinforce a desire to stay forever young and fight rather than accept normal age-related degenerations; magazine articles that mislead patients into changing their doctor if their pain is not taken away, all promote a "patient's right" to be pain-free—which is misguided and more likely to detract from than enhance health and wellness.

MULTIDISCIPLINARY TREATMENT TEAMS

Multidisciplinary treatment teams that consider the psychosocial as well as the biomedical aspects of illness have proven useful in the management of the most common idiopathic pain conditions, including backache and headache (Bruce et al., 2008; Flor et al., 1992; Gatchel, 2006), as well as more discrete pain conditions such as arthritis (Keefe et al., 1990). These teams typically include surgeons, physiatrists and other non-operative care providers, occupational therapists, medical assistants, and behavioral medicine specialists (i.e., psychologists). The role of each provider depends on the individual patient's presentation.

Although many hand and arm pains are poorly understood or incompletely treatable, and psychosocial factors such as depression and anxiety often exacerbate discrete pain conditions, hand surgeons and hand therapists have been slow to implement multidisciplinary treatment teams. Instead, they continue to operate largely under a biomedical model of illness, potentially neglecting prominent and treatable psychosocial factors. In spite of scientific support for the unique contribution of psychologists to the understanding of the multifactorial nature of pain (Simon & Folen, 2001), as well as recommendations from governing bodies such as the Joint Commission on the Accreditation of Health Care (JACHO) and the Commission on the Accreditation of Rehabilitation Facilities (CARF), and several professional organizations (American Pain Society, American Academy of Neurology), the psychiatrist or psychologist's role is underappreciated, seen as potentially offensive, and is currently undervalued by patients, health providers, and insurers. A multidisciplinary approach to the treatment of hand and arm pain conditions is consistent with evidence-based practice and fits well within the patient-centered model of medical decision-making. Having more than one listener allows the patient to feel cared for, as there is a team of doctors and therapists, rather than

one, attending to the pain concern. This may increase the patient's confidence that nothing is overlooked and all possibilities for increasing wellness are considered.

The gap between the utility and the utilization of a multidisciplinary treatment team is at least partly due to the difficulty communicating the value of a biopsychosocial approach to illness to patients and their healthcare providers. This gap itself represents an example of the need for good communication in the integration and practice of evidence-based medicine and patient-centered care. The quest for best evidence necessitates input that is more multilayered and considers myriad possibilities, reflecting less tissue-focused specificity and greater richness and breadth than the historically valued reductionist approach associated with the biomedical model. Treating illness, not just disease, requires that various aspects of the patient's situation be addressed, even though these factors may be ambiguous or contradictory. It requires more involvement of our patients, increasing their empowerment. This is best implemented by a multidisciplinary team through treatment processes that value and embrace effective communication skills.

MODEL OF CARE—RECOMMENDATIONS FOR ORTHOPEDIC HAND SPECIALISTS

A large body of research shows that the first visit to an orthopedics department, where patients are initially referred or present for treatment, is a strong predictor of the course of illness in pain patients (Malmivaara & Hakkinen, 1995).

At the first visit, patients need a thorough medical evaluation, including examination, review of available tests, and reassurance that nothing is neglected and no opportunities for improvement in the physical condition are or will be overlooked. The multidisciplinary approach to treatment needs to be emphasized to patients, as means of addressing the interrelation between mind and body and improving their quality of life. Patients need room to answer questions, provide feedback, and participate in the decision-making process. Often first visits are uneventful, diagnoses are easily made, and patients are able to follow recommendations. However, there are situations in which psychosocial factors are prominent.

There are many situations when patients with a discrete pain condition amenable to medical interventions present with depressed mood, misconceptions about pain and medical treatment, and psychosocial stressors. Hand specialists should be aware of warning signs such as flat affect, squeamishness about pain, complaints of poor sleep and frustration, fear of activity or of returning to work, which should not be ignored. It is in these situations that a behavioral medicine intervention would be particularly helpful, as patients work to improve important psychosocial issues along with their medical care. When surgeons introduce mind-body concepts to patients, normalize them, and offer services immediately in their office—as opposed to referrals elsewhere, which are rarely followed through—patients feel cared for and are more accepting of psychological help.

When the patient presentation is puzzling and does not fit within specific medical diagnosis categories, hand specialists will benefit from keeping an open mind about alternatives to a purely medical cause of the condition. Given the challenge of living with chronic unexplained symptoms, the behavioral medicine specialist has a key role. It is important to mention that, although surgeons need to be honest about their findings, they need to be careful not to dichotomize mind–body issues or suggest in any way that symptoms are conscious or unconsciously produced (e.g., factitious disorder or conversion disorder). In such cases, as in the cases of heightened illness-concern and somatization, a better approach is to schedule additional appointments aimed to provide additional reassurance to patients, while reinforcing the need to work with the behavioral medicine specialist on improving their quality of life.

Regardless of the degree of medical pathology, reassurance from the hand specialist is particularly important, given that patients came to the surgical practice to receive medical care. In the absence of empathy and effective communication and reassurance, patients may feel that their pain is not taken seriously, and become frustrated and upset. Comments such as, “Although there is pain, structurally you are intact—there may be some misconceptions here that we can help improve upon in order to increase your sense of wellness”; “Some cars have squeaky brakes, but they are safe to drive; your wrist has pain, but it is a healthy wrist”; or “You do need surgery, but let’s get you sleeping better and in a better disposition first,” can reassure patients that their pain is taken seriously. With idiopathic pain conditions, it is particularly helpful to schedule additional regular appointments to ensure that nothing will be overlooked, and increase the patient’s awareness, understanding, and acceptance of chronic nonspecific conditions.

In addition, patients need advice and clear recommendations. Rather than communicating “all is fine, no restrictions in activity,” try a message such as: “It is very important to move your arm to avoid stiffness and loss of range of motion. You will feel pain, but that is not a sign of damage. There are more risks associated with not moving your arm than with moving it. Do you think you can do this?”

It is important to avoid misguiding and mismanaging patients via unnecessary tests or procedures, or over-interpretation of test results. Examples include incidental or age-related findings that do not correspond with or fully explain the complaint, and cortisone shots or other treatments without an explanation that they are at best palliative and without an open discussion of their scientific basis or lack thereof. When patients ask questions about a specific time-frame for their recovery, it is critical to manage their expectations. Rather than setting a date on the calendar after which the patient and healthcare provider will be disappointed or even concerned, discuss the normal progression of disease while discussing how everyone is different, and reinforcing how the patient himself can speed up recovery with what he does, including following recommendations and keeping a positive attitude.

Because of the interrelationship between physical and psychosocial factors in the manifestation of disease, many patients

will benefit from meeting with a behavioral medicine specialist for a brief consult focused on evaluating current psychosocial functioning and effective coping skills. Misconceptions about pain and medical treatments are extremely prevalent, and a short conversation about these issues is often enough to place the patient on an optimal recovery path. Based on the initial evaluation, some patients may continue to meet with the behavioral medicine specialist, while others may be well equipped for effective coping on their own. It is important that a treatment plan and a set of goals be put in place at the end of the first visit, along with a list of written recommendations that the patient can take with him. Vranceanu et al. (2009) provide a description of a multidisciplinary treatment approach for hand and arm illnesses.

PSYCHOSOCIAL ASSESSMENT AND TREATMENT

The recommended approach to psychosocial assessment and treatment is to be delivered as part of a multidisciplinary team approach integrated within the orthopedics department. Ideally, assessment is done at the first visit, in conjunction with the medical appointment. If this is not possible, a referral to a team member in the same office may be accepted more readily than a referral elsewhere. The assessment includes an interview, focused mainly on understanding the patient’s disability, the value of effective coping with pain and optimal mood, as well as the reason for the visit and appropriate goals. In addition to the interview, self-report instruments can be very helpful.

Usually psychosocial assessment ends with a discussion of the disease, its natural progression, and the role of psychosocial factors. Goals for treatment are also established. Patients are also provided educational information on the cognitive-behavioral model of pain and how it might apply to the patient’s problem, as well as how cognitive-behavioral therapy (CBT) works.

CBT is a well-researched, scientific treatment approach that specifies how thoughts (beliefs, attitudes), behaviors, feelings, and sensations are interrelated. As discovered through research, in many cases, pain triggers negative thoughts such as catastrophizing (rumination, magnification, helplessness), heightened illness-concern (intense worry about pain and health that is resistant to reassurance), fear-based avoidance (avoidance of activities that cause pain for fear of reinjury or causing more damage), and affective reactions that include frustration, irritability, anger, depression, and anxiety. These interactions can become self-maintaining such that distress and disability, as well as physiological arousal, may continue in spite of the absence of original sensory input; patients thus can transition into chronic pain syndromes (Sharp, 2001). A key element in CBT treatments is identifying patient’s thoughts when experiencing the pain sensation. As depicted above, these thoughts are non-adaptive and associated with behavioral avoidance and emotional distress. Identifying specific negative automatic thoughts about pain and medical treatments appears thus as a crux of successful CBT for pain.

The most salient treatment issue is to help patient understand the interaction between the mind and body, normalize the situation to avoid stigmatization, and specifically show how the treatment will benefit the patient.

There are many advantages to delivering CBT in an orthopedic practice. First, addressing psychosocial factors and providing educational information early on in the experience of pain may prevent transition toward chronic pain syndromes, while improving quality of life while the pain condition takes its course. Many orthopedic pain conditions have a normal recovery course that ebbs and flows over the course of a year or more, and it is important that patients be aware of this course and learn how to cope with the pain so that they maintain their quality of life and conditioning, and do not develop complications such as stiffness or depression and anxiety. Second, CBT is delivered along with medical treatments, and appointments are scheduled at the same time, when possible, which saves patient money and time, and also allows communication and planning by the providers. Patients also feel “cared for” and do not feel that their physical complaints are being ignored. Third, in many cases, patients with clinical depression or anxiety who are in need of psychological interventions often neglect to follow up with referrals to psychiatric departments, or face long wait times. Lastly, CBT delivered in an orthopedics department can improve the efficacy of medical and surgical interventions.

It is also important to note that not all patients presenting to an orthopedics department benefit from CBT. There are many situations in which patients are resilient and cope well. There are also situations in which patients have severe pathology such as untreated severe anxiety disorders or depression, which have been present prior to pain and are exacerbated by pain. In such situations it is important to address these issues, while simultaneously working with patients on pain coping skills.

OTHER ORTHOPEDIC PROBLEMS

Building on this explanation of an integrated approach to orthopedic problems and chronic pain of the hand and arm, we will discuss the biopsychosocial elements of other orthopedic problems. These include patients who present with functional weakness of lower extremities, a conversion disorder; hip fracture; generalized musculoskeletal pain; chronic back pain; amputation; neuropathic pain; and analgesics.

FUNCTIONAL WEAKNESS OF LOWER EXTREMITIES, A CONVERSION DISORDER

Functional neurological symptoms or conversion disorder can present as leg weakness or gait disorder. Both psychic distress and issues related to disability-related state financial benefits are important elements of evaluation (Carson et al., 2011). The reliability of the classic finding “*la belle indifférence*” on mental status exam has been questioned (Stone et al., 2005); some patients seem indifferent but may be trying hard to be stoic and to be taken seriously. One series of 107 patients with

functional weakness seen by neurologists (Stone et al., 2012) were 79% female, mean age 39, with median nine months’ duration of weakness. Sudden onset was noted in 46%; others presented with symptoms on waking or gradual onset. Comorbid panic (59%) and dissociative symptoms (39%) were common, and injury to the relevant limb had occurred in 20%. Non-epileptic attacks, migraine, fatigue, and sleep paralysis were also associated conditions.

Stone et al. (2005) made crisp recommendations for the interview of patients with conversion disorder seen in the medical or neurological setting as physicians consider other diagnoses. These are wise guidelines:

1. Ask about dissociation, depersonalization, de-realization, and panic attacks. Patients may refer to being “dizzy or spaced out,” outside themselves, as if watching everything on television. These syndromes also occur in the setting of migraine or epilepsy.
2. In order to assess disability, ask about the course of a typical day and how much time is spent in or out of bed or away from home. Is the patient disabled by fear of falling? Think of graphing the natural course: for instance, the character of onset and severity over time in counterpoint to cessation of work, major life events or medical interventions, troubles with the law, marriage, or money.
3. Ask about what happened with previous doctors. The stories about disappointing explanations from previous doctors give the listener an opportunity to show interest in the patient’s suffering and to offer information about explanations that patients are likely to reject.
4. In exploring the patient’s illness beliefs, ask what the patient thinks is causing her symptoms and what should be done. Does the patient think that the problem will get better, or is there a fear of a particular illness like multiple sclerosis?
5. In looking for a model, the interviewer may find that the family history provides models of disability in people close to the patient.
6. Ask about vegetative symptoms like fatigue, poor concentration, and poor sleep first, leaving questions about emotions to the end when the somatic symptom has already been taken seriously.
7. Be cautious about exploring questions of abuse in a short medical visit. These are tender topics that are difficult to approach quickly and are better left to a separate visit. Patients with a history of trauma may have been the subjects of childhood abuse or neglect.
8. Exploration of the old records will show whether there is a history of other functional symptoms or surgery for symptoms that were not explicitly associated with documented pathology.

The physiology of severe anxiety with hyperventilation and metabolic alkalosis may provide a partial explanation of the

odd sensation in the limb. Intensive psychologically oriented CBT has been effective for patients with functional symptoms who seek it (Allen et al., 2006; Escobar et al., 2007). Sharpe et al. (2011) found that CBT based on a functional explanation can be acceptable to relatively unselected neurology patients with weakness and gait disturbance, and that CBT-based guided self-help therapy improved self-reported general health in patients with functional presentations of weakness and gait disturbance. This treatment began with a workbook, one session of guidance in its use, and an approach similar to CBT for depression and anxiety. The book explained functional symptoms as changes in nervous system functioning that were influenced by psychological and behavioral factors. It included an explanation of how functional symptoms are diagnosed; a description of common symptoms and the associated anatomy, physiology, and psychology; and self-management techniques such as ways to reduce unhelpful thinking and increase coping with these symptoms. Four half-hour sessions over three months were given face-to-face (by telephone if the patient was unable to attend the hospital) by a nurse or psychologist trained in CBT. The benefit of guided self-help diminished at six months; however, symptoms improved, belief in the symptoms' being permanent diminished, satisfaction with care improved, and clinical physical functioning improved.

This approach highlights a treatment for conversion disorder that is optimistic and focused on activation, rehabilitation, and reducing anxiety. In the setting of the general hospital, many with functional weakness get better, while a subset continue to relapse (Folks et al., 1984). In general, patients can be told that the symptoms will get better very gradually. Their strengths and conviction that they can cope will be supported with graded physical therapy, and their concerns with emotional valence can be heard out over time. This treatment philosophy does not negate the psychodynamic thesis that conversion symptoms occur in the setting of unconscious conflict or trauma or negate the role of other interventions like hypnosis (see Chapter 16) or other psychotherapies; however, the important psychological history can be heard and respected over time as the focus on the patient's functioning is sustained. A comorbid disorder like major depressive disorder, panic disorder, or schizophrenia can be diagnosed and treated with medications if appropriate. To aim for the best outcome, physicians should be mindful of rehabilitation to prevent atrophy and contractures of disuse. Caution is appropriate in regard to medications associated with physical dependency like benzodiazepines and narcotics.

HIP FRACTURE

Hip fracture is associated with clinical depression in 14–20% patients (Lenze et al., 2007; Voshaar et al., 2010). Depressive symptoms in patients with hip fracture are associated with poor outcomes at two years (Burns et al., 2012). Fear of falling may limit patients' return to functioning; and the importance of rehabilitation in addressing avoidance early on may be underestimated.

CHRONIC MUSCULOSKELETAL PAIN

Depression as it amplifies chronic pain is an important consideration in patients with a long course of orthopedic pain. Pain, even without affective symptoms, especially associated with joint pain and multiple sites of pain, is a risk indicator for the development of depressive and anxiety disorders (Gerrits et al., 2013). A systemic review of 45 studies of musculoskeletal pain in primary care found that 11 factors were markers of poor prognosis: higher pain severity at baseline, longer duration, multiple sites, previous pain episodes, greater movement restriction, anxiety and/or depression, higher somatic perceptions and/or distress, adverse coping strategies, low social support, older age, and high baseline disability (Mallen et al., 2007). Catastrophizing predicts degrees of pain and disability and mediates treatment efficacy in most studies, as noted in regard to upper-extremity pain (Wertli et al., 2013).

CHRONIC LOW-BACK PAIN

Nonspecific chronic low-back pain is so common that serious medical causes can be ignored in error. Red flags to screen for malignancy and fracture are worth remembering. For cancer: a history of malignancy is the red flag; for fracture: older age, prolonged use of corticosteroid drugs, severe trauma, and presence of a contusion or abrasion are important clues (Bownie et al., 2013).

LUMBAR STENOSIS

Lumbar stenosis—narrowing of the space available for the thecal sac and nerve roots—is caused by mechanical factors and biochemical changes within the intervertebral disk that lead to collapse of the disk space, facet joint hypertrophy, soft-tissue infolding, and osteophyte formation. Flexing the back increases the surface area of the foramen, and extending the back, especially when standing, increases epidural pressure and decreases surface area of the foramen. Symptoms come from vascular compromise of the vessels supplying the cauda equina, or pressure on the nerve root complex by the degenerative changes.

As reviewed by Genevay and Atlas (2010), *neurogenic claudication* refers to leg symptoms—fatigue, heaviness, weakness, and paresthesia—in the buttock, groin, and anterior thigh, as well as radiation down the posterior part of the leg to the feet. Nocturnal leg cramps and neurogenic bladder are also seen. Standing makes symptoms worse, and sitting makes them better. Lying flat is not as much a relief as lying on the side with lumbar flexion. The patient with neurogenic claudication can walk a more variable distance than the patient with vascular claudication. The patient who bends the torso forward can walk further; therefore, people with lumbar stenosis seen from a distance are recognized by their ape-like stance with hips and knees bent. They feel better walking uphill than downhill. Exercise on a stationary bicycle in a seated, flexed position is better tolerated than walking in the erect position (Genevay & Atlas, 2010).

The natural course of the condition varies. Lumbar stenosis does not always get progressively worse (Issack, 2012). The anatomical definition of spinal stenosis may not correlate with pain and functional impairment; therefore, identifying which patients will benefit from surgical or nonsurgical treatments is complex and requires assessment of symptoms. The patient must weigh in on the decision (Atlas et al., 2011). Nonsurgical management consists of nonsteroidal anti-inflammatory agents, physical therapy, and epidural steroid injections. Laminectomy is the most common surgery. In randomized controlled trials for spinal stenosis, surgery is superior to nonsurgical management for controlling pain and improving function (Issack, 2012). With or without degenerative spondylolisthesis, there is good evidence that decompressive surgery is moderately superior to nonsurgical therapy over one to two years (Chou et al., 2009; Loeser, 2009).

LUMBAR RADICULOPATHY

For radiculopathy with herniated lumbar disc, Chou's review found good evidence that standard open discectomy and microdiscectomy are moderately superior to nonsurgical therapy for improvement in pain and function through two to three months. For both lumbar stenosis and radiculopathy, patients on average experience improvement either with or without surgery, and benefits associated with surgery decrease with long-term follow-up in some trials (Chou, 2009).

BIOPSYCHOSOCIAL CARE

Presurgical emotional distress identifies the patients at risk for poor outcome from lumbar surgery (Trief et al., 2000). Presurgical anxiety and depression predicted failure to return to work, failure to report improvement in pain, and failure to report improved functional abilities. Active rehabilitation makes a difference in the outcome after lumbar stenosis surgery (McGregor et al., 2013), and psychologically informed physical therapy that addresses obstacles to resuming life activities improves long-term outcomes among patients with back pain, even those with greater pain and a less favorable prognosis (von Korff et al., 2005).

Chronic back pain lasting more than 12 weeks occurs in a biopsychosocial context (Polatin et al., 1993). Although the biopsychosocial model has been valued for the understanding of low-back pain patients, the synthesis of that knowledge in planning care has not been fully developed for the majority of patients (Pincus et al., 2013), and psychological interventions have shown benefit mostly in the short term (Pincus & McCracken, 2013). Recovery requires patience, disciplined rest, graded exercise, and an awareness of what activities may lead to injury, relapse, and perpetuation of the pain. In one recent review (Chou et al., 2013), antidepressants were reported to show a small net benefit overall. Only tricyclic antidepressants have been shown to be effective. There was no evidence on duloxetine or venlafaxine. The benefit of skeletal muscle relaxants and benzodiazepines was unclear.

STRATIFIED CARE

An important strategy to improve care of back pain patients, taking into consideration the psychosocial dimension, individualizes care by how likely patients are to get better. Reliable assessment of the prognosis can be based on the first-encounter physician's assessment of pain intensity, pain duration, pain interference with daily activity, pain presence at multiple body sites, and a brief screen for depression—as well as the physician's prediction of the expected outcome (Mallen et al., 2013; von Korff, 2013). This assessment predicted six-month outcomes in seven of ten older patients with non-inflammatory musculoskeletal pain (Mallen et al., 2013). The brief assessment by the general physician includes elements that would be noteworthy to a medical psychiatrist or psychologist:

1. a direct consideration of depressed mood,
2. the patients' tendency to avoid activities for fear of injury,
3. troubling thoughts about the causes and consequences of pain, and
4. life circumstances that affect their motivation to resume activities.

The presence of both physical and psychosocial symptoms at the outset affects the treatment approach, bringing more tailored interventions to those with more psychosocial distress. A randomized controlled trial sub-grouping patients with back pain for targeted treatment in the United Kingdom found that more patients in the intermediate and high-risk subgroups had greater than 30% improvement if they were treated with the stratified approach rather than the current best practice approach (Hill et al., 2011).

Both the concept of stratification for targeted treatment and the elements of the three different interventions highlight practical integration of physical and psychological treatments. In this trial, the low-risk intervention was a 90-minute small-group session by a physiotherapist promoting active management of back symptoms, outlining a positive message on maintaining a healthy spine, normalizing the episode of pain, emphasizing the benefit of exercise, and gradually increasing activity levels at local centers. Medium-risk patients who do not have high psychosocial distress but do have disabling low-back pain, referred leg pain, and comorbid pain received four 90-minute group exercise and education sessions. Psychoeducation included the benefits of exercise, a review of spinal anatomy, direction on lifting and handling, ergonomic advice, weight management, and information on the impact of stress, anxiety, and low mood on low-back pain. This was added to a stability exercise program. Patients kept an exercise log on four sessions at home per week. They were urged to do more active walking, cycling, swimming, or other forms of aerobic exercise. The high-risk group with psychosocial distress had four 130-minute group sessions involving CBT strategies to address unhelpful beliefs and behaviors around low-back pain. The biopsychosocial model, the impact of persistent

pain, goal-setting based on the patient's functional and social limitations, graded activity, relaxation training, and relapse-management were included. There was a focus on behavior change. The exercise program was similar to that in the medium-risk group. Cognitive-behavioral principles included pacing and goal setting. Exercises were done independently at home for eight weeks (Hay et al., 2008).

Certainly motivation to exercise affects outcome. When an exercise intervention interferes with everyday life, or appears to be ineffective or too difficult to implement, people make a reasoned decision to discontinue (Slade et al., 2013). People are likely to prefer and participate in exercise or training programs and activities that are designed with consideration of their preferences, circumstances, fitness levels, and exercise experiences. Patients tend to believe that there is a difference between general activity, real fitness exercise, and medical exercise. Treatment, to be accepted, requires consideration of patient abilities and experience. Targeting disability and fear-avoidance behaviors makes a difference (Monticone et al., 2013).

From the medical psychiatrist's or psychologist's perspective, the best outcomes for the patient with low-back pain will require tailored clarification about back mechanics, a feasible program of exercise and rehabilitation, pacing and goal setting, activation and encouragement to maintain functioning and limit avoidance, smart use of pain medications, and optimal treatment of depressive disorder. The effectiveness and feasibility of narcotics in chronic back pain are related in part to individual differences, acute vs. chronic course, and the ability to predict and identify aberrant drug-related behaviors.

AMPUTATION AND PHANTOM PAIN

Traumatic limb-amputation often occurs in young, active people, often these days as a major consequence of combat. Surgical decisions after leg injury about limb salvage or amputation are determined by feasibility and the collaborative decision about what offers a better quality of life. The surgeon considers what will lead to a useful and painless limb. Subsequent disability is related to pain, psychological illness, decreased physical and vocational function, and increased cardiovascular morbidity and mortality (Perkins et al., 2011). Adjustment to the loss of a leg is associated with anxiety, depression, PTSD, and substance abuse. (This is discussed in more detail in the chapter 20 on rehabilitation.)

At least half of amputees, and probably 80%, have neuropathic pain and the discomfiting sensation of the missing limb. Sometimes this improves with time. Both peripheral and autonomic nervous systems contribute to the cortical pain memory. Most patients with combat-related traumatic amputations in one series received gabapentin, although some reported greater pain relief from distraction and relaxation techniques. The data for benefit of gabapentin in limited studies are mixed, but there is a trend to benefit (Ketz, 2008; Alviar et al., 2012). Many amputees do not use analgesics for phantom limb pain (Hanley et al., 2006). The severity of the pain is related to the

severity and duration of pain before amputation, the pain after amputation, and affective factors (Flor, 2002). Effective analgesia with ketamine or morphine preoperatively may therefore reduce postoperative pain (Huse et al., 2001).

NEUROPATHIC PAIN

The likelihood of neuropathic pain after surgery depends on the likelihood that nerves were injured (Haroutinunian, 2013). Neuropathic pain has a distinct symptom profile that distinguishes it from somatic pain. It is associated with these descriptors: burning, squeezing, electric shocks, tingling, lancinating, pins and needles, itching, and numbness (Bouhassira & Attal, 2010). It is associated with allodynia (pain on the skin from something like a light touch or the sheet over the body). Most patients do not develop chronic neuropathic pain after nerve injury. However, when changes in pain sensitivity become persistent, pain can occur spontaneously with a low threshold. Minor stimuli can produce pain with greater amplitude. At that point, neuropathic pain becomes a condition in its own right (von Hehn et al., 2012). It is often associated with poor sleep, depression, and anxiety (Turk et al., 2010).

The use of opioids for neuropathic pain continues to be controversial. Opioids are useful for spontaneous neuropathic pain and have been recommended as second-line treatments (Dworkin et al., 2007). Compared to placebo, intermediate-term studies (12 weeks or less) of opioids showed some benefit, but their efficacy for chronic neuropathic pain was quite uncertain (McNicol et al., 2013).

Gabapentin and pregabalin, calcium channel alpha-2-delta binding agents, are first-line choices in neuropathic pain, with neither clearly superior (Finnerup et al., 2010). Lidocaine patch 5% or capsaicin 8% (for peripheral neuropathic pain in non-diabetic patients) have also been recommended (Kalso et al., 2013). Both duloxetine and venlafaxine have efficacy in painful polyneuropathy (Rowbotham et al., 2004; Raskin et al., 2005). Amitriptyline has a long history of benefit for neuropathic pain (Moore et al., 2012). Duloxetine has been shown to ameliorate neuropathic pain in diabetic neuropathy and chemotherapy-induced neuropathic pain syndromes. Venlafaxine also has benefit (Finnerup et al., 2010). Lumbosacral radiculopathy, the most common type of neuropathic pain, has not been well treated by any of these medications (Dworkin et al., 2007).

CLINICAL PEARLS

- Unexplained swelling of the hand or arm may be a result of the patient's surreptitious application of a tourniquet to the extremity.
- Secretan's syndrome is a condition caused by the patient's repeatedly striking the dorsum of the hand with a blunt object or against a blunt object, causing diffuse swelling as a result of a peritendinous fibrosis of the extensor tendons. It is an injury that may be self-inflicted, either for secondary gain or as a conversion reaction, and it is best

treated with conservative care and psychiatric counseling (Moretta & Cooley, 2002).

- Conversion motor paralysis is associated with comorbid panic; dissociative symptoms were common, as was previous injury to the relevant limb. Non-epileptic attacks, migraine, fatigue, and sleep paralysis were also associated conditions.
- Depressive symptoms in patients with hip fracture are associated with poor outcomes at two years (Burns et al., 2012). Fear of falling may limit return to function.
- In consideration of diagnostic tests in patients with chronic low-back pain, for cancer: a history of malignancy is the red flag; for fracture: older age, prolonged use of corticosteroid drugs, severe trauma, and presence of a contusion or abrasion are important clues.
- The anatomical definition of spinal stenosis may not correlate with pain and functional impairment.
- People with lumbar stenosis can be recognized at a distance as they assume an ape-like stance with hip and knee bent. They feel better walking uphill than downhill, better sitting than standing.
- The severity of the phantom pain post-amputation is related to the severity and duration of the pain before amputation.

SEXUAL AND PSYCHOLOGICAL ASPECTS OF REHABILITATION AFTER SPINAL CORD INJURY

Robert M. Kohut, Allen D. Seftel, Stanley H. Ducharme, Barry S. Fogel, and Donald R. Bodner

INTRODUCTION

The estimated annual incidence of spinal cord injury (SCI), excluding those who die at the scene of the accident, is approximately 40 cases per million population in the United States, or approximately 12,000 new cases each year. The average age of victims is 40.7% and approximately 80% are males. The estimated number of people in the United States alive with SCI in 2010 has been estimated to be 265,000 (National Spinal Cord Injury Statistical Center [NSCISC], 2011). The most common causes of SCI are motor vehicle accidents (40.4%), falls (27.9%) and acts of violence (15%). Of the cases reported to the National Spinal Cord Injury Database between 2005 and 2010, neurological status at discharge from the initial hospitalization for SCI was incomplete tetraplegia in 39.5%, complete paraplegia in 22.1%, incomplete paraplegia in 21.7%, and complete tetraplegia in 16.3% (NSCISC, 2011).

Over the last three decades, there has been a 40% decline in mortality during the critical first two years after injury, which is attributed to improvements in critical care following the acute injury, and a comprehensive approach to the subsequent management of the SCI patient (Strauss, Devivo, Paculdo, & Shavelle, 2006). Although short-term mortality has declined dramatically, a person's average life expectancy following a spinal cord injury remains shorter than the norm for person of the same age and sex without SCI. Life expectancy is shorter with more rostral lesions and greater neurological impairment (NSCISC, 2011; Strauss et al., 2006). Historically, urosepsis was the most common cause of death in patients with SCI, but with the advent of effective antibiotics for bacteria causing urinary tract infections and a lower incidence of renal failure because of improved management of SCI-associated bladder dysfunction, renal failure now usually can be prevented. At present respiratory and cardiovascular conditions are the main causes of post-SCI mortality (Lai & Boone, 2008).

Following the initial insult, it is of utmost importance for the rehabilitative team to integrate the patient back into society. Most patients with SCI are younger adults without major chronic diseases, who prior to their injuries looked forward to occupational achievements, sexual experiences, forming families, and pursuing avocations over the coming years. Addressing sexual and relationship concerns, the impact of

the injury of work and leisure activities, and emotional adaptation to a radically altered body image is a prominent part of SCI patients' overall rehabilitation. A satisfying sexual life relates reciprocally to many other adaptive issues; it improves relationships, helps with acceptance of physical disabilities, and it improves mood. For this reason, and because anxiety about future sexual function is a frequent early concern in SCI patients, the sexual aspect of SCI rehabilitation has received much attention.

In 2010 the Consortium for Spinal Cord Medicine published a clinical practice guideline for addressing sexuality and reproductive health in SCI patients; these guidelines are integrated into the recommendations provided in this chapter (Consortium for Spinal Cord Medicine, 2010). In the remainder of this chapter the guideline will be referenced as the "Consortium SRH Guideline."

HISTORICAL BACKGROUND

The earliest documented mention of SCI was in the Edwin Smith Surgical Papyrus, transcribed by Smith during the seventeenth century and thought to originate circa 3000 BC (Breasted, 1930). During the time of the pharaohs, SCI was considered to be a fatal condition that was not treatable. In ancient Greece, Hippocrates first described the complications of SCI, including the loss of control of the bowel and bladder (Adams, 1886).

There was little progress in the clinical management of the SCI patient for many centuries. Despite the achievements in understanding neuroanatomy and neurophysiology, during World War I, most spinal cord-injured patients nevertheless eventually died of urosepsis (Holmes, 1915). The emphasis at that time was on neurological assessment, not treatment, as the prognosis of SCI was considered so dismal.

During World War II, great strides were made in the understanding and management of the SCI patient. It was learned that catheterizing the flaccid neurogenic bladder caused by spinal shock immediately reduced mortality due to urosepsis from 100% to 50%. Sir Ludwig Guttman, a German immigrant in the United Kingdom, established a multidisciplinary unit to deal with SCI; he is considered to be the father of modern SCI treatment. In the United States during this

same period, Donald Munro in the private sector and Ernest Bors through the Veterans Administration were early pioneers in establishing regional units specializing in the treatment of SCI. The Veterans Administration should be credited for the systematic development of regional SCI units in the United States.

Great progress was made in the urological management of the SCI patient during the 1970s and 1980s. Renal failure was once the leading cause of death in this group of patients, but with improved understanding and management of neurogenic bladder dysfunction, it is no longer so (Dietrick & Russi, 1958; Freed, Bakst, & Barrie, 1966; Mesard, Carmody, Mannarino, & Ruge, 1978). As medical advances have improved the life expectancy of SCI patients, physicians treating SCI have increasingly focused on improving their patients' quality of life. The primary goals of current urological management of patients with SCI are to preserve kidney function, to prevent bladder and kidney infections, and to avoid the use of indwelling catheters whenever possible. With greater success in accomplishing these goals, sexual concerns have emerged as an important part of neurourological rehabilitation.

Sexual education, a need of all SCI patients, is best accomplished by a team that includes a psychologist or psychiatrist (or both), and a urologist familiar with spinal cord injury. Instruction should be commenced shortly after injury and continued throughout the rehabilitation period. Continued access to sexual education, medical problem-solving and peer support is especially important after the patient has been discharged from inpatient rehabilitation. Community surveys of SCI patients have shown that many patients have unaddressed sexual concerns that they feel have been insufficiently addressed by clinicians, and many are dissatisfied with their access to help for sexual issues (Forsythe & Horsewell, 2006; Kreuter, Taft, Siösteen, & Beiring-Sørensen, 2011).

The ability to have satisfying sexual intercourse is important to almost all men and women, and the ability to have genetic offspring is important to most. Concerns of sexuality and procreation are equally important to the spouses and partners of SCI patients; they should be part of educational efforts from the beginning, and they usually will play a role in medical solutions to specific sexual dysfunctions. For many SCI patients who are not married and do not have a regular partner concerns related to the sexual consequences of the injury interact with issues of finding a suitable mate. For these patients general education about the impact of SCI on sexual function should be supplemented by a more individualized approach to issues of initiating and maintaining social and sexual relationships in the presence of a severe disability.

NEUROLOGICAL PATHWAYS AND SEXUAL FUNCTION

The neurology of sexual function is the key to understanding the patterns of sexual dysfunction that can arise following SCI, including the consequences of incomplete injury and the implications of collateral damage to peripheral nerves from trauma or neuropathy. Relatively more attention has been

given in the SCI injury to the neuroanatomy and neurophysiology of erection and ejaculation, but the more limited work on female sexual function following SCI suggests that the physiology is analogous—female lubrication and genital vasocongestion corresponds to male erections, and female orgasm corresponds to male ejaculation and orgasm (Forsythe & Horsewell, 2006).

PHYSIOLOGY OF ERECTION

Following appropriate neural input, erections require sinusoidal relaxation, arterial inflow, and venous compression (Lue, Takamura, Schmidt, Palubinskas, & Tanagho, 1983). The corpora cavernosa are the spongy, bilateralcylindrical bodies that together with the corpus spongiosum make constitute the bulk of the penile shaft. The corpora cavernosa and corpus spongiosum are lined by the tunica albuginea, which is thick and relatively noncompliant over the corpora cavernosa and thinner and more compliant over the corpus spongiosum. Inside the corpora cavernosa is a complex network of smooth-muscle-lined sinusoids that are tonically contracted in the flaccid state, preventing massive arterial inflow. The arterial supply to the penis is the penile artery, supplied by the internal pudendal artery. The penile artery then gives off three divisions: the dorsal, bulbourethral, and cavernosal. The cavernosal branches traverse the corpora cavernosa. From the cavernosal arteries arise the helicine arteries, which supply blood to the sinusoids in the corpora cavernosa. The venous drainage originates in venules from the peripheral sinusoids immediately beneath the tunica albuginea. These venules travel in the trabeculae between the tunica and the peripheral sinusoids to form the subtunical venous plexus before exiting as the emissary veins (Lue, 2011). The tunica albuginea constrict the swelling of the corpora cavernosa; with vascular engorgement the intracavernosal pressure rises dramatically, compressing the emissary veins and impeding venous return. When this happens the corpus spongiosum functions as an arteriovenous shunt to compensate for the loss of flow through the corpora cavernosa (Dean & Lue, 2005). Both autonomic and somatic neural pathways are involved in erections. Sympathetic fibers from the hypogastric plexus arise from the intermediolateral columns of the T10–T12 spinal segments, travel through the pelvic plexus and where they join sacral parasympathetic nerves to form the cavernous nerves. Stimulation of the penile sympathetic nerves causes detumescence; their inhibition can cause a partial but not fully rigid erection. The parasympathetic pathway arises from neurons in the intermediolateral cell columns of the S2–S4 spinal cord segments. Because the parasympathetic nerves predominate in the pelvic plexus, stimulation of the pelvic plexus and the cavernous nerves induces erection (Lue, 2011; Dean & Lue, 2005). The dorsal nerve, which arises from the pudendal nerve, provides sensory innervation of the penis and the somatic muscular innervation of the bulbocavernosus (aka bulbospongiosus) and ischiocavernosus muscles. Onuf's nucleus in the S2–S4 spinal segments is the center of somatomotor penile innervation. The respective nerve fibers travel within the sacral nerves to the pudendal nerve to innervate the ischiocavernosus and

bulbocavernosus muscles. Contraction of the ischiocavernosus muscles produces the rigid-erection phase, in which the penis typically forms an acute angle with the anterior abdominal wall. Rhythmic contraction of the bulbocavernosus muscle is necessary for ejaculation.

Erections can be reflexogenic or psychogenic. Many patients with sacral SCI retain psychogenic erectile ability even though reflexogenic erection is abolished. Psychogenic erections are mediated by the inhibition of the sympathetic nerve supply to the penis. They typically are triggered by external audiovisual cues but can also be triggered by sexual thoughts. Because they rely on central control of lower thoracic sympathetic neurons, they do not occur in patients with complete cord lesions above T9 and usually are absent in patients with partial lesions above T9. They are most often found in patients with lower motor neuron lesions of the lumbosacral cord, which leave the more rostral sympathetic nuclei completely intact. These LMN lesions eliminate the parasympathetic input to the cavernous nerves; in the absence of parasympathetic input the reduction of tonic sympathetic stimulation can initiate cavernosal engorgement and thus penile erection (Courtois, Goulet, Charvier, & Leriche, 1999; Dean & Lue, 2005). Patients with cord lesions that spare the sacral cord and cauda equina can attain erections mediated by the reflexogenic pathway, that is, via the stimulation of sacral parasympathetic activity as a reflex response to sacral somatic sensation (see Box 78.1).

The central pathways involved in erection include an oxytocin-mediated connection between the hippocampus and the hypothalamus. An alternate pathway can be activated by stimulation of the paraventricular nucleus (PVN) of the hypothalamus, which produces a marked increase in intracavernosal pressure without a similar effect on systemic blood pressure (Chen, Chan, Chang, & Chan, 1997). These changes are related to the stimulus intensity and frequency of PVN activation. The PVN connects to both sympathetic and parasympathetic neural pathways involved in penile erection. Fibers from the PVN connect to preganglionic parasympathetic

fibers, as well as to the spinal nucleus of the bulbocavernosus (SNB) and the dorsolateral intermediolateral nucleus in the lumbosacral spinal cord. Axons from these latter nuclei innervate the striated penile muscles and the bulbocavernosus muscles. Retrograde tracer and immunohistochemical studies reveal that the PVN fibers that project to the SNB contain neurophysin, the co-product of oxytocin and vasopressin. The role of oxytocin in the central pathways mediating erection suggests a potential role for oxytocin as an adjunctive therapy for erectile dysfunction, a use demonstrated in a recent case report (MacDonald & Feifel, 2012). In fact, oxytocin has a broad range of functions in the CNS related to sexuality, ranging from mediating social interaction and romantic attachment to influencing semen quality (Thackare, Nicholson, & Whittington, 2006; Schneiderman, Zagoory-Sharon, Leckman, & Feldman, 2012). Research on the potential role of oxytocin in the sexual rehabilitation of SCI patients has not as yet been reported. In the rat, the central pathways connecting to the penile (somatic) muscles—the bulbospongiosus and the ischiocavernosus—were shown to involve the locus ceruleus, raphe nuclei, periaqueductal grey and the PVN of the hypothalamus—regions also associated with central control of autonomic function (Marson & McKenna, 1996; Marson, Platt, & McKenna, 1993; Vizzard, Erickson, Card, Roppolo, & de Groat, 1995). Damage to these central pathways contributes to the greater severity of sexual dysfunction when SCI is accompanied by concomitant traumatic brain injury.

Ejaculation is mediated via the sympathetic nervous system and thus by the thoracolumbar portion of the spinal cord. Closure of bladder neck so that reflux of ejaculate into the bladder is prevented, and contraction of the bulbocavernosus muscles, which requires the input of sacral somatic efferents. It is preceded by the secretion of seminal fluid—stimulated by parasympathetic nerves and emission of semen—stimulated by sympathetic nerves. Emission and ejaculation do not require erection (Giuliano, 2011). The sensory experience of orgasm is mediated by vagus nerve afferents from the genital region to the nucleus tractus solitarius.

The neurological pathways for vaginal lubrication and orgasm in women are similar. Sacral parasympathetics mediate reflex genital vasocongestion and lubrication, thoracolumbar sympathetics mediate psychogenic vasocongestion and lubrication, the efferent control of the motor component of orgasm is mediated by the sympathetics, and the sensory experience of orgasm is mediated by the vagus nerve (Griffith & Trieschmann, 1975; Sipski & Arenas, 2006).

LOCAL PHYSIOLOGY OF ERECTION AND THE ROLE OF NITRIC OXIDE (NO)

For over 20 years nitric oxide has been recognized as an important neurotransmitter for erectile function in men—and, homologously, for clitoral vasocongestion in women. Much evidence exists to strongly implicate NO in the physiology of penile erection. Rajfer et al. (1992) and Kim et al. (1991) independently demonstrated that nonadrenergic-noncholinergic (NANC) neurotransmission in the corpus cavernosum involves NO (Kim, Azadzi, Goldstein, & Saenz de Tejada,

Box 78.1 CLASSIFICATION OF ERECTIONS

Reflex Erections

- Produced by direct stimulation of the penis
- Mediated by the parasympathetic nervous system
- Require the S2–S4 nerve roots (sacral reflex arc) to be intact
- Occur independently of erotic stimuli or thoughts
- Are generally preserved with spinal cord injury above the L2 vertebral level (S2–S4 nerve roots)

Psychogenic Erections

- Produced by thoughts and erotic stimuli
- Mediated by the sympathetic nervous system
- Occur independently of direct stimulation of the penis
- Require the thoracolumbar nerve roots be intact
- Often lost with injury to the thoracic and cervical cord

1991; Rajfer, Aronson, Bush, Dorey, & Ignarro, 1992). NO was shown to induce cavernosal smooth-muscle relaxation. Azadzoi et al. demonstrated that endothelium-dependent relaxation, a cholinergically mediated function, also involves NO pathway (Azadzoi et al., 1992). Using various animal models, several investigators have shown that inhibitors of NO-synthesis prevent or attenuate penile erection *in vivo* and *in vitro* (Burnett, Lowenstein, Bredt, Chang, & Snyder, 1992; Seftel, Viola, Kasner, & Ganz, 1996).

NO is a neurotransmitter synthesized from L-arginine via a reaction catalyzed by nitric oxide synthase (NOS). Three NOS isoforms have been identified: endothelial NOS (eNOS), neural NOS (nNOS), and inducible NOS (iNOS) (Seftel et al., 1997).

The last of these is induced within macrophages by cytokines such as gamma-interferon. Inducible NOS is persistent once induced; it is inhibited by glucocorticoids. The penile corpora cavernosa contain nNOS, eNOS and/or iNOS; inhibition of the form(s) of NOS present in an individual patients will impair erectile function (Garban et al., 1997; Seftel et al., 1997).

EFFECT OF SPINAL CORD INJURY ON SEXUAL FUNCTION

The ability to obtain an erection and to produce an ejaculate in a male patient with SCI depends on many factors, such as level of the lesion, the completeness of the lesion, and the patient's comorbidities. The residual sexual function of an SCI patient should be assessed with a standardized neurological examination reported using the International Standards for Neurological Classification of Spinal Cord Injury (ISNCSCI) worksheet (American Spinal Injury Association, 2013), shown in Figure 78.xx. The ISNCSCI examination includes testing of light touch and pinprick sensation in each dermatome on each side as well as the perception of deep anal pressure; motor testing includes rating voluntary contraction of key muscles in the four extremities, and evaluation of voluntary anal contraction.

Reflexogenic erections are mediated by sacral parasympathetic nerves arising from the S2-S4 roots. Reflex erection requires preserved (though not necessarily completely normal) sensation in sacral dermatomes and an intact parasympathetic nerve supply to the penis. Psychogenic erection is mediated by sympathetic nerves arising from T10 through L1; thus it can be preserved after damage to sacral cord or cauda equina that cause the loss of reflex erections. Complete cord lesions above T10 lead to a loss of psychogenic erections as the sympathetic nerve nuclei are disconnected from cerebral input (Sipski, Alexander, Gomez-Marin, & Spalding, 2007).

The degree of preservation of combined pinprick and light-touch sensation in the T11-L2 dermatomes can be used to predict patient's ability to achieve psychogenic erections. As reflexogenic erections rely on an intact S2-S4 reflex arc, assessing the functionality of the bulbocavernosus reflex can aid in determining the level of a spinal cord lesion. Although the efferent limb of the bulbocavernosus reflex is

somatic rather than parasympathetic, the function of the somatic efferent nerves is closely correlated with that of the autonomic efferents. The reflex is tested by pressing firmly on the glans penis (or glans clitoris in women) or tugging on an indwelling Foley catheter and looking for contraction of the anal sphincter or movement of the perineum. For an individual with either complete or incomplete SCI with preserved sensation and/or voluntary motor control of the S2-S5 area and any presence of a bulbocavernosus reflex, reflexogenic erections are typically preserved. In some patients the bulbocavernosus reflex cannot be elicited clinically but can be shown to be present with electrical stimulation of the penis and EMG recording from the bulbocavernosus muscle (Podnar, 2008).

Patients with a complete injury at S2-S5 will have an absent bulbocavernosus reflex and will be unable to have reflexogenic erections. Psychogenic erections are possible if the sympathetic nerve supply of the penis remains intact. While such erections are less rigid than either reflexogenic erections or erections produced in uninjured men, they can be adequate for intercourse, especially if intensified by the use of PDE5 inhibitors. When reflexogenic erections do not take place in patients with suprasacral lesions, concurrent peripheral nerve damage may be present.

Even a complete SCI is compatible with the capacity for orgasm if the sacral cord is intact between S2 and S5, and the sympathetic innervation of the penis is preserved. A precondition for physiological orgasm is the presence of bulbocavernosus and/or anal wink reflexes (Sipski, Alexander, & Rosen, 2001).

To have a satisfying sexual life, a patient with SCI must find ways to experience sexual pleasure that circumvent sensory and motor deficits. Fortunately, SCI patients can learn to experience sensual pleasure and sexual excitement from stimulation of areas that were not sexually salient before the injury. Patients can discover new "erogenous zones" spontaneously, or they can follow suggestions from physicians, professional sex educators, or peers with SCI who have successfully adapted their post-injury sex lives. Typically after SCI there is a level below which there is no sensation and a level above which there is intact sensation. In the zone of transition between these two levels sensation is altered, and that altered sensation sometimes becomes a source of erotic pleasure (Tepper, 2002). For example, women with thoracic cord lesions that put their breasts in a sensory transition zone might experience increased pleasure from breast stimulation, and might be able to reach orgasm from breast stimulation alone when that was not the case pre-SCI.

About two-thirds of men with SCIs are eventually able to experience orgasm after recovering from their acute injury. Compared with their orgasms before their injury those experienced following SCI take more time and more stimulation to achieve, and usually involve stimulation in multiple sensory modalities as well as mental imagery from memories or fantasies. Most men having post-SCI orgasms would rate them as weaker than the ones they had before (Dahlberg, Alaranta, Kautiainen, & Kotila, 2007; also see Box 78.2).

**Box 78.2 RELATION OF LEVEL OF INJURY
TO SEXUAL FUNCTION EFFECT**

Cauda Equina/Conus Injury

Flaccid bladder

- Loss of external urethral tone
- Loss of anal tone
- Bulbocavernous reflex absent

Males

- Usually no reflex erections
- Rare psychogenic erection
- Occasional ejaculation

Females

- Vaginal secretion often absent
- Patients generally fertile

Lumbar Injury

Reflex bladder

- Anal and external urethral tone present

Males

- Reflex erections can occur
- Psychogenic erections can occur
- Ejaculation is rare

Females

- Vaginal secretions present as part of sacral/genital reflex
- Fertility is preserved

Thoracic/Cervical Injury

Reflex bladder

- Anal sphincter tone present
- External urethral sphincter often spastic

Males

- Reflex erections predominate
- Psychogenic erections are generally absent
- Ejaculation occurs occasionally

Females

- Vaginal secretions are present as part of genital reflex
- Fertility is preserved

Sensation of labor pain is absent

INITIAL REHABILITATION

Traumatic SCI entails severe impairments in physical function that translate into functional dependencies and medical risks. In a matter of seconds, individuals are transformed from fully functioning adults into people who depend on others for their very existence (DeLisa & Gans, 1998).

During initial rehabilitation following SCI, a patient must learn to accomplish everyday physical activities despite his or her impairments, including getting around and dealing with one's bowels and bladder. Acquiring mobility usually entails learning to use a wheelchair. Managing a neurogenic bladder usually requires learning the technique of intermittent self-catheterization. Avoiding both constipation and fecal incontinence requires an effective bowel program. The basic

issues of physical rehabilitation overlap with the issues of the patient's post-SCI sexual life. SCI patients' difficulties in physically positioning themselves for sexual activity are a major reason for unsatisfying sexual experiences. For both men and women, concern about incontinence during sexual activity can diminish sexual confidence and sexual desire, and the associated anxiety can interfere with sexual arousal and the ability to experience orgasm. (This problem can sometimes be mitigated by good communication between the sexual partners about the issue, accompanied by a sense of humor when accidents do happen.) Adjustment to SCI is best facilitated through a multidisciplinary team approach. Central to the team are a psychiatrist or psychologist and a urologist familiar with SCI; the input of a neurologist can help in complex cases. Virtually all patients will have sexual concerns following SCI, but they will vary in the ease with which they will talk about them, in the best way to deliver information, and in the best time for introducing information. Sexual concerns often arise immediately following SCI, but the patient may at first only be able to take in basic information and reassurance that when a person with SCI wants a sexual life there is almost always a way to have one. As patients recover from their injuries they—and their partners or spouses—will have many more questions. Community studies of SCI patients suggest that needs for education and assistance with sexual issues often are neglected in the months following acute rehabilitation (Forsythe & Horsewell, 2006). A medical psychiatrist involved in the outpatient treatment of a SCI patient can help the patient access sexual information and sexual rehabilitation during this post-acute phase. Internet-based education and peer support groups complement treatment by professionals; many patients prefer to learn from other SCI patients how they solved sexuality-related problems.

Virtually all men with SCI have early concerns about their capacity for erection and ejaculation, and most women are concerned about arousal and orgasm. Women in relationships often worry about how their physical dependencies and changes in sexual function will impact their relationship with their spouse or partner. Men and women who have not yet had children are concerned about the impact of the SCI on their fertility.

The development of a confident yet realistic self-concept is often a precondition to a satisfying sexual life post-SCI; at the same time having a satisfying sexual and emotional relationship with a spouse or partner can be a great help in developing a positive self-concept. Attention to family relationships, assessment and treatment of sexual dysfunction, management of specific physical symptoms, and addressing mental health issues complement one another in the rehabilitation of the patient with SCI.

PSYCHOLOGICAL CONSIDERATIONS IN SCI REHABILITATION

Patients with SCI must adjust to a new body-image, implying an altered self-concept. At times the initial self-concept is a negative one, with patients seeing themselves as disfigured

and helpless, useless and burdensome to others. They may feel socially isolated, alone with their pain and suffering. The future may seem oppressively, uncertain.

During the period of rehabilitation patients will face a range of medical complications and physical symptoms. These include incontinence, urinary tract infections, respiratory problems, unstable vital signs, pain, spasticity, joint contractures, skin breakdown, and sexual dysfunction, notably erectile dysfunction in male patients. Understanding these problems and actively managing can build a patient's self-confidence and sense of mastery. Physicians can help by seeing their task as enabling their SCI patients to care for themselves, and to help their loved ones assist them in doing so.

DEVELOPMENTAL PERSPECTIVE

Most spinal cord injuries are sustained by male adolescents and young adults. These patients' developmental tasks comprise separating from one's family of origin, completing one's education, establishing oneself in productive work, and making and maintaining intimate relationships. The consequences of the SCI disrupt, delay, modify or redirect the patient's efforts to accomplish these tasks. Further, the SCI itself might have occurred because of risk-taking behavior that represented independent self-assertion—potentially raising issues of blame, self-blame, shame and guilt. A sense of grief over lost functions and lost opportunities is universal.

Successful adaptation following SCI requires working through the grief reaction without becoming immobilized by it, and requires resumption of the patients developmental tasks, with appropriate changes in details and pace. Educational or occupational accomplishments are typical objective measures of successful adaptation.

MANAGING ANGER AND NONCOMPLIANCE DURING REHABILITATION

In many cases, the patient's emotional reaction fluctuates between intense feelings of depression and anger. Patients sometimes experience feelings of self-blame regarding their injury and sometimes feel that others have disappointed them and abandoned them in their hope to recover fully—a hope that many patients hold on to for years after the injury. Even the most cooperative patients can become overly demanding in their attitude and behavior toward staff members. Throughout the patient's hospitalization, anger and excessive demands are best handled by reassurance and firm limit-setting by the rehabilitation staff. Setting firm and clear limits is essential for the patient to feel safe and cared about (Krueger, 1984). However, limit setting must be done in an empathetic and supportive manner so as not to be viewed as punitive. (See Chapter 40 for further discussion of limit setting.) Limit setting communicates expectations and encourages a sense of independence and self-control. Patients learn that they must still assume responsibility and meet certain expectations, despite the severity of their injury. Staff and family should promote as much independence as possible and not be

excessively solicitous and helpful in a way that fosters behavioral regression.

If a patient continues to demonstrate noncompliance and anger despite consistent and sympathetic limit setting and adequate emotional support, a formal behavior therapy program should be considered. A psychologist skilled in behavior therapy can design a program that reinforces the patient's cooperation and active participation in rehabilitation and other medical care. Such programs often include a written contract between patient and staff that makes clear the patient's responsibility, what the staff will and will not do for the patient, and the consequences of further noncompliance with medical treatment. Involving significant others—family or friends—in addressing anger and noncompliance often helps. However, the physician should not meet with significant others without the patient present, unless the patient knows and agrees.

Negative self-concepts and poor family relationships that existed before injury generally persist after injury and may even be exacerbated. But maintaining normal relationships, when they exist, is important and must be encouraged. Dysfunctional relationships and poor family systems should also be addressed through family or couple therapy when problems either predate the injury or surface after the rehabilitation process. Often after an SCI, family communication is diminished, and the stress of an injured family member can intensify underlying family psychopathology. However, the involvement of positive and supportive family members can only improve patient cooperation and further the goals of the medical team. Groups for caregivers and family members led by experienced clinicians can be very helpful for patients and their family members alike.

In many respects, the entire family structure and extended support system must adjust to the disability. The impact on the family is not only emotional, but also often physical and economical. The roles and responsibilities previously assumed by the person with the SCI must be temporarily or permanently assumed by other members of the family. In addition, new responsibilities for the physical care of the person with the disability may be assumed by family members. The family must be an integral part of any treatment program, for they will need assistance in coping with the disability and their response to the disabled person, and in dealing with their own feelings, responsibilities, and increased pressures. An early assessment of the capacity of the family to cope and manage with such changes is critical in integrating the patient successfully back into the community. In view of the potential impact of SCI on a family's income and its expenses, consulting an accountant or financial planner is a frequently useful recommendation to the family. Depression is a common psychiatric sequel of SCI, with the point prevalence of a clinically diagnosable depressive disorder being approximately 22% in patients who have had a SCI, according to a recent meta-analysis. This is significantly higher than the 6.7% reported 12-month prevalence of depressive disorders in general medical clinic populations (Williams & Murray, 2014). This after an SCI, Grief and sadness are observed in most patients following SCI; it is clinically important to distinguish a

depressive disorder needing pharmacologic treatment from a grief reaction best managed with support and empathy. In any case, when depressive symptoms cause functional impairment or interfere with physical rehabilitation they should be treated, regardless of the precise diagnosis of a specific depressive disorder. SSRIs, the first-line treatment of depression for most clinicians, have drawbacks in the SCI population, which is particularly vulnerable to their sexual side effects. Alternatives to SSRIs and SNRIs such as bupropion, mirtazapine, vilazodone and perhaps vortioxetine should be considered (Clayton, Croft, & Handiwala, 2014). Furthermore, recent research suggests that SSRIs can have adverse effects on semen quality (Koyuncu, Serefoglu, Ozdemir, & Hellstrom, 2012). It is not yet certain which antidepressants will not adversely effect semen, so if the issue is relevant for a particular patient performing a semen analysis before and after instituting therapy with an antidepressant would be a reasonable precaution. Selective serotonin-reuptake inhibitors (SSRIs) have been first-line treatments for many years, though recent research has raised the issue of a deleterious effect of SSRIs on semen quality. For male SCI patients planning to father children, alternatives to SSRIs should be considered when it is necessary to treat depression.

Reactive depression, or a relatively transient adjustment disorder marked by grief, is most frequently noted, especially among individuals who were extremely active prior to the injury and relied on physical activity to deal with problems in the past. If the depression persists, or if the patient demonstrates suicidal ideation, medication may need to be reconsidered. This is especially true if there are not adequate emotional supports in the community or if the patient's safety becomes a concern.

ASSOCIATED TRAUMATIC BRAIN INJURY

Spinal cord injury often is accompanied by traumatic brain injury (TBI) (Caplan, 1982). TBI is especially common in connection with lesions of the high cervical cord. In such cases, neurological consultation and neuropsychological assessment are necessary to determine the nature, severity, and implications of the brain injury. Assessment can be difficult, however, when functional impairments due to the SCI limit the use of usual procedures for testing brain function. For this reason, TBI concurrent with SCI sometimes goes undiagnosed. Neurology and neuropsychology should typically be consulted early after admission in every case of upper cervical cord injury and in cases where the patient or others are concerned about a change in mental functioning or the patient's behavior during rehabilitation raises an issue of impairment in memory or other cognitive functions. Neurological and/or neuropsychological assessment may need to be repeated, for example when recovery from acute physical impairments enables a more detailed examination for more subtle cognitive functions. Re-evaluation is also important when a patient's cognition, memory, and/or communication improve markedly, as they might if the patient had a brief hypoxic episode at the time of the SCI. Characterization of neuropsychological deficits and offering a prognosis for them is essential in planning

rehabilitation and planning for the patient's ultimate return to the community. Neuropsychological status, along with mental health, is more critical to the feasibility of independent living after an SCI than is the level of the spinal injury or the degree of impairment of motor function. The approach taken to physical and occupational therapy, and to physician-patient interaction, will be more explicit, concrete, repetitive and multi-modal if the patient's intellectual function has been impaired by a concurrent TBI. Cognitive impairment also bears on issues capacity, competency, and consent.

ASSOCIATED SUBSTANCE ABUSE

Addressing alcohol and chemical dependency and abuse is especially critical in patients with SCI. Often the onset of such an injury is related to substance abuse. Vehicular crashes, sporting accidents, and falls, especially while the individual is under the influence of alcohol, account for a large proportion of admissions to rehabilitation centers (Schnoll, Heinemann, Doll, & Armstrong, 1989). In other cases, secondary complications of the SCI are related excessive drinking of alcohol or the misuse of various prescription or nonprescription medications. Many young people with SCI have had substance abuse problems before their injury and continue these patterns long afterwards. Despite the relatively high prevalence of substance use disorders in SCI patients, substance abuse issues often are neglected by physicians treating such patients, perhaps because their physical disabilities are so salient. Routine, structured screening for substance use disorders mitigates this problem. Screening for alcohol use disorders is important both because of the impact of excessive alcohol on bodily functions as well as on behavior. Alcohol can potentiate the action of prescribed medications, most notably central nervous system depressants including opiate analgesics and many of the drugs used to treat spasticity and neuropathic pain. In addition, altered consciousness due to alcohol or its combination with prescription drugs can make SCI patients insensitive to prolonged pressure on the skin, leading to the development of pressure ulcers. If excessive alcohol is regularly ingested in the form of beer, the large fluid volumes consumed can seriously compromise a bladder-retraining program.

Alcohol use disorders are highly prevalent in the SCI population. A retrospective claims review study of 8338 SCI patients in veterans' clinics showed that over a 2-year period 12% had diagnoses of alcohol use disorders and another 14% had comorbid alcohol use disorders and mental illness (Banerjee, Findley, Smith, Findley, & Sambamoorthi, 2009). A survey of 1,549 civilian SCI patients found that 19.3% were heavy drinkers (Saunders & Krause, 2011). The period of acute rehabilitation following SCI offers an opportunity for secondary prevention of substance abuse disorders in those with pre-injury substance abuse, because patients are forcibly confronted with the consequences and/or risks of heavy drinking. In a study of 139 consecutive admissions to an acute inpatient SCI rehabilitation hospital, 38% reported lifetime alcohol-related problems and 33% reported recent

illicit drug abuse. 71% of at-risk drinkers reported either considering changes in their alcohol use or were already taking action (Stroud, Bombardier, Dyer, Rimmele, & Esselman, 2011). Notwithstanding, personal and family denial of the substance abuse can still be a problem, particularly in more severely affected patients.

With regard to drug abuse, a special concern with SCI patients is the abuse of prescription drugs. Patients with SCI frequently receive appropriate prescriptions for controlled substances including opiates and benzodiazepines. These drugs produce physiologic tolerance and dependence, leading to escalating consumption in patients vulnerable to substance abuse.

For patients with such problems, substance abuse intervention needs to begin early after admission to treat withdrawal reactions, and continue following discharge from the acute inpatient rehabilitation program. Potential interventions include individual counseling from a substance abuse specialist, group or self-help meetings, and discharge to a day or residential substance abuse program. In more extreme cases, treatment of the substance abuse disorder before or concurrent with the initiation of physical rehabilitation is necessary. Timely access to substance abuse treatment can be impeded by delayed recognition of the problem, denial, and local unavailability of appropriate treatment programs. Education about substance abuse for physicians treatment SCI patients, and education about SCI for substance abuse professionals, can help address the problem of access, and the medical psychiatrist working with a SCI service may be able to provide or facilitate this education. Use of structured screening instruments for alcohol and drug use disorders is becoming a standard of practice in acute SCI rehabilitation settings. Periodic re-screening for substance abuse should be considered during long-term follow up. In particular, patients who had SCIs in adolescence can develop substance abuse problems in adulthood; 55% of patients aged 21–25 who had adolescent SCIs reported regular alcohol use (Hwang, Chlan Vogel, & Zebracki 2012).

It is hoped that systematic assessment and concurrent treatment of substance abuse disorders will become routine SCI rehabilitation centers, since such disorders a significant risk factor for later medical complications of SCI. Although some progress has been made, the lack of standard policy and inadequate training continue to be issues.

In summary, spinal cord injury is a life-threatening physical trauma and an intense psychological assault. Adjustment to this injury is a multifaceted process that continues throughout the patient's life. It has a highly variable course that is influenced by the patient's personality, coping style, level of injury, pre-injury mental health and cognitive function, concurrent injuries, comorbid mental illness, and social, financial, and community resources. As the patient undergoes the rehabilitation process, the support and reassurance of the rehabilitation team are fundamental to the patient's adjustment. Setting limits when needed provides a sense of safety to patients, reducing their anxiety. If emotional issues are not addressed from the outset of rehabilitation, one can expect the recurrence of medical complications, long periods of emotional turmoil, and

greater difficulty with re-entry into the community. Health professionals have an obligation to address such issues and to assist the patient in achieving a satisfying and rewarding life after SCI. The involvement of a medical psychiatrist in the rehabilitation team helps the team meet this obligation. Initially, psychotherapy SCI patients emphasizes issues of anger, despair depression, self-esteem, and body-image. Sexual concerns a relevant to all of these themes, and beginning to address them early on can improve the outcome of psychotherapy.

INITIAL EVALUATION AND MANAGEMENT OF SCI WITH ATTENTION TO SEXUAL REHABILITATION

Erections are initially lost during the period of spinal shock and may take several days to weeks to return with an incomplete lesion, and possibly a year or more with complete lesions. Invasive treatments for sexual dysfunction (e.g., penile implants) should be avoided during this time, as sexual function can recover spontaneously over a year or even longer following SCI. Furthermore, sexual function takes place in a context of culture, medical conditions, partner relationships, current mental health and substance use, current function, and the patient's evolving existential situation. One exception might be made to this principle, however—the retrieval of sperm from younger male patients during the first two weeks following the injury, if they are sufficiently stable medically. This issue will be discussed further below.

Initiating a dialogue with the patient about sexuality is important and should be done early in the rehabilitation process. Sexuality consistently is identified as one of the most important topics for individuals after SCI (Widerstrom-Noga, Felipe-Cuervo, Broton, Duncan, & Yeziarski, 1999). A patient's readiness to hear and discuss issues of sexuality will vary from one individual to another. Some patients may want their healthcare providers to do nothing more than dispel myths or clear up misconceptions while others may be ready to listen to more detailed information about their sexual functions. In many cases, the sexual history is the first step in sexual education because it introduces a sensitive topic and aids in establishing rapport. Questioning should be done in a nonjudgemental and straightforward manner. The goal of the examiner is to determine the patient's interest and readiness to learn about sexual functioning following his or her SCI, while being aware that some patients initially may not feel comfortable talking about the topic directly. An important component of the initial evaluation is to ask individuals with SCI if they have experienced any previous sexual trauma, sexual dysfunction, or a sexually transmitted disease that could affect their sexual functioning following injury. Should a preexisting problem exist, the patient should be referred to the appropriate specialist—often a medical psychiatrist. A physical examination using the ISNCSCI form (Figure 78.1) should be performed. Special attention to the preservation

REV 04/11

Figure 78.1 International Standards for Neurological Classification of Spinal Cord Injury (ISNCSCI) Examination Sheet.

Muscle Function Grading

0 = total paralysis

1 = palpable or visible contraction

2 = active movement, full range of motion (ROM) with gravity eliminated

3 = active movement, full ROM against gravity

4 = active movement, full ROM against gravity and moderate resistance in a muscle specific position.

5 = (normal) active movement, full ROM against gravity and full resistance in a muscle specific position expected from an otherwise unimpaired person.

5* = (normal) active movement, full ROM against gravity and sufficient resistance to be considered normal if identified inhibiting factors (i.e. pain, disuse) were not present.

NT = not testable (i.e. due to immobilization, severe pain such that the patient cannot be graded, amputation of limb, or contracture of >50% of the range of motion).

ASIA Impairment (AIS) Scale

☐ **A = Complete.** No sensory or motor function is preserved in the sacral segments S4-S5.

☐ **B = Sensory Incomplete.** Sensory but not motor function is preserved below the neurological level and includes the sacral segments S4-S5 (light touch, pin prick at S4-S5: or deep anal pressure (DAP)), AND no motor function is preserved more than three levels below the motor level on either side of the body.

☐ **C = Motor Incomplete.** Motor function is preserved below the neurological level**, and more than half of key muscle functions below the single neurological level of injury (NLI) have a muscle grade less than 3 (Grades 0-2).

☐ **D = Motor Incomplete.** Motor function is preserved below the neurological level**, and at least half (half or more) of key muscle functions below the NLI have a muscle grade ≥ 3 .

☐ **E = Normal.** If sensation and motor function as tested with the ISNCSCI are graded as normal in all segments, and the patient had prior deficits, then the AIS grade is E. Someone without an initial SCI does not receive an AIS grade.

**For an individual to receive a grade of C or D, i.e. motor incomplete status, they must have either (1) voluntary anal sphincter contraction or (2) sacral sensory sparing with sparing of motor function more than three levels below the motor level for that side of the body. The Standards at this time allows even non-key muscle function more than 3 levels below the motor level to be used in determining motor incomplete status (AIS B versus C).

NOTE: When assessing the extent of motor sparing below the level for distinguishing between AIS B and C, the **motor level** on each side is used; whereas to differentiate between AIS C and D (based on proportion of key muscle functions with strength grade 3 or greater) the **single neurological level** is used.

Steps in Classification

The following order is recommended in determining the classification of individuals with SCI.

- Determine sensory levels for right and left sides.
- Determine motor levels for right and left sides.
Note: in regions where there is no myotome to test, the motor level is presumed to be the same as the sensory level, if testable motor function above that level is also normal.
- Determine the single neurological level.
This is the lowest segment where motor and sensory function is normal on both sides, and is the most cephalad of the sensory and motor levels determined in steps 1 and 2.
- Determine whether the injury is Complete or Incomplete. (i.e. absence or presence of sacral sparing)
If voluntary anal contraction = No AND all S4-5 sensory scores = 0 AND deep anal pressure = No, then injury is COMPLETE. Otherwise, injury is incomplete.

- Determine ASIA Impairment Scale (AIS) Grade:

Is injury Complete?

NO

If YES, AIS=A and can record ZPP (lowest dermatome or myotome on each side with some preservation)

Is injury motor Incomplete?

YES

If NO, AIS=B (Yes=voluntary anal contraction OR motor function more than three levels below the motor level on a given side, if the patient has sensory incomplete classification)

Are at least half of the key muscles below the single neurological level graded 3 or better?

NO

AIS=C

YES

AIS=D

If sensation and motor function is normal in all segments, AIS=E

Note: AIS E is used in follow-up testing when an individual with a documented SCI has recovered normal function. If at initial testing no deficits are found, the individual is neurologically intact; the ASIA Impairment Scale does not apply.

Table 78.1 PHYSICAL EXAMINATION FINDINGS AFTER SPINAL SHOCK*

PARAMETER	INJURY LEVEL		
	SPINAL SHOCK	CAUDA EQUINA	THORACIC/CERVICAL
Rectal tone	Absent/decreased	Absent/decreased	Increased
Bulbocavernous reflex	Absent/decreased	Absent/decreased	Present
Perineal sensation	Absent/decreased	Absent/decreased	Absent
Reflex penile erections	Absent/decreased	Absent/decreased	Present
Spontaneous bladder contractions	Absent	Absent	Present

*Spinal shock generally lasts from several days to approximately six weeks after spinal cord injury.

Table 78.2 COMMONLY USED MEDICATIONS IN SCI PATIENTS

DRUG	PURPOSE	SIDE EFFECTS
Oxybutynin	Bladder relaxant	Dry mouth; impotence
Propantheline	Bladder relaxant	Dry mouth; impotence
Baclofen	Muscle relaxant	Drowsiness; impotence
Diazepam	Muscle relaxant	Drowsiness
Phenoxybenzamine	Sphincter relaxant	Hypotension; inhibition of ejaculation
Prazosin	Sphincter relaxant	Hypotension; inhibition of ejaculation
Terazosin	Sphincter relaxant	Hypotension; inhibition of ejaculation
Tamsulosin	Sphincter relaxant	Hypotension; inhibition of ejaculation
Silodosin	Sphincter relaxant	Hypotension; inhibition of ejaculation

of sensation from T11–L2 and S2–S5, along with determination of the presence of voluntary anal contraction and the anal wink and bulbocavernosus or clitorocavernosus reflexes, can be used to predict remaining sexual function (see Table 78.1). Aside from a complete neurological exam, a thorough physical exam should be performed, assessing the breasts and genitalia, as well as screenings for cervical, ovarian, uterine, breast, prostatic, and testicular cancers. Screening for sexually transmitted diseases, including HIV/AIDS, should be provided as deemed appropriate on an individual basis. A thorough review of the patient's medications should be performed, as polypharmacy is the norm in individuals with SCI (see Table 78.2). More than 100 specific medications or classifications of medications have been associated with sexual dysfunction (Thomas, 2003). Some classes of medications that can affect sexual function include antidepressants (e.g., SSRIs, heterocyclic and tricyclic medications), neuroleptics, anxiolytics (e.g., diazepam), antiepileptic drugs, cardiovascular medications, sympatholytic agents, diuretics, lipid-lowering agents, vasodilators, gastrointestinal medications, opioids, anticholinergics, and chemotherapeutic agents. Following the sexual evaluation, the healthcare provider should be able to develop a treatment plan based on the individual's physical examination, sexual history, and specific personal concerns.

Following the injury, the patient is usually hospitalized for a long period of time to undergo multidisciplinary rehabilitation. Should a patient be ready to explore sexual issues with a partner or himself, offering a private apartment or hospital room for intimacy is an important statement and a first step in restoring post-injury sexual confidence (SRH SCI Guideline, 2010). Information on sexual assistive devices (sex toys) should be provided, along with education on their cautions and contraindications. For example, penile rings can interfere with normal blood flow from the penis and should never be kept in place for longer than 30 minutes. Vibrators may cause dysreflexia in individuals with SCI at T6 and above, while any device that causes friction on the skin may lead to skin breakdown.

PHYSICAL AND PRACTICAL CONSIDERATIONS

Once an SCI patient is ready to engage in sexual activity, he or she can be discouraged by functional limitations, mobility issues, equipment concerns, and so on. In addition, it is important that people with SCI and their partners understand how such issues as bladder and bowel management, skin care, and risk of autonomic dysreflexia (AD) can affect their sexual functions. Because many people may not become sexually active until long after the injury occurs, they may not be aware of the full impact of the injury on their sexual activity.

As many SCI patients have bladder dysfunction along with external drainage devices, incorporating bladder management into their sexual routine becomes important. Although bladder incontinence during intimate activity

may be a source of anxiety, it does not necessarily preclude the enjoyment of sexual activity for people with SCI (Anderson, Borisoff, Johnson, Stiens, & Elliott, 2007a, 2007b). Men should determine if having a full bladder assists with or impairs their ability to achieve an erection and should use this information to determine when to empty their bladders. However, a full bladder may cause increased sympathetic activity that can result in AD. This possibility must be discussed and contingency plans put in place should AD occur. Towels or disposable protective bed pads can be used in case leakage or secretion of bodily fluids occurs. Persons with SCI using indwelling urethral catheters need to take precautions to prevent dislodging or contaminating them during sexual activity. For some people, removing the catheter and replacing it after sexual activity is preferred, although this may be problematic if assistance from an untrained partner is necessary. Some men who use indwelling catheters fold the tubing down the shaft of the penis or clamp the end of the catheter and place a condom over the penis and tubing prior to intercourse. This technique can damage the balloon port tubing and cause the balloon to remain inflated. Damage to the balloon port may cause bladder distention, ultimately resulting in a urinary tract infection, sepsis, or AD in men who have injuries at T6 and above. To avoid AD as a result of the issues associated with an indwelling catheter, some people with SCI find that a switch to a suprapubic catheter may be more conducive to sexual activity. Patients who perform intermittent catheterization would simply drain the bladder before sexual activity, and perhaps restrict fluids for a few hours before sex. Instillation of oxybutynin at the time of the last catheterization before intercourse is used by some SCI patients to further reduce the risk of urinary incontinence during or after intercourse (Vaidyanathan et al., 1998). The presence of skin wounds and healing ulcers does not preclude a person with SCI from having sexual relations. They should avoid activities or practices that could exacerbate their skin condition. Dressings should be reapplied following sexual activity if they became dislodged. A practice that should be incorporated into a sexual routine is examining insensate skin regions at its conclusion. Women may experience decreased or absent genital lubrication, and men may experience decreased pre-ejaculatory fluid, resulting in irritation of the skin during intercourse. Use of artificial water-soluble lubricants (preferably gels) can provide additional lubrication, but it is recommended that lubricants be uncolored and unflavored. The gel should be applied to the genitals prior to intercourse. If the person with SCI has limited hand mobility, the partner can apply the lubrication as part of the sexual encounter (SRH SCI Guideline, 2010).

Persons with SCI at or above T6 are at risk for AD, which is the body's response to stimulation with an increase in sympathetic output (Sheel, Krassioukov, Inglis, & Elliott, 2005). Individuals with SCI who are at risk for AD should receive early basic education on how to prevent, respond to, and intervene if AD should occur. Symptoms and signs of AD comprise elevated blood pressure that can reach dangerously high

levels,, slowed heart rate, pounding headache, sweating, flushing, pallor, nasal congestion, blurred vision, nausea, and piloerection. Sexual activity, especially orgasm and ejaculation, can trigger the onset of AD. If an individual experiences AD during sexual activity, the activity should stop, and the person should sit up immediately while the medical provider is notified. Even if warning signs subside, the individual should be instructed to call a healthcare provider. The use of prophylactic medication, such as sublingual nifedipine, prazosin, or nitroglycerin paste, should be considered after physician assessment (SRH SCI Guideline, 2010).

RESTORATION OF ERECTIONS

Erectile dysfunction is defined as "the inability to attain and/or maintain penile erection sufficient for satisfactory sexual performance" (Montague et al., 2005). Within six months following SCI, 60–80% of males will have the ability to obtain an erection, depending on the completeness and level of the lesion (Tsuji, Nakajima, Morimoto, & Nounaka, 1961). Eventually, 80–95% will be able to achieve an erection of some kind—reflexogenic, psychogenic, or mixed. Although not absolutely determinative, the level of spinal cord lesion can be predictive of preserved erectile function. In a systematic review, covering 12 observational studies, Higgins reported that 85–90% of patients with T12 and above lesions maintained erectile function of any kind, while those with lesions L1 and below preserved function 40–80% of the time (Higgins, 1979). Reflexogenic erections are preserved in approximately 80% of patients with T12 lesions and above, while psychogenic erections remain only 0–10% of the time in the same population. In patients with lesions L1 one study found capacity for psychogenic erections in 40–50% (Higgins, 1979).

Even though most men with SCI can have erections, they may not be of sufficient rigidity or duration for intercourse. The percentage of successful intercourse without treatment in men with SCI ranges from 5–75%, depending on the level and completeness of injury (Moemen, Fahmy, AbdelAal, Kamel, Mansour, & Arafa, 2008).

Current guidelines recommend a stepwise approach to erectile dysfunction by starting with conservative measures first, while keeping surgical treatment as an option for refractory cases. The first step should be to encourage men with SCI to enhance their existing sexual function before using medical interventions. Does the patient have the ability to become aroused naturally? Has the patient tried stimulation of areas with preserved sensation, even if there were not erogenous zones of choice before the injury? In addition, healthcare providers should discuss treatments that can be used to address pain, spasm, incontinence, or other interfering factors (SRH SCI Guideline, 2010). Once these issues are addressed and their management is optimized, hypogonadism, which is discussed in a later section, should be ruled out. This can be a cause of decreased libido, worse erectile dysfunction, and a less satisfactory response to PDE5 inhibitor therapy, and replacement therapy should be tried if the testosterone level is low (see Chapter 35). Men with erectile

dysfunction should be assessed for the capacity to achieve psychogenic or reflexogenic erections (Deforge et al., 2006). A thorough history will elucidate whether erectile dysfunction existed pre-injury. Men with SCI who are not able to attain or maintain an erection following injury need to be informed of all current medical options for treating ED, along with the efficacy, possible adverse reactions, and cost. With this in mind, the steps in the treatment ladder, which are similar to those for the non-SCI patient with ED, involve first the addition of oral medications, followed by injectable agents, then vacuum devices, and lastly surgical implantation of a penile prosthesis.

ORAL DRUG THERAPY

The discovery of phosphodiesterase type 5 (PDE5) inhibitors revolutionized the treatment of ED. PDE5 inhibitors prevent the intracorporal breakdown of cyclic guanosine monophosphate (cGMP), resulting in enhanced erection by prolonging smooth-muscle relaxation. It must be remembered that PDE5 inhibitors do not initiate an erection, they simply make one stronger. Physical stimulation and/or psychological arousal is required to initiate an erection before the medications can take effect. The medications, which include sildenafil, vardenafil, and tadalafil, have proven efficacy and a relatively benign side-effect profile. Phosphodiesterase isozymes exist elsewhere in the body, and PDE5 inhibitors have some affinity for them, giving each of the three options a different side-effect profile based on its binding to other phosphodiesterase isoenzymes. For example, PDE type 6 is located in the retina and is responsible for visual disturbances; these are most frequently seen with sildenafil. Absolute contraindications to the use of PDE5 inhibitors include the concomitant use of nitrates or the presence of retinitis pigmentosa. Relative contraindications include symptomatic hypotension, the use of alpha-blockers, and use of other erection-enhancement therapies, the last because of the risk of priapism with combined treatments. The main concern is inducing severe hypotension when using nitrates or alpha-blockers. Other side effects include headache, dyspepsia, flushing, and nasal congestion (Deforge et al., 2006). Both sildenafil's and vardenafil's systemic absorption is affected by fatty food, and patients should be instructed to take them on an empty stomach for greater efficacy.

Of the three PDE5 inhibitors approved by the Food and Drug Administration (FDA) for ED, sildenafil has been the most studied in SCI patients specifically. Sildenafil (Viagra) demonstrated superiority to placebo in a randomized, double-blind, placebo-controlled, flexible-dose, two-way crossover study. Seventy-six percent of men reported improved erections and preferred sildenafil over placebo. The median proportion of attempts at sexual intercourse that were successful was 55% with sildenafil treatment compared with 0% with placebo. Most patients required the maximal dose of 100 mg to achieve these results. Of note, 64% of the 25 patients in this study who had no erectile function at all prior to drug treatment had improvement with sildenafil (Giuliano et al., 1999).

The effectiveness of PDE5 inhibitors has been shown to depend on the level of injury. Reflexogenic erections are more often preserved in upper motor-neuron (UMN) injuries than in lower motor-neuron (LMN) injuries. In a study comparing the effectiveness of sildenafil in patients with either UMN or LMN injuries, sildenafil was effective in 82% of patients, and its efficacy was statistically higher than placebo's (82% vs. 25%, $p < 0.05$). However, 28% of patients with non-UMN lesions had a response rate similar to placebo. Sildenafil is more effective in the treatment of neurogenic ED secondary to UMN SCI compared with that secondary to LMN injury (Khorrami et al., 2010). It has also been shown that males with SCI with preserved function of at least one component of the erection phenomenon, reflexive and/or psychogenic, respond well to sildenafil, and the usual dose required to achieve erections sufficient for sexual intercourse is 50 mg (Schmid, Schurch, & Hauri, 2000). Successful intercourse was achieved by 93% of the patients. Complete absence of both types of erections correlated with a lack of response to sildenafil (Schmid et al., 2000).

Vardenafil and tadalafil both demonstrated statistically significant improvement in the International Index of Erectile Function erectile function domain score (22.0 and 22.6 vs. 13.5) and penetration efficacy (76% and 75.4% vs. 41%) when compared to placebo in SCI patients in two separate multi-center, randomized controlled trials (Giuliano et al., 2006, 2007). Soler et al., in an open-label study, demonstrated all three FDA-approved PDE5 inhibitors had similar efficacy and were safe in SCI patients (Soler, Previnaire, Denys, & Chartier-Kastler, 2007). Tadalafil has a longer duration of action than both sildenafil and vardenafil and was shown to be effective when taken 24 hours in advance of sexual stimulation (Del Popolo, Li Marzi, Mondaini, & Lombardi, 2004). When starting a patient on a PDE5 inhibitor, the lowest dose should be started; if it is shown to be ineffective, the dosage can then be up-titrated until a clinical response is achieved.

PDE5 inhibitors have been tested as treatment for sexual dysfunction in women; the literature is inconclusive. Case series suggest it can improve arousal and orgasm, but controlled studies have been inconclusive, in part because of a high placebo response rate (Foster, Mears, & Goldmeier, 2009; Chivers & Rosen, 2010). There have been no controlled studies specifically in women with SCI.

INTRACAVERNOSAL INJECTION OF VASOACTIVE MEDICATIONS

The next step in the therapeutic ladder for the treatment of ED in SCI patients after failure of oral medications is intracavernosal injection (ICI) of alprostadil (prostaglandin E1), papaverine, and/or phentolamine. The aforementioned injected substances are given as monotherapy or in combinations of two or three. Alprostadil works by activating adenylate cyclase, subsequently increasing cyclic adenosine monophosphate (cAMP). Papaverine non-selectively inhibits phosphodiesterases types 2–5, resulting in an increase in cAMP and cGMP. Phentolamine inhibits norepinephrine

Figure 78.2 Site of injection. The needle is inserted into the corpora cavernosa at the base of the penis.

from binding to the alpha-1 receptor and functions to inhibit detumescence. Deforge et al. in a systematic review pooled the results of eight case-series and showed a 90% “satisfactory erection” response rate in SCI patients using ICI (Deforge et al., 2006).

Bodner et al. reported their results with long-term follow-up on 50 men with SCI using ICI and demonstrated its safety and effectiveness. Monotherapy (papaverine) was used in 24 patients and dual therapy (papaverine and phenolamine) in the remaining 26 patients. Early complications included priapism in four patients, requiring aspiration of the corpora cavernosa and injection of a dilute epinephrine solution (1/100,000). Rigid erections were obtained in all but five patients who injected (95%). Late complications included penile plaque in three patients (6%). However, 31 (62%) of the patients eventually dropped out of the program, most during the drug-titration period. The next most common reason was the lack of a partner. The average frequency of injection was twice a month (Bodner, Leffler, & Frost, 1992). In another study, ICI of papaverine was compared to oral sildenafil in SCI patients with injuries less than one year and lesions T6 and below. Baseline erection characteristics were obtained and used as the control arm, followed by ICI of papaverine, and then after a washout period, oral sildenafil was given. Both ICI of papaverine and oral sildenafil were significantly more efficacious than placebo in enabling erections. Erections were of similar quality between the treatment arms, and it was concluded that either intracavernosal papaverine or oral sildenafil can be used to treat ED in SCI patients (Yildiz, Gokkaya, Koseoglu, Gokkaya, & Comert, 2011).

The initial trial dose of ICI therapy should be administered under healthcare provider supervision according to the American Urologic Association (AUA) Guideline on ED (Montague et al., 2005). After the man or his partner receives

instruction on the proper penile injection method, a careful titration of the medication is used to determine the correct dose and strength of the compound to allow for an erection to occur within 5–10 minutes and last approximately one hour. The proper technique is demonstrated in the figure below (see Figure 78.2). Some men with sensation in the penis may experience a short period of minor pain at the injection site, which can be reduced with proper injection technique. Pressure should be applied to the injection site to prevent scarring. Trauma from injections into the cavernosal tissue through the tunica may cause inflammation, thus resulting in tunica scarring, microhemorrhage along the needle track, and calcium deposits. These may lead to penile curvature. Priapism is another potential complication of injection therapy. Priapism is when an erect penis does not return to its flaccid state, despite the absence of physical and psychological stimulation, within four hours. Urological consultation should be sought in a patient with priapism. Due to the risk of priapism, it is recommended that only one injection be given per 24-hour period (Montague et al., 2005). Patients with LMN injuries, who are less likely to respond to PDE5 inhibitors, may respond to ICI. As PDE5 inhibitors are contraindicated in patients taking nitrates, ICI can be offered to this subgroup (Deforge et al., 2006).

VACUUM CONSTRICTION DEVICES

Vacuum constriction devices (VCDs) have been used for over a century to help improve erections in males with ED. A VCD consists of an elongated tube that is placed over the shaft of the penis. A vacuum is then created in the tube either by a battery-operated device or manual pumping action. As the vacuum is created, blood gradually fills the corporal chambers of the penis. When the penis achieves a satisfactory degree of rigidity, an elastic penile ring is slipped off the tube and placed over the base of the penis to contain the blood and maintain the erection so that sexual intercourse can occur. When used with proper instruction and according to the manufacturer’s specifications, VCDs have very low morbidity with no irreversible effects. Minor side effects include penile edema and petechiae. Subcutaneous penile hemorrhage in patients using anticoagulant therapy and penile gangrene are serious complications of which VCDs also are contraindicated in patients with sickle-cell disease. The ring should never be left on longer than 30 minutes (see Figure 78.3).

Heller et al. (1992) in a small study of 17 patients showed that after a mean follow-up of 21 months, over 50% of the patients were actively using their VCD. The frequency of coitus increased from 0.3 times per week to 1.5 times per week. It was concluded that VCDs are a noninvasive method to treat ED in males with SCI (Heller, Keren, Aloni, & Davidoff, 1992). Denil et al. (1996) reported on 20 couples using VCDs. After three months, 93% of the men and 83% of their partners reported rigidity sufficient for vaginal penetration, with an average duration of 18 minutes. At six months, 41% of the men and 45% of the women were satisfied with the VCD. The most commonly reported complaint was premature loss of rigidity during intercourse. Sixty percent of men

Figure 78.3 Vacuum erection devices are placed about the penis, and a watertight seal is achieved against the abdomen. The vacuum is applied, creating the erection, and then a rubber band is left at the base of the penis to maintain the erection for as long as 30 minutes.

and 42% of women indicated an improvement of the sexual relationship. Although not universally accepted, the VCDs had a significant impact on sexual activity and sexual satisfaction for nearly half the couples (Denil, Ohl, & Smythe, 1996). Moemen et al. reported 70% of SCI patients had restoration of normal erections and significant improvement in sexual function after using VCDs (Moemen et al., 2008). This wide range of variation in response of patients might be related to the acceptability by the patient and his partner. Patients tend to reject the use of VCDs because they want to have more naturally occurring erections within the context of sexual stimulation by a partner. VCDs are more accepted by men in established sexual relationships where spontaneity is not a major issue.

An analogous portable battery-powered vacuum device for producing clitoral engorgement is available for women. It has been used successfully to improve sexual function in women with sexual dysfunction after irradiation for cervical cancer and in anatomically normal women with impaired sexual arousal (Billups, 2002; Shroder et al., 2005). It is applied during foreplay prior to intercourse; no effort is made to maintain engorgement of the clitoris during intercourse itself. There are no published data on the use of the device in women with spinal cord injury.

INTRAURETHRAL THERAPY

Prostaglandin E1, although typically used as an ICI, also comes in an intraurethral formulation. The Medicated Urethral System for Erection (MUSE) study group reported on the efficacy of intraurethral alprostadil in non-SCI males with ED. When MUSE was administered in the clinic, 65.9% of men responded satisfactorily. Of those initial responders, only 64.9% had a satisfactory response with at-home use (Padma-Nathan et al., 1997). Bodner and colleagues (1999) reported their results with MUSE in SCI patients.

Intraurethral alprostadil was tested in 15 SCI patients who previously responded favorably to ICI, and the erections were compared using each delivery method. The quality of the erection varied and appeared to be less rigid in all patients when compared to ICI. It was concluded that MUSE was effective at creating erections that were of lesser quality than those with ICI (Bodner, Haas, Krueger, & Seftel, 1999). Common side effects of intraurethral alprostadil include unsatisfactory erections, pain in the urethra, dysuria, and hypotension if MUSE is not administered with a constricting band at the proximal penile shaft (Bodner et al., 1999). The absorption of alprostadil from the urethral lumen can be variable, especially in patients with SCI who manage their bladders with intermittent catheterization, which makes MUSE less efficacious than ICI of prostaglandin E1.

Although intraurethral medications have been popular in the past, currently they are not readily available and have been found to be less effective than ICI in the SCI population and are therefore seldom prescribed. With this being said, intraurethral therapy should be offered to patients who are deterred by the morbidity of self-injection, due to its being less invasive (SRH SCI Guideline, 2010).

PENILE PROSTHETICS

Prior to the advent of oral and ICI therapies for ED, surgery was the only option. It is now the final rung of the ladder for the treatment of ED in both non-SCI and SCI patients. Besides being effective for the treatment of ED, in patients with SCI a penile prosthesis can also be inserted to aid in the application of external drainage devices, such as condom catheters. Options include an inflatable penile prosthesis (IPP) or a malleable, semi-rigid prosthesis. The malleable prosthesis consists of two bendable rods, which are surgically implanted in the corporal chambers of the penis. With the malleable device, the penis is always semi-rigid and needs only to be

moved into the right position for penetration. The malleable implant can be helpful in keeping a condom catheter in place; however, it is less popular because it maintains the penis in an erect state, which may have cosmetic disadvantages. The IPP consists of a pair of inflatable cylinders that are surgically implanted into the erectile chambers. A pump for the implant is also surgically inserted into the scrotum. A reservoir for the pump fluid is placed within the abdominal cavity. In what is referred to as a two-piece inflatable implant, a scrotal fluid reservoir is substituted for the abdominal reservoir. When a man desires an erection, he or his partner squeezes the pump, which moves fluid into the inflatable cylinders and allows the cylinders to become rigid. When deflated, the penis returns to a naturally flaccid state (SRH SCI Guideline, 2010).

Initial results in the 1980s demonstrated a propensity for SCI patients with IPPs to develop infections around the device, requiring its removal (Kabalin & Kessler, 1988). Complication rates differ among older studies. A 33% complication rate was reported in 63 patients who underwent insertion of an IPP or semi-rigid device, while another study had a 13.3% complication rate (Collins & Hackler, 1988; Kimoto & Iwatsubo, 1994). Perkash and colleagues (1992) implanted penile prostheses in 60 men with SCI and performed a retrospective review. The primary indication for implantation was the loss of condom catheter with a small, retractile penis. Mean follow-up was seven years, and 81% reported no accidents with condom loss after implantation. All patients who were catheter dependent, except one, were able to rid themselves of indwelling catheters. The overall infection rate was 2% (Perkash, Kabalin, Lennon, & Wolfe, 1992). Kim et al. reported a wound infection rate of 8.3% in their experience with malleable penile prosthesis insertion in 48 patients with SCI (Kim, Yang, Lee, Jung, & Shim, 2008). In a more recent study, Zermann et al. had a 5% infection rate after the implantation of 245 penile prostheses of various types (Zermann, Kutzenberger, Sauerwein, Schubert, & Loeffler, 2006).

Implantation of a penile prosthesis is a safe procedure for ED and/or urinary incontinence in neurologically impaired patients. Based on technical advances, the complication rates have significantly decreased during the years, and the devices should be offered to patients with SCI after they have exhausted other sources for ED.

HYPOGONADISM

Patients with SCI are prone to develop metabolic disturbances, including testosterone deficiency (Bauman & Spungen, 2000). However, a cause-and-effect relationship between SCI and low serum testosterone levels has yet to be proven. Normal total testosterone levels vary with age, but generally run between 300 and 1000 ng/dl. When compared to able-bodied controls, tetraplegics were shown to have decreased testosterone, luteinizing hormone (LH), and follicular stimulating hormone (FSH) (Kostovski, Iversen, Birkeland, Torjesen, & Hjeltne, 2008). Another study demonstrated similar findings. When compared to normal controls, 50% of the subjects with SCI had decreased values of

at least one of the aforementioned hormones (Safarinejad, 2001). The previous studies were in patients with chronic SCI. In a screened population of men with SCI admitted to inpatient rehabilitation, 83% who had sustained injuries less than four months previously had low testosterone levels, while less than 10% of those with injuries longer than four months previously had low testosterone levels (Schopp et al., 2006). The same principal investigators corroborated this study with another of larger sample size, and the prevalence of low testosterone was found to be 60% for all patients and 69% for those in the acute phase (under 4 months) (Clark et al., 2008). Another group reported a 43.3% prevalence of hypogonadism in healthy SCI patients with chronic injuries. There were associations with injury severity and opioid usage (Durga, Sepahpanah, Regozzi, Hastings, & Crane, 2011).

Potential testosterone deficiency should be evaluated in men with SCI presenting with suppressed libido, reduced strength, fatigue, or poor response to PDE5 inhibitors for erectile dysfunction (SRH SCI Guideline, 2010). Suspected causes of hypogonadism after SCI include chronic illnesses, bladder and testicular infections, concomitant brain injury, hyperprolactinemia, metabolic syndrome, diabetes, and the use of medications that increase prolactin or suppress testosterone (e.g., opioids). Treatment of these illnesses and alterations in medications may assist in the return of normal testosterone levels. The use of testosterone replacement in men with SCI should be based on symptoms and signs rather than on a testosterone level alone; relevant symptoms and signs include sexual dysfunction, fatigue, weakness, and osteopenia. Hypogonadism is confirmed by finding a low free testosterone level in the morning. If gonadotropin and prolactin levels are not elevated and no other cause of hypogonadism is found and treated (i.e., medication side effects or diagnosed illness), primary hypothalamic/pituitary pathology should be ruled out prior to initiation of testosterone replacement. Traumatic brain injury concurrent with the SCI is one potential cause of this problem. Testosterone replacement therapy can have a beneficial effect on the general health (i.e., cardiovascular, bone health, and body fat composition), mood, and sexual function of men with SCI; it can, however, diminish fertility by suppressing LH and FSH. Bauman et al. (2011) recently demonstrated the safety of transdermal testosterone replacement therapy in SCI. Eleven hypogonadal men with SCI were treated and followed for one year. Testosterone replacement therapy significantly improved lean tissue mass and energy expenditure (Bauman, Cirnigliaro, La Fountaine, Jensen, Wecht, et al., 2011).

Men on testosterone replacement need to be monitored with serum testosterone levels and other biochemical markers, as indicated by current best clinical practices for testosterone replacement therapy. Exogenous testosterone replacement will suppress spermatogenesis and therefore should not be the treatment of choice in hypogonadal men with SCI wishing to pursue biological fatherhood. The contraindications for hormone replacement treatment are severe renal disease, cardiovascular disease, liver disease, and prostate cancer. Side effects should be discussed with patients and may include acne, myalgias, flushing, edema, hypertension, insomnia, hyperlipidemia, and polycythemia.

FERTILITY

Fertility is a concern for both men and women who have had spinal cord injuries. While females with SCI are thought to have normal fertility, the majority of women who have not had children before SCI do not have them afterwards. Men with SCI have markedly reduced fertility, with less than half of male SCI patients able to biologically father children (Brown, Hill, & Baker, 2006).

ISSUES FOR WOMEN

Pre-menopausal women with SCIs can become amenorrheic for several months following the injury, even if their periods were regular before it. The disruption in the menstrual cycle is presumably related to the extreme stress of the injury; in some cases, the amenorrhea is accompanied by an increase in serum prolactin that resolves in several months, concurrent with the resumption of menses (Rutberg, Fridén, & Karlsson, 2008).

Women who lose their periods immediately following SCI should have an appropriate diagnostic evaluation; if there is no other cause for the amenorrhea the patient can be reassured that her menses will return in several months.

Otherwise healthy women with SCI who become pregnant usually can carry their pregnancies to term and have a vaginal delivery; in fact, delivery will be less painful for most women with SCI because of diminished pelvic sensation. Nonetheless pregnancies of women with SCI are classified as high risk for two reasons. First, the incidence of UTI is very high, with potential complications if UTIs are not treated promptly. Second, the intense abdominal and pelvic stimulation associated with labor can provoke severe autonomic dysreflexia, with severe and even life-threatening hypertension. In late pregnancy the mobility limitations of women with SCI become more challenging because of weight gain. Admission to hospital several days before delivery is anticipated may be necessary for comfort and for risk management.

Despite the challenges that pregnancy, delivery and child care present for women with SCI, overall quality of life is on average higher in female SCI patients who do bear children (Westgren & Levy, 1994). Informing a young woman with a recent SCI that her injury will not preclude future motherhood can be helpful emotionally, and the reassurance offered would be supported by evidence.

ISSUES FOR MEN

The situation for men with SCI is more discouraging: Only about 5% of men with SCI are able to biologically father children without medical assistance, and less than half are able to do so even with maximal medical assistance. While only about 10% of men with SCI are able to ejaculate with sexual activity alone, semen can be obtained by mechanical or electrical stimulation in another 80%. The more fundamental problem is poor semen quality (Patki, Woodhouse, Hamid, Craggs, & Shah, 2008; Das, Soni, Sharma,

Gazvani, & Lewis-Jones, 2006). The sperm count can be low, but even when it is normal there usually are problems with sperm motility or with the properties of the seminal fluid that impede fertilization. Deterioration in the quality of semen begins approximately 2 weeks after an acute SCI; the cause is multifactorial and not completely understood. If a man with SCI and a woman are determined to conceive a child together they might need to resort to in-vitro fertilization with intracytoplasmic sperm injection (ICSI) to maximize their chance of success. In connection with the issue of semen quality, Das and colleagues (2006) point out that if a male patient with an SCI is sufficiently stable medically in the second week following his injury, it is rational to propose that he undergo an electroejaculation (see below) to produce semen that can be frozen for potential use if he wishes to father children in the future.

For men with SCI who cannot ejaculate with sexual activity, the usual first step in the pursuit of conception is medically-assisted ejaculation to obtain semen to be used for intravaginal or intrauterine insemination. When satisfactory semen can be obtained by ejaculation the discomfort and expense of testicular aspiration or testicular biopsy can be avoided.

The two basic approaches to medically-assisted ejaculation are penile vibratory stimulation (PVS) and electroejaculation (EEJ). The former elicits ejaculation by applying intense vibratory stimulation to the penis to elicit a spinal reflex. The latter directly stimulates the skeletal muscles and smooth muscles involved in ejaculation by applying a pulsatile electrical stimulus through a rectal probe. While PVS requires an intact sacral reflex arc, EEJ can be effective even when the sacral cord has been damaged. Considering all male SCI patients, about 80% will ejaculate with PVS and 90-95% will ejaculate with EEJ.

A final point is that sperm quality declines rapidly following SCI. Sperm retrieved, by EEJ if necessary, during the first two weeks following SCI can be normal and suitable for intravaginal or intrauterine insemination, while sperm obtained later on will be unsatisfactory for these purposes. If the patient's is sufficiently stable medically, the collection and freezing of semen in the two weeks following SCI is a reasonable consideration for younger men likely to consider fathering children in the future (Das et al., 2006; Brown, Hill, & Baker, 2006).

Ejaculation is a spinal reflex elicited by stimulation of the dorsal penile nerve, which is the sensory branch of the pudendal nerve terminating in sacral spinal cord segments S2-S4 (Brackett, Lynne Ibrahim, Ohl, & Sonksen, 2010). The basis of ejaculation in reflex pathways wholly within the spinal cord is demonstrated by the induction of ejaculation by PVS in patients with complete spinal cord transection above the T10 segmental level. In these patients sacral sensory input is intact, as is thoracolumbar sympathetic output and sacral somatic and parasympathetic output. The ability of a peripheral stimulation to induce ejaculation despite the complete loss of reciprocal connections with supraspinal structures implies the existence of an ejaculation control center at the spinal cord level (Everaert, de Waard, Van Hoof, Kiekens, Mulliez, & D'Herde, 2010).

It is more likely that a man with a SCI will be able to ejaculate with sexual activity alone if there is significant preservation of genital sensation and voluntary anal control, a strong bulbocavernosus reflex, and the man is not taking anticholinergic medication, SSRIs, or other drugs known to impair orgasm and ejaculation even in patients who are anatomically intact. SCI patients sometimes regain ejaculatory with the passage of time without any specific treatment (SRH SCI Guideline, 2010).

Penile Vibratory Stimulation (PVS)

Penile vibratory stimulation (PVS) is performed by placing a powerful vibrator on the dorsum or frenulum of the glans penis—or sandwiching the penis between two vibrators—and delivering mechanical stimulation until ejaculation occurs. The vibrator stimulates the dorsal penile nerve; if the latter is blocked the reflex cannot be elicited (Wieder, Brackett, Lynne, Green, & Aballa, 2000). PVS has been shown to be more effective in men with cord lesions at T10 or higher than in men with lesions at T11 or below. PVS with the more rostral lesions had an 88% success rate, while those with the more caudal lesions had a 15% success rate (Brackett et al., 2010). Patients with lesions above the T6 spinal level can experience autonomic dysreflexia with PVS. Sublingual nifedipine can be used for initial treatment if it occurs. If autonomic dysreflexia was experienced with previous sessions of PVS, nifedipine can be used prophylactically.

Electroejaculation (EEJ)

Electroejaculation (EEJ), the stimulation of ejaculation by pulsed electrical current administered via a rectal probe, was first used clinically in 1975 and became an established practice in the 1990s, offering a way to retrieve sperm without needle aspiration or testicular biopsy in patients incapable of ejaculation even with high-intensity PVS (O'Kelly, Manecksha, Cullen, McDermott, Flynn & Grainger, 2011). EEJ, which is carried out by a physician with specialized training, using a device specifically approved for performing the procedure, is successful in 95% of attempts.

To perform EEJ, the operator inserts a catheter and drains the patient's bladder. A buffering solution is instilled into the bladder; semen ejaculated in a retrograde direction will mix with this buffering solution rather than with urine. The catheter is removed and the patient is placed in the lateral decubitus position. A probe is inserted transrectally, and an applied current causes emission of semen. The current should be delivered in an interrupted fashion instead of continuously, as ejaculation occurs when the current is switched off. A recommended procedure is to deliver electricity in 2–5 volt increments. At each increment, the peak voltage should be held for five seconds, and then abruptly switched off (Brackett et al., 2010). Following the procedure, the bladder is catheterized to obtain the specimen. Most patients can undergo EEJ without anesthesia unless they have preserved sensation, as the procedure can cause significant discomfort. Complications associated with EEJ are uncommon, but thermal rectal injury is avoided

by an automatic shutoff of the probe if temperatures exceed 40°C. AD can occur in patients with lesions at T6 or above. When the patient is at high risk for AD, sublingual nifedipine is given prophylactically and blood pressure is monitored continually during the procedure (Steinberger, Ohl, Bennett, McCabe, & Wang, 1990; O'Kelly et al., 2011).

Compared to PVS, EEJ is more expensive and invasive, although more successful, as no preservation of an ejaculatory reflex is needed. Using a treatment algorithm similar to that recommended by the Consortium of Spinal Cord Medicine, Brackett et al. (2010) reported a 3% failure rate in obtaining sperm from 500 patients with SCI. Using masturbation, 9% were able to provide semen. PVS was successful in 86% of patients with a T10 or higher injury level. EEJ was successful in most cases of failed PVS. Overall, semen was obtained without surgical retrieval methods in 97% of patients (Brackett, Ibrahim, Iremashvili, Aballa, & Lynne, 2010).

A semen analysis for men interested in biological fatherhood should be performed in order to provide information and make recommendations for achieving pregnancy. Men with SCI typically have abnormal semen parameters, with normal sperm numbers and decreased motility and viability when compared to those of normal men (Patki, Woodhouse, Hamid, Craggs, & Shah, 2008). The root causes of this problem have not been fully established, but it is thought to be multifactorial. It has been demonstrated that semen quality is better from antegrade specimens than from retrograde specimens. As such, semen quality is typically higher with PVS than with EEJ (SRH SCI Guideline, 2010). The same treatments that are effective for assisting conception in couples with non-SCI male factor infertility are effective in assisting conception in patients with SCI male factor infertility, and fecundity tends to increase as the invasiveness of treatment increases (Brackett et al., 2010).

Infertility is usually not associated with SCI in females. As such, females with SCI should not be dissuaded from pregnancy. Quality of life for a woman with SCI increases after childbirth, despite the additional demands and challenges of raising a child (Westgren & Levi, 1994). Still, women with SCI face unique problems associated with pregnancy; these issues should be discussed so that women can make informed decisions if they are considering becoming pregnant. Women with SCI have reported receiving little information about pregnancy post-injury, and the information provided often is found to be inadequate (Ghidini, Healey, Andreani, & Simonson, 2008). Pregnant women with SCI have an increased risk of uterine tract infections, AD, and changes in respiratory function. They also have specific biomechanical needs related to being in a wheelchair. Women with SCI should discuss with their obstetrician exactly how labor and delivery will be managed, and in some cases early hospitalization will be necessary (Jackson & Wadley, 1999). Diminished sensation and absence of pain may result in unrecognized conventional labor symptoms or atypical labor symptomatology, especially in women whose levels are T10 and above (Jackson & Wadley, 1999). The obstetrician needs to be able to differentiate AD from preeclampsia, as the treatment of each differs.

SUMMARY

Spinal cord injury is a devastating injury that forces the affected person to make lifelong adjustments. Great progress has been made in the medical management of these patients, and their life expectancy now approaches that of age-matched controls. The multidisciplinary approach to management of these patients is essential to their successful reintegration into society. The role of the medical psychiatrist and other mental health professionals is central, beginning at the time of injury and continuing indefinitely. Patients must first cope with the injury and understand what changes will occur in their functional ability. The patient should experiment to determine how sexual function can be optimized after the injury. When erections are not satisfactory for a male patient, further assessment is indicated. Restoring penile erections can effectively be accomplished with oral medications. Only rarely are penile prostheses required. When receiving treatment for sexual dysfunction, patients should be followed as closely by a psychotherapist for support and adjustment as they are followed by an urologist. Hypogonadism is very common in the SCI population and should be screened for, and further studies will elucidate whether treatment in asymptomatic men is beneficial. For the man who does not ejaculate and desires to father a child, semen is often successfully obtained using minimally invasive approaches. Very rarely should surgery be required to obtain sperm. It is critical for psychiatrists to know the state of the art in the treatment of SCI patients so as to refer them appropriately while treating them with psychotherapy and medications improve their adjustment to their situation. This includes awareness of local and regional resources for substance abuse treatment and for assisted reproduction. Professional staff of all disciplines who treat SCI patients can at times struggle with feelings of helplessness as well as deal with their countertransference to particular patients—overidentification and overprotectiveness are common reactions. Ongoing dialogue with peers about these feelings will diminish their adverse impact on patients' treatment.

All staff members on a rehabilitation unit—not only mental health professionals—need to be sensitive to the emotional and psychosocial needs of their patients and their families. Often, empathetic listening to patients during physical and occupational therapy sessions and offering positive support can be psychotherapeutic. Rehabilitation staff must be able to tolerate the patient's sadness without offering quick solutions or cutting off the patient's verbalizations and expressions of emotion. Patients must come to see a future for themselves and achieve a realization that life will continue after SCI, and that life after SCI can potentially be as fulfilling and meaningful as life without one, despite physical challenges. The staff member who helps the patient in their grieving while also looking toward the future in a positive and reassuring manner will be a valuable asset for the patient's emotional adjustment. Rehabilitation should be a time of focusing on the strengths of the patient, and this includes the social and emotional resources and strengths of the individual as well as the residual physical capabilities demonstrated in physical therapy.

Individual psychotherapy a critical component of a good rehabilitation program, and almost all patients will benefit from it. Medical-psychiatric assessment of the patient and ongoing psychotherapy should begin as soon as the patient arrives on the rehabilitation unit. In an acute-care setting, beginning such services even while the patient is in the intensive care unit is advisable. In that manner, a therapeutic alliance can be formed prior to beginning aggressive rehabilitation, and the therapist can be an important support during the early weeks in rehabilitation. When the acute hospital and the rehabilitation hospital are not linked the handoff from one therapist to the other must be handled sensitively. Family and/or couple therapy also are valuable components of a successful rehabilitation program. Such treatment modalities can address communication issues, mobilize emotional support, and provide important assistance to siblings, children, and other members of the family. When non-related friends of the patient have a central supportive role, they should be included in education programs and, if relevant, in conjoint therapy sessions.

Throughout the rehabilitation program, individual treatment and couples therapy should address sexual issues through general education and individualized counseling. The topic can be gently introduced as early as possible in the rehabilitation program. The patient needs information about how the injury will affect sexual expression, and will require counseling to assist in the sexual adjustment that will be necessary. If the patient has not raised such issues by the time of discharge, the mental health professional should introduce the topic in a non-threatening and sensitive manner. Information regarding erections and lubrication, fertility, bladder and bowel functioning, positioning, sensation, and orgasm should be introduced and discussed with the patient and partner whenever possible. All members of the rehabilitation team can be helpful in this regard by affirming the patient's sense of masculinity or femininity and providing reassurance that the patient can be desirable and that sexual expression can continue, or in the case of a younger patient, begin at an appropriate time. Sexual issues may arise or evolve during long term follow up following acute rehabilitation. Patients should know that their physicians will be open to discussing sexual issues at any time, and physicians should periodically make tactful inquiries to re-open the topic if the patient wishes.

CLINICAL PEARLS

- Many patients with sacral spinal cord injury retain psychogenic erectile ability even though reflexogenic erection is abolished. Psychogenic erections are found more frequently in patients with lower motor-neuron lesions below T12; no psychogenic erection occurs in patients with lesions above T9. Patients with higher lesions can maintain erections using the reflexogenic pathway. (See Table 78.1.) Psychogenic erections may be insufficient for intercourse, but may become adequate if augmented by PDE5 inhibitors.

- Nitric oxide (NO) plays an important role in penile erection. PDE5 inhibitors enhance the effect of NO on erection, strengthening erections triggered by any pathway.
- Reflexogenic erections are typically preserved for an individual with either complete or incomplete SCI with preserved sensation and/or voluntary motor control of the S2–S5 area and any presence of a bulbocavernosus.
- The effect of SCI on orgasm can be determined by assessing the impact of injury on the bulbocavernosus and anal wink reflexes and the degree of completeness of injury at the S2–S5 level. It is unlikely that individuals with complete injuries at the S2–S5 level with an absent bulbocavernosus and anal wink reflex will be able to achieve a complete physiological orgasm. However, vagal afferents, which are not damaged by SCI, can be the basis of the psychological experience of orgasm. Thus, it is important to educate the patient to explore new areas of the body that may lead to sexual pleasure and orgasm.
- Often a region of skin exists just below the lowest dermatome with pre-injury levels of sensation which has present but altered sensation. This area, known as “the transition zone,” often can be a source of erotic pleasure. Stimulation of this area can be arousing for both partners.
- Common medical complications of SCI include bladder and bowel problems, recurrent urinary tract infections, pain, spasticity, respiratory compromise, skin breakdown, erectile dysfunction, and autonomic dysreflexia (AD).
- Throughout a patient’s initial hospitalization for rehabilitation following SCI, anger and excessive demands are best handled by reassurance and firm limit-setting by the rehabilitation staff. Setting firm and clear limits is essential for the patient to feel safe and cared for. It should be done in an empathetic, supportive, and non-punitive manner. Limit setting communicates expectations for recovery of function and encourages a sense of independence and self-control.
- Patients with SCI when intoxicated with alcohol or drugs may fail to reposition themselves to avoid pressure-related skin breakdown.
- Spinal shock can cause a reversible loss of erections following SCI. With incomplete lesions the capacity for erections can return days to weeks after the injury; with complete lesions it can return as long as a year or more after the injury. For these reasons surgical treatment for post-SCI erectile dysfunction should not be employed during the first year following the injury.
- Vibrators can cause autonomic dysreflexia in individuals with SCI at T6 or Sexual aids that cause friction on the skin may cause skin breakdown in denervated areas of skin.
- Individuals with SCI at or above T6 who are at risk for autonomic dysreflexia (AD) should receive early basic education on how to prevent, respond to, and intervene if AD should occur. Symptoms and signs of AD include very high blood pressure, slowed heart rate, pounding headache, sweating, flushing, pallor, nasal congestion, blurred vision, nausea, and piloerection. Sublingual nifedipine can be used both for treatment and for prophylaxis of recurrent AD: other options include nitroglycerin paste and prazosin.
- Consider low testosterone in the differential of low libidos in SCI patients. Also, consider the diagnosis when neural pathways for erection are intact but the patient has erectile dysfunction not resolved with PDE5 inhibitors.
- PDE5 inhibitors do not initiate erections; they simply make them stronger.
- PDE6 type 6 is located in the retina and is responsible for visual disturbances with PDE5 inhibitors. Visual adverse effects of PDE5 inhibitors are most frequent with sildenafil because it is the least selective of the drugs in the class.
- Absolute contraindications to the use of PDE5 inhibitors include the concomitant use of nitrates or the presence of retinitis pigmentosa.
- Ejaculation is a spinal reflex elicited by stimulation of the dorsal penile nerve, which is the sensory branch of the pudendal nerve terminating in sacral spinal cord segments S2–S4. This reflex arc is best illustrated by the ability of vibratory stimulation of the penis to induce ejaculation in patients with complete spinal cord transection above the T10 segmental level.
- Treatment of depression in patients with SCI should when possible utilize antidepressant drugs with a low incidence of sexual dysfunction. Men with SCI develop qualitative abnormalities of sperm two weeks after the injury. Collection of semen for cryopreservation should be considered during the two weeks post-injury, if the patient is medically stable and potentially interested in fathering children.

PART IX

CHILDREN AND ADOLESCENTS

PSYCHIATRIC ASSESSMENT OF THE PHYSICALLY ILL CHILD

Wendy Froehlich-Santino, Hans Steiner, and Richard J. Shaw

THE DEVELOPMENTAL PERSPECTIVE

One of the most critical differences between the approach to the assessment and management of child and adolescent patients compared to adult patients is the need to incorporate a developmental perspective. This approach, which was originally grounded in psychoanalytic theory and developmental psychology, informs the work of the pediatric psychiatrist (Cicchetti & Cohen, 1995; Steiner, 1997b). It is an approach that is now more limited in adult psychiatric practice, partly in response to the impact of current phenomenologically based diagnostic classification systems, such as the International Statistical Classification of Diseases and Related Health Problems (ICD)-10 (World Health Organization, 1992) and the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (American Psychiatric Association, 2013). Conceptually, the developmental approach is a special instance of the biopsychosocial paradigm. The developmental approach in children gives special consideration to the temporal relationship of the biological, psychological, and social variables evaluated and described in the patient, as the child's individual development unfolds and progresses over time. Three concepts—continuity, context, and complexity—help differentiate the developmental approach proposed in this chapter and clarify essential differences between this approach and purely descriptive and biological-psychiatric models of diagnosis and treatment.

CONTINUITY

Many so-called psychopathological symptoms appear to be widely present in non-clinical populations; symptoms sometimes diagnosed as pathological may be continuous with, and represent no more than an exaggeration of, normal behavior. For example, somatization, or the vigilant surveillance of one's bodily functioning, cannot immediately be assumed to be pathological. Somatization and the use of somatically based words to describe affective distress (somatothymia) is widespread in the general population (Stoudemire, 1991). In certain circumstances, however, such as when a child is suffering from a chronic physical illness, somatic symptoms of emotional distress may reach a level of intensity that interferes with the child's treatment and functioning. The developmentally

oriented clinician continuously weighs the available clinical evidence when deciding which behaviors are and are not pathological or are within the norm for the child's age.

In line with epidemiological data, "continuity" also describes the concept that psychiatric illness results from the gradual accumulation of risk factors over time, particularly in the absence of sufficient protective or "buffering" factors (Figure 79.1). These risk factors for psychiatric illness may be diverse and include ecological, constitutional, genetic, interpersonal, and intrapsychic variables. Psychiatric disorders rarely result from a single event, although post-traumatic stress disorder (PTSD) can be an exception. Typically, psychiatric disorders evolve over time, becoming manifest after a generally prolonged exposure to various risk factors. The study of prodromal syndromes can be as important as evaluation of fully evolved psychiatric disorders. Early identification of prodromal syndromes can alert clinicians to the need for early intervention and may enable the prevention of more severe manifestations (Gyllenberg et al., 2010; Mrazek & Haggerty, 1994; Skovgaard, 2010).

The concept of continuity also suggests that there may be psychological sequelae in the aftermath of an acute mental disorder. Complete resolution of symptoms is the exception rather than the rule. As in adults, it is common for children and adolescents to have special sensitivities and higher relapse rates, even following successful initial treatment. Awareness of this possibility should lead to caution regarding the expectations for cure, as well as greater vigilance when the child or adolescent negotiates subsequent stressful developmental transitions.

CONTEXT

The importance of the larger *social context* has been well delineated by proponents of the social-ecology model of mental health. Bronfenbrenner's theory is of particular relevance for children (Bronfenbrenner & Crouter, 1983). It states that development co-occurs in several contexts, including the micro-system (family), mesosystem (interactions between the family, schools, and hospitals), exosystem (social support networks), and macro-system (society, culture, and policy). Social context is important for both the definition and the delineation of psychopathology. The social environment of the child

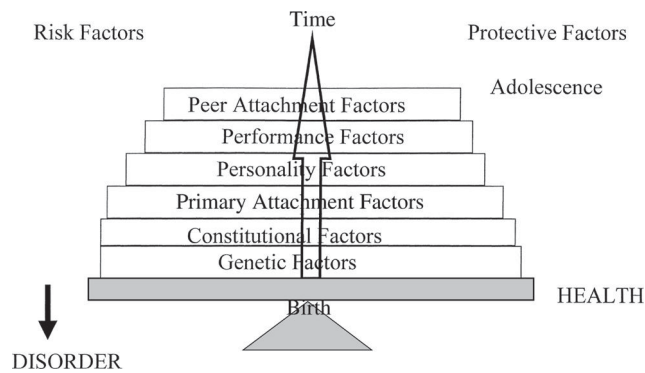

Figure 79.1 The vulnerability/resilience model for the development of psychopathology

is a crucial element in terms of providing a supportive context in which to provide appropriate medical or psychiatric treatment. Sometimes, the social environment itself is the major factor in the genesis of psychopathology in the patient. Examples include families of physically ill children whose parents refuse treatment for religious reasons, or the direct result of injurious behavior caused by parents in the cases of factitious disorder by proxy (Shaw, Dayal, Hartman, & DeMaso, 2008).

It is also important to consider the concept of the *temporal context* in which symptoms present. As children pass through their distinct phases of development, *domains of functioning* change in sometimes dramatic and unpredictable ways (Kagan, 1989). What is considered “normal” one day may be pathological the next. For example, “stranger anxiety” may be normal for an infant, but it suggests pathology in the case of an adolescent with separation anxiety disorder.

It is absolutely critical to consider age-specific developmental norms in the approach to psychopathology. While it is true that much of development proceeds in a progressive and predictable sequence, qualitative and unexpected shifts frequently occur. A child’s or adolescent’s behavior can only be understood in the context and spectrum of the child’s overall developmental progression.

COMPLEXITY

As children develop new competencies and skills, the central nervous system becomes increasingly differentiated and complex. Complex behaviors and mental states emerge but are based on their less complex antecedents. For example, new skills supersede old ones, but contain within them the nucleus of older, mastered skills. This principle of past behavior being enveloped in current behavior is important with regard to the emergence of psychopathology. If a child is unable to sufficiently resolve the issues of an early stage of development, it is likely that these issues will reemerge later in subsequent developmental transitions, usually under some sort of stress. For example, disorders of attachment in relation to the primary attachment figure may result in difficulties in adult attachment relationships (Cicchetti & Cohen, 1995). Conversely, difficulties in attachment may be repaired by the experience of a positive relationship with an

adult outside of the family (Rutter, 1988). Such relationships can contribute to resilience in youth at risk (Rutter, 1988; Werner & Smith, 1992).

Complexity of functioning also can change in situations of extreme stress, particularly in situations when the child or adolescent has only recently acquired newly developed skills. In such cases, it is possible to see a return to less complex and less mature levels of functioning, the reemergence of old behaviors and problems, and the loss of newly acquired skills. This type of behavior is known as *regression* and is common even in physically ill adults.

Acute medical illness, inpatient hospitalizations, and the stress of pain or invasive medical procedures often result in regression in the behavior of hospitalized children as well as adults. Children may manifest increased clinginess and anxiety around separations, bed-wetting, and, in extreme cases, even regression in their use of language. Regression to earlier phases of development must be carefully differentiated from the more serious phenomenon of developmental “arrest.” The bio-genetic drive toward healthy development, which is genetically preprogrammed in children, will often serve to repair temporary regressions without the need for intensive psychiatric interventions.

THE DEVELOPMENTAL APPROACH TO PSYCHOPATHOLOGY: IMPLICATIONS FOR DIAGNOSIS AND TREATMENT

Having outlined the essential tenets of the developmental approach, we now turn to a discussion of the implications for the diagnosis and treatment of children and adolescents. Clearly, it is important to adjust the assessment and intervention strategies to match the level of cognitive and social development of the child, taking into account the child’s limitations, but also respecting the child’s particular age-specific strengths and skills.

DIAGNOSTIC APPROACHES

Although the psychiatric assessment of the child and family has much in common with that of adult patients, there are some important practical and conceptual differences. As with adult patients, the history is the foundation of the assessment.

Assessment is more difficult with younger children, since they are often not able to accurately report their behavior and symptoms and may not have an adult comprehension of such concepts as “cause and effect.” Later in this chapter, reference will be made to problems with overreliance on self-reported symptoms and history, as well as the need to engage parents in the assessment process. Box 79.1 outlines the major areas that should be covered in the assessment. Box 79.2 focuses more on addressing specific areas related to the impact of the illness on the micro-system (family) and exo-system (friends), as well as investigating how the illness is viewed and fits into the overall macro-system. The American Academy of Child and Adolescent Psychiatry (AACAP) Practice

**Box 79.2 PROTOCOL FOR THE PSYCHIATRIC
ASSESSMENT OF THE PHYSICALLY ILL CHILD**

- *What are the illness factors?*
 - Stage—new, relapse, chronic
 - Course—relapsing, single event, inter-interval recovery, chronic deteriorating
 - Prognosis—preservation of function with treatment, decline, terminal
 - Treatment—hospitalizations, clinic visits, medications, adherence, traumatic procedures
- *What is the understanding of the illness by the child and parent?*
 - How explained, realistic comprehension, adequate understanding, cognitive factors, cultural issues
- *What is the emotional impact of the illness on the child?*
 - Premorbid, current, degree of acceptance
- *What is the impact of the illness on family functioning?*
 - Family, marital, occupational, financial issues
- *What is the impact of the illness on the healthy siblings?*
 - Decreased parental availability and/or resources; emotional reactions
- *What is the impact of the illness on social and peer relationships?*
 - Stigma, decreased contact, impact on dating and sexuality
- *What is the impact of the illness on academic functioning?*
 - Premorbid, current, problems with school reintegration, special education needs
- *What are the child's habitual coping mechanisms?*
 - Family, friends, religious, social withdrawal, denial, avoidance, maladaptive coping
- *What is the role of religion and spirituality?*
 - Affiliation, beliefs, role as social support in family
- *What is the relationship of the family with the medical team?*
 - Level of trust, quality of communication, family's involvement in decision-making

Source. Adapted from Shaw, R. J., & DeMaso, D. R. (2006). The pediatric consultation psychiatry assessment. In *Clinical manual of pediatric psychosomatic medicine: Mental health consultation with physically ill children and adolescents* (pp. 43–45). American Psychiatric Publishing, Inc. Washington DC. Used with permission.

Parameters (DeMaso et al., 2009) recommend beginning with open-ended questions about these interrelated domains and stress the importance of a biopsychosocial approach, as opposed to trying to separate the medical illness from psychiatric and social functioning. These same principles and recommended areas of inquiry are further discussed in detail in Chapter 3 of *The Textbook of Pediatric Psychosomatic Medicine* (Goldman, Shaw, & Demaso, 2010).

To perform a comprehensive consultation, clinicians must collate information from parents, caretakers, schoolteachers, and counselors. In physically ill and hospitalized children, information from nurses and medical staff involved in their care is often helpful. This is particularly important when there

are questions about treatment adherence. In general, separate meetings with the parents are recommended to collect a full and comprehensive developmental and clinical history. The AACAP Practice Parameters point out that even very ill children are able to listen and ponder information they hear, so it is important to give parents their own opportunity to meet privately with the clinician so that sensitive issues may be addressed without the child listening (DeMaso et al., 2009). This also allows the clinician to be less focused on collecting historical data during the child interview and permits more attention to developing a positive therapeutic rapport with the patient and to observing their play. Parents who are engaged in the assessment can then facilitate the introduction of the mental health consultant and advise on the best ways to engage the child.

During the child interview, it is usually advisable to explain to the child the purpose of the meeting, in simple and age-appropriate language. It is also important to clarify the limits of confidentiality as they apply in a consultation relationship, and the circumstances in which confidential information may be disclosed to outside agencies; for example, when there are allegations of child abuse. For older children and adolescents, it is typically recommended that the interviewer spend some time alone with patients during the assessment so that patients may answer questions openly (DeMaso et al., 2009). This applies not only to questions regarding trauma, substance use, and sexual history, but also to psychiatric symptoms in general. Often, children and adolescents may not disclose the extent of their thoughts and emotions, in an effort to protect their parents or caretakers.

Preschool-age and school-age children are likely to respond better if offered the opportunity to meet in a playroom or to draw or play at the bedside. In younger or preverbal children, the play session is the primary instrument to assess the child's mental status, and it may involve a direct observation of the child's interactions with the parent, particularly when there are questions about parenting, feeding disorders, or disorders of attachment. It is important to observe the parent's ability to attend to and read the child's cues (the concept of affect "attunement") (Stern, 1985). It is also valuable to note the child's response to separation from the parent, the child's ability to engage in symbolic and age-appropriate play, and the child's reaction to the ending of the session.

SOURCES OF INFORMATION

Using the child as an informant to obtain a history or description of symptoms is perfectly admissible when the patient is older than 11 years of age, but doing so is problematic with younger children. Young children's capacity for self-observation and their ability to report on their bodily and mental functioning, behavior, or inner mental states is limited due to cognitive abilities that have not yet emerged. In addition, preschoolers are particularly vulnerable to suggestion and "leading" questioning (Flavell, 1985); that is, detecting and giving the answer the examiner wants. Suggestibility is influenced by both theory of mind and inhibitory control

(Scullin & Bonner, 2006), two cognitive skills that are still developing during early childhood. Because younger children have an underdeveloped theory of mind, they may be influenced by an incorrect perception of what they believe examiners are seeking. Concurrently, their lack of inhibitory control may sway them toward giving an answer they believe an examiner desires. Parental reports become increasingly important as one approaches the early school-age child, and is absolutely necessary when dealing with preschool-age children.

In adolescents, there is a similar divergence between self-report, parent-report, and the use of structured diagnostic interviews, but for very different reasons (Erickson & Steiner, 1999; Harris, Canning, & Kelleher, 1996; Steiner, 1996; Steiner & Canning, 1994). Although adolescents have sufficient cognitive skills to accurately report their history, there may be motivational factors that influence the self-report, including the wish to present themselves in a socially desirable manner. This wish may lead the patient to conceal risk-taking or pathological behaviors from perceived authority figures. Adolescents are prone to (unconscious) denial as well as conscious deception of others (Erickson & Steiner, 1999; Steiner, 1996). Many of the issues that need to be considered with regard to adolescents' reports on their health behaviors and various methods to obtain this information, such as cognitive and environmental factors, are reviewed in Sieving and Shrier's chapter *Measuring Adolescents Health Behaviors* (2009) and are summarized in Table 79.1.

Empirical data on the issue of convergence and divergence of measures in children support the importance of paying attention to these issues. Harris et al. (1996) showed that there was good concurrent validity when comparing three different parent-report measures in a sample of medically ill children. However, agreement between instruments and diagnoses determined by structured interviews of both parents and children was only "moderate." This study and a previous study by the same authors (Canning & Kelleher, 1994) found that parent-report and self-report instruments underestimated the proportion of children with chronic physical illness who had significant psychiatric comorbidity. Fewer psychiatric diagnoses will be missed if the clinician gathers information by interviewing both the patient and parents, and additional sources of information may reveal even more comorbidities. While parent and self-report instruments may have good specificity, sensitivities in these studies were low. These results demonstrate the need for a comprehensive approach in the assessment of physically ill pediatric patients.

Although self-report tools and parent-report tools completed by pediatric patients or their parents may underestimate the presence of psychiatric comorbidity, they can also play a significant role as screening tools. The Children's Depression Inventory (CDI) is a self-report tool for depression worded for children aged 8–13 years (Saylor, Finch, Spirito, & Bennett, 1984), and children as young as 6 or 7 years of age may be able to complete this measure. The Children's Depression Rating Scale (CDRS) is another self-report tool, for children ages 6–12, that has been shown to be useful in identifying depression in the pediatric medical setting (Poznanski, Cook, & Carroll, 1979). Additionally, shown in Table 79.2, the

Pediatric Symptom Checklist (PSC) is a short parent-report screening tool designed to use in a clinic or hospital setting that has been shown to be valid in children with chronic illness (Stoppelbein et al., 2005). It is also available as a self-report measure known as the Youth Pediatric Symptom Checklist (Y-PSC) for adolescents 11 years old and older. Measures such as these can be used to identify psychiatric comorbidities in the medical setting that may otherwise go undiagnosed.

DEVELOPMENTAL HISTORY

At the most rudimentary level, the developmental approach relies heavily on having a comprehensive developmental history. This section of the history includes cataloging the child's maturational milestones in addition to noting their successful mastery of crucial tasks at different key phases of development (Table 79.3). Categorizing the developmental trajectories in the major domains of functioning, along with an appropriate charting of milestones, impediments, and sensitivities, is essential in constructing a clear longitudinal picture of the child's development. Such an assessment helps differentiate between symptoms that may reflect a temporary regression in behavior, developmental arrest, or precocious development.

One area requiring special sensitivity is the assessment of psychosexual development in adolescents. Steiner and Lock's review (1998) of this topic is helpful in outlining a theoretical model to approach this subject in adolescents with chronic medical illness. The review highlights several studies demonstrating that various medical illnesses can negatively affect sexual development for both psychological and biological

reasons. Psychologically, children with chronic physical illness are more socially isolated with fewer opportunities for sexual development, may have overprotective parents, and may have more body-image disturbance, which can have a realistic basis in medical trauma and/or physical deformity. Biologically, many childhood illnesses and treatments may directly affect the endocrine system, resulting in various changes in hormonal levels affecting sexual maturation and development. Even disorders not typically thought of as endocrine disorders may adversely affect the endocrine system and sexual development. For example, boys with epilepsy have been shown to be at risk for delayed puberty, and often have abnormalities in levels of testosterone and/or estradiol (El-Khayat et al., 2003).

DOMAINS OF FUNCTIONING

Another essential component of developmental diagnostic practice is the acknowledgement of the *multidimensionality* of behavior, both normal and abnormal, in terms of *multiple domains of functioning*. These multiple dimensions are rarely fully captured by conventional descriptive and strictly empirically based diagnostic systems. The developmental formulation should include a description of problem behaviors, but in addition provide a picture of current adaptive skills of the patient as well as their past achievements in broad areas of functioning. In childhood, these developmental achievements include bodily functioning, and intrapsychic, interpersonal, academic, vocational, and recreational domains. Developmental diagnosis combines the categorical or "classification" method of diagnosis with the multidimensional

assessment of domains of functioning to get a comprehensive diagnostic picture and to clarify diagnostic subtypes. Discrete diagnostic categories, even if adjusted for specific age groups, rarely capture the entire clinical picture of the pediatric patient. For example, an adolescent with anorexia nervosa whose functioning in the domains of school and recreation is relatively unimpaired differs significantly from another patient with the same diagnosis but with severe school problems. In the case of children and adolescents, it is clear that school dysfunction is one of the key areas of concern with respect to both intervention and prognosis (Smith, Feldman, Nasserbakht, & Steiner, 1993).

ADAPTIVE VALUE OF THE SYMPTOM

The developmental clinician attempts to consider the positive or adaptive value of a syndrome or disorder in the child's life. Symptoms do not occur in a psychosocial vacuum;—they often fulfill a function for the child that can be understood by assessing the child's social and temporal context and their overall social equilibrium. Behavioral symptoms in children and adolescents are rarely a simple expression of a disease or illness that causes symptoms, and usually also

have adaptive value for the child. Behavioral symptoms tend to help resolve conflict. For example, stomach pain that cannot be explained by medical causes alone may allow a child to avoid going to school, or concern for the ill child may be a distraction for quarreling parents and result in parents arguing less. Unfortunately, when a pattern of behavior becomes established, it is likely to continue, even when the specific psychosocial stressor that initiated the behavior resolves or changes, and the behavior is no longer of adaptive value. For example, a toddler whose mother is depressed and unable to cope with age-appropriate tantrums may respond by adopting an attitude of stoic acceptance and precocious functioning. In the short term, this behavior may have adaptive value both for the child, who is faced with a constant and real threat of abandonment, and for the parent. This same child, deprived of the opportunity to use ordinary expressive behaviors or demands to get attention for his or her basic emotional needs, may resort to a variety of maneuvers to engage the mother's attention. One such maneuver is the presentation of physical symptoms that may be exaggerated or even feigned; these might be acceptable to and bearable by the depressed mother in a way that temper tantrums are not. Reinforcement of this behavior by maternal attention and care can ultimately generate a

chronic pattern of excessive illness behavior and the inappropriate use of health care to meet emotional needs.

CASE FORMULATION

The hallmark of the developmental assessment is the summary case formulation, in which an attempt is made to integrate the information obtained during the assessment, with the ultimate goal of guiding the treatment intervention. AACAP Practice Parameters recommend integrating the assessment factors into a “developmentally informed biopsychosocial formulation” that can be used to establish an appropriate treatment plan (DeMaso et al., 2009). This formulation should include the special strengths of the child and the emotionally relevant protective factors, in addition to the more conventional description of symptoms, risks, and vulnerabilities. The formulation includes a careful weighing of those factors in the patient’s life that promote development and may facilitate recovery. Two prospective outcome studies with conduct-disordered and eating-disordered adolescents have shown that such sub-typing based on risk factors can help predict outcomes 4.5 and 6 years after initial diagnosis (Smith et al., 1993; Steiner & Lock, 1998). Other studies have also shown significant effects of various risk and protective factors in mediating psychological outcomes. These include studies investigating peer and parental acceptance and rejection (Sentse, Lindenberg, Omvlee, Ormel, & Veenstra, 2010); warm family (parent and sibling) relationships and positive home environments (Bowes, Maughan, Caspi, Moffitt, & Arseneault, 2010); family routines and levels of parental monitoring (Murphy, Marelich, Herbeck, & Payne, 2009); and participation in group activities such as school clubs, sports, and religious groups (Piko & Fitzpatrick, 2004).

TREATMENT

Treatment Is Usually Multimodal

The recognition that a biopsychosocially oriented developmental formulation describes a complex mixture of symptoms, often in different domains of functioning, suggests that treatment interventions need to be multimodal in nature. This is in accordance with Principle 6 of the AACAP Guidelines, which states, “Psychotherapeutic management should consider multiple treatment modalities,” and highlights individual therapy, family therapy, and behavior modification as treatment options, in addition to consideration of psychopharmacological management (DeMaso et al., 2009). Single-intervention packages, regardless of whether these employ psychopharmacological, psychotherapeutic, psychoeducational, or environmental manipulation, are rarely successful. The developmental approach is oriented toward multiple factors that affect development and that interact over time. Thus it is, by definition, non-reductionist. The developmentally oriented clinician does not expect that mood, appetite, sleep, social skills, and academic performance in a depressed child will all respond to the administration of an antidepressant. Although some of the basic

biological symptoms of depression may respond, higher levels of functioning such as social skills and coping strategies generally require more complex and multimodal interventions that target both the child and the family, and in many cases may also require involvement of the school. Although interventions with children are often more complex, and as a result more costly, the failure to involve family members in the treatment is likely to interfere with the child’s recovery.

The Timing of the Intervention

Wherever possible, the clinician should attempt to intervene early to prevent the development of psychiatric disorders. The assessment of risk and protective factors can help in the identification of children with particular risks and vulnerabilities. Pre-syndromal disturbances may be addressed in a timely manner with the goal of *primary* or *secondary* prevention. The prevention and prophylactic treatment of severe anticipatory anxiety in children related to invasive procedures or surgery, discussed below, provides a model for this type of intervention.

Intervention Is Driven by the Appropriate Formulation of the Problem

Knowledge of the progressive and hierarchical organization of development as well as the phenomena of behavioral *regression* and developmental *arrest* is essential in planning treatment. For example, the symptoms of a child with an eating disorder may represent the expression of enforced and precocious development—in adaptive response to stressful demands in the child’s family context. The body-image distortion in an adolescent who grows up in a family and cultural milieu that highly values physical appearance and emphasizes health-oriented behaviors may result from pressure to conform to the demands of their social environment to the detriment of their functioning in other domains. In this case, the intervention should include efforts to change the family’s expectations and to provide the child with strategies to manage peer group and social pressures. In contrast, body-image distortion in another adolescent patient may indicate developmental regression in response to an acute psychosocial stressor, such as the breakup of a romantic relationship or an episode of physical or sexual abuse. In this situation, the treatment is likely to be shorter term and to focus on helping the patient identify and address the relevant stressors, as well as promoting the use of more adaptive coping skills. In contrast, body-image distortion may persist in the form of a pattern of behavior such as a fixed preoccupation with body image and appearance well beyond the early adolescent years, and it is important to differentiate established eating disorders from more temporary changes in eating in response to stress.

Intervention Is Aimed at Restoration of the Normal Developmental Trajectory

One powerful tool for the clinician is that the momentum of the normal developmental process can work synergistically with the therapist. By adopting a longitudinal perspective

and by having confidence in the restorative powers of time if stressors are decreased and maturation is allowed to proceed normally, bringing better adaptations, the clinician may sometimes decide that intensive psychiatric intervention is not needed. This is particularly true if the family can be relied upon to provide an environment that promotes development. For example, acute stress disorder following an acute trauma will not necessarily lead to the syndrome of PTSD in non-susceptible individuals, provided that the parents are able to provide appropriate support. Generally, the goal of all treatment interventions is to try to reestablish the normal developmental trajectory, and treatments are often made briefer and more rewarding by the resilience of children. The stability and supportive functioning of the family is a major determinant of short- and long-term outcome.

As noted earlier, interventions for children and adolescents will in almost all cases begin with both individual and family psychotherapy. Treatment will often begin with psychoeducation for the family to provide a context for the child's symptoms, and in many cases, behavioral interventions to address problematic behaviors. The nature of the psychotherapy work will be influenced by the child's symptoms. If the child fails to make progress, or if it becomes apparent that the family environment cannot support the child's treatment, it may be necessary to use more intensive treatments, including day treatment programs, or longer term residential treatment.

INVOLVEMENT OF THE FAMILY IN THE ASSESSMENT AND TREATMENT OF CHILDREN AND ADOLESCENTS

The child's dependency on the family (micro-system), friends (exosystem), and the larger circle of adults and society (macro-system) dictates that the family be at least considered, and more often than not involved, in the assessment process. Accordingly, the AACAP Practice Parameters highlight the importance of including the family in both the assessment and the treatment of physically ill children (DeMaso et al., 2009). This involvement of the family presents new and unexpected complexities for the clinician. The issues of the treatment alliance and confidentiality can become complex and challenging. The age of the child, the family's ability to provide the age-appropriate support, and the setting in which the child is seen, all determine the level of involvement between the family and the clinician.

PREPARING THE FAMILY FOR THE PSYCHIATRIC ASSESSMENT

Involving the family in psychiatric assessment and the treatment plan can prevent problems in the hospitalized physically ill child. The request for psychiatric consultation is generally initiated by one of the child's medical care providers and is not necessarily initially welcomed by the family. It may be the family's first contact with a psychiatrist, and unless the family are adequately prepared and agree to the consultation, it may not necessarily proceed smoothly. Many families will

have stereotyped perceptions of the role of the mental health consultant and interpret the consultation request as a communication from the medical team that they are not coping adequately. In addition, the stress of the child's medical illness may make the family much less receptive to meeting with a representative from a service that they do not perceive as necessary for their child's care. Initial defensiveness by the family should be no surprise and is more the norm than the exception.

Shaw and DeMaso (2006) describe the various steps involved in the consultation process. The first step in involving the family starts with the medical team explaining the rationale for the consultation. It is important for parents to understand that the consultation is being requested by the medical team, and in some cases it may be necessary for the attending physician to meet with the family to obtain their agreement. It may be helpful to explain that the consultation is necessary to provide help to the medical team in their work with the child. Clinicians should also bear in mind that many families may not have had previous experience with mental health professionals and may be primarily focused on medical diagnosis and treatment, with less emphasis on emotional well-being. Most families, however, will respond to the idea that hospitalizations are stressful for both the child and parents, and that their child may benefit from the added support provided by meeting with a therapist. Parents are usually open to the concept of relaxation or biofeedback to reduce anticipatory anxiety or assist with pain management. In high-stress procedures such as stem cell transplantation, it may be useful to present the psychiatric consultation as a routine part of the evaluation of all patients (if this is indeed the case) to make it more acceptable to the family. On rare occasions, when the child's psychiatric issues compromise the medical treatment or could put the child or others in danger, the medical team may need to insist on the family's agreement to the consultation as a condition of the child's continued medical treatment. For example, specialized treatment programs for pediatric pain or somatoform disorders in which psychiatric issues are commonly identified require participation in individual and family therapy as a mandatory component of the program.

The first meeting with the family should in most cases be with the parents or guardians alone, without the patient present. It is important to establish a working relationship with the family to facilitate the evaluation of the child or adolescent. It may be important to clarify with the family the reason for the consultation and the goals of the assessment. Any resistance should be explored to minimize the risk that the parents may consciously or subconsciously sabotage the assessment. One helpful approach to engage the family is to start with an inquiry about the *medical* history, and the impact of the *physical* condition on the child and family in the different domains of the child's functioning. A psychoeducational approach can also be helpful in terms of explaining to the parents the developmental issues and usual reactions of children to the stresses of treatment and hospitalization. It may also be necessary to explain some practical aspects of the evaluation that may be unfamiliar to parents, such as the

need to meet separately with the child, and the importance of confidentiality around sensitive information. Parents often may have suggestions as to how to introduce the mental health consultant to the child and often can be engaged as allies in the therapeutic process.

FAMILY INVOLVEMENT AS A FUNCTION OF AGE OF THE CHILD

In preschool-age children, the parent is an essential conduit into the mental life of the child. In their roles as primary caretakers, parents need to be intimately involved in all phases of assessment and treatment, even in cases where the parent is suspected to be a perpetrator of abuse. Clearly, the family serves as the primary source of the history, although it is important to supplement this information with reports from other caregivers and by direct observation of the child. In some situations and cultures, extended-family members may serve as surrogate parents.

The focus of the evaluation is often on the nature of the relationship between the child and the parents or parent surrogate. Disorders of attachment and difficulties negotiating the developmental tasks of separation-individuation are defined in reference to the parent-child relationship and the family's culture.

In school-age children, there are significant changes in terms of the child's ability to report symptoms and history, although, as noted earlier, there are problems when history is based purely on a child's self-report. It is always important to gather history from parents, and when possible, schoolteachers who are often able to make important observations on the child's functioning in the peer and social context. It is also important to note that school-age children retain primary loyalty for their family of origin, even when, paradoxically, a parent is the perpetrator of abuse or neglect. Family "secrets" are difficult to elicit, and it is not uncommon for children to change their story, depending on which parent is present. This can be a particular problem in custody evaluations.

In adolescence, the situation may become even more complex, especially as the patient approaches the age of 18 years. State laws generally respect the confidentiality of psychiatric and medical records in certain circumstances; for example, birth control and termination of pregnancies (Litt, 1990). With adolescent patients, it is important to focus on establishing a therapeutic alliance primarily with the patient, and secondarily with the family—the reverse of the situation with younger patients. Younger children typically require behavioral interventions enforced by parents and caregivers. Therefore, consultants work primarily with parents and caregivers to implement behavioral modification programs. However, identifying the patient as the primary client is preferred for older children and adolescents whose developmental levels allow them to use cognitive techniques and who also are able to utilize self-motivation for engaging in behavioral treatments. It may be very difficult to develop and maintain a working alliance if the adolescent perceives the clinician as an overt or covert "agent" of the parents. Parents may need education about the adolescent's needs for autonomy and

separation from the family of origin in cases where the parents are protective, controlling, or intrusive. Nonetheless, it is important not to ignore the relationship with the parents, and in some cases, it may be helpful to have separate individual and family therapists. While family therapy may be useful for a vast number of child and adolescent disorders, there is evidence that prior to the age of 18 years, family treatment alone can be effective, and at times more effective than individual therapy, in treating certain adolescent psychiatric disorders, such as substance use, trauma-related disorders, oppositional behavioral disorders, and eating disorders (Carr, 2000; Kmett Danielson et al., 2010; Lock et al., 2010; Sanders, Kapphahn, & Steiner, 1997). Thus, family therapy alone may be recommended for some cases, though it is frequently recommended as part of a multimodal treatment plan.

PARENTAL ABUSE AND NEGLECT

Working with families who are suspected of (or known to be) abusing or neglecting their children raises a number of issues. Angry reactions and other, often unconsciously determined countertransference reactions by the treatment team may tax their ability to remain professional and outwardly neutral toward the parent perpetrators (or suspected perpetrators). It is useful to remind nurses and clinicians of the important fact that parents who abuse or neglect their children often have been victimized themselves. Such efforts are usually helpful in reestablishing the ability of the treatment team to maintain an appropriate and professional attitude towards the family. At times, the best efforts at psychiatric intervention with the family will be unsuccessful in preventing further abuse from occurring. Protection of the child will then be the responsibility of the social agencies the law requires to be involved in such cases.

The mandatory reporting of the suspicion of, or overt, abuse or neglect of a child can best be presented to the family as a way to engage social and psychiatric resources to help the parents. Needless to say, most parents are not initially likely to experience the reporting as supportive and may be angry, defensive, and even litigious. In the inpatient setting, for cases in which abuse is not disclosed exclusively to the psychiatric consultant, it may be better to have the medical team make the report while the mental health team is available to provide support to the parents and to help in processing their feelings about the report. This approach may also help reduce the risk of the family's rejecting subsequent mental health interventions.

THE EPIDEMIOLOGY OF PEDIATRIC PSYCHIATRY: COMMON PEDIATRIC DISEASES

The most common reasons for psychiatric consultation in physically ill children include difficulties in adjustment to illness (for child and/or parent), delirium, differential diagnosis of somatoform disorders, disruptive behaviors, medication consultation, treatment nonadherence, pain management,

procedural anxiety, and suicide assessment (Shaw, Wamboldt, Bursch, & Stuber, 2006). A review of the clinical findings and research on treatment approaches provides a useful overview of these issues (Knapp & Harris, 1998). Many recent population- and clinic-based studies have prospective designs that allow for the identification of risk factors and protective factors as well as the identification of syndromal illness.

Pediatric and psychiatric comorbidity may be classified as being either coincidental or causal (Figure 79.2). *Coincidental comorbidity* refers to the coincidental or chance occurrence of both medical and psychiatric illness in the same patient, such that the two conditions are not thought to have a causal relationship. By contrast, *causal comorbidity* refers to the situation in which psychiatric and medical disorders coexist, and one of the disorders is thought to be responsible for generating the other. In many cases, there may also be an interaction between both physical and psychiatric illness.

COINCIDENTAL COMORBIDITY

Coincidental comorbidity may be more common than is generally appreciated. Between 10% and 31% of youth suffer from chronic medical illnesses, and another 10–20% suffer from psychiatric illness (Costello et al., 1988; Knapp & Harris, 1998; Newacheck & Taylor, 1992; Steiner, 1997a). The nature of the comorbid psychiatric conditions is dependent to some degree on the age of the child (see Box 79.3). Three volumes edited by Steiner (Steiner, 1996, 1997c, 1997d) review by age group the common psychiatric syndromes that can complicate the medical management of children with chronic physical illness.

In our experience, anxiety disorders are particularly likely to be exacerbated during acute physical illnesses and hospitalizations, while chronic physical illness is often associated with issues related to body image and lowered self-esteem. In addition, intellectual delay, learning disabilities, and attention-deficit hyperactivity disorder (ADHD) may all interfere with the child's understanding of the illness and her or his ability to comply with treatment recommendations. Coincidental comorbidity is associated with both extensive and at times inappropriate healthcare utilization, particularly when the psychiatric disorders go unrecognized (Lavigne et al., 1998). There are also implications for treatment and outcome (Perrin & MacLean, 1988).

Bipolar disorder
Schizophrenia

It is quite clear that a substantial number of children seen by pediatricians and in primary care suffer from coincidental comorbidity (Knapp & Harris, 1998). It is estimated that up to 20% of patients are so affected. In tertiary care centers, this percentage may be even higher, probably as a direct result of the chronic nature of their illnesses, and also potentially in response to the inherently traumatic nature of many medical interventions. While as many as 30% of adult patients in the general medical setting may have psychiatric comorbidity (Bronheim et al., 1998), far fewer studies have documented the prevalence of psychiatric comorbidity in the pediatric population. However, in a sample of 112 children with chronic illness, Canning (1994) found that 50% of these children qualified for at least one psychiatric diagnosis when using information from both parent and child interviews.

It is also clear that the majority of these cases are not identified by pediatricians, and that of those that are

identified, only a relatively small percentage are referred to mental health professionals for further evaluation (Costello et al., 1988; Kataoka, Zhang, & Wells, 2002; Owens et al., 2002). Simple screening instruments such as the Pediatric Symptom Checklist (Jellinek, Little, Murphy, & Pagano, 1995) may be helpful in identifying patients at risk. Once identified, patients should be referred to a mental health clinician for further evaluation and treatment. Most children and adolescents respond well to appropriate interventions targeted toward their symptoms. However, for severe cases that do not respond to first-line interventions, it may be necessary for families to be referred to highly specialized programs such as the Hasbro Partial Hospitalization Program at Hasbro Children's Hospital in Providence, Rhode Island, which bring together pediatricians and child psychiatrists to jointly address both mental health disorders and physical illnesses experienced by children and adolescents with comorbid conditions (Roesler, Glazer, Fritz, Dyer, & Rickerby, 2010).

CAUSAL COMORBIDITY

It is possible for psychiatric illness to perpetrate pediatric illness, and vice versa. *Psychosomatic* disorders are classically defined as psychiatric illnesses resulting in the genesis of somatic illnesses and symptoms. Eating disorders provide one example of how complex assumptions about body-state and composition result in the refusal to maintain appropriate body weight. This subsequently leads to a wide variety of somatic disturbances, some of which may in turn perpetuate the faulty body-image conceptualization. Other examples include factitious disorder and factitious disorder by proxy (previously known as Munchausen syndrome by proxy, nonadherence to treatment, delusional disorders leading to emaciation, and depression leading to weight loss).

In contrast to psychiatric illness's generating somatic symptoms, primary medical illnesses can also result in psychiatric symptoms or illness. Examples include delirium, mood disorders, psychotic disorders, and personality changes secondary to medical illness. Frequently, causation of psychiatric and somatic symptoms may be impossible to determine, and instead coexist as combinations of interrelated symptoms.

PSYCHOSOMATIC ILLNESS

Classic psychosomatic disorders, such as eating disorders, frequently present in primary care settings and benefit from a joint pediatric and psychiatric treatment approach. The description and discussion of these disorders is beyond the scope of this chapter, but the reader is referred to Lock (2011 and Steiner and Lock (1998), and the chapter on eating disorders in the medically ill in this volume by Brennan et al. While these illnesses are complex, they have been well studied, and there is a substantial base of evidence and experience to aid in their diagnosis and treatment (Steiner & Lock, 1998; Steinhausen, 1997).

The illnesses traditionally of great interest and with particular relevance for the consulting psychiatric clinician in the medical setting are the somatoform and factitious illnesses. Somatic symptoms are extremely common in childhood, with an estimated 10% of children in the general population manifesting unexplained physical complaints (Campo & Fritsch, 1994; Garralda, 2010). Furthermore, somatic symptoms of emotional distress often accompany chronic medical illness and emotional trauma (Erickson & Steiner, 1999; Steiner, 1997a). Many of these patients receive extensive and costly medical investigations that could be avoided by routine inquiry into their psychiatric and trauma history. Factitious disorder in children is rare but becomes increasingly common in adolescence. As might be expected, such illnesses are very often seen in children with histories of trauma and in delinquent youth with diagnoses of disruptive behavior disorders (Steiner, 1997b). "Factitious disorder by proxy," the fabrication of physical or psychological symptoms in children by their parents or caregivers, is a rare but important condition to be considered in pediatric patients (Shaw et al., 2008). It is a form of child abuse, and is also known as "medical child abuse." Recurrent infections, unusual bacteria, multiple treatment providers, multiple children with illnesses, and parents with medical backgrounds are some of the features that may raise concern for factitious disorder by proxy. Treatment studies are rare but document the extreme recalcitrance of these behaviors (Sanders et al., 1997).

CHRONIC SOMATOPSYCHIC ILLNESS¹

Patients with chronic medical illness have been shown to have significant psychosocial risk (Steiner, 1997a). Approximately 25% of children with physical illness develop emotional disorders, compared to 18–20% of medically healthy children (Wallander & Thompson, 1995). The data from prospective outcome studies using both objective and subjective assessment measures are consistent in showing that chronic illness poses risks in academic, vocational, interpersonal, psychological, and recreational domains of functioning (Pless, Power, & Peckham, 1993). The risks are significantly higher in younger children, boys, and those raised in single-parent or economically disadvantaged families. Generally, the patient's psychiatric status worsens over time, especially for those whose disability becomes permanent or who have poor social support (Pless et al., 1993).

The literature on chronic physical illness leading to psychiatric comorbidity is vast, although the quality of the studies is variable (Knapp & Harris, 1998; Steiner, 1997a). Almost all illness groups have been studied, the most common ones being bronchial asthma, diabetes mellitus, cancer, cardiac illness, epilepsy, and delirium; and more recently, HIV infection and chronic fatigue syndrome (Knapp & Harris, 1998). It is apparent that specific illnesses may contribute to different patterns of psychopathology and maladjusted behavior. General issues to be considered include the visibility of the physical illness, the presence or absence of pain, and the degree of disability.

¹ "Somatopsychic illness" refers to psychiatric symptoms caused by medical illness.

In comparison to the literature on chronic illness, much less is known about the acute psychiatric complications of pediatric medical illness. It is quite clear from a clinical point of view that children suffer from delirium and other forms of acute brain syndromes. There is also a growing literature on the acute complications of illness leading to PTSD (Bronner, Knoester, Bos, Last, & Grootenhuys, 2008; Colville, Kerry, & Pierce, 2008; Davydow, Katon, & Zatzick, 2009; Judge, Nadel, Vergnaud, & Garralda, 2002; Knapp & Harris, 1998; Shears, Nadel, Gledhill, & Garralda, 2005; Stuber, Nader, Houskamp, & Pynoos, 1996) and other psychiatric sequelae (Davydow et al., 2009; DeMaso et al., 1991; Muranjan, Birajdar, Shah, Sundaraman, & Tullu, 2008; Rees, Gledhill, Garralda, & Nadel, 2004). Studies have shown that between 13% and 34% of children surviving burns and other traumatic injuries, and 10–28% of pediatric intensive care unit (PICU) survivors with illnesses not related to inflicted physical trauma, demonstrate symptoms of acute stress or PTSD. These rates are similar to those reported in studies of adults with PTSD following intensive care unit (ICU) stays, which range from less than 2% to 64% (Davydow, Gifford, Desai, Needham, & Bienvenu, 2008). Additionally, 13% of pediatric burn survivors and 7–13% of PICU survivors suffer from clinically significant depressive symptoms (Davydow et al., 2009).

DIAGNOSIS AND MANAGEMENT OF COMMON CHILDHOOD DISORDERS IN THE MEDICAL SETTING

BEHAVIORAL REGRESSION

Behavioral regression is one of the most common reasons for referral to child psychiatry services in the medical setting (Fritz & Spirito, 1993). The treatment team encounters behavior and mentation which are grossly inconsistent with the child's chronological age and level of emotional development.

CASE HISTORY

Amanda, a ten-year-old girl, was hospitalized for unexplained episodes of fever that had not responded to outpatient intervention. Previously a very healthy child from rural northern California, Amanda was usually active, fond of the outdoors, and also competent and accomplished in taking care of horses and cows on the family farm. The oldest of four children, Amanda was her mother's "auxiliary parent" and usually took care of her younger siblings when their mother was unavailable.

This was Amanda's first hospitalization, and the experience radically changed her demeanor. She was completely passive and listless during the day, despite the fact that her fevers were gradually subsiding in response to treatment. Instead of appearing healthier and more energetic, Amanda became extremely demanding when her mother was present, and quiet and withdrawn when she was alone with the nursing staff. In her mother's presence, Amanda whined and

cried incessantly, demanding to be taken home. When her demands were not met, she refused to cooperate altogether, making her medical management prolonged and difficult. Both parents reacted with surprise and embarrassment, since her behavior was so out of keeping with her habitual level of functioning. The mother attempted to get Amanda to "act her age" by encouraging her to be tough and by reminding her of the days when she could be relied on to help out in even the most difficult situation. All of these efforts, however, were unsuccessful.

The child psychiatry consultation team found a very sullen and resentful girl who essentially was mute and withdrawn. Much of the evaluation required her mother's presence and support to gain Amanda's trust. Amanda's mother was both sleep-deprived and tired. She was unable to respond to her daughter's demands for care-taking, since she herself was a stranger to the hospital environment with little understanding of the medical interventions. The first intervention suggested by the child psychiatry team was to establish a flowchart of Amanda's daily activities. With encouragement, Amanda was able to contribute to the observations. Contacts with the staff were organized in such a way as to be brief and extremely predictable. As the team began to intervene, it became clear that structure and protection would be helpful to Amanda. Laboratory tests were scheduled at predictable times of the day, and procedures were scheduled together with the agreement of both Amanda and her mother. Amanda's father was asked to provide relief for the mother, who had been the sole resource for their child during the prolonged hospital stay. Art and play psychotherapy sessions were scheduled, during which Amanda's mother was asked to leave and go to the cafeteria to restore herself. Additionally, nursing and medical staff were asked not to interrupt. For each new procedure, preparatory sessions were scheduled, with the aim of enhancing the patient's and the mother's understandings of the purpose of the upcoming intervention.

After three days, Amanda was again fully functional and an active participant in her care. Serial blood cultures and cardiac investigations eventually confirmed a diagnosis of bacterial endocarditis. Amanda was treated with an appropriate course of intravenous (IV) antibiotics initiated in the hospital and completed at home with a peripherally inserted central catheter (PICC) line. One month after discharge and after completion of antibiotics, there were no apparent sequelae, and, in fact, Amanda appeared to have only a very dim memory of the details of her hospital stay. Six months after the initial stay, she remained symptom-free and was back to her regular behavior on the farm without any further special intervention.

This case is a good example of how overwhelming stressors and a less than optimally functioning parent can lead to the temporary emergence of age-inappropriate behavior. The intervention involved simple environmental manipulation, with the goal of restoring the patient's sense of control and mastery. Since there was no preexisting psychopathology in the child and her family, her symptoms resolved relatively easily and quickly without the need for any longer term treatment. The emergence of immature behavior under extreme duress in previously healthy individuals has to be carefully differentiated from more serious psychopathology. Making this distinction depends on the detailed understanding of the child's previous development (Steiner, 1996, pp. 1–41).

Anxiety Disorder

A wide variety of anxiety disorders may present in children in the medical setting. These may include adjustment disorders with features of anxiety, procedural anxiety, separation anxiety, panic, post-traumatic stress and acute stress disorders, and exacerbation of generalized anxiety. While some anxiety is to be expected, given the change in environment, physical discomfort, and often uncertainties about procedures or outcomes that are associated with inpatient hospitalization, anxiety that causes disturbances in daily functioning should be addressed and treated.

CASE HISTORY

Martina, a seven-year-old girl, was the victim of a severe and traumatic motor vehicle accident. She was a passenger in the rear seat of a car driven by her mother, and she was not wearing a seatbelt at the time of the accident. Martina was thrown from the car and sustained multiple injuries, including a degloving injury of her right lower leg and extensive disfiguring of the soft tissue on her face. She underwent several emergency surgeries after admission and needed multiple invasive medical procedures during the early part of her hospitalization.

Psychiatry consultation was requested for Martina after she started to refuse even routine medical procedures, requiring sedation and physical restraint for blood tests and dressing changes. She was extremely apprehensive and resistant to physical examinations, and the medical staff had been unable to persuade her to undergo a necessary magnetic resonance imaging (MRI) scan. Nursing staff reported that Martina was waking multiple times during the night with traumatic recollections of the car accident. Her mother reported that Martina had also become exceptionally clingy and anxious, and was not able to tolerate her mother leaving her room without having severe episodes of anxiety.

During the initial psychiatric assessment, it was noted that Martina's mother was having almost as difficult a time as her daughter. She was consumed with feelings of guilt, since she had been the driver of the car, and was unable even to discuss the events as a result of her own associated traumatic memories. She was withdrawn and tearful in Martina's presence, and unable to provide appropriate parental support for her child's treatment.

Martina was assessed as having symptoms of an acute stress reaction, with increased anxiety, flashbacks, and intrusive memories of the accident. She also had symptoms consistent with separation anxiety, reflecting psychological regression in the face of overwhelming trauma. In addition, she had symptoms best explained as a manifestation of medical trauma, which included intense anxiety and hypervigilance related to contact with medical personnel, as well as avoidance of procedures.

Treatment in Martina's case was multimodal. A pain service consult was requested to provide recommendations for pharmacological and behavioral approaches to better manage her wound pain, and for preventive pain management during medical procedures. She was referred to the hospital's surgery-preparation program to participate in medical play, a technique in which the child role-plays a doctor carrying out medical procedures on dolls. Medical play can be helpful in desensitizing a patient and reducing anxiety related to

the medical procedures. A behavior modification protocol was established to encourage her compliance with treatment, using rewards and incentives. Martina was also seen by the psychiatry service for individual-play psychotherapy to help her process her feelings about the accident. Finally, family therapy sessions were scheduled to help the entire family—in particular, Martina's mother, whose feelings of guilt had prevented her from fully participating in Martina's treatment.

Martina's case illustrates many of the principles used in the management of anxiety disorders presenting in children in the medical setting. Firstly, it is important to note that anxiety is a common presenting symptom in many situations. Separation anxiety, for example, is normal and developmentally appropriate in young infants. It is also not unusual or inappropriate to observe symptoms of anxiety and obsessive-compulsive behaviors in response to the stress of acute illness or hospitalization. In Martina's case, anxiety was a manifestation of an acute traumatic reaction, compounded by recurrent trauma related to medical treatment. Finally, anxiety may reflect an underlying and comorbid psychiatric disorder, including depression or one of the various anxiety disorders seen in children (Steiner, 1996; Steiner, 1997d).

In the acute medical setting, it is usually necessary to resort to multiple treatment approaches, aside from standard pharmacological approaches. Children in general respond very well to behavioral interventions, including hypnosis, biofeedback, and standard behavior modification protocols, provided the interventions take into account the child's developmental level. As in Martina's case, it is important not to neglect individual and family therapy as part of a comprehensive treatment plan.

PREVENTION AND TREATMENT OF ANTICIPATORY ANXIETY

Children are susceptible to a number of emotional and behavioral problems related to medical procedures and hospitalization. These include anticipatory anxiety, post-traumatic stress reactions, sleep and appetite disturbances, adjustment disorders, and problems with aggression. For example, Lumley et al. (Lumley, Melamed, & Abeles, 1993) reported that 11% of children experienced severe behavior problems within two weeks of surgery, and children who are unprepared appear to be at particular risk. While this section will briefly discuss procedural anxiety, Mednick (2010) provides a more detailed overview of factors influencing procedural anxiety and techniques for preparing pediatric patients for medical procedures.

CASE HISTORY

Emily, a nine-year-old girl, had been diagnosed with leukemia at the age of four years. She had one relapse of her disease, and was being treated aggressively with chemotherapy in the hope that she would be a candidate for stem cell transplantation. She was also diagnosed with a neurogenic bladder, after presenting with urinary retention. The urology service made the recommendation for intermittent catheterization four times each day, while efforts were being made to understand the etiology of her urinary problem. Indwelling Foley

catheterization was not thought to be a good option, due to the risk of infection in the setting of her immunosuppression.

The first three catheterizations were very traumatic for Emily, who had already had to endure numerous invasive medical procedures for her leukemia, including bone marrow aspirations, spinal taps, and venipuncture. Psychiatry consultation was called because Emily was refusing the procedure, and manifesting extreme anticipatory anxiety. Emily's mother, who had been present during the catheterizations, was also upset and insisting on an alternate approach. Given the acute nature of the problem, and the need for regular urinary outflow, the recommendation was made for temporary Foley catheterization while efforts were made to desensitize Emily to the procedure. She and her mother were shown a videotape of a child calmly undergoing self-catheterization, and then a tape on the use of medical hypnosis and guided imagery in a pediatric medical setting. It was considered critical to engage her parents' support for the treatment, since any opposition was thought likely to sabotage the intervention. After discussion with her parents, it was decided to try medical hypnosis. Emily was found to be highly hypnotizable, and was able to use the image of a familiar and safe place she could go to while practicing deep breathing and progressive relaxation. She was also instructed in imagery techniques to relax her pelvic area and visualize the catheter passing easily into her bladder. Over the next three days, Emily also participated in daily medical-play sessions in which she practiced inserting a catheter into an anatomically correct doll, playing the role of the doctor who was coaching her patient to relax and use guided imagery during the catheterization.

The next phase in the treatment was to get Emily used to manipulating the indwelling Foley catheter while in a state of deep relaxation. A sticker chart was created with rewards for progressive efforts to manipulate the catheter, and it was found that this further helped motivate Emily to proceed with the program. Emily was given the decision about when she felt ready to proceed with her first catheterization. It was felt that it was important to give her a sense of some control in a setting where practically all control had been taken from her as a consequence of her illness. With the presence of the team who had prepared her for the procedure, she was able to successfully remove and reinsert a catheter, and begin the transition to regular catheterization.

Efforts to reduce distress related to anticipatory anxiety fall into two major categories: education and modeling, and enhancement of coping strategies (Harbeck-Weber & Hepps McKee, 1995). Surgery-preparation programs incorporate the use of videotapes of hospital procedures, provision of information in the form of classes, and simulation of actual procedures (Rosenberg et al., 1997). These programs are reviewed in Kain et al. (Kain, Caldwell-Andrews, & Wang, 2002), and Kain and Caldwell-Andrews (2005).

In summary, studies have suggested that participation of parents and children in these programs can lead to significantly reduced levels of anxiety and distress and behavioral changes, based on both self- and observer-report (Kain et al., 1998; Saile, Burgmeier, & Schmidt, 1988). Enhancement of coping strategies includes education and rehearsal of techniques such as deep muscle relaxation, breathing, guided imagery, distraction, and hypnosis (Butler, Symons, Henderson, Shortliffe, & Spiegel, 2005; Lukins, Davan, & Drummond, 1997; Rickert, Kozlowski, Warren, Hendon, & Davis, 1994; Thompson & Coppens, 1994). Reports suggest that children

who participate in these measures prior to surgery tend to exhibit less distress and are more cooperative with procedures. Programs that also incorporate stress-management and anxiety-reduction techniques for the parents appear to have even greater efficacy (Campbell & Cueva, 1995). While ideally such programs would be available at all hospitals conducting elective pediatric surgery, for hospitals that lack routine pre-surgery-preparation programs, screening before and after surgery for anxiety and/or post-traumatic symptoms is recommended.

It is also important to consider the child's previous experiences of hospitalizations. Young children who have had previous traumatic experiences may undergo a paradoxical increase in anxiety in response to surgery-preparation programs (Melamed, Dearborn, & Hermecz, 1983), so it is important to tailor interventions to match each individual patient. Other issues that affect the nature of the intervention may include the age and developmental level of the patient, the child's coping style, the timing of the intervention, and family factors (Blount, R. J., Piira, T., & Cohen, L. L. (2005).) (see Chapter 13).

DEVELOPMENTAL ISSUES

The child's level of cognitive development is an important consideration in determining the nature of the intervention. Children at the pre-operational stage of cognitive development (cognitive functioning characterized by illogical, magical, and nonreversible thinking, as well as egocentrism [Inhelder & Piaget, 1958]) are less able to use cognitive-behavioral strategies to manage anxiety. In addition, younger children are more likely to have misperceptions about their illness, are less likely to ask questions, and seem to receive fewer benefits from conventional surgery-preparation programs (Vernon & Thompson, 1993). Programs that take into account the child's developmental level and modify methods of presenting information accordingly have better results in terms of reduced levels of distress in children following procedures (Rasnake & Linscheid, 1989). Preparation programs targeted toward children at the preoperational stage of development might include visits to the hospital and medical play with models of surgical suites, IV lines, gowns and masks, and so on. Related issues to consider include the presence or absence of developmental delays, children with auditory or visual processing difficulties, or those with comorbid psychiatric disorders such as attention-deficit hyperactivity, which may affect their ability to benefit from preparation programs.

COPING STYLES

The child's coping style is an important variable to be considered in designing treatment interventions. Schultheis and colleagues (Schultheis, Peterson, & Selby, 1987) have proposed that individuals can be categorized on the basis of whether they are "sensitizers" or "repressors." Sensitizers cope with stress by gathering as much information as possible about the planned procedures and may prefer to watch procedures such as venipuncture rather than closing their eyes or relying

on distraction. Repressors, by contrast, tend to use denial and distraction, and may benefit more from guided imagery or hypnotic strategies designed to draw their attention away from the procedure.

TIMING OF PREPARATION

There are conflicting data about the timing of surgery-preparation programs. In general, it is better to schedule participation close to the actual procedure (Beddows, 1997). Younger children in particular may not be able to retain information presented too early. However, Faust and Melamed (1984) compared children prepared the day before surgery with children prepared the day of surgery, and reported that same-day preparation may have resulted in increased anticipatory anxiety. Overall, preparation shortly before procedures seems to increase children's knowledge about the procedures, but the efficacy of these programs in reducing fear and distress, and on longer term outcomes, has not been clearly documented (Harbeck-Weber & Hepps McKee, 1995).

FAMILY ISSUES

It is also important to consider the role of the parents. The presence of a parent is nearly always helpful in reducing the child's level of distress, especially if the parent's level of anxiety is contained and they are able to provide support (Cameron, Bond, & Pointer, 1996; Kain et al., 1996). Parental anxiety has a strong impact on the child's ability to cope, and combination of high parent and high child anxiety is particularly problematic. Parents who received stress-management training reported reduced levels of anxiety and tension, while their children used more adaptive behaviors during procedures (Campbell & Cueva, 1995).

Finally, it is important to anticipate delayed psychological reactions and sequelae long after the procedure has taken place. Studies suggest that cancer treatment has traumatic implications years after initial treatment in long-term cancer survivors (Calaminus, Weinspach, Teske, & Gobel, 2007; Eilertsen, Rannestad, Indredavik, & Vik, 2011; Erickson & Steiner, 1999). Although such trauma-related psychopathology may not appear as a full clinical syndrome, problems may manifest in the form of avoidance of necessary medical procedures and follow-up medical appointments, or, paradoxically, the intense preoccupation with and seeking out of inappropriate medical procedures.

DEPRESSION

Children admitted to the hospital with physical illness are expected to experience a degree of dysphoria related to a variety of factors, including physical discomfort, limited activity, removal from the home environment, loss of privacy, and awareness of poor health. However, when changes in their mood begin to negatively impact physical symptoms or hinder their ability to complete daily tasks, the diagnosis of a mood disorder or of adjustment disorder with depressed mood should be considered.

CASE HISTORY

Sergei, a 14-year-old adolescent boy diagnosed with acute lymphoblastic leukemia, was admitted for matched, unrelated, stem cell transplantation after his first relapse. Although the bone marrow donor was not a perfect match, Sergei's risk of future relapse was sufficient to warrant the risk of transplant. Psychiatry consultation was called three weeks into his transplant because he appeared to have given up hope and was expressing a wish to stop treatment. Sergei was described as apathetic and withdrawn, and he was refusing to cooperate with his treatment. He had also had several painful medical complications related to his chemotherapy regimen, including pancreatitis and mucositis. His pediatric oncologist questioned whether Sergei might benefit from an antidepressant.

In the psychiatric evaluation, Sergei endorsed many of the symptoms of major depression, including depressed mood and feelings of hopelessness, in addition to anorexia, weight loss, lethargy, and insomnia. Sergei also reported having overheard his parents discussing the death of another patient on the unit two weeks previously, following the identical complication of his pancreatitis. His mother gave additional family history that a paternal uncle had died of pancreatic carcinoma.

This case raises many of the common issues in the assessment of depression in the medically ill adolescent. These issues are reviewed in detail in a chapter on mood disorders (Chapter 6, pp. 77–100) in the *Textbook of Pediatric Psychosomatic Medicine* by Benton and DeMaso (2010). One issue is that traditional diagnostic criteria for major depression (American Psychiatric Association, 2000) overlap significantly with physical illness itself. Many of the findings—"fatigue and loss of energy, insomnia, decreased appetite and weight loss, and difficulties with concentration"—may occur as sequelae of medical illness or its treatment, particularly disorders with significant pain. While some authors (e.g., Kathol et al., 1990) have suggested adapting the diagnostic criteria in medically ill patients, the difficulties of clinically differentiating these issues persist. It is also important to consider the possibility that specific medical disorders or medications may precipitate depression. In Sergei's case, many of his symptoms could be accounted for by his medical condition. Anorexia, weight loss, and lethargy are common in the course of bone marrow transplantation, and his insomnia was also easily explained by his severe pain. There were also justifiable medical concerns as well as relevant psychological issues that could account for his feelings of hopelessness. Burke and Elliott (1999) have drawn attention to the need to consider depression in the medically ill child as a potential outcome of the interactions between the child's biological vulnerability for depression, the characteristics of the illness, as well as relevant environmental stressors.

While treatment with antidepressants may often be indicated in medically ill children, it is common in pediatric practice to find that the depressive symptoms remit spontaneously as the acute medical issues resolve. Following general psychiatric principles, we tend to recommend very careful assessment and several meetings before recommending antidepressants in medically ill children. In cases where a child is refusing treatment, it is important to clarify possible misconceptions about the medical illness, since it is common for younger children to misinterpret or misunderstand information. In children with severe or terminal illness, the request for

psychiatric medications often comes out of feelings of hopelessness in the medical team and the family. In lifelong illnesses requiring chronic aggressive medical regimens with limited benefit, adolescents and young adults sometimes make legitimate decisions to end treatment, or choose less aggressive treatment that is often called “educated non-compliance,” in the interests of preserving their quality of life. It is important to respect these decisions as long as they are made autonomously, not coerced, and not automatically regarded as psychopathological. When the decision is made to treat with antidepressants, is important to be clear about what can be reasonably expected in terms of the likely response, as well as the usual delay in onset of action. The reader is referred to Steiner (1996) for further details on the specifics of assessing and treating depression in children and adolescents.

ACUTE PSYCHOTIC REACTIONS

Although less common than symptoms of anxiety and depression, psychotic reactions may also be seen in conjunction with physical illness and inpatient hospitalization. These reactions may be due to medications or medication withdrawal, prolonged stay in ICUs, head trauma, infection, or metabolic disturbances.

CASE HISTORY

Vanessa, a nine-year-old girl, presented to the emergency room in an acutely agitated state, reporting beliefs that her older brother had been sexually molesting her at home. She was extremely paranoid, reported visual hallucinations, and had apparently not slept for three days prior to her admission. Vanessa had been diagnosed with inflammatory bowel disease at the age of six and needed several hospitalizations, including a recent admission for total colectomy and placement of a colostomy. Despite the surgery, Vanessa had continued to have persistent and severe bloody diarrhea, with weight loss, requiring her to be restarted on high doses of prednisone. Previous treatment with steroids had precipitated episodes of hypomania, treated aggressively with IV haloperidol during her inpatient admissions, and managed with oral risperidone during outpatient treatment, due to concerns about her susceptibility to severe extrapyramidal reactions related to previous treatment with haloperidol.

Vanessa was admitted under the medical service with a provisional diagnosis of psychotic disorder due to steroid treatment, induced by treatment with prednisone. Her mother reported noticing pill fragments in the colostomy bag, and it was presumed that she had not been absorbing adequate doses of her oral (*per os*—PO) risperidone. Vanessa was restarted on IV haloperidol 1 mg twice daily, and she needed additional “as needed” (*pro re nata*—PRN) treatment during the first few days of her hospitalization. She also developed symptoms of akathisia, which were managed with low doses of IV lorazepam.

After resolution of her acute psychotic symptoms, Vanessa’s medications were switched to PO liquid haloperidol and diphenhydramine, and she was able to continue the needed medical treatment with prednisone without recurrence of her psychosis. Vanessa subsequently denied her earlier allegations of sexual abuse. Because

her mental status had changed so significantly during the time when allegations were reported, the allegations seemed clearly related to the psychosis, and it was not necessary to report the case to Children’s Protective Services.

The principles in the assessment and management of acute psychotic reactions are similar to those in adult patients (Box 79.4). There needs to be an immediate assessment of the safety issues, including a determination as to whether or not the patient can be safely managed in the hospital facility. Often, the medical issues make it unrealistic for the patient to be transferred to a psychiatric facility, and as a result it is important to recommend whatever measures are necessary, which may include one-on-one observation, pharmacological treatment of agitation, and sometimes physical restraints. Although immediate attention will be given to the diagnostic issues, it may still be necessary to treat the

Box 79.4 ASSESSMENT AND MANAGEMENT OF ACUTE PSYCHOTIC REACTIONS

Immediate Assessment of Safety Issues

- Elopement risk
- Potential for violence
- Need for 1:1 observation
- Need for physical restraints
- Need for pharmacological treatment of acute agitation.
- Need for transfer to inpatient psychiatric facility

Differential Diagnosis

Delirium

- Medication-induced psychotic disorder (e.g., steroids)
- Substance-induced psychotic disorder (e.g., amphetamine)
- Drug withdrawal reaction (e.g., alcohol)
- Endocrine disorders (e.g., thyroid)
- Connective tissue disorders (e.g., Systemic Lupus Erythematosus)
- Central nervous system disorders (e.g., neoplasms)
- Partial complex seizures
- Vitamin deficiencies
- Heavy-metal toxicity (e.g., lead poisoning)
- ICU psychosis
- Schizophrenia
- Bipolar disorder

Medication Management

Initial dose of antipsychotics

- Haloperidol 0.5–1 mg i.v.
- Olanzapine 6.25–24 mg p.o.
- Risperidone 0.5–1 mg p.o.
Extrapyramidal symptoms
- Benztropine 0.5–1 mg i.v.
- Diphenhydramine 12.5–25 mg i.v.
Akathisia
- Lorazepam 0.5–1 mg i.v.

**Box 79.5 NON-ILLNESS AND ILLNESS
TASKS FACING FAMILIES WITH
PEDIATRIC PHYSICAL ILLNESSES**

Non-Illness Family Tasks

1. Maintaining family connections
2. Maintaining family morale and a sense of meaning
3. Ensuring attention to parental relationships and opportunities for intimacy
4. Providing attention, encouragement, and supervision for siblings
5. Ensuring opportunities for play, recreation, and enjoyment
6. Ensuring adequate financial resources
7. Maintaining connections to extended family, community supports, and friendships
8. Continuing with family spiritual life
9. Dealing with other important family stresses—other family illness, moving, job loss, or job change

Illness Family Tasks

1. Developing a shared understanding of the illness
2. Resolving disagreements about the child's condition or care
3. Developing routines that embed illness care into family life as much as possible
4. Assigning and monitoring illness tasks, especially making sure that the ill child can be and is responsible for his or her tasks
5. Building some flexibility into parental roles and avoiding rigid role definition
6. Developing a shared view that illness-management builds family competence
7. Communicating with siblings about the illness and their experience of the illness
8. Experiencing, communicating about, and managing emotional reactions to the illness
9. Collaborating effectively with the medical team
10. Ensuring that all members of the family and medical team are known to and engage with each other

psychosis symptomatically with antipsychotics while the medical workup is in progress. It is not uncommon to find that pediatric staff are unfamiliar with dosages of the psychotropics, and it is important to make very clear recommendations about specific doses, and to monitor the patient carefully for extrapyramidal symptoms and akathisia. The reader is referred to Chapter 5 by Turkel (2010) in Shaw (2010) for a fuller account of the diagnostic and treatment issues in acute psychotic reactions and delirium.

Generally, low doses of intravenous haliperidol are recommended for children who are unable to take oral food or medication (nothing *per os*—NPO). However, if children are able to take medication by mouth, low-dose risperidone is recommended for hypoactive delirium, and haloperidol is recommended for hyperactive delirium.

**TREATMENT: PSYCHOTHERAPY AND
PSYCHOPHARMACOLOGY**

The comprehensive treatment of children and adolescents has become increasingly differentiated and sophisticated. Psychotherapy encompasses a wide variety of techniques, ranging from supportive to exploratory; educational to cathartic; interpersonal to playful. A detailed discussion of these techniques is beyond the scope of this chapter, and the reader is referred to three volumes detailing the treatment of the preschool-age child (Steiner, 1997c), the school-age child (Steiner, 1997d), and the adolescent (Steiner, 1996). Additionally, problem-specific treatments are reviewed in their respective chapters in Shaw and DeMaso's *Textbook of Psychosomatic Medicine* (2010). Psychopharmacological treatments and their medical side effects are reviewed in the next chapter of this book. Suffice it to say that there is increasing evidence for the specificity of interventions and their effectiveness in children and adolescents across a variety of symptoms. All classes of treatment and psychopharmacology are employed, and the modal intervention in this population targets multiple symptoms using a carefully coordinated treatment package.

Child psychiatrists tend to be more conservative about the use of pharmacological management for children than for adults, for several reasons. Most pharmacological studies are conducted in adults, so less is known about the side effects and pharmacokinetics of many medications in children. Additionally, there are few long-term studies addressing long-term effects of psychopharmacological agents on the developing brain. Because children depend largely on adults for creating their social environments, as well as positive and negative reinforcers, it is typically easier to use behavioral techniques with children,

**Box 79.6 INDICATIONS FOR REFERRAL FOR
FAMILY THERAPY**

1. Marked family distress
2. Poor collaboration and communication with medical team
3. Disabling emotional and/or behavioral symptoms in the ill child and/or siblings
4. Marked marital stress that involves the ill child and/or siblings
5. Problems ensuring that the ill child adheres to the treatment regimen
6. Exhaustion, anxiety, burnout, and/or depression in one or both parents

as caregivers and teachers can be responsible for providing the appropriate reinforcers. For these reasons, families should be involved in assessment and treatment. Boxes 79.5 and 79.6 highlight the non-illness and illness tasks facing families with pediatric physical illnesses as well as the indications for referral to family therapy. Finally, there is strong evidence to suggest that, while medication alone may be effective for certain disorders such as depression and ADHD with associated comorbidities, the combination of therapy and medication provides the greatest benefits (March et al., 2004; Swanson et al., 2008).

CLINICAL PEARLS

- Difficulties in attachment may be repaired by experience of a positive relationship with an adult outside the family (Rutter, 1988).
- Adolescents are prone to (unconscious) denial as well as conscious deception of others (Erickson & Steiner, 1999; Steiner, 1996).
- Fewer psychiatric diagnoses will be missed if the clinician gathers information by interviewing both the patient and parents, and additional sources of information may reveal even more comorbidities.
- Categorizing the developmental trajectories in the major domains of functioning, along with an appropriate charting of milestones, impediments, and sensitivities, is essential for constructing a clear longitudinal picture of the child's development.
- Discrete diagnostic categories, even if adjusted for specific age groups, rarely capture the entire clinical picture of the pediatric patient.
- Symptoms do not occur in a psychosocial vacuum—they often fulfill a function for the child that can be understood by assessing the child's social and temporal context and overall social equilibrium.
- Behavioral symptoms tend to help resolve conflict.
- Clinicians should consider and carefully weigh the factors in the patient's life that promote development and may facilitate recovery.
- Single-intervention packages are rarely successful.
- Clinicians should attempt to intervene early to prevent the development of psychiatric disorders.
- The momentum of normal growth and development can work synergistically with the therapist.
- The goal of all treatment interventions is to try to reestablish the normal developmental trajectory.
- The mandatory reporting of the suspicion of, or overt, abuse or neglect of a child can best be presented to the family as a way to engage social and psychiatric resources to help the parents.

DISCLOSURE STATEMENTS

Dr. Froehlich, Dr. Steiner, and Dr. Shaw have no possible conflicts of interest, financial or otherwise, including direct or indirect financial or personal relationships, interests, and affiliations, whether or not directly related to the subject of the chapter. This chapter was supported in part by grants to Dr. Steiner from the Eucalyptus Foundation.

ADAPTATION OF PSYCHIATRIC DRUG TREATMENTS TO CHILDREN AND ADOLESCENTS

Eric P. Hazen

INTRODUCTION

Managing psychiatric medications in the pediatric population presents a unique set of challenges to the clinician. Clinical experience supports the oft-repeated maxim that “children are not just small adults.” Children and adolescents may have different responses to medication than the adult population and may be more sensitive to the side effects of some medications. Furthermore, the challenges of conducting clinical trials in the pediatric population have resulted in a relatively limited evidence base for psychopharmacological interventions in the pediatric population relative to the evidence base for the adult population. As a result, there are not clear dosing guidelines for some medications, and many medications are used off-label, without a Food and Drug Administration (FDA) indication, based on clinical experience or small, open-label trials.

Despite these challenges, medications are a vital tool in the treatment of mental illness in children and adolescents. When managed properly, medication can be part of a treatment regimen that allows a young patient to get back on a healthy developmental trajectory, potentially preventing long-term psychological, social, and occupational impairment. In this chapter, we will discuss the general approach to managing psychiatric medications for children and adolescents before moving on to a discussion of specific issues involved in the more common psychiatric disorders in this population.

APPROACH TO MANAGING PSYCHIATRIC MEDICATIONS IN PEDIATRIC PATIENTS

While there are several special considerations in the management of medications in children and adolescents, general principles of good psychopharmacological practice apply. Because these principles are critically important in safe use of medications in the pediatric population, they bear brief mention here. These principles include:

- Establishing effective communication and a collaborative relationship with the patient and family
- Integrating medication into an overall treatment plan for the patient based upon a biopsychosocial formulation
- Starting medication only after a thorough medical and psychiatric evaluation, including detailed review of past medication trials and their effects
- Starting medications at the low end of the effective dose range and gradually titrating to effectiveness
- Employing the simplest medication regimen necessary to effectively manage the patient’s symptoms, using polypharmacy only when indicated to treat residual symptoms, comorbid diagnoses, or side effects from other medications
- Taking one step at a time when possible, avoiding making multiple changes at once that will make subsequent changes in clinical presentation difficult to interpret
- Taking a systematic approach, assuring that each medication trial has been allowed adequate time at an adequate dosage before deeming it ineffective and moving to the next step in treatment
- Closely monitoring efficacy and side effects, using objective measures and structured rating scales when they are available
- Explicitly asking patients about their adherence to the medication regimen rather than assuming the medication is being taken as prescribed
- Monitoring drug levels when there is an established therapeutic range and it is known that there is significant inter-individual variability in the drug’s pharmacokinetics
- Simplifying medication regimens when possible to avoid confusion and non-adherence
- Adhering to current practice guidelines for monitoring side effects of specific medications
- Being fully aware of all the drugs the patient has been prescribed by other physicians, as well as the patient’s use of over-the-counter medications, nutritional supplements, and complementary treatments

- Maintaining communication with other medical and psychiatric providers involved in the patient's care
- Providing clear documentation of the patient's care, preferably in electronic form

DEVELOPMENTAL CONSIDERATIONS

In addition to these general principles, there are several considerations specific to the care of children that should be considered in managing medications. Perhaps most importantly, the child's stage of development must be taken into account in the approach to medication. From a physiological perspective, children metabolize medications differently than adults do. A greater ratio of liver mass to body mass and a more rapid glomerular filtration rate leads to many medications being metabolized more rapidly in children than they are in adults (Anderson & Lynn, 2009). Thus, for some medications, young patients may require higher doses per kilogram of body weight than adult patients. However, for other medications, lower activity of specific enzymes in the cytochrome P450 system implies slower metabolism and relatively higher blood levels (Benedetti et al., 2007).

At the same time, physiological differences can make pediatric patients more sensitive to some side effects. For example, children and adolescents have a higher density of dopamine receptors in the central nervous system than adults do (Boyson & Adams, 1997; Rinne et al., 1990). Differences in baseline dopaminergic transmission help explain why pediatric patients are more likely to develop acute dystonia in response to dopamine-blocking drugs, especially the high-potency, first-generation antipsychotic drugs. Development plays a role, not only in the physiology of the medication, but in the approach to discussing medication with a pediatric patient. Regardless of age, pediatric patients should be active participants in their psychiatric care and should be included in discussions about their medications, though it is critical to carry on the discussion in a developmentally appropriate way. Young children typically benefit from a simple, straightforward explanation of the goal of the medication, with a concrete example of how it might help them (e.g., "We think this will help you listen and learn better in school and be more in control of your body, so you don't get sent to the principal's office quite so often.") Young children may need reassurance that a medication will not change who they are or make them do things they do not want to do. They may become overwhelmed or anxious when confronted with long and detailed lists of possible side effects and may do better with a more general instruction to let their parents know if there is anything they feel on the medication that they do not like.

In contrast, most adolescent patients are able to grasp a more abstract, nuanced explanation of medication and its role in their treatment, and most want to know what specific side effects they might experience. As adolescents are often confused and dismayed by their changing bodies, it is particularly important to let them know about potentially embarrassing side effects that could be particularly distressing for an adolescent, such as sexual side effects of selective serotonin reuptake inhibitors (SSRIs) and

serotonin-norepinephrine reuptake inhibitors (SNRIs), priapism in boys taking trazodone, or lactation in girls taking risperidone or other antipsychotic drugs that elevate prolactin levels. An adolescent taken by surprise by such an effect may lose trust in the clinician, with devastating consequences for the treatment.

Before a patient reaches the age of legal majority, informed consent must be given by the legal guardian, as we will discuss below. However, for pediatric patients who are mature enough to understand a medication and its risks and benefits, the clinician should seek the assent of the patient. "Assent" in this context refers to willingness of a minor to participate in a proposed treatment based on her or his understanding of the associated risks and benefits. Younger children who lack the capacity to understand the need for treatment at times may be coerced into taking medication, such as through behavioral consequences for refusal. A graduated approach to assent is taken for older children and adolescents, according to the developmental level of the patient. In most cases, these patients should be willing participants in their treatment. Coercion is acceptable only when they are severely impaired by their illness, they present a danger to themselves or others, or they are unable to understand the risks and benefits of medication. Once adolescent patients have reached the legal age of majority, adult legal criteria apply for involuntary treatment. Patients of all ages may grapple to make sense of medication and the meaning that it has in their emerging sense of self, and their developmental stage plays a key role in this process. Younger children may have difficulty understanding why they need to take medication or may feel medication means they are sick or that there is something wrong with them. Concerns about being different or being looked down on by peers often peak in early adolescence along with the increased concern about belonging that is part of normal development at this age. Addressing these issues is an essential component of pediatric psychopharmacology, as failure to do so may have significant implications for patients' self-esteem and adherence to medication.

The lives of children and adolescents often flow to the rhythms of school, sports, and other activities. This flow should be considered in the timing of medication adjustments. In non-crisis situations, one should avoid major medication changes at transition times or periods of high stress. For example, if an adolescent with ADHD was facing the SAT exam in a week and was responding only partially to a stimulant, it would be preferable to raise the dose of the current drug rather than switch to a new one. Reductions in dose and discontinuation of medication are no less challenging to the body and mind than dosage increases and medication changes: they are best done in low-stress periods. For many patients, the summer is a good time for medication changes. However, for patients who are more socially isolated during the summer and do not have structured activities to replace the routines of school, summer can actually be more stressful than the school year.

ROLE OF THE PARENTS

For pediatric patients, the parents or legal guardians are essential partners in the medication management. It is critical to identify the legal custodian(s) of a pediatric patient

before proceeding with treatment, as their informed consent is required. The legal custodian is not necessarily the person bringing the child in for treatment, even when that person is a parent. In some situations of divorce or separation with joint custody, the consent of one parent may be insufficient. In cases of shared custody, such as after a divorce, it is important to communicate with both parents and engage them both in the treatment to the greatest extent possible. Not only is consent an issue, but parents may differ in how they administer medication to a child, how they deal with medication refusal, how they explain the medication to the child, and how adherent they are to the treatment regimen. Even in intact families, parents often have differences of opinion about medication. Therefore, it is necessary to explore the concerns of the parents and the meaning of the medication for the parents as well as for the child during treatment. Often one parent will be more involved in the treatment than the other, but it is important to reach out to the less-involved parent to speak by telephone and encourage them to come in periodically to discuss the treatment.

When the possibility of medication is raised, a detailed discussion about treatment options is warranted, including discussion of non-pharmacological interventions, goals for medication treatment, possible risks and side effects, dose schedule, and need for monitoring and follow-up. It is important to discuss reasonable expectations of the medication, including the time course over which it might be expected to work and the symptoms that the medication might and might not help. Many parents come to treatment with hopes that medication will quickly fix a complex, multifaceted problem, so it is important to help them develop realistic expectations.

The initial discussion of medication should also include planning about which family member or members are responsible for dispensing the medication and making sure that it is taken as prescribed. Parents of some adolescent patients may incorrectly assume their child has a sufficient level of maturity and responsibility to manage their own medication, leading to inconsistent adherence. While it is important for adolescent patients to begin taking increasing responsibility for their medications and their overall treatment as they approach adulthood, parents still need to monitor the situation and check in periodically to assure that the medication is being taken as prescribed. Pill containers can help sometimes-forgetful adolescents keep track of their medication and allow parents to discreetly monitor adherence without annoying an irritable teen with frequent questioning. For patients at risk for suicide, the possibility of overdose should be addressed with parents; and thought should be given as to how the medication, as well as other medications in the house, should be stored.

ADDITIONAL CONCERNS AND CONSIDERATIONS

In addition to the developmental, social, and physiological challenges in the psychopharmacological treatment of children, clinicians are also confronted by a relatively small evidence base. Conducting clinical trials with children and adolescents

as subjects is often costlier and more time-consuming than it is with adults. Thus, the evidence-based literature related to psychopharmacology for children and adolescents is considerably smaller.

The lack of a strong evidence base forces clinicians treating severely ill children to operate under less certain conditions. Medications are frequently used off-label and sometimes on the basis of adult data extrapolated to children, small open-label trials, or clinical experience. For many medications, clear dosing and monitoring guidelines for the treatment of children have not been established. Experienced clinicians typically respond to this uncertainty by taking a conservative approach, using very small starting doses, titrating doses more gradually, and monitoring more closely than they would for an adult patient.

Obese and cachectic children present additional challenges, and there is little to no literature to address medication dosing for these patients. For the obese child, as with adult-sized adolescents, adult dosing guidelines are generally applied when the weight-based milligram per kilogram dosage reaches or exceeds adult dose levels. However, given the awareness that children are not “little adults” and may be more sensitive to certain adverse effects, a conservative approach is often taken, starting with doses slightly lower than might be used in an adult. Cachectic children can be dosed according to weight, but careful consideration must be paid to any underlying medical issues or existing medications that might interfere with the metabolism of the medication that is being considered.

MEDICATIONS FOR SPECIFIC PSYCHIATRIC CONDITIONS

MAJOR DEPRESSION

As in the adult populations, SSRIs are generally considered the first line of pharmacological treatment for depression in children and adolescents. However, controversy has arisen in recent years over the use of these medications, in terms of both their efficacy and their safety. An influential meta-analysis published in the *Lancet* in 2004 examined randomized controlled trials of SSRIs for treatment of depression in children and adolescents. This analysis demonstrated clear efficacy only for fluoxetine and questioned the risk–benefit profile for other SSRIs, particularly when data from unpublished studies were taken into account (Whittington et al., 2004).

In the same year, the U.S. FDA conducted an analysis of suicidal thoughts and behaviors using data pooled together from multiple individual studies of six SSRIs and three additional antidepressants (mirtazapine, bupropion, and venlafaxine) in children and adolescents. This analysis, involving over 4,400 subjects, showed that children treated with antidepressants had a 4% rate of suicidal thoughts and behaviors, compared to 2% in the placebo group. There were no completed suicides in this analysis. Based on this finding, the FDA issued a “black box warning” indicating the possible risks of suicidality associated with antidepressant use in children and

adolescents (available at www.fda.gov/Drugs/DrugSafety/PublicHealthAdvisories/ucm161679.htm, accessed August 28, 2011).

In the wake of the FDA warning, concern about suicidality associated with antidepressant use was the probable explanation of an observed decline in rates of prescription of antidepressants for adolescents, with a 22% drop in overall prescriptions and a 58% decline in new prescriptions for patients under 18 years of age from 2003 to 2004 (Cheung et al., 2008). At the same time, the youth suicide rate in the United States rose significantly for the first time in 2004, after more than a decade of steady decline (Gibbons et al., 2007), leading some to question whether the reduction in antidepressant prescriptions contributed an *increase* in youth suicides.

Despite these controversies, there is a strong body of evidence supporting the use of SSRIs in children and adolescents for the treatment of depression. Randomized controlled trials have demonstrated efficacy for fluoxetine (Emslie et al., 1997; Emslie et al., 2002), sertraline (Wagner et al., 2003), citalopram (Wagner et al., 2004), and escitalopram (Emslie et al., 2009) in pediatric populations. The influential, non-industry funded Treatment for Adolescents with Depression Study (TADS) demonstrated a 71% response rate at 12 weeks for patients receiving combined fluoxetine and cognitive behavioral therapy (CBT) treatment, 61% for fluoxetine treatment alone, and 43% for CBT alone (March et al., 2004). These findings support the use of a combined approach of medication and therapy in the treatment of adolescent depression.

Given the evidence base, the first-line medications in the treatment of children and adolescents with depression are fluoxetine, citalopram, and sertraline, although at present sertraline does not carry an FDA indication for the treatment of children and adolescents with depression. Many clinicians consider fluoxetine to be the SSRI of choice, given that it has the strongest evidence base. However, there is a great deal of variation in individual practice. Other factors, including a family history of response to a particular antidepressant or the presence of psychiatric comorbidity, may influence the choice for a particular individual.

The typical dosing of SSRIs in the treatment of children and adolescents is summarized in Table 80.1. Dosing for prepubertal children generally begins at the lowest end of the

dose range and is gradually titrated upward to effectiveness. Fluoxetine and sertraline are both available in liquid suspensions to allow for greater ease of administration to younger patients. Adolescents, particularly older adolescents, may start at typical adult doses, though a lower initial dose may be chosen in cases where there is particular concern about risk of activation or induction of mania, which might be indicated by the patient's personal and family history of these reactions, or symptoms suggestive of a possible bipolar-spectrum illness.

SSRIs are generally well tolerated by children and adolescents. Side effects tend to be similar to those seen in adult patients and include gastrointestinal symptoms such as nausea, stomach ache or diarrhea, dizziness, headache, fatigue, sleep disturbance, and vivid dreams. Sexual side effects can occur in adolescents just as they do in adults. Children and adolescents appear to be more sensitive to behavioral activation from SSRIs. Symptoms of activation include restlessness, agitation, insomnia, disinhibition, and impulsivity (King et al., 1991). These symptoms most commonly emerge early in the course of medication treatment or shortly after dose increases. Given the concerns about behavioral activation and potential suicidality in pediatric patients, close monitoring is recommended, with frequent appointments in the early phase of treatment. The FDA has recommended weekly face-to-face meetings over the first four weeks of treatment, bi-weekly meetings over the following four weeks, another meeting at week 12 of treatment, and then meeting as clinically indicated. Communication with the patient's therapist can also be helpful in monitoring the patient's safety during initiation of an SSRI trial.

When SSRIs are ineffective or poorly tolerated, commonly considered second-line treatments include bupropion, venlafaxine, duloxetine, and mirtazapine. However, there are relatively few data to support the use of these medications in the pediatric population. Small open-label studies have demonstrated the efficacy of bupropion in adolescent depression (Glod et al., 2003). This medication also has some efficacy, albeit relatively weak compared to other medications, in the treatment of attention-deficit hyperactivity disorder (ADHD) (Conners et al., 1996), leading some clinicians to favor this medication in cases of comorbid depression and ADHD. Bupropion is also favored in patients who have

Table 80.1 DOSING OF COMMONLY USED SSRIS IN CHILDREN AND ADOLESCENTS FOR DEPRESSION AND ANXIETY

MEDICATION	STARTING DOSE FOR PREADOLESCENTS(MG)	STARTING DOSE FOR ADOLESCENTS (MG)	TYPICAL DOSE RANGE FOR DEPRESSION AND ANXIETY (MAY BE LOWER FOR YOUNGER PATIENTS)
Citalopram	5–10	10–20	10–40
Escitalopram	5–10	5–10	10–20
Fluoxetine	5–10	10–20	20–60
Fluvoxamine*	12.5–25	25–50	50–300
Sertraline	12.5–25	25–50	50–200

*Used primarily in OCD and anxiety disorders

demonstrated signs of activation or mania on SSRIs, as it is believed to be less likely to induce these problems, though it can increase anxiety in some patients. Side effects of bupropion include decreased appetite, irritability, insomnia, and gastrointestinal upset. Bupropion also reduces the seizure threshold and thus should be avoided in patients at high risk for seizure, including patients with an active comorbid eating disorder and those with poorly controlled epilepsy.

ANXIETY DISORDERS

Anxiety disorders are the most prevalent psychiatric condition in childhood and adolescents (Costello et al., 1996). Anxiety disorders commonly diagnosed in children and adolescents include generalized anxiety disorder (GAD), social anxiety disorder, separation anxiety disorder, and obsessive-compulsive disorder (OCD). Most often, the best approach to treating anxiety disorders is multimodal, including individual psychotherapy and parent training. When medication treatment is indicated for the treatment of anxiety, in most cases it should be combined with psychotherapy. According to practice parameters from the American Academy of Child and Adolescent Psychiatry, SSRIs are the recommended first-line medication treatment for anxiety disorders in children and adolescents (Connolly & Bernstein, 2007). However, there is no FDA indication for the use of these medications to treat anxiety disorders other than OCD in children.

The evidence base for the use of SSRIs in the treatment of GAD and related disorders is not as robust as it is in adult populations, but there are randomized controlled studies supporting their use, including studies of fluoxetine (Birmaher et al., 2003) and fluvoxamine (Walkup et al., 2001). The influential Child/Adolescent Anxiety Multimodal Study (CAMS) demonstrated that efficacy of sertraline over placebo, with a combined sertraline-CBT group demonstrating the greatest efficacy (Walkup et al., 2008). There is also some evidence to support the use of the SNRI venlafaxine in treating generalized anxiety disorder in children (Rynn et al., 2007).

SSRIs have demonstrated clear efficacy in the treatment of OCD in children and adolescents (Geller et al., 2003). While clomipramine has also demonstrated good efficacy in the treatment of pediatric OCD (Flament et al., 1985), it is generally considered a second-line treatment due to its side effect profile, including a risk of life-threatening cardiac arrhythmias. Use of clomipramine requires an electrocardiogram before beginning treatment, and a follow-up electrocardiogram once the patient has reached a stable dose of the medication. If the electrocardiogram shows QTc prolongation or other abnormalities, consultation with a pediatric cardiologist is indicated before proceeding with the medication trial, and a switch to another medication may be indicated.

Potential side effects of SSRIs are mentioned above in the discussion of depression treatment. It should be noted that concerns about potential for behavioral activation, induction of mania, and suicidal ideation apply in the treatment of anxiety disorders just as they do in the treatment

of depression. Therefore, close monitoring for safety and for signs of activation is necessary. Dosing of SSRIs for GAD, social anxiety disorder, and separation anxiety disorder is generally the same as for the treatment of depression, and is summarized in Table 80.1. It should be noted, however, that many patients with anxiety disorders are particularly prone to somatic side effects of medications. For these patients, even lower initial dosing and even smaller incremental increases may be necessary. There is some evidence to suggest that treatment of OCD may require higher doses of SSRIs than the treatment of depression and other anxiety disorders, but the same dosing guidelines summarized in Table 80.1 still apply.

Despite their utility in treating anxiety disorders in adults, benzodiazepines are used less commonly in children and adolescents. This is partly due to the limited evidence from controlled studies to support their use. Randomized controlled trials have failed to show clear efficacy of benzodiazepines over placebo for treatment of anxiety in children and adolescents (Bernstein et al., 1990; Simeon et al., 1992; Graae et al., 1994). Furthermore, there is concern that younger patients may be at greater risk of potential disinhibitory or “paradoxical” reactions to benzodiazepines, which may be characterized by agitation, aggression, heightened anxiety, mood lability, excessive talking, or other emotional or behavioral disturbances (Gutierrez et al., 2001; Mancuso et al., 2004). Side effects of drowsiness and impaired learning and memory also cause concern in pediatric patients, as does the potential for abuse and dependence.

Nonetheless, when used judiciously, benzodiazepines can be a helpful adjunctive treatment for some children and adolescents. The immediate onset of benzodiazepines gives them an advantage over other treatments. Thus, they may be used to provide symptomatic relief while the clinician waits for an SSRI to take effect. They may also have a role as an “as-needed” medication for intense episodes of breakthrough anxiety or as abortive therapy in cases of panic disorder.

Other medications that are sometimes used in the treatment of pediatric anxiety disorders include the tricyclic antidepressants, whose use is limited by a relatively poor side effect profile and the potential for toxicity. Tricyclics may be particularly useful in treating patient with comorbid chronic pain, and low doses of imipramine and nortriptyline are sometimes used to treat enuresis. Dosing of tricyclic antidepressants is summarized in Table 80.2. A physical exam and thorough individual and family medical history should be conducted before starting a tricyclic. It is also advisable to check an electrocardiogram and vital signs at baseline and again when maintenance dose has been achieved, as these medications can cause arrhythmias and prolong QTc.

Buspirone is also used to treat anxiety symptoms in children and adolescents. Though it is often well tolerated, it has limited evidence to support its use. Potential side effects of buspirone include light-headedness, headache, and stomach upset. Buspar is typically started at 5 mg given once daily, and increased in increments of 5 mg/day, usually in divided doses of twice to three times daily, up to a maximum of 60 mg/day.

Table 80.2 DOSING OF TRICYCLIC ANTIDEPRESSANTS IN CHILDREN AND ADOLESCENTS

MEDICATION	STARTING DOSE FOR PREADOLESCENTS	STARTING DOSE FOR ADOLESCENTS	TYPICAL DOSE RANGE FOR DEPRESSION AND ANXIETY
Amitriptyline	1–3 mg/kg/day divided TID	25 mg–50 mg qHS	1–3 mg/kg/day, or 25–150 mg/day in adolescents, usually given in divided doses Therapeutic level = 120–250 ng/mL of amitriptyline + nortriptyline
Imipramine	1.5 mg/kg/day divided TID	30–40 mg/day divided QD to TID	1–3 mg/kg/day, or 25–75 mg/day for adolescents Therapeutic level = 180–350 ng/mL of imipramine + desipramine
Nortriptyline	1 mg/kg/day divided TID-QID	30 mg/day divided QD-QID	1–3 mg/kg/day, or 30–50 mg/day for adolescents Therapeutic level = 50–150 ng/mL
Clomipramine*	Indicated for > 10 years old	25 mg QD	50–150 mg/day (3 mg/kg/day max)

*Clomipramine is indicated specifically for the treatment of OCD in children over 10 years old

ATTENTION-DEFICIT HYPERACTIVITY DISORDER

Stimulants are the first line of treatment for ADHD. They have demonstrated a high degree of efficacy in numerous randomized controlled trials (Pliszka, 2007). They are currently the most commonly prescribed psychiatric medication for patients under the age of 18 in the United States (National Center for Health Statistics Report, 2010). In the landmark Multimodal Treatment of ADHD (MTA) study, children assigned to the stimulant treatment group and the combined stimulant and behavioral treatment group demonstrated significantly greater improvement than children treated with intensive behavioral treatment alone or standard community care (MTA Cooperative Group, 1999). While not every child with ADHD requires medication, and many may do very well with behavioral treatment and other psychosocial interventions, this study clearly demonstrated that medication treatment is more effective than behavioral therapy alone. When stimulants and other ADHD medications are used, they should be part of a comprehensive treatment plan that may also include behavioral therapy and school-based interventions to facilitate learning.

The first-line stimulants used in the treatment of ADHD are methylphenidate and mixed amphetamine salts. Both medications are available in long-acting formulations for ease of dosing. While there is some relationship between dose response and weight, there is a wide range of responsiveness to a given dose between patients. Thus, it is best to start with a low dose and titrate up to effect. When titrating ADHD medications, communication with collateral sources is essential, as patients may not be reliable reporters and parents may not be aware of the level of symptoms in school. Use of symptom-rating scales for parents can be helpful in tracking symptoms.

Dosing of stimulant medications for ADHD is summarized in Table 80.3. Typical therapeutic doses are 0.3–2 mg/kg/day for methylphenidate and 0.15–1 mg/kg/day for mixed amphetamine salts. The maximum recommended dose is 60 mg/day for methylphenidate and 40 mg/day of mixed amphetamine salts. D-isomeric formulations of both medications are

available, as dex-methylphenidate and dextroamphetamine, under the theory that these isomeric forms may be better tolerated than the mixed d,l isomer formulations. These medications typically require lower doses than their mixed isomer counterparts. Lisdexamfetamine is a newly available pro-drug form of amphetamine with an amino acid that must be cleaved in the gut before it is biologically active, reducing the medication's abuse potential.

Stimulants are generally well tolerated, but they do have the potential to cause significant side effects in some patients. Common side effects include decreased appetite and possible associated decreases in growth, insomnia, headaches, and stomach aches. Stimulants can have a significant impact on mood, causing irritability and sadness in some patients. They are believed to have potential to induce mania in patients predisposed to bipolar disorder and may induce psychotic symptoms in rare cases. Stimulants can also induce or exacerbate tics, which is particularly relevant to clinicians, given the high degree of comorbidity of tic disorder and ADHD. Stimulants can raise blood pressure, though usually in small amounts at therapeutic levels.

There have been reports of sudden death of children taking stimulants (Villalba, 2006), and this has fueled controversy in recent years regarding potential adverse cardiac effects, including fatal arrhythmias, from these medications. Given that these serious adverse events are extremely rare, despite the large numbers of children taking these medications, many have questioned whether there is a true increase in risk of sudden cardiac death associated with stimulants or whether the reported events are consistent with the base rate of these rare but tragic events in the general population. One recent retrospective cohort study examined medical records of over 55,000 children over a period of ten years (Winterstein et al., 2007). This study found no association between stimulant use and sudden cardiac death. The authors reported no deaths in over 42,000 person-years of stimulant use compared to five deaths in the no-use and former-stimulant-use groups, and they reported no increase in hospitalizations from cardiac causes associated with stimulant use.

Table 80.3 DOSING OF STIMULANT MEDICATIONS IN THE TREATMENT OF ADHD

MEDICATION	DURATION OF ACTION	TYPICAL DOSE RANGE	MAXIMUM RECOMMENDED DOSE
<i>METHYLPHENIDATES</i>			
<i>Short-acting:</i>			
Ritalin, Methylin	3–4 hours	0.3–2 mg/kg/day	60 mg/day
Focalin (dexmethylphenidate)	3–5 hours	0.15–1 mg/kg/day	20 mg/day
<i>Intermediate:</i>			
Ritalin SR, Metadate ER, Methylin ER	4–8 hours	0.3–2 mg/kg/day	60 mg/day
<i>Long-acting:</i>			
Daytrana (methylphenidate patch), Metadate CD, Ritalin LA	8–12 hours	0.3–2 mg/kg/day	60 mg/day
Concerta	10–16 hours	0.3–2 mg/kg/day	72 mg/day
Focalin XR	8–12 hours	0.15–1 mg/kg/day	30 mg/day
<i>AMPHETAMINES</i>			
<i>Short-acting:</i>			
Adderall (mixed amphetamine salts)	4–6 hours	0.15 mg/kg/day	40 mg/day
Dexedrine, Dextrostat (dextroamphetamine)	4–6 hours	0.15 mg/kg/day	40 mg/day
<i>Long-acting:</i>			
Adderall XR	8–12 hours	0.15 mg/kg/day	30 mg/day
Dexedrine Spansules	8 hours	0.15 mg/kg/day	40 mg/day
Vyvanse (lisdexamfetamine)	8–12 hours	Varies	70 mg/day

Despite the questionable association between stimulants and sudden death and the rare occurrence of these events, the devastating nature of such an event warrants a cautious approach. In 2008, the American Academy of Pediatrics published guidelines regarding appropriate monitoring for pediatric patients prescribed stimulant medications (Perrin et al., 2008). These guidelines call for a thorough medical history prior to treatment, including review of past cardiac problems, surgeries, and heart murmurs as well as history of syncope, palpitations, dizziness during exercise, or seizures. The guidelines call for a review of family history, including history of sudden unexplained deaths in the family, myocardial infarction in relatives under the age of 35, and history of cardiomyopathies, structural heart disease, or arrhythmias. Finally, the guidelines call for a thorough physical exam including a cardiac exam. If there is cause for concern based on this evaluation, additional steps, including an electrocardiogram or consultation with a pediatric cardiologist, may be necessary before proceeding with a stimulant trial. For patients taking stimulants, blood pressure, heart rate, height, and weight should be monitored regularly.

For patients who are unable to tolerate stimulants or who do not respond to stimulants, several non-stimulant

medications are available for the treatment of ADHD. Dosing of non-stimulant medications is summarized in Table 80.4. Atomoxetine is a noradrenergic reuptake inhibitor with demonstrated efficacy in ADHD in randomized controlled trials (Michelson et al., 2002), though treatment response appears to be less robust than that of the stimulants (Faraone et al., 2006). Atomoxetine is typically started at doses of 0.5 mg/kg/day and increased to a target dose of 1.2 mg/kg/day, with a maximum recommended dose of 1.4 mg/kg/day or 100 mg/day, whichever is less. Common side effects of atomoxetine include gastrointestinal upset, headaches, decreased appetite, insomnia, and drowsiness. Mood changes, including rare behavioral activation and suicidal thinking, are possible with atomoxetine, and patients should be monitored for these changes.

Because treatment response to atomoxetine is not as robust as it is to the stimulants, it is most often used as a second-line medication. However, in some situations, it may be tried first. For example, a clinician might choose to start with atomoxetine for patients who are underweight or who have feeding issues at baseline. Anecdotally, atomoxetine also appears to be helpful for many children and adolescents who have ADHD with comorbid anxiety disorders.

Table 80.4 NON-STIMULANT MEDICATIONS IN THE TREATMENT OF ADHD

MEDICATION	STARTING DOSE	TYPICAL DOSE RANGE	NOTES
Strattera (atomoxetine)	0.5 mg/kg/day	1.2–1.4 mg/kg/day	<ul style="list-style-type: none"> • Norepinephrine reuptake inhibitor • Given once or twice daily
Tenex (guanfacine)	0.5 mg–1 mg/day	1–4 mg/day	<ul style="list-style-type: none"> • Alpha-2 adrenergic agonist • Usually dosed BID or TID • Extended release formulation (Intuniv) dosed once daily, available as 1 mg, 2 mg, 3 mg, and 4 mg tablets
Clonidine	<ul style="list-style-type: none"> • 0.025–0.05 mg/day • 0.1 mg at bedtime for extended release (Kapvay) 	0.05 mg–0.4 mg	<ul style="list-style-type: none"> • Alpha-2 adrenergic agonist • Usually dosed BID, TID, or QID • Extended release formulation (Kapvay) dosed once daily • Dosing of extended release is not interchangeable with other formulations and should not be substituted mg for mg • Typically more sedating than guanfacine

Alpha-2 adrenergic agonists, which include guanfacine and clonidine, are commonly used as adjunctive treatment or second-line treatment for children and adolescents with ADHD. These medications have shown some efficacy, though they appear to work primarily on symptoms of hyperactivity and impulsivity and are less effective for the cognitive symptoms of ADHD (Scahill et al., 2001; Palumbo et al., 2008). New extended-release formulations of both medications have allowed greater ease of dosing. Sedation is often a limiting side-effect with these medications. Other possible side effects include hypotension, dizziness, headache, gastrointestinal upset, constipation, and dry mouth. Cardiac effects, including bradyarrhythmia and atrioventricular block, are also possible due to the autonomic effects of these medications. Use of these medications for children with cardiac conduction problems and cardiac arrhythmias should only be considered after consultation with a pediatric cardiologist and if there is a strong clinical indication for their use.

Other medications sometimes used in the treatment of ADHD include bupropion and tricyclic antidepressants such as imipramine and nortriptyline. These medications tend to be considered second- or third-line treatments for ADHD, as they appear to be less effective (Pliszka, 2003).

BIPOLAR DISORDER

Once thought to occur only rarely in youth, the diagnosis of bipolar disorder in children and adolescents has risen dramatically over the past decade. While there is some controversy surrounding the diagnosis and the nomenclature for children with severe mood symptoms, it is clear that there is a population of children with severe disturbances in mood and behavior whose symptoms are categorically distinct from those diagnosed with major depressive disorder and who respond to different forms of treatment.

The typical presentation of children and adolescents with bipolar disorder is different from that of adults. Children and adolescents typically present with more mixed mood episodes rather than distinct periods of mania and depression; more

frequent rapid cycling, more chronic impairment without improvement between episodes, and more prominent irritability, explosiveness, anger, and dysphoria (Wozniak et al., 1995; Biederman et al., 2004).

The treatment of bipolar disorder in children and adolescents requires a multifaceted approach, usually involving individual therapy and parent support and training and often requiring school-based interventions and other psychosocial treatments. Medication can play a critical role as part of a comprehensive treatment plan—stabilizing mood, helping maintain safety, and reducing aggression and other severe problem behaviors to allow patients to engage more successfully in treatment. Pharmacotherapy for pediatric bipolar disorder is frequently complex and challenging. Subspecialty management by an experienced child and adolescent psychiatrist is warranted whenever possible. Accurate diagnosis and recognition of comorbid psychiatric issues, which are common in pediatric patients with bipolar disorder, are essential to effective treatment.

Medications commonly used to treat pediatric bipolar disorder include second-generation neuroleptics, antiepileptic drugs, and lithium. There is no clear consensus at present about which of these medications should be viewed as first-line, and there are differences in practice between providers.

Second-generation neuroleptics are used by many clinicians as the first line of treatment for children and adolescents with bipolar disorder, as they have demonstrated efficacy (Thomas et al., 2011) and do not require monitoring of serum drug levels. Dosing of antipsychotic medications in children and adolescents is summarized in Table 80.5. Risperidone, aripiprazole, and quetiapine have all been approved by the FDA for treatment of mania and mixed episodes in children age ten and older. Olanzapine has also been shown to be effective but is less commonly used because it is associated with a greater degree of weight gain and metabolic changes than other equally effective drugs in this class (Correll et al., 2009). Similarly, ziprasidone has some evidence suggesting efficacy (Thomas et al., 2011), but concerns about QTc prolongation (Blair et al., 2005) have led most clinicians to consider it a second- or third-line treatment.

Table 80.5 ATYPICAL ANTIPSYCHOTICS FOR THE TREATMENT OF PEDIATRIC BIPOLAR DISORDER

MEDICATION	FDA APPROVAL FOR BIPOLAR DISORDER?	STARTING DOSE	MAX RECOMMENDED DOSE FOR BIPOLAR DISORDER	NOTES
Abilify (aripiprazole)	10 years and older	2 mg once daily	30 mg	<ul style="list-style-type: none"> • May cause less weight gain than other atypicals • May be a greater incidence of restlessness/akathisia
Geodon (ziprasidone)	No	20 mg once daily	80 mg (no formal dosing guidelines for pediatric population)	<ul style="list-style-type: none"> • Greater concern about QTc prolongation compared to other atypicals
Risperdal (risperidone)	10 years and older	0.25 mg–0.5 mg at bedtime	2.5 mg/day	<ul style="list-style-type: none"> • Greater degree of dopamine D2 antagonism may increase risk for dystonia, extrapyramidal side effects, hyperprolactinemia
Seroquel (quetiapine)	10 years and older	25–50 mg at bedtime	600 mg/day	<ul style="list-style-type: none"> • More sedating than other atypicals • Can cause orthostatic hypotension • Lower risk of extrapyramidal side effects, akathisia
Zyprexa (olanzapine)	13 years and older	2.5–5 mg at bedtime	20 mg/day	<ul style="list-style-type: none"> • Appears to be associated with greater degree of weight gain than other atypicals • Sedating

Second-generation neuroleptics can cause a number of side effects, including sedation, restlessness, orthostatic hypotension, dizziness, and constipation. Females may experience lactation and menstrual irregularities, particularly with risperidone. While they are much less common, worrisome side effects of the first-generation (typical) neuroleptics may also occur with second-generation neuroleptics, including tardive dyskinesia, dystonia, Parkinsonism, akathisia, neuroleptic-induced catatonia, and neuroleptic malignant syndrome.

One of the most common problems seen with atypical antipsychotics is weight gain and metabolic changes, including impaired glucose metabolism and hyperlipidemia, which may predispose patients to the development of type II diabetes and cardiovascular disease. The American Diabetes Association and the American Psychiatric Association developed joint guidelines for the monitoring of patients prescribed these medications (ADA & APA, 2004). The guidelines call for baseline measurement and regular monitoring of height, weight, blood pressure, fasting glucose, and fasting lipid profile, as well as taking a history of personal and family history of diabetes, cardiac disease, and hyperlipidemia. Counseling patients and parents about the metabolic risks of these medications and concrete measures, including dietary changes and exercise, that can reduce these risks is essential.

Anticonvulsants commonly used in the treatment of pediatric bipolar disorder include divalproex sodium, lamotrigine, carbamazepine, and oxcarbazepine. Use of divalproex sodium is based primarily on evidence from adult studies; data to support its use in the pediatric population are limited (Thomas

et al., 2011). It is sometimes preferred in patients with rapid cycling and mixed episodes, though this is based on adult data. Use of divalproex sodium requires monitoring of serum levels, with target therapeutic levels of between 50 and 125 mcg/mL. Pediatric patients are usually maintained on the low end of this range, though some patients may require higher levels to achieve therapeutic effect, particularly in cases of acute mania. Monitoring of liver function tests due to potential liver toxicity, and complete blood count due to potential thrombocytopenia and leukopenia, are also necessary for patients taking divalproex sodium. Pediatric patients, particularly younger children, may be more susceptible to these effects than adults. There is some variability in practice, but generally a complete blood count is taken and liver function tests are checked at baseline, after a therapeutic dose has been attained, and again every three to six months thereafter, along with a serum valproate level. If these values remain stable over the first year of treatment, laboratory testing may be performed less frequently. Female patients should have a pregnancy test prior to starting treatment, due to teratogenicity, including an increased risk of neural tube defects, and should use a reliable method of contraception if they are sexually active. Other potential side effects include weight gain, nausea, hair loss, sedation, and, more rarely, pancreatitis. Adolescent girls taking divalproex sodium are at risk of developing polycystic ovarian syndrome, which may present with menstrual irregularities, hirsutism, acne, and weight gain.

Lamotrigine is being used with increasing frequency in the treatment of pediatric bipolar disorder. While there are few data to support its use outside of the adult population, some

open-label studies have demonstrated efficacy in adolescents (Chang et al., 2006; Pavuluri et al., 2009). In adults, there is some evidence that lamotrigine may be effective in treating bipolar depression (Calabrese et al., 1999), on which many other mood stabilizers have minimal effect. It has a further advantage in that it does not require monitoring of serum levels. However, lamotrigine requires a very gradual dose titration due to the associated risk of severe cutaneous reactions, including Stevens-Johnson syndrome and toxic epidermal necrolysis. Risk of these rare but potentially fatal reactions may be greater in youth compared to adults, with an estimated rate of 0.8% in pediatric patients compared to 0.3% in adult patients (Seo et al., 2011). This risk is minimized by avoiding sudden increases in dose (Kowatch & Delbello, 2006). In adolescents, this also requires discussion with patients and parents about the risks associated with non-adherence and the need to contact the prescribing clinician before restarting lamotrigine if a patient has missed more than one dose. More common side effects of lamotrigine include blurry vision, constipation, gastrointestinal upset, decreased coordination, sedation, insomnia, benign rashes, and runny nose.

The structurally similar anticonvulsants carbamazepine and oxcarbazepine are sometimes used to treat bipolar disorder in children and adolescents with bipolar disorder, though again there are few data demonstrating their efficacy in the pediatric population (Thomas et al., 2011). Monitoring of serum levels is required for carbamazepine, with a target range of 4–12 mcg/mL. Pediatric patients are usually maintained on the low end of this range, though some patients may require higher levels to achieve therapeutic effect. Side effect profiles of carbamazepine and oxcarbazepine are similar. Both may cause nausea, sedation, dizziness, ataxia, rash, and headaches. Less commonly, both medications carry a risk of Stevens-Johnson syndrome, and both may cause hyponatremia. Carbamazepine may cause blood dyscrasias, including aplastic anemia as well as liver toxicity, and these problems may occur more commonly in the pediatric population. Bone marrow suppression and liver toxicity are less common with oxcarbazepine. It should also be noted that carbamazepine induces enzymes in the cytochrome P450 system, which may lead to more rapid metabolism of some medications, including oral contraceptives.

Before starting treatment with carbamazepine, baseline renal function tests, thyroid function tests, liver function tests, and complete blood count including platelets must be obtained. The complete blood count and liver function tests should be monitored every two to three weeks during the initial four months of treatment and can be decreased in frequency to every six to 12 months thereafter. There are no clear guidelines for monitoring of oxcarbazepine in treatment of pediatric mood disorders, but it is good practice to follow monitoring parameters similar to those used with carbamazepine, given the similarities in side effect profiles of the two medications. Serum sodium should also be monitored for patients on oxcarbazepine given the risk of hyponatremia. For both medications, it is also important to educate patients and parents about the signs of liver abnormalities and blood dyscrasias and advise them to contact the prescribing physician if they have any concerns.

The first agent to be granted FDA approval for treatment of bipolar disorder in youths (age 12 and older) was lithium. Lithium has long been a mainstay of treatment for bipolar disorder in adults, and it has shown efficacy in several double-blind placebo-controlled trials in adolescents as well, though it has been noted that these trials are limited by relatively small sample sizes (McClellan et al., 2007). However, the narrow therapeutic window of lithium, the potential for significant toxicity, the need for close monitoring of serum levels, and its side effect profile have limited its use.

Lithium requires close monitoring of serum levels, with target levels between 0.6 and 1.2 mEq/L, with levels on the higher end of this range for acute mania. While not well studied in children under 12, lithium is generally well tolerated by adolescent patients, who may be less susceptible to its adverse effects than adult patients. However, lithium has the potential to cause significant toxicity, including renal and thyroid toxicity as well as cardiac-conduction abnormalities. Given these potential effects, serum electrolytes, complete blood count, thyroid function tests, renal function tests, serum calcium, urinalysis, and electrocardiogram (ECG) should be checked at baseline prior to initiating treatment. Females of reproductive age should also have a pregnancy test prior to starting treatment. Once a stable therapeutic dose has been reached, lithium levels, renal function tests, thyroid function tests, and urinalysis should be checked every three to six months, and a repeat ECG should be obtained at the therapeutic level. Other potential side effects of lithium include sedation, nausea, diarrhea, tremor, hair loss, acne, weight gain, polyuria, and polydipsia. In following patients on lithium, clinicians should be aware that dehydration, such as that caused by gastroenteritis, can push levels into the toxic range. Lithium can also interact with several commonly prescribed medications, most notably non-steroidal anti-inflammatory drugs (NSAIDs), which interfere with its renal clearance.

SUMMARY

The treatment of psychiatric illness in children and adolescents requires a multifaceted approach involving multiple treatment modalities. When managed appropriately, psychiatric medications can be an effective component of treatment for many patients. Management of medications for pediatric patients requires close collaboration with the patient, the family, the primary medical doctor, and often school personnel and other sources of collateral information. Development plays a critical role in pediatric psychopharmacology, as the patient's developmental level must be taken into account in every aspect of treatment, including choice and dose of medication, nature of the discussion about the medication and its effects and risks, and plans for ensuring the patient's safety and adherence.

CLINICAL PEARLS

- Young children may need reassurance that a medication will not change who they are or make them do things they do not want to do. They may become overwhelmed

or anxious when confronted with long and detailed lists of possible side effects and may do better with a more general instruction to let their parents know if there is anything they feel while on the medication that they do not like.

- In non-crisis situations, one should avoid major medication changes at transition times or periods of high stress.
- Establish effective communication and a collaborative relationship with the patient and family.
- Integrate medication into an overall treatment plan for the patient based upon a biopsychosocial formulation.
- Start medication only after a thorough medical and psychiatric evaluation, including detailed review of past medication trials and their effects.
- Start medications at the low end of the effective dose range and gradually titrate to effectiveness.
- Employ the simplest medication regimen necessary to effectively manage the patient's symptoms, using poly-pharmacy only when indicated to treat residual symptoms, comorbid diagnoses, or side effects from other medications.
- Take one step at a time when possible, avoiding making multiple changes at once that will make subsequent changes in clinical presentation difficult to interpret.
- Take a systematic approach, assuring that each medication trial has been allowed adequate time at an adequate dosage before deeming it ineffective and moving to the next step in treatment.
- Closely monitor efficacy and side effects, using objective measures and structured rating scales when they are available.
- Explicitly ask patients about their adherence to the medication regimen rather than assuming the medication is being taken as prescribed.
- Monitor drug levels when there is an established therapeutic range and it is known that there is significant inter-individual variability in the drug's pharmacokinetics.
- Simplify medication regimens when possible, to avoid confusion and non-adherence.
- Adhere to current practice guidelines for monitoring side effects of specific medications.
- Be fully aware of all the drugs the patient has been prescribed by other physicians, as well as the patient's use of over-the-counter medications, nutritional supplements, and complementary treatments.
- Maintain communication with other medical and psychiatric providers involved in the patient's care.
- Provide clear documentation of the patient's care, preferably in electronic form.

DEATH AND GRIEF COUNSELING FOR CHILDREN AND ADOLESCENTS

Patricia J. O'Malley, Hillary G. D'Amato, and Frederick J. Stoddard, Jr.

INTRODUCTION

There are few situations in medicine more challenging, humbling, and significant than accompanying children and their families through passages to loss, dying, and grief. These may arise in the context of a child's sudden death, gradual decline, or death after a long illness, as well as when a child faces the loss of a family member or loved one. In the usual context of care of children in hospitals, as well as after disasters (Lemaire, 2011; Shibley & Stoddard, 2011; Farmer, 2011), the medical psychiatrist has expertise in ways of relating to those facing loss or death, understands anticipatory and accomplished grief and developmental concepts of death, and can choose language carefully in order to support the need for patient, family, and caregivers to care for themselves.

The subject of this chapter is both the child facing his or her own death, and the child facing the death of a family member or loved one. Its goal is to provide clinicians with practical approaches, choices, and suggestions for dealing with death in children and adolescents and the grief that follows. As difficult as the responsibilities attendant on clinicians can be, they may be some of the most rewarding and profound encounters in medicine.

DEATH OF A CHILD OR ADOLESCENT

Death in childhood or adolescence is no longer commonplace in developed countries. Although 30% of the American population is under age 18, only 2% of all deaths annually occur in this age group, in marked contrast to the previous century, when 30% of all deaths annually were of children under age five. While these data point to wonderful progress in maternal and child health, they also underscore that death in childhood or adolescence has become a singular tragedy in our society and an increasingly uncommon event in the professional lives of clinicians, even those whose practice is exclusively pediatric. Death of a child is clearly identified as one of the most stressful and difficult situations clinicians face (Crammond, 1969; Schowalter, 1983; Ahrens, Hart, & Maruyama, 1997; McKelvey, 2007).

It is helpful to be aware of the heterogeneous etiologies of child death, if only because much of our information about

the way patients, families, and providers deal with children's death comes from studying childhood cancer care, whereas in fact cancer causes less than 4% of deaths between birth and 19 years. Of roughly 50,000 deaths in 2008, over half (28,000) were in the first year of life, from congenital anomalies, prematurity, low birth weight, and sudden infant death syndrome (SIDS). Another 45% is due to acute unanticipated injury from trauma (Matthews et al., 2011). Children are more likely than adults to die in a hospital, most often in an intensive care setting (Leuthner et al., 2004). Because of the heterogeneity of trajectories of dying in childhood, it may be useful to review three common scenarios: acute unanticipated death, as with trauma; failure of medical treatment to effect a cure, as with cancer; and the ups and downs of a chronic condition that at any time might end in death, as with chronic respiratory, neurological, or metabolic disease.

BREAKING THE NEWS OF IMPENDING OR ACTUAL DEATH IN AN ACUTE CARE SETTING

Clinicians in developed countries often hold an unspoken belief that death is a failure by the medical system, and the culture of acute care settings such as the intensive care unit (ICU) or the emergency department is perhaps most particularly vulnerable to this belief. A first step in supporting clinicians dealing with a child's death is to acknowledge that death is not avoidable in many of the conditions they are called upon to treat in these acute settings. A second step can be to remind clinicians that their presence, empathy, practical assistance, and information enable them to provide a bereaved family with essential assistance that they will need to adjust to their loss.

According to Janzen et al. (2003), families who lose a child through an acute and unanticipated event have at least to address these five tasks:

1. Understand the events leading up to death,
2. Feel that they can exert some control over a universe suddenly completely out of control,
3. Be able to say goodbye to their child in some meaningful way,
4. Be able to make sense of the death, and

5. Be able somehow to carry the child forward in their lives as they negotiate a new and ongoing relationship with the child they have lost.

The clinician's role in telling the family about the death of their child can help them move towards accomplishing these tasks. Families will benefit from instrumental support, such as providing private time for them to be with the child's body; informational support, as in clarifying medical questions or the likely course of events before and subsequent to the death; and from the authentic empathy and compassion of staff. (Table 81.1 shows a matrix of these tasks and clinician responses adapted from Janzen et al., 2003.)

Particularly in the setting of an unanticipated death, clinicians often struggle for the "right words," but in fact, families will remember how they were treated more clearly than any actual words spoken. One suggested approach to disclosing the news of a child's death is detailed in Box 81.1.

Clinicians often feel constrained in reaching out to families who have sustained acute unanticipated loss, with whom they have had only brief encounters, feeling that they do not have a longstanding basis for continued contact. In fact, for these families there are few other people, even the closest of friends or family, who can understand what they have experienced (Ahrens, Hart, & Maruyama, 1997). Expressions of sympathy following the event, such as with a condolence card or a comfort basket, are highly valued by families, even if they had no prior relationship with the providers (Levetown et al., 2008).

HELPING A CHILD, FAMILY, AND CAREGIVERS COME TO TERMS WITH LIKELY DEATH DUE TO PROGRESSION OF DISEASE

Pediatric patients facing the end of treatment options for a fatal cancer, and their families, have been studied in some

Table 81.1 "BREAKING THE NEWS" MATRIX

TASKS FOR BEREAVED FAMILIES	INSTRUMENTAL ASSISTANCE	ASSISTANCE WITH INFORMATION	COMPASSION AND EMPATHY
Understanding events leading up to death	<ul style="list-style-type: none"> Offering/providing pictures or reports Providing access to child's body 	<ul style="list-style-type: none"> Providing details of death and events leading up to death Timely information Written information Verbal repetition of information 	<ul style="list-style-type: none"> Give them control over timing and detail of information Listen actively Present a calm, warm presence
Regaining some control	<ul style="list-style-type: none"> Listening to needs/wishes of parents Respecting parents' decisions Providing access to child's body 	<ul style="list-style-type: none"> Explain procedures and processes Offer explanations if parents' wishes cannot be accommodated 	<ul style="list-style-type: none"> Be sensitive to family's vulnerability Be present but not intrusive Offer and provide comfort as requested by parents
Saying goodbye	<ul style="list-style-type: none"> Allow time and privacy with child's body Encourage involvement in planning memorial services If desired, permit family to participate in preparing the body 	<ul style="list-style-type: none"> Explain what to expect as child dies Explain what parents will see, hear, etc., when seeing child's body 	<ul style="list-style-type: none"> Show respect for the child's body Make child's body appear cared for; e.g., cover with blanket, clean blood and wounds Provide support
Making sense and meaning of the death	<ul style="list-style-type: none"> Provide access to child's medical chart, autopsy report, police report, pictures if requested 	<ul style="list-style-type: none"> Provide information regarding death and death surroundings Provide information about organ/tissue donation if desired, engaging organ bank specialists Assist in processing information 	<ul style="list-style-type: none"> Be an active listener Acknowledge the immensity of the loss Be sensitive to family's needs Facilitate process of making sense of the death
Renegotiating a parent-child relationship after loss	<ul style="list-style-type: none"> Help family identify mementos of the child to keep Offer memory-making opportunities Preserve any articles of clothing, possessions, etc., of the child's for the parents to take home with them 	<ul style="list-style-type: none"> Provide information about what is possible or permitted regarding memory-making activities Provide information about what other families have found important at this time Assist in developing rituals and memorials 	<ul style="list-style-type: none"> Be supportive of family's faith beliefs Support family in carrying out any death rituals Provide follow-up support in the days and weeks that follow

Adapted from Janzen et al., 2003

Preparation

First, take a moment for self-reflection, to acknowledge your own feelings (inadequacy, guilt, sadness, anger, fear) and perhaps to find a colleague with whom to share those emotions beforehand. Take note of those emotions, whatever they are, and then, without comment or criticism, allow yourself to put them aside. Find a partner—either someone who has already established a relationship with the family, another physician, or staff from chaplaincy, social work, nursing, or child life—to join you.

Think for a moment how you might act if a dear friend told you he or she had just received terrible news—what would you do, as one human being to another? Use that as a model of how best to help this family with the news you have to give them.

Families take it as a mark of respect and an indication of how importantly we view their loved one, when the responsible attending physician is the one notifying the family.

Assure that the right family members have been gathered, to the degree possible, and available resources assembled (which might include emergency department [ED] chaplaincy, social worker, child life specialist or outside family supports such as family chaplain, primary care provider).

Use a skilled medical interpreter, not a family member, for any translation needs. If using a family member is the only recourse, acknowledge to the family interpreter how difficult it is to hear bad news and then to have to share that news.

Choose an appropriate setting that is quiet, provides privacy, and has enough places to sit for all who need to be present, with water and tissues available. Make yourself available and presentable (turn off beeper, check your appearance, be sure to sit down.)

Provide a written copy of your name and contact information. You may want to include other staff member names as well, such as the primary nurse, the social worker, child life specialist, etc.

Know and use the child's name.

Steps in the Process

Introduce yourself and state your role in the care of their child, shake hands or touch family members if appropriate, and sit down.

If family are able to tolerate any questions, determine what the patient and family understand about the present situation. "Please tell me what you already know about what has happened to [your child]."

Prepare them with fair warning: "I am so sorry that I have to give you this terrible news." Hold them in your gaze.

Continue to hold them in your gaze and inform them of the death in a gentle but direct manner, even though this is very difficult for any clinician, specifically using the words "die" or "death": e.g., "We did everything we possibly could, but [your child] has died."

Sit quietly and allow the family and patient to respond. The entire range of human emotions is possible at this moment. Sitting with the silence that often follows, and allowing the family to be the first to break that silence, can be very difficult. Resist the temptation to fill that silence with information or reassurances, and simply wait.

Hear and respond to the family and patient's emotions, and provide additional information at the family's or patient's pace. (*Avoid statements that begin with "I know you must be feeling very...."*) Instead, acknowledge what you see or feel. "I cannot imagine how difficult it must be to hear this news."

Solicit questions, assess their understanding, and follow the family's lead. "I have given you such terrible news. Would you like some time alone, or would it help to see [your child] now? Do you have any questions for me, anything that I can explain better?" "There may be other questions that occur to you later—please feel free to ask me then."

Families may not ask, but may be comforted to know that their child did not suffer, so if it is possible to give that reassurance, do so.

Parental guilt is likely when a child dies, even when they have no responsibility for it, and everything possible was done to prevent it. If it is possible to give reassurance about the family role in the event, or to note any contribution they made that was helpful, do so. "I don't see any way this accident could have been anticipated." Or, "Your information about her medical problems in the past was essential information for us." Realistic praise of the parents helps lessen their guilt feelings.

Be prepared to repeat information, as it is nearly impossible to take in new information when under the kind of stress a parent experiences at this time. Nevertheless, understanding and sometimes even reconstructing the events that led up to their child's death is often an essential part of family acceptance and well-being following the loss of a child. Even simple information about what will happen next or what choices they have, for instance regarding holding their child, will be helpful. Your ability to give the information they need and ask for, at the pace that they require, and to repeat the information as needed, can be one of the most therapeutic "procedures" you can offer. To ensure that very important facts are understood, it can be helpful to inquire what a parent has understood of what you have presented. This is especially important for grieving parents under stress, and even more so when they do not speak English and may not fully understand. Offer to help the family share this news with others, such as siblings or young children. Let them know that you will be notifying the child's primary care provider and any relevant specialists. They may appreciate role-play of how to tell other family members, and your presence with them when they are telling them.

Give your contact information in written form and let the family know of any follow-up arrangements, such as a call from the ED social worker in the next day or so.

Consider writing a condolence note to any family to whom you have had to give the news of their child's death, regardless of the length of your prior relationship. It is an act with remarkable potential for healing.

detail. Bluebond-Langner et al. (2007) interviewed parents of children with cancer for whom standard treatment had failed, and found that they

came to understand their role and responsibility as parents as the responsibility to keep options open for their child. They were not necessarily committed to search for cure. Parents bargained and traded for time. Parents chose options with infinitesimal odds because the prize they sought was of immeasurable worth. (Bluebond-Langner, 2007.)

Parents also value complete and honest information, ready access to staff, coordination of the communication from multiple providers, expression of emotion and empathetic support from staff, preservation of the integrity of the parent-child relationship, and acknowledgement of the role of faith and meaning-making. Mack et al. (2007) have found that providers' attempts to shield parents from the full disclosure of a child's prognosis may be ill-conceived and that, on the contrary, parents may derive greater hope from a full understanding of a child's likelihood for recovery. Similar data from adult studies suggest that accurate prognostic information led to better mental health, better death, and improved adjustment in bereaved family members (Ray et al., 2006). Perception of their child's suffering and pain is a touchstone for parents' decision-making, along with their broader assessment of quality of life and expected neurological recovery (Wolfe et al., 2000; Meyer et al., 2002; Meyer et al., 2006).

Kars et al. (2009, 2010) have surmised that when a parent's perception of the child's suffering becomes a greater burden than the parent's fear of loss of the child, the parent begins to make different choices and come to accept that loss. They found that until that tipping point, parents were reluctant to discuss prognosis with their child for fear that the child would lose the will to live, that parents might decline helpful supports such as a hospital bed in the home if they saw it as a sign of a downward course, and that they would fragment the clinical picture into manageable symptoms rather than look at the whole picture. Beyond the tipping point, the authors found that parents were able to experience control in exerting parenting aimed at the child's well-being and family togetherness, preparing the child for what might be coming, and mitigating what they perceived as the child's suffering (Kars et al., 2009). When patients and families learn that there is no further treatment available, they often misunderstand that also to mean that the clinicians who have cared for them will no longer be available to them. When these fears of abandonment are unspoken, they may be expressed as anger or may even in part fuel a desperate search for alternative opinions and treatments. The clinician should make explicit his or her intentions and commitment regarding continued care. Especially when there is "nothing more we can offer," assurance of the clinician's continued presence accompanying the patient and family is a most powerful and healing intervention.

WISHES

Clinicians often frame difficult discussions near the end of life in terms of wishes, hopes, fears, and "what-ifs." When faced with the expression of unrealistic hopes by patient or parents, using the framework of wishes, hopes, and worries allows the clinician to realign and partner with them and to join them in those wishes—wishes that in fact are often honestly shared by caregivers—and to acknowledge the loss and anticipatory grief between the lines. It then may be possible to redirect the patient and family towards more likely goals or alert them to alternative possibilities. For instance, an adolescent nearing death might express the unrealistic plan to have children or graduate college. The clinician could say, "I wish that for you, too. I can imagine what a wonderful parent/student you would make. I wish more than anything that I could guarantee you a cure. But I worry that our treatments are not working for you and those wishes may not come true. Do you worry about that too?"

HOPES

Using the language of hoping, the clinician can explore a patient and family's hopes beyond cure or prolongation of life and understand which of those might be more attainable goals. For instance, the clinician might ask, "Given what we know you are up against now, what are you hoping for?" or offer, "I hope that we are going to be able to get you home from the hospital, so you can spend as much of your time with family and friends as possible." Feudtner (2009) writes eloquently that hope is not a single monolithic entity, but rather is composed of many smaller discrete acts of hoping that provide orientation and motivation in end-of-life situations. Clinicians worry that they are destroying hope when clearly articulating a terminal condition, but Feudtner argues that when the hope for survival is receding, other hopes emerge; that the process of hoping endures. He states that discussing hopes does not engender false hope, as long as the clinician is willing to explore patiently what lies beyond the hopes for miracles, cures, and waking from bad dreams. "Can you talk about what else you might be hoping for?" He argues that it is not necessary to judge whether a hope is realistic or unfounded, but rather to judge how well we as clinicians can explore and nurture "a diversity of hopes," pointing out that whether or not clinicians want the responsibility, they are inextricably interacting with their patients' hopes.

WORRIES AND WHAT-IFS

Using the language of "worries," the clinician can introduce likely bad outcomes in a somewhat more hypothetical fashion, one that is sometimes better tolerated by patients and families. "But what I worry about is that your pain may interfere with the good time you have left, and I want to work with you to make sure we are managing that in the best way for you." In combination with expressions of wishes and hopes,

the clinician's worries acknowledge and share the uncertainty, align with the patient and family, and present what the clinician views as likely problems in an honest fashion. In situations where there is no clear prognosis, as is often the case with pediatric conditions, using the language of "what-if" again keeps the discussion in a hypothetical space where it can sometimes be more easily handled and examined, and where choices can be clarified, at least in that moment. "What if we knew for certain that no matter what we do, (you/your child) only had another few months to live—what would become most important then?" or "What if we knew for certain that she cannot survive without being on a ventilator, what would you and she want then?"

BELIEF IN MIRACLES, AND GRIEVING

Clinicians sometimes are confused or confounded by patients' or families' expressions of unrealistic hopes or reliance on miracles, despite clear communication about dwindling chances for cure. They may feel that they need to redouble their efforts to point out the hopelessness of the situation, resulting in an antagonistic stand-off. While the reliance on holding out for a miracle may be a way of denying or defying reality, the clinician can also understand it as a way for family members to enter into the grieving process, a way to express unbearable loss. At the very least, an appeal for a miracle recognizes a reality that medical management has nothing further to offer. The clinician can use respectful exploration, including inquiry into previous experiences of loss and death, acknowledge the underlying helplessness, accept that some parents may not feel that they have the authority to make life-and-death decisions for their child, and try to reframe what might constitute a miracle. Involving hospital chaplaincy or the family's own community pastor before a power struggle develops may provide further illumination. Many faith traditions would support the idea that respecting the belief in an omnipotent God does not mean that the dying process of a vulnerable, voiceless patient should need to be prolonged by providing non-beneficial treatment.

HELPING FAMILIES NAVIGATE THE UPS AND DOWNS OF CHRONIC, LIFESPAN-LIMITING CHILDHOOD CONDITIONS

In the United States, there are as many as 50,000 children living with severe and complex disabilities, living at home but often dependent on technological interventions such as gastrostomy, tracheostomy, home oxygen, suction, and even ventilator support (US Dept. of Health and Human Services [DHHS], 2008). Where available, such interventions are often supported by home services such as block nursing, special school placement, and community-based respite and palliative care services. Patients are often cared for by a bewildering array of specialists. Some children may have a condition that is known to progress to inevitable decline; others may have a static brain injury, spinal cord compromise, or muscle disorder that makes them prone to frequent and severe

life-threatening events, such as aspiration pneumonia, airway obstruction, or seizures, any one of which might cause death.

For these families and children, it is very helpful to identify a lead clinician, whether primary care, palliative care, or specialist, who is able to help a family navigate choices for life-sustaining treatment in the event of an acute downturn, and to explore with them the values and goals that can provide touchstones for decision-making. These goals should be explicitly revisited whenever there is a change in health status, venue of care, or new treatment choice. With advanced technological and medical supports, home-based care resources, and the knowledgeable and often fierce advocacy of their parents, these children may long outlast predictions of their lifespan made at time of diagnosis. Because of that, it is often difficult for parents to envision a time when the child will not recover from these intermittent crises. In this setting, it is useful to reflect on changes over the recent past in terms of the child's ability to give and get love, and the quality of life as perceived by those who know the child at his or her best, who can assess whether the child is experiencing suffering, and how any of the burdens of extended complex medical treatment may have changed. Hospital-based clinicians who only see the child during periods of maximum stress and illness often are not able to visualize any meaningful quality of life for such a child, and often experience distress about treatments offered or limited medical resources squandered. This distress can sometimes be mitigated by asking the family to describe or bring in pictures of the child's good days.

The lead clinician can often gently explore values and choices with parents, beginning with acknowledging the uncertainty of any prognostic estimate, and inquiring if the parents have ever visualized what they thought might be a good death for their child, including the venue of care. "It's hard enough for us to imagine our own death, and yet what I am going to ask you is even more difficult. Knowing that [child's name] would not have a normal lifespan, have you ever imagined what a good death would look like for him?" The borders between benefit and burden can become blurred in the care of children who are already heavily dependent on technological interventions; the clinician and the family can contract to share honestly when either party feels that treatment might be doing things to, rather than for, the child, or simply prolonging a dying process. These discussions can help uncover the values that might help guide families in their choices when the child experiences a medical crisis. If a medical crisis precipitates a discussion of prognosis, Feudtner (2007) proposes using a "collaborative practice" model that reflects the understanding that, for children with complex chronic conditions, prognosis does not simply mean how much time is left to live, but also encompasses consideration of prior quality of life, the likelihood that the child will survive this current crisis, what is required to survive this crisis, what the anticipated new quality of life will be, and how frequent or severe future crises might be. Another tool that has been used in the United Kingdom is the "personal resuscitation plan," which provides a much more nuanced set of interventions than is usually possible within the template of a Do Not Resuscitate (DNR) or Medical Orders for Life-Sustaining Treatments (MOLST) form (Wolff et al., 2010).

Although developed for the purpose of facilitating emergency care of children with complex medical needs, the Emergency Information Form (EIF) developed jointly by the American Academy of Pediatrics and the American College of Emergency Medicine can serve a similar purpose of clarifying goals of care. Emergency care plans for palliative care patients who are at risk of frequent life-threatening events have been incorporated into the electronic medical record and given to parents on a memory stick. As useful as these tools are in the event of a crisis, the actual process of developing them, with parents and invested caregivers, is in itself a valuable opportunity to explore a family's hopes and values regarding the end-of-life care for their child, particularly when the focus is placed on describing desired interventions, rather than interventions to withhold.

TALKING WITH CHILDREN AND ADOLESCENTS ABOUT THEIR OWN DEATH

Talking with a child or adolescent about his or her own death is a rare and difficult privilege in clinical practice. Because the number of children who die is small, and many are too young to be verbal and still others are rendered nonverbal by their condition, few practitioners have the opportunity to gain experience in this difficult task; perhaps night nurses, child life specialists, pediatric chaplaincy staff, and clinicians who care for children with cancer or chronic respiratory and muscle disorders have the greatest opportunities. Even in these limited situations, there are formidable obstacles to talking with children about their own death. The first reason is clear—it is simply too hard, too painful for either parents or healthcare providers to talk with children about the possibility of the child's death. On all sides there is the deep desire to protect all participants from the pain and sadness. Parents want to protect children; and children, even very young children, want to protect their parents from sadness or disappointment. Glaser and Strauss describe the protective silence of "mutual pretense" where each party in the interaction intuitively knows the prognosis but does not openly acknowledge this to the other party. This phenomenon involves staff as well and is not rare in many settings of a critically ill, dying child, perhaps especially those who are well known to caretakers and whose death the caretakers themselves are grieving, or the children who die who were expected to survive and then took a sudden turn for the worse.

Providers often rightly feel that parental permission is required to enter the very private territory of speaking with a child about his or her death; therefore, the parents' expert knowledge of their child's nature should be explicitly elicited and the subject of communicating with the child explicitly addressed with parents. Beyond this obstacle, there are often dark fears that live below the level of logic. It is very hard even for logical beings to remember that naming death will not make it happen, and yet both parents and providers fear that naming death will imply that we are giving up. It is often helpful to name this fear out loud. Parents and providers alike may be reassured to learn of a study of bereaved parents in Sweden, Kreicsberg et al. (2004) who reported on

their practice regarding talking with their child about death; the authors found that only a third of parents had done so. Interestingly, none of those parents had regrets about talking with their child, whereas nearly half of the parents who did not talk with their child did have regrets.

Additional obstacles to communicating with children bear consideration. Prognostic uncertainty often leads to deferring discussion with the child until "we know for certain." Developmental biases—that "kids don't understand death," or that "kids don't need to know because they are not making the decisions"—may prevent providers from exploring a child's understanding. *Decisional capacity* can be understood as (1) having a reasonable understanding of the nature of one's illness, the treatment and nontreatment options, the potential burdens, the benefits and consequences of those options; and (2) an understanding of death as permanent and irreversible. Although Solomon et al. (2003) have offered a general guideline that children over age ten are developing a capacity for understanding death and the consequences of choices, and that in general children over age 14 can be considered "decisional," it is clear from many reports that age does not determine understanding of death—for instance, in one study, the number of years of attendance at cancer camp was a better predictor of understanding than age, gender, years from diagnosis, site of treatment, or diagnosis (Bluebond-Langner et al., 1991).

It can be very helpful for clinicians to explore with parents why they would want any particular information withheld from their child. "What frightens you the most; what are you most afraid will happen if [child's name] asks about dying?" Inquiry may reveal the worries or denial of the parent; for instance, that they fear their child will give up hope and die sooner. It is also helpful to share with parents our experience that children almost always have an understanding beyond what has been discussed openly with them, because they overhear conversations, minutely observe and interpret their family's reactions, and can sense what their body is telling them. What is imagined may be worse than what is, and silence can add to a child's isolation, the rupture of trust, and the loss of autonomy, giving the child no chance for handling unfinished business. When children are given the information in an age-appropriate manner, it can give them an opportunity to talk about their fears, ask questions about what is going to happen, express their feelings, and say their goodbyes. When parents are able to be honest with their child and include their child in discussions about the plan of care, it gives the child some control over an otherwise out-of-control situation. Parents can thus sometimes be helped to understand that the best way to care for and protect their child is to prevent the isolation, so the child "does not need to be alone with his worries." They may welcome suggestions about how to approach talking with their child, whether they take on the primary role or wish to have a clinician partner in the conversations.

Sequencing meetings, first with the parents, and then with parents and child, may optimize communication and allow for the opportunity to explore the child's understanding in the parents' presence. Parents interviewed about their perceptions of having their child present during difficult conversations

acknowledge the benefits of such openness; however, they also report that those benefits come at a cost, reporting that they are less likely to ask questions and less able simultaneously to focus on the discussion and to care for their child emotionally. Separate meetings allow parents the opportunity to ask questions freely, absorb information, and consider the best ways to present that information to their child (Young et al., 2011). Although it is routine practice in primary pediatrics to offer solo time with the child patient, beginning around the onset of puberty, this practice is not routine in the subspecialty care of children with chronic or life-threatening disease, where arguably the need for autonomy and privacy may be greater. Normalizing a routine of solo time with the child when curative options are still within reach makes it easier to provide this opportunity near the end of life to have the child voice his or her feelings without fear of upsetting or disappointing parents. Bluebond-Langner et al. (2010) describe this as one feature of a kind of “shuttle diplomacy” to involve the child in decision-making, in a way that acknowledges that the parents are probably still going to be the final decision-makers, but also to make sure that the parents know and understand their child’s comprehension and wishes. Even if it is clear that the final decision-making rests with the parents, there is still room for dissent and negotiation.

Parental refusal to allow children to receive crucial information for the child’s own coping and grieving can create a tremendous burden for staff who believe that the sharing of such information is essential to providing good care. When parents still do not want their child told, it is important to maintain a connection with the family, validating the difficult task of acting in the child’s best interest, offering to help facilitate conversation, asking how they would like further conversation to be conducted, and telling no more than the patient needs. “I am going to need your help to tell me how much you would like to know.” Parents may be helped to know that dying children know they are dying, and the denial by family will not counterweigh their perception. It is sometimes possible to negotiate with parents that, while caregivers will agree not to tell the child certain information, they also cannot lie to the child if asked directly. Much of our understanding of the wishes of terminally ill children comes from the interpretation of play, pictures, and music created by children. However, in an interview with Mattie Stepanek, a 14-year-old poet who died of muscular dystrophy, Mattie spoke compellingly of the wish to have choices in aspects of his treatment, and to have a sense that people were listening to his wishes and worries (Initiative for Pediatric Palliative Care, 2003.) Like dying adults, dying children may likely wish for autonomy, dignity, comfort, and the opportunity to make meaning out of their lives and leave a legacy to those they love, as well as an opportunity to resolve conflicts prior to their death. Dying children may struggle with how best to protect their family, and may fear being forgotten.

Even when it is not possible to discuss the terminal nature of a child’s condition directly, parents, and even older children and adolescents, can be supported by a listening presence and by asking reflective questions that help them examine and understand the story of their journey. Block and Billings

have developed a series of questions as part of a postgraduate course, designed to “deepen the conversation” by exploring domains such as the effects of the illness on the patient’s and family’s physical and emotional well-being and sense of personhood; identifying coping strengths and supports; and clarifying preferences. Table 81.2 lists those domains with a few example questions.

Other published tools that have been used in discussion of pediatric advance directives include the pediatric modification of “Five Wishes,” called “My Wishes,” (Pediatric My Wishes), the young adult modification called “Voicing My Choices, (Voicing My Choices; Wiener et al., 2012) and the Decision Making Tool developed by the Seattle Children’s Advanced Care Team (Hayes, 1998). For young adults who are 18 or older, the designation of a healthcare proxy can be the occasion for elucidating a young person’s wishes regarding life-sustaining treatment. Tolerance for child autonomy is likely to be different depending on context, such as whether the decisions involved are likely to reverse disease, or simply prolong a dying process. However, an important pediatric consideration is that children who have experienced chronic disease may defy any standard rubric of developmental capacity, and the weight of their experience should give their voice additional moral power. It is difficult to improve upon what William Easson wrote about the dying child in 1970; namely, that “the best treatment of the dying youngster can be based only on the knowledge of what his approaching death means to him and how this young person can reasonably cope with this very personal reality.”

SPECIAL ISSUES: BRAIN DEATH, ORGAN DONATION, WITHDRAWAL OF SUPPORT, DO NOT RESUSCITATE ORDERS

Additional issues relating to end-of-life decisions invariably arise with terminally ill children, and the physician needs to be aware of and prepared to deal with additional difficult questions when they are voiced. A few issues deserve emphasis. Brain death *is* death, and once brain death has been ascertained by accepted criteria, no additional permission is necessary for termination of medical support. Indeed, the only indication for continuation of medical support in the setting of brain death is organ donation. Caregivers need to have a clear understanding of this principle before interacting with the family so that there is no confusion or unnecessary added worry or pain around discontinuing mechanical ventilation, intravenous fluids and medications, and other life-support measures.

It is also important that the roles of caregiver for the patient and advocate for organ donation be kept completely separate, to avoid any confusion for the family. The only role the physician caring for the child should take with regard to organ donation is to notify the representative of the regional organ bank of the possibility of a donor. Physicians should refer any questions regarding potential organ donation to the organ bank or the transplant team so that the family understands that the physician’s sole concern is whatever is best for the child. (For a more complete discussion of issues surrounding organ transplantation, see Chapter 65.)

Table 81.2 DEEPENING THE CONVERSATION

DOMAIN	SAMPLE QUESTION
Hearing bad news	<i>Tell me how you first found out about your/your child's illness: what was that like for you?</i>
Information sharing and prognosis	<i>How do you make sense of your/your child's illness? What is likely to happen going forward?</i>
Effects of illness: Physical or emotional	<i>What are some of the moments when you've felt the most discouraged and downhearted as you've faced this?</i>
Coping: Past and present	<i>Have there been other tough times you have had to face? Other serious illnesses or losses?</i>
Supports: Formal and informal	<i>How have you been helped by family and friends/ your health care team? How have they responded? How have they disappointed or not been helpful for you?</i>
Religion and spirituality	<i>Do you have any (devotional) practice that brings you closer to a sense of peace or strength or wholeness?</i>
Facing a life-threatening or terminal illness	<i>Have you had to make or change any big plans because of your/your child's illness?</i>
Preferences for site of care	<i>How do you feel about being at home when you/your child is sick? Or about being in the hospital?</i>
Family coping and support	<i>How do you think your family or siblings/close friends have been affected? What do they understand about your/your child's illness?</i>
Personhood	<i>How has your/your child's illness changed you as a person?</i>
Reconciliation and closure	<i>What could you do that would help you feel that this has been a meaningful time for you and your family?</i>
Envisioning a good death	<i>If it had to be, what would your idea of a good death for you (for your child) look like?</i>

Modified from Billings, A. J., & Block, S. (2010). Palliative care education and practice. Harvard Medical School postgraduate course.

GRIEF

UNDERSTANDING GRIEVING AS THE WORK TO RECONSTRUCT MEANING IN AN ASSUMPTIVE WORLD RUPTURED BY LOSS

Bereavement following the loss of a child challenges traditional models of grief that describe universal and fixed stages ending in recovery, as if “successful” grieving required that grief be resolved and the loss of the loved one be somehow put away. Such constructs do not match well with the lifelong impact of a child’s death on parents and siblings. Anticipated loss of a child, as an event, can invalidate the basic assumptions by which those who are grieving have previously lived, or may seem like alien and new experiences for which they have no preconceived construction.

A more recent model proposes to understand grief as the “act of affirming or reconstructing a personal world of meaning that has been challenged by loss” (Neimeyer, 2006). With this model, grief can be understood as a continuing and transformative process, acknowledging that bereaved parents do not necessarily “let go” of their grief or their lost child, but transform them by renewing the meaning invested in them and continuing the relationship in new ways. The deceased child continues to be “a significant other,” an active and living memory, even a presence. This meaning-making can create positive social legacies, such as with organizations like Mothers Against Drunk Driving.

Folded into the death of a child is the death of so many imagined futures encompassing that child’s evolving

personhood and the parents’ vision of themselves fulfilled as parents. These losses are suffered repeatedly over time as other children in their lives attain the milestones that the lost child will never see. Because child death is uncommon, it may be hard for bereaved parents to find a place where they can speak openly about their loss. Some parents may feel that they have to pretend that they have not lost a child as they experience how many people, even close friends, become nervous or withdraw when parents try to share their ongoing grief.

Because there are so few norms for bereaved parents, seemingly small details can become huge:

“Should I keep the door to my deceased child’s room open or closed?”

“How do we sign our holiday cards that we always signed with everyone’s name?”

“What do we do on her birthday?”

For the grieving parents, it takes time and precious energy to figure out when they want to engage with people on the subject of their dead child. Answering the casual question “How many children do you have?” can be fraught with difficulty. Some parents describe that they feel like a loaded shotgun goes off when they answer questions like that truthfully, leaving the person who asked the question wondering what hit them. It is difficult to predict when someone is going to ask sympathetically for more details, or simply turn pale and withdraw. And yet not to name and count the child who has died may feel like a betrayal. “Being a bereaved parent sometimes feels as if you are from a different planet from everyone else.” Finding a place where people remember their child

and are comfortable talking with them about the child is very comforting, and the staff who cared for their child before death are often an important oasis for parents. Naming and sharing memories of a deceased child is an ongoing gift that staff who were part of that child's care can give to bereaved families. Families do want to talk about the loss of their child and generally welcome calls, emails, or letters from caregivers. For bereaved families, it is never too late to learn that their child is remembered by a caregiver.

CARE OF THE BEREAVED FAMILY AT THE TIME OF DEATH AND AFTER

Even when anticipated, death is always a surprise and a mystery. For some families, their child's death may be the first such loss they have experienced, and they will not know what to do, how to act, or what is allowed. Staff can suggest what they have found helpful to other families, such as private time with the body or helping staff to bathe and prepare the body. Staff should try to elicit information about rituals or customs important to the family's culture or religion, and honor those as much as is possible. Physical separation from the body is often an extremely difficult time, burdened with multiple practical concerns such as institutional needs to utilize clinical space, identifying a funeral home, and notifying family and friends. Families, including siblings, should be offered opportunities to participate in memory-making activities such as creating ink handprints and footprints or molds of the child's hand out of clay, saving a lock of the child's hair, or taking photographs of the child. If this can be done before the child's death it can be a very moving and important activity for the family and child, if the child participates. If this is offered to a family after the death, it becomes an opportunity for a final interaction with their child. Some families will not want to participate in this activity, and if that is the case, they should be asked if they would like the staff (child life specialist, nurse, social worker) to do it for them. These articles can be placed in a memory box and offered to the family when they leave, or kept for them if they wish. Families have reported that having a memory box, articles of the child's clothing or belongings, or even simply a special blanket that has been used to wrap the child in after death, to take with them eases the time of separation from the body. Thought should be given to the moment of transfer when the child's body leaves the family's sight to be delivered to the morgue or to the funeral home staff. It may be easier for family to see their child being carried away in a staff member's arms or otherwise treated like a person rather than a corpse. If possible, it is a caring gesture to families leaving the hospital to accompany them to their car and attend to any parking fees.

Clinicians often underestimate the meaningfulness of attendance at a child's wake or funeral for bereaved families. Continued contact with staff who have cared for the child, at milestones from the death, such as one week, one month, six months, and anniversaries of birth and death, is highly valued by families. Institutional memorial services are a meaningful venue for families and staff alike to honor the children they have cared for. Autopsy or clinical

care review is another opportunity to reunite caregivers and family. If the child died in the hospital, the first time a parent returns to the hospital for whatever reason can be overwhelming. Staff who are aware of this milestone should make every effort to be supportive.

Inviting a family to return for a clinical review is not routinely practiced. Meert et al. (2007) reported that, for families whose child died in the pediatric ICU, only 13% had a scheduled clinical care review meeting after the child's death, although a majority (59%) would have wanted to, and of those, 82% would have been willing to return to the hospital. Families reported wanting the opportunity to review the chronology, treatment, redirection of care, ways to help others, bereavement support, what to tell other family members; and to express gratitude and complaints.

The family should be offered the opportunity to meet with the reviewing physician in a quiet, private space removed from the clinical setting, optimizing ample time for a relaxed, personal conversation. At this meeting, the physician solicits and addresses outstanding question or unresolved issues, reviews what happened and why, and explains what the autopsy results were, if any. An attempt should be made to set a tone of the physician and family coming together to discuss a painful, shared experience as equals, not as physician-patient, and to make it clear to the family that their relationship with the physician continues.

Community-based hospices provide an invaluable follow-up resource for the bereavement process. This resource can be used to maximum advantage when it is combined with an integrated follow-up program through the hospital where the child has died. Families should be offered follow-up sessions with social workers, nursing staff, and physicians at two to three, six, and 12 months after their loss, and at additional sessions if requested or needed. Hospice bereavement services may be offered to the family as early as two months after the child's death. In addition to their own services, hospices have access to other community-based bereavement groups such as Compassionate Friends (877-969-0010). The National Hospice Organization (800-648-8898) also can provide information about local resources.

Family-centered care includes the care and emotional well-being of the patient's siblings. Both before and after a child's death, siblings often fear that they are responsible for or vulnerable to the same suffering as the affected child, and often have difficulty finding a safe place in which to reveal those fears. Many children, teens, and adults find it helpful to attend bereavement support groups or camps. These groups provide children, teens, and parents opportunities to connect with others who are grieving a similar loss. Being with others who understand the experience of loss can be supportive, therapeutic, and educational and offers opportunities to talk about feelings and memories about the child who has died.

CARE OF STAFF

Caring for dying children generates distress among clinicians: "There is nothing right about the death of a child," reports one of the clinicians interviewed by McKelvey in his book,

“When a child dies: how pediatric physicians and nurses cope.” (McKelvey, 2007). He notes that the death of a child patient can leave staff feeling emotionally labile, guilty, and unable to sleep or concentrate. Most vulnerable are likely to be trainees and those newest to the field. Clinicians may question their competence or whether they have chosen the right profession. In the hierarchical culture of a teaching hospital, the distress associated with the death of a child can be translated into blame, which then may be assigned to or assumed by trainees. A sense of guilt, failure, or inadequacy can prevent trainees from being supportive or compassionate with a dying child’s family. Moreover, for younger staff, caring for dying adolescents presents challenges of over-identification and fears of one’s own mortality. The motivation to enter medicine as a profession in order to save lives can be challenged by the death of a young patient, and staff can become defensive rather than supportive. Few residency or clinical programs offer education in reflection, coping, or how to deal with the death of a child. Nevertheless, debriefings, reflection rounds, or caregiver gatherings after the death of a child provide opportunities to reflect on the care that was provided to the child, the family, and each other. Offering reflection rounds or multidisciplinary caregiver rounds to honor the care provided to a child and family gives staff a venue for understanding the richness of the care delivered, acceptance that they are part of a bereaved community, and recognition that often they are not alone in their feelings of anger, sadness, or guilt following the death of a child. Even when further details are sad, somehow a more complete picture of the child’s death brings comfort and a sense of control to caregivers, much as it does for parents.

Clinicians report that the most helpful experience that promoted comfort with dealing with a dying child was a personal experience of the death of a close friend or family member (McKelvey, 2007). While even seasoned practitioners have clear and often still troubling memories of the first death of a child under their care, subsequent experiences with death may become easier to manage as clinicians learn to manage their own distress. However, over time, many practitioners recognize the limitations of distancing themselves from their patients and develop other ways to cope, such as by focusing on what could be learned from the death or from keeping a child as comfortable as possible. It is likely that no practitioner keeps this balance right all the time. McKelvey highlights situations that are particularly poignant, including:

The child or parent who reminds the practitioner of themselves or their own family;

An abandoned child or one seldom visited by his or her own family who elicits parental and protective feelings from professional caregivers;

A child with a particular insight or sense of humor that made the inability to save the child more of a personal failure;

The child who suffers from a treatment error.

Many clinicians find that the laypersons’ world outside of medicine offers little understanding of their distress or support for coping, and that sharing troubling medical experiences can be so upsetting for their non-medical acquaintances that they end up having to comfort the comforter. Spouses vary in their ability to provide support. Most clinicians find that their most reliable support comes from other clinicians engaged in the same kind of work. Trainees in particular may be more likely to rely on other peers, fearing that supervising staff might judge or grade them.

A child’s death shatters the protective denial that shields us from being aware of how truly fragile and transient life is. Trainees and seasoned clinicians alike are forced to reflect on their own mortality, but perhaps even more painfully on the possible loss of their own loved ones. Staff with young children are particularly vulnerable to identifying with bereaved parents: “each one of us is only a day away from standing in the shoes of those PICU parents” (McKelvey, 2007). Trainees who are parents report consciously seeking out situations outside of work where there are healthy children playing, to redress the balance of their experiences. They may experience support from being able to go home to hug their own children and to lose themselves in loving them.

McKelvey notes that while training, experience, and the observed behavior of colleagues all contribute to the ability to cope with child death, the clinician’s childhood experiences of how death was dealt with by one’s own parents and family provide the best predictor of coping. Many physicians identify personal loss as the most meaningful experience in terms of deepening their ability to provide compassionate care and to cope with the death of a child patient. Reflecting on those experiences and models may help clinicians understand how best to cope with their own distress, and to acknowledge the need to open up the possibility of other ways of coping. Continued contact with bereaved families is beneficial for clinicians as well as family; clinicians may find comfort and meaning in how families have carried the memory of their child forward in their lives. In Box 81.2 are practical suggestions for self-care following the death of a child patient.

PART TWO: TALKING WITH CHILDREN ABOUT THE DEATH OF A LOVED ONE

Few tasks are more painful to families or caregivers than that of telling a child about the death of his or her mother, father, sibling, or friend. However, children are aware of death from an early age through everyday experiences, whether through the media, the death of a pet, a wild animal killed by the roadside, or the loss of an elder in the extended family. Death is therefore a reality that children can learn to accept much as adults must; however, they need to make sense of their own experiences in order to understand death as a normal part of life. The child’s own experiences and developmental capacity will help determine how best to talk with her or him about the death of a loved one. A full developmental understanding of death is one that comprehends it as universal and irreversible, with the loss of all functionality, informed by a realistic

**Box 81.2 PRACTICAL SUGGESTIONS FOR WAYS TO
MANAGE THE DISTRESS AND DIFFICULTY SUR-
ROUNDING THE DEATH OF A PATIENT**

Take care of yourself—do something for yourself that renews you, because *you* have experienced a loss—you are a bereaved person.

Don't imagine that you are the only one feeling this way; understand that you are part of a bereaved community.

Be aware of feelings of guilt and try not to blame yourself. Recognize that a patient's death is not your personal failure.

Seek out colleagues with whom you can share difficult experiences. These may not be your closest friends or family, but rather people who have had similar experiences.

Tears are a good way to cleanse your body of distress. Drink liquids and cry as much as you need.

Seek out institutional venues for support such as an Employee Assistance Program.

Consider reaching out to the family in the form of a letter, phone call, or visit, and know that it is *never* too late to do so. Know also that the family will value your thoughts and care, even if they cannot in their grief even recall your face or name.

Journaling is a way to put difficult situations into perspective and enables you to see events in a new light.

understanding of the causes of death. Each child comes to this understanding in his or her own way, but Table 81.3 below offers a general developmental evolution.

It is helpful to ask what beliefs the family has about what happens after death. For a child, using clear, age appropriate language, the words “dead” or “died”—instead of euphemisms such as “He is sleeping,” “The angels took him,” and “He has gone on a long journey”—minimizes confusion. Children and teenagers need to be reassured that they are safe and will be taken care of. They also need ample opportunities to ask questions about the death and to trust that they are getting honest answers from a caring adult who is listening for their concerns.

When telling a child or teenager about the death of a loved one, it is important to know what they may have already been told. It is also helpful to understand what beliefs, religious or otherwise, the child and family may hold. Common childhood misapprehensions such as “I caused it; I could catch it; this happened because I was bad” can be allayed by explicit reassurances. Children and teens may also need to be assured that their feelings, whatever they may be, are normal and okay. Unspoken fears may include “Could that happen to me, or to another person I love?” and “Who will take care of me now?” Concrete concerns can best be addressed by clarifying a child's worry or question, as the child may be asking from a very different point of view from the adult attempting to answer. Using the strategy of saying “That's a very good question! What got you wondering about it?” will help you shape the answer to best address the child's understanding and concerns.

Those around the child may question whether the child should visit the dying person or participate in the funeral. In

fact, children may treasure having had the chance to spend time with a loved one during that person's last days, and can assimilate values through participation in the death of a loved one. They may later resent being excluded, whereas their involvement may assist them with their own grieving. Problems are most likely to arise when children are forced to participate against their will or excluded when they wished to participate, so if children are physically able, it is usually advisable to ask if they wish to visit a dying loved one or attend the funeral. It is always important to prepare children for what they might see, and to plan for alternatives in the event that a child wants to leave or cannot maintain composure during a visit or a long service. Funerals and religious services are important death rituals that facilitate the grief process and usually serve to mobilize social support for the survivors. Children can benefit in meaningful ways by helping to plan or attend funerals, especially if they are given the opportunity to ask questions.

Adults often feel that they must be “strong” or suppress emotions that they feel might be upsetting to a child. In fact, sharing the emotions of sadness or anger around loss with a bereaved child helps validate the child's own feelings and lessen the isolation he or she may be feeling. The child can learn from the emotional reactions of the adults around him that it is our human capacity to love that makes us both vulnerable to loss and capable of providing comfort (see Table 81.3).

ADVERSE OUTCOMES

There are risks of adverse outcomes when counseling the bereaved. While grief is a normal reaction to loss, and while the staff need to be cautious of not “pathologizing” grief, one does need to be aware of abnormal grief reactions. Children, especially those with prior emotional problems, may be at risk for disruptions in development, including somatoform disorders, disruptive behavior, school problems, or anxiety or mood disorders. There is increased risk of post-traumatic stress disorder following a sudden death. Children and adults are at increased risk who have a recent history of other major losses or deaths, depression, suicide attempts, another mental or medical illness, or alcohol or drug abuse. There is risk over the course of bereavement of the relapse of preexisting mental or physical illness. Some children or parents may have an unresolved pathological bereavement reaction that evolves into major depression. Patients or family members at such risk should be informed of the available bereavement resources, including referral for psychiatric care. The recognition and management of unresolved or pathological grief in adults has been described by Brown and Stoudemire (1983).

CLINICAL PEARLS

- A first step in supporting clinicians dealing with a child's death is to acknowledge that death is unavoidable for many of the conditions they are called upon to treat. A second step can be to remind clinicians that their

Table 81.3 DEVELOPMENTAL UNDERSTANDING OF DEATH

AGE CHARACTERISTICS	CONCEPT OF DEATH	IMPACT OF DEATH	INTERVENTION
0–2 Sensory and motor relationship with environment Limited language skills Achieves object permanence May sense something is wrong, react to the emotions of adults	None, or as a separation	Disruption of normal care routines Separation anxiety	Provide stable physical nurturance and comfort with simple physical communication and with familiar, beloved relatives and objects Maintain routines
>2–6 Uses magical and animistic thinking Egocentric Engages in symbolic play, acquiring language skills	Believes death is temporary and reversible like sleep Does not personalize death Believes death can be caused by thoughts, wishes, or misdeeds	Regression Guilt Fearfulness	Minimize separation from usual caregivers Clarify understanding before attempting to answer questions Evaluate for sense of guilt and assuage if present Use precise language (“dying, dead”) and child’s own language for loss Maintain routines
>6–12 Uses concrete thinking	Development of adult concepts of death Understands death can be personal Interested in physiology and details of death	Preoccupation with potential for physical suffering of the deceased Fear of similar consequences to self or other loved ones	Evaluate child’s fears of abandonment Provide concrete details if asked Support child’s efforts to achieve control and mastery Maintain access to peers Be truthful Allow child to participate in decision-making Maintain routines
>12–18 Reality becomes objective Capable of self-reflection Self-esteem and body image are paramount	Explores non-physical explanations of death	May mask feelings or act as if they do not want help or the chance to talk	Reinforce self-esteem Allow to express strong feelings Allow privacy Promote independence and access to peers Be truthful Allow to participate in decision-making Maintain routines

Modified from Himelstein et al., 2004

presence, empathy, practical assistance, and information enable them to provide a bereaved family with essential assistance that they will need to adjust to their loss (Janzen et al., 2003).

- Families will remember how they were treated more clearly than what actual words were spoken.
- Naming and sharing memories of a deceased child is an ongoing gift that staff who were part of that child’s care can give to bereaved families. Families do want to talk about the loss of their child and generally welcome calls, emails, or letters from caregivers. For bereaved families, it is never too late to learn that their child is remembered by a caregiver.
- A framework of wishes, hopes, and worries allows the clinician talking about the end of life to realign and partner with parents and patient and to acknowledge loss and anticipatory grief “between the lines.”
- The clinician can understand holding onto hope for a miracle as a way for family members to express unbearable loss and to enter into a grieving process.
- None of the parents studied regretted talking with their child [about his or her death], whereas nearly half of the parents who did not talk with their child [about death] did have regrets (Kreicsberg et al., 2004).
- Normalizing a clinical routine of solo time with the child when curative options are still within reach makes

it easier to provide this opportunity near the end of the child's life, in order to allow the child to voice feelings without fear of upsetting or disappointing parents.

- Common childhood misapprehensions such as "I caused it; I could catch it; this happened because I was bad," can be allayed by explicit reassurances. Children and teens may also need to be reassured that their feelings, whatever they may be, are normal and okay. Unspoken fears may include "Could that happen to me, or to another person I love?" and "Who will take care of me now?" Always clarify the context of a child's question before attempting to answer it.

PART X

MEDICAL PSYCHIATRY IN THE EVOLVING SYSTEM OF CARE

SECOND MEDICAL OPINIONS IN THE ERA OF PERSONALIZED MEDICINE

Mayanka Tickoo, Aditya Bardia, and Lidia Schapira

INTRODUCTION

In the past two decades, we have witnessed a major shift towards a patient-centered approach in medicine, with important consequences for all participants. Patients have become increasingly vocal and involved in their own care; professionals value and promote self-advocacy; and physicians are now trained to engage patients in important value-oriented discussions prior to recommending specific treatments. The need for informed consent for treatment is an accepted mandate, and respect for a patient's autonomy has risen to the top of the list of ethical values (Schneider, 1998). The prevalent model for consultations involves at least some consideration of the patient's agenda, although practices vary according to specialty and the particular style of consultants.

The concept of sharing power in medical consultations and the formal study of communication between physicians and patients is relatively new. Shared decision-making has replaced a more directive or paternalistic approach in the United States and other developed countries. By "shared decision-making" we mean a collaborative relationship wherein "patients are involved as active partners with professionals in clarifying acceptable diagnosis, treatment, management and support options, discussing goals and priorities, and together planning and implementing a preferred course of action" (O'Connor, 2007). In a comparative study of the conventional models of medical practice (paternalistic, deliberative, interpretive, and informative), the informative model is seen to present maximum opportunities for patient guided decision-making with the physician presenting the available treatment options and the patient deciding the course of his or her treatment (Ahern, 2012). However, the deliberative model may be a better fit for second opinions, with the bulk of the decision-making power still resting with the patient, and the physician acting as an expert guide. Experienced physicians understand the need to be flexible and to have a wide repertoire of skills that can be tailored to meet individual needs. Emergencies call for authoritative and quick decisions, similar to those made by a pilot facing an emergency landing, or by a commander in the field. In times of crisis, patients value clarity and support, and consultants can assist by adding their perspective without causing undue delay in implementing treatments.

It is now customary for patients to seek information independently after receiving a diagnosis, and they often seek a second opinion. Second medical opinions (SMOs) can enhance the patients' say in regard to their treatment and the choices available to them, and involve a thorough reevaluation of the patient's case, including revision of diagnostic material (Mellink, 2004). They have become fairly common in certain communities of patients, fostered by the perception that they constitute both a right and a requirement for informed decision-making, and by the availability of consultants. In our clinical practice treating breast cancer, it is common to meet patients who have already scheduled a second opinion prior to receiving the first!

The number of patients who seek second opinions varies, depending on the specialty of medicine as well as other factors. A survey of 2,274 people in the United States in 1999 revealed that one in every five people who had visited a health professional in the past year had sought a second opinion (Wagner, 1999). In another study of patients who self-report having survived a cancer, 56% of 1,020 patients were found to have obtained at least one second opinion (Hewitt, 1999). The definition of a "second medical opinion" used in these studies typically defined it as seeking an opinion from a second health professional of the same specialty as the one who had given already given an opinion earlier (Tattersall, 2009), or as a search for additional information that would "help the patient decide what to do and what not to do, where, when and with whom" (Moumjid et al., 2007). Most patients who have private medical insurance in the United States are entitled to a second opinion consultation, and this may partially account for its widespread use. The availability of medical information through the Internet and media has fostered public demand for expert opinion (Barsky, 1998). Unfortunately, there are no data regarding the effectiveness or costs of such opinions. Similarly, we do not know how patients integrate the information received in both consultations, or what criteria they most often use to select their treatment or treating physician.

In this chapter, we will review common reasons for SMO referrals, provide suggestions for how to assist the patient with decision-making, and reflect on how the practice of SMO referrals can be improved.

UNDERSTANDING THE MOTIVATION BEHIND A REQUEST FOR A SECOND MEDICAL OPINION

SMO referrals can broadly be classified into those that are driven primarily by the physician, by the patient, or by the medical system. These are discussed in detail below, and outlined in Figure 82.1 as a fish-bone diagram.

PHYSICIAN-DRIVEN SMOS

Requests for second opinions are often sought in the case of diagnostic or management uncertainty and difficulty (Sutherland, 1994; Townsley, 2003; Bradley, 2011). A primary care physician, acting as an advocate for his or her patient, may facilitate the referral by identifying an expert and initiating the process. In such cases, it is customary for the physician to call, to send a facsimile or email request directly to the consultant, and to expedite the transfer of the appropriate laboratory or imaging studies needed for the second opinion consultation. The requesting physician in turn expects the consultant to communicate directly and in a timely manner after the consultation is complete.

Less often, the consultant suggests to the patient that they consider obtaining another opinion because there are no established treatment guidelines or only limited options for treatments exist. Requests can be motivated by the search of novel approaches available only through clinical research trials at academic centers (Philichi, 2010; Poowuttikul, 2011). Such physician-initiated second opinions are more likely to be directed towards specialists working at dedicated specialty units who have access to innovative treatments, or towards colleagues with considerable authorship in the field.

A third scenario to consider is when a psychiatrist requests an SMO for the purpose of reducing the patient's anxiety, or to resolve the clinician's own doubts about the accuracy of the physician's diagnosis or appropriateness of the recommended treatment. In such situations, it is advisable for the professional giving the SMO to address the patient's and the psychiatrist's questions separately and directly, and to avoid any ambiguity that could only reinforce doubt or cause confusion. With the patient's consent, we recommend speaking directly with the psychiatrist to ensure the smooth transfer of information and to facilitate a resolution.

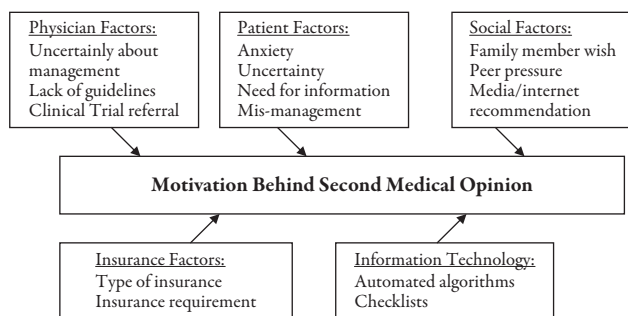

Figure 82.1 Fish-bone diagram outlining the major motivating factors behind SMO.

PATIENT-DRIVEN SMOS

Most commonly, second medical opinions are sought directly by patients who have consulted a physician and for whom a treatment plan has already been formulated or started. There are multiple reasons for seeking a second opinion. The primary motive for a patient usually is the cognitive need for information and the emotional need for reassurance to facilitate their coping and subsequent decision-making (Olden, 2007). In a study conducted in the United States over a decade ago, Wagner and colleagues found that women, older individuals, and those with a college education were more likely to seek SMOs (Wagner, 1999). An Australian study by Tattersall found that women were more likely to seek a second medical opinion, and that these patients tended to be younger, more educated, and preferred more detailed information (Tattersall, 2009). Among cancer patients seeking second surgical opinions, breast cancer patients tend to seek more SMOs than any other group (Mellink, 2003). It is quite possible that women with breast cancer are generally better informed as a result of the growth of advocacy and activist movements urging women to seek a second opinion prior to committing to treatment. Men diagnosed with early-stage prostate cancer face similar choices or dilemmas, and it is reasonable to assume they would also benefit from multidisciplinary consultations or second opinions.

Other factors identified as significant drivers of second opinions include anxiety and the presence of psychiatric conditions such as depression and panic disorders (Burton, 2011). Mellink et al. (2004) report that patients with external motives for seeking SMOs related to a negative appraisal by these patients of different aspects of the care given by the first specialist, including doubts about the advice given; that they had higher anxiety than other patients, and that they hoped more frequently for a different second opinion. Anxious patients often pose unique challenges and are not easily satisfied. In our experience, they typically will seek more tests and opinions, and they find it very difficult to tolerate any measure of ambiguity or uncertainty. Here, too, a more authoritative approach may have greater impact. Besides psychological reasons, a variety of medical reasons have been identified as significant contributors to driving patients towards seeking SMOs. Patients who felt they were treated unfairly or improperly were more likely to ask for another opinion (Townsend, 2008; Hungin, 2009). For patients with non-malignant diseases, these factors were reported to be more commonly related to the need for information and also to perceived difficulties in communication between the patient and his or her physician (Van Dalen, 2001). In a study of healthcare utilization patterns, Sutherland reported that patients referred for second opinions to a Canadian gastroenterology clinic had already consulted two or more general physicians or specialists over the preceding year (Sutherland, 1989). These patients were significantly more likely to rate their own health as "fair to poor," have a chronic duration of symptoms, and be very concerned about their health status. It is possible that patients with a higher level of preoccupation with their health, or with a greater burden of somatic symptoms, are more likely to seek

out consultants. This highlights the importance of good communication between patients and physicians as an important part of allaying patient anxiety.

Unlike those with non-malignant conditions, patients with cancer generally obtain second opinions to seek reassurance and information, rather than to express dissatisfaction with their first consultant (Mellink, 2003; Philip, 2009; Tattersall, 2009). An Australian study reported by Philip and colleagues surveyed patients with advanced cancer and also their consultant oncologists in order to determine the reason for such consultations (Philip et al., 2009). They reported that patients were motivated by what they understood to be the extreme nature of the situation (32%), need for reassurance (13%), and concern with management (13%). Tattersall et al. reported similar results and highlighted the fact that cancer patients need both more information about treatment as well as reassurance (Tattersal et al., 2009).

Patient–physician trust is another important determinant, and indeed, in some cases, loyalty to a physician may lead a patient to hold back and avoid seeking another opinion, even when others would encourage him or her to do so. Finally, not uncommonly, patient referrals can stem, not from patient concerns, but rather from the wishes of a worried family member, particularly if the diagnosis is one of a life-threatening illness such as cancer (Delva, 2011).

MEDICAL SYSTEM FACTORS

In situations such as the need for elective surgeries, insurance companies may request a second opinion to ascertain whether the surgery is needed and whether referral to a tertiary center is appropriate (Martin, 1982). This is particularly true when resources are limited, as studies have suggested that such referrals are cost-efficient (Ruchlin, 1982; Dudley, 2000). Indeed,

access, one’s type of insurance, and cost considerations do affect the frequency with which patients seek out a second opinion (Wagner, 1999).

Another medical system factor that is increasingly being utilized in the era of informatics and technology is the use of automated medical decision-making algorithms. For example, a study reported the use of pharmacist-initiated referrals to efficiently correct sub-optimal asthma management (Bereznicki, 2008). Such algorithms, if found to be efficient and successful, may turn out to be cost-effective as well. Finally, another factor that may prompt a consultant to recommend obtaining another expert opinion is the fear of litigation (Hartz, 1993; Schattner, 2009; Kowey, 2011).

THE CONSULTANT’S ROLE IN ASSISTING PATIENTS WITH DECISION-MAKING

There is etiquette and an art to giving a useful and valuable second opinion. The elements involved vary slightly from those typically encountered in other medical settings, and they have not received sufficient attention in medical education and practice. While there are no clear guidelines regarding the most effective method of approaching second medical opinions, a clear understanding and personalized approach to each consult is ideal.

In the following section, we list five recommendations that we have identified as integral to the process. Following these specific steps and completing the tasks outlined below, will help assure the consultant that the SMO is on target and thus meets the objective for which it was sought. It can be remembered with the mnemonic “PREP-PCP,” or Prepare, Evaluate, Personalize, Provide, Closure, as outlined in Table 82.1.

Table 82.1 PREP-PCP: FIVE RECOMMENDATIONS AND EXAMPLES OF COMMUNICATIONS STYLES TO HELP A CONSULTANT PROVIDING AN SMO

RECOMMENDATION	DETAILS	EXAMPLE
1 PREPARE for visit	Encourage the patient to prepare for the consult and set goals for the visit. Prior to the consult, the physician must review the history, diagnostic results, imaging, and therapy.	“What are the top 5 questions or issues you would like addressed today?”
2 EVALUATE motivation	Evaluate patient and/or physician motivations behind seeking SMO, and their specific questions. Identify all information seekers in the consult, including family and friends.	“What prompted you to seek a SMO?” “What would you like to accomplish in this visit?”
3 PERSONALIZE communication	Provide personalized communication that is tailored to meet the needs of each patient. Avoid statistics, lecturing, and less-relevant information about other subtypes of disease.	“Given the size and location of this tumor, I would recommend this procedure for you.”
4 PROVIDE plan	Important for the patients to feel that they leave the consult with defined plan. Communicate relevant opinion and reaffirm patient understanding.	“To summarize, based on our discussions, the next best step would be for you to do XX.”
5 CLOSURE with primary PHYSICIAN	Close the loop by communicating with referring physician in a timely and effective manner.	“Did I answer your consult question?”

PREPARE (PREPARE FOR THE CONSULTATION)

The first step is to be prepared. Since the second opinion setting is different in the sense that a fair number of diagnostic and treatment variables have already been assessed and communicated to the patient, it is fundamental for the consultant to familiarize him- or herself with the available data. It is necessary to review the available patient history, exam findings, diagnostic results, relevant histopathology and imaging, and treatment.

It is not uncommon for physicians to categorize patients who seek second opinions (even before the visit) as having greater information needs and psychosocial needs, and requiring more energy and time (Phillip, 2010). While it is true that patients seeking SMOs may in fact take more of the physician's time and energy, it is important to realize that this patient population has unmet needs that deserve attention. Second opinions can indeed be a very satisfying experience for both the patient and the consultant. Among patients who seek a second opinion for communication-oriented reasons, almost always the second consultation appears to be more satisfactory for the patient. Some of the variables contributing to this increased satisfaction include a longer consultation, more active listening, answering of patients' specific concerns, and a friendlier attitude on the part of the physician (Tattersall, 2009).

Time is of essence for a busy clinician, so it is important to understand and negotiate the agenda for the consultation at the outset and together with patients, decide how best to apportion time. We suggest asking the patient how much she or he wants to know, giving them opportunities to ask questions, checking their understanding, and providing a summary and written materials if they are available. Often

the consultant does not need to repeat a physical exam or review all the various aspects of the patient's past medical history, thus freeing up more time for dialogue and information exchange. The use of tools such as a "patient question prompt sheet," (Box 82.1) prepared to help guide the patient to clarify his or her own needs and questions and sent to the patient in advance of the appointment, can also considerably shorten the consult visit without compromising its effectiveness (Brown, 2001; Bruera, 2003; Glynne-Jones, 2006).

EVALUATE (EVALUATE THE REASON FOR THE SMO AND ADDRESS IT SPECIFICALLY)

As we described in the preceding section, not all patients who schedule a second opinion are driven by the same motives or do so simply for the stated purpose of confirming the diagnosis or treatment plans. Consultants need to take into account the complex interplay of the patient's motivation, and emotional and information needs, in order to provide an opinion that will satisfy the patient and his family and expedite their coping with the adverse consequences of illness, as outlined in Figure 82.1. A good first question to ask in the patient-physician encounter is "What brings you here today?" or to be very direct and ask, "What prompted you to seek a second opinion?" If the reason remains unclear, or if the consultant suspects there may be additional motives, we would encourage them to explore this up front. Without such insight and clarity, the consultant may not be able to plan an efficient use of his or her time, or fail to address the fear, concerns, or grievance that prompted the appointment. Understanding the goals of the visit early on will greatly help one tailor the

Box 82.1 PATIENT CHECKLIST FOR A SECOND OPINION

Prior to the meeting with the consultant, we suggest you tell us about:

1. Your reason for seeking the second opinion (please circle):

- I am here because I would like you to confirm the opinion of the first oncologist.
- I am here because you have many trials open and I am interested in new treatments.
- I am here because I am not happy with my primary oncologist and would like to switch.
- I am here because you treated my _____.

2. Your worries and concerns (please write):

- I am confused about _____.
- I worry that _____.
- I wonder if there are alternatives to the treatment proposed back home such as _____.

3. Your goals and expectations (please circle):

- I am prepared to do anything to get the best results.
- I need to support my family during treatment.
- I am ambivalent about the choices that I heard from my first oncologist.

4. And finally, please write the top 3 questions you need answered in the visit (please write):

1. _____
2. _____
3. _____

type of therapeutic response needed and the level of information that should be provided, and it will facilitate a more efficient use of the visit (Feldman-Stewart, 2005).

In situations where the consultation was requested by the patient's primary physician for assistance with problem-solving in the face of uncertainty, it is fundamental to communicate directly with the referring physician in a timely manner. Written reports are obviously required for documentation and for billing purposes, and every attempt should be made to send these immediately to the requesting physician, either electronically or via facsimile. We also recommend a personal phone call in order to allow the referring physician to discuss the case and to review the recommendations and plans for management without intermediaries.

If the consultant ascertains that the SMO stems from patient anxiety or ambivalence, the consultant may choose to be especially empathetic in listening to the patient's concerns and providing both information and reassurance. Such patients are more likely to be satisfied by frequent contact with the medical system and may benefit from a follow-up phone call or email by a member of the professional team. In some cases, it becomes clear over time that the concern or anxiety does not abate. Patients with excessive demands for contact and who seem unsatisfied by reasonable amounts of information and support may need to be referred to mental health professionals for more detailed evaluations and treatment. On the other hand, the patient may strictly be looking for more detailed information available only to an expert, or a greater understanding of the treatment options (Oskay-Ozelik, 2007).

Patient preferences about second opinions in hematology-oncology patients were carefully analyzed by Goldman through in-depth interviews (Goldman, 2009). She reported that patients typically were looking for a treatment plan specifically tailored to their case scenario, and that they wanted the consultant to apply expertise to their individual situation. In this study, patients universally felt that personalized advice indicated the highest level of expertise as well as the greatest respect. Additionally, patients reacted negatively when the consultant appeared dismissive, was not personable, or appeared not to have reviewed the records prior to the consultation or ignored factors that the patient felt were important or unique to the patient's particular case (Goldman, 2009). Other studies have also confirmed that patients were highly disappointed if they only received statistics or generalized information about the possible course of the disease and the sub-types of disease, and treatment options not pertaining to them (Kagan, 2005).

It is important to ascertain early on in the course of the consultation what drove the patient to obtain the second opinion. As discussed previously, reasons are varied and motivations complex. Common concerns include frustration or discontent with the manner or approach of the physician who gave the first opinion or has been regularly treating the patient for a chronic condition; concerns about insufficient information or discussion; feeling rushed; or feeling excluded from participating in making important health-related decisions. Such patients may require a longer consultation, more active listening, a more skilled communicative approach, or a different style of communication in order to be satisfied. If the motive

of the second opinion consultation is indeed to find validation for such needs, then the consultant may or may not be able to satisfy such needs, depending on circumstances and the effort expended. If the consultant can diagnose a mismatch in communicative needs and styles between the primary physician and the patient and accomplish the dual goal of reassuring the patient and providing helpful tips to the referring colleague, then the SMO consultation can be considered useful and a valuable investment of time and resources.

PERSONALIZE (PERSONALIZE COMMUNICATION AND RECOMMENDATIONS)

Patients' expectations of a consultant may be quite different from those of the physician they see for longitudinal care. Studies have suggested that patients who received explicit emotional support from their SMO physicians were grateful and satisfied but did not consider it a requirement for a satisfactory consult (Brown, 1997; Salmon, 2005; Goldman, 2009). Patients greatly appreciated when their physicians were involved with them as individuals and were pleased when the discussion touched on how the disease or treatment would affect the totality of their life. This indicates that an empathetic relationship does not necessarily require overtly emotional talk. Indeed, earning trust through demonstration of expertise and detailed discussion of the disease and treatment is more important than a display of emotions.

While there are various opinions about the preferred style of the physician's communication, generally patients do not appreciate "lectures" (Epstein, 2007). Patients are not looking for learned monologues from their consultants, but for a timely application of complex knowledge to their individual situation (Kidane, 2011). Physicians should thus use their expertise to deliver a personalized recommendation that takes into consideration the patient's individual values, resources, preferences, and that is likely to offer the best possible outcome (Veazie, 2007).

Good communication between patients and physicians is a requisite for informed decision-making and quality care. It has been linked to improved adherence to treatment, decreased litigation, better coping, and increased satisfaction (Epstein, 2007). It is also important to ensure that the set-up for the patient encounter is conducive to an open line of communication, not only with the patient, but also with the family members. Many a time the consult is driven by a family member's wishes, and it is crucial to identify the actual seekers of information and to address their concerns. It is also important to identify the underlying motivations of the patient or family behind seeking the SMO and to clearly define the goals for the consult. This would enable the consultant to tailor the conversation in a more directed manner and facilitate effective discussions.

PROVIDE PLAN (PROVIDE THE FINAL OPINION AND PLAN)

It is important to bear in mind that the patient and family made the effort to attend the consultation in order to obtain an expert opinion and treatment plan. Failure to formulate

a plan can be profoundly disappointing and does a disservice to the patient and possibly to a referring colleague as well. Although we certainly favor a deliberative model for consultations, and following communication protocols that place the patient's agenda front and center, at the end of the day it is important to remember that in order to meet the patient's needs, the consultant needs to provide guidance and a clear plan of action. Even if the facts of the case leave room for uncertainty, or if two diagnostic or treatment options appear equally effective, it is expected of the consultant to express a preference and to provide a plan of action. In some cases, the consultant can do so within the first ten minutes of the visit and then spend the rest of the time discussing alternatives or answering other questions for the patient. In other cases, it may take most of the hour to figure out just what is best, given the constellation of symptoms, resources, and preferences. In either case, however, the consultant needs to give his or her opinion and confirm that the patient has in fact understood the recommendation. Print materials or websites for the public can provide valuable tools to facilitate understanding. At times a referral to a local resource room or support group can also help the patient understand his disease and treatment and connect with others facing similar challenges.

So how is a consultant to proceed in the face of diagnostic uncertainty or if there is no standard therapy? Sometimes treatment options vary considerably, as do the risks and possible benefits. Imagine a patient with refractory leukemia referred to an academic center for a second opinion. She is presented with two reasonable treatment options: one involves a bone marrow transplant, which offers a chance of a prolonged remission but carries with it a risk of death from the procedure itself, or other potentially debilitating side-effects that can be long-lasting; the other offers a palliative treatment that is guaranteed to be well tolerated but can offer only moderate relief of symptoms and no meaningful extension of life. Guiding a patient to make such decisions requires not only considerable technical expertise, but a patient, respectful, and collaborative approach. It may also require the assistance of other members of a multidisciplinary team, including a nurse, a social worker, and perhaps even a psychologist or psychiatrist to provide support and to help the patient and her family sort through the diverse options and to consider all alternatives in the context of her personal values and preferences.

Finally, if the consultant ascertains that psychological factors are a major driving force for the patient's need for a second opinion, it may be helpful to consider a joint consultation with both a psychiatrist and the medical consultant (Hoedeman, 2010). For most patients, however, a personalized second opinion delivered with respect and in a clear fashion will suffice. Referrals to colleagues with expertise in mental health will address unmet emotional needs that may delay or impede the patient in opting for a particular course of action. As with any other problem in medicine, the consultant needs a strategy to ensure the patient's needs are met in the best way possible.

Whatever the final recommendation might be, providing the next best course of action to the patient is important. It

might be helpful to summarize the conversation and highlight the key points. It is important for the patients to feel that they have come out of the consult with a defined plan.

CLOSURE WITH PHYSICIAN (CLOSE THE LOOP BY COMMUNICATING WITH REFERRING PHYSICIAN)

If the consultation was requested by a colleague or a generalist within the same practice or hospital, it is preferable to communicate directly via phone or email on the same day of the consultation. After all, when the patient leaves the consultant, one assumes that a recommendation has been made, or at least that there is a plan for a follow-up. Even if all the details of the case have not been resolved, or if there remains some uncertainty about the treatment or follow-up care, it is useful to reach out to the referring physician and to keep him or her duly informed. There are certain situations that make this particular exchange slightly more difficult or challenging for the consultant, and we will address these next, providing advice derived from our experience rather than scientific evidence.

Sometimes the patient who seeks a second expert opinion is also "shopping for" another physician. If the patient prefers the style, the location, or the treatment plan offered by the consultant, he may request that this physician take over his care. This may pose a slight conflict for the consultant, especially if the referring physician or primary specialist is a respected colleague. Some consultants may actually choose to turn down such requests if the actual treatment plan can be offered elsewhere, to enhance the continuity of care, but most will accede to the patient's wishes. How to handle these situations and still preserve the trust of the referring physician is a challenge that requires considerable tact and diplomacy in communication.

Finally, a special category of patients seeking a second opinion is those who actually have been mismanaged. Some may have experienced a diagnostic delay, an incorrect diagnosis, a treatment error, or an unexpected complication of treatment. In some cases, patients may be fully aware of the medical details and prepared to discuss these with the consultant, while others may have incomplete information. The consultant may struggle with how much to tell the patient or perhaps with the dilemma of whether or not to communicate directly with the physician or physicians responsible for the patient's care. There are simply no guidelines or steadfast rules to guide consultants, who must use their own judgement in both reporting and documenting the extent of the problem. In these situations, it is more common for the consultant to offer to assume the care of the patient or to make a suitable referral for longitudinal care.

VALUE AND FUTURE OF SECOND MEDICAL OPINIONS

While SMOs were initially seen as a checkpoint to avoid over-expenditures in the managed-care setting by avoiding unnecessary procedures, their independent financial burden

on the healthcare set-up cannot be ignored. Studies have suggested that while many ailments can be treated satisfactorily at primary clinics, SMOs tend to drain the resources of a healthcare system (Mahmoud, 2010). On the other hand, SMOs have their value in appropriate cases and can actually result in improved patient care at minimal cost to third-party payers (Benson, 2001).

Questions have also been raised about the independence of a second opinion, since most physicians are wary of second-guessing their colleagues and tend to side with the initial plan more frequently. Ideally, a checks and balances approach is needed. Some authors have raised a concern about the need for SMOs in the era of evidence-based medicine (Moumjid, 2007). If we establish more guidelines for treatment of diseases, and these are posted in the public domain where they can be easily retrieved by the public, will we see a drop-off in requests for SMOs? Or will the increasing trend towards personalized medicine continue to drive requests for personalized expert recommendations?

We imagine that public demand is not likely to fall, even if more and better-quality information becomes available. Perhaps the new research frontier for scientists and health services researchers is to figure out how best to help patients gather as much information as possible in advance of the planned consultation and to prioritize their questions and needs. Ideally, web- or phone-based services from patient-advocacy groups could help match the patients to the consultants who are best suited to meet their needs. Such a match-making service could improve the satisfaction of patients and the efficiency of consultants. Other possible interventions include the use of buddy or peer support programs, and similar interventions using a psycho-educational approach that helps patients find their own sources of strength and support. Preparing experts to provide a consultation using specific steps, and paying attention to process and task, are also key to promoting better understanding and satisfaction for those seeking a second opinion.

SUMMARY

Good communication between patients and physicians is a requisite for informed decision-making and quality care. It has been linked to improved adherence to treatment, decreased litigation, better patient coping, and increased satisfaction. Patients seeking a second opinion should be encouraged to communicate their agendas and expectations to physicians clearly in the course of the consultation. For some, having a list of questions ahead of time will help them clarify and prioritize concerns. Physicians should also in turn actively try to understand the underlying reason for the visit and address the prepared questions in an orderly and methodical fashion. It is recommended that physicians understand and negotiate the agenda for the consultation at the outset and, with the patients, decide how best to apportion time.

The cost and time-constraints associated with a second opinion cannot be ignored, and a structured approach to SMOs is essential. Access to a multi-specialty clinic where patients are able to obtain several opinions under one umbrella

organization are more useful or lead to greater satisfaction. Use of efficient tools such as a “patient question prompt sheet” can considerably shorten the consult visit without compromising its effectiveness. Training physicians in communication skills may lead to a more personalized delivery of information and allow consultants who give first, second, or third opinions to tailor their presentation to address the specific needs of the individual.

CLINICAL PEARLS

- There is etiquette and an art to giving a useful and valuable second opinion.
- A longer consultation, more active listening, answering of patient-specific concerns, and a friendlier attitude by the physician increases patient satisfaction (Tattersal, 2009).
- Negotiate the agenda for the consultation at the outset and, together with patients, decide how best to apportion time.
- Understanding the goals of the visit early on will help tailor the type of therapeutic response needed and determine the level of information to be provided (Feldman-Stewart, 2005).
- Patients universally felt that personalized advice indicated the highest level of expertise as well as the greatest respect.
- Even if the facts of the case leave room for uncertainty, or if two diagnostic or treatment options appear equally effective, the consultant is expected to express a preference and to provide a plan of action.

THE CONTINUUM OF CHRONIC CARE: NURSING HOMES, ASSISTED LIVING, HOME CARE

Hong-Phuc T. Tran and David B. Reuben

DEFINITIONS OF CHRONIC CARE

Chronic care relates to a variety of populations and health states, and the term can be used in different ways. First, chronic care can refer to the (bio)medical care of chronic diseases. Especially in the elderly population, multiple chronic illnesses are common; 43% of Medicare beneficiaries have three or more conditions (Institute of Medicine Committee on the Future of Health Care Workforce for Older Americans 2008), and 23% have more than five. (These numbers refer only to explicitly diagnosed conditions; and particularly in the realm of mental disorders, undiagnosed but clinically important conditions are common.) Moreover, the percentage of persons with multiple chronic conditions rises with increasing age (Wolff, Starfield, et al., 2002).

Second, “chronic care” can refer to a broader set of services, including self-management, aid rendered by family and friends, and community-based supportive services of a non-medical nature. (Wagner, 1998) has described The “Chronic Care Model,” is an approach to improving health-care outcomes by linking medical care to community-based services through four components: delivery system design, self-management support, decision support, and clinical information systems. Patients become more informed and activated, and practice teams are more prepared to be proactive, with the intended result of improved clinical and functional outcomes (Wagner, 1998). Although implementing this model may be difficult in smaller practices, as providers increasingly join larger groups, this approach may be more feasible.

Third, “chronic care” may include community-based services and residential structures to compensate for functional impairments. This is commonly referred to as “long-term care.” The Centers for Medicare and Medicaid Services (CMS) defines long-term care as “a variety of services that help people with their medical and non-medical needs over a period of time. Long-term care can be provided at home, in the community, or in various types of facilities, including nursing homes and assisted living facilities. Most long-term care is custodial care” (US Government Medicare, August 12, 2011).

In this chapter, we discuss chronic care as it is most broadly defined, comprising both institutional and community-based

care, in both its medical and non-medical aspects. We will refer to chronic care using Medicare terminology (US Government Medicare, March 17, 2013).

SITES WHERE CHRONIC CARE IS PROVIDED

Community-based long-term care includes care provided at medical offices, at community-based organizations (e.g., adult day care centers), in private homes, in independent living facilities, in assisted living facilities, and in the parts of continuing-care retirement communities that do not offer continuous skilled nursing care. Assisted living facilities may be large (housing over 100 residents) or very small (with just a handful of residents); small assisted living facilities sometimes are referred to as “board-and-care homes.” Some assisted living facilities have locked dementia units for patients with dementia with behavioral issues such as wandering. Assisted living facilities differ from institutional long-term care facilities in terms of licensure and regulation; they are regulated only at the state level. Institutional long-term care is usually provided in nursing homes, also known as “nursing facilities” (NFs) or “skilled nursing facilities” (SNFs—commonly pronounced “sniffs”).

NFs are tightly regulated both by states and by the federal government. NFs, as distinct from SNFs, provide basic nursing care (e.g., administration of daily medications; provision of special diets) and assistance with activities of daily living. This type of care, which does not require the continual involvement of licensed nurses (registered nurses or licensed practical nurses), is referred to as “custodial care.”

SNFs provide 24-hour coverage by licensed nurses and daily coverage by registered nurses, and thus are able to care for sicker patients and those requiring invasive interventions such as intravenous medications, rehabilitation, and wound care. SNFs are a major source of post-acute care services, caring for patients for up to 100 days following an acute hospitalization, when patients need daily licensed nursing care but no longer require the technological resources and daily physician involvement available in the hospital.

The other major institutional settings for post-acute care are LTACHs (long-term acute care hospitals) and IRFs

Table 83.1 TYPES OF CARE, THEIR DEFINITIONS AND EXPLANATIONS

TERM	DEFINITION	EXPLANATION
Long-Term Care	Medical and non-medical care provided to people with chronic conditions or disability.	Long-term care can be provided in the home, community, assisted living or nursing homes. LTC includes assistance with basic activities of daily living, such as dressing and bathing.
Custodial Care	A term used to describe supportive services for activities of daily living, such as bathing, dressing, grooming, toileting.	Custodial care is a sub-category of LTC. Medicare does not pay for this type of care, as it is considered “non-skilled” care.

Adapted from Reuben, D. B., Herr, K. A., et al. (Eds.) (2011). *Geriatrics at your fingertips 2011*. New York: American Geriatrics Society.

(independent rehabilitation facilities). LTACHs often care for ventilator-dependent patients who require a greater intensity of nursing care and medical services than are usually available in a SNF but do not need the full spectrum of services provided by a general hospital. IRFs offer intensive physical therapy, occupational therapy, and speech therapy, as well as consulting specialists in physical medicine, neurology, orthopedics, and psychiatry, and tend to focus on patients with complex problems and a high premorbid baseline, such as young stroke patients and victims of multiple trauma. For psychiatric patients with extended stays in state mental hospitals (e.g., spanning decades), state mental hospitals can be viewed as part of the long-term care continuum (Fisher, Barreira, et al., 2001).

In general, the appropriateness of a patient for a particular residential setting depends upon the person’s functional status, cognition (including whether or not there are behavioral problems), and mobility.

FUNCTIONAL STATUS

Functional status is usually considered at two levels: activities of daily living (ADLs) and instrumental activities of daily living (IADLs). ADLs include:

- Bathing
- Dressing
- Toileting
- Transferring (e.g., from a bed to a chair)
- Maintaining continence
- Feeding

IADLs include:

- Using the telephone
- Shopping
- Preparing meals
- Housekeeping
- Doing laundry
- Using public transportation or driving

- Taking medication
- Handling personal finances

ADL and IADL performance is characterized as *independent* (done with no assistance) or *not independent* (requiring assistance). The amount of assistance needed and the frequency and timing of the need for assistance are major considerations in selecting an appropriate site. Related to ADL and IADL performance is the patient’s awareness of ADL or IADL deficits and their willingness to accept assistance when it is needed. This issue is discussed in detail in the chapter on competence.

Approximately 25% of community-dwelling older persons have at least one IADL or ADL impairment (Hung, Ross, et al., 2011). Community-based agencies can provide some services (e.g., Meals-on-Wheels, homemaker services, transportation) to compensate for IADL impairments for older and disabled persons who want to stay in their homes. Nonprofit and government agencies frequently price these services according to patients’ ability to pay; similar services may be offered by for-profit providers at market prices. Effective use of supportive services usually requires case-management oversight either by a social worker or by a nurse, or equivalent oversight by an involved and informed family member or friend. Professional case-management services are covered to variable extents by Medicaid, Medicare managed-care plans, and some types of private long-term care insurance, but they are not covered by fee-for-service Medicare. Those without coverage for case management, without the means to buy it privately, or without sufficiently informed and involved family members are at risk for poorly planned and uncoordinated care.

Adult daycare centers provide a social environment for persons with long-term care needs and also relief for family caregivers during the day (Kane, 2011). Patients who go to adult daycare centers may have multiple, chronic medical conditions but are usually clinically stable. Some adult daycare centers may provide basic medical services, such as medication administration and blood pressure and blood glucose monitoring. Adult daycare centers may take patients with psychiatric conditions, but typically the psychiatric conditions will need to be already well controlled. Some adult daycare centers specialize in caring for patients with dementia (dementia daycare centers).

The population of patients cared for in nursing homes includes some who could successfully live in the

Table 83.2 FACILITY OPTIONS FOR ELDERLY, FUNCTIONALLY IMPAIRED PATIENTS WITH PSYCHIATRIC ILLNESS

TYPE OF PATIENT	APPROPRIATE SETTINGS	SERVICES	PAYER
IADL Impaired/ No Behavioral Symptoms	<ul style="list-style-type: none"> Assisted living facility Foster care 	<ul style="list-style-type: none"> IADL care Medication administration 	Usually out-of-pocket* though some accept Medicaid
IADL Impaired/ Mild to Moderate Behavioral Symptoms	<ul style="list-style-type: none"> Assisted living facilities with dementia units Some foster care facilities 	<ul style="list-style-type: none"> IADL care Medication administration Non-pharmacological approaches to symptoms 	Usually out-of-pocket* though some accept Medicaid
ADL Impaired without or with Mild Behavioral Disturbances	<ul style="list-style-type: none"> Nursing home 	<ul style="list-style-type: none"> ADL and IADL care 	Out-of-pocket* or Medicaid

community—at home or in an assisted living or independent living facility—if they had sufficiently intense supportive services, skilled nursing involvement, and physician participation. Some communities offer a Program for All-inclusive Care for the Elderly (PACE), which is designed to help frail elders avoid institutionalization. PACE programs provide supportive and skilled nursing services comparable to those provided in nursing homes, but persons enrolled in these programs remain at home (Eng, Pedulla, et al., 1997). Financing of PACE programs is capitated—i.e., with a fixed sum allotted each year for the care of each patient, based on that patient's expected healthcare utilization. Funding of PACE primarily comes from both Medicare and Medicaid programs; individuals with only Medicare coverage usually cannot participate because of the high copayment costs. Some PACE programs accept community-dwelling patients with both functional impairments and mental illness or behavioral problems; an interdisciplinary team consisting of healthcare professionals assesses a patient's needs and devise a care plan to best help the patient (Substance Abuse and Mental Health Services Administration, March 17, 2013).

The more IADL impairments a person has, the less likely it is that the person can remain at home. When a person is unable to live at home, there is a spectrum of types of facilities that provide housing and other services, which vary in size and amount of services (Hung, Ross, et al., 2011). Independent living facilities are similar to hotels in that they provide rooms, some or all meals, and light housekeeping, but no personal services. Assisted living facilities (ALFs) typically provide assistance with IADLs and care for persons who are less disabled than those residing in nursing homes. The services provided by ALFs vary considerably, and many provide additional services (e.g., personal care) or tiers of service for additional cost. Some have dementia units. These facilities also vary greatly in their amenities, luxury, and cost, with high-end facilities charging monthly fees of \$8000 or more for their base services. Another living-situation option is adult foster care, a small group-living setting in which ADL

and/or IADL support is provided by non-professionals. (See Table 83.2).

Persons with chronic ADL dependencies (other than isolated dependency in bathing) need personal assistance seven days a week, several times a day. Assistance can be provided in the home by family or friends or by paid assistants (direct care providers), or at ALFs or nursing homes. These services are not covered by Medicare but may be covered by Medicaid to some extent for eligible persons. Patients who are not safe without continuous supervision may also require institutional care even if they do not have multiple ADL dependencies. This category includes patients with dementia and significantly impaired judgement.

IMPAIRED COGNITION, MENTAL HEALTH, AND BEHAVIORAL PROBLEMS

Impaired cognition and mental health and behavioral problems are other major determinants of where a person lives. Mental and behavioral problems can occur in the absence of cognitive impairment, and cognitive impairment can occur without behavioral problems, particularly in its early stages. IADLs usually are impaired much earlier in the course of dementia than are ADLs. However, patients with an awareness of their deficit and willingness to accept help can remain in the community much longer than those without those attributes. Cognitive deficits and mental health and behavioral problems become important when they impair function, and when they exceed the capacity of family or caregivers to provide care in the home setting.

IMMOBILITY

Finally, immobility often precipitates a change in where a person can live. Disabled persons who need to be lifted or require more than one person's assistance to move can

rarely be accommodated in their own homes. The additional help of multiple staff that are available at some ALFs or at nursing homes makes these better choices for the severely mobility-impaired.

As noted, there are wide variations in what kinds of patients can be accommodated at various locations. Through case-management services and as-needed in-home care, which is paid for almost entirely out-of-pocket, many people with serious chronic diseases or functional limitations are able to remain at home. Some ALFs are able to provide help with ADLs at an additional cost, or have dementia units that permit those with even severe disease to avoid nursing home placement. In addition, continuing-care retirement communities (also called “life care communities”) offer a range of services and living options, from independent living through nursing home care, on one campus. In this manner, patients can transition to more or less assistance as needed, and couples can live on the same campus, albeit in different facilities. These are typically very expensive but provide the peace of mind that all services can and will be provided for the remainder of the person’s life, at one site.

Ultimately, the decision of where a patient with chronic illness resides depends on the individual combination of medical disease burden, functional impairment, personal preferences, and resources. Decision-making must balance the ethical principle of patient autonomy with patient safety. However, frequently financial considerations are important in the decision-making process. The medical components of long-term care (e.g., home health physical therapy, medications, and some disease-management programs) are generally covered through insurance (e.g., Medicare for older or disabled persons) but the housing, meals, and personal assistance (including custodial care at nursing homes) are not covered unless people have purchased long-term care insurance or

qualify for Medicaid, and must be paid for out-of-pocket. In contrast, post-acute medical care at SNFs or through home health agencies, which can be provided either at home or in ALFs, is covered at least partially by insurance (see below). Most private long-term-care (LTC) insurance covers community-based services, while Medicaid coverage is mainly for nursing homes and often does not cover community-based services. Those who do not meet the income and asset limits for Medicaid or do not have private means or private LTC insurance must “spend down” both financially and personally (i.e., the patient runs out of money and caregivers run out of energy and patience), and the patient must be placed in a nursing home with Medicaid covering the costs.

Another important issue in chronic care is the coordination of transitions between sites. As noted above, care can be provided in a variety of sites. Based on the status of their health conditions and how well their current environment is able to cope with acute and chronic changes, people with chronic conditions frequently move from one site to another. Figure 83.1 describes the transitions between sites based on the acuity of conditions, including flares and decompensation of stable chronic diseases.

Persons with chronic conditions who live in the community or at nursing homes may develop acute illnesses or flares of their chronic conditions and require hospitalization. Following hospitalization, they may return home, to other residential facilities in the community, or to nursing homes for post-acute or chronic care. In addition, when living in the community, they may receive specific disease- or case-management. Each of these transitions is an opportunity for discontinuity of care and for mistakes to occur. For example, when a person residing in an assisted living facility is hospitalized, the person’s specific medications may not be on the hospital formulary, and substitutions may be made.

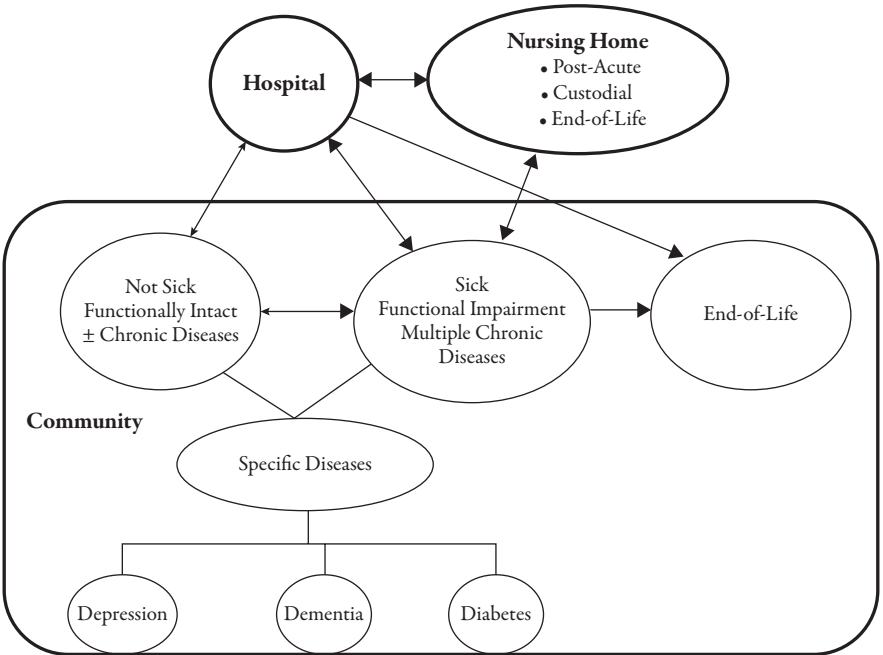

Figure 83.1 Transitions between sites of care based on acuity of illness, chronic conditions, and functional status.

At the time of discharge, the person may be discharged with the substituted medications, and the patient may mistakenly take both. Similarly, appointments that were scheduled for the time during the hospitalization may be missed and not rescheduled. Primary care physicians and other healthcare providers may not be notified of the hospitalization or not be sent a timely discharge summary. As larger healthcare systems coalesce and begin to assume a greater proportion of care under structures such as Accountable Care Organizations, such tracking and communication will become easier. In addition, some electronic health records can span across systems and perform functions such as notifying all providers on a patient's team that he or she has been seen in the emergency department or hospitalized.

MEDICAL AND PSYCHIATRIC CARE IN LONG-TERM-CARE SETTINGS

PROVIDER INVOLVEMENT

The efforts and experiences of multiple providers are necessary to provide coordinated, efficient, and safe care to patients who live in various LTC settings. These providers include generalist physicians (family practitioners and general internists), SNF physicians, psychiatrists with special interests in the problems encountered in LTC—including medical psychiatrists, geriatric psychiatrists, neuropsychiatrists, and psychologists.

Generalist physicians practice in various settings, including single-specialty medical offices, multi-specialty clinics, and hospital-based practices. Although some may visit and provide care for patients in their independent or ALFs, typically patients living at these facilities travel to the physicians' offices for their care. However, there are exceptions when a facility is large enough to have either a full-time or a part-time physician who follows patients on-site. Generalist physicians differ in their willingness to follow patients into the nursing home. The Medicare requirements (monthly visits for the first 90 days, and visits every 60 days thereafter) and the inconvenience of traveling to a nursing home to see just a few patients often cause physicians to decide to stop following their patients once they become long-stay nursing home residents. Patients whose primary care physicians do not practice in SNFs can be followed by the medical director of the facility or by other physicians who go to that nursing home. A new and increasing trend is for some physicians to focus their practices on providing care in skilled nursing facilities; these physicians are called "SNFists." Another trend is for hospitalists to follow patients after discharge from the hospital into post-acute care NFs; these hospitalists are called "extensivists" (Reuben, 2011).

When transferring a patient from a hospital to a SNF, three components are necessary (Reuben, Herr, et al., 2011):

- A discharge summary that includes the patient's baseline functional status, important tests for which results are pending, and needed next steps, including physician follow-up appointments;
- Verbal physician-to-physician sign-out to ensure that any questions that the receiving physician has can be answered.

Following these steps ensures a safe "handoff" of the patient, and helps apprise the receiving physician of any important discussions that may have previously occurred among the patient, patient's family, and primary provider. Some of these discussions may have focused on the patient's advance directives and goals of care, which will influence the nursing home's management of the patient. Several programs to ensure good care transitions to nursing homes and home have been developed and evaluated (Naylor, Brooten, et al., 1999; Coleman, Parry, et al., 2006). The Care Transitions Program includes a personal health record, a discharge preparation checklist, and transition coaches who work with patients/caregivers prior to and after the transition to SNF or home settings (Naylor, Brooten, et al., 1999). In the transitional care model, a transitional care nurse bridges hospital and post-discharge care by providing continuity of care in both settings (Centers for Disease Control, 2013). Because best practices for communication at the time of transition from the hospital are not always followed, a good rule is for the psychiatrist consulting on a patient recently admitted to a SNF to review the handoff process and see if there were errors or omissions. On the hospital side, the inpatient consulting psychiatrist can personally oversee the handoff and make sure that the psychiatric aspects are handled well.

Approximately two-thirds of patients in SNFs have mental disorder diagnoses (Centers for Disease Control, 2013) such as dementia (with or without behavioral disturbances), anxiety disorders, various forms of depression, and sleep disorders. These diagnoses often are not made or not recorded in the hospital prior to discharge to a SNF—even when there are several psychotropic drugs on the patient's discharge medication list. Another role for the consulting psychiatrist in improving care transitions is ensuring that psychiatric diagnoses are recorded early in the SNF stay; the psychiatrist can act either on the hospital or the SNF side of the care transition.

PAYMENT

In the United States, at least 70% of people over age 65 will at some point receive care in a skilled nursing home; typically, post-acute care or rehabilitation following hospitalization for acute medical illness, surgery, or trauma (Department of Veterans Affairs, August 2011). In contrast to acute hospital services, a significant proportion of fees for nursing home services are paid out-of-pocket by patients and their families. In addition to such private payment, there are five main sources of payment for nursing home services: fee-for-service Medicare, Medicaid, managed-care plans combining Medicare with other payment sources, private LTC insurance, and private health insurance.

- An interfacility transfer form including discharge medications, discontinuation dates for short-term medications, and any dosage changes in all medications;

Medicare is a federal health insurance program for people age 65 and older and for those under age 65 receiving Social Security disability benefits or with end-stage renal disease (ESRD) on hemodialysis. It is administered by the Centers for Medicare and Medicaid Services (CMS). Qualification is based on age or disability and not on income or assets. Medicare is divided into parts that cover different types of medical services. Medicare Part A covers institutional care in hospitals, SNFs, LTACHs, and IRFs, as well as home nursing care (but not home ADL support) and hospice. Medicare Part B covers professional fees of physicians; physical, occupational and speech therapists; clinical social workers providing mental health services; psychologists; nurse practitioners and physicians' assistants; laboratory tests; outpatient diagnostic procedures; and durable medical equipment. Medicare Part D covers certain prescription medications (Centers for Medicare & Medicaid Services, August 2011). Each part of Medicare has complex rules determining the scope and duration of coverage. Of great importance for SNF care, Medicare covers in full only the first 20 days of a SNF stay; after that, the patient is responsible for a 20% copayment. Of note, many patients and families often have the erroneous belief that Medicare covers SNF services in the same way that it covers hospital care; further details about the "three midnights" requirement, copayments, and limitations of SNF services are in discussed in subsequent paragraphs below (See Table 83.3).

In the Balanced Budget Act of 1997, Congress mandated that most of the services (including rehabilitation, medications, and laboratory tests) provided to patients in a Medicare-covered stay at a SNF be covered in a bundled prospective payment system (PPS). The PPS uses the Minimum Data Set (MDS), which is described later in this chapter, to calculate a Resource Utilization Group (RUG) for each Medicare beneficiary. Each RUG has a dollar amount associated with it that is the daily rate paid to a SNF for a beneficiary. SNFs bill the Medicare Administrative Contractor (MAC) for the consolidated services. During Medicare Part A-covered stays, medical services (including rehabilitation therapy, medications, and laboratory tests) as well as room-and-board are covered. If Medicare Part A benefits have been exhausted, then medical services are still covered by Medicare Part B, but room-and-board is not. There are several services that are excluded from bundled billing in the skilled nursing home. For patients covered under Medicare Part A, services excluded from bundled payment (i.e., separately payable) include the following:

- Physician's professional services
- Some dialysis-related services, including covered ambulance transportation services to dialysis centers
- Some ambulance services, including ambulance transfer from hospital to SNF, transport from SNF to home, transfers from SNF to specified types of emergency or intensive outpatient hospital services, transfer to dialysis centers for dialysis services
- Erythropoietin for some dialysis patients

- Some chemotherapy drugs
- Some chemotherapy administration services
- Radioisotope services
- Customized prosthetic devices

For patients who are not covered under a Medicare Part A stay, only therapy services are subject to consolidated billing (Centers for Medicare & Medicaid Services, August 2011). While some chemotherapy drugs are excluded from bundled payment, expensive pain medications, psychotropic drugs, and certain expensive antibiotics are not. High-cost medications can result in a net loss of revenue for SNFs who care for patients with multiple comorbidities.

To qualify for Part A Medicare coverage for a nursing home stay, patients must meet the following criteria:

1. Patient was hospitalized (i.e., admitted to the hospital, not merely held for observation) for at least three consecutive midnights in the 30 days preceding the admission to the nursing home;
2. Nursing home must be a certified skilled nursing facility (SNF);
3. A physician must certify that patient is medically benefiting from *daily* skilled care;
4. The reason for admission to SNF is a condition that was treated during the hospital stay (Centers for Medicare & Medicaid Services, August 2011).

Of note, a patient may have multiple comorbidities, such as deconditioning, gait disorder, and muscular weakness, which would qualify for SNF stay although these comorbidities might not be the primary diagnosis during the hospital stay; CMS does not deny Medicare reimbursements to the SNF in these situations.

There are several limitations to Medicare coverage. Although Medicare allows for a maximum of 100 days of nursing home benefit each year, only about 18% of patients receiving Medicare will actually use all 100 days in that year (Centers for Medicare & Medicaid Services, August 2011). The Medicare requirement that the patient is medically benefiting (i.e., demonstrates continued improvement and would gain from further treatment) usually limits the nursing home coverage to a period of 10–20 days for rehabilitation of most medical conditions (Centers for Medicare & Medicaid Services, August 2011). However, there are exceptions (e.g., stroke rehabilitation). In addition, the consulting psychiatrist can help by indicating improvements in the patient's mental health conditions that are the result of skilled care delivered by the facility. If the patient has exhausted Medicare coverage, either because of lack of benefit or because of reaching the maximum days of coverage, patients will typically switch to Medicaid or private pay. As mentioned above, Medicare does not cover the costs for custodial care in assisted living, board-and-care, or NFs. Although home health services for

valid medical indications are covered by Medicare Part A for limited time periods, caregiver assistance in the home is not (Centers for Medicare & Medicaid Services, August 2011).

Medicaid is state-level government health insurance for patients with low income and limited assets. Although each state manages its own Medicaid system, most of the funds for Medicaid programs come from the federal government. As mentioned above, in order to qualify for Medicaid, patients must meet certain financial criteria, requiring them to “spend down” their assets and commit their most of their Social Security income to their LTC. However, laws intended to prevent impoverishment of non-disabled spouses may allow families to retain assets and income while still having Medicaid pay for the patient’s LTC (Centers for Medicare & Medicaid Services, August 2011). Medicaid provides coverage for nursing home care in either a SNF or a NF; however, not all facilities are Medicaid-certified, and not all beds in a SNF are necessarily Medicaid-certified. In many states, Medicaid also provides coverage for custodial care ALFs. There is no limit on the period of time that Medicaid will pay for necessary custodial care in certified settings. Medications are also covered, but drug formularies are restricted, and prior authorizations may be required for medications commonly prescribed by psychiatrists, including second-generation antipsychotic drugs and non-generic antidepressants. In many states, Medicaid also provides some coverage for in-home assistance for patients needing custodial care. However, this coverage is usually limited to 20 hours per week or less. Some states permit relatives to receive funds for providing this care, whereas other states preclude relatives from receiving funds for caregiving (Centers for Medicare & Medicaid Services, August 2011).

Medicare and Medicaid can help offset a large percentage of the cost of LTC, but a significant proportion (about 30%) (Centers for Medicare & Medicaid Services, August 2011) of the overall costs of LTC are paid out-of-pocket (private pay), which presents a burdensome challenge for many patients and their families.

KEY PROBLEMS IN LONG-TERM CARE

MEDICAL PROBLEMS

Functional Impairment and Immobility

Functional impairment and the need for assistance are common reasons for nursing home placement. Virtually all (97%) nursing home residents require help in at least one ADL (Centers for Disease Control & Prevention, August 28, 2011). Immobility is a major problem among nursing home residents. Only 21% of nursing home residents are able to transfer independently, and 23% are totally dependent in this activity. Only 16% receive no help in walking. Assistive devices (e.g., canes and walkers) are helpful, but their value is limited for many patients in nursing homes. Canes are inappropriate for those with moderate or severe balance disorders or who need to bear substantial weight on the

assistive device. In general, front-wheeled walkers are safest and are the most commonly used assistive device in nursing homes for frail elderly patients. Immobility, in turn, predisposes to incontinence (see below) and pressure ulcers as well as other complications of deconditioning.

Overall, 12% of nursing home residents have pressure ulcers, and there is an inverse relationship with age, perhaps because younger nursing home residents often have more severe medical conditions such as spinal cord injury (Centers for Disease Control & Prevention, August 28, 2011). Mental status, including depression and delirium, have been identified as risk factors for development of pressure ulcers in some studies (Coleman, Gorecki, et al., 2013), but it is unknown whether treating these conditions reduces the ulcer risk. Moreover, whether pressure sores are preventable remains a controversial issue (Thomas, 2006).

Incontinence

The majority of nursing home residents are incontinent: 16% bladder only, 5% bowel only, and 43% bowel and bladder (dual incontinence) (Centers for Disease Control & Prevention, August 2011). Almost all nursing home residents with dual incontinence have impaired cognition and mobility. Despite having similar ages and numbers of conditions to those with urinary or no incontinence, those with dual incontinence have significantly fewer days of hospital care (Chiang, Ouslander, et al., 2000). This suggests that this group receives less aggressive treatment.

Bladder incontinence has several specific medical causes superimposed on physiological changes of bladder functioning with aging, such as reduction in bladder capacity, uninhibited contractions, decreased urinary flow rate, diminished urethral pressure profile, and increased post-void residual volume. Transient and reversible causes of urinary incontinence include urinary tract infection and polyuria from uncontrolled diabetes. Established urinary incontinence has four major types:

- Urge incontinence due to uninhibited bladder contraction, which may be due to local factors (e.g., stones, infections, tumors) or central factors (e.g., stroke or other central nervous system conditions). Urgency symptoms (e.g., “Do you experience such a strong and sudden urge to void that you leak before reaching the toilet?”) are sensitive and specific for the diagnosis of urge incontinence (Holroyd-Leduc, Tannenbaum, et al., 2008).
- Stress incontinence due to increased abdominal pressure (e.g., during coughing and sneezing) exceeding the ability of sphincter closure mechanisms, most commonly due to inadequate pelvic support in women or following prostate surgery in men.
- Overflow incontinence due to impaired contractility of the bladder (e.g., due to diabetic neuropathy, spinal disease) or obstruction (e.g., due to prostatic hyperplasia or urethral stricture).
- Mixed incontinence, which is a combination of stress and urge incontinence.

Another type, functional incontinence, is of special importance in nursing homes. In this type, patients are incontinent because of immobility and the inability to get to the toilet or delays in receiving toileting assistance, rather than because of intrinsic bladder dysfunction.

The treatment of urinary incontinence is based on the type of incontinence, with behavioral approaches (e.g., bladder training, timed voiding, Kegel's exercises) being preferred for stress and urge incontinence, medications for urge incontinence, and intermittent catheterization for overflow incontinence. For cognitively impaired nursing home residents, a trial of prompted voiding (asking patients if they would like to go to the toilet at scheduled times) may be successful and can be combined with medications. Surgical procedures, neuromodulation, and botulinum toxin injections may be helpful in selected cases. Depending upon local availability, these may be performed by a urologist who has expertise in managing incontinence, or by a uro-gynecologist.

Falls

Up to 75% of nursing home residents fall annually, and the rate of falling is 1.5 falls per nursing home bed per year (Rubenstein, Josephson, et al., 1994). About one-third of falls occur in non-ambulatory residents (Thapa, Brockman, et al., 1996). In addition to weakness, gait disorders, and functional impairment, medications, especially psychotropic medications, are associated with falling in nursing home residents (Mustard & Mayer, 1997; Ray, Thapa, et al., 2000; Centers for Disease Control & Prevention, August 28, 2011). In particular, during the first four days after changes (either initiation or increasing the dose) in antidepressant medications (other than serotonergic reuptake inhibitors) nursing home residents are at higher risk of falls (Berry, Zhang, et al., 2011). All classes of psychotropic drug have been associated with increased risk of fall. Selective serotonin-reuptake inhibitors (SSRIs), tricyclic antidepressants, and antipsychotics are all associated with increased risk of falls (Thapa, Gideon, et al., 1998; Blair & Grumen, 2005; Echt, Samelson, et al., 2013). In general, tricyclic antidepressants should be avoided if possible in geriatric patients—even in the absence of orthostatic hypotension—due to their increased risk of adverse, anticholinergic effects, including constipation, dry mouth, dry eyes, urine retention, and confusion. There are very few studies evaluating risk of fall with use of bupropion alone. One study showed that subjects on paroxetine who had augmentation with bupropion have higher risk of a fall; however, the study was limited by the small number of participants who received bupropion (Joo, Lenze, et al., 2002). Restraints do not reduce the risk of falling and may increase the risk of falls with injuries (adjusted odds-ratio 1.34) but this estimate is based on observational studies with propensity score adjustments rather than on clinical trials (Castle & Engberg, 2009). Paradoxically, elimination of restraints may reduce the risk of falling (Ejaz, Jones, et al., 1994). Restraints such as bilateral bed rails, belts, and fixed tables and do not significantly decrease risk of fall and fall-related fractures (Köpke, Mühlhauser, et al., 2012). In a longitudinal, prospective

clinical trial, bilateral side-rail use showed no decreased risk of falls or recurrent falls when adjusted for cognition and functional and behavioral status (adjusted odds-ratio 1.13) (Capezuti, Maislin, et al., 2002). Nevertheless, restraints may be indicated when an agitated patient is at risk of harming her- or himself or others. If bedrails are utilized, half-rails should be chosen over full bed rails to minimize risk of potential fall-related injuries. Psychiatrists may help with determination of whether there is an indication for restraints and whether a patient can refuse restraints. Multidisciplinary and multifactorial approaches to falls prevention, often including supervised exercise programs, are used, though the evidence for their effectiveness in nursing homes is limited (Cameron, Murray, et al., 2010).

Other Conditions and Comorbidities

Most people living in nursing homes have several diseases. Among the most common medical disorders are hypertension (53%), musculoskeletal disorder (45%), heart disease (42%), diabetes (24%), and anemia (19%) (Centers for Disease Control, August 28, 2011). Some of these diseases (e.g., hypertension, diabetes, and heart disease) require medications that can interact and cause adverse events. Others (e.g., musculoskeletal disorders) contribute to immobility and functional impairment. The long-term benefit of treatment of conditions such as osteoporosis and hyperlipidemia must also be considered in the context of a shortened lifespan (i.e., will the patient survive long enough to accrue the benefits of treatment?) and weighed against the adverse effects of treatment. In some instances (e.g., target Hemoglobin A_{1c} [HbA_{1c}] levels for elderly diabetics, systolic blood pressure), the target levels for patients with limited life expectancy may be different from those for younger and more robust older persons, since aggressive management may lead to adverse events, such as increased risk of hypoglycemia, falls, or mortality. Discussions about whether to treat and how aggressively should occur with patients if they have capacity to make these decisions, or with proxies if they do not.

Polypharmacy

Almost half (48%) of nursing home residents take nine or more medications, and only 13% take four or fewer medications (Centers for Disease Control, August 28, 2011). The number of medications and a history of prior adverse drug events are major predictors of adverse drug reactions. Hospitalized older persons prescribed four or more meds have a 1.9-fold increased risk of adverse drug reactions, and those receiving eight or more drugs are at a four-fold risk (Onder, Petrovic, et al., 2010). In a study of two academic LTC facilities, the overall rate of adverse drug events (ADEs) was 9.8 per 100 resident-months; 42% of the ADEs were deemed preventable. The more serious the adverse event, the more likely it was to be considered potentially preventable. The most likely drugs causing ADEs were antipsychotics (adjusted odds-ratio [aOR] 3.0), anticoagulants (aOR 2.8), diuretics (aOR 2.3), and anticonvulsants (aOR 2.0) (Gurwitz, Field, et al., 2005).

The best way to avoid adverse drug reactions is to review medications regularly and, before prescribing a new medication, including checking for potential interactions, start a low dose and titrate based on tolerability and response; and avoid medications that are high-risk in older persons. A detailed list is provided in the 2012 Beers Criteria (American Geriatrics Society 2012 Beers Criteria Update Expert Panel, 2012). The time of transition between settings of care is an opportunity to review medications and discontinue medications if harms outweigh benefits, there is minimal or no effectiveness, there is no ongoing indication for the medication, or the medication is not being taken.

PSYCHIATRIC PROBLEMS

All patients seeking admission to Medicaid-certified NFs must complete a Preadmission Screening Residential Review (PASRR), regardless of whether the stay will be paid for by Medicaid, Medicare, or other resources. The PASRR (formerly called PASARR—Preadmission Screening and Annual Resident Review) determines whether a patient with a diagnosis of mental illness or intellectual or developmental disability meets criteria for admission to a SNF and the type of needed specialized services (New Hampshire Department of Health and Human Services, March 2013). Mandated by the federal government in 1989, it was implemented in 1990. The annual evaluation requirement was eliminated in 1997 after many states felt it posed undue financial burdens (Dual Diagnosis Management Ascend [DDM Ascend], March 18, 2013).

Psychiatric disorders encountered in LTC settings include preexisting mental illnesses and mental and behavioral problems that newly arise in the LTC setting. In the first category, it is important to identify an LTC setting that is comfortable with caring for patients with certain preexisting mental illnesses. Nursing homes, ALFs, and home care agencies differ in their comfort with mentally ill or behaviorally disturbed patients and in their ability to provide access to psychiatric and psychological services. At a minimum, home care agencies should be able to provide psychological services through either a clinical psychologist or a clinical social worker. Many nursing homes are able to provide access to an in-house psychiatrist, and some can offer access to a psychologist.

In the latter category, the most common reasons for referral are:

1. delirium due to new drugs or withdrawal of old ones, or to the development of a new medical condition;
2. behavioral disturbances—usually occurring in cognitively impaired people—because of untreated pain or discomfort, because of abuse or mistreatment by staff, other residents (of a facility) or by family members;
3. depression or anxiety occurring as a reaction to a change in living arrangements, specifically, placement in a nursing home or a move to an assisted living facility or the home of a family member.

The relative frequency of each of these is unknown, and a systematic approach may be helpful to distinguish among them. Such an approach begins with a review of the patient's medication list, focusing on newly started or recently discontinued medications. If no obvious precipitant is identified, then causes such as pain and depression or anxiety should be sought. Although many brief pain scales are available, some may be inappropriate for cognitively impaired patients, and collateral informants (e.g., nursing home staff, family) should be obtained to assess whether there are other signs of pain (e.g., grimacing). For depression, the Patient Health Questionnaire-9 (PHQ-9) has been validated in nursing home settings. (Saliba, DiFilippo, et al., 2012). If an explanation cannot be found, or if there are signs of injury (e.g., skin tears or bruises), then the possibility of elder abuse must be considered and investigated.

Use of restraints, chemical and physical, is highly regulated in SNFs. Physicians are required to attempt gradual dose reductions of all psychotropics used in SNFs since psychotropics are considered chemical restraints. Even patients who have been on long-standing use of antidepressants without adverse effects need documented attempts of gradual dose reductions. If a physician believes that gradual dose reduction will be more harmful than beneficial to the patient, then documentation of potential harms (e.g., clinical decompensation) is necessary. Note, however, that all chemical and physical restraints in SNFs need informed consent from the patient or his or her responsible party. Use of psychotropics in ALFs and board-and-care homes are not under as strict regulations as in the nursing home, because ALFs and board-and-care homes are not federally regulated.

Sleep Disorders

Changes in sleep patterns are part of normal aging, but they can be a problem for elderly patients who consider good sleep an important part of their quality of life. These physiological changes include decreased sleep time, decreased sleep efficiency (time asleep divided by time in bed), and increased sleep latency.

Sleep disorders are common in older adults. Common sleep complaints include having difficulty falling asleep, nighttime awakening, early morning awakening, and daytime sleepiness. Risk factors associated with sleep disorders include underlying mood disorder, dementia, comorbid medical conditions, and use of multiple medications (Alessi, Martin, et al., 2005; Bloom, Ahmed, et al., 2009). In LTC settings, some modifiable factors contribute to abnormal sleep–wake patterns; these include inadequate sunlight exposure, inadequate physical activity, and disruptive nighttime environment (i.e., too much noise and/or light). Non-pharmacological interventions geared at improving these modifiable factors may be helpful in improving sleep–wake cycles in elderly patients.

Some sleep disorders are more common in the older patient, such as restless legs syndrome, periodic limb-movement disorder, sleep-related breathing disorders (e.g., obstructive sleep apnea), and circadian rhythm sleep

disorders. A sleep diary, sleep study, and/or consultation with sleep specialist may be useful in diagnosis and management of these disorders.

Many older patients take medications that may contribute to insomnia. These medications include diuretics and stimulating medications such as activating psychiatric medications, bronchodilators, and sympathomimetics. If the above medications are necessary, then they should be administered during the daytime if possible. Conversely, sedating medications should be administered at nighttime, if possible.

For most patients, behavioral approaches should be attempted first. These include stimulus control (e.g., no television watching in bed, regular bedtime, and a routine of relaxation). Other non-pharmacological approaches include cognitive-behavioral therapy, relaxation techniques, bright lights, and sleep restriction (reducing bed time to estimated sleep time and gradually increasing it). Specific treatments that are recommended in the nursing home include morning bright-light treatment, exercise (e.g., stationary bicycle) and physical activity, reduction of nighttime noise and light interruptions, a regular bedtime and a routine of pre-bedtime activities, and the reduction of stimuli at bedtime (e.g., television). Combinations of these may be helpful.

Hypnotic drugs for insomnia may be utilized when non-pharmacological approaches are unsuccessful and if benefits (e.g., quality of life, better participation in activities during the daytime) outweigh the risks. The pharmacological management of insomnia should avoid benzodiazepines, anticholinergics (e.g., tricyclic antidepressants), and antihistamines (e.g., diphenhydramine). Non-benzodiazepine hypnotics (e.g., zolpidem, zaleplon, and eszopiclone) may be helpful but should be restricted to short-term use (three to four weeks). Sometimes patients have been using benzodiazepine or non-benzodiazepine hypnotics for years without apparent adverse effects. The decision about whether to attempt to taper and discontinue these must be made on a case-by-case basis, depending upon the patient's other comorbid conditions and preferences, and considering the risks of continuing the medication. Melatonin and a receptor agonist, ramelteon, may also be helpful. Some physicians also prescribe trazodone for sleep disorders in elderly patients. If hypnotics are prescribed for insomnia, they should be prescribed initially on an as needed (P.R.N.) basis in cognitively intact patients who are able to express their needs. For patients who are cognitively impaired, it is usually at the discretion of the nursing staff when the hypnotic is administered.

Delirium

Delirium is often encountered in nursing homes and sometimes in ALFs. Patients with hypoactive delirium, in general, can be managed in these settings as long as they are hemodynamically and medically stable. However, patients with hyperactive delirium (e.g., with behavioral disturbances such as aggression resulting in potential harm to self or others) are more difficult to manage in these settings and should be transferred to the hospital.

MEASURING AND IMPROVING QUALITY IN LONG-TERM CARE SETTINGS

For more than two decades, national efforts have been underway to improve the quality of nursing home care and quality of life for its residents. The need for improvement was first nationally recognized when the Institute of Medicine published a report in 1983 documenting significant deficiencies in the care in nursing homes. These findings ultimately led to the passage of the landmark Omnibus Budget Reconciliation Act (OBRA) of 1987. OBRA set forth new, higher standards of care in NFs that are reimbursed by Medicare and Medicaid via the Centers for Medicare and Medicaid Services (CMS), an agency of the U.S. Department of Health and Human Services (DHHS). CMS has multiple responsibilities, including paying Medicare claims, writing regulations for Medicaid that are administered by each state's Medicaid program, and interpreting legislation into written regulations for SNFs. For SNFs to be reimbursed by Medicare and Medicaid, they must comply with regulations set forth by CMS (Centers for Medicare & Medicaid Services, August 2011).

In November 2002, the CMS began the national Nursing Home Quality Initiative (NHQI) to provide information that allows consumers, providers, and researchers to compare the quality of care provided in nursing homes in the United States. Nursing home quality measures assess the residents' condition (physical, clinical, and mental), capabilities, limitations, and preferences about resuscitation. These measures are obtained from data that nursing homes collect in a standardized manner on their residents at specified intervals during their stay, the Minimum Data Set (MDS) (Saliba & Buchanan, 2008). MDS measures are assessed, monitored, and reported publicly on the CMS website. The MDS allows a particular nursing home to identify its strengths and pinpoint areas needing improvement.

The MDS 3.0, implemented in October 2010, is the latest version and has major updates of the MDS 2.0 (Alessi, Martin, et al., 2005). The MDS 3.0 has improved reliability and validity compared to MDS 2.0. It is more clinically relevant and allows nursing home residents to have a voice by including a direct resident interview, which was not mandatory in MDS 2.0. It also includes improvements in various assessment sections. MDS 3.0 has a new delirium assessment section using the CAM; improved depression assessment using the PHQ-9 (an interview version for verbal patients, and a staff observational version for patients who cannot complete the interview); improved cognitive assessment using the Brief Interview for Mental Status (BIMS), which is highly correlated with the Mini-Mental State Examination; and a new Patient Preference tool (PAT) to evaluate a patient's preferences and views regarding quality of life. The MDS 3.0 also includes revisions in the following content areas: behavior symptoms, continence, pain, and ADLs. The MDS 3.0 also differs from the MDS 2.0 in that the data are transmitted to a federal (rather than state) data-collection system.

In June 2011, the National Quality Forum (NQF) endorsed 17 nursing home quality measures derived from the MDS that nursing homes collect and submit (Centers

Table 83.3 MEDICARE COVERAGE IN SKILLED NURSING FACILITIES

SERVICE	MEDICARE COVERS	PATIENT AND/OR FAMILY PAYS
Skilled nursing for days 1–20	All eligible expenses	Nothing
Skilled nursing for days 21–100	All eligible expenses after patient pays daily copayment	Daily copayment *
Skilled nursing for days 100+	Nothing	Everything

*Medicare supplemental insurance (MedSup or Medigap) may cover some or all of Medicare's copayments and/or deductibles.

for Medicare & Medicaid Services, September 19, 2011). The NQF is an organization representing consumers, purchasers, providers, and researchers, and helps establish standards of care (National Quality Forum, September 19, 2011). The nursing home quality measures that are endorsed are outlined in Table 83.4.

Each nursing home's quality measures and the results of surveys are publicly available at the Nursing Home Compare website, <http://www.medicare.gov/NursingHomeCompare/search.aspx?bhcp=1>. Specifically, consumers can get the following information about individual nursing homes from the website:

- Five-star quality ratings of overall performance and individual performance on health inspection surveys, quality measures, and hours of care provided per resident by staff performing nursing care tasks.
- Health inspection results and complaints, detailed and summary information about deficiencies found during the three most recent state inspections, and recent complaint investigations.
- Nursing home staffing information about the number of registered nurses, licensed practical or vocational nurses, physical therapists, and nursing assistants in each nursing home.

- A set of quality measures that describe the quality of care in nursing homes (e.g., percent of residents with pressure sores, percent of residents with urinary incontinence).
- Any penalties and enforcement actions against a nursing home.

Additionally, state survey agencies are mandated to visit nursing homes at least once annually and as needed (if there are deficiencies or complaints to the state) to inspect and assess the quality of care provided in nursing homes. The state survey agency visits are typically unannounced. If a nursing home does not meet regulatory standards of care, then it is cited with a deficiency, which carries penalties including monetary fines and, in the worst-case scenario, the nursing home's closure. There are also Long-Term Care Ombudsmen available whom nursing home residents and their families, friends, and caregivers can contact if they have any concerns about the quality of care that is being provided in their nursing home. The MDS, state surveyors, and ombudsman programs are all part of an ongoing national effort to improve the quality of care provided in nursing home settings.

A similar effort aimed adults receiving home health care, the Outcome and Assessment Information Set (OASIS), contains items assessing cognitive function ability/ confusion, anxiety, or depression, as well as demonstrated cognitive,

Table 83.4 QUALITY MEASURES IN NURSING HOMES

SHORT-STAY QUALITY MEASURES	LONG-STAY QUALITY MEASURES
<ul style="list-style-type: none"> • % residents on scheduled pain medication regimen on admission who report decrease in pain intensity or frequency • % residents who self-report moderate to severe pain • % residents with pressure ulcers that are new or worsened • % residents assessed and given, appropriately, seasonal influenza vaccine • % residents assessed and given, appropriately, pneumococcal vaccine 	<ul style="list-style-type: none"> • % residents experiencing one or more falls with major injury • % residents who self-report moderate to severe pain • % high-risk residents with pressure ulcers • % long-stay residents assessed and given, appropriately, the seasonal influenza vaccine • % long-stay residents assessed and given, appropriately, the pneumococcal vaccine • % long-stay residents with a urinary tract infection • % low-risk residents who lose control of their bowels or bladder • % residents who have/had a catheter inserted and left in their bladder • % residents who were physically restrained • % residents whose need for help with daily activities has increased • % long-stay residents who lose too much weight • % residents who have depressive symptoms

behavioral, and psychiatric symptoms. Like the MDS, psychiatric symptoms can be used by clinicians to detect psychiatric problems. However, these instruments are valuable clinically only if the information is brought to the attention of the clinicians and probed deeper. The OASIS is also limited because patients tend to receive home health services for only short periods of time.

Although similar federal efforts have not been applied to other LTC settings (e.g., assisted living and other residential facilities), perhaps in the future, these settings will also be the focus of quality improvement efforts. ALFs and home care agencies are currently regulated only at the state level; there is no rating system as yet for them. The Assisted Living Federation of America (ALFA) is an organization that monitors the assisted living statutes in each state and provides an updated contact for the licensing organization in each state, in an effort to help providers become aware of the licensing requirements and regulations. The website can be found accessed at <http://www.alfa.org> (ALFA, March 18, 2013). Common citations by state inspectors can be found at the ALFA website (ALFA, March 18, 2013). For specific information on what type of psychiatric problems ALFs and home care agencies can handle, it is best to send specific inquiries to these facilities. Nursing-patient ratio, the type of help available, presence or absence of higher levels of care within the assisted living facility, and presence and absence of a locked dementia care unit are important considerations for the patient with psychiatric issues.

CLINICAL PEARLS

- Functional status is usually considered at two levels: basic activities of daily living (ADLs) and instrumental activities of daily living (IADLs). ADLs include bathing, dressing, toileting, transferring (e.g., from a bed to a chair), maintaining continence, and feeding. IADLs include using the telephone, shopping, preparing meals, housekeeping, doing laundry, using public transportation or driving, taking medication, and handling personal finances.
- The patient's awareness of ADL or IADL deficits and their willingness to accept assistance when it is needed is related to ADL and IADL performance.
- Medications, especially psychotropic medications, are associated with falling in nursing home residents (Blair & Gumen, 2005; Cameron, Murray, et al., 2010). The rate of falling is 1.5 falls per nursing home bed per year (Cameron, Murray, et al., 2010).
- All patients seeking admission to Medicaid-certified NFs must complete a Preadmission Screening Residential Review (PASRR), regardless of whether the stay will be paid for by Medicaid, Medicare, or other resources. The PASRR determines whether a patient with a diagnosis of mental illness, intellectual or developmental disability meets criteria for admission to a SNF and the type of

needed specialized services (PASRR, 2013). The Assisted Living Federation of America (ALFA) is an organization that monitors the assisted living statutes in each state and provides an updated contact for the licensing organization in each state, in an effort to help providers become aware of the licensing requirements and regulations. The website can be found accessed at <http://www.alfa.org> (ALFA, 2013). Common citations by state inspectors can be found at the ALFA website (see above). Each nursing home's quality measures and the results of surveys are at the Nursing Home Compare website: <http://www.medicare.gov/NursingHomeCompare/search.aspx?bhcp=1>.

END-OF-LIFE ISSUES

John L. Shuster, Harvey Max Chochinov, and Natalie L. Jacobowski

INTRODUCTION

Illness causes suffering. Obviously, the most effective way to relieve suffering caused by illness is to eradicate or control the underlying disease process. Many acute-care interventions increase short-term suffering in exchange for a cure, long-term relief, or the hope of a possible cure. Even in the acute medical setting, where both patient and physician expect complete remission of symptoms or a cure to result, every treatment intervention should be tempered with attention to the suffering caused by both disease and treatment. Once the prospect of a cure becomes an unreasonable expectation, the focus of care shifts to relief and reduction of suffering, including the discomfort and pain induced by treatments themselves.

This is the palliative approach to medical care. In the broadest sense, the management of chronic or incurable illnesses (e.g., Alzheimer's disease) is essentially palliative. For many people, however, the term "palliative care" connotes the care of terminally ill patients who are receiving hospice care. A patient is "terminally ill" as defined in the United States Medicare Hospice Benefit when the patient has an expected survival of six months or less. In this setting, continued treatment aimed at cure is deemed clinically or even ethically inappropriate, since the potential benefits to the patient would not outweigh the potential risks and side effects.

PALLIATIVE CARE

The verb *palliate* means "to reduce the violence of (a disease)," or "to moderate the intensity of" a disease process (*Webster's New Collegiate Dictionary*, 1979). Root word meanings include "to shield," "to cloak," "to conceal," and "to protect." Palliative care, then, is properly understood as the means of shielding and protecting patients from the violence of disease, especially the violence of disease at the end of life. The World Health Organization (1990) defines palliative care as:

the active total care of patients whose disease is not responsive to curative treatment. Control of pain, other symptoms, and of psychological, social, and spiritual problems, is paramount. The goal of palliative care is achievement of the best quality of life for patients and their families.

HOSPICE CARE

Hospice is a multidisciplinary approach to the care of terminally ill patients that provides comprehensive palliative care. Distinctive features of hospice care include:

- A multidisciplinary team approach to care (including the expertise of physicians, nurses, social workers, chaplains, volunteers, and others);
- The focus of care shifts from cure or survival to reducing suffering and maximizing quality of life;
- To the extent possible, the care delivered by a hospice team occurs in the patient's preferred care setting, usually at home. Hospice care can also be delivered in other settings, such as general hospitals, nursing homes, and specialized hospice or palliative medicine units;
- Care for the family is also provided, including practical assistance with care of the dying patient, maintenance of the home, and bereavement aftercare services.

In the United States, the system of hospice care provided in a patient's home generally works well, provided that the patient actually has a home, has family members who are capable and willing to provide care for the patient at home, and has symptoms that can be managed primarily by lay individuals outside the hospital setting. When these conditions are not met, home hospice care is not feasible. A growing availability of inpatient and residential hospice and palliative care is occurring in response to this need.

GOALS OF HOSPICE AND PALLIATIVE CARE

The goals of hospice care and palliative care include assuring patients they will not be abandoned, aggressive control of painful or noxious symptoms, maintenance or repair of stressed interpersonal relationships, preservation of a comforting care environment, and attention to important life goals and spiritual or religious concerns. Physicians have much to offer patients, even when expected survival is measured in months, weeks, or days. First, however, the physician's help must be offered. Every patient dreads hearing

the words “There’s nothing more I can do for you.” Letting the patient and family know (by both words and actions) that they will not be expected to face the end of life alone is a great comfort. Seldom is the doctor–patient relationship more important. Even in the context of making a referral to an excellent hospice program, physicians should assure their patients of their ongoing involvement in and commitment to the patient’s care, augmented by the expertise and resources of the hospice team.

This kind of ongoing physician involvement helps soothe possibly the greatest fear of dying patients: the process of dying is usually feared more than death itself. Worries about abandonment, helplessness, dependency, preservation of worth and dignity, and undertreated (or untreated) suffering are sources of great concern to terminally ill patients and their families. The tendency, even among many physicians, to withdraw from the terminally ill intensifies a patient’s fear or dying. Dying must seem dreadful indeed, if even physicians cannot bear to attend the patient as death approaches. The converse is certainly true: when physicians demonstrate that they will not abandon their patients and stand ready to do what they can to address suffering as it arises, the process of dying is easier to bear. The control of symptoms that interfere with quality of life (e.g., pain, depression, nausea, anxiety, and fatigue) should be aggressively pursued. Relief of symptoms and suffering at the end of life should be provided with the same diligence and dedication with which cure is pursued in acute illness. Widely available and commonly accepted treatments for most end-of-life symptoms (e.g., opiates for pain, benzodiazepines for anxiety) are reliably effective. Still, not all symptoms can necessarily be relieved, even with the most expert intervention. In these instances, patients’ main source of relief may be the knowledge that their physician and hospice team will continue to try to help them. Box 84.1 summarizes the principles of good symptom management at the end of life. This chapter focuses on the control of psychiatric and neuropsychiatric symptoms at the end of life. The Academy of Psychosomatic Medicine has published a position statement on psychiatric care at the end of life (Shuster et al., 1998), which readers may also wish to review.

Conflict with relatives and close friends can cause emotional suffering at the end of life. Long-standing disputes and grudges may be amenable to repair in the setting of a terminal illness. Dealing directly and confrontationally with family conflicts should occur if there is reasonable expectation of benefit from such an intervention. The strain of caring for a seriously ill and dying relative causes marked distress in a family. Acknowledgement that the task is difficult, and strategies that anticipate caretakers’ becoming exhausted—the periodic respite care that is integral to the Medicare Hospice Benefit, for example—can contribute to the preservation of a comforting home environment.

The end of life can potentially be an enriching, life-affirming experience for patients and their families. If a life can be viewed in narrative terms, it will require a meaningful concluding chapter. A focus on meaningful life goals is one strategy that may be helpful to patients. For some, such goals might include feeling well enough to enjoy a wedding

Box 84.1 PRINCIPLES OF GOOD SYMPTOM CONTROL IN PALLIATIVE CARE

- Do not limit the use of analgesics for fear of an overdose. Start with a conservative dose and advance as rapidly as needed and tolerated, allowing for a substantial margin of safety.
- When potentially addictive drugs are used for a palliative indication, concern about addiction or dependence should be tempered by the need to provide comfort and relief. Tolerance may develop but is manageable with dose adjustments.
- Listen carefully and patiently to the patient. Use the treatment and the dose needed to provide maximum symptom control. Take the patient’s report of symptom control at face value.
- Severe suffering from pain and other symptoms can occur long before a patient dies. Do not wait until the last few days of life to treat symptoms aggressively.
- A patient need not forgo a narcotic or other treatment now in order to benefit later, when the symptom gets worse. The dose may need to change, or agents may need to be rotated to maximize tolerability and effectiveness, but analgesics still work in an advancing disease, though dose requirements may increase.
- Symptom relief is always the objective when someone is dying, even if high doses of a drug are required which that unintentionally contribute to their death. This is an ethical approach well established and respected from medical, legal, and religious perspectives.

Adapted from Webb (1997) with permission.

or graduation ceremony; for others, it might involve writing a book, endowing a scholarship, or sharing important anecdotes, beliefs, and other gifts with family and friends. These activities can bring a sense of resolution and peace to the patient with a terminal illness. For dying patients to make the most of the time they have left, excellent symptom control and comfort is an absolute prerequisite.

Finally, excellent end-of-life care is sensitive to the patient’s spiritual and existential beliefs and concerns. More than 90% of Americans state that they believe in God or some “higher power” (Gallup Poll, 1997). Beliefs about religion and the nature of an afterlife typically become more important as death approaches. Many people find peace and palliation through their religious traditions. Understanding a patient’s personal system of belief and relationship to a community of believers is key to understanding the patient well. Apart from formal religious beliefs, all people have existential concerns (e.g., life goals achieved or abandoned, regrets about past events, concern about welfare of family members after their death) (Jacobsen & Breitbart, 1996).

Good care of the dying patient often involves open but sensitive discussion of religious beliefs and concerns. As a part

of such conversations, patients may inquire about the religious traditions and beliefs of their physicians. In contrast to other settings for psychiatric care, such inquiries are usually best dealt with in a way that is as direct as is comfortable for the physician, as free of analysis as possible, and always respectful of the patient's beliefs and traditions (or lack thereof). While the end of life is never an appropriate time for proselytizing, many religious people take comfort in knowing that their physician is also a person of faith, even if the physician comes from a different faith tradition than their own. Clergy from the patient's faith community or a hospice chaplain are valuable collaborators and sources of information in providing for the spiritual and existential care of terminally ill patients. If in doubt, ask. Physicians, whether or not they themselves are religious, can provide comfort to their religious patients by promptly mobilizing pastoral and chaplaincy support.

A GENERAL APPROACH TO PALLIATIVE MEDICAL CARE

A general approach to palliative medical care, summarized by Shuster and James (1998), suggests that physicians ask first about suffering in a general way (e.g., "What causes you to suffer most?"). The experience of suffering is unique to each individual. The treatment should emphasize the patient's priorities and reflect respect for the patient's treatment preferences. Vigilance for symptoms of pain, nausea and vomiting, weakness, anorexia, and dyspnea is essential to palliative care, as undertreated physical symptoms can cause psychological symptoms—for example, depression often is precipitated by undertreated pain (Spiegel et al., 1994). Patients with terminal illness should be routinely screened for mental disorders like depression, anxiety, and delirium.

Respect for the patient's priorities and tolerance for the patient's preferences are best rooted in an ongoing discussion regarding advance directives. Formal documents such as living wills or even declarations of a healthcare proxy actually may fall short of their potential utility when implemented. The conversations held in the context of discussing these documents are very useful in helping the patient, family, and physician come to a mutual understanding of the patient's wishes regarding end-of-life care. Ideally, such conversations will begin well before a time of crisis. A foundation of clear understanding of the patient's priorities and preferences can lessen the burden of what might otherwise be agonizing decisions at the end of life. Patients and families should be encouraged to view participation in these conversations in advance as a loving gift to one another. Chapter 85 deals extensively with advance directives.

PRACTICAL PROBLEMS WITH HOSPICE AND PALLIATIVE CARE

The median length of stay in American hospices, designed for up to six months, has been reported as being in the range of 30 days (Christakis & Escarce, 1996). Since hospice eligibility is directly linked to an expected survival of six months or less,

difficulty in arriving at an accurate prognosis, especially for non-cancer diagnoses, limits the availability of hospice care. To make prognostic estimates more reliable, the National Hospice and Palliative Care Organization (NHPCO) has published guidelines for determining prognosis related to hospice eligibility (National Hospice Organization Medical Guidelines Task Force, 1995).

Useful as such guidelines are, they represent an attempt to adapt to the six-month criterion, which is not meaningful for patients dying from certain diseases. For example, the guidelines present a set of criteria to predict six-month survival in end-stage dementia, which may progress over the course of a decade. However, use of these criteria for patients with Alzheimer's disease limits hospice care to patients with such extreme cognitive impairment that most of the goals of hospice and palliative care are difficult or impossible to achieve.

It is often difficult for a patient to shift the focus of treatment from cure to palliative care. Hesitancy about discussing these issues can delay access to palliative care further. This discussion requires that doctors understand the patient's preferences about curative and end-of-life care. Physicians should be able to provide an open and realistic discussion of the prognosis, be comfortable with breaking any bad news gently, be willing to dispel myths about the end of life and hospice care, and be committed to educating patients and families about the dying process (Shuster & Jones, 1998). This discussion allows the opportunity to avoid futile treatments, to treat patients' suffering adequately, and to proceed with a plan of treatment consistent with the patient's wishes.

Even though discussion of the shift to palliative treatment is necessary for optimal end-of-life care, it is also difficult and even painful for the physician as well as the patient. Physicians are trained to treat disease; some perceive a patient's death as a professional and personal failure. Additionally, a physician's own death anxiety can hinder him or her from engaging patients in discussions about end-of-life care. Approaches such as seeking training and experience in palliative care, acknowledging the importance of symptom control and palliative interventions, and helping patients set meaningful and achievable goals can make providing end-of-life care bearable, even rewarding, for physicians.

Breaking bad news and discussing end-of-life care with patients are skills that need to be developed over time (Creagan, 1994; Garg et al., 1997). When breaking bad news to a patient, care should be taken to be gentle but clear. Expect the patient to be distressed and to have difficulty assimilating details initially. The physician should be seated during sensitive conversations and should ensure adequate privacy after determining whom the patient would like to have present for the discussion. The physician should next determine what patients already know about their condition and what details they would like to receive about their prognosis. Some patients are burdened by excessive detail or even a direct statement of their poor prognosis; their preference "not to know" should be respected and a suitable proxy identified. Next, the physician should fill in the gaps in the patient's understanding of their condition, according to their preference about degree of detail. Without being evasive or mincing words, the physician

should be calm and as reassuring as appropriate. While hope for cure cannot be offered, the physician can soothe patients' concerns about abandonment and the dying process and provide information about palliative interventions.

Finally, questions should be invited before ending the initial session. End-of-life discussions should be viewed as an ongoing dialogue and not a single event. An initial conversation similar to that described above makes subsequent contacts much easier and more rewarding for both patient and physician. Involvement of spouses and other close family members and friends is essential.

PSYCHIATRIC SYMPTOM MANAGEMENT AT THE END OF LIFE

For a number of reasons, psychiatric and neuropsychiatric complications of terminal illness are very common and often overlooked (Shuster et al., 1998; Shuster & Jones, 1998). First, it is widely held that symptoms, especially depression, are a "normal" part of the dying process. In addition, psychiatric diagnosis is more difficult in the presence of physical illness, and medical staff may be unduly pessimistic about the chances that the patient will respond to treatment. Reactions to the patient's hopelessness may augment this pessimism in their caregivers. While symptomatic treatment is emphasized in palliative care, treatment based on formal psychiatric diagnoses (e.g., mental disorder) is not sufficiently emphasized. The stigma associated with psychiatric evaluations or the assignment of a psychiatric diagnosis inhibits the use of psychiatric services, even in hospice settings. Finally, there are significant structural barriers to including team members with mental health expertise in the care of dying patients. Successful psychiatric symptom control at the end of life necessitates overcoming these barriers to treatment. A palliative approach to psychiatric symptom control also involves shifting the focus of assessment and treatment. While recognition and treatment of formal mental disorders has a prime importance for the psychiatrist caring for a terminally ill patient, that psychiatrist must also be ready to provide symptomatic treatment to relieve suffering and maximize quality of life. Similarly, some psychiatric problems at the end of life that meet full diagnostic criteria for a mental disorder (e.g., quiet delirium in the final days or hours of life) are sometimes best left untreated. Providing adequate relief from psychiatric symptoms at the end of life requires relief of pain, nausea, dyspnea, or other distressing symptoms. A general physical assessment and examination, in conjunction with attention to the patient's complaints, will usually pinpoint physical sources of pain and suffering.

DEPRESSION

Depression is very common in the setting of terminal illness. Estimated prevalence rates range from 20% to 50% (Breitbart et al., 1995; Shuster et al., 1998). While depressive symptoms affect an even larger percentage of patients, there is a median prevalence of 15% for depression in advanced disease that meets criteria for a major depressive episode (Hotopf et al., 2002). Depression becomes more prevalent

and severe as comorbid physical illness progresses (Rodin et al., 1991). Depression clearly diminishes one's quality of life (Wells et al., 1989). Depression has been shown to be a determining factor in the desire to die in many patients who opt for assisted death (Chochinov et al., 1995). Consequently, depression is a problem of major clinical importance in the care of terminally ill patients and should be a priority in routine assessment.

Screening for depression in terminally ill patients is challenging. There is significant variability in assessment methods for depression among patients with advanced illness. A review of published studies of depression assessment in palliative cancer patients found that over 100 different assessment methods were used, two-thirds of which were unique to only one paper. Furthermore, the full range of *Diagnostic and Statistical Manual IV* (DSM-IV) diagnostic criteria were seldom assessed in published studies (Wasteson et al., 2009). The ideal screening procedure would be brief yet accurate. Many patients in need of palliative care cannot tolerate extended or even relatively modest diagnostic assessments. A personal or family history of a mood disorder argues for a depressive episode, especially if the patient reports that the subjective experience is similar to prior episodes. A simple question, essentially "Are you depressed?" is an accurate and reliable initial screen for depression of clinical significance in terminally ill patients (Chochinov et al., 1997). Among formal screening tools, the Hospital Anxiety and Depression Scale (HADS) has been validated against a standardized psychiatric interview and has similar sensitivity, specificity, and positive predictive value (Lloyd-Williams et al., 2003). Although not extensively studied in palliative care, the Patient Health Questionnaire (PHQ-9) is also a brief and well-validated measure for detecting and monitoring depression (Kroenke et al., 2010). While diagnostic confidence is increased and target symptoms are obtained by determining that the patient meets more formal criteria (American Psychiatric Association, 1994) which remain applicable to patients at the end of life, treating any significant symptom, above or below formal diagnostic thresholds, is consistent with the palliative approach to care.

Successful treatment of depression in the terminally ill patient requires attention to commonly comorbid physical conditions. The patient's level of pain cannot be overlooked, as patients with severe pain are less likely to respond to depression treatment (Laird et al., 2009). Adequate analgesia provides relief from the pain and the dysphoria associated with it. Pain, when severe or unremitting, is often interpreted as a constant reminder of serious illness and disease progression. Pain, as a distracting stimulus, makes attending to other, more pleasant activities difficult. Similarly, nausea and vomiting, when severe or recurrent, are very likely to produce dysphoric distress, depression, and isolation. Progressive loss of stamina or functional capacity is usually accompanied by grief or even depression, and this should be taken into account when assessing depression in the dying patient. A differential diagnosis of the conditions that can cause or exacerbate depression in terminally ill patients is listed in Box 84.2.

Treatment for depression in the terminally ill patient primarily requires use of antidepressants, especially

**Box 84.2 DIFFERENTIAL CONSIDERATIONS
OF DEPRESSIVE SYMPTOMS IN TERMINAL ILLNESS**

Mood disorders (major depression, dysthymia, bipolar disorder)
Adjustment disorder with depressed mood
Anger
Feelings of abandonment by family, physicians, God
Anxiety
Coping/personality style (avoidant, schizoid)
Delirium (“quiet” type)
Dementia
Emotional “numbing”
Interpersonal problems/conflicts
Narcissistic injury/damage to self-esteem
Side effects of treatment (medication-induced depression—
e.g., prednisone)
Spiritual/existential anxieties/foreboding
Strong feelings of loss of control or autonomy
Undertreated nausea/vomiting
Undertreated pain
Other undertreated physical complications (e.g., hypo
thyroidism)

Adapted from Shuster & Jones (1988) with permission.

psychostimulants (Breitbart et al., 1998; Block, 2006). Table 84.1 summarizes the antidepressant agents commonly used for depression in this setting. Standard antidepressants appear to be effective in advanced illness, but their use in this population has one chief drawback: the two- to four-week lag time to onset of benefit. Given the short length of survival typical after admission to hospice care, and the palliative care goal of maximizing the quality of life and the capacity to enjoy every precious day, agents that are not apt to work for two to eight weeks are rarely acceptable as first-line treatments. For most cases of depression in the terminally ill, the psychostimulants are better alternatives.

Psychostimulants (e.g., dextroamphetamine, methylphenidate) have been widely used and studied in the depressed medically ill, including patients with advanced disease (Masand & Tesar, 1996; Macleod 1998; Homsy et al., 2001; Howard et al., 2010). Despite the long history of use, there are limited formal studies to support their use as antidepressants, but the available evidence suggests their efficacy, with stronger evidence for tolerability (Hardy, 2009). Beneficial effect has been shown in several nonrandomized studies in patients with cancer, and even stronger studies exist in HIV literature, where randomized controlled trials of stimulants in patients with HIV for fatigue have shown significant improvement in fatigue as well as depression (Block, 2006). Stimulants are commonly used in hospice and palliative care settings and are the agents of choice in

this setting unless contraindicated. Response occurs within hours after a given dose. Clearance of the drug is also rapid if side effects occur.

There is little information available regarding differential efficacy or tolerability of the psychostimulants, so the choice among the commonly used agents is largely based on personal experience, subjective preference, and availability. A treatment protocol for using stimulants in the end-of-life setting is summarized in Box 84.3. Treatment should be initiated with a relatively low dose of the selected agent. Treatment response is rapidly apparent (usually within a few hours), allowing for daily dose adjustments. Dose should be adjusted daily in small increments until one of the following occurs: (1) the desired antidepressant response is achieved, (2) intolerable side effects emerge, or (3) the high dose range listed in Box 84.3 is reached without obtaining a beneficial response. The “high” dose is not high in the absolute sense, but rather high in that it is higher than the dose usually required to obtain therapeutic benefit in this setting. The high dose listed here is not to be considered an absolute dose ceiling for using stimulants for depression in the terminally ill, but as a reminder to reconsider diagnosis and treatment strategy before proceeding with further dose escalation (which may be necessary to obtain the desired benefit).

Though well tolerated by medically ill patients, stimulants are not without adverse effects. Side effects that are usually dose-related may include tachycardia, hypertension, insomnia, and agitation. Anorexia is a common side effect of stimulants in medically healthy populations (and a treatment indication when these agents are used as appetite suppressants), but stimulants commonly boost appetite in medically ill patients, especially if the diminished appetite is secondary to depression or apathy. In patients at high risk for developing delirium, as many terminally ill patients are, or those who seem depressed but have a “quiet,” hypoactive, non-agitated delirium, administration of stimulants can precipitate or worsen a delirious state. Finally, while this is unusual in the medical population, tolerance may develop with prolonged use, requiring dose escalation to maintain the therapeutic effect. Withdrawal depression may occur if stimulants are abruptly discontinued. The limited life expectancy of terminally ill patients makes many of these side effects of little concern in this population, however.

Standard antidepressant treatment also has a role in the control of depressive symptoms that complicate terminal illness. When patients are unable to tolerate stimulants, fail to respond to stimulant treatment, or have a history of vigorous response to a known antidepressant, standard antidepressants may be a better choice than stimulants for depression at the end of life. Additionally, patients with a terminal prognosis but with a relatively long life expectancy may do better over the long term on a standard antidepressant. Patients maintained on stimulants for a long period of time (many weeks or months) are best gradually switched to a standard antidepressant for maintenance therapy. Patients who achieve suboptimal response to psychostimulants may achieve better control

Table 84.1 PHARMACOLOGICAL TREATMENTS FOR DEPRESSION IN TERMINAL ILLNESS

GENERIC NAME	APPROXIMATE DAILY DOSE RANGE (MG)	ROUTE	COMMENTS
PSYCHOSTIMULANTS			
dextroamphetamine qAM and afternoon	2.5–20 daily (also available in time-release form)	PO PO	Rapid onset of action and clearance if side effects emerge. Tolerance may develop, requiring dose increase. May precipitate agitation or delirium in susceptible patients. May be drugs of choice in terminal illness.
2.5–20 bid modafinil	methylphenidate 100–200 qAM	PO	
SEROTONIN REUPTAKE INHIBITORS			
fluoxetine	10–80 daily	PO	SSRIs all may cause mild headache, jitteriness, GI upset. May (rarely) cause serotonin syndrome in combination with other serotonergic agents. May affect metabolism of other drugs cleared through the cytochrome P450-2D6 system.
paroxetine	10–40 daily	PO	
sertraline	50–200 daily	PO	
citalopram	20–40 daily	PO	
escitalopram	10–20 daily	PO	
TRICYCLIC ANTIDEPRESSANTS			
desipramine	12.5–150 daily	PO	Anticholinergic, sedation, orthostasis, and dry mouth are potentially troublesome side effects of all TCAs. Can worsen constipation caused by opiates. Can help treat pain, especially neuropathic pain. May stimulate appetite.
doxepin	12.5–150 daily	PO	
imipramine	12.5–150 daily	PO, IM	
nortriptyline	10–125 daily	PO	
amitriptyline	50–100 daily	PO	
OTHERS			
bupropion	75–450 daily in divided doses	PO	Stimulating, risk of seizures
mirtazapine	15–60 daily	PO	Sedating, appetite stimulant Sedating, can induce orthostasis; risk of priapism. Used in low doses 50–100 mg as sedative/hypnotic qhs. Nauseating on empty stomach.
trazodone	25–300 daily	PO	
duloxetine	40–60 daily	PO	FDA indication for diabetic neuropathy Can cause hypertension in high dose ranges
venlafaxine	75–375 daily	PO	

Key: qAM = daily; bid = twice daily; IM = intramuscular; PO = oral.

Key: qAM = daily; bid = twice daily; IM = intramuscular; PO = oral.

of depressive symptoms with combined use of stimulants with standard antidepressants.

As there is limited evidence to support any particular standard antidepressant as a “drug of choice” for depressed palliative care patients, choice of agent should be guided by comorbid physical illness, the patient’s symptom profile, drug interactions, and potential side effects, both positive and negative (Rayner, Price, Hotopf, & Higginson, 2011). Newer agents appear to be better tolerated in general than older antidepressants such as tricyclics, in the terminally ill patient. Monoamine oxidase inhibitors (MAOIs) are rarely if ever used in this setting, for various reasons, including the required dietary restrictions. Though tricyclics have a greater overall side effect burden in the medically ill than some of the newer agents, they do have a role in the management of depression in the terminally ill patient with neuropathic pain, substantial appetite reduction, severe insomnia, or a past history of good response to tricyclics. Among the newer agents, the serotonin reuptake inhibitors (SSRIs) have the most extensive history of use in medically ill populations and are most commonly used.

Psychotherapy has a role in the management of depressive symptoms at the end of life. Though most patients with terminal illnesses may be unable to tolerate extensive psychotherapeutic interventions, a variety of psychotherapies can be modified for use in the care of terminally ill patients and their families. Clinical trials have shown benefit of various psychosocial interventions, including psychoeducation, problem-solving therapy, cognitive-behavioral therapy (CBT), non-cognitive-behavioral therapy (relaxation techniques, hypnosis), and individual and group supportive therapies (Lorenz et al., 2008; Akechi et al., 2008). Dignity therapy, an individualized and reflective intervention designed for people living with terminal illness, has been shown to improve self-reported end-of-life experiences, sadness, and spiritual well-being, and shows promise in mitigating distress due to depression (Chochinov et al., 2011). In addition to the various psychotherapies, an initial study of a structured exercise program for palliative care patients suggests that a 50-minute group exercise program offered twice weekly for six weeks was associated with benefits in emotional functioning and fatigue (Oldervoll et al., 2006).

**Box 84.3 PSYCHOSTIMULANTS FOR DEPRESSION
IN TERMINAL ILLNESS**

Advantages

Well tolerated and effective
No lag time to effect
Rapid clearance
Paradoxically improve appetite in the physically ill

Disadvantages (Usually Dose-Related)

Can only be given by the PO route
May worsen/precipitate delirium
Side effects—insomnia, hypertension, tachycardia, restlessness, hallucinations (dose-related)
May induce tolerance
Withdrawal depression after prolonged use if stopped abruptly

Agents

Dextroamphetamine

*Starting dose: 2.5–5.0 mg each morning
*“High” dose: 20 mg/day
* Some patients may require BID dosing (morning and noon) if effect wears off too quickly

Methylphenidate (Ritalin)

*Starting dose: 2.5–5.0 mg BID (morning and noon)
*“High” dose: 40 mg/day

Modafinil

* Starting dose: 100 mg each morning
* “High” dose: 200 mg/day
* Doses up to 400 mg/day have been used

Protocol

Begin with starting dose.
Check response daily.
Raise dose by smallest increments until one of the following occurs: resolution of depression, emergence of intolerable side effects, “high” dose approached or exceeded.*
Avoid evening dosing.

*“High” dose is not an absolute dose ceiling, but exceeds the dose usually required for depression in terminal illness. Achieving this dose should serve as a flag to reassess diagnosis and response before continuation or further dose increases.

ANXIETY

Some degree of anxiety or fearfulness is probably universal at the end of life. This fact makes anxiety difficult to evaluate in the setting of terminal illness and probably contributes to the under-recognition of anxiety disorders in the dying (Shuster et al., 1998). Anxiety and anxiety disorders can cause a great deal of suffering in dying patients, especially when anxiety complicates respiratory distress (Rosenbaum et al., 1997; Breitbart et al., 1998). Even anxiety that does not meet criteria for a formal psychiatric disorder (American Psychiatric

Association, 1994) can cause substantial suffering and is an appropriate focus of palliative intervention.

The prevalence of significant anxiety in terminal illness is not well studied, but the available literature suggests it is very common, exceeding 70% by some patient self-reports (Portenoy et al., 1994; Breitbart et al., 1995). Rates of anxiety at the end of life increase with the presence and severity of concomitant physical illness.

The goals of palliative care cannot be achieved when the patient is overly anxious. Anxiety presents a barrier to relaxation and attention to important relationships, achievement of life goals, and integration of the experience of dying. Insomnia, depression, fatigue, difficulty swallowing, nausea, or other types of physical distress may result from anxiety. Such symptoms may be difficult to control without attending to comorbid anxiety.

Like depression, the prevalence of anxiety and anxiety disorders at the end of life, combined with the ready availability of effective treatments, makes anxiety an important focus of palliative care. In most cases, substantial anxiety is readily apparent or easily uncovered by simple questioning. Prior history of anxiety disorders should be explored and effective treatments documented. A differential diagnosis of the conditions that can cause or exacerbate anxiety in terminally ill patients is listed in Box 84.4. It is extremely important to evaluate the patient’s anxiety, agitation, and insomnia to determine if they are secondary to major depression or undertreated pain.

Treatment for anxiety in the terminally ill patient should be designed to provide rapid relief without placing excessive demands on the patient. Therefore, emotional support, aggressive treatment of comorbid anxiogenic physical symptoms (e.g. pain, nausea, dyspnea), reassurance (where appropriate), pastoral care support, and (in selected cases) individual or family psychotherapy may be of benefit. Specific fears (e.g., fears of dying, fears of unwanted medical interventions) should be explored and discussed. If major depression or poorly controlled pain is present, treatment with antidepressants and/or analgesics would take top priority.

Optimal relief from anxiety in terminal illness generally requires the use of anxiolytic drugs, as summarized in Table 84.2. However, a systematic review concluded that there is inadequate evidence to draw firm conclusions from the current literature about pharmacotherapy for anxiety in palliative care patients (Jackson & Lipman, 2004).

Benzodiazepines, particularly lorazepam, are the first-line pharmacological treatment for anxiety in terminal illness. Benzodiazepines remain reliably effective in this setting. Though their suppression of respiratory drive is a risk in the frail patient with advanced medical illness, these agents can be safely used in dying patients if carefully titrated. Concerns about side effects should not be allowed to interfere with the primary goal of relieving suffering in the dying patient.

Anxiolytic alternatives to benzodiazepines for terminally ill patients include low-dose antidepressants and, sometimes, low doses of antipsychotics (Rosenbaum et al., 1997; Breitbart et al., 1998; Block, 2006). The primary disadvantage of using antidepressants as anxiolytics in the setting of

terminal illness is the delay typically seen prior to the onset of therapeutic effect. Among the antidepressants, SSRIs and tricyclics, such as nortriptyline, are the most reliably effective for anxiety. Antipsychotic drugs, particularly atypical antipsychotics, are especially useful when the patient has cognitive disturbance, cannot tolerate sedation or suppression of respiratory drive from other anxiolytics, or cannot tolerate benzodiazepines (e.g., those who have exhibited disinhibition in response to prior trials of benzodiazepines). Medically ill patients are sensitive to the side effects of neuroleptics, so these drugs should be dosed conservatively for anxiety.

DELIRIUM

Confusional states are extremely common at the end of life, especially in the days and hours immediately preceding death. Rates of delirium range from 20% to nearly 50% in palliative care setting, and this rate increases to up to 90% in the hours or days before death (Conill et al., 1997; De Fabbro et al., 2006; Leonard et al., 2008). Delirium is, of course, more common in the presence of serious physical illness (Lipowski, 1990). (See also Chapter 31.)

Detection of delirium, particularly the agitated subtype, is generally straightforward in terminally ill patients. As many as one-third of cases of delirium seen in the terminally ill are reversible (Bruera et al., 1995; de Stoutz et al., 1995), but some cases are only manageable by intentional comfort sedation (Fainsinger et al., 1991; Stiefel et al., 1992; Shuster et al., 1998). Diligent serial assessment is the key to detection of delirium at the end of life. In all palliative care settings, between one-third and two-thirds of cases of delirium are misdiagnosed, detected late, or not detected at all (Leonard et al., 2008). Screening tools such as the Mini-Mental State Exam (Folstein et al., 1975), the Confusion Assessment Method (Inouye et al., 1990), or the Memorial Delirium Assessment Scale (Breitbart et al., 1997) can be useful aids.

Since delirium impairs cognition and the patient's ability to report symptoms with reliability, the suffering experienced during an episode of delirium is difficult to assess. On the other hand, the distress experienced by the family of an agitated, delirious patient is usually obvious. Family members, as well as patients who recover from an episode of delirium, commonly report that the experience is significantly distressing (Breitbart, Gibson, & Tremblay, 2002; Bruera et al., 2009; Grover & Shah, 2011). Family education, including an explanation of the process of delirium in layman's terms, a description of the planned interventions, and an explanation of how the symptoms of delirium are related to the underlying terminal illness, can provide great relief to the family. Obviously, reduction or elimination of agitation will also provide substantial relief.

Differential diagnosis of delirium is similar to that employed in the setting of acute illness (see Chapter 41), with a few differences in emphasis. Efforts should be focused on finding reversible causes of delirium, which in the setting of terminal illness are most commonly related to medication side effects (commonly opiates and antihistamines/anticholinergics), dehydration, infection, elevated intracranial pressure (ICP), and metabolic disturbances, such as hypercalcemia (Leonard et al., 2008). In the syndrome of opioid neurotoxicity, which includes delirium, myoclonus, allodynia, hyperalgesia, and seizures in extreme cases, treatment via opioid dose-reduction or opioid switching often results in significant improvement in delirium (de Stoutz et al., 1995). Withdrawal states always deserve consideration as possible causes of delirium at the end of life. In contrast to delirium in the setting of acute illness, terminal delirium is mostly gradual in onset, more likely to result from multiple etiological factors, and less likely to resolve (Breitbart et al., 1998).

Medications to treat delirium, once reversal of the underlying causes of the delirium has been addressed, are summarized in Table 84.3. As in the setting of acute illness, antipsychotic drugs are a primary treatment for delirium in terminal illness (Wise & Trzepacz, 1996; Breitbart et al., 1998; Leonard et al., 2008). The older antipsychotic drugs (e.g., haloperidol) have been accepted as effective treatments for delirium for many years. A butyrophenone agent, haloperidol has probably been used more than any other neuroleptic agent to treat delirium, and it remains a drug of choice due to its having few anticholinergic side effects, few active metabolites, and a small likelihood of sedation (de Fabbro et al., 2006; Markowitz & Narasimhan, 2008). Given their decreased risk of extrapyramidal side effects, atypical antipsychotics are frequently used for treatment of delirium. Although there are limited studies in terminal patients, delirium treatment studies have shown comparable efficacy of haloperidol, risperidone, and olanzapine, and there is increasing evidence about the benefit of quetiapine as well (Lonergan et al., 2007; Markowitz & Narashiman, 2008).

Benzodiazepines, especially lorazepam, are commonly used in the treatment of delirium, either alone or in combination with antipsychotics (Wise & Trzepacz, 1996; Trzepacz, 1996; Breitbart et al., 1998). In the setting of terminal illness, benzodiazepines may sometimes be more effective than

Box 84.4 DIFFERENTIAL DIAGNOSIS OF ANXIETY SYMPTOMS IN TERMINAL ILLNESS

Anxiety disorders (panic disorder, generalized anxiety disorder, posttraumatic stress disorder)
Adjustment disorder with anxiety
Coping/personality style (avoidant, dependent)
Delirium
Fear
Side effects from medications (akathisia from antipsychotics or antiemetics such as metoclopramide)
Spiritual/existential concerns
Undertreated pain
Other undertreated physical complications (dyspnea, sepsis)
Withdrawal states (opiates, sedatives)
Physiological abnormalities (hyperthyroidism, hypercalcemia)

Table 84.2 ANXIOLYTIC MEDICATIONS USED IN TERMINAL ILLNESS

GENERIC NAME	APPROXIMATE DAILY DOSAGE RANGE (MG)	ROUTE
BENZODIAZEPINES		
Very short-acting (parenteral) midazolam	10–60 per 24h	IV, SC, IM
Intermediate acting: alprazolam	0.25–2 tid-qid	PO, SL
oxazepam	10–15 tid-qid	PO
lorazepam	0.5–2 tid-qid	PO, SL, IV, IM
Intermediate acting: chlordiazepoxide	10–50 tid-qid	PO, IM
Long acting: diazepam	5–10 bid-qid	PO, IV, PR
clorazepate	7.5–15 bid-qid	PO
clonazepam	0.5–2 bid-qid	PO
NON-BENZODIAZAPINE		
(Delay of onset 2–3 weeks) buspirone	5–20 tid	PO
ANTIDEPRESSANTS		
Serotonin reuptake inhibitors (start with low doses): fluoxetine	10–80 daily	PO
paroxetine	10–60 daily	PO
sertraline	50–200 daily	PO
citalopram	20–40 daily	PO
TRICYCLIC ANTIDEPRESSANTS		
amitriptyline	10–150 daily	PO
disipramine	12.5–150 daily	PO, IM
doxepin**	12.5–150 daily	PO, PR
imipramine	12.5–150 daily	PO, IM
nortriptyline*	10–125 daily	PO
OTHERS		
mirtazapine	15–60 daily	PO
duloxetine	40–60 daily	PO
venlafaxine	75–375 daily	PO
ANTIPSYCHOTICS		
chlorpromazine	12.5–50 q4-12h	PO, IM, IV
haloperidol	0.5–5 q2-12h	IV, PO, IM
methotrimeprazine	10–20 q4-8h	SC, PO, IM
olanzapine	5–15 daily	PO
quetiapine	25–200 daily	PO
risperidone	1–3 daily	PO
thioridazine	10–125 daily	PO
ANTI-HISTAMINES		
hydroxyzine	25–50 q4-6h	PO, IV, SC

Key: PO = per oral; IM = intramuscular; PR = per rectum; IV = intravenous; SC = subcutaneous; SL = sublingual; bid = two times a day; tid = three times a day; qid = four times a day; q4–8h = every 4–8 hours. Parenteral doses are generally twice as potent as oral doses; intravenous bolus injections should be administered slowly.

*Tricyclic of choice.

**Per rectal administration of doxepin requires pharmacy preparation (Storey & Trumble, 1992).

Adapted from Breitbart et al., 1998; Shuster & Jones, 1998, with permission.

Table 84.3 MEDICATIONS USED FOR DELIRIUM IN TERMINAL ILLNESS

GENERIC NAME	APPROXIMATE DAILY DOSAGE RANGE (MG)	ROUTE
NEUROLEPTICS		
haloperidol	0.5–5 q2–12h	PO, IV, SC, IM
thioridazine	10–75 q4–8h	PO
chlorpromazine	12.5–50 q4–12h	PO, IV, IM
methotrimeprazine	12.5–50 q4–8h	IV, SC, PO
ATYPICAL ANTIPSYCHOTICS		
risperidone	1 daily–3 bid	PO
olanzapine	5–10 daily	PO
quetiapine	25–200 daily	PO
BENZODIAZEPINES		
lorazepam*	0.5–2.0 q1–4h	PO, IV, IM
midazolam*	30–100 per 24h	IV, SC, IM
OPIATES*		
	(Doses vary)	PO, IV, SC

*Denotes a drug used primarily for purposes of sedation when indicated for treatment of delirium.

Parenteral doses are generally twice as potent as oral doses. IV—intravenous infusions or bolus injections should be administered slowly; IM—intramuscular injections should be avoided if repeated use becomes necessary; PO—oral forms of medication are preferred; or SC—subcutaneous infusions are generally accepted modes of drug administration in the terminally ill.

Adapted with permission from Breitbart et al., 1998.

neuroleptics, in contrast to delirium associated with more acute illness (Breitbart et al., 1998), but are more likely to reduce agitation by means of sedation and less likely to restore cognitive functioning and meaningful communication with family.

Sedation may be required to control the agitation of delirium in the last few hours to days of life (Bruera et al., 1987; Breitbart et al., 1998). When applied as an intervention of last resort for a delirious, dying patient who is agitated and appears to be suffering, so-called palliative sedation is the standard of care, and is neither euthanasia nor assisted suicide (Shuster et al., 1998; deGraeff & Dean, 2007). In fact, there is accumulating evidence that, when provided to relieve refractory symptoms in patients who are actively dying, palliative sedation does not shorten survival (Sykes and Thorns, 2003; Maltoni et al., 2009). The sedation is therapeutically calming and comforting, allowing the patient to die peacefully of the underlying disease.

It is possible that earlier and more aggressive intervention for evolving confusional states might avoid severe delirium at the end of life. However, once severe, treatment-refractory terminal delirium develops, failure to act therapeutically exposes the patient to unnecessary suffering and greatly increases the burden on the family, who must witness such agitation as

death approaches. Infusions of benzodiazepines (e.g., lorazepam, midazolam) or opiates can serve this purpose.

DEPRESSION AND GRIEF

Bereavement, as defined by Parkes (1998), is the situation of anyone who has lost a person to whom one is attached. *Grief* is a set of psychological and emotional reactions to bereavement. *Mourning* is the social face of grief. Bereavement and grief may emerge after an actual loss or as anticipatory grief as the threatened loss approaches. Grief and bereavement may be seen in the terminally ill patient, family, and friends, or their professional caregivers. “Normal” grief has a very broad range—individual variation is the rule. Grief is not itself a mental disorder or pathological state—*Bereavement* is a “V code” in the DSM classification system, the category for conditions that are not mental disorders yet are still commonly the focus of clinical attention. Most people navigate their grief without professional help and do well. Still, not all reactions to bereavement and loss are “normal” in the sense that they are not all adaptive.

The five stages of grief (Kubler-Ross, 1969) have been helpful in introducing the concept of grief as a process and are interesting from a historical perspective, but they should not be viewed as a reliable and universal pattern for grieving. Individuals move in and out of theorized grief stages, often changing stages out of sequence, skipping stages altogether, or returning to deal further with an earlier stage. It is more helpful to think of grief as a process that begins with a period of disruption (characterized by intense sadness, crying, preoccupation with the deceased, diminished interest and concentration) that proceeds toward gradual resolution of these features of acute grief and moves toward integration of the loss (Zisook & Shear, 2009).

The symptoms of acute grief may be misinterpreted as signs of significant psychopathology. Tearfulness, emotional numbing, pangs of grief, searching for the lost person, feeling that the death did not actually happen, or brief non-delusional hallucinations of the deceased are all within the normal range of grief experiences (Rando, 1984; Corr & Doka, 1994; Parkes, 1998). While there are no reliable general rules about the time range for the resolution of normal grief, these acute reactions should lessen and generally resolve over time (Rando, 1984; Corr & Doka, 1994; Parkes, 1998). Complications may occur if the grieving process is avoided, inhibited, delayed, or conflicted (Rando, 1984; Corr & Doka, 1994; Parkes, 1998; Brown & Stoudemire, 1983).

The stress of grief may precipitate a formal psychiatric disorder, such as major depression, panic disorder, or alcohol dependence. These conditions add greatly to suffering and should be treated aggressively, especially since formal mental disorders complicating bereavement tend to persist and adversely affect quality of life and the grief process for months (Zisook & Shuchter, 1991, 1992).

Since the normal range of grief covers such a broad territory and some of the acute symptoms mimic formal mental disorders, distinguishing pathological grief from normal grief can be a formidable challenge. Still, there are some

reliable indicators of pathological grief. Suicidal ideation or self-loathing are not components of normal grief and should be interpreted as indicators of pathology. A high level of grief-related distress, but not depression, was more closely associated with a wish to die among a group of patients with advanced cancer (Jacobsen et al., 2010). Failure to progress toward integration of grief over time, persistent symptoms of acute grief, persistent social withdrawal, or prolonged disruption of interpersonal, social, or occupational functioning merit assessment. Generally, any grief that prevents the bereaved person from maintaining a desired level of functioning merits attention, especially given the principles of palliative care.

Bereavement-associated depression is an important complication to recognize and treat. Though bereavement is the only life event that is listed as an exclusionary criterion for the diagnosis of a major depressive episode (MDE), there is emerging evidence that this exclusion may need to be reconsidered (Zisook & Shear, 2009; Zisook et al., 2010). In a population-based study, depression in bereaved individuals compared to the non-bereaved depressed demonstrated a similar symptom profile and presentation, but there was a longer episode duration among bereaved persons with depression (Karam et al., 2009). A case-control study of 17,988 depressed patients found that 8.5% would have not qualified for MDE by DSM due to bereavement. These “excluded” patients were more severely depressed than controls (depressed patients without bereavement) and more likely to express suicidal ideation or worthlessness (Corruble et al., 2009). Many mostly open-label trials have demonstrated that antidepressants (including desipramine, nortriptyline, paroxetine, bupropion, sertraline, escitalopram, and duloxetine) are effective for bereavement-related depression (Jacobs, Nelson, & Zisook, 1987; Pasternak et al., 1991; Zygmunt et al., 1998; Reynolds et al., 1999; Zisook et al., 2001; Oakley et al., 2002; Simon, Thompson, Pollack, & Shear, 2007; Hensley, Slonimski, Uhlenhuth, & Clayton, 2009).

There is growing evidence to support a proposed new diagnostic category for *complicated bereavement* or *prolonged grief disorder* (Lichtenthal et al., 2004; Zhang, Jawahri, & Prigerson, 2006; Prigerson et al., 2009; Zisook et al., 2010; Shear et al., 2011). This syndrome is characterized by a variety of manifestations of a failure to integrate the loss of the deceased loved one “over time” (defined as at least six months). Individuals with complicated grief demonstrate continued severe separation distress, with some of the following features: yearning, refusal to accept the death, compulsions to seek tangible reminders of the deceased. Individuals with *complicated grief* also characteristically have a variety of persistently distressing thoughts and behaviors about the deceased, including rumination about the death, emotional/physiological reactivity to reminders, or a belief that joy and satisfaction are no longer possible (Prigerson et al., 2009; Zisook et al., 2010). A substantial minority of the bereaved meet these criteria, and complicated grief/prolonged grief disorder can be differentiated from adaptive grief, MDD, and PTSD (American Psychiatric Association, 1994; Kim & Jacobs, 1991; Prigerson et al., 1995; 1996; Horowitz et al., 1997; Zhang et al., 2009;

Prigerson et al., 2009; Zisook et al., 2010; Shear et al., 2011). Furthermore, a specific therapy (complicated grief therapy) has been developed and tested (Shear et al., 2005). Even if complicated bereavement is a distinct entity, there is a large degree of overlap or comorbidity with mood disorders and anxiety disorders. For example, previous histories of mental disorder, especially depression, predict complicated bereavement, as does family conflict or a maladaptive pattern of conflict resolution (Kim & Jacobs, 1991; Kissane et al., 1996).

All who grieve are not alike. There are important cultural and religious differences in responses and adaptations to grief and loss, as well as differences in death and funeral rituals. Grief responses vary in part due to differences in gender, overall coping style, degree of perceived social support, physical and mental health, and the age of the grieving person. Children, in particular, have variable responses to loss, since understanding of loss and response to bereavement are strongly influenced by a child’s state of cognitive and emotional development.

Intuitively, the best and most effective interventions to assist in the bereavement process should begin before the death of the patient. Effective symptom control, patient and family education, and achievement of the goals of palliative care and hospice in preparation for the patient’s death not only ease the burden of caring for a dying relative but ease the burden of grief and bereavement as well (Chentsova-Dutton et al., 2002; Barry et al., 2002; Wright et al., 2010).

Apart from the specialized care a psychiatrist can provide, a few basic interventions by the doctor are almost always helpful. In addition to providing excellent palliative care before the patient’s death, the physician should meet with the family during the patient’s terminal illness and after the patient’s death to offer support, condolences, and answers to questions. The physician is in an excellent position to educate families about grief and the grieving process, thus potentially preventing some cases of complicated or unresolved bereavement. When complicated bereavement occurs, physicians who do not provide treatment for such conditions should know how to refer the person to community bereavement-care resources.

DEPRESSION AND ASSISTED DYING

There is a limited literature that provides some insight into the mental state of patients considering death-hastening decisions. While much has been said about euthanasia and physician-assisted suicide, the contribution of mental health professionals to this debate has also been limited. Yet, it could be argued that, as a special case of suicide, mental health concerns represent a basic consideration in approaching the issue of assisted dying.

Relatively few studies have actually examined the clinical relationship between a desire for death and depression. Yet depression is a critical consideration in discussions of cancer suicide and death-hastening requests, given that it is thought to place patients at up to 25 times the risk of completed suicide compared to the general population (Guze & Robins, 1970).

One of the first studies to broach this topic reported that 10 of 44 patients in a palliative care facility endorsed a desire for hastened death (Brown et al., 1986). Of those ten patients, all were reported to have concomitant clinical depression. This indicates that maintaining a high clinical index of suspicion for depression in patients making death-hastening requests is critical, and in fact, a review of depression-screening tools included this type of request as an indicator of the need for more complete depression screening (Lloyd-Williams et al., 2003). A study of 200 terminally ill patients, recruited from a palliative care facility, reported that 44.5% acknowledged at least a fleeting desire for an early death (Chochinov et al., 1995). In most instances these episodes were brief and did not reflect a sustained or committed desire, as would be required in a death-hastening decision. However, 8.5% of the study group reported a persistent, genuine desire for an early death. The prevalence of clinical depression in this group was significantly higher than among patients without a desire for death (58.8% versus 7.7%). The prevalence of pain, which was of moderate severity or greater, was higher among patients with a desire for death (76.5%) compared to patients without a desire for death (46.2%). In a logistic regression model of these data, depression entered as the only significant predictor of a genuine desire for death. Therefore, the importance of depression in discussions pertaining to assisted suicide cannot be overstated.

While attending to pain and physical sources of symptom distress remains critical, such data indicate that death-hastening requests appear to be largely psychologically mediated. In addition to motivation from an underlying depressive disorder, other psychological and social factors play a role in patients' interest in assisted suicide. In the above study of 200 terminally ill patients, patients' perceived level of social support was lower in the "desire for death" group compared to the remainder of the study group (Chochinov et al., 1995). Similarly, Breitbart and colleagues (1996) found that among autoimmune-deficiency syndrome (AIDS) patients, interest in assisted suicide appeared to be more a function of psychological and social factors (i.e., depression, lack of social support, and fears of becoming a burden to one's friends) rather than physical factors such as pain, symptom distress, and disease status.

Of additional importance, in the study by Chochinov et al. (1995), of the 17 patients who had originally endorsed a desire for hastened death, only six were available to be re-interviewed two weeks later. The others had either died, become too ill to participate, or had opted for discharge to home care. Of these six patients, four had essentially changed their minds. Thus, the evaluation of death-hastening requests must include a heightened awareness of the extent to which these requests may fluctuate over time and perhaps resolve, with some of that fluctuation likely to be secondary to changes in underlying depressive symptoms.

In a recent review of the prevalence of depression in granted and refused requests for euthanasia and physician-assisted suicide, Levene and Parker (2011) found that most studies estimated that a quarter to a half of

requests for a hastened death came from depressed patients. Among the higher quality studies, there was conflicting evidence regarding the difference, or lack of significant difference, in the depression rate between groups with death-hastening requests and similar patients who did not make such a request. They identified a few high- and medium-quality studies that compared rates of depression in those with death-hastening requests, those who did not, and those with completed requests. These studies provide convincing evidence to show that depression is a significant factor in deciding whether to refuse death-hastening requests (Ruijs, Kerkhof, van der Wal, & Onwuteaka-Philipsen, 2011; Jansen-van der Weide, Onwuteaka-Philipsen, & van der Wal, 2005; Haverkate et al., 2005; Groenewoud et al., 2004), but the rate of depression in completed euthanasia or physician-assisted suicide cases is not significantly different from the overall rate in comparison populations of seriously ill patients (Ruijs et al., 2011; Maessen et al., 2009; Georges et al., 2005).

The discussion of depression rates in patients making requests to hasten death prompts the question "Does treatment of depression result in changed desire regarding those requests?" Studies in elderly depressed patients have shown an increased acceptance and desire for life-sustaining medical therapies following treatment of depression (Hooper et al., 1997; Hooper et al., 1996; Ganzini et al., 1994). The patients with the most significant treatment effect had initially been the most severely depressed and subsequently were initially more hopeless and likely to overestimate the risks and underestimate the benefits of treatment (Ganzini et al., 1994). In a group of patients with advanced AIDS, desire for death was highly associated with depression, and response to antidepressant therapy was associated with a reduction in desire for hastened death (Breitbart et al., 2010). Further studies are needed to explore whether this treatment effect exists only in severely depressed patients and to determine if this effect is stable across varying severe underlying illnesses. However, this suggests that decisions about life-sustaining therapy, especially among the severely depressed, should be discouraged until after effective treatment of their depression.

An additional issue that arises from this discussion of depression among patients with death-hastening requests is whether depression should exclude a patient from having a request for euthanasia or physician-assisted suicide granted. As noted above, although many requests by depressed patients were not granted, and rates of depression in patients with granted requests compared to the surrounding population of severely ill patients were similar, patients with depression did have their requests granted. This reality has raised some concern about whether those with depression have capacity to make such a request, but in reality, most patients with depression maintain the capacity to make medical decisions (Grisso & Applebaum, 1995). This suggests a need for assessment that is able to identify the patients whose desire for hastened death is motivated by depression, not just those in whom depression is present. This assessment, however, is no easy

task, as noted in a study of Oregon psychiatrists by Ganzini et al. (1996) in which only 6% of psychiatrists felt they would be able to assess in a single evaluation whether psychiatric factors were affecting a patient's request for assisted suicide. The approach and feasibility of conducting this type of evaluation requires ongoing discussion.

Given the challenges and uncertainties discussed above, requests for a hastened death tend to engender anxiety and uncertainty in healthcare providers. The following are clinical guidelines, which care providers may wish to consider in evaluating death-hastening requests:

1. *Treating depression.* Patients who are effectively treated for their depression often relinquish their desire for death and recover the capacity for enjoyment. Successful treatment often improves energy, sleep, and appetite, and renews their ability to find meaning in life despite impending death.
2. *Attending to symptom distress.* The ability to skillfully attend to distressing symptoms demonstrates to the patient that dying need not be accompanied by unnecessary distress. Aggressive, skillful, and compassionate palliative care, particularly pain and other symptom control, must be made available to all patients approaching the end of life.
3. *Providing continuity of care.* Maintaining contact with patients accomplishes several critical tasks. It ensures that patients will be continually reevaluated, given the temporal fluctuations in "desire for death" and oftentimes accompanying symptom distress. It also provides reassurance to patients that they will not be abandoned and that care will be forthcoming and available throughout their terminal course.
4. *Establishing therapeutic dialogue.* Patients need to be given permission—implicit or explicit—to discuss their fears, concerns, or wishes, even if they include the wish for hastened death. Inviting such a dialogue will decrease their sense of isolation, allow them an opportunity to explore concerns, and show that no topic is so sensitive as to preclude its discussion. These discussions can provide an opportunity to give reassurance when the wish for hastened death is spawned by concerns about remediable sources of suffering (e.g., depression, pain, or dyspnea).
5. *Exploring the underlying meaning of death-hastening requests.* It is critical to understand what is behind the patient's request. How do patients view their future? What are their values? Does the family understand or know about their requests? Is there any aspect of the life of the patient that he or she experiences as being meaningful? Are they concerned about being an undue financial or care burden on their family? Is there family conflict that contributes to the request?
6. *Evaluating decision-making capacity.* It is critical to ensure the following: (a) that the patient's mental processes are unimpaired by psychiatric illness, cognitive impairment,

or severe emotional distress (which might result in an impulsive request, which quickly changes with circumstances); (b) that the patient has a realistic assessment of his or her situation; and (c) that the motives for the decision are understandable to other observers.

7. *Bolstering social support.* It is important to mobilize as much support for the patient as possible. Involving close family members or friends is very helpful. Ultimately, the physician must take sufficient time to understand the patient's wishes.
8. *Seeking out consultation.* Death-hastening requests are among the most demanding of clinical situations healthcare providers face. However, in a national survey, only 2% of physicians reported having sought psychiatric consultation for patients requesting assistance in dying. Seeking out a second opinion may provide additional options and expertise, or, at the very least, support for the care provider grappling with the demands of a death-hastening request (Meier et al., 1998).
9. *Maintaining a clinical stance.* Rather than becoming overly focused on moral and legal issues, it is critical for the physician to remain attuned to the clinical challenges that such requests invariably present. Preoccupation with whether the patient has the "right to assisted suicide" can sometimes interfere with attending to clinical needs and can create an unnecessary standoff between the patient and physician.

Emanuel (1998) described an eight-step approach to assessing requests for assisted suicide. She described assessment and treatment of depression as the initial step in such an evaluation. Subsequent steps are assessment for decision-making capacity, discussion of advance care planning, assessment and treatment of root causes of the request, providing full information about assisted suicide and attempting to dissuade the patient, seeking consultation, reviewing adherence to the agreed-upon care plan and searching for unwanted interventions, and, finally, in her practice, declining to provide assisted suicide if the request persists. By paying strict attention to the uncontroversial principles of freedom from unwanted intervention and the physician's obligation to provide suffering patients with comfort care, Emanuel proposed that such an approach would respond appropriately to the despair underlying death-hastening requests by terminally ill patients. However, Emanuel's approach has been criticized as unrealistic, burdensome, and more helpful to physicians than to patients (Back, 1999; Ganzini & Sullivan, 1999). While such guidelines do not theoretically resolve whether physician-assisted suicide is morally justifiable, they nevertheless highlight the clinical imperatives that must be considered in these situations. The goal is, ultimately, to help patients attain as much comfort as possible, so they might examine their own personal circumstances, shape their death, and live the remainder of their life with as much grace, dignity, and meaning as possible.

CLINICAL PEARLS

- Every patient dreads hearing the words “There’s nothing more I can do for you.” Letting the patient and family know (by both words and actions) that they will not be expected to face the end of life alone is a great comfort. Seldom is the doctor–patient relationship more important.
- Dealing directly and confrontationally with family conflicts should occur if there is reasonable expectation of benefit from such an intervention.
- The periodic respite care integral to the Medicare Hospice Benefit can contribute to the preservation of a comforting home environment.
- Physicians should ask first about suffering in a general way (e.g., “What causes you to suffer most?”). The experience of suffering is unique to each individual.
- When breaking bad news to a patient, care should be taken to be gentle but clear. . . . The physician should be seated . . . and should ensure adequate privacy after determining whom the patient would like to have present for the discussion. The physician should next determine what patients already know about their condition and what details they would like to receive about their prognosis.
- Some patients are burdened by excessive detail or even a direct statement of their poor prognosis; their preference “not to know” should be respected and a suitable proxy identified.
- Despite the long history of the use of stimulants for depression in the medically ill, there are limited formal studies to support their use as antidepressants, but the available evidence suggests efficacy with stronger evidence for tolerability (Hardy, 2009).
- Though most patients with terminal illnesses may be unable to tolerate extensive psychotherapeutic interventions for depressive symptoms, a variety of psychotherapies can be modified for use in the care of terminally ill patients and their families.
- Diligent serial assessment is the key to detection of delirium at the end of life.
- Opioid dose reduction or opioid switching often results in significant improvement in delirium for the syndrome of opioid neurotoxicity (delirium, myoclonus, allodynia, hyperalgesia, and seizures) (de Stoutz et al., 1995).
- The physician is in an excellent position to educate families about grief and the grieving process, thus potentially preventing some cases of complicated or unresolved bereavement.

CAPACITY, COMPETENCY AND CONSENT IN MEDICAL PSYCHIATRY

Barry S. Fogel

INTRODUCTION

In inpatient settings, medical psychiatrists often are called on to assess patients' decision-making capacity, usually in connection with their ability to choose or refuse a treatment or procedure. A survey of medical psychiatrists found that one in six general hospital psychiatry consultations involved the assessment of a patient's decision-making capacity (Seyfried et al., 2013). In outpatient settings, questions often concern issues such as the ability to drive a car safely, to handle one's own finances, or to make or change a will. The psychiatrist's assessment of capacity may be sufficient to convince other physicians—or the psychiatrist him/herself—that a patient's decision regarding treatment should be honored or that a patient's driving or financial decisions should not be questioned. When assessments suggest that a patient's capacity is insufficient, legal mechanisms are triggered, which can be as simple as triggering the application of a durable power of attorney or the activation of a health-care proxy, or as complex as a formal hearing on competency and the appointment of a legal guardian or conservator if the patient is found to be incompetent. In the last situation, the psychiatrist provides input to a process that involves at a minimum a lawyer and a judge, and at most a full-scale adversarial proceeding with different parties represented by counsel. The psychiatrist in that case may be identified as an expert for one side in a dispute. Fortunately, most cases related to diminished capacity due to medical conditions affecting brain function do not entail a full-scale legal process; if they did, it is hard to see how timely interventions could be made in acute care.

A theme of this book is that as the organization and context of healthcare change, so does the practice of medical psychiatry. The psychiatric literature on capacity, competency, and consent historically has focused on issues such as the right to refuse psychiatric treatment, including hospitalization, antipsychotic drugs, and electroconvulsive therapy (ECT), the criminal responsibility of people with chronic mental illness, and conditions for involuntary psychiatric treatment. The corresponding issues in general hospital psychiatry have related to such matters as competency to consent to a risky treatment or to refuse a usual treatment, competency to consent to participate in research, competency to

opt for palliative care and decline more active but potentially futile treatments, and mental status considerations in the execution of advance directives. The issues that have become more salient in recent years relate to the long-term course of chronic diseases that affect brain functioning, especially the dementias and other neurodegenerative conditions, but also including the late effects of traumatic brain injury. In these conditions, the loss of decision-making capacity or other functional capacities can be gradual and progressive, partial and persistent, or episodic. Capacities lost range from occupational competence and appropriate financial decision-making to maintenance of one's living space, safe use of medication, and safe driving. Bad decisions or inappropriate behavior due to lost capacities can have devastating consequences for patients and for other people as well, yet binary formal legal determinations of competency do not match the specificity and nuance of patients' actual situations. Optimal solutions can require the ongoing involvement of a clinician such as a medical psychiatrist with awareness and consideration of the patient's brain, mind, social context, and personal narrative. Ideal solutions are proactive, anticipating issues and preventing crises.

This chapter is intended to be a point of departure for clinicians involved in caring for patients with current or anticipated impairments in decision-making capacity. Its emphasis is necessarily clinical, as legal details will vary by venue; within the United States, state laws differ greatly, and some other countries' legal systems have procedures very different from those of the United States.

LEGAL AND ETHICAL CONCEPTS

All of the concepts described below are described specifically as they apply in a medical context. Non-medical applications, such as the legal definition of consent to a sexual act, are beyond the scope of this chapter. The interpretation of these legal concepts can vary by jurisdiction; the clinician should know the locally applicable version of each. Underlying legal differences between U.S. states and even more between countries reflect cultural differences; for example, in the perception of the value of life, which can be seen primarily as intrinsic, instrumental, or self-determined. Likewise, countries differ

in the relative value they give to a patient's autonomy when it is in conflict with his or her best interests (Jox et al., 2013).

CAPACITY AND COMPETENCY

A person's capacity to make a decision or perform an act comprises willingness to do it and the ability to accomplish its purpose. Capacity can be normal, diminished or absent. Incapacity can refer to "can't," "won't," or a combination of the two: A person has equally diminished capacity to cross a street safely if he cannot see the oncoming traffic or if he will not look.

Competency refers to a legal determination that the action of a person—such as signing a contract, making a will, or consenting to a surgical procedure—should be regarded as the valid act of a person who is of legal age and has sufficient capacity to perform the action in his or her own interest. Adults are presumed to be competent unless there is affirmative determination that they are not.

CONSENT

In the medical context, *consent* is a specific, affirmative act in which a person agrees to an action by a healthcare provider. The affirmative act of consent typically is a signature on a form, but a signature alone is neither necessary nor sufficient. A signature given by a patient who does not understand what they are signing is not valid consent, while a verbal "yes" or even a nod of the head can be valid consent if the patient is fully aware of what he or she is agreeing to and has signaled agreement after due consideration. Consent given verbally or by gesture must be carefully documented. In high-stakes situations, a video recording may be useful in establishing that consent was fully informed and freely given.

ASSENT, COMPLIANCE, AND ADHERENCE

Assent is a patient's permitting an action by a healthcare provider without explicitly and affirmatively consenting to it. For example, a patient holding out her arm for a phlebotomist, who then takes the blood sample to the laboratory, is assenting to the drawing of blood and to the communication of blood test results to healthcare providers involved in her care.

Compliance, a medical term and not a legal one, refers to doing what a healthcare provider has suggested, recommended, or ordered: one can comply or not with positive directions like taking a medication or negative ones like not smoking. *Adherence* (to a plan of treatment) is a softer concept with a similar meaning: a patient *complies* with orders but *adheres* to a recommended plan.

Refusal is an affirmative statement by a patient that he or she does not wish a healthcare provider to do a specific thing, such as perform a procedure or share certain information, or an affirmative statement that he or she will not comply with a particular clinical directive. Examples are refusing to release psychiatric records to a general medical physician, or refusing to take a prescribed antipsychotic drug.

Resistance to care is a patient's actively not allowing a healthcare provider to do something the provider is attempting to do; for example, a patient not permitting a nurse to give him or her a bath, or actively pulling out an intravenous line just after it has been placed. Resistance to care may be—but is not necessarily—associated with refusal of treatment.

NON-COMPLIANCE AND NON-ADHERENCE

Non-compliance or *non-adherence* refers to a patient's not doing what a healthcare provider has directed; such as not taking prescribed medication. Non-compliance can be either passive or active, depending on whether the direction required taking an action or refraining from one—but it does not include an explicit, affirmative rejection of the clinical prescription.

People with cognitive dysfunction or psychotic ambivalence can—and frequently do—consent to treatment but do not comply with clinical directives; or refuse treatment but assent to care. Psychiatrists sometimes need to explain these phenomena to legal personnel unfamiliar with neuropsychiatric disorders.

IMPLIED CONSENT

Implied consent is the legal doctrine that in an emergency situation, a physician or other healthcare provider has a right to perform treatment without the explicit consent of a patient or a legal substitute. A medical emergency is an occasion for implied consent if the patient does not have the capacity to give consent because of impairment in consciousness, cognition, or communication; no authorized surrogate decision-maker is immediately available; and delay in action has a significant likelihood of causing serious harm to the patient. For example, a physician has implied consent to treat a patient who is exsanguinating without looking for someone to sign a consent form. A subtler point is that physicians can reasonably assert they have implied consent to immediately begin diagnostic and treatment interventions when patients present with new-onset delirium of unknown cause, as potential causes include conditions like electrolyte disturbances, severe hypoglycemia, or sepsis that could threaten life or could cause significant brain damage if not promptly treated. Note that implied consent to emergency treatment does not extend to follow-up treatment once the patient is out of danger. And, in the situation where a patient was near the end of life and had opted to decline life-saving treatment via a living will, implied consent would end once the physician knew there was a valid advance directive.

LEGAL STATUS OF THE NEXT OF KIN

In a true emergency situation, when significant injury could result from a delay in treatment, physicians are empowered to act in the best interest of the patient. If a proxy decision-maker was selected by the patient in advance of the emergency, that individual's consent should be sought and his or her (competent) refusal should be honored, but treatment

should not be delayed if the proxy decision-maker cannot readily be contacted. If no proxy was nominated by the patient prior to the emergency, the patient's next of kin does not have an automatic legal right to overrule a physician's judgment that a particular treatment should be given (Simpson, 2011).

CATEGORIES OF AGENTS

The law, with variation in detail between jurisdictions, recognizes various kinds of agents or surrogate decision-makers invested with the authority and responsibility to make decisions and commitments on behalf of another individual. Importantly, authority and responsibility are linked: patients' agents and surrogate decision-makers are not only empowered to act on their behalf, but they are expected to do so, reliably and honestly.

Guardians and *conservators* are individuals invested via a legal procedure involving a judge with the authority and responsibility to make decisions on behalf of a person who is incompetent or incapacitated. Guardianship can be limited to healthcare decisions or can cover a broader scope, including decisions about finances and living arrangements. Conservatorship is a similar legally sanctioned relationship of authority and responsibility, limited to financial affairs only.

Trustees are individuals with legal authority and responsibility for the management and disposition of trusts—entities that own and control financial assets. Trustees' powers and responsibilities are described in trust documents—instruments set up by trustors, who transfer assets to the trust and specify how and by whom they are to be invested and for whom and for what purposes they are to be spent. In many trusts, the trustor is also the trustee until the trustor dies or becomes incapacitated, at which point a successor trustee takes over.

Attorneys-in-fact are agents empowered to represent an individual in business-related transactions. The powers of an attorney-in-fact are specified in a document known as a *power of attorney*. Powers of attorney can be general, covering all of an individual's personal business; or limited to specific purposes like paying a person's bills or signing documents related to a real estate transaction. A person must be competent in order to sign a valid power of attorney, and ordinary powers of attorney terminate when the person granting them becomes incompetent. A *durable power of attorney* (DPoA) persists even if the person granting it becomes incompetent; typically, it is designed to go into effect only if the grantor is incapacitated, and to cease if and when the grantor regains the capacity to make valid decisions. A durable power of attorney for healthcare, or *healthcare proxy*, is a specialized power of attorney that grants a designated person authority and responsibility for making healthcare decisions if and when the grantor is incapable of making such decisions for him/herself.

Validity of a DPoA requires adequate decision-making capacity *at the time the DPoA is signed*. When there is much at stake, when the motives or judgment of the attorney-in-fact are questionable, when there is dissent or contention in the family, or when the patient's cognitive function is

unstable, a medical evaluation (ideally a medical-psychiatric one) of decision-making capacity should be done contemporaneously with the execution of the DPoA. Prevention of conflict and litigation justifies the added inconvenience and expense of scheduling the medical and legal appointments close together on the same day—or even at the same time (Lui et al., 2014).

The *activation* of a DPoA or the empowerment of a successor trustee requires a signed statement by the patient's physician—and in some jurisdictions, the concurring opinion of a second physician—that the patient is incapacitated and unable to make valid decisions. Return of decision-making authority to the patient would similarly require a signed physician's statement. In contrast to the appointment of a guardian or conservator, the empowerment of attorneys-in-fact, healthcare agents (proxies), and successor trustees does not require judicial action, and it is reversible without judicial action if and when the patient recovers capacity. This fact, and the flexibility and specificity of such arrangements, makes them much preferable to guardianships for dealing with illness-related changes in decision-making capacity.

ADVANCE DIRECTIVES

Advance directives are formal statements by individuals about how they would like to be treated under certain medical circumstances in which they would be unable to make or express a decision regarding their healthcare; for example, how they would like to be treated if they entered an irreversible coma. These directives often are accompanied by a statement of whom the person nominates to be his or her agent to give or withhold consent to treatment in such circumstances; i.e., a surrogate decision-maker. Advance directives *only* apply if a person is unable to make and communicate healthcare-related preferences at the time; they can be overridden at any time by the person who signed the advance directive. A *living will* is a form of advance directive that in some jurisdictions is legally binding on clinicians; in other jurisdictions, a living will offers non-binding guidance to the surrogate decision-maker.

Health care proxies are documents in which an individual designates an agent to make healthcare decisions on his/her behalf if he/she is unable to make such decisions personally. The *agent* designated in a healthcare proxy (sometimes also referred to as a healthcare proxy) has decision-making authority only concerning the patient's health care; the agent does not have the authority to make financial or business decisions on the patient's behalf. A patient can have the capacity to execute a valid healthcare proxy even though he or she does not have the capacity to make a competent decision about medical treatment itself (Dunn & Alici, 2013). The criteria for the capacity to select a surrogate decision-maker are not defined by law or published consensus, but at the minimum, a patient should know the nature of the decision being made, and the surrogate should be appropriate—that is, someone who could reasonably be expected to have adequate decision-making capacity and to act either according to the patient's previously expressed wishes or according to the patient's best interests.

Advance directives typically discuss if and when life-sustaining treatments are to be withheld, in relation to the severity of the patient's impairments, the prognosis, and the intensity of intervention(s) necessary to keep the patient alive. Advance directives cannot possibly anticipate all medical circumstances, so they work best when there is also a healthcare proxy who knows the patient well and can adequately represent what the patient would want in various circumstances. When the exact circumstances of the patient are not described in the advance directives, the healthcare proxy must make a judgment based on what they think the patient would have wanted, all things considered. It is useful if the proxy knows how much leeway the patient would have wanted him or her to have in adapting the advance directive to current unforeseen circumstances.

One drawback of typical advance directives is that they focus on only the most severe and hopeless situations—and neither patients, nor families, nor physicians easily give up all hope. For example, Teno et al. (1998), in recounting qualitative aspects of a study of end-of-life decision-making, described how a physician told a patient she had a 25% chance of survival, when in fact her predicted six-month survival using a validated model was less than one percent. Advance directives tend to focus on the very end of life, and rarely deal with the circumstances under which a patient might choose hospice care and forgo continued aggressive medical treatment, as opposed to forgoing life-sustaining treatments in the narrow sense. Yet, by the time that a patient's prognosis is obviously terminal, the patient might lack the capacity to make that choice.

For a patient's living will to be valid, he or she must be competent when it is signed, he or she must fully understand the issues involved; and he/she must be free of undue influence. The treating physician may not be the legal witness for the document. Many jurisdictions do not permit the treating physician to be a patient's healthcare proxy, and in any case it is not advisable.

Because patients and physicians cannot foresee or describe every potential clinical situation that might occur, advance directives should include the nomination of a surrogate decision-maker, and ideally they will indicate how much leeway the surrogate decision-maker has to deviate from the explicit directives if doing so appears to be in the patient's best interest. Smith et al. (2013) commented on the conflict that can occur between an advance directive and the patient's best interests, not because the advance directive was poorly conceived, but because the precise circumstances of the patient are different in important ways from those envisioned when the advance directive was written. For example, one can conceive of situations in which "comfort care" could conceivably involve surgery, as when failure to surgically stabilize a broken bone would cause continual pain and greatly decreased mobility. Smith and colleagues propose consideration of five points:

1. Is the clinical situation an emergency?
2. In view of the patient's values and goals, how likely is it that the benefits of the intervention will outweigh the burdens?

3. How well does the advance directive fit the situation at hand?
4. How much leeway did the patient allow the surrogate for overriding the advance directive?
5. How well does the surrogate represent the patient's best interests?

The idea that advance directives should have built-in leeway is supported by the work of Imhof et al. (2011), who interviewed 40 physicians and 52 nurses in Swiss acute-care hospitals on their views on the process of making "do not attempt resuscitation" (DNR) decisions. In Switzerland, patients' advance directives are not legally binding. Physicians and nurses nonetheless greatly valued them and expressed the wish that more patients had them. For most of those interviewed, the ideal process for soliciting advance directives was a dialogue between a senior physician and the patient, and the ideal process for actually deciding on a DNR order was a consensus-building process involving physicians, nurses, the patient, and the patient's family. Implicit in this process is the idea that changing circumstances may require modifying or superseding an existing advance directive. In the intensive care unit (ICU) environment, disagreements between attending physicians and surrogate decision-makers are common: resolving them often requires not only dialogue, but also enough time for the surrogate to come to terms emotionally with the patient's diagnosis and prognosis (Brush et al., 2012).

A group of medical ethicists at Indiana University conducted in-depth interviews with 35 surrogate decision-makers who had recently made a healthcare decision in one of two urban acute-care hospitals. They found that, when actually making healthcare decisions, surrogates considered both patient-centered factors and surrogate-centered factors. The former included respecting the patient's input, using past knowledge of the patient to infer the patient's wishes, and considering the patient's best interests. The latter included the surrogate's own wishes if he or she were in the patient's situation, the surrogate's personal interests, the surrogate's religious beliefs or spirituality, family consensus, and obligation and guilt (Fritch et al., 2013). Their findings underscore the great importance of the choice of a surrogate decision-maker. Ideally, the patient would spend as much time getting to know the surrogate's beliefs and preferences as the surrogate would spend getting to know the patient's. In reality, surrogate decision-makers often report they wish they knew more about the prior wishes and preferences of those they represent. Patients choosing surrogate decision-makers usually pick individuals with whom they have had long-term or even lifetime relationships. Even so, some of the surrogate-centered factors described by Fritch et al. (2013) might not be known to them.

THE FOUR PRINCIPLES (BEAUCHAMP & CHILDRESS, 2009)

Medical ethicists have advanced four basic principles to guide ethical medical decision-making: *autonomy* (respect

for individual decisions), *beneficence* (relieving, lessening or preventing harm; providing benefits that justify risks and costs), *non-maleficence* (not doing harm), and *social justice* (fair distribution of risks, benefits, and costs). Historically, paternalistic physicians emphasized their beneficence and acted on the presumption that they knew what was best for the patient. Nowadays, in the United States in particular, the patient's autonomy is the most important factor: patients are permitted to refuse treatments prescribed by their physician even when doing so will hasten their death (Will, 2011). Notwithstanding, the recent literature on advance directives reveal that beneficence—and concern for the patient's best interests—refuses to die. Physicians who see a need for flexibility in following advance directives may simply be recognizing that both patients' feelings and clinical situations are nuanced and not easily reduced to checkboxes on a form. The position is not necessarily paternalistic, it is just professional—but the risks of countertransference, personal bias, and excessive influence by opinionated family members are ever-present.

AUTONOMY—AGENCY AND AUTHENTICITY

Autonomy in particular has a subtlety that psychiatrists may be particularly well-suited to appreciate. Autonomy involves *agency*—choosing a course of action in a particular specific situation—and *authenticity*—choosing a lifestyle, a set of values, and a view of human experience (Brudney & Lantos, 2011). Specific circumstances and a patient's emotional reaction to them can prompt him or her to make immediate decisions that are inconsistent with their personality, philosophy, and a long history of other decisions. This can occur without such severe emotional disturbance as to render the patient incompetent by virtue of mental illness. However, it would seem wrong to honor an unwise and potentially fatal refusal of medical care because of a transient state of mind inconsistent with the patient's entire life narrative. The usual resolution is to temporize, asking the psychiatrist or other counselor (e.g., pastoral counselor or psychologist) to engage the patient in dialogue in the hope that the patient's mind will change. In some cases, the psychiatrist can assert that the patient is not competent to make the given decision, though not globally incompetent, but at least in the United States, getting legal authority to override the patient's refusal of care in such a situation would be difficult.

SUBSTITUTED JUDGMENT

Substituted judgment refers to surrogate decision-making in which the surrogate makes the decision he or she believes the patient would have made if they had had the capacity to decide. Doing this involves consideration, not only of the patient's prior expressed wishes and opinions, but also of what is known about their values, beliefs, personality, and lifestyle. This comprehensive perspective is important because people's views change with their experience of illness. A patient who once said they would rather die than go to a nursing home may feel very differently when they are sick and lonely, and

find that a particular nursing home is a pleasant place to live. On the other hand, a cancer patient who once said they would want the physician to “do everything” might become so tired of pain, medication side effects, loss of privacy, and invasiveness of active treatment they would now choose palliative care if able to express a preference. Medical psychiatrists, experienced in eliciting life stories and in assessing personality and emotional state, may be especially helpful to a health-care proxy trying to implement substituted judgment in the absence of a legally binding advance directive.

BEST INTERESTS

Best interests is a principle for surrogate decision-making that is the major alternative to substituted judgment. Under this principle, the surrogate decision-maker acts in a way that is expected to promote the greatest overall welfare of the patient, considering all relevant factors, including professional and ethical standards. It is arguable whether best interests or substituted judgment is a preferable principle for proxy decision-making in the absence of advance directives, though contemporary practice favors substituted judgment when there is sufficient knowledge of the patient's personality, prior decisions, and stated wishes and beliefs. The application of the best interests principle is inevitably affected by the surrogate decision-maker's personality and beliefs, the surrogate's medical knowledge, and what physicians tell the surrogate about the prognosis and their expectations of the outcome of various treatments.

When 34 prospective subjects in dementia research, all of whom had mild to moderate cognitive impairment, were asked about how they would want their surrogates to make decisions for them related to research participation, the majority preferred using best interests or a combination of best interests and substituted judgment as the principle. Only 15% favored using substituted judgment alone (Black et al., 2013). This small but very interesting study suggests that the current philosophical—and in many jurisdictions—legal emphasis on patient autonomy as the most important principle of all does not comport with many patients' own views. A similar study of 40 proxy decision-makers for potential Alzheimer's disease research subjects revealed a common preference for a balancing substituted judgment and best interests, and as well as appreciation that a patient's premorbid preferences and present preferences might be different. Thus a premorbid preference expressed in an advance directive or a discussion with the surrogate might not be the “gold standard” for surrogate decision-making (Dunn et al., 2013).

Muthalagappan et al. (2013) cite evidence that a substantial proportion of older people do not want personal control over their medical decisions, and proposed that shared decision-making, a process that has been described as “the pinnacle of patient-centered care” (Barry, 2012), is optimal for making the decision of how to manage end-stage renal disease in frail elders with multiple comorbidities. Muthalagappan and colleagues point out that nephrologists lack the time, and often the communication skills, needed

to implement shared decision-making. Medical psychiatrists, who combine empathy and communication skills with general medical knowledge, would appear ideally qualified to do the job.

CLINICAL CONCEPTS

DECISION-MAKING CAPACITY

The elements of decision-making capacity have been described as being able: to understand the decision to be made, to express a preference, to offer a rational reason for it, and to appreciate the context and implications of the choice. It is evident that the most complex and potentially subjective aspect of assessing decision-making capacity concerns the element of appreciation. Appreciation of the context of a decision requires accurate, non-delusional perceptions and memories and understanding of their meaning, including recall and understanding of relationships with people who might be affected by one's decision. Appreciation of the implications of a decision requires the kind of foresight that adults learn through education and life experience, and may also involve knowledge of one's health conditions and appropriate trust in one's physician's advice.

A patient can have adequate capacity to make a valid decision yet make a decision that most people would regard as a bad judgment. Consider a hypothetical patient at high risk for myocardial infarction (MI) who comes to an emergency room with chest pain. He is examined and blood is drawn; while awaiting the results of laboratory tests, he decides to go home against medical advice (AMA). He appreciates that he might have a myocardial infarction and that if he does he might develop an arrhythmia that could threaten his life if not promptly treated—something done more readily in a hospital. He states, however, that:

1. He thinks stress is bad for the heart and he will be far more relaxed at home;
2. He does not have health insurance and he knows that more time at the hospital means a larger bill—something that would worry him greatly;
3. He is willing to return to the hospital if they call and tell him he has had a significant myocardial infarction—but if the lab tests do not suggest an MI, or suggest a very small one, he prefers to remain at home and follow up as an outpatient.

He gives his mobile phone number and asks to be contacted with the laboratory result—whatever it is. This hypothetical patient's decision to leave the emergency room is clearly valid, because the patient understood his situation, knew what his options were, appreciated the risks inherent in his choice, could communicate a preference, and could offer a rational reason for that preference. He should be discharged from the emergency room AMA, with clear contemporaneous documentation that he was informed of the

risks of leaving, that he understood and accepted the risks, and that he had the capacity to make a valid decision (Levy et al., 2012).

A patient like the one just described should not be discharged AMA if there is significant doubt about his decision-making capacity. Such doubt would be raised if the patient could not remember the probable diagnosis or the risks of AMA discharge five minutes after they were presented by the emergency room (ER) physician, or if his explanation of why he wanted to leave AMA was incoherent and rambling. If the patient were to articulate a clear reason for leaving AMA that was entirely based on a paranoid delusion or a command hallucination, a medical psychiatrist probably would be called to address the question of whether to hold the patient against his will. If the patient recalled and understood the medical risks sufficiently and his reasoning and communication were clear, the basis for detaining the patient would be potential danger to himself and not his decisional incapacity. In situations like these, the medical psychiatrist's role is complex. He or she usually tries to engage the patient and encourage him or her to accept medical advice, while evaluating the patient for cognitive dysfunction and psychosis and for suicidal or violent ideation and intent. If cognition is intact and the patient rejects proposed medical care solely because of delusional thinking, hallucinations, or psychotic misperceptions, the key question is how imminent the harm would be if the patient refused treatment and left the emergency room or hospital AMA. For the psychiatrist to certify the patient as dangerous to self and compel treatment, it would have to be more likely than not that the patient would suffer harm in the very short term if not treated. Even then, some jurisdictions' mental health laws limit the scope of the medical care that can be given involuntarily to psychiatric treatments only. In almost all jurisdictions, permissible involuntary treatment would not include cardiac surgery.

While delusions might not in themselves invalidate a patient's decisions about medical care, they might invalidate other decisions, such as the revision of a will. For example, consider a patient with dementia and psychosis who has the delusional belief that her husband is unfaithful to her, and who has fond feelings for the nurses' aide who has cared for her for the past two weeks. The patient says she has decided to revoke her will and leave all of her assets to the aide rather than to her husband. She clearly and rationally states that she would prefer to reward kindness rather than betrayal. She knows that her assets comprise the house the couple lives in, which she inherited from her parents and is in her name, and the retirement plan from her former employer. She is aware that without these assets her husband would have no place to live and would have much less income, but she says he can go live with his secret lover.

In this example, the patient knows what the decision is about, can express a preference and can give a rational reason for it, but she is basing the decision on a false and delusional premise. Now consider the situation where there is no delusion of infidelity but where the wife is merely angry at her husband for being, in her view, insufficiently inattentive to her since she became ill. She gives great weight to his recent

behavior and little to their generally happy 50-year marriage, and does not grasp how much her husband would be hurt by being disinherited. In this situation, her bad judgment is so extreme that most clinicians would judge it incompetent—and they also would suspect undue influence by the aide.

One could move closer to a line of uncertainty and controversy by imagining a widow who had enjoyed years of assiduous care and attention from a neighbor as she gradually declined from a neurodegenerative disease, while being relatively neglected by her only son, whose calls and visits were infrequent and perfunctory. Her leaving her estate to the neighbor rather than her son might be viewed by one clinician as rational and justifiable, and by another as reflecting the disinheriting of a natural heir under a greedy neighbor's undue influence.

Neuropsychiatric disorders involving language circuits but leaving most of the frontal system and association cortex intact can produce circumstances in which a patient can make a competent decision but cannot express it effectively or accurately. When patients are aphasic, it cannot be presumed that they lack decision-making capacity. When the neurological diagnosis (e.g., an isolated embolic stroke affecting language) suggests a potential dissociation of decision-making from expression of choices, an effort must be made to establish a channel of communication; for example, an explanation of a proposed treatment might be given in pictures or through a video, rather than verbally.

Neuropsychiatric disorders affecting frontal systems can produce a situation where a patient expresses a pseudo-rational choice. For example, the author treated a young woman with schizophrenia who had sustained a major traumatic brain injury a few years earlier and had major deficits in her frontal lobe function. She persisted in hitchhiking alone at night, despite having been robbed and raped on several occasions. When asked why she persisted in hitchhiking, she said without irony, "What would you have me do, doctor, take the bus?"

Frontal deficits can also lead to the dissociation of consent to treatment and compliance with it. For example, a patient agrees to be hospitalized for psychosis but then refuses all medications that are offered, or a patient agrees to receive antibiotics but pulls out intravenous lines before they can be infused. In this case, the patient's consent may be competently given but completely ineffective, potentially leading to the paradox of giving involuntary treatment to a person who has consented to receive it.

RELATIONSHIPS AS REASONS

Rational and contextually valid reasons for making decisions—e.g., clinical or financial ones—can be expressed as a weighing of pros and cons and the more and less probable outcomes of alternative choices. However, equally valid and rational reasons can be expressed in terms of important relationships. For example, it can be rational for a patient to agree to a particular surgical procedure because his surgeon recommended it and he trusts his judgment and skill. While in obtaining consent one would want to offer the patient comprehensive information

about the procedure and its risks and benefits, a rational ultimate decision might legitimately be based almost entirely on the trusting physician-patient relationship. Similarly, a patient might make a decision affecting her personal finances entirely because of the recommendation of a trusted spouse or child, rather than because of her independent evaluation of the decision itself. In this situation, judgment of the patient's decision-making capacity rests on how much the decision to rely on a particular relative is compatible with the patient's history, the current context, and the relative's apparent decision-making competence. Pragmatically, the clinician must look at the latter point simply. If a patient has always relied on her spouse to invest the couple's money and pay the bills, it is presumed rational that she continue to do so, absent positive evidence that something has changed such as the spouse's health. On the other hand, a patient's basing a financial decision on the advice of a son who is an alcoholic and compulsive gambler would raise appropriate suspicion.

EXECUTIVE FUNCTION AND METACOGNITION: CRITICAL TO CAPACITY

EXECUTIVE FUNCTION

Adequate executive function is a prerequisite for successful goal-directed activity, for safe independent living, and for acceptable performance of complex activities like driving, managing money or practicing a profession. Medical conditions that impair cognition can impair executive function disproportionately.

Executive function is the most important *cognitive* factor in determining the performance of instrumental activities of daily living (IADL) in patients with dementia, schizophrenia, and a wide range of other medical conditions. While patients, families, and sometimes legal authorities focus on cognitive functions such as memory, orientation, and language to gauge a patient's cognitive impairment, a patient with severe impairment of executive function can be incapable of reasonable decisions even when these functions are normal. Frontotemporal lobar degeneration (FTLD), Lewy body dementia, the dementias associated with Parkinson's disease, amyotrophic lateral sclerosis (ALS), and progressive supranuclear palsy (PSP) can all show a pattern of disproportionate executive impairment.

On the other hand, a patient with quite significant memory loss and even recent episodes of getting lost might nonetheless be able to make subtle decisions if executive function were preserved. Focal and multi-focal cerebral diseases, including stroke, multiple sclerosis (MS), and brain tumors can produce such a pattern if they largely spare the frontal region and its subcortical and cerebellar connections.

If neuropsychological testing is not done, the medical psychiatrist's office-based or bedside evaluation of decision-making capacity should assess executive dysfunction using procedures like the Clock Drawing Test, the Luria hand sequence, Trail Making B, or presentation of conflicting

stimuli (for example, asking the patient to raise the right arm quickly if the command is given in a soft voice and slowly if the command is given in a loud voice). The Executive Interview Test (Royall & Mahurin, 1992; Royall et al., 2004) is a concise, practical survey of executive function that takes 10–15 minutes to do and can be administered by a nurse or technician.

METACOGNITION

Metacognition has two dimensions: the “feeling of knowing” and confidence in one’s knowledge. Metacognition requires adequate functioning of the dorsomedial frontal region, especially in the right hemisphere, and the right parietal lobe. Certainty about wrong answers and gross denial of deficits is a great threat to competent decision-making; it is more likely to occur when there is disproportionate impairment of right hemisphere function, as there can be in the early course of some neurodegenerative diseases, or in with focal or multifocal brain lesions that involve the right hemisphere mainly or exclusively.

Cognitive testing in the clinician’s office affords a natural opportunity to assess the patient’s awareness of their cognitive deficits. Comparison of directly measured and self-assessed deficits can be quantified (Williamson et al., 2010), but a more qualitative approach provides additional information that is useful in competency assessment. Before testing, the clinician can ask patients how they think they will do on tests of memory and concentration and other cognitive abilities. Separately, the clinician can ask family members whether the patient’s behavior reflects any adjustment for cognitive impairments. After the test but before being told the results, patients are asked again to assess their performance. After being given the results, they are asked if they agree or disagree, and it is noted if they acknowledge a poor performance but excuse it or minimize its import. If the patient does not accept the presence of a cognitive deficit during the office visit, he or she is given a written report to review at home and is asked again about awareness of deficits on the next visit. In this way, patients can be placed on a continuum of self-awareness that progresses from full appreciation of deficits to frank denial. Some points on the continuum are:

1. Knowing they have cognitive deficits, appreciating their implications, and making adjustments to their behavior to account for them;
2. Knowing they have cognitive deficits, appreciating their implications, but not modifying their behavior;
3. Knowing they have cognitive deficits, but not appreciating their implications;
4. Acknowledging cognitive deficits after failing a test but before being told of the test results, and then showing appreciation of the implications;
5. Acknowledging cognitive deficits after failing a test but before being told of the test results, but excusing their

performance or regarding the results as insignificant or irrelevant;

6. Acknowledging cognitive deficits only after being confronted with test results and their significance by the physician;
7. Acknowledging deficits after extensive persuasion and review of a written report of performance; and
8. Completely denying deficits despite the physician’s efforts at persuasion and confrontation with evidence.

Metacognition, which is closely related to self-awareness and insight, is, like executive functioning, only moderately correlated with other cognitive impairments, and in some specific neurological situations it can be disproportionately preserved or affected. For example, patients with early Alzheimer’s disease with asymmetrical right-hemisphere involvement can show mild cognitive deficits that they totally deny, in fact being quite sure of misremembered and sometimes crucial “facts.”

Patients lacking awareness of their limitations will not ask for help when they need it, may refuse help when it is offered, and may persist in dangerous behavior. Those who are aware of their deficits will modify their behavior to compensate. For example, patients with reduced insight and self-awareness are likely to be unsafe drivers, even when cognitive impairment in other domains is relatively mild (Kay et al., 2009).

THE SPECIFICITY OF CAPACITY

Given the complexity of the brain and the many ways in which brain disease, primary mental disorders, systemic illness, and medication effects can interact, impairments in capacity can be highly specific. A patient can have the capacity to do daily shopping but not to manage his or her savings and investments, *or the reverse*. A patient can be able to drive safely during the daytime in good weather and in light traffic, but not otherwise. A patient can be able to take public transit on familiar routes, but not navigate someplace new. A patient can be able to adhere reliably to a regimen of three medications taken together once a day, but not with a regimen of three medications taken on different schedules. Lui et al. (2013) studied the relationship of financial decision-making capacity and medical decision-making capacity in a group comprising subjects with mild cognitive impairment (MCI), subjects with mild Alzheimer disease (AD), and aged controls, measuring medical decision-making competence with the MacArthur Competence Assessment Tool for Treatment (MacCAT-T) and financial decision-making competence with the Assessment of Capacity for Everyday Decision-Making, a similar structured interview-based assessment. Scores for the Understanding, Reasoning, and Appreciation components of competency for medical versus financial decisions were moderately correlated, but subjects with AD could be judged competent to make one kind of decision but not the other. Only 5% of the subjects with MCI were judged incompetent to make financial decisions, but 20% were judged incompetent to make medical decisions.

A valuable service the medical psychiatrist can perform is to delineate the boundaries of a patient's capacity with some precision. An occupational therapist (OT) can contribute by directly assessing the performance of IADLs. A visit to the patient's home is the best way to value the ability to maintain a safe and healthy environment, one that offers the additional benefit of revealing ways to prevent falls and accidental injuries and improve the accommodation of the home to the patient's functional impairments. A neuropsychologist can contribute by doing focused testing that is properly calibrated to the patient's premorbid functioning and its expected change from baseline. Both the OT and the neuropsychologist can assess metacognition and insight by observing how well the patient anticipates any impairments that are found, and whether her or she accepts the findings of impairment when confronted with them. Both can assess elements of executive functioning such as inhibition of inappropriate behavior, persistence, and resistance to environmental distractions; these are best evaluated by systematic observation of the patient's behavior during the clinical encounter.

Another clue to the extent of a patients' impairment—and of their rate of decline from their baseline—is in documents that patients have produced in connection with their occupation, with written or electronic communications with other people, and with the business of living. These include work-related correspondence (if applicable), handwritten checks, letters and emails, tax returns, bank and credit card statements, and statements from investment accounts. For example, when a retired businessman makes multiple arithmetical errors on his tax return, his checks become illegible, and his credit card statement shows evidence of impulsive buying of unneeded items, his loss of financial competence is self-evident.

The careful delineation of a patients' current capacities, along with a clinically based projection of the likely future course of their impairments, is a rational basis for clinical and legal interventions to maximize a patients' independence within their safety zones, while protecting them from the harm that could result from their going outside those zones. Care in documenting impairments and support for claims of incapacity with face-valid evidence, such as photographs of squalid living quarters or receipts for inappropriate purchases, can be helpful when the patient resists a legal intervention or when there is dissent within the family regarding the steps needed to protect the patient.

CONTEXT-DEPENDENCY OF CAPACITY

Capacity is not only specific to a decision or task, but also to its context. Patients may be able to make a decision or carry out a task when well rested but not when fatigued, or when they are comfortable but not when they are in pain. Recognizing optimal and adverse circumstances for decision-making can be used to preserve patient's autonomy while protecting them from self-damaging decisions. For example, if a patient's cognitive status and decision-making capacity are best in the morning, when she is well rested,

and when she is at home rather than in the hospital, an informed-consent discussion for elective surgery might be conducted in the morning, at home, by a visiting nurse representing the prospective surgeon. Under similar circumstances, if the issue were the revision of a will, for example, the patient's lawyer might visit the patient at home in the morning rather than have her come to the office for an afternoon appointment. When context-dependent fluctuation is noted and there is no healthcare proxy, the discussion of appointing and instructing a surrogate decision-maker should be carried out in the optimal decision-making context.

THE TIME COURSE OF INCAPACITY

A further nuance of decision-making capacity is that it changes over time, influenced by disease processes and exogenous substances that directly or indirectly affect the brain. Changes can take place from hour to hour when exogenous substances are involved. Impairments can be episodic, as in bipolar disorder, or progressive, as in neurodegenerative diseases. In many conditions, decision-making capacity can improve with treatment, at least for a while.

Because of the potential for decision-making capacity to change over time, the legal mechanism of a judicial determination of incompetence does not comport with the principle of compromising the patient's autonomy to the minimum necessary extent. Courtroom proceedings to declare incompetence and to appoint a guardian or conservator are expensive, time-consuming, and stigmatizing, and they lack the flexibility to accommodate frequent and sometimes rapid changes in the patient's clinical status.

Practical suggestions for assessing the decision-making capacity of patients with fluctuating mental status and communication impairments were summarized in an article by members of a Canadian Regional Capacity Assessment Team. They note that clinicians often underestimate the decision-making capacity of patients with aphasia. Their approach begins with "a shift in thinking from 'Is this person capable?' to 'How can this person's capacity for this particular task be revealed?'" (Pachet et al., 2012).

THE ROLE OF NEUROPSYCHOLOGICAL TESTS

Neuropsychological tests and other standardized cognitive performance scales have the virtues of being quantitative, standardized, normed, and useful for assessing the course and prognosis of a progressive condition. Several suggestions can be offered for maximizing the value of neuropsychological testing:

1. Work regularly with one or two neuropsychologists; if possible, finding ones with extensive experience in competency assessment and a compatible outlook on competency-related issues.
2. Provide the neuropsychologist with personal and clinical background on each patient that will enable him or

her to give tests of appropriate difficulty to avoid “floor and ceiling” effects on measurement, and tests that will adequately test the areas where specific deficits are suspected.

3. Ask neuropsychologists to provide the actual results of tests performed as well as the conclusions they reached from reviewing the scores, and to provide a description of the patient’s behavior during the examination and his or her approach to specific tasks, if these are remarkable. Such observations might include inconsistent effort, fatigability of performance, or inappropriately jocular or profane remarks during the testing.
4. Ask the neuropsychologist to assess the patient’s metacognition and insight into any deficits found on testing.
5. Ask the neuropsychologist to suggest bedside- or office-based measures that can be used to follow the patient’s performance over time in areas found to be abnormal on comprehensive testing.

TESTING VERSUS OBSERVATION

Direct observation of patients’ behavior and task performance in their natural setting provides information complementary to information from neuropsychological testing. While it is not standardized, normed, and quantitative, such observation has three virtues of particular relevance in the assessment of capacity and competency:

1. Direct observation is face valid. For example, a patient whose home environment is squalid either is incapable of cleaning and maintaining the home, or is unwilling to do what is ordinarily expected of a competent adult. A patient who continually misses mortgage or rent payments, despite adequate funds to make them, manifestly has a problem managing his or her financial affairs.
2. Direct observation may demonstrate capacities not obvious from test results. Patients doing everyday tasks in their usual home or work environment have more environmental cues and can rely more on over-learned habits than when they take unfamiliar tests in a neuropsychologist’s office. Patients may be able to carry out well-practiced tasks with adequate cueing that would seem beyond their capacity based on neuropsychological testing results alone. For example, a patient might be able to fill her usual weekly shopping list at a neighborhood grocery store, pay her usual tab with \$20 bills, and know that she has received approximately correct change, even though she could not do accurate calculations when tested or name the items on the list from memory.
3. Direct observation also shows how the patient responds to environmental distractions and to unexpected events not present in the controlled environment of the neuropsychologist’s office.

STANDARDIZED ASSESSMENT OF COMPETENCE (ADAPTED FROM FOGEL, 2014)

In addition to standard neuropsychological tests, specialized tests for decision-making competence have been devised, focusing on competency to consent to medical treatments and procedures. One, the MacArthur Competence Assessment Tool (MacCAT) (Grisso & Appelbaum, 1998), has been most widely utilized in clinical research and in studies of the neuropsychological basis of decision-making competence, and has relatively strong empirical support (Dunn et al., 2006). One version, the MacCAT-T, targets competency to consent to medical treatment; another version, the MacArthur Competence Assessment Tool for Clinical Research MacCAT-CR (Appelbaum & Grisso, 2001), targets competency to consent to clinical research. The MacCAT is based on presenting the patient with a vignette specifically designed for the clinical decision in question, then conducting a semi-structured interview to assess the patient’s understanding of the vignette, appreciation of its personal relevance and implications, reasoning about risks and benefits, and ability to express a decision. Each of these is rated on an ordinal scale; in the end, the clinician makes a binary judgment of competence or incompetence to make the clinical decision. There are no specific cutoff scores on the ordinal items that link them to the final judgment; this allows room for consideration of contextual factors. The MacCAT requires training to administer reliably, and variability in how the vignettes are related to actual clinical circumstances is a potential source of unreliability.

While the MacCAT-T and some of the less widely used standardized tests have shown acceptable psychometric properties, patients can do poorly on such tests yet make competent decisions about their own medical treatment, for several reasons:

1. Actual clinical decisions have a rich context of cues, motivations, and circumstances that are absent from a standardized vignette.
2. Patients with impaired verbal fluency can have a hard time articulating rational reasons for their choice when they do in fact have them; studies validating the MacCAT have not specifically enrolled subjects with language disorders.
3. A patient facing a difficult decision might choose to rely on a trusted physician’s advice rather than try to understand a complex medical issue at all, basing this reliance on the rational reason that the physician’s past advice has been sound, or that the issues are complex and arcane and recommendations are offered by a well-reputed specialist with extensive knowledge and experience with those issues.
4. Or, a patient may have a long-held personal belief that trumps other considerations and implies what choice should be made; e.g., a belief that it is always better to live than die, regardless of the expected quality of life.

5. A patient can make a well-considered choice to delegate responsibility for the choice to a surrogate decision-maker. For example, a choice by a patient with mild cognitive impairment to delegate a medical decision to his physician daughter might be a wiser one than his trying to make sense of alternatives, risks, and benefits himself.

WHY ASSESSORS MAY DISAGREE

Professionals assessing patients' competence may disagree—and often do—for several reasons:

1. Cognitive test results, task performances, and actual decisions are highly specific and context-dependent and may change over time. If two examiners see a patient at different times, their conclusions may differ because the patient's performance was not the same on the two occasions.
2. Professionals may apply different criteria to determining whether a test was passed or failed, a task was done adequately, or a decision made was reasonable.
3. Professionals may have different thresholds of performance for declaring that a patient has adequate decision-making capacity. This is a particular problem when they are reporting to a judge making a binary decision about the need for a guardian or conservator. In a study of inter-rater reliability of structured instruments for the assessment of capacity to decide about medical treatment, disagreements between raters mainly concerned patients with intermediate scores on the Mini-Mental State Examination (MMSE) and intermediate scores on one or more subscales of the structured capacity assessment, the scales being understanding, reasoning, appreciation, and expressing a choice (Raymont et al., 2007). Apparently, different assessors had different implicit cutoff scores for the decisional capacity subscales.
4. In addition to differences in the circumstances of assessment and differences in assessors' knowledge, skills, and criteria, assessors may ultimately have different views of how concern for patient autonomy should be weighed against concern for the patient's safety and health.

Differences of professional opinion usually can be resolved—or at least explained—when each party's reasoning is traced from primary observations through conclusions.

SPECIFIC SITUATIONS

PSYCHIATRIC AND MEDICAL EMERGENCIES

In true medical emergencies, it is unlikely that a medical psychiatrist will be called, because the doctrine of implied consent will be invoked if the patient is incapable of giving informed consent to treatment and there is no known,

authorized, and immediately available surrogate decision-maker. Medical psychiatrists' involvement typically commences after the patient has survived the immediate crisis and decisions must be made about non-emergency treatment—perhaps treatment of an infection or heart failure—and eventually about follow-up care, perhaps involving transfer to a post-acute care facility such as a nursing home or long-term acute care hospital. Even when acutely ill patients are not able to make informed and thoughtful decisions about their post-acute treatment and rehabilitation, physicians seldom use formal legal mechanisms for surrogate decision-making, even when there is no authorized surrogate decision-maker like a healthcare proxy or (much more rarely) a legal guardian. The treatment team, which usually includes a continuing-care nurse or social worker, makes a recommendation for post-acute care, obtains the consent of the principal family caregiver (usually a spouse, partner, or child), and, as long as the patient offers no resistance, a transfer to post-acute care is made. Sometimes the patient even objects to the transfer, but if the team regards the objection as unreasonable, the transfer takes place anyway.

In many jurisdictions, such processes do not have legal support. Nonetheless, if a medical psychiatrist becomes involved, his or her main agenda should not be to advocate for legal formalities per se. Instead, the goal should be to determine how much the patient can reasonably participate in the post-acute care planning decision, and to enable the patient's valid input to the greatest extent. For example, a patient who has had a stroke and a delirium that has not quite cleared might be referred to a skilled nursing facility (SNF) for post-acute care and rehabilitation. He may insist on going home, and be unable to grasp that his home would not be physically safe for him in his current condition, and that he would not be able to get at home the intensive rehabilitation needed to optimize his long-term functioning. Nonetheless, he might be able to articulate a well-founded preference as to which SNF he would choose if he had to go to one—mentioning, perhaps, its religious affiliation, its being close to his daughter's house, etc. Transferring him to his SNF of choice would show a pragmatic respect for the patient's autonomy, and it is unlikely that anyone would raise a legal objection.

INDEPENDENT LIVING

In contrast to the example just given of a transfer to post-acute care over a patient's objection, the issue of coercing a patient—however mildly—into a permanent change in residence is so momentous as to warrant the protections inherent in greater legal formality. The typical clinical situation is that dementia, or a combination of medical conditions involving cognitive dysfunction and impairment in IADLs or ADLs, makes it unsafe or unhealthy for a person to continue his or her current living arrangements. In this situation, the patient lives alone or lives with a spouse or significant other who is not able to compensate for the patient's deficits. The issue of decision-making capacity arises when the patient chooses not to move, despite medical advice.

The medical psychiatrist called to assist in this situation may have been asked to assess competency or even, more directly, to document findings that could be used in a legal proceeding to compel the patient to move out of situation the medical team does not find to be in the patient's best interest. While this may be the request, it usually is not what the psychiatrist should do.

Before interviewing the patient, the medical psychiatrist should gather whatever information is available from nursing, OT, physical therapy (PT), neuropsychology, and the family about the patient's current level of cognitive impairment, functional independence, safety awareness, and insight into these things, taking special note of actual observations of unsafe behavior or unhealthy living conditions. When deciding what weight to give input from the family, consideration should be given to the possibility that a family member might have an agenda incompatible with the patient's best interests. In some unfortunate cases, the apparently concerned family member might be mistreating or exploiting the patient (Williams et al., 2014).

If the patient has been assessed by an occupational therapist (OT), the therapist (or the OT records) should be queried about how the patient might perform with optimal environmental modification and/or adaptive or monitoring devices, and what those optimal interventions would involve. Similar information from nurses and physical therapists would concern how much supervision, setup, and/or physical assistance the patient would require to live safely at home, and on what schedule it would be required. A prognosis should be estimated from other physicians' notes, with follow-up questions if necessary. Finally, a social worker should be queried about the patient's means and the informal caregiving resources available to the patient.

With such information, the medical psychiatrist can reach a conclusion about the feasibility of the patient's having a safe and healthy life at home. If a safe and healthy living situation is feasible with sufficient resource inputs, the clinician should estimate the resources that might be required and for how long a modified home situation might be viable given the patient's prognosis.

The process just described is an ideal that usually is not attained, given the constraints of time and the nature of care in hospitals, and not every type of input is needed in every case. Sometimes it is obvious that a patient's needs for care at home would be far beyond what the patient could afford or what could be practically arranged in a given locality. However, what the psychiatrist does know prior to seeing the patient can be compared with this ideal, so the psychiatrist is aware of the gaps in his or her knowledge and does not reach definite conclusions prematurely.

Medical-psychiatric assessments in this context includes exploration of how patients view their current situations in the context of their lives, how they understand their illnesses and their limitations, what they think they would need to be safe and maintain their health at home, what financial and informal care resources they think they have, and how they see their situations changing in the future. Cognition and meta-cognition are tested. If the patient is said to have a physical

limitation like a risk of falling, the psychiatrist should directly examine the patient to understand the severity of the problem and the relative contribution of visual, motor, sensory, autonomic, cognitive, and emotional factors.

The psychiatrist then reaches a conclusion as to whether the patient's returning home—with appropriate environmental modifications, adaptive devices, and supportive services—is a realistic option and one that would make sense given the patient's personality, values, and resources. These considerations include the patient's risk tolerance: a patient may be realistically willing to take some risk of injury in order to live independently, and the balance of risk and benefit is quantitative and individual rather than absolute.

If the conclusion is that returning home does not make sense, even allowing for the value of the patient's autonomy and the patient's acceptance of risk, the psychiatrist discusses his or her considerations with the patient. If the patient proves refractory to rational argument because of denial of deficit or impaired reasoning, there may be a basis for pursuing guardianship. Documentation of the patient's denial or defective reasoning will be useful in persuading a judge.

Note that the conclusion of the process might be a creative adaptation of the patient's environment or use of new assistive or monitoring technology rather than coercing the patient to move to a new residence. Or, the exploratory process may lead to identifying new family caregiving resources, to making a different decision about how to spend money on the patient's care, or to a greater acceptance of risk by the patient's loved ones.

DRIVING (ADAPTED FROM FOGEL, 2014)

Many of the diseases, disabilities, and treatments commonly encountered in medical psychiatry have effects on patients' ability to drive safely. At the same time, giving up driving can have major effects on patients' independence, health-related quality of life, and ultimately on their health itself. Some conditions, like uncontrolled seizures and moderate-to-severe dementia, are totally incompatible with safe driving, and in most states it is compulsory for physicians to report them. Other conditions, like hearing loss, increased glare sensitivity, and mild cognitive impairment, can affect driving capacity in a relative and selective way, undoubtedly increasing overall crash risk but implying a moderate and tolerable increase in risk under specific favorable conditions. Furthermore, many older drivers with sensory or attentional problems that increase their crash risk self-limit their driving to some extent, tending to avoid driving at night, in bad weather, and in heavy traffic (Ball et al., 1998). When drivers with cognitive or sensory impairments do *not* limit their driving to less demanding situations, there is greater reason to be concerned about the safety of their continuing to drive. Among older drivers referred for a formal driving evaluation, those who thought they were better drivers than others of their age were four times as likely to be *unsafe* drivers (as assessed by driving simulation) than those who did not (Freund et al., 2005).

Medical psychiatrists become involved with driving-related interventions in several ways. They may be asked to:

1. Assess whether a patient with some combination of general medical, neurological, and psychiatric symptoms can drive safely;
2. Suggest that a patient known to be an unsafe driver to stop driving;
3. Help a patient deal with—either in advance or after the fact—the consequences of driving cessation on his or her life activities and mental health; and/or
4. Advise a patient with limited and selective impairments in driving capacity how to make adjustments in his or her medical treatment, activity schedule, driving habits, and perhaps the vehicle, to enable safe driving despite the medical condition.

An additional task, rarely requested at the outset but often relevant, is helping patients and families anticipate future changes in the patient's driving capacity in a way that will reduce their effects on the patient's health and quality of life and on the burden of family caregivers. The evaluation of driving-related capacities will usually involve some combination of disciplines—neurology, neuropsychology, OT, ophthalmology, and audiology all can be relevant. Psychiatrists can make unique contributions by describing and analyzing patients' moods and behavior and how they interact with cognitive dysfunction and sensory and motor deficits to impair driving ability. They also can contribute their skills in helping patients and their families accept and adapt to a major life change.

When a patient clearly cannot drive safely—as is the case for any patient with moderate or severe dementia—and he or she is currently driving, the patient should be unequivocally advised—both orally and in writing—to stop driving immediately. In states where reporting of such patients to the licensing authority is mandatory, the report should be made without delay. Consent of the patient should be requested if the patient lives in a jurisdiction that does not permit reporting without it. Whether or not patients consent to reporting to the licensing authority, the psychiatrist should ask them for permission to talk to family members or significant others about the driving issue; families have both the time and the interest to work on persuading a patient to give up driving. Of course, if the patient has such severe impairment of decision-making capacity that he or she is not competent in general, a guardianship can be established. The guardian would then relinquish the driver's license and dispose of the car, acting as the patient's agent.

Since failing to make a required report on an impaired driver is a major legal risk, clinicians should know whether their state has mandatory reporting, and which diagnoses or other criteria require such reporting. In some states, the diagnosis of Alzheimer's disease *per se* would trigger mandatory reporting, even if the disease process were at an early stage, causing only mild cognitive impairment and not greatly affecting driving performance on familiar routes under favorable

conditions. The contemporary view of separating the clinical syndrome of dementia from the presumed neuropathology has not yet penetrated most motor vehicle licensing agencies.

Advising patients about driving when they have definite cognitive impairment but not a full syndrome of dementia is especially challenging, because for many patients driving is essential to independence, activity, quality of life, and self-esteem; driving cessation for such patients can lead to an acceleration of functional decline, increased caregiver burden, earlier institutionalization, and even earlier mortality. On the other hand, the increase in crash risk associated with full-blown dementia is unequivocal. Specific errors associated with dementia in general include driving at a lower and more variable speed, errors at intersections with an increase in rear-end collisions, increased steering variability, less awareness of pedestrians and other drivers, worse lane control, and unexpected braking.

Even very mild dementia is associated with increased crash risk. The increase in risk is greater for mild dementia (Clinical Dementia Rating [CDR] 1.0) than it is for very mild dementia (CDR 0.5). A road test study of dementia clinic patients at Washington University showed that 14% of patients with CDR 0.5 were unsafe and 42% of those with CDR 1.0 were unsafe. Half of the CDR 1.0 patients who were judged safe at baseline were unsafe when tested six months later; half of the CDR 0.5 patients judged safe at baseline were unsafe one year later (Duchek et al., 2003). Dementia patients with impairment in executive function, especially those with impaired insight, are likely to be unsafe drivers even when there is relatively mild impairment in other cognitive domains. Other neurodegenerative disorders, notably those affecting the basal ganglia, frequently cause driving impairment relatively early in their course because of a combination of cognitive and motor control impairments. The driving impairment seen early in Huntington's disease exemplifies this phenomenon (Devos et al., 2014). Unsafe driving behavior in mild to moderate Parkinson's disease is best explained by a combination of visual-spatial dysfunction (as measured by performance on the Block Design Test), psychomotor slowing (as measured by performance on the Trail-Making Test part A), and executive dysfunction (as measured by performance on the n-back test and the Plus Minus Task) (Ranchet et al., 2013).

Asimakopulos et al. (2012) comprehensively reviewed studies of neuropsychological tests of executive function that have been correlated with driving performance, providing very strong evidence that executive function is probably the most consistent cognitive determinant of driving performance. In their review they noted the criteria of driving performance used in each study cited—the four most common being on-road tests, driving simulation, a history of crashes, and subsequent cessation of driving.

Driving impairment due to neurodegenerative diseases or gross brain lesions can be exacerbated by their neuropsychiatric complications. Depression is associated with psychomotor slowing, increased reaction time, and lapses of attention. Patients with psychosis can misperceive their environment while driving, or be distracted by internal stimuli. Aggressiveness and impulsivity associated with orbitofrontal

dysfunction can manifest as aggressive driving. Apathetic patients fail to anticipate predictable road hazards, although their overall crash risk is mitigated by their decreased desire to drive.

There are several historical points that have a strong association with increased crash risk: recent actual at-fault crashes, getting lost while driving, falling while getting into or out of a car, and having traffic violations due to the failure to heed signs or signals. However, fault in a crash can be ambiguous, so even with the history of a crash or a single moving violation, patients with cognitive impairment who greatly depend on driving for their mobility may insist upon being tested before giving up their car keys. Getting lost while driving in itself implies an unacceptable risk of continuing to drive, with a potential exception for getting lost while suffering from a medication side effect. In that case, the patient should be advised to abstain from driving until further evaluation of their driving ability can be done. Falls when getting into or out of a car suggest problems with weakness or coordination of the legs that could interfere with a timely response to a traffic situation.

There are several ways in which the extent of increased crash risk can be estimated:

1. Office-based testing or neuropsychological testing of cognitive functions known to be associated with driving performance and crash risk, such as reaction time, visual perception, and ability to read and interpret road signs: A few of the specific test performances that have been explicitly linked to increase crash risk include recalling two or fewer of four words on delayed recall, a Trails B time of greater than 180 seconds, and a time outside of normal limits for navigating a maze on a computer screen (Emerson et al., 2012; Ott et al., 2008; Anderson et al., 2012). The Clock Drawing Test (CDT), scored on a seven-point scale with a cutoff for abnormality of four or less, may be a highly specific screening test for unsafe driving (Freund et al., 2005). In a study of 119 older drivers evaluated with a driving simulator, the test was 64.2% sensitive and 97.7% specific in identifying unsafe drivers. The inter-rater reliability of the seven-point scale for scoring the CDT was 0.95 in that study. The combination of low cost, brief administration time, and high reliability are impressive, but the results need to be confirmed on a larger and more diverse sample of older drivers.
2. Testing of the Useful Field of View (UFOV), a standardized, computer-administered test of visual attention: The UFOV measures the visual information that can be acquired in a brief glance, with or without a distracting condition. The developers of the test present evidence that a reduction of 40% or more in UFOV is associated with a seven-fold increase in crash risk. The same criterion is 89% sensitive and 81% specific in predicting that an older individual will have one or more motor vehicle crashes if he or she continues to drive (See the developer's website, www.visualawareness.com, for a summary of research findings and bibliography).
3. Testing of driving performance in the virtual reality of a driving simulator: Driving simulation can present the patient with unexpected events and emergency situations—things a patient with dementia may find difficult to manage, and things that cannot be incorporated into an on-the-road test. The best validated and most widely researched driving simulators are those developed and marketed by Systems Technology Incorporated under the STISIM Drive® trademark (www.stisimdrive.com). The system comprises hardware mimicking the windshield, instrument panel and controls of a car, and software that presents numerous driving scenarios, including ones involving unexpected events. The base configuration of the system includes 80 different driving scenarios; the software counts crashes and near misses as well as driving irregularities such as lane departures.
4. Automated analysis of “black box” (telematics) recordings of actual driving behavior: Systems for recording and analyzing driver behavior currently are used by some automobile insurance carriers for rate-setting, and by motor vehicle fleet operators to monitor their professional drivers. Current technology can detect and record several of the driving problems commonly seen in cognitively impaired patients, including lane departures, excessive variation in speed, inappropriately slow driving, sudden stops and abrupt turns. Units with Global Positioning System (GPS) functionality can establish whether drivers got lost on familiar routes, even if they eventually found their way home.
5. On-road testing by an examiner specializing in assessing the safety of older drivers and people with diseases that can affect driving ability: A road test by a specialized examiner will be more sensitive than a road test for a driver's license renewal. Such a test will look for potentially risky behavior that would not in itself cause the driver to fail the test for licensure.

In addition, the patient should have tests of hearing and vision if these were not recently done and passed. However, it has been established that while visual acuity is what is tested by licensing authorities, poor visual acuity alone does not predict motor vehicle crashes in older drivers. Glare sensitivity, loss of peripheral vision, and diminished useful field of view all are associated with a significant increase in crash risk. The evidence for these relationships is direct; it comes from a study where baseline visual testing was performed in 1,801 drivers aged 65–84; state motor vehicle crash records were then reviewed at a specific time point two to four years later, by which point 120 drivers had been involved in crashes (Rubin et al., 2007).

On-road testing is *not* the gold standard of driving evaluation. While failing a road test implies impaired driving performance under the conditions of the test, road test performance can be worsened by anxiety or fatigue and may not be representative of patients' performance in the particular situations in which they usually drive. On the other hand, passing a road test does not imply that a patient could cope

with the additional demands of night driving, bad weather, or heavy traffic, and does not imply that the patient will respond appropriately and in time to an unexpected event, like a child running across the street in front of his or her car. The assessment of these capabilities is better done in a driving simulator. The special value of road tests, however, is that failing one can get an unsafe driver off the road immediately.

The expense and inconvenience of road testing or testing in a driving simulator can be avoided if the results of cognitive testing or UFOV testing are sufficiently bad to be highly specific for unsafe driving. When it becomes widely available, “black box” recording and automated analysis of actual driving behavior may be an efficient method for evaluating driving competence that offers the advantage of not requiring a *test*—a situation that may evoke the patient’s anxiety or potentially their resistance.

In persuading a patient to discontinue driving, it is useful to identify any *non-cognitive* reason why the person’s driving might be unsafe. In addition to impaired hearing or vision (especially impaired peripheral vision, glare intolerance, or decreased UFOV), decreased neck mobility, diminished limb strength, impaired balance, peripheral sensory loss, and falls getting into and out of a car should be considered. Quadriceps strength has a powerful and non-linear effect on driving safety; beyond a certain level of weakness, driving rapidly becomes unsafe (Lacherez et al., 2014). Driving cessation for a non-cognitive reason is face-saving for the patient and may be more readily accepted.

For those patients who continue to drive, crash risk can be mitigated somewhat by specifying circumstances under which the patient should not drive. Also, patients should be strongly cautioned against using a mobile phone while driving. Crash risk for any driver increases with mobile phone use. The incremental risk for drivers with MCI or mild dementia is greater because of their difficulty dealing with distractions, redirecting attention, and processing conflicting stimuli.

Also, case-control studies of motor vehicle crashes have led to identification of classes of drugs associated with increased crash risk. Some, like opiates, barbiturates, and benzodiazepines, non-benzodiazepine hypnotics (including zolpidem, zopiclone, and zaleplon), first-generation antihistamines, most of the antipsychotic drugs, and most of the anti-epileptic drugs, have obvious sedative effects. Others are not as obvious, but are noteworthy as potentially driver-impairing drugs because they are commonly prescribed or, in some cases, purchased over the counter. They are: (1) antidepressants (virtually all classes are associated with increased risk), (2) nonsteroidal anti-inflammatory drugs (NSAIDs), (3) proton pump inhibitors, (4) H2 blockers, (5) dextromethorphan, (6) cetirizine, and (7) dopamine agonist drugs (Hetland et al., 2014). While most patients taking these drugs are not unsafe drivers, the drugs’ potential effects should be considered when assessing a patient’s overall driving risk.

ACCESS TO FIREARMS

In the United States, one-third of adults own a gun, and almost one-half of adults live in a household where there is a gun (Gallup.com, 2013). Rates of individual gun ownership vary greatly by demographics, from 10% in unmarried

non-Southern women to 64% in married Southern men. Rates of household gun ownership are significantly higher, ranging from 18% in unmarried non-Southern women to 70% in married Southern men. 44% of Americans over 65 have a gun in the household. Thus, gun ownership is high in an age group that bears the greatest burden of chronic illness in general and brain diseases in particular. Eighty percent of all homicides committed by persons over 65 are committed using guns, as are more than half of all suicides (Merten & Sorenson, 2012). Impairments in judgment and impulse control, mood disturbances, and paranoid thinking associated with neuropsychiatric illness increase the risk of violence in general and gun violence in particular. For this reason, cognitively impaired patients should not have access to firearms; at the very least, firearms in their possession should be disabled. Symptoms of anger, aggressiveness, and loss of inhibition raise particular concern, as does the syndrome of major depression.

When a medical psychiatrist is called to assess a patient’s competence, the question of firearms in the home should always be considered, and should be raised in the initial evaluation of outpatients or patients about to be discharged to the community from an inpatient or post-acute care setting. If the patient is not able or willing to answer questions about firearms, questions should be asked of others who know the patient. Patients found to be incompetent thereby losing control of finances, living arrangements, or their mobility may become angry and/or depressed. The combination of diminished mental capacity, hostile or depressive ideation, and ready access to a firearm is potentially deadly. The finding of this combination on psychiatric assessment warrants assertive action to remove, disable, or lock up the guns to which the patient would have access. Family members may be able to assist; when this is not an option, the police can be involved, with the legal theory either being imminent danger to self or others (if the patient has suicidal or homicidal ideation) or legal incompetence, a condition under which the legal guardian or conservator would have control over the patient’s firearms, as they are personal property.

When a patient is severely cognitively impaired, firearm-related risk can be controlled by locking the guns up in a gun safe and securing the key, or by removing ammunition from the home; obviously, complete removal of firearms is safest, but it is not always acceptable to the patient’s family. The most challenging situation is when a patient has sufficient neuropsychiatric disturbance—e.g., a combination of paranoid thinking and impaired impulse control—to be very dangerous with a firearm, but not so grossly impaired that he or she would be found incompetent and eligible to have a guardian or conservator. Informal solutions involving concerned family members should be considered but may not be feasible in particular cases. When facing this dilemma, the medical psychiatrist and the patient’s principal physician should discuss the problem with their hospital’s legal or risk-management department, to share responsibility and benefit from others’ experience and resources.

FINANCIAL DECISIONS

Competence to manage money concerns a continuum ranging from management of an investment portfolio to determining

whether one has received correct change at a convenience store. Patients with diminished capacity for financial decision-making are at risk for exploitation or victimization, as well as for dire consequences from unpaid bills if they have primary responsibility for paying for housing, taxes, and utilities. The consequences of financial mistakes are greater in money terms when the patient has more money; but the consequences of lost money for daily life are greater when the patient has less money.

Money-related behavior is of special diagnostic interest because financial transactions other than cash payments leave a documentary record. Review of credit card and checking account statements and cancelled checks can show such inappropriate financial behavior as repeated payment of the same bills, failure to make necessary payments, or irrational purchases. Examination of brokerage account statements can show behavior like unexpected and unnecessary withdrawals and transfers of funds, erratic patterns of buying and selling securities, investment choices inconsistent with the patient's goals and past behavior, or activity suggesting the influence of a self-serving financial advisor. The onset and progression of signs of bad financial judgment can be used to support a diagnosis of a neurodegenerative disease and to estimate its rate of progression. Furthermore, financial records may be useful objective evidence in legal proceedings. Review of financial records of course requires the patient's written permission or their physical delivery of the records; however, if accounts are jointly held with a caregiving spouse, it may suffice to obtain and record the patient's verbal consent to the physician's discussion of financial details with the caregiver.

As an alternative to the direct examination of financial records, patients' financial competency can be assessed with a structured instrument, the Financial Capacity Instrument (FCI-9) (Martin et al., 2008). The FCI-9 tests the patient on 18 financial tasks covering nine domains; they range from identifying coins and currency and making change, to explaining the parts of a bank statement and comparing investment options. It has acceptable psychometric properties, and its face validity is particularly appealing.

The impetus for a medical psychiatrist to assess a patient's money-related competencies might come from another physician in the form of a consultation request, from a patient's concerned family, from the patient, or from a bank or lawyer responsible for a trust of which the patient is a trustee or a beneficiary. The psychiatrist's follow-up on an assessment that shows a patient has impaired financial decision-making will depend on the psychiatrist's role or "license" in the specific case. If the psychiatrist is providing a consultation, his or her job is to describe the nature and severity of the patient's impairments in financial decision-making capacity, to offer a diagnosis and prognosis if possible, and to make suggestions for mitigating their adverse effects. If the psychiatrist has an ongoing relationship with the patient, the task would be to work with the patient and, with the patient's consent, the family or significant others—to mitigate potential harm related to impaired financial capacity.

In one common situation, the patient has a general medical or neuropsychiatric condition that can impair

decision-making capacity; he or she has made minor financial mistakes or shown errors in calculation, memory, and/or executive function that could cause such mistakes, but they has not yet made any seriously harmful financial errors. Here the physician should point out that the patient has an illness that can affect financial ability and suggest that accommodations should be made for the illness *before* the patient loses money—and perhaps the family's money as well. The specific emphasis in the appeal to the patient can take advantage of the patient's expressed concerns such as a fear of being cheated or the wish to leave a legacy. Changes in credit cards, the right to sign checks, and authority over brokerage accounts must be made while the patient is competent to make them. When the patient has a neurodegenerative condition, there is no time to lose. Competence to change financial arrangements requires a basic understanding of what one's assets are, what bills one is responsible for paying, who would control the assets following a change, and an appropriate rationale for choosing that person. A patient can retain this competence even after losing their ability to handle financial details such as paying bills on time and not paying the same bills twice.

As soon as possible after the diagnosis of a disease that affects decision-making capacity or eventually will do so, patient should be asked if there is someone, typically a family member, whom they would trust to handle their money when or if they were not able. If the answer is other than an unqualified yes, the reason should be investigated, either by the psychiatrist or by a social worker or family therapist. If the issue of mistrust within a family cannot be resolved, an unrelated trustee might be needed to protect the patient's assets.

When patients have substantial assets well beyond those needed to ensure their own care, it is likely that there are already lawyers, bankers, money managers, and/or other professionals involved in financial planning and estate planning. Here the medical psychiatrist can perform—as always with the patient's consent—a valuable service by explaining to the patient's advisors the patient's current decision-making capacity and how it is likely to change over time with the patient's illness. Depending on the audience, the psychiatrist can discuss the patient's testamentary capacity, susceptibility to undue influence, and capacities that are preserved. The latter might range from the ability to make small purchases to the ability to competently object to proposed investments that the patient finds socially or environmentally objectionable.

TESTAMENTARY CAPACITY

When patients with substantial assets disinherit their natural heirs or change their wills in unexpected ways in the setting of general medical or neuropsychiatric disorders that can alter their mental status, the patients' wills often are contested posthumously. Contested wills can lead to expensive and emotionally stressful litigation. In this litigation, physicians are called to testify regarding the patient's mental state at the time of writing (or rewriting) their will. The opinion of a medical psychiatrist who examined the patient contemporaneously with

change in the will is likely to be especially important to the court.

1. When a medical psychiatrist will be involved in the ongoing treatment of a patient with a neuropsychiatric or general medical condition that threatens life and/or will eventually reduce decision-making capacity, the psychiatrist should ask the patient if he or she has a will and how recently the will was updated. Patients should be encouraged to deal with their wills and other estate-planning tasks at a time when they have the energy, insight, and judgment to do the job well. It can be emotionally difficult for anyone to plan for death, and it is even more difficult when the patient can foresee his or her death or the loss of life as they have known it. Even so, consciously choosing one's legacy is part of a person's self-actualization and a healthy response to a heightened awareness of mortality. In assisting the patient with this task, the medical psychiatrist utilizes both psychotherapeutic skills and diagnostic assessment skills. The former are applied to help the patient clarify his or her preferences and reconcile emotional conflicts concerning family members and other loved ones. The latter skills are applied to establish and document that the patient had testamentary capacity at the time a will and/or estate plan was changed. Doing this requires assessment and documentation of six elements, specifically that the patient:
 - a. Knows what a will is;
 - b. Knows what his or her assets are;
 - c. Knows which people have a reasonable claim to be beneficiaries;
 - d. Understands the impact of a particular distribution of assets;
 - e. Does not have delusions or other psychotic phenomena that would affect the decisions made; and
 - f. Can express his or her wishes clearly and consistently.
2. When a patient with known cognitive impairment or diagnosed mental illness writes or changes a will, it is useful to document that the elements of testamentary capacity were evaluated and found to be adequate. When there is anything unusual about the patient's bequests and/or there is a large estate, a video recording should be made of the interview in which testamentary capacity was evaluated. This helps prevent conflict within the family and reduces the chance of a successful challenge to the validity of the will.
3. A medical psychiatrist may be called to consult by the lawyer for an individual who is making changes in a will and/or estate plan that is likely to be challenged by a potential beneficiary (or ex-beneficiary). In this case, the primary purpose of the clinical assessment is not treatment of the patient, but assessment and documentation of the six essentials of testamentary capacity. Many people, including some lawyers and some physicians, have the misconception that a diagnosis of major mental illness, a diagnosis of Alzheimer's disease or of any dementia, or demonstration of significant cognitive dysfunction implies that a new will or trust document will not be valid (Gutheil, 2007). This is not so, for several reasons. First, testamentary capacity is highly specific; a patient with moderate short-term memory loss and episodic disorientation could still have it. Second, the threshold of cognitive performance needed for testamentary capacity is lower if the will leaves most of the patient's assets to natural heirs and does not disinherit anyone who would reasonably expect to be a beneficiary. Similarly, modifications of wills and trusts that do not represent radical departures from earlier versions do not demand a high standard of proof of testamentary capacity. Shifting the percentages of financial assets received by particular children or changing who receives a particular piece of tangible property might induce emotional reactions in the heirs involved, but it is less likely to lead to a successful challenge of a will than more radical changes, such as leaving substantial sums to unrelated parties only recently involved in the patient's life.
4. A medical psychiatrist may be called to consult by family members affected by a recent or contemplated change to an individual's will or estate plan, either to advise those family members, or, if the testator agrees, to see them in consultation to help settle the issue of testamentary capacity and thus mitigate the risk of future family conflicts or litigation. In this situation, the first thing the psychiatrist must do is establish who the client is—the testator or the family member requesting the consultation. Family members, depending on their interests in the will or trust involved, will be hoping for a specific outcome of the evaluation, and it can be presumed that the testator would hope to be found competent to make a valid will.
5. A medical psychiatrist may be engaged by a lawyer to offer a post-mortem opinion of testamentary capacity in connection with a contested will. Retrospective signs of potential testamentary incapacity include:
 - a. Radical change from previous wills;
 - b. Changes that disinherit natural heirs, such as a spouse or a child;
 - c. Changes made reflecting probable delusions, misperceptions, or misunderstandings;
 - d. Changes that disregard the testator's personal history and reflect only the person's current circumstances; and
 - e. Changes suggesting undue influence, such as an unusually large bequest to a recent caregiver who is not related and who was not named at all in the previous will.

TESTAMENTARY CAPACITY AND LIVING WILLS

Validly making or changing a will requires adequate cognitive function and a sufficiently accurate perception of reality; the

more a will deviates from usual expectations, the more positive evidence is necessary that the testator's intentions were rationally formed and free from undue influence or duress. The same considerations applicable to wills are applicable to living wills. In a jurisdiction where living wills are binding on healthcare professionals, a living will that declines life-saving treatment can potentially compel a physician to act against his or her assessment of the patient's best interests. Many hospitals encourage all patients to give advance directives that include a healthcare proxy and a living will. While this is well intentioned, often a patient's cognitive function and emotional state on the day of admission to a hospital may be worse than usual, with implications for the choices the patient might foresee making in various hypothetical situations. The patient might be able to make a valid and rational choice of a healthcare proxy but not be able to get into the details to the extent needed to write a precise living will. In addition, feelings of hopelessness or depression can influence a living will, even though those feelings might be transient, as they can be when they are brought on by severe pain or the shock of a new diagnosis. As with many of the decisions discussed in this chapter, medical psychiatrists are rarely called in to prospectively validate living wills by vouching for their makers' testamentary capacity. However, a medical psychiatrist evaluating patients at any point in their course can ask them about their advance directives. A problem with binding living wills is that it is hard to specify in advance every combination of potentially relevant considerations that might apply to decisions about life-sustaining treatment.

PROFESSIONAL COMPETENCE

As people in business and the professions retire later than they did in the past, there will be ever more cases of impaired professional performance due to neurological and general medical conditions and drugs that affect the central nervous system (CNS). Bad professional or business judgments by physicians, lawyers, accountants, money managers, small business owners, and corporate executives, among others, can have very serious consequences, including harm to clients, financial losses, and the destruction of reputations built over lifetimes. Competent professional practice and satisfactory managerial performance both require a high level of executive functioning, appropriate social behavior, working memory, and the recall of many details. Thus business and professional activities make a greater demand on mental capacity than do ordinary IADLs, and they can be impaired by insults to the brain that do not cause obvious dysfunction in daily life.

At the time this first occurs, standard cognitive screening in a physicians' office or at the bedside—which is designed for detection of delirium and dementia rather than milder or more limited deficits—usually is above the cutoff for abnormality, all the more so because professionals are highly educated and begin with superior baseline performance. When a medical psychiatrist determines that a patient's executive cognitive function, working memory, metacognition, or judgment are affected by a medical condition of any kind, and that the impairment is likely to persist or progress, he or she should

consider whether the patient is still employed and inquire in detail about the actual duties of the job. (In some family businesses and partnerships, senior people are paid but have essentially honorary roles.) If it appears that the observed cognitive dysfunction or other neuropsychiatric symptoms might have an adverse effect on the patient's occupational performance, the issue should be followed up. Neuropsychological testing is almost always helpful, even when the diagnosis is not at issue, because of its value in quantifying specific deficits and in relating them to norms and to the patient's estimated premorbid function. The neuropsychologist should be asked to concentrate on areas of cognitive performance essential to the patient's professional activities.

If relevant deficits are confirmed, the next step depends on the psychiatrist's "license" in the given case. If the patient has a treatment relationship with the psychiatrist, the psychiatrist should meet with the patient and explain the risk of a costly or embarrassing professional mistake if the patient continues to work, emphasizing that it is far better to retire with honor than to be forced out in disgrace. With the patient's consent, family members or trusted professional colleagues can be included in the conversation. If the patient is under the age for full pension benefits at the time of the diagnosis, he or she should be encouraged assert a disability claim rather than simply retire early. If the medical psychiatrist is called in for consultation only and no ongoing treatment relationship is expected, the dialogue just described would be the responsibility of the patient's primary care or principal care physician, or of a mental health professional with an ongoing relationship with the patient.

CONSENT TO PARTICIPATE IN RESEARCH

As with making decisions about clinical care, a patient's capacity to give valid consent to participate in clinical research is characterized by *specificity*, *context dependence*, and *change over time*. Similar as well is the principle that more capacity is needed to validly make a decision that entails greater risk: consenting to a different schedule for taking vital signs requires very little capacity, while consenting to a face transplant requires a very high standard of understanding, reasoning, and appreciation. The fundamental difference between research consent and clinical consent is that a research subject does not necessarily have a rational expectation of direct personal clinical benefit *from the experimental part* of the study.

SHORT-TERM AND LONG-TERM CONSENT

Because of potential changes in decision-making capacity over time, validity of consent to participate in research is a different issue for short-term interventions like diagnostic tests or surgical procedures than it is for long-term ones like trials of treatments for chronic neuropsychiatric conditions such as dementia or bipolar disorder. In the former case, a patient's consent is regarded as valid for the entire procedure unless the patient actively withdraws it. If consent is withdrawn,

participation will end as soon as it can be discontinued without undue risk of harm. In the latter case, consent that is valid at the start of a study may become invalid later on because at that future time the subject's mental condition is different, and capacity to give valid consent has been lost.

In longer-term studies where a subject loses the capacity to consent at some point during the study—either transiently or permanently—the subject's interests are protected by their having a healthcare proxy, in the jurisdictions that permit surrogate consent for participation in research (Gong et al., 2010). The proxy would review the subject's current clinical situation, question the investigator if necessary, and decide whether the subject should continue participating under the aegis of the proxy's consent. The potential role of the medical psychiatrist is in determining that the subject's decision-making capacity is so impaired that the healthcare proxy should be activated. If the subject improves to the extent that he or she can once again make competent healthcare decisions, the healthcare proxy will no longer have authority for either clinical decisions or decisions concerning research participation. Note that, in any case, a research subject can withdraw from a study at any time—withdrawal of assent is valid even if the subject's consent would no longer be regarded as valid.

Patients with cognitive impairment can validly consent to clinical procedures without subtle understanding of their risks and benefits. Patients who are study subjects should, however, be able to indicate their understanding of the following concepts:

1. That they will be participating in research, and that the experimental part of the study should not be expected to have direct personal clinical benefit;
2. That they can withdraw from the study at any time without affecting their clinical care;
3. The general nature of the study interventions, with awareness of any aspect of the study that is invasive, uncomfortable, or unusual;
4. The overall riskiness of participation;
5. An example of a common potential adverse effect of the study intervention (if there are such);
6. An example of a severe potential adverse effect of participation; and
7. Why they want to participate in the study (e.g., "to help science," "because I might get an experimental drug that might help me").

The quality of a cognitively impaired patients' decisions to participate in research can be improved by their identifying a cognitively intact family member or significant other who will accompany them during the informed consent process as an informal auxiliary decision-maker. The patient would agree to participate only if the auxiliary decision-maker concurs. Ideally, this person would also be the patient's healthcare proxy in the event of the patient's incapacity to make clinical decisions.

Medical psychiatrists and professionals of related disciplines like neuropsychiatry and neuropsychology are seldom utilized as part of the research consent process; the policy in virtually all clinical research centers is to exclude patients from a study if there is the slightest doubt about their ability to give competent informed consent. However, psychiatrists do have roles to play in the design and review of studies involving subjects with impaired decision-making capacity and in determining the appropriate time to activate a healthcare proxy during the long-term course of a research subject's care.

Medical psychiatrists also have a potential role to play in protecting vulnerable patients from participation in clinical research that exposes them to risks they would not accept if their decision-making were not compromised. Patients with impairments in cognition, insight, or judgment may minimize or deny the risks of research participation if they are strongly motivated by the expectation of improvement, or by transference toward the physician referring them to the study.

THE THERAPEUTIC MISCONCEPTION

The majority of patients receiving an experimental medication believe it will help them, even if they are told that the benefit of the medication is unknown (Henderson et al., 2007; Kim et al., 2009). This phenomenon, called the *therapeutic misconception*, is almost universal in Phase 1 trials of new cancer drugs, where subjects are patients desperate for a remission from their cancer (Miller & Joffe, 2008). Patients with intact decision-making capacities can at least intellectually understand the therapeutic misconception, even if they cannot stop hoping. With this intellectual understanding, they can weigh the potential for adverse effects. Patients with impaired cognition, insight, or judgment may have unshakeable therapeutic misconceptions that prevent them from appreciating risks that they might find unacceptable.

TRANSFERENCE AND RESEARCH REFERRALS

A patient with a strong positive transference to a physician might sign up for participation in research because that physician referred them to the study—even if the patient has concerns or reservations. Patients insecurely attached to their physicians might participate in research out of fear of disappointing their doctor. In both cases, the risk of inappropriate judgments driven by transference is greatest when critical thinking, insight, and judgment are impaired. In both cases, a research coordinator might not perceive the issue, but it might be uncovered in a medical-psychiatric interview conducted for another reason.

The MacArthur Competence Assessment Tool for Clinical Research (MacCAT-CR), described above, is based on presenting the patient with a vignette specifically designed for the decision to participate as a research subject, and then conducting a semi-structured interview to assess the patient's understanding, appreciation, reasoning, and ability to express a decision. The virtue of the MacCAT-CR is that it brings consistency to the assessment of competence to consent to research; however, the appropriateness of using it will vary

according to how well the vignette captures the issues relevant to the decision to participate. Also, patients with impaired communication due to neurological disorders may have intact decision-making capacity, but require a non-standardized approach to communicating the questions and to understanding the patient's answers. For these reasons, when investigators design consent procedures—or an Institutional Review Board (IRB) reviews ones—that involve the MacCAT, they should pay close attention to the wording and content of the vignettes used. And if the study will involve patients with potential communication impairments, the expected adaptation of the assessment should be described. The input of a speech therapist and/or neuropsychologist may be helpful in doing this.

Despite its limitations, the use of a standardized assessment like the MacCAT is appropriate for assessing capacity to consent to clinical trials of treatments for patients with medical conditions affecting cognition. When a patient's participation in a clinical trial is completely elective, a false negative on a test of decision-making capacity does no harm, and documentation of a rigorous, standardized assessment of capacity to consent protects the researcher—and the research—if there is an adverse event during the study.

LONG-TERM STRATEGY

ESTABLISHING A “LICENSE”

A recurrent theme in this book is that, as healthcare becomes more complex, there is a great need for rationalizing, integrating, and prioritizing the elements of a patient's care—carrying out an overall executive function with respect to the various healthcare providers, formal and informal caregivers, and other stakeholders such as insurance companies and concerned friends. Rarely does anyone formally hold the executive position; primary care physicians and professional care managers tend to influence the decisions of others, but not to control them. Patients themselves, if self-confident and well-informed, sometimes serve as their own “healthcare executives,” but in cases of impaired capacity the patient cannot do this. In some cases, well-informed friends or relatives can do the job. The unmet need for an executive function can offer an opportunity for medical-psychiatric intervention.

In any case, the medical psychiatrist can be most helpful if the scope of his or her “license” in a given case is well-defined. Is it simply to perform and document a detailed mental status examination and offer and document an opinion about decision-making capacity? Or is it to have an ongoing professional relationship with the patient's lawyer and periodic sessions with the patient and their family, and to be available as needed to advise the other medical specialists caring for the patient regarding the patient's current capacities and evolving preferences? If the clinician receives a well-defined request from a medical colleague or from a lawyer, there may be no ambiguity. If the request for consultation from another professional is more open-ended, or if the request comes from the patient or from a relative or friend, the clinician should assess the patient's overall system of care and support and

consider what scope of intervention would be most helpful to the patient, and then seek an appropriate license. This involves explaining one's recommended role to the patient and family, and, based on their acceptance of the recommendation, reaching out to the other professionals involved and establishing one's role with them.

PROMOTING CONSISTENCY WITH THE LIFE NARRATIVE

A widely accepted principle is that surrogate decision-makers should be guided by what patients would have done if they had the capacity to decide for themselves, rather than by the surrogate decision-makers' personal opinions and preferences. This process is facilitated by the patient's participation in planning of the broadest kind long before acute illness forces the issue. Even when planning is done in advance and there is plenty of time, patients may find it hard to do, and they may discover that they disagree with their spouses or significant others. The medical psychiatrist sometimes can help patients find their way by reviewing their life narratives with them—guiding patients in recalling important episodes in their work, relationships, and family lives, to help them see how certain choices would be most consistent with how they have lived to date and with how significant others have behaved in the past. For example, a woman currently feeling distant from an adult son might recall happier times in their relationship and recall that he has always shown good judgment and integrity in financial matters. This might lead to her talking with her son about his being her agent in financial matters if she is incapacitated, and, depending on the outcome of the conversation, naming him as her agent in a durable power of attorney. Without the anamnesis, she might have chosen someone else currently closer to her but with perhaps worse judgment in financial matters.

When the patient has already lost decision-making capacity and no longer has the capacity to articulate meaningful and consistent preferences, the medical psychiatrist must rely on significant others, typically those who present themselves at the hospital or the medical office. The psychiatrist should bear in mind that those who show up are not necessarily those most knowledgeable about the patient's wishes, even if they are those most interested in the outcome of decisions made on the patient's behalf. Before making suggestions to surrogate decision-makers or offering an opinion about who might be a suitable surrogate decision-maker, the psychiatrist should consider whether there are other parties not present whose input should be sought. And, when eliciting opinions from family members, it can help to review the patient's personal history of decisions, values, and relationships with the family, introducing the idea that current decisions on behalf of the patient should be compatible with the patient's life narrative.

ANTICIPATING THE ISSUES

Each disease or combination of diseases has a foreseeable course with respect to periods of incapacity. The nature of incapacity is characteristic and somewhat predictable, even though

the precise time course is not. In neurodegenerative diseases and other invariably progressive diseases, eventual incapacity is certain; in relapsing-remitting conditions it may not be certain, but the risk is large enough to require management. In the behavioral variant of frontotemporal lobar degeneration, for example, driving performance is likely to deteriorate and become unsafe early in the course of the illness. With certain cancers, there are brief periods of physical incapacity, sometimes associated with delirium, accompanying rounds of chemotherapy. With systemic lupus erythematosus (SLE), there is an ongoing risk of brain involvement, which can present with confusion, psychosis, or seizures; the first two imply impaired decision-making, and the last implies driving risk. With bipolar disorder, there is the ongoing risk of a manic episode with the special risk of financial misbehavior. In relapsing-remitting multiple sclerosis (MS), relapses can begin with altered mental status, and vision can be affected with implications for driving. Furthermore, the association of MS with bipolar disorder, euphoria, and frontal lobe syndromes implies an increased risk of the dangerous combination of lost capacity with lost insight.

While talking with patients about their likely future incapacity is never easy, it is essential. Patients are most able to think rationally about issues like writing advance directives, choosing a surrogate decision-maker, or setting up a trust when cognitive impairment is at worst mild, when they are not depressed, and when their significant relationships are not severely stressed by caregiving. Because of technological advances and broader public awareness of dementia, patients with neurodegenerative diseases often are diagnosed at an early stage, when they still have the capacity to choose surrogate decision-makers even though other specific capacities may have already been lost. In a patient with Alzheimer's disease, the modest improvement in cognition attainable with a nootropic agent like donepezil or memantine may restore their capacity to choose a surrogate decision-maker, execute an advance directive, or validly change a will or trust.

For patients involved in a family business or a professional practice, succession planning can be important financially as well as emotionally. Financial and tax issues make the topic relevant as people age, even when there is no expectation of loss of capacity. For this reason, the topic can be introduced as a natural one for the patient's stage of life—one that can be addressed without embarrassment.

KNOWING THE STAKEHOLDERS

In a chronic care situation, there are more "stakeholders"—individuals with interests in the individual's decisions and behavior—than just the patient and the immediate family members who might visit them in the hospital or join them at an outpatient visit. These include:

1. All family members and close friends who either have a caregiving role or might have one, or might reasonably be expected to have one at some point in the patient's course;
2. People who depend upon the patient in some way: financially, emotionally or otherwise;

3. Heirs, potential heirs, or potential beneficiaries of the patient's assets;
4. Professionals and institutions involved in the patient's care; and
5. The public, as represented by laws and regulations. Stakeholders' interests often conflict; legal niceties must be observed especially carefully when there are obvious conflicts of interest and when there are significant assets involved.

MAINTAINING BOUNDARIES WITH FAMILIES

When first interviewing a patient with an issue of impaired capacity of some kind, there is often a family member around who expresses concern about the patient and offers to provide collateral information. If the patient is severely impaired in cognitive functioning or communication, it is customary to talk about the patient with whoever is present in the office or at the bedside, without explicitly seeking the patient's agreement. But when patients are less severely impaired, physicians should ask their permission to share information with family members. When a patient is brought to an outpatient visit by family members, the physician should not talk with the family without the patient present, unless the patient agrees. While these considerations can seem unduly picky when patients are acutely ill, difficult situations of intra-family conflict are not helped by blurred boundaries and fuzzy rules of engagement. Medical psychiatrists should be particularly careful about maintaining boundaries with families, to reduce the risk of being unduly influenced by an opinionated or self-interested family member and the risk of losing the patient's trust and confidence.

IS DECISION-MAKING CAPACITY THE REAL ISSUE?

Requests to evaluate patients' decision-making capacity constitute a significant part of inpatient psychiatric consultation requests, but a well-founded suspicion of impaired decision-making capacity is not present behind many such requests (Kornfeld et al., 2009). Instead, requests for capacity evaluation can arise from an irreconcilable difference between a physician and a patient regarding a decision that the physician sees as against the patient's best interests, as impinging unfairly on other people, or otherwise unacceptable (Kontos et al., 2012). A psychiatric finding of decisional incapacity would settle the conflict by denying the legitimacy of one side. When a psychiatrist identifies such a situation, his or her role shifts to one of identifying the real underlying issue and communicating it to the patient and the medical staff involved. Depending on the issue, the psychiatrist may serve as a mediator, or may simply give the medical staff permission to allow the patient to make what the staff see as an undesirable decision.

At the same time, actual decision-making incapacity probably is under-recognized in general medical settings, probably because if patients assent to care and families do not object, care goes on without concern about whether patients'

signatures on informed consent documents are valid. Using the MacCAT to assess medical decision-making competence, Raymont et al. (2004) found that 31% of a series of 159 acute medical inpatients lacked medical decision-making capacity. None of the patients had been identified by the medical staff as having an issue of competence to consent to treatment. Apparently, the issue of medical decision-making capacity is rarely raised unless a patient objects to a treatment recommended by his or her physician. In the absence of such an objection, it would be unlikely that a psychiatrist would ever be called to evaluate decisional capacity, except in the special case of an unusually high-risk or otherwise controversial procedure.

KNOWING THE LEGAL OPTIONS

Specific laws regarding involuntary psychiatric treatment, surrogate consent, advance directives, and guardianship vary by jurisdiction. As any of these legal devices might be relevant in a given case, the medical psychiatrist should be familiar with all of them. Non-psychiatric physicians often have misconceptions about legal issues.

CHOOSING AND USING A LAWYER

Optimizing patients' legal arrangements to respect their autonomy, their safety, their concerns for their significant others, their personal philosophy, and their desired legacy may require a combination of advance directives and trusts, or, if the patient has become incompetent before making prospective arrangements, a guardianship or conservatorship with a well-chosen surrogate decision-maker with an appropriate scope of authority. The lawyer responsible for drafting documents should understand the concepts outlined in this chapter such as the specificity and context-dependency of capacity and the difference between giving rational reasons and fully appreciating their context and implications. They should also have mediation skills, as intra-family conflict is not unusual.

In the author's experience, lawyers with strong technical and interpersonal skills will develop into outstanding resources for patients and families once they have acquired the relevant medical and neuropsychiatric knowledge. This happens naturally when a medical psychiatrist and a lawyer work together on several cases. The lawyer then becomes a resource to whom the psychiatrist can refer additional patients.

Patients' specific legal issues may touch family law, elder law, the law of estates and trusts, and even insurance law. It is unlikely that one lawyer will have the technical knowledge necessary to address every case. The medical psychiatrist might work with a few lawyers with different legal subspecialties, or might work with one who can easily access subspecialty advice through a firm or professional network.

IDENTIFYING OTHER RESOURCES

In addition to lawyers, the medical psychiatrist with a license to address strategic issues related to patients' changes in

capacity and competency will at times need access to six other resources:

1. Neuropsychologists with experience in doing problem-focused and ecologically valid assessments of cognitive functions relevant to decision-making capacity. They would be able to measure and comment on metacognition and awareness of deficits, fluctuation with context and/or setting, and the potential for compensatory strategies. They would be able to say whether the pattern of observed cognitive dysfunction was compatible with known diagnoses, or whether it suggested additional or different ones. They would be able to relate the observed deficits to relevant functions like medical decision-making, driving, and financial decision-making, and to explain the relationships to families and lawyers as well as to other healthcare professionals.
2. Occupational therapists skilled at assessing functional capacity in natural settings, including patients' homes, and in making home safety assessments.
3. Family therapists with an interest in the family issues of chronic disease and disability, including family obligations and reciprocity, generations' expectations of one another, and sibling conflicts regarding rights, responsibilities, and authority within the family. They would be aware of relevant cultural and religious differences and would know of resources for helping diverse families.
4. Social workers familiar with local supportive resources and residential options. One set of resources and options is applicable to patients and families with means, and another set applies to those without means. In the author's experience, a social worker familiar with one set of resources and options will not necessarily be familiar with the other.
5. A facility for driving assessment, preferably one offering driving simulation as well as the road test option, since certain types of driving-related impairments are better demonstrated in a simulator than by a typical road test.
6. Clergy of various denominations experienced in counseling patients and families about spiritual and religious issues related to competency and decision-making, including issues of intergenerational and spousal obligation and issues related to advance directives and end-of-life care.

These six types of professionals form the medical-psychiatrist's virtual team for comprehensively addressing the legal, ethical, and practical issues that arise when a patient's chronic illness affects decision-making capacity and essential instrumental functions.

CLINICAL PEARLS

- People with cognitive dysfunction or psychotic ambivalence can—and frequently do—consent to treatment but

do not comply with clinical directives; or refuse treatment but do assent to care. Psychiatrists sometimes need to explain these phenomena to legal personnel unfamiliar with neuropsychiatric disorders.

- Advance directives cannot possibly anticipate all medical circumstances, so they work best when there is also a healthcare proxy who knows the patient well and can adequately represent what the patient would want in various circumstances.
- Advance directives should have built-in leeway.
- Resolving conflicts in the very ill often requires not only dialogue, but also enough time for the surrogate to come to terms emotionally with the patient's diagnosis and prognosis (Brush et al., 2013).
- When actually making healthcare decisions, surrogates consider both *patient factors*: respect for the patient's input, past knowledge of the patient's wishes, and the patient's best interests; as well as *surrogate factors*: their own wishes if they were in the patient's situation, their personal interests, religious beliefs or spirituality; family consensus, and obligation and guilt (Fritch et al., 2013).
- Autonomy has a subtlety that psychiatrists may be particularly well suited to appreciate: autonomy involves agency—choosing a course of action in a particular specific situation; and authenticity—choosing a lifestyle, a set of values, and a view of human experience (Brudney & Lantos, 2011).
- People's views change with their experience of illness.
- Some patients speaking in advance of their incapacity prefer balancing substituted judgment and best interests. They also appreciate that their premorbid preferences and present preferences might be different.
- Metacognition has two dimensions, the “feeling of knowing,” and confidence in one's knowledge. Asking patients in the clinical evaluation to assess their capacity on tests allows the physician to place the patient on a continuum of self-awareness that progresses from full appreciation of deficits to frank denial.
- The Clock Drawing Test, scored on a seven-point scale with a cutoff for abnormality of four or less, may be a highly specific screening test for unsafe driving (Freund et al., 2005).
- The medical psychiatrist can work with the patient to anticipate issues, promote consistency with the life narrative, know the stakeholders, maintain family boundaries, and clarify whether decision-making capacity is really the issue.

OBJECTIVE PSYCHIATRIC ASSESSMENT AND MANAGEMENT OF CHRONIC DISABILITY SYNDROMES

C. Donald Williams

INTRODUCTION

Practicing psychiatrists play a complex role in the diagnosis and treatment of patients who present with acute or chronic disabilities that prevent them from functioning in the workplace. Disability is a multifaceted, emotionally charged concept that has important public policy implications: financial and emotional costs endured by disabled workers and their families, and economic burdens on employers and responsible tax-funded government agencies. Psychiatrists can easily find themselves entangled in agendas that extend far beyond the routine doctor–patient relationship when the patient requests certification supporting his or her disability claim.

Our aim in this chapter is to call attention to the different and sometimes mutually exclusive roles that may arise when we are working with patients with disabilities. The role of caregiver is the most familiar role to the majority of clinicians, but psychiatrists may also be serving as consultants to the referring treating physicians, and such consultation may evolve into providing direct care. In another setting, their role may be as an independent psychiatric evaluator hired by a third party to provide an expert opinion. Advocates or adjudicators may then use this opinion to determine the nature and severity of the psychiatric disorder, if any; its causation; whether it is permanent or temporary; and how much, if any, compensation is due to the individual. We will present our view of how evaluations may be best conducted and guidelines that will enhance consistency and objectivity. We will also address the issue of informed consent and limitations on confidentiality.

LOSS OF WORKERS DUE TO DISABILITY

The loss of workers due to disability is a major problem in the United States and other industrialized nations. During the 1990s, insurance companies that insured against disabilities saw claims rise sharply. Claims for disability resulting from disorders that were relatively unknown during the previous decade, such as repetitive strain injury (RSI) and post-traumatic stress disorder (PTSD) grew most quickly. The increased frequency of diagnoses such as PTSD has challenged psychiatrists to distinguish between real and feigned

disorders in a disability context. Between the first quarter of 1989 and the first quarter of 1994, disability insurers saw claims for some diagnoses rise more than 100% (Quint, 1994).

The apparent costs of work-related injuries (defined as injuries or illnesses that cause loss of time from work) have also grown. In 1992, there were 13.2 million nonfatal injuries and 862,200 illnesses in the American workforce. There were approximately 6,500 job-related deaths due to injuries and 60,300 deaths due to disease. The estimated total of the direct and indirect costs of these injuries and illnesses was \$171 billion (Leigh et al., 1997). As of 2008, Leigh estimated that the total of the direct and indirect costs of occupational illness, injuries, and fatalities was, conservatively, \$163.3 billion (Leigh, 2008).

The prevalence of disability remained unchanged from 1999 (22.0%) to 2005 (21.8%). However, as a result of the aging American population, the estimated absolute number of persons reporting a disability increased 7.7% from 44.1 million to 47.5 million. Women had a significantly higher prevalence of disability compared with men at all ages. The prevalence of disability for both sexes doubled in successive age groups (18–44 years, 11.0%; 45–64 years, 23.9%; and >65 years, 51.8%). Because of the size of the “Baby Boomer generation,” the number of adults with disability is likely to increase greatly (see <http://www.cdc.gov/mmwr/preview/mmwrhtml/mm5816a2.htm>).

Contrary to expectations, the economic downturn did not appear to significantly affect the incidence of claims; however, it did seem to affect employment decisions. According to the 2010 Council for Disability Awareness’s Long-Term Disability Claims Review (available at Council for Disability Awareness, Long-Term Disability Claims Review, 2010: http://www.disabilitycanhappen.org/research/CDA_LTD_Claims_Survey_2010.asp), long-term disability claims increased 2.9% from 2008 to 2009 among private insurers.

PSYCHIATRIC ROLES IN DETERMINING IMPAIRMENT

Psychiatrists are tasked with assessing and treating individuals with psychiatric disorders, some of whom have

work-related impairments with disabilities that may result from the impairments. Broadly speaking, the role of psychiatrists in disability matters is to accomplish one or more of the following tasks: (1) provide an expert opinion regarding the presence of any psychiatric diagnoses and their multifactorial causation; (2) describe functional *impairments*—which are limitations to specific functions that may impair the patient’s ability to perform the essential duties of particular occupations; and (3) offer recommendations regarding treatment for the identified conditions. Psychiatrists may also have roles within the broader context of the assessment and treatment of disability, which may involve interfacing with other physicians, vocational counselors, businesses and their representatives, insurance companies, state agencies, and the courts. The complex nature of these relationships is depicted in Figure 86.1.

The actual determination of *disability* results from either an *administrative* or *judicial decision* that weighs evidence and expert opinions, including those provided by psychiatrists; the adjudicators are the “finders of fact.” Adjudicators usually have no formal training in psychiatry or neuropsychology, and rely upon expert opinion.

DEFINITIONS OF DISABILITY

Disability is dimensional, depending on diagnosis, severity of impairment, and life context. In its website (www.who.int/classifications/icf/en/, 2011) the World Health Organization (WHO) defines *disability* as “the outcome or result of a complex relationship between an individual’s health condition and personal factors, and the external factors that represent the circumstance in which the individual lives.” The Social Security Office of Disability programs (www.ssa.gov/disability/, 2011) defines disability as “the inability to engage in any substantial gainful activity by reason of any medically determinable physical or mental impairment(s) which can be expected to result in death or which has lasted or can be expected to last for a continuous period of not less than 12 months.” Private disability insurance policies and state workers’ compensation statutes have their own definitions for what constitutes compensable disability. For example, relative to workers’ compensation, in *Re: Leonard Norgren*, Docket No. 04 18211, The Washington State Board of Industrial Insurance Appeals (www.biia.wa.gov/, 2011) defined disability more specifically in occupational terms: “Disability

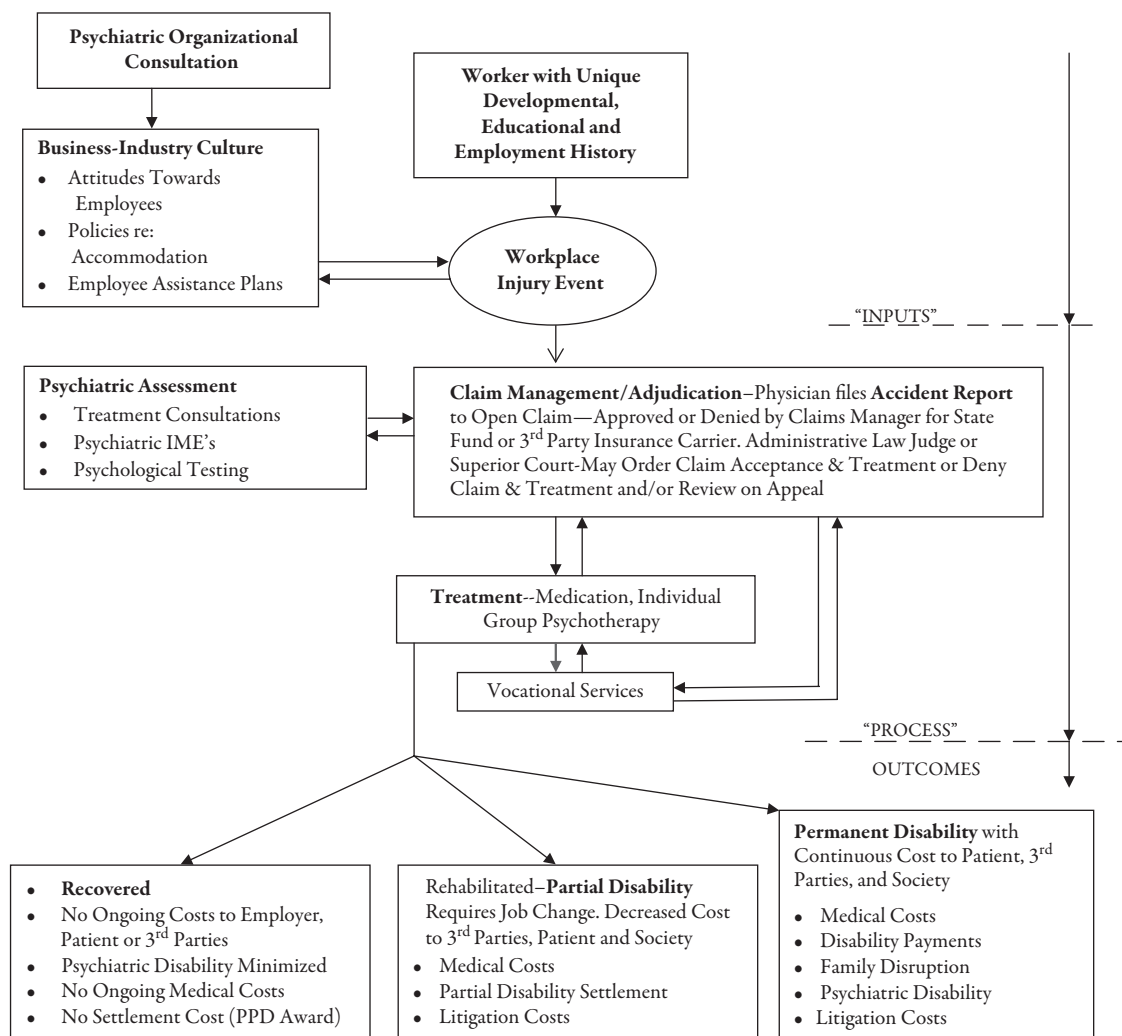

Figure 86.1 Relationship between psychiatrists and stakeholders involving organization and psychiatric disability.

means the impairment of the workman's mental or physical efficiency. It embraces any loss of physical or mental functions which detracts from the former efficiency of the individual in the ordinary pursuits of life. It connotes a loss of earning power."

These definitions imply that disability is an "either-or" condition—i.e., someone is disabled or they are not. The reality is more complex, and in this chapter we take the approach that "disability determination" should be approached taking into account the *diagnosis*, its *severity*, and the life *context* of the person being evaluated.

Independent medical evaluations (IMEs) of disability, perhaps most prominently in the workers' compensation arena, are known for their inconsistency and perceived bias (Shuman & Greenberg, 2003; *New York Times*, 2009; Gold & Shuman, 2009). Bias can be associated with role conflict when the treating clinician is drawn into the role of assessing impairment in the context of a disability claim (Strasburger, Gutheil, & Brodsky, 1997). In this classic paper, Strasburger et al. described the importance of not "wearing two hats"—those of a treating psychiatrist and of an evaluating psychiatrist in a professional relationship with the same person. An evaluator is obligated to be a seeker of truth, whereas a treater's primary duty is to the patient as a seeker of cure and comfort. Gold and Shuman (2009) provide an in-depth examination of bias that arises from other causes, such as failing to maintain a balance between considering the role of real external factors in the workplace such as a hostile work environment, and an individual worker's personal, idiosyncratic response to the work.

In some situations, a treating psychiatrist is compelled by statute or regulation to assume an evaluative role. When this does take place, a psychiatrist's awareness of the potential for role conflict to occur may mitigate its impact. For example, a psychiatrist performing a treatment consultation at the request of an occupational physician under a worker's compensation statute is required to submit a comprehensive psychiatric evaluation using DSM-5 criteria and an opinion about whether the diagnosed conditions are unrelated to an injury, aggravated by the injury, or causally related to the injury, in addition to making recommendations for treatment.

Where necessary, and when circumstances allow, evaluations that require assessment of causation, credibility, and severity, we suggest an enhanced *dimensional* method for assessing psychiatric impairment that incorporates both formal psychological testing and a comprehensive medical record (chart) review and interview of the examinee/patient. We contend that this approach will contribute to greater reliability in diagnosis, causal attribution, and severity ratings. This method, which includes partially quantitative elements, utilizes a *cross-reference grid* that incorporates various rating scales, with definitions for five levels of impairment that enable the rater to "triangulate" the rating by cross-checking one scale against the others (Williams, 2006, 2010). Psychological testing—including the Minnesota Multiphasic Personality Inventory-2 (MMPI-2) and the Minnesota Multiphasic Personality Inventory-2 Restructured Form (MMPI-2-RF) (MMPI-2, 1989; and MMPI-2 RF, 2008), which has been the

subject of many empirical studies that enhance its forensic role in disability assessment applications—can also be added to this comparison grid used for rating psychiatric impairment as shown in Table 86.1.

DIAGNOSES AND THEIR VOCATIONAL IMPACT

Throughout this chapter, we will refer in our discussion to the both the draft version and whenever possible to the final version of the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders*, 5th edition (DSM-5) (available at www.psychiatryonline.org). DSM-5 substantially revised the definition of *Somatoform disorders* to render them more consistent with personality theory and clinical practice. The DSM-5 emphasizes *dimensional* severity determinations for Axis I disorders and revises the definitions of several disorders, which is intended to bring greater clarity to the psychiatric disability assessment and impairment-rating process (Helzer et al., 2008). In assessing the vocational impact of diagnosed psychiatric conditions, we will refer to Fischler and Booth's volume, *Vocational Impact of Psychiatric Disorders* (1999) which correlates the impact of impairment arising from various conditions on the ability to work in different settings.

Finally, we will discuss the conduct of an independent psychiatric evaluation using each of these tools to develop an intellectually consistent, data-driven narrative that incorporates empirically validated psychological testing when indicated to arrive at conclusions regarding the degree of causal relationship between an event, such as an industrial injury; and a mental disorder, such as depression. Our examples will illustrate the use of the interview; the record review; psychological testing to support an opinion regarding diagnoses and their severity; the presence or absence of defensiveness, exaggeration, or in the most extreme cases, malingering or deliberate feigning of symptoms; and the presence or absence of a pre-existing condition that may have been aggravated by the injury or event in question.

For the purposes of this chapter, we will reference the DSM-5 in draft form available in 2011 when this chapter was first written, or when possible the final May 2013 published form because of its improved conceptual clarity. The DSM-IV will be referenced in discussing literature published prior to the publication of DSM-5 in May 2013.

ROLES OF PSYCHIATRISTS IN DISABILITY EVALUATIONS

Psychiatrists may be asked to diagnose and to rate the degree of an individual's psychiatric impairment *or* to treat a person with a psychiatric disorder that contributes to an occupational impairment. Treating psychiatrists may be asked to complete forms in support of their patients' claims for disability benefits or compensation resulting from psychiatric conditions. Independent psychiatric evaluations (IMEs) may

<p>GAF 61–80</p> <p>If symptoms are present, they are transient and expectable reactions to psychosocial stressors (e.g., difficulty concentrating after family argument); no more than slight impairment in social, occupational, or school functioning (e.g., temporarily falling behind in schoolwork).</p> <p>Some mild symptoms (e.g., depressed mood and mild insomnia) OR some difficulty in social, occupational, or school functioning within the household), but generally functioning pretty well, has some meaningful interpersonal relationships.</p>	<p>AMA Guide Class 2 – Mild Impairment</p> <p>“Impairment levels are compatible with most useful functioning”</p>	<p>Profile elevation = 62–68</p> <p>RCd T score range = 65–70</p>	<p>WAC Category (2)</p> <p>Any and all permanent worsening of preexisting personality traits or character disorders where aggravation of preexisting personality trait or character disorder is the major diagnosis; mild loss of insight, mildly deficient judgment, or rare difficulty in controlling behaviour, anxiety with feelings of tension that occasionally limit activity; lack of energy or mild apathy with malaise; brief phobic reactions under usually avoidable conditions; mildly unusual and overly rigid responses that cause mild disturbance in personal or social adjustment; rare and usually self-limiting psycho-physiological reactions; episodic hysterical or conversion reactions with occasional self-limiting losses of physical functions; a history of misinterpreted conversations or events, which is not a preoccupation; is aware of being absentminded, forgetful, thinking slowly occasionally or recognizes some unusual thoughts; mild behaviour deviations not particularly disturbing to others; shows mild over-activity or depression; personal appearance is mildly unkempt. Despite such features, productive activity is possible most of the time. If organicity is present, some difficulty may exist with orientation; language skills, comprehension, memory; judgment; capacity to make decisions; insight; or unusual social behaviour; but the patient is able to carry out usual work day activities unassisted.</p>
<p>GAF 41–60</p> <p>Moderate symptoms (e.g., flat affect and circumstantial speech, occasional panic attacks) OR moderate difficulty in social, occupational, or school functioning (e.g., few friends, conflicts with peers or co-workers).</p> <p>Serious symptoms (e.g., suicidal ideation, severe obsessional rituals, frequent shoplifting) OR any serious impairment in social, occupational, or school functioning (e.g., no friends, unable to keep a job).</p>	<p>AMA Guide Class 3 – Moderate Impairment</p> <p>Impairment levels are compatible with some, but not all, useful functioning</p>	<p>Profile elevation = 69–67</p> <p>RCd T score = 71–76</p>	<p>WAC Category (3)</p> <p>Episodic loss of self-control with risk of causing damage to the community or self; moments of morbid apprehension; periodic depression that disturbs sleep and eating habits or causes loss of interest in usual daily activities but self-care is not a problem; fear-motivated behaviour causing mild interference with daily life, frequent emotogenic organ dysfunctions requiring treatment; obsessive-compulsive reactions which limit usual activity; periodic losses of physical function from hysterical or conversion reactions; disturbed perception in that patient does not always distinguish daydreams from reality; recognizes his fantasies about power and money are unusual and tends to keep them secret; thought disturbances cause patient to fear the presence of serious mental trouble; deviant social behaviour can be controlled on request; exhibits periodic lack of appropriate emotional control; mild disturbance from organic brain disease such that a few work day activities require supervision.</p>

GAF 21–40

Some impairment in reality testing or communication (e.g., speech is at times illogical, obscure, or irrelevant) OR major impairment in several areas, such as work or school, family relations, judgment, thinking, or mood (e.g., depressed man avoids friends, neglects family, and is unable to work; child frequently beats up younger children, is defiant at home, and is failing at school).

Behavior is considerably influenced by delusions or hallucinations OR serious impairment in communication or judgment (e.g., sometimes incoherent, acts grossly inappropriately, suicidal preoccupation) OR inability to function in almost all areas (e.g., stays in bed all day; no job, home, or friends).

AMA Guide Class 4 – Marked Impairment

Impairment levels significantly impede useful functioning

Profile elevation = 77–81

RCd T score = 77–84

WAC Category (4)

Very poor judgment, marked apprehension with startle reactions, foreboding leading to indecision, fear of being alone and/or insomnia; some psychomotor retardation or suicidal preoccupation; fear-motivated behaviour causing moderate interference with daily life; frequently recurrent and disruptive organ dysfunction with pathology of organ or tissues; obsessive-compulsive reactions causing inability to work with others or adapt; episodic losses of physical function from hysterical or conversion reactions lasting longer than several weeks; misperceptions including sense of persecution or grandiosity which may cause domineering, irritable or suspicious behaviour; thought disturbance causing memory loss that interferes with work or recreation; periods of confusion of vivid daydreams that cause withdrawal or reverie; deviations in social behaviour which cause concern to others; lack of emotional control that is a nuisance to family and associates; moderate disturbance from organic brain disease such as to require a moderate amount of supervision and direction of work day activities.

be commissioned for individuals with whom they have no doctor–patient relationship, to assess disability in connection with such claims. These roles can be broken down into three categories as set forth in Table 86.2.

1. A *treating* psychiatrist is asked to certify the partial or complete inability of the patient to perform the essential duties of an occupation in order for the patient to receive disability insurance benefits. Fischler and Booth (1999) describe the vocational impact of Axis I and Axis II DSM-IV conditions and present detailed suggestions about their management to improve the rate of successful return to employment. If the inability is partial, then accommodations by the employer may permit either full-time or part-time work, which may affect the amount of disability benefit. Many treating psychiatrists decline to perform this function. They do so because agreeing or declining to certify the patient as disabled has the potential to create a conflict of interest that can damage or destroy the doctor–patient relationship due to possible damage to the financial interests of the patient, causing a breach of trust. To protect the treatment relationship and also to promote an objective opinion, treating psychiatrists usually recommend that an independent psychiatric evaluation be performed. There are special situations in which this may not be possible, but they should be examined carefully prior to making an exception (Strasburger, Gutheil, & Brodsky, 1997; Gold et al., 2008; Gold & Shuman, 2009).
2. A *consulting* psychiatrist is asked to evaluate and possibly treat a patient with a psychiatric condition; this is termed a *treatment evaluation*. This usually involves a directed record review, a patient interview, and psychological testing. The nature of the evaluation is made clear to the potential patient at the outset. The patient to be evaluated is told who is paying for the evaluation, who will receive a copy of the evaluation, and the limitations on confidentiality. The patient is informed that a treatment relationship may be established with the evaluator if a treatable condition is identified, if treatment is authorized, and if both the examinee and the evaluator come to an agreement regarding a plan of a treatment.
3. An *independent psychiatric evaluation* of an individual is commissioned with an explicit bar on assuming a

treatment relationship, in order to avoid a conflict of interest that might compromise the objectivity of the assessment or the welfare of the examinee. This evaluation entails a comprehensive record review, which often extends years into pre-injury medical records, an interview of the examinee, and in many cases psychological testing (Williams, 2006; Williams & Schouten, 2008; Gold et al., 2008; Gold & Shuman, 2009). Informed consent is obtained and documented, including the fact that no doctor–patient relationship is being established, nor will one be established; notification as to who is paying for the report; and notification as to whom a copy of the report will be provided. The examinee has the right to decline the evaluation, although this may have an impact on their benefit status.

THE MEANING OF IMPAIRMENT TO THE INDIVIDUAL

Impairments are limitations to specific functions resulting from an illness or condition. For example, in the case of depression, impairments can take the form of difficulties with memory, attention, affect-regulation, and decision-making. The meaning of impairment to an individual depends on the interplay of a number of factors:

1. If their impairment is relevant to their work, it will have a more negative impact than if it is irrelevant to their work.
2. If their education and experience qualify them for alternative employment, their adaptation to impairment will be easier.
3. If they have a high level of personality functioning as defined by the DSM-5, then they will be better able to cope with the social and intrapsychic consequences of a new impairment.
4. As a consequence, individuals with similar objective impairments may experience widely varying degrees of *disability*. The work impact of a physical injury that prevents standing for long periods of time is different for a surgeon than it is for a psychiatrist. Colorblindness results in only a few employment restrictions, and little psychiatric morbidity. Other impairments, such as complete sightlessness, result in greater limitations, although

Table 86.2 PSYCHIATRIST ROLES IN DISABILITY EVALUATIONS

PSYCHIATRIST ROLE	TREATMENT	CERTIFY DISABILITY	RECOMMEND ACCOMMODATIONS
Treating	Yes	May be required, but conflict of interest avoided when done by IME psychiatrist	May be required, but conflict of interest avoided when done by IME psychiatrist
Treatment consultation	Depends on need, authorization and mutual agreement	Yes, required by authority	Yes
Independent psychiatric evaluation	No with very rare exceptions	Yes	Yes

substantial community support and having an identity within the community may lessen the impact. Psychiatric disorders may cause direct suffering from illness-related symptoms such as depression, anxiety, panic, pain, and psychotic symptoms.

5. Indirect suffering, resulting from the damage to the patient's self-esteem related to loss of functional capacity and all the losses this entails, may cause greater distress.
6. Unemployment resulting from disability can lead to disturbance of self-functioning through damage to the identity and self-direction. As with physical disabilities, the most common chief complaint encountered in a psychiatric disability evaluation is some variation on the theme of "I can't do what I used to do."
7. Vulnerability to psychic damage in these arenas is related to the individual's *internal resources*; i.e., level of personality integration prior to suffering the disability, as well as to their *external resources*; i.e., access to medical, financial, and social support. A person with no impairment in *self-identity* as defined by the DSM-5—"awareness of having a unique identity, grounded in personal history, along with continuity in self-states and the ability to think about and make sense of internal experience"—is equipped to cope much more successfully with the stress of injury and disability than someone with even a moderate level of impairment, for whom the regulation of self-states often depends on context (e.g., prestige and recognition in the community) and who has an impaired capacity to think about internal experience.

Access to external resources, such as replacement income from a disability insurance policy coupled with continued health insurance, will reduce anxiety and depression as well as improve the prospect for recovery of health and maintenance of the patient's family's daily functioning. If, in contrast, unemployment resulting from disability leads to loss of income, health insurance, and access to health care, it is a near certainty that the individual will experience at least some degree of anxiety and depression, as well as face an increased risk of interpersonal conflict with damage to the individual's capacity for intimacy and empathy. The degree to which the individual may be subject to decreased functioning in either the self or interpersonal functioning is related to their premorbid level of functioning (internal resources), the severity of their injury or illness-caused impairment, and their life circumstance (external resources).

A thought experiment may help the clinician better appreciate the impact of physical and mental impairments on employment and income. Much has been written about the emotional trauma experienced by the 10% of the workforce who are considered to be "long-term unemployed" as a result of the recession of 2008–2011 and their uncertain work future. Those unemployed because of larger economic forces receive some societal sympathy and up to 99 weeks of unemployment insurance (see http://www.edd.ca.gov/Unemployment/Federal_Unemployment_Insurance_Extensions.htm). In contrast, individuals who are unemployed because of a psychiatric impairment in connection

with a job-related injury suffer the stigma of being at least "different," or viewed as dishonest, often in combination with mental and sometimes physical pain. They experience loss of their work-role identity within the family, their community, and among their friends. In addition, they experience a loss of personal worth because they drain rather than contribute to the family's financial well-being.

Economic hardship is a common consequence of disability. Virtually all disabled people experience economic anxiety. For many families, the loss of "everything I worked for" and possibly actual bankruptcy are the outcome.

The *psychological meaning* of the disability to the individual is determined by factors that provide a context for the injury or illness, define its consequences, and either support or impede recovery. These factors are listed in Box 86.1.

The *duration* of disability influences the degree of trauma. A rapid return to work entails little emotional distress. In contrast, prolonged disability and unemployment may lead to depression, anxiety disorders, and somatoform disorders.

PSYCHIATRIC CONDITIONS COMMONLY ASSOCIATED WITH DISABILITY

Depression

Depression is an important cause and consequence of disability with economic impact, both as a primary disorder and in combination with other medical illnesses. The total estimated workplace costs of absenteeism and impaired working ability associated with depression amounted to \$44 billion in 2001–2002, and nearly 80% of the lost productive time was invisible to the employer, as it resulted from decreased productivity while at work, termed "presenteeism" (Stewart, Ricci, Chee, Hahn, & Morganstein, 2003).

In a classic article, as relevant today as when it was originally published, Gallagher and Meyers (1996) describe how untreated depression leads to increased costs and disability. Patterns of delay in specialist referrals reflected patterns of conflicts present in the disability arena. Worse outcomes and increased costs were related to the average delay from injury to obtaining approval for a specialist referral, and from specialist referral to a comprehensive pain rehabilitation center. Indeed, mild to severe depression is the most common psychiatric finding after disabling injury (Williams & Schouten, 2008). The severity of pain associated with the injury is significantly correlated with the development of depression over time (Gallagher & Meyers, 1996; Fishbain et al, 1997) and negatively correlated with return to work. Not only its severity, but the affective dimension of pain is closely related to return to work after injury. In a longitudinal study of 185 injured workers (Corbiere, Sullivan, Stanish, & Adams, 2007), the *sensory* dimension of the pain experience was distinguished from the *affective* dimension on the Short-form McGill Pain Questionnaire (SF-MPQ-2) (Dworkin et al., 2009; Melzac, 1983; Melzac, 1987). The affective dimension included four items: *tiring-exhausting*, *sickening*, *fearful*, and *punishing-cruel*. The 11 sensory items describe physical sensations without an affective valence. Examples include *hot-burning* and *cramping*.

Box 86.1 FACTORS INFLUENCING THE MEANING OF DISABILITY TO THE INDIVIDUAL

Gender
Age of onset
Congenital or acquired impairment
Severity
Adaptive capacity of the individual
Single or multiple disabilities
Absence or presence of pre-existing mental illness
Level of personality functioning per DSM-5
Effect on vital functions, e.g., work, recreation, sex
Prognosis for recovery
Financial impact
Prior level of functioning
Family and social support
Pain distribution, quality, intensity
Access to quality medical and rehabilitation services

Depression was assessed for the purposes of the study by the Beck Depression Inventory (BDI-II) (Beck, Steer, & Brown, 1996). This study confirmed a strong association between affective pain and depression over time. Both the level of affective pain and depression severity correlated negatively with return to work, and the effect size was great. Eighty-five percent of workers ($N = 74$) with only “normal ups and downs” and low affective pain levels returned to work. In contrast, only about 20% of workers ($N = 41$) with moderate to severe depression and high affective pain levels returned to work. The BDI-II and the SF-MPQ may be measuring similar *somato-affective elements*. Another widely used screening test for measuring depression is the Patient Health Questionnaire (PHQ-9, 1999) available at www.Phqscreeners.com/overview.aspx.

A detailed comparison of the PHQ-9, DSM-IV-TR, and the BDI-II with recommended questions for the assessment of depression is presented by Williams and Schouten (2008) in Figure 86.2.

Regardless of the assessment tool used, these findings are consistent with the DSM-5 reformulation of *Somatoform disorders*. Depression that follows an injury serious enough to

DSM-IV-TR	PHQ-9	BDI-II	Suggested Screening Questions for Occupational Physician Interview
Criteria for major depressive episode: Five (or more) of the following symptoms have been present during the same 2-week period and represent a change from previous functioning; at least one of the symptoms is either (1) depressed mood or (2) loss of interest or pleasure.	Over the last 2 weeks, how often have you been bothered by any of the following problems? Read each item carefully and circle your response.	Each of the 21 categories listed below contains a group of 4 statements, scored from 0–3. The categories are matched to the estimated closest DSM IV listing.	
Depressed mood most of the day nearly every day	Feeling down, depressed, or hopelessness	Sadness, pessimism, self-dislike	Have you or the people you are around noticed that your average mood has changed over the last month or so or compared to before you were injured?
Markedly diminished interest or pleasure in activities most of the day, nearly every day	Little interest or pleasure in doing things	Loss of pleasures, loss of interest, loss of interest in sex	Do you enjoy doing things less or are you less interested in doing things than you used to be?
Change of more than 5% body weight in a month or decrease or increase of appetite nearly every day	Poor appetite or overeating	Changes in appetite	Have you gained or lost more than 5 or 10 pounds in the last month? Has your appetite changed?
Insomnia or hypersomnia nearly every day	Trouble falling asleep, staying asleep; or sleeping too much	Changes in sleeping pattern	Please describe your sleep pattern to me. When do you usually fall asleep at night; how many times do you wake up during the nights; and when do you get up for good? Do you take naps during the day?
Psychomotor agitation or retardation nearly every day	Moving or speaking so slowly that other people could have noticed. Or being so fidgety or restless that you have been moving around a lot more than usual	Agitation, irritability	How would you and the people you live with describe your temper and irritability? Do you feel like you are more restless and on edge, or do you feel like you can't ever get going?

Figure 86.2 Comparison of DSM-IV TR, PHQ-9, BDI-II, and Suggested Screening Questions.

Fatigue or loss of energy nearly every day	Feeling tired or having little energy	Loss of energy, tiredness, or fatigue	What would you estimate your energy is now as a percentage of what it used to be?
Feelings of worthlessness or inappropriate guilt nearly every day	Feeling bad about yourself, feeling you are a failure, or feeling you have let yourself or your family down	Past failure, guilty feelings, punishment feelings, self-criticalness, worthlessness	Do you feel guilty or worthless?
Diminished ability to think or concentrate nearly every day	Trouble concentrating on things such as reading a newspaper or watching television	Indecisiveness, concentration difficulty	How would you describe your memory for recent events? Is it harder for you to read a newspaper or pay attention to what you were doing? When do the changes occur?
Recurrent thoughts of death, suicidal ideation, or suicide attempt	Thinking that you would be better off dead or that you want to hurt yourself in some way	Suicidal thoughts or wishes	Do you find yourself thinking about death more than you used to? Do you sometimes wish you wouldn't wake up? Have you thought of suicide, or ever made any plans or attempts to kill yourself?
N/A	N/A	Crying	How often do you become tearful or have crying spells? Several times per day/week/month?
<p>“The symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.”</p> <p>“The symptoms are not better accounted for by bereavement or by the direct physiological effects of a substance (e.g., a drug or abuse or a medication) or a general medical condition (e.g., hypothyroidism)”</p>	<p>If you checked off any problem on this questionnaire so far, how difficult have these problems made it for you to do your work, take care of things at home, or get along with other people?</p> <ul style="list-style-type: none"> - Not difficult at all - Somewhat difficult - Very difficult - Extremely difficult <p>Response for each question: 0 = Not at all 1 = Several days 2 = More than half the days 3 = Nearly every day</p>	<p>Each category contains four statements that are scored from 0–3, depending on the severity of symptom. (Statements omitted for space and copyright reasons.)</p>	<p>If the patient endorses thoughts of suicide or gives a positive responses to two or more of the other questions, further assessment is indicated</p>
Consult reference to “Practice Guidelines” published by the APA	<p>≤ 4 The score suggests the patient may not need depression treatment.</p> <p>> 5–14 Physician uses clinical judgement about treatment, based on patient’s duration of symptoms and functional impairment.</p> <p>≥ 15 Warrants treatment for depression, using antidepressant, psychotherapy, or a combination of treatments.</p>	<p>0–13 points = minimal depression</p> <p>14–19 points = mild depression</p> <p>20–28 points = moderate depression</p> <p>29–63 points = severe depression</p>	

Figure 86.2 continued

cause a significant disruption of work is usually the result of multiple losses:

- Loss of role status, both in the family and in the community, which impacts the self-identity as described in DSM-5
- Loss of hope of recovery
- Loss of normal recreational outlets involving high-demand physical activity such as hunting, fishing, and other sports
- Sexual dysfunction, with adverse impact on overall life satisfaction and the partner relationship
- Chronic pain resulting in a loss of sense of well-being
- Shame, blame, depression, and anger are nearly universal reactions to the loss of the ability to work

The risk of suicide should never be underestimated and should always be assessed when treating or evaluating the disabled worker. It is increased in the presence of substance abuse, in single males without a social support system, and for those with comorbid psychiatric disorders, including psychotic disorders and/or impulse control disorders.

Somatic Symptom and Related Disorders

Somatoform (formerly “psychosomatic”) disorders are among the most common causes of employee disability, but they have not been generally well understood or effectively treated (Bass, Peveler, & House, 2001), and they come with cultural and developmental bias (Stoudemire, 1991). In DSM-5 the new

category *Somatic Symptom and Related Disorders* replaces the DSM-IV category of Somatoform Disorders. All the disorders share prominent somatic symptoms associated with significant distress and impairment (see <http://www.psychiatryonline.org>, 2014). Within this new category 300.82 *Somatic symptom disorder* incorporated Somatization disorder, and both Pain disorder diagnoses (with and without a general medical condition) from DSM-IV. 300.7 *Illness anxiety disorder* corresponds to Hypochondriasis in DSM-. 300.11 *Conversion disorder* retains the same coding as in DSM-IV. 316 *Psychological factors affecting other medical conditions* is a new DSM-5 diagnosis. 300.19 *Factitious disorder* had a separate category in DSM-IV but is included among Somatic Symptom and Related Disorders in DSM-5. 300.89 *Other specified somatic symptom and related disorder* is used when a somatic symptom disorder or illness anxiety disorder is of less than 6 months duration. 300.82 *Unspecified somatic symptom and related disorders* replaces Somatoform disorder NOS and is used only “in decidedly unusual situations where there is insufficient information to make a more specific diagnosis.” The proposed change responded to the criticism that the DSM-IV nosology was confusing, suggested a mind–body dualism, and unreliably required the identification of “medically unexplained symptoms.” The DSM-5 formulation recognizes that many of the DSM-IV *Somatoform disorder* diagnoses incorporated cognitive distortions and somatic symptoms.

These changes will simplify the diagnostic work of the psychiatric evaluator by providing a conceptual framework that is more consistent and has less overlap and confusion. Table 86.3 illustrates the relationship between the DSM-IV and DSM-5 somatoform terms and diagnoses.

Table 86.3 SOMATOFORM TERMS IN DSM IV AND DSM 5

DSM IV-TR	DSM-5
Somatoform disorders – emphasized medically unexplained symptoms – “unreliable and pejorative”	Somatic symptom and related disorders (new category in DSM-5) – all share prominent somatic symptoms associated with psychological distress and impairment – “more useful for primary care and other medical clinicians”
300.81 – Somatization disorder	300.82 – Somatic symptom disorder – may or may not be associated with another medical condition, but with high levels of worry about illness – emphasis on distressing symptoms and impairment rather than absence of medical explanation.
307.89 – Pain disorder associated with psychological factors and a general medical condition	Specifiers
307.8 – Pain disorder associated with psychological factors	<ul style="list-style-type: none">• With predominant pain (most commonly)• Persistent• Mild, moderate, severe
300.7 – Hypochondriasis	300.7 – Illness anxiety disorder (hypochondriasis without somatic symptoms) – care seeking or care avoidant
300.11 – Conversion disorder	300.11 – Conversion disorder (Functional neurological disorder) – specific qualifiers do not change coding. May be diagnosed in addition to Somatic symptom disorder.
In separate category in DSM-IV	316 – Psychological factors affecting other medical conditions – includes patterns of interpersonal interaction, coping style, and maladaptive health behaviors
	300.19 – Factitious disorder (intentional falsification of physical or psychological symptoms)
	300.89 – Other specified somatic symptom and related disorder – do not meet full criteria for any of the disorders in the somatic symptom or related disorders class
300.82 – Somatoform disorder NOS	300.82 – Unspecified somatic symptom and related disorder – to be used in decidedly unusual situations

Anxiety Disorders

Anxiety disorders are commonly associated with disability. The normal worry and concern associated with any health problem increases as a disability becomes chronic and the workers' normal life pattern is broken. Panic disorder, with or without agoraphobia, is a common outcome and is usually associated with depression. The real loss of income associated with damage to the worker's self-esteem connected with loss of work-role identity contributes significantly to uncertainty, fear of the future, and the exacerbation of anxiety disorders.

Personality Disorders

Personality disorders have been defined as "an enduring pattern of inner experience and behavior that deviates markedly from the expectations of the individual's culture" in two or more areas, including *cognition, affectivity, interpersonal functioning, and impulse control*. Because "the enduring pattern is inflexible and pervasive across a broad range of personal and social situations," the personality disorder allows for less adaptability in individuals who have impairments. As a result, a given impairment often leads to greater disability in someone with a personality disorder than in an individual without one.

CLINICIANS AND FORENSIC EVALUATORS HAVE DIFFERENT ROLES

Viewing psychiatric practice broadly, there are two fundamental types of diagnostic evaluations, *forensic* and *clinical* (Strasburger et al., 1997; Gold & Shuman, 2009). These two types of evaluations have separate goals, and whenever possible should be conducted by separate psychiatrists, although this may sometimes be difficult to achieve in actual practice. A clinical evaluation is undertaken to formulate an effective treatment plan and is properly carried out by the potential or current treating psychiatrist. Its focus is on the patient's symptoms, the patient's subjective view of him- or herself and the world, and how best to relieve the patient's suffering. A forensic evaluation, in addition to identifying symptoms and eliciting the evaluatee's subjective views, is aimed at an objective determination of symptoms, their severity, and often causation. Although the two types of evaluations overlap, there is a difference in emphasis, and there are intrinsic conflicts between the two roles.

At the heart of this conflict is the fundamental notion that the clinician and the independent evaluator serve "different masters." The clinician has an ethical duty to act only in the best interests of the patient. Thus, if patients are distressed and unhappy at work, the clinician may believe it is necessary to assist them in staying out of work until the causes of the distress have been addressed and corrected. The independent evaluator, on the other hand, has an obligation to provide an objective, scientifically based opinion. The relationship is one of evaluator–evaluatee, not doctor–patient, although a limited

duty remains even in an evaluator relationship. For example, if the evaluator discovers in the course of the evaluation that the examinee is acutely suicidal, the evaluator is obligated to take any necessary steps for the purpose of preservation of life, as in any clinical situation. In essence, a duty to protect exists in a clinical setting and in an evaluator–evaluatee relationship.

Another major difference between the clinician and the independent evaluator is how the information they glean is used. Under the traditional psychotherapeutic model, the treating clinician attempts to see the world through the eyes of the patient: historical accuracy is less important than individual perception. As a result, the treating clinician may or may not review prior medical records. In addition, the treating clinician rarely looks to outside sources to corroborate the patient's story. Even contact with family members may be controversial. The independent evaluator, on the other hand, is in search of an objective, accurate assessment, and must evaluate the medical records as extensively and closely as possible. The independent evaluator will also evaluate other sources of information, including court records, reports of private investigators, and personnel records. Such materials rarely serve any purpose in the treatment of the patient, yet they can make a crucial difference in the forensic assessment of disability. Finally, the treating clinician who fills out forms or gives testimony in a manner contrary to what the patient sees as being in his or her best interests may find that the treatment relationship is damaged or destroyed.

Patients have real health considerations that must be factored into their psychiatric treatment. For this reason, it is important for the treating psychiatrist to review medical records related to their patients to accurately provide coordinated diagnosis and treatment.

Patients commonly become involved in the legal system in pursuit of their disability claims. This could further complicate the treatment relationship. It is prudent for clinicians to resist external pressures emanating from the attorney or patient, and the internal pressures from the therapist's allegiance to the patient. The legal process is directed toward the resolution of disputes; psychotherapy pursues the medical goal of healing. Although these purposes may be congruent, the legal processes may create an irreconcilable role conflict. In essence, treatment in psychotherapy is brought about through an empathic relationship that has no place in, and is unlikely to survive, the questioning and public reporting of a forensic evaluation (Strasburger et al., 1997).

Institutional policies often force treating psychiatrists to function in both roles in disability determinations, such as, for example, by requiring either concurrence or non-concurrence with independent medical evaluations (IMEs). Court testimony is frequently required in administrative law hearings when disputes arise, where by law the testimony of the treating psychiatrist is given more weight than is that of the forensic evaluator, on the grounds that the treating psychiatrist is more knowledgeable about the patient. When the treating psychiatrist must participate in

the disability evaluation process, the following principles should be kept in mind:

- Obtain and document informed consent from the patient to disclose information provided during the course of the treatment.
- Have a clear understanding of the patient's job duties.

Occasionally a patient in treatment will seek disability benefits, and the psychiatrist may view that as contrary to their best interests. In some instances, this issue can be productively discussed and treatment advanced. In other cases, the patient may be acting out dependency issues or other, more serious character problems, and a second opinion and consultation will help. If this does not resolve the impasse, and if the psychiatrist believes that the patient's course of action is incompatible with treatment, an orderly termination may be best. Alternatively, the patient may quit treatment when he or she realizes that the psychiatrist will not participate in their effort to be declared disabled.

TYPES OF PSYCHIATRIC DISABILITY EVALUATIONS

Different types of psychiatric disability evaluations have differing requirements. Table 86.4 outlines their distinctions.

SOCIAL SECURITY DISABILITY EVALUATIONS

A Social Security Disability (SSD) evaluation requires an assessment of mental health impairment *without* reference to causation, and is less complex than worker's compensation evaluations (Williams, 2010, 2013). Disability Determination Services (DDS) contracts with "consultative examiners" to provide psychiatric evaluations. No opinion is requested regarding causation, and testimony is not required. The psychiatric evaluation includes a detailed description of a "typical day" for the claimant and a detailed mental status examination. The report includes an opinion about treatment, the prognosis, and the claimant's ability to manage their funds. DDS supplies records for review, typically fewer than 20 pages. The Social

Table 86.4 TYPES OF PSYCHIATRIC EVALUATIONS AND THEIR DISTINCTIONS

EVALUATION TYPE	DSM-IV DIAGNOSIS	SEVERITY OF IMPAIRMENT RATING	WORK RESTRICTION OPTION	TREATMENT RECOMMENDATION	CAUSATION OPINION
Social Security Disability	Yes	Global – is examinee incapable of any gainful employment by reason of listed impairments in Mental Functional Residual Capacity Evaluation?	Limited to whether examinee is capable of full time gainful employment	No	No
Fitness for duty	No	Do the impairments impact the ability of the examinee to perform the essential duties of their job?	Yes	May be requested	No
Personal injury	Yes	Yes – as it relates to loss of ability to function at pre-injury level in determining amount of economic damage	Yes	No	Yes
Private disability insurance	Yes	Global – is examinee capable of work according to the terms of their disability insurance policy?	Yes	Yes	No
Worker's Compensation – <i>treatment consultation</i>	Yes	General – for purpose of authorizing treatment, not for financial award	Yes	Yes – may offer psychiatric treatment if authorized	Yes, to determine whether treatment should be authorized for related condition or as aid to recovery
Worker's compensation – <i>forensic</i>	Yes	Yes – referencing statutory guidelines for purpose of financial award	Yes	Yes – may not become treating psychiatrist	Yes; rating for purpose of determining financial award

Security Disability Insurance (SSDI) benefit program serves as a backup benefit system for workers' compensation (Bresnitz et al., 1994).

Attorneys representing a claimant may request a psychiatric evaluation on their client's behalf to assist in an appeal. Because evidence is under judicial review, psychological testing is often used to provide more facts regarding the claimant and may be ordered specifically by the administrative law judge or by the attorney representing the claimant. An opinion is required regarding whether the claimant meets the definition of having a *listed mental disorder*, and if so, whether their impairment(s) meet the threshold criteria specified by the Social Security Administration. Definitions or "listings" of mental disorders are similar to those in the DSM-IV TR, and are contained in the *Social Security Blue Book*, which is available online (at <http://www.ssa.gov/disability/professionals/bluebook/12.00-MentalDisorders-Adult.htm>). Mental disorders are listed and defined in Sections 12.01 through 12.10, and are contained in the "Psychiatric Review Technique Form." Form SSA-2506-BK organizes and presents the "mental findings" in a concise and consistent manner and evaluates aspects of mental impairment relevant to the individual's ability to perform work-related mental functions. If the examinee meets or exceeds the criteria of the listings, then a "Mental Residual Functional Capacity Assessment" is completed. This form, SSA-4734-F4-SUP (<http://ssaconnect.com/tfiles/SSA-4734-F4-SUP.pdf>), lists 20 mental capacities in four categories of mental functioning, each with five possible severity ratings—*not significantly limited*; *moderately limited*; *markedly limited*; *no evidence of limitation in this category*; or *not ratable on available evidence*. Some of these capacities are:

1. *Understanding and memory*—the ability to remember locations, procedures, and simple and detailed instructions.
2. *Sustained concentration and persistence*—the ability to carry out simple or detailed instructions, adhere to a schedule, maintain a routine, work around other people, make work-related decisions, and complete a normal workday and work week at a consistent pace without interruptions.
3. *Social interaction*—the ability to interact appropriately with the general public, the ability to ask questions and request assistance, the ability to accept instructions and respond appropriately to criticism from supervisors, the ability to get along with co-workers or peers, the ability to maintain socially appropriate behavior and maintain basic standards of neatness and cleanliness.
4. *Adaptation*—the ability to adapt to changes in the work setting, to recognize hazards and take precautions, to travel in unfamiliar places or use public transportation, and to set realistic goals and work independently.

The judge reviews the evidence at a hearing, interviews the claimant and other witnesses, and renders a decision on the claimant's application.

In summary, the impairments resulting from the examinee's psychiatric disorders are described in the psychiatric evaluation, but the decision regarding whether or not the criteria for disability under the Social Security Act were met are the responsibility of the adjudicator.

"FITNESS FOR DUTY" EVALUATIONS FOCUS ON EXAMINEE'S ABILITY TO PERFORM THE ESSENTIAL DUTIES OF A SPECIFIC JOB

"Fitness for duty" (FFD) evaluations may be requested under two common scenarios. The first is when an individual employee's health status changes, raising questions about his or her ability to safely and effectively perform the essential functions of the job. The second scenario arises when an employee has been out of work due to illness, and his or her fitness for duty needs to be assessed prior to their return. In contrast to SSD and workers' compensation evaluations, it is usually not necessary for a FFD evaluation to describe the examinee's developmental history and background unless elements of them are specifically relevant to the assignment (Williams, 2010). For example, a nurse's aide may develop a major depressive illness accompanied by markedly increased irritability, crying spells, and impaired concentration and memory. The evaluator may conclude that until the major depressive episode has resolved, it would be unsafe for this individual to provide patient care, and may judge the nurse's aide to be temporarily disabled for that position. The challenge of these evaluations is to focus on the individual's ability to function in a certain job.

Petersen-Crair, Marangell, Flack, Harper, Soety, and Gabbard (2003) describe the assessment of a 36-year-old physician with complex comorbidity that entailed a standard psychiatric evaluation, a substance abuse evaluation, projective psychological testing, and the MMPI-2. They walk the reader through their assessment and thought processes, diagnosing a *Bipolar disorder*, *Substance abuse*, and *Personality disorder NOS* in the context of a history of trauma. Their sensitive and succinct discussion of assessment, diagnosis, and treatment recommendations to allow for safe return to work exemplifies the competent and ethical management of a complex case. Gold et al. (2008) and Gold and Shuman (2009) can also be consulted for an in-depth treatment of this subject.

PERSONAL INJURY CLAIMS WITH DETERMINATION OF CAUSALITY AND AMOUNT OF DAMAGES

Personal injury lawsuits in which emotional-distress damages are claimed require psychiatric assessments that apportion causation and gauge the degree of impairment resulting from the alleged tortious event. The amount of damages awarded is open-ended. A request for assessment may come from the defense attorney representing an insurance company or an individual defendant, or from the plaintiff's attorney. Accurate apportionment of liability requires a determination of damage related to the alleged event, taking into account any preexisting impairment and contributory negligence (Knoll & Gerbasi, 2006). An estimate of the extent of the

injury and the need for and costs of care related to the injury will be requested. The opinion should be supported by reference to information obtained from the review of legal, employment, medical, and/or school records, as well as objective psychological test data.

PRIVATE INSURANCE DISABILITY EVALUATIONS

Evaluating Degree of Impairment and Making Treatment Recommendations Without Determination of Causation

Private insurance companies that underwrite group or individual disability insurance policies primarily rely upon the reports of treating clinicians when initially determining disability claims. Claims managers and in-house medical reviewers then review these reports. Based on those reviews, the insurer may request confirmation of the findings and a review of the treatment being provided. The goal of the insurance company is to minimize disability claims that result from substandard care, to insure that accurate diagnoses are made, and to determine whether the terms of the policy's coverage are being satisfied. Some policies were written that allowed for full benefits if policyholders become unable to perform the tasks of their own occupation, but those are now difficult to obtain. Current policies usually provide benefits only if the insured is unable to perform the tasks associated with *any* job. In recent years, a number of disability carriers have altered their contracts to limit payments for "nervous and mental" (i.e., psychiatric disability) claims to two years. The entity requesting the evaluation typically provides a specific list of questions to be answered and requires a comprehensive evaluation. The evaluator is instructed to release the information only to the requesting entity, much as an evaluation requested by an attorney goes only to the attorney. Objective psychological testing can be of considerable value in this process, as it provides additional data on which to base an opinion.

TWO TYPES OF WORKERS' COMPENSATION EVALUATIONS: TREATMENT CONSULTATIONS AND INDEPENDENT PSYCHIATRIC EVALUATIONS

Workers' compensation programs require a determination of whether one or more psychiatric conditions are causally related to a workplace injury on "a more probable than not" basis to determine whether medical treatment is payable, and whether compensatory "time-loss" income benefits—typically amounting to 60% of wages—are due the worker. In this type of assessment, the determination of causation requires that the diagnosed psychiatric condition(s) be judged to be the result of the workplace injury in question with a 51% or greater degree of probability. Fault is not at issue in worker's compensation claims, and settlements—in the event that residual impairments are present at the time of claim closure—are paid according to a schedule. If the individual is determined not to be capable of reasonably continuous full-time gainful employment following treatment, a pension may be awarded.

In Washington State, the examiner must assign each diagnosis to one of four categories posed by the Department of Labor and Industries:

1. The injured worker's psychiatric condition was not caused or aggravated by the industrial injury, but it creates a barrier to recovery from a condition for which the department has accepted liability.
2. The injured worker's psychiatric condition was caused by the industrial injury.
3. The injured worker's psychiatric condition is a preexisting condition that was aggravated by the industrial injury.
4. The injured worker's psychiatric condition was neither caused nor aggravated by the industrial injury, nor is it creating a barrier to recovery from a condition for which the department has accepted liability.

Determining whether a condition is "more probable than not" proximately caused by an industrial injury in a worker's compensation case is often complex and adversarial because of the economic consequences to the contending parties and because analysis of the injury is often complicated by preexisting conditions, personality disorders, and/or trait disturbances.

Both psychiatrists performing IMEs and treating psychiatrists are often asked to approve or disapprove job analyses (JAs) for several different positions, such as "cashier" or "meat packer." Each job analysis describes the essential functions of the job, and both the treating psychiatrist and the IME psychiatrist may be asked to approve, approve with restrictions, or disapprove the specific jobs described by their respective JAs. These are formal descriptions of the workplace environmental conditions, the physical maneuvers that are required, and their frequency in performing job tasks, including the cognitive and emotional tasks associated with the position, and so forth. When the injured worker nears "maximum medical improvement," expert opinions guide the claims manager and vocational consultant in determining whether the claimant is able to return to the job of injury, is able to work at a job for which they have transferable skills, requires retraining for another job, or whether they should be referred for pension determination.

Worker's compensation claims vary enormously in their complexity and in their degree of controversy. Simple claims may be disposed of administratively with little dispute between the worker and the insurance company. However, when claims are complex, controversial, and involve substantial financial consequences, expert witnesses may be called by both sides in order to determine causation and degree of impairment. The responsibility of the IME psychiatrist—regardless of who the contracting party may be, is to be an independent "seeker of truth" and except in rare circumstances, not to establish a doctor-patient relationship (Strasburger et al., 1997). Cases may be litigated through several levels of review beyond the administrative board level, up through courts of superior jurisdiction, appellate courts, and to the state supreme court.

OUTLINE OF THE PSYCHIATRIC DISABILITY EVALUATION

Psychiatric disability evaluations are conducted differently than routine treatment consultations. Box 86.2 presents an outline of a psychiatric disability evaluation that can be adapted to the needs of the particular evaluation.

The psychiatrist performing an independent evaluation at the request of a third party does not owe the same duty to the examinee as does a psychiatrist performing an evaluation for treatment purposes. It is important that confidentiality limitations and roles be clearly explained to the examinee before undertaking the evaluation, and a signed release should be obtained, specifying the authorized recipients of the evaluation (Gold & Davidson, 2007). Without such information it is impossible for the patient to give informed consent to the evaluation process (Williams & Schouten, 2008).

When an *independent* evaluation is being conducted at the request of a third party, the examinee must be informed that there will be no follow-up treatment relationship with the examining psychiatrist, as that could create a conflict of

interest. Rare exceptions to this guideline are addressed by Strasburger et al. (1997).

When a *treatment* consultation is performed (as might be the case when a patient is referred by an occupational physician) the patient and psychiatrist may choose to establish a doctor–patient relationship. It is good practice to explicitly inform the patient that they are free to select another provider. This is particularly important in disability treatment situations since, for therapy to be effective, the patient must have trust and confidence in the treating psychiatrist. In workers' compensation treatment settings, regular reports to the administrative agency are required, and the patient should be informed that the confidentiality is limited. Sensitive material not necessary to the administration of the claim should be excluded from reports; such reports should primarily document diagnoses, treatment modalities employed, and progress in treatment. In most situations, telling the patient that they are entitled to a copy of any document produced by their psychiatrist related to their treatment promotes trust through transparency, and it also serves to remind the treating psychiatrist of the importance of discretion. It is also good practice

Box 86.2 PSYCHIATRIC DISABILITY EVALUATION OUTLINE

A. General considerations

1. Reasons for a disability evaluation

- a. Employer request
- b. Insurance company request
 - (1) Private disability coverage
 - (2) Second opinions re: treatment
- c. Physician request for psychiatric assessment as adjunct to general medical care—treatment rather than causality issues central (e.g., orthopedist requests psychiatric consultation for depressed patient)

2. Role and boundary issues

- a. Confidentiality is waived
 - (1) This is made explicit to the examinee, who is advised to whom the report will be provided
 - (2) The examinee is advised that examination does not constitute nor is a substitute for medical treatment
- b. Role of the independent psychiatrist evaluator
 - (1) No follow-up treatment responsibility
 - (2) Potential adversarial relationship to patient
- c. Role of the treating psychiatrist
 - (1) Follow-up reports are often required by statute or insurance carrier, so patient must be informed
 - (2) Some confidentiality limitations: make explicit to patient
Information usually confined to diagnoses, medications, and general impression regarding progress in treatment or lack thereof
Advise patient that second or independent opinions may be requested in ambiguous situations

3. Consequences of psychiatric disability for the patient

- a. Suffering from a psychiatric condition: both psychiatric symptoms (e.g., depression, anxiety, panic, pain symptoms, phobias, etc.) and damage to self-concept
- b. Work life and love life similar/equivalent in importance for individual fulfillment
- c. Consequences of loss of work role
 - (1) Devaluation within the family
 - (2) Loss of community prestige
 - (3) Economic loss, insecurity
 - (4) Loss of sublimations for the expression of aggression

(continued)

B. The psychiatric evaluation procedure

1. History
 - a. Medical and collateral record review
 - b. Reason for the evaluation
 - c. Presenting problem in patient's own words
 - d. History of the presenting problem
 - (1) New or recurrent problem?
 - (2) Static or changing?
 - (3) Impact on home and work functioning?
2. Social history
 - a. Family's socioeconomic status
 - b. Role of work in family life
3. Educational history
 - a. Detail elementary, middle, and high school
 - b. Strong and weak subject areas
 - c. Relationship with teachers
 - d. High school dropouts at increased risk
4. Employment history
 - a. Job types
 - b. Performance level
 - c. Length of employment
 - d. Reasons for prior changes in employment
 - e. Job satisfaction at the time of injury
5. Current income sources: impact of illness
 - a. Evaluate for primary gain in maintaining disability if receiving benefits
 - b. If no benefits, motivation to forgo treatment and return to work prematurely, inviting further injury
6. Past medical history
7. Current medical problems and names of physicians. Include any abnormal laboratory or radiographic findings.
8. Medications
9. Substance use/abuse history
10. Legal problems
11. Past personal psychiatric history
 - a. Hospitalizations: Complaint, dates, hospital, duration, outcome
 - b. Outpatient history: Complaint, dates, treating professional, duration, outcome
 - c. Anxiety disorder
 - d. Alcohol and substance abuse
 - e. Other
12. Developmental history
 - a. Family structure
 - (1) Parents together or divorced; stepparents
 - (2) Nature of patient-parent relationship
 - (3) Birth order; relationships with siblings
 - (4) Neglect or abuse history; duration and severity
 - b. Work role models: Parent work history
 - c. Age when patient began work: Premature responsibility increases disability risk
 - d. Illness history in family or patient
 - e. Relationship with authority figures

to advise the patient that a second opinion may be requested by the doctor, the patient, or the claims manager. Psychiatric treatment consultation guidelines are presented in Box 86.3.

THE ROLE OF PSYCHOLOGICAL TESTING: BRIEF SELF-REPORT TESTS, THE MMPI-2/MMPI-2-RF, AND THE SIRS/SIRS-2

Psychological testing provides a method for refining diagnostic impressions in disability evaluations developed through

the record review and interview process, and it also can assist in developing an objective measure of severity of the condition (Williams & Schouten, 2008; Graham, 2012). Psychological testing can also assist in treatment planning and assessment of the effectiveness of treatment as it proceeds through serial administration. *Brief* self-report tests such as the Beck Depression Inventory–II (BDI-II) and the PHQ-9 have demonstrated value in *clinical* practice. Many other brief self-report tests are used for the assessment of PTSD, anxiety disorders, and other conditions. They are easy to use and require little time to administer, but they do not assess the examinee’s cooperation with the evaluation process, and most

**Box 86.3 PSYCHIATRIC TREATMENT
CONSULTATION GUIDELINES**

- Referred by party involved in patient's healthcare, e.g., physician, vocational counselor
- Informed consent—who receives report, limited confidentiality
- Purpose is to diagnose and recommend treatment for psychiatric disorders.
- Record review brief compared to IME since the purpose is not primarily for apportioning causation
- Psychiatrist performing treatment consultation may provide treatment if mutually agreed

brief tests assess only one diagnostic category. They are open to challenge in *forensic* practice because they lack validity scales. For example, it is argued that an individual claiming compensation for depression might intentionally exaggerate the depression symptoms reported on the BDI-II or the PHQ-9 in order to “prove” their condition, or that a person with pain complaints would do likewise. In settings where only treatment is sought, it is more realistic to expect that the examinee will cooperate and respond truthfully.

The MMPI-2 is a 567-item test in which the examinee is asked to endorse each item as *true* or *false*, and it requires about 90 minutes to complete. Although psychologists most commonly administer and interpret the test, there are avenues for other clinicians to obtain training since it is necessary to qualify professionally to purchase and administer the test (Graham, 2012). Because the MMPI-2 is cited so frequently in a disability context, it will be discussed in some detail. The MMPI-2 has been empirically validated both on clinical and non-clinical populations. It is available only through Pearson Assessments in English, Spanish, and Hmong, and in both written and audio formats; the audio format is useful for test takers who have limited reading skills.

The MMPI-2-RF (Restructured Form) was published in 2008 by Pearson Assessments and adds significantly to the information available through the MMPI-2. The MMPI-2-RF consists of 338 items drawn from the 567 MMPI-2 items “designed to represent the clinically significant substance of the [567] MMPI-2 item pool with a comprehensive set of psychometrically efficient measures.” The MMPI-2 Restructured Clinical (RC) scales assess the major distinctive core components of the test's Clinical scales and have been carried over to the MMPI-2-RF with no changes. The RC scales are supplemented by “broad-band higher order” measures of psychological dysfunction and other scales that focus more specifically on a variety of internalizing, externalizing, and interpersonal characteristics.

The MMPI-2 and MMPI-2-RF have greater utility than brief self-report tests in forensic settings because they possess *validity scales* and because in clinical settings they have the advantage of measuring a broad array of psychopathology instead of only one aspect of personality functioning. The test materials can be administered by paper and pencil, by CD or

cassette tape, or by computer. Validity has been established for English, Spanish, and Hmong for the MMPI-2 and for English for the MMPI-2-RF. Scoring by computer is faster than scoring with hand templates and eliminates the potential for errors associated with use of hand-scoring. After purchasing a site license for the computer software for about \$100 per year, individual tests can be scored and the results stored for an additional cost that ranges between about \$15 and \$35 per test administration, depending on whether the written interpretive report is desired in addition to the scale-profile printout. In order to qualify to purchase and administer the MMPI-2 or MMPI-2-RF, a psychiatrist will need to take one of the workshops on the MMPI-2 and/or MMPI-2-RF offered by Pearson Assessments, which are offered several times a year at different locations around the United States. The Pearson Assessments website provides detailed information on workshop scheduling and ordering test materials.

The raw scores—that is, the number of items endorsed in the keyed direction on each MMPI-2 or MMPI-2-RF scale—are statistically transformed into uniform “T scores,” with the result that a T score of 65 for one scale has the same meaning as T score of 65 on another scale. For example, T scores of 65 correspond to the 92nd percentile for each scale, and in general, T scores >65 are clinically significant and interpretable. Profiles are graphed using the T scores for the individual scales on each *profile*. For the remainder of this chapter, it is understood that when a scale score is mentioned, it refers to the T score and not the raw score.

THE MMPI-2 SCALES

The MMPI-2 contains a *validity scale* profile, a *clinical scales* profile, a *restructured clinical scales* profile, a *content scales* profile, a *supplementary scales* profile, and the Personality Psychopathology-5 (PSY-5) scales profile. We will focus most of our attention on the *profile elevation* (which is the arithmetic mean of the statistically derived T scores of clinical scales 1, 2, 3, 4, 6, 7, 8, and 9), the *validity scales*, the *RC scales*, and the *PSY-5 scales* to simplify our discussion. Graham (2012) and Butcher and Williams (2000) can be consulted for detailed guidelines regarding the development and composition of each scale, and for *interpretive strategies* as well as their theoretical and research background underpinnings.

VALIDITY SCALES

The validity scales identify random response patterns, inconsistent response patterns, defensive response patterns, and exaggerated response patterns, providing a forensically valuable advantage over test instruments without such scales (Graham, 2012). In 1989, new *validity scales* were added to the three basic validity scales, F (infrequency), K (defensiveness), and L (lie), from the original MMPI, thus providing much more information about the test-taker's approach to the test. VRIN (variable response inconsistency) and TRIN (true response inconsistency) scales elevated beyond a certain point indicate that the individual is

not attending to the content of the items and is responding in a random fashion, resulting in an invalid profile or that they responded to the items with a bias either to respond “true” or respond “false”. Since release of the MMPI-2 in 1989, other validity scales have been added after demonstrating utility in identifying defensive or exaggerated response patterns. For example, the Fp scale (infrequency psychopathology) consists of 27 items endorsed infrequently by both psychiatric inpatients and the MMPI-2 normative sample. Consequently, a significant elevation produced on the Fp scale is more likely to reflect deliberate exaggeration or feigning of severe psychopathology. The F scale items, in contrast, were chosen because they were infrequently endorsed in a *non-clinical* normative population. Because psychiatric subjects more frequently endorse items on the F scale, a high Fp scale score is more likely to reflect *exaggeration* and non-credible responding than a high F scale score; this corrects an important deficiency in the original MMPI. The Fake Bad Scale (FBS), a symptom validity scale, has been a controversial scale since it was introduced in 1991 by Lees-Haley, English, and Glenn. Graham (2012), after surveying the literature, “concluded that when appropriate cutoff scores are used, the FBS scale has utility in identifying persons who give noncredible reports of cognitive deficits.” L scale elevations, which may indicate that the test taker is attempting to deny even normal shortcomings and claiming unusual virtue, may result in a profile that minimizes the severity and extent of their psychological problems. Such *underreporting* of psychological problems is more likely to occur when the person is trying to present themselves as psychologically healthy, as in an employment examination or a child custody evaluation. It may also occur for individuals with “traditional values based” and unsophisticated backgrounds who define themselves in terms of their aspirational values, and who are trying to fit into a dominant culture that espouses those values. Detailed information regarding guidelines for assessing validity is available in several references (Graham, 2012; Butcher & Williams, 2000). In particular, the Fp scale has particular value in identifying non-credible reporting of psychiatric symptoms in individuals seeking compensation (Arbisi, Ben-Porath, & McNulty, 2006).

CLINICAL SCALES

There are ten clinical scales, either referred to by their numbers from 1 to 10, or by names, some of which are no longer in common use: *hypochondriasis*, *depression*, *hysteria*, *psychopathic deviate*, *masculinity-femininity*, *paranoia*, *psychasthenia*, *schizophrenia*, *hypomania*, and *social introversion*. Graham (2012) provides a detailed discussion of the qualities associated with each scale.

Code types refer to the number (i.e., 1–9) designations of the scales’ T scores that are most elevated in the profile; these may refer either to *two-point* or *three-point* code types. Code types are a way of interpreting the MMPI-2 profile and can be used to identify patient-specific behaviors and coping patterns (Graham, 2012; Butcher & Williams, 2000).

RESTRUCTURED CLINICAL (RC) SCALES

The nine Restructured Clinical (RC) scales were developed by Tellegen, Ben-Porath, McNulty, Arbisi, and Graham (2003) to achieve improved convergent and discriminant validity compared to the clinical scales, and they represent a significant addition to the power of the MMPI-2 (Graham, 2012; Ben-Porath & Tellegen, 2008, 2011). The RC scales have been carried forward without change from the MMPI-2 to the MMPI-2-RF. *Convergent validity* means that the scores on a scale are significantly related to conceptually relevant extra-test measures. For example, individuals with high RC4 scores often have histories of difficulties with the law and are prone to substance abuse, and typically have work-related problems, which is what it was intended to measure. *Discriminant validity* is demonstrated when scores on a scale are not related to extra-test measures that are unrelated to what the scale is intended to measure (Graham, 2012). Thus, since RC4 does not significantly relate to other measures of depression or anxiety or thought disorders, it is said to have discriminant validity. Both the clinical scales and the RC scales have good convergent validity, but many studies have demonstrated that the RC scales have better discriminant validity.

Tellegen et al. (2003) described the development of these scales, beginning with the RCd scale labeled “Demoralization,” which contains items which related to overall emotional distress, emotional discomfort, and turmoil that contaminated many of the other original clinical scales. A sophisticated statistical approach was employed to remove redundant items from the original clinical scales that were associated with non-specific general distress and demoralization and retain items associated with the core construct(s) of each scale. In general, except for the RCd scale, each RC scale represents a distinctive core construct of the parent clinical scale with the same number designation, even though in some cases the item selection is considerably different. Thus RC1 (somatic concerns) is similar to Clinical Scale 1; RC2 (low positive emotions) is similar to clinical scale 2; and so forth. No RC scale was developed to correlate with Clinical Scale 5 or Clinical Scale 10. RC3 (cynicism) has so far not been shown to have any strong correlates in clinical samples, although it has utility in predicting treatment compliance. The practical result of this project is that when there are “across the board” elevations of the clinical scales, the RC scales are often elevated more selectively, which makes it possible to develop a more fine-grained understanding of the primary problems with psychological functioning in a given subject. Thus, for example, an examinee may have T score elevations >65 on clinical scales 1, 2, 3, 6, 7, and 8, but the RC scales may only be elevated >65 on RCd (demoralization) and RC2 (low positive emotions). As Graham (2012) states, “When the clinical scale score is high but the corresponding RC scale score is not, one should be quite cautious about making inferences that the test-taker has characteristics consistent with the core construct associated with the clinical scale.” In the example given, the elevated RCd score would imply that the person had a high level of overall emotional distress, is demoralized and pessimistic, and that they might report anxiety and depression. The elevated

RC2 score indicates anhedonia and an increased risk of clinical depression. This profile would not be interpreted as indicating paranoia or psychosis, since although clinical scales 6 and 8 are elevated, the corresponding RC scales reflecting ideas of persecution (RC6) and aberrant experiences (RC8) are not elevated, suggesting the observed elevations on the clinical scales associated with thought disorder were due to the endorsement of non-specific items reflecting misery and demoralization rather than items reflecting thought disorder and paranoia. The RC Scale correlates have been studied in psychiatric inpatients

THE PERSONALITY PSYCHOPATHOLOGY
FIVE (PSY-5) MODEL

The Personality psychopathology Five Model (PSY-5) (which preceded the development of the MMPI-2 PSY-5 scales) is described in a monograph by Harkness and McNulty (1994) and a subsequent paper by Harkness, McNulty and Ben-Porath (1995). These *dimensional* scales (aggressiveness, AGGR; psychoticism, PSYC; disconstraint, DISC; negative emotionality/neuroticism, NEGE; introversion/low positive emotionality, INTR) were developed to assess personality traits that are present in normal persons, but are pathological when they are extreme. The PSY-5 scales were derived theoretically, based on the constructs of the PSY-5 model, and the PSY-5 model was developed independently of the MMPI item pool. They were restructured for the MMPI-2-RF to improve their psychometric validity (Ben-Porath & Tellegen, 2011).

In a 2014 paper of broad historical and theoretical scope, Harkness, Reynolds, and Lilienfeld explain that the PSY-5 *scales* each correspond to separate measurable *psychological systems* that evolved for adaptation to the external environment. They argue that assessing the status of each of these psychological systems is conceptually identical to conducting a “review of systems” in general medicine (cardiovascular, endocrine, etc.). Diagnoses of specific psychiatric disorders are then layered on the appraisal of the underlying systems, which map to PSY-5 scales. This approach has clinical utility and treatment implications and will “promote integration across sciences rather than fostering the isolation of sciences allowed by atheoretical observation terms, as in the DSM.” The relationship to adaptive psychological systems and the

DSM-5 presented in the paper by Harkness, Reynolds and Lilienfeld (2014) is presented in Table 86.5.

Finn et al. (2014) focused on the five-factor model proposed for DSM-5 and the ten personality disorders from DSM-IV that were carried forward to DSM-5. The Personality Psychopathology—Five (PSY-5) Model developed by Harkness and McNulty (1994) and Harkness, McNulty and Ben-Porath (1995) “was designed to bridge normal and abnormal personality variances by utilizing distance matrices based on layperson sortings of personality and personality pathology descriptors.” The PSY-5 *scales* have been shown to be relatively stable over a five-year period, as one would expect given their correspondence to underlying evolved adaptive systems of psychological functioning. When they deviate significantly from established non-clinical population norms, they indicate personality trait disturbances that are conceptually relevant, although not identical to the previously proposed DSM-5 conceptual model of personality disorders. In the *Alternative DSM-5 Model for Personality Disorders* in Section III of the **DSM-5** personality disorders are characterized by impairments of personality functioning and pathological personality traits, as described in the PSY-5 model. DSM-5 further defines *self* and *interpersonal* functioning differentiated into 5 levels of impairment for Self functioning (identity and self-direction) and Interpersonal functioning (empathy and intimacy). Personality disorders increase the vulnerability of individuals to developing psychiatric disorders (e.g. anxiety, depression) in response to external stressors, such as injuries, as schematically depicted in Figure 86.3. The MMPI-2 and MMPI-2-RF help the examiner or treating psychiatrist distinguish between persons with depression *but* with no evidence of personality trait disturbance, and individuals with depression arising from an external stressor *and* evidence of preexisting personality trait pathology.

THE MMPI-2-RF IS A REVISION OF THE
MMPI-2 THAT PROVIDES ADDITIONAL
INFORMATION REGARDING
COMPARISON POPULATIONS

In 2008, the MMPI-2 RF (Restructured Form) was published by Pearson Assessments. This test instrument contains RC scales that are identical to those of the MMPI-2, along with

Table 86.5 RELATIONSHIP BETWEEN “PSYCHOLOGICAL SYSTEMS”, PSY-5 SCALES ON THE MMPI-2 AND THE DSM-5

MAJOR SYSTEMS TO BE REVIEWED	PSY-5 SCALES (1994, 2002)	DSM-5 (AMERICAN PSYCHIATRIC ASSOCIATION, 2013)

validity scales and PSY-5 scales that are similar, although not identical, to those of the MMPI-2. The clinical scales, content scales, and supplementary scales are not present in the MMPI-2-RF. Because of differences in validity scale composition, when the 567-item MMPI-2 is administered, and Pearson Assessment software is used to produce both an MMP-2 and MMPI-2-RF profile, sometimes one of the profiles may be valid while the other is invalid, making it useful to obtain both profiles. The MMPI-2 RF consists of 338 of the MMPI-2's 567 questions.

All scales are *visually displayed* as vertical range bands for *comparison groups* that can be selected for several different population samples, such as *forensic disability claimants*, *prison inmates*, personnel screening for *clergy*, *corrections*, and *law enforcement*, as well as *outpatient mental health clinics* and other specialized medical clinic settings. For example, it is

possible to see at a glance whether a particular examinee falls outside one standard deviation for a similar population, like female forensic disability claimants. The RC scales are supplemented by broadband higher order measures of psychological dysfunction and other scales that focus more specifically on a variety of internalizing, externalizing, and interpersonal characteristics. The MMPI-2-RF validity scales provide a more detailed picture of *under-reporting* and *over-reporting* along both psychological and somatic dimensions than the MMPI-2, which has no comparable measure of non-credible reporting of somatic symptoms. Table 86.6 provides a comparison of the scales in the MMPI-2 and MMPI-2-RF.

The MMPI-2 and MMPI-2-RF are complementary to one another. The MMPI-2 has scales not on the MMPI-2-RF, as well as research on code-types that are associated with a wealth of clinical research. When the full MMPI-2 is administered,

software licensed by the publisher (Q-local) can efficiently produce both MMPI-2 and MMPI-2-RF reports. Each report carries a separate charge of between \$15 and \$35, depending on whether or not an interpretive report is requested in addition to the reporting of scale scores.

The MMPI-2-RF also includes nine validity indicators, two of which are revised versions of the MMPI-2 Variable Response Inconsistency (VRIN-r) and True Response Inconsistency (TRIN-r) scales. The test contains revised versions of the MMPI-2 L scale, now labeled Uncommon Virtues (L-r) and the Correction scale, now labeled Adjustment Validity (K-r), two measures of under-reporting scales in clinical and non-clinical samples. The MMPI-2-RF has five over-reporting indicators, including the recently added (2011) Response Bias Scale (RBS), which predicts overstated memory complaints, a capability absent in the MMPI-2. Recent research (Wygant et al., 2011) suggests that the MMPI-2-RF validity scales can be helpful in forensic evaluations. The MMPI-2-RF manual can be consulted for cutoff scores.

One advantage of using the MMPI-2-RF is that it provides a nuanced picture of long-standing personality traits and a finely grained picture of over- and under-reporting along both psychological and somatic dimensions, with fewer items and thus requiring less time. Another useful feature of the MMPI-2-RF is that means and standard deviations for many specific population groups, including injured workers and personal injury claimants, are *graphically* depicted in the computer printed report for all MMPI-2-RF scales, making it possible to see at a glance how an examinee’s response pattern compares to that of a relevant comparison group. For more detailed information regarding the development and use of

the MMPI-2-RF, see Ben-Porath (2012). Figure 86.4 provides a sample MMPI-2-RF depiction of Higher-order scales and Restructured Clinical Scales for a patient with commentary on their significance. The figure also shows a comparison of the test subject to the relevant comparison group.

**THE STRUCTURED INTERVIEW
OF REPORTED SYMPTOMS (SIRS)
AND THE STRUCTURED INTERVIEW
OF REPORTED SYMPTOMS-2 (SIRS-2)
ASSESS FEIGNED PSYCHOTIC MENTAL
DISORDERS**

The Structured Interview of Reported Symptoms (SIRS) was published in 1992 (Rogers, Bagby, & Dickens, 1992), and the SIRS-2 (Rogers, Sewell, & Gillard, 2010) was published in 2010. The development of the SIRS and the successor SIRS-2 is described by Rogers in the *Professional Manual for SIRS-2* (Rogers, Sewell, & Gillard, 2010). The SIRS-2 can serve as a useful adjunct to the MMPI-2/MMPI-2-RF in the detection of feigned mental disorders, particularly for malingering of major psychiatric disorders. It has standardized administration and scoring, high inter-rater reliability, and validation in both simulation and known group studies. Rubenzer (2010) suggests that it requires more external validation data to support its utility for detecting the feigning of less severe disorders, for which the MMPI-2 and MMPI-2-RF remain the instruments of choice. The SIRS-2 is administered by the evaluator (not a technician) after establishing rapport in an unstructured interview and usually requires between 30

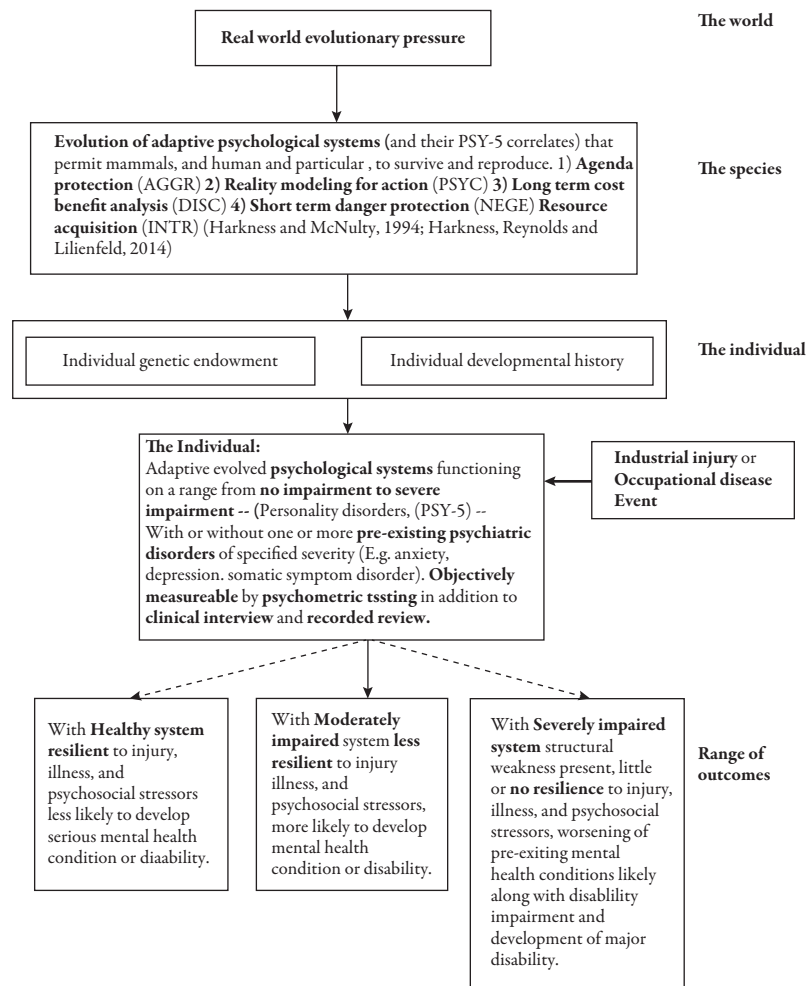

Figure 86.3 Process of personality structure formation and development.

and 45 minutes. Guidelines for administration are provided in the professional manual. Rogers describes the classification of malingering and related response styles with an analysis of "key terms for malingering and related constructs." These include *malingering*, *factitious disorder*, *feigning*, *dissimulation*, *over-reporting*, *secondary gain*, *symptom magnification*, and *disengagement*.

Rogers notes that *malingering* is a V-code classification, which is a "simple categorization" and not a diagnosis, as it lacks "the essential inclusion and exclusion criteria that are fundamental to DSM-IV diagnoses." He analyzes the remaining constructs and suggests that "feigning" rather than "malingering" be used to describe "the deliberate fabrication or gross exaggeration of psychological or physical symptoms without any assumptions about its goals." He suggests that "over-reporting" be avoided as a forensic term because it is simply descriptive without addressing intentionality.

"Secondary gain" has three different definitions: in psychodynamic practice, it is an unconscious process shielding the patient from intra-psychic conflict. In behavioral medicine, it refers to the subtle but influential reinforcement of the illness by healthcare providers. In forensic practice, it is understood to mean that the examinee is motivated by a

desire to secure monetary advantage and special attention. Rogers recommends that "secondary gain" not be used as an explanatory term in forensic medicine because of its multiple and unclear meanings.

"Symptom magnification" is a construct that is poorly defined and vague, with no distinction as to whether magnification or fabrication is present, and Rogers recommends that term be avoided in forensic reports.

DETECTION STRATEGIES EMPLOYED BY THE SIRS-2, THE MMPI-2, AND THE MMPI-2-RF

The SIRS-2 employs eight detection strategies for feigned mental disorders, which are measured by different scales linked to specific questions in the test. The SIRS-2 scoring algorithm includes a flow chart, the addition of a new scale, and two indexes and subdivision of the categories of feigning. Rogers et al. (2010) describe two broad categories of detection strategies—*unlikely* and *amplified detection strategies*. Improbable symptoms and bogus complaints are detected by unlikely detection strategies. Amplified detection strategies

MMPI-2-RF Higher-Order (H-O) and Restructured Clinical (RC) Scales

Figure 86.4 Sample MMPI-2-RF commentary on evaluation with reference to comparable population.

identify discrepancies between report levels for patients with genuine disorders, and report levels of feigners. Rogers describes the different strategies required to detect feigned cognitive impairment as opposed to feigned mental disorders, and points out that the SIRS-2 is designed to detect feigned mental disorders, not feigned cognitive disorders.

The MMPI-2 and MMPI-2-RF validity scales were described earlier. The VRIN (variable response inconsistency) and TRIN (true response inconsistency) scales are designed to detect random response patterns and response patterns biased either in the true or false direction. Thus, they may identify lack of comprehension or lack of cooperation, but they do not identify malingering. The F scales, which include F, Fb, and Fp, are designed to measure *infrequent* responses. Because the F and Fb scales were established with non-clinical populations, major elevations (T > 100) may simply reflect serious psychopathology. Only the Fp scale was developed by identifying infrequent or rare responses in a clinical population—namely psychiatric inpatients (Arbisi & Ben-Porath, 1995). Graham's guidelines (2012) suggest that Fp T scores > 100 indicate probable malingering, T scores from 80–99 indicate that "malingering is possible and external information must be sought,"

scores from 70–79 indicate "indeterminate validity," and that T scores < 70 indicate a valid profile, assuming that the prior validity tests are met.

Recent research with the MMPI-2-RF suggests that it has utility in the detection of feigned somatic impairment and feigned cognitive impairment as well as feigned mental disorders (Wygant et al., 2011). The Fs (infrequent somatic responses) scale was added to measure somatic complaints and contains 16 items that were rarely endorsed in large medical and chronic pain samples. A revised version of the FBS scale (symptom validity) was included—the FBS-r. It assesses neurocognitive and somatic complaints. In 2011, the RBS (Response Bias Scale) was officially added to the MMPI-2-RF (Gervais, Ben-Porath, Wygant, & Green, 2007). The MMPI-2-RF has been found to be effective in predicting performance on Symptom Validity Tests (SVTs) in disability, criminal forensic, and Veterans Affairs (VA) patients.

A key consideration in assessing the positive predictive power and specificity of an instrument is the assumed *base rate* of what is being measured. For example, validity scales have greater predictive power and specificity if the trait being measured has a base rate of .40 instead of .10 (Wygant et al.,

2011). Rogers (2008) emphasized the importance of reducing false-positive classification because of the serious impact of such a finding for examinees, and for this reason higher cutoff scores are recommended. One should *always* utilize external corroborating data, including the clinical interview, medical records, and other collateral information, in addition to psychological test data, in forming an opinion regarding the presence or absence of feigning. With higher cutoffs, however, evaluators can be confident that feigning of symptoms is highly probable (e.g. $F-r>T110$, $Fp-r>T70$, $Fs>T100$, $FBS-r>T100$, and $RBS>T100$).

WORKERS' COMPENSATION CLAIMANTS REFERRED FOR TREATMENT AND FOR IMES FOR LITIGATION HAVE SIMILAR MMPI-2 PROFILES

In the author's private practice, consisting of individuals with workers' compensation claims, MMPI-2 data were compiled for 98 consecutive cases over 12 months. Of these, 86 produced valid MMPI-2 profiles. Both treatment consultations and IME evaluations yielded nearly identical means and standard deviations for the *profile elevation*, the *RC scales*, and the *PK scale*, which suggests that their psychological characteristics are quite similar with regard to both diagnoses and severity. This implies that similar levels of genuine psychopathology are present for treatment-referral patients and workers' compensation cases referred for independent psychiatric evaluations, when cases producing valid MMPI-2 protocols are compared.

DISABILITY RELATES TO INTERACTION BETWEEN SPECIFIC IMPAIRMENTS AND ADAPTIVE CAPACITY

The examiner frequently encounters situations in which it is difficult to determine the relative balance of depression, anxiety, somatization, and character pathology. In these situations, the additional information supplied by the MMPI-2 can be of significant benefit. For example, a man who sustained whole-body burns in a methane explosion on the job, followed by two months of treatment on an inpatient burn unit, returned to work three months after discharge. He was referred for treatment of PTSD that emerged months later when he had difficulty at the site of the accident. MMPI-2 testing revealed expected elevations on scales related to anxiety and traumatic stress, but no elevation on the PSY-5 scales or other scales indicating personality disturbance. Eight months of psychiatric treatment, including individual and group psychotherapy, resulted in remission of his symptoms and maintenance of employment.

Persons with *preexisting* personality disturbance and depression may sustain injuries on the job and become significantly more disturbed. For example, a middle-aged construction worker with a history of returning to work following prior workplace injuries sustained another back injury while working on a construction site, and medical treatment failed

to bring about improvement. He was referred for treatment because of suicidal ideation. The MMPI-2 profile revealed demoralization, depression, and somatization on the RC scales. Significant personality disturbance was evident on the PSY-5 scales. Suicide was averted, but his serious ongoing problems with day-to-day functioning continued.

Although no conclusion should be drawn solely on the basis of MMPI-2 results or those of any psychological test, the examiner should weigh these findings in apportioning causality of the depression. For example, depending on information obtained from the record review and the subject interview, the examiner might infer that a ratable psychiatric condition was preexisting, but that there was a worsening of the condition as a consequence of the injury. Depending on the forensic setting, a preexisting condition may affect compensation paid to the patient, or it may have no effect on it.

THE ASSIGNMENT OF IMPAIRMENT RATINGS

Psychiatric or mental health impairment ratings are assigned according to criteria established by the relevant authority or jurisdiction or the definitions incorporated in a rating scale. To lessen the confusion regarding the rating process, Williams (2006; 2008; 2010) proposed a grid that cross-referenced the Global Assessment of Functioning scale (GAF) of the DSM IV-TR; the Class of Impairment Due to Mental and Behavioral Disorders of the *AMA Guide to Impairments*, 6th edition (Rondinelli, et al., 2008); and the five categories of impairment definitions defined by Washington State by Washington Administrative Code (WAC)-296-20-340, the latter serving as an example of impairment defined by legislation. The GAF ratings were divided into quintiles, in order to correspond with the other rating scales. Thus, for example, a GAF rating from 61–80 would correspond to Class 2 impairment by the AMA Guide and Category 2 impairment by the Washington State criteria. Similarly, a GAF rating from 41–60 would correspond to an AMA rating of Class 3, and a Washington State rating of Category 3; a GAF rating of 21–40 would correlate with an AMA rating of Class 4, and a Washington State rating of Category 4. This cross-correlation was proposed with the idea that each rating scale could be divided into five sections or quintiles. When the DSM-5 was published in 2013 the multi-axial diagnostic system of DSM-IV was discarded, and GAF ratings were discontinued. Nevertheless, the concept of cross-referencing a variety of rating scales remains valid as a means of improving reliability and consistency.

The AMA guide to impairment ratings is the easiest to grasp at a glance, and the DSM-IV-TR GAF rating scale utilized definitions that were readily understandable, albeit not precise and of questionable psychometric validity. The Washington State criteria employ archaic language, and are difficult to parse from one category rating to another (Williams 2006; 2010; Williams & Schouten, 2008). The intention of the table is not to override legislatively determined criteria but to assist the clinician who is attempting to apply it accurately and consistently.

In a “close call” situation, the MMPI-2 may be of assistance in tipping the rating to a higher or lower category, although there is little published research at this point. For example, consider an individual who appears by interview and record review to straddle the line between a Category 3 and Category 4 level of impairment defined by WAC 296-20-340, who appears to have a GAF of 40–45 on Axis V, and who appears to correspond to a Class 3 level of impairment by the AMA guide. If a valid MMPI-2 profile without evidence of exaggeration of psychological symptoms has been obtained, it could be argued that a profile elevation of 81 and an RCd T score of 80 might tip the balance in favor of Category 4, since less than 1% of the sample population have scores over 80 (Butcher, et al., 2001). By the same token, a lower profile elevation of 63 and an RCd score of 67 might tip the balance in the direction of a Category 2 rating, since those scores, although clinically significant, are more moderate. Graham (2012) discusses research establishing the profile elevation, the RCd scale, and other scales as measures of overall emotional discomfort and maladjustment. Research using known group comparisons will be needed to determine where the appropriate cut scores are for each impairment category by statistical analysis. A possible starting point could be to have Category 3 correspond to a profile elevation of 69–76 and RCd T scores from 71–76; Category 4 to a profile elevation of 77–81 and RCd T scores from 77–84. For statistical reasons, no T score over 88 is possible for RCd. An additional column was added to the grid (Figure 86.1) to accommodate the profile elevation scores and the RCd T score from the MMPI-2 for purposes of illustration.

THE ROLE OF PSYCHOLOGICAL TESTING IN TREATMENT PLANNING AND ASSESSMENT OF TREATMENT PROGRESS

When there is an indication of personal turmoil and emotional distress, treatment should be considered. With the brief report scales such as the BDI-II or the PHQ-9, evidence of moderate depression would strengthen the recommendation for treatment based on clinical interview and record review.

The MMPI-2 and MMPI-2-RF have several clinical scales that are indicative of emotional turmoil. Inferences can be drawn from these scales regarding the potential treatment outcome. As a rule, people who are in emotional distress are more likely to put the effort into treatment and tolerate the discomfort associated with it than people that are not, unless their distress is too great for them to focus, in which case more structure may be needed (Harkness, McNulty, Ben-Porath, and Graham, 2002). Persons experiencing very little distress may lack the motivation to work in treatment, and respond poorly to treatment. Thus, for example, someone with elevated scales reflecting anxiety or depression is more likely to be a good therapy candidate than someone who denies responsibility. High scorers on RC4, which assesses antisocial and other forms of externalizing behavior, may agree to treatment to escape another, less pleasant alternative, but they are likely

to terminate treatment early when the external pressure is off. The MMPI-2/RF can provide the clinician with valuable information at the start of treatment, saving time in the initial phases and lessening the chance that important psychological problems are being overlooked.

Serial MMPI-2/MMPI-2-RF testing at intervals through treatment can provide an objective means of measuring therapeutic progress by separately measuring gains made in resolving somatization, depression, and other psychological problems (Graham, 2012). The author routinely shares MMPI-2-RF findings with patients at the beginning of treatment while formulating a treatment plan and at intervals during treatment to explain what progress has been achieved and what additional work in therapy remains. The MMPI-2-RF is particularly well suited to patient education because it graphically compares the patient’s scores to that of a comparable population. For example, the professional can show the patient his or her profile graphs and provide a running commentary about what are and what are not areas of concern. This procedure is analogous to the practice of other medical professionals who show their patients MRIs or CT scans that visually demonstrate his or her injury or illness in order to enhance patient understanding and cooperation.

ASSESSING MALINGERING AND EXAGGERATION WITH PSYCHOLOGICAL TESTING

Malingering is defined as the intentional production of false or grossly exaggerated physical or psychological symptoms, motivated by external incentives. The term “malingering” suggests that a “yes or no” determination is to be made, but malingering is a *dimensional* and not a *categorical* construct. Rogers (2008) provides a comprehensive discussion of levels of intentionality, ranging from intentional fabrication of symptoms, through false imputation of the cause of real symptoms, to exaggerated claims of the impact. The hypothesis that malingering should be viewed as a *dimensional* as opposed to *taxonic* construct (i.e., either/or) was confirmed by Walters et al. (2008) through a statistical analysis of the response patterns in the validity scales on the MMPI-2 and the Structured Interview of Reported Symptoms (SIRS) developed by Rogers, Bagby, and Dickens (1992). The distribution of scores for both test instruments was consistent with a graduated range of non-credible self-report along a continuum, analogous to the GAF scale rather than a “yes/no” dichotomous “present or absent” determination. This is consistent with the increased emphasis on a dimensional approach to other areas of diagnosis and severity rating.

An erroneous diagnosis of malingering can have a devastating impact on an individual’s access to medical care and other benefits. From an ethical perspective, as Gold et al. (2008) stated, “The psychiatrist has a duty to the referral source to provide a complete and thorough evaluation as well as certain duties to the evaluatee, similar to but more limited than those in a traditional doctor–patient relationship.” Objectivity and

precision in the assessment of malingering and exaggeration can be enhanced by approaching assessment systematically, utilizing psychological test instruments best suited to the diagnostic questions in combination with a clinical interview and record review. This practice could lessen the impact of “blind spots” or bias in the performance of complex evaluations where malingering or exaggeration may be present.

CASE STUDY 1—PROBABLE MALINGERING

A 46-year-old divorced male was evaluated at the request of his attending physician. He presented with a history of a fall two years previously from a height of ten feet, landing on concrete, sustaining a head injury and a broken sternum. A neuropsychologist administered a battery of tests, including Tombaugh’s (1996) Test of Memory Malingering (TOMM), which revealed poor effort. Another clinical psychologist diagnosed an anxiety disorder and a pain disorder and recommended mental health treatment. The examinee expressed frustration that he was clumsy and that he was no longer able to engage in his hobby of building and racing cars. He reported minimal activities of daily living. The examiner experienced little rapport with the examinee in the interview. His speech was fluent and logically connected. He performed adequately on the mental status exam. He reported that the future appeared grim. He scored 36 points on the BDI-II, which is in the severe range of depression. He completed the MMPI-2 and the profile was invalid. It was clear that he understood the questions, as the VRIN and TRIN T scores were within acceptable limits. The infrequency scales (F, Fb, and Fp) all had T scores of 120. According to Graham (2012), an Fp score at this level indicates “probable malingering” and represents endorsement of considerably more psychological symptoms than are found in psychiatric inpatients (Arbisi & Ben-Porath, 1999). In this case, no interview data or medical record review suggested that there was a credible relationship between the reported injury and the claimed symptoms. No psychiatric treatment was recommended.

Rogers (2008) provides a scholarly analysis of the strengths and weaknesses of many test instruments, and asserts that using the MMPI-2 and the SIRS together represents the “gold standard” for the detection of malingered mental illness.

Six years later, a second psychiatric IME was performed. This psychiatrist diagnosed *Pain disorder with a general medical condition* and *Depressive disorder NOS* on Axis I. He assigned GAF = 50–55 on Axis V. He stated that an MMPI-2 was invalid solely on the basis of an F scale T score >110. No other data were presented from the MMPI-2. This is an example of an incorrect use of the MMPI-2 and lack of familiarity with current interpretive guidelines.

A third psychiatric IME was requested by the claimant’s attorney. A record review revealed that depression was documented, and sertraline was prescribed nine months following the injury, in early 2002. Four or five psychotherapy appointments were noted in 2006, but treatment was terminated without a reason being given. A micro-cervical laminotomy and foraminotomy were recommended, but the claimant again declined because of the fear of surgery. Medical records showed that the claimant had bizarre fears of contamination of metal in the eye, which caused her to delay a cervical MRI. The occupational physician noted that developmental trauma was evident and requested reauthorization for psychiatric care in 2007. An orthopedist performing an IME alleged patient fraud, based on his misreading of an investigation by the insurance carrier that cleared the person of fraud. A BDI-II was completed, with a score indicating severe depression. An MMPI-2 was completed that produced a valid profile. Among the validity profiles, VRIN and TRIN had T scores of 58 and 65, F and Fb had T scores of 85 and 97, and the Fp T score was 49, confirming that there was no exaggeration of rare psychological symptoms. The scores presented in Figure 86.5 were obtained on the RC scales which indicated demoralization, depression, anxiety, health concerns, feelings of persecution, and unusual beliefs. Note that there was no elevation for antisocial behavior on scale RC4.

Because fraud had been alleged (on the basis of an incomplete document review, which, as noted, cleared the claimant) the SIRS was administered. The claimant had five of eight primary scales in the “honest responder” range, which in Rogers’ studies correlated with a 73% likelihood of the *absence of feigning*. A Physical Capacities Evaluation (PCE) performed in 2009 reported that the subject’s pain reports were unreliable. However, the presence of somatic delusions, including the fear of “metal bodies” being in her

CASE STUDY 2—PREEXISTING CONDITION
AGGRAVATED, WITH MALINGERING ALLEGED BUT
NOT SUBSTANTIATED

A 60-year-old woman who was in a 20-year relationship presented with a history of two documented injuries eight years ago, in close succession. One resulted in a herniated cervical disk, and the second in a herniated lumbar disk. A neurosurgical IME physician recommended consideration of surgery, but the subject was frightened of surgery because of a frightening prior anesthetic experience.

Six years earlier, a psychiatrist performing an IME recommended psychiatric treatment, and diagnosed *Major depression, recurrent*; *Pain disorder*, and *Polysubstance abuse in remission*. He diagnosed “maladaptive traits” on Axis II, and assigned GAF = 51–55 on Axis V. He recommended psychiatric treatment, but no treatment was provided.

Restructured Clinical scale (RC)	T score
RCd	81
RC1	93
RC2	91
RC3	66
RC4	55
RC6	70
RC7	76
RC8	69
RC9	56

Figure 86.5 Case study 2.

eye as well as the fear of surgery, suggested that a delusional disorder was present. Because all psychiatric IMEs reported diagnoses of depression and pain disorder, and because each IME assigned a GAF score within the range of 45–55, it was obviously the consensus opinion that the claimant had a serious psychiatric disturbance. Because the claimant had a long-term steady work history prior to the current claim, because the psychological test results were valid and indicated the presence of a pain disorder and recurrent major depression, because of the elevated PSY-5 scales, and because the allegation that fraud had been committed was without substance, the finding was that a preexisting mental health disorder had been aggravated by the injury in question. Psychiatric treatment was recommended on a trial basis, with combination antidepressant and second-generation antipsychotic medication. The psychiatric examiner diagnosed *Major depressive disorder, recurrent and severe with psychotic features* and *Pain disorder associated with psychological factors and a general medical condition* on Axis I. On Axis II, *Personality disorder NOS* was diagnosed. On Axis V, GAF = 45–50 was assigned.

CASE STUDY 3—EXAGGERATION OF SYMPTOMS WITHOUT MALINGERING

A 42-year-old married man with a 20-year continuous work history in food services sales developed a hernia while assembling a food display. He underwent a hernia repair and subsequently developed a herpetic lesion. He cooperated well with treatment for the first year, but the medical records then indicated increasing clinician concern regarding his opiate dependence. Concurrently, the claimant experienced increasing conflict with family members and healthcare providers. A pain specialist noted the presence of depression one year following the injury. A psychiatric IME two years following the injury was extremely brief and concluded that no psychiatric diagnosis was present and that no treatment was needed. A psychiatric IME performed three years after the injury concluded that depression and a pain disorder were present, but that they were not related to the injury. A review of employment records confirmed continuous employment for 15–20 years prior to the injury, with steady earnings of between \$2,000 and \$4,000 per month.

During the interview, the claimant had difficulty with temporal sequence when asked about his history. He acknowledged irritability, problems with memory and concentration, frequent crying spells, and feelings of worthlessness. There was good rapport and cooperation through the evaluation. He expressed a desire to return to work. Several times he acknowledged that he exaggerated his psychological problems. He felt that he had been treated unfairly by the industrial insurance system, and wanted redress for his grievances. He felt that he might benefit from psychiatric treatment because “It might help me focus and separate stuff so that I don’t bottle it up and take it out on other people.” The BDI-II was administered, and severe depression was indicated. The MMPI-2 was administered, and although the VRIN and TRIN scales indicated that he attended well to the items, the Fp T score was 70, which Graham (2012) describes as reflecting “indeterminate” validity with the recommendation that external information be obtained. Most of the RC scales were elevated, including RCd, RC1, RC2, RC6, RC7, and RC8. These indicate problems with demoralization, anxiety, depression, health

concerns, obsessional anxiety, and unusual beliefs. The PSY-5 scales reflected extreme psychoticism (PSYC T score = 97) as well as significant elevations for negative emotionality and introversion. The SIRS was administered because the MMPI-2 was inconclusive with respect to malingering. It revealed four scales in the “probable feigning” category, which correlates with a 100% probability of feigning in empirical studies. Because the claimant had a history of success in the workplace, it did not seem likely that he would consciously choose to trade a good living for conflict with a bureaucracy. His functioning began to deteriorate concurrently with the concern regarding opioid abuse. He performed well on a physical capacities evaluation early in his treatment, but poorly after the opioid dependence had taken hold. He had conflict with a vocational counselor and with his older son in the same time frame.

Based on the history obtained from the interview, the record review, and the psychological testing, the examiner concluded that outright fabrication of symptoms was not happening, but that the claimant was exaggerating his symptoms in order to secure attention for his concerns. His credibility was enhanced because he acknowledged that he may have exaggerated his psychological problems. The recommendation was that a substance abuse evaluation and recommended treatment be carried out, and that a follow-up evaluation be conducted when the opioid dependence had been resolved. No final psychiatric assessment could be carried out while the narcotic addiction was in play.

POST-TRAUMATIC STRESS DISORDER

Returning soldiers from the wars in the Middle East have rates of PTSD that increases with the number of deployments. The Post Traumatic Stress Disorder – Keane (PK) scale of the MMPI-2 has demonstrated good correlation with PTSD in combat veterans. “Resilience” has been posited as a protective feature that lessens the susceptibility to developing PTSD, which may be analogous to higher levels of personality functioning as defined in the DSM-5. This is probably similar to differences in vulnerability to developing chronic disability in workplace injuries encountered in injured workers with similar injuries but widely varying adaptive capacities. The Fp scale of the MMPI-2 has been demonstrated to be effective in distinguishing between feigned and actual PTSD (Arbisi et al., 2006). Wolf et al. (2008) and Arbisi, Ben-Porath, and McNulty (2004) explore the use of the MMPI-2 RC scales in the assessment of PTSD and comorbid disorders. Case Study 4 describes a non-military case of PTSD with relevant psychometric case findings.

CASE STUDY 4—TRAUMATIC BRAIN INJURY

Traumatic brain injury (TBI) is probably under-diagnosed, particularly in cases of “mild” TBI. Neuropsychological testing is helpful in defining the nature and extent of brain injury, and is interpreted by neuropsychologists, who have extensive additional training in correlating specialized test findings with observed deficits. Determining where TBI and PTSD converge can be challenging diagnostically (Stein & McAllister, 2009). Arbisi et al. (2006) and Arbisi and Ben-Porath (1999) have studied the use of the MMPI-2 to in this

population and describe its utility in identifying depression, anxiety, and other psychological problems, as well as present data demonstrating its utility in detecting malingering.

A 30-year-old married man sustained a severe documented head injury and was referred by his neuropsychologist for psychiatric treatment. There was consensus regarding the seriousness of the TBI. The neuropsychologist attempted to treat the injured worker in a group for other head-injury patients, but felt that psychopharmacological treatment was indicated and referred the patient for pharmacological consultation and management. A valid MMPI-2 profile was obtained. The overall profile elevation (which is the arithmetic average of clinical scales 1–4 and 6–9) was 89.6, indicating extreme emotional distress.

The profile presented in Figure 86.6 reflects severe emotional distress with demoralization, depression, serious worries about health, obsessional anxiety, and some disconnection from reality. The VRIN and TRIN scales indicated that the examinee was able to attend adequately to the test items. The Fp scale reflected no exaggeration of rare psychological symptoms. The RC scales indicated that severe distress was indeed present. This person was incapable of cooperating consistently with treatment, as he was unable to remember his appointments and attend them with any consistency, or to take medication as prescribed, despite reminder calls and the enlistment of familial support. Because of his inability to participate in treatment, care was terminated with a recommendation for a pension.

In a situation such as this, a community care model with case managers that make home visits would probably be more effective at palliation and support, since regulations typically require that care provided under workers' compensation claims be curative and not merely palliative.

The MMPI-2-RF profiles of soldiers who report experiencing a mild TBI in Iraq, but who do *not* report PTSD symptoms, are not significantly different on the RC scales (identical to the MMPI-2 RC scales) from those of soldiers who do not report mild TBI or screen positive for PTSD. This suggests “there was little evidence of a long-term negative impact of concussion/MTBI history on these outcomes after accounting for PTSD.” (Polusny, Kehle, Nelson, Erbes, Arbisi, and Thuras, 2011).

Validity scales	VRIN	T score = 50
	TRIN	T score = 64F

POTENTIAL MISUSE OF THE MMPI-2
AND MMPI-2-RF

Because the MMPI-2 and MMPI-2-RF are so widely used in a disability context, unless they have ready access to qualified psychologists, psychiatrists who seek to utilize it in their disability evaluations are advised to remain current with MMPI-2/MMPI-2-RF research through workshop attendance and literature review. Even if a psychologist is available to administer and interpret the MMPI-2/MMPI-2RF, familiarity with current developments in the literature makes the IME review and report-writing process easier.

One commonly encountered error in IMEs is to find excessive reliance on quotes from the computer-generated interpretations. Graham (2012) and Butcher (2000) point out that automated interpretive systems can become fixed at a naive level, and that in response to critics, only minor cosmetic changes may be made by the publishers. Computer-generated interpretations should be regarded as consultations between one professional and another. Blind reliance on computer interpretations can lead to major errors, as occurred in Case Study 2, when a profile was labeled “invalid” because of an elevated F scale T score. As another example, the diagnosis of malingering from an elevated “Symptom Validity Scale (FBS)” T score is generally incorrect, except in forensic neuropsychological assessments, and then only when careful attention is given to cutoff scores. The FBS scale was developed to detect malingering of psychological distress by personal injury claimants based on unpublished frequency counts of malingers’ MMPI item responses and “observations of personal injury malingers.” However, Butcher, Arbisi, Atlis, and McNulty (2003) reported that subsequent published cut scores for the FBS inappropriately classified too many individuals who were experiencing genuine psychological distress as malingerers, and, given the existing research on the scale and the published interpretation guidelines, “the FBS should not be used in clinical settings nor should it be used during disability evaluations to determine malingering.” In late 2008, Ben-Porath and Tellegen issued a statement published on the Pearson Assessments website summarizing the view of a panel of experts that the FBS was useful in identifying “potentially exaggerated claims of disability, primarily in the context of forensic neuropsychological evaluations.” As is the case with all psychological testing, however, the FBS should be considered in the context of the other validity scales.

Another error to be avoided is deviation from the prescribed administration protocol. The MMPI-2 and MMPI-2-RF were standardized under controlled administration conditions; it is *not permissible* for the examiner to read, translate, or explain any of the test items to the test-taker, because unconscious bias has been shown to change the response pattern (Graham, 2012). If these conditions are violated, the test results have no forensic validity. The MMPI-2 is available in both written and audio English and Spanish versions, and in Hmong in written form. The MMPI-2-RF is only available in English at the time of this writing. Finally, if the MMPI-2 or MMPI-2-RF is

administered in written form using the bubble answer sheet, the scorer should *verify* the accuracy of their data entry by re-entering the data as prompted by the software.

In summary, the MMPI-2 and MMPI-2-RF are sources of information that the examiner can rely upon to reach a diagnosis or to address interrogatories. Helpful inferences can be drawn about both diagnoses and the severity of psychological conditions from the MMPI-2, and about the presence or absence of exaggeration or dissimulation as one of three elements of a forensic diagnostic investigation, the other two being a comprehensive record review and a comprehensive clinical diagnostic interview. Although inferences can be drawn regarding diagnoses, one cannot render DSM-5 diagnoses solely on the basis of MMPI-2 or MMPI-2-RF results, nor indeed solely on the basis of any psychological test.

QUALITY REPORT WRITING

The most compelling reports have novel-like qualities. They should evoke the personality of the examinee, with clarity and a lack of jargon, and address the questions posed by the requesting party. These questions include diagnoses, apportionment of causation, and indications of whether maximum medical improvement has been achieved and whether the impairment is partial or complete. Other questions include recommended treatment, whether or not the person can return to the job of injury with or without accommodations, and whether the examinee could benefit from vocational services (Williams, 2006).

DSM-5 DIAGNOSES MUST BE RECORDED

Treatment recommendations are based on the integrated assessment of the patient that takes into account all psychiatric conditions and psychological test results. Personality trait disturbances or full disorders are present in a majority of affected patients in some subpopulations, and require sophisticated clinical skills. Effective treatment may include group and individual therapy, along with appropriate pharmacotherapy (Williams & Schouten, 2008). With the introduction of the DSM-5, the multiaxial diagnostic system has been scrapped, but the need for careful diagnosis and formulation remains. The treatment plan must take all conditions into account, and the clinician's awareness of comorbid disorders is critical to successful outcomes (Oldham et al., 1995).

DISABILITY AND THE AMERICANS WITH DISABILITIES ACT

With passage of the Americans with Disabilities Act (ADA) in 1990, the federal government barred discrimination against individuals with disabilities with regard to employment and access to public accommodations. States have done the same through passage of analogous statutes. The ADA was passed to counter commonly held biases that individuals

with mental or physical disabilities are necessarily disabled from working.

As we noted above, it is important to keep in mind the distinction between disabilities and impairments. Impairments are the cognitive and affective abnormalities associated with disorders. Disabilities are the restrictions that are imposed by impairments in functioning, including work and relationships. Thus, an individual with a disorder may or may not have an impairment, and that impairment may or may not amount to a disability. The ADA prohibits discrimination against individuals who have disabilities, or who are perceived as having disabilities, if they can perform the essential functions of the job, with or without reasonable accommodation (Langer, 1996; Zuckerman, 1993).

Clinicians, and society in general, seem to be of two minds with regard to disability and individuals seeking disability status. On one hand, society has developed insurance plans, both public and private, that insure workers against the possibility that they will no longer be able to earn a living. The systems established to provide financial and emotional support for individuals who become disabled from work as the result of illness or injury represent major social advances. Yet, while we have established and endowed these systems, those who utilize them may find themselves the objects of scorn and derision. After all, American society values work and the work ethic (Hubbard, 1998). Those who ask to be relieved of the obligation to work often elicit disdain from caretakers, co-workers, and family members.

The growth of attention to disabilities and the disabled is no doubt related to the increasing numbers of disabled individuals in the workplace and the growing number of disability claims. Some authors have predicted that the combined impacts of the Americans with Disabilities Act and aging of the Baby Boom generation will result in a significant increase in the number of disabled workers in the next decade (Zwerling et al., 1997).

As noted above, individuals with disabilities are protected against discrimination by the Americans with Disabilities Act and similar state statutes (Langer, 1996). Those same individuals may require disability insurance benefits to cover living expenses during periods when they cannot work. Some individuals have filed suit alleging disability-based discrimination by their employers, while also filing claims for disability benefits. The courts have differed as to whether both claims can be made simultaneously. Some have rejected such claims—cf. *Cleveland v. Policy Management Systems Corp.*, 120 F. 3d 513 (5th Circuit, 1997). Others, noting that claims for disability benefits do not involve the question of reasonable accommodations, allow both claims, cf. *Swanks v. Washington Metropolitan Transit Authority*, 116 F. 3d 382 (D.C. Circuit, 1997).

In 1999, the United States Supreme Court resolved this issue when it heard the appeal in *Cleveland v. Policy Management Systems Corp.*, 526 U.S. 795; 119 S. Ct. 1597, cited above. Ms. Cleveland had suffered a stroke and was granted SSDI benefits after making a sworn statement that she was unable to work. She also filed an ADA claim that her employer had failed to make reasonable accommodations that

would have allowed her to continue working. The District Court granted summary judgement for the employer, dismissing her claim on the basis that she could not both claim to be unable to work, and simultaneously claim that she could perform the essentials of her job with or without accommodations, as required by the ADA. The U.S. Court of Appeals for the Fifth Circuit affirmed.

In overturning the decision of the Court of Appeals, the court held that receipt of Social Security Disability payments did not automatically bar Ms. Cleveland from bringing an action under the ADA, and summary judgement was inappropriate where she had provided sufficient explanation of inconsistencies in her statements. Where such inconsistencies exist, however, courts will consider receipt of disability benefits as evidence that the individual plaintiff could not, in fact, perform the essential functions of the job.

Discrimination against those with mental and physical disabilities is a real phenomenon. The bias may be overt or subtle; it may be based on actual experience or, more commonly, on stereotypes. For example, HIV/AIDS raised unique ethical and medico-legal problems relevant to disability claims (Gostin, Feldblum, & Webber, 1999). Clinicians treating those with mental and physical disabilities can make a major contribution to getting their patients back to work and helping them overcome the bias against those with mental and physical disabilities. They can do so by conducting objective evaluations of the patient's specific abilities to function in different settings, and by being willing to cooperate with the employer's request for information. Such cooperation and sharing of information must only occur with the patient's permission, of course. The treating clinician should be clear with those requesting the information that the evaluation is not an independent evaluation, and that it is based on more limited information.

While treating clinicians can serve as the patient's advocate in helping them get back to work, they can also put their patient and the patient's co-workers at risk. It is essential that any clinician who states that a patient is able to return to work after a period of disability have a clear sense of the nature and responsibilities of the job, as well as the patient's clinical condition (Maffeo, 1990). For example, one treating social worker opined that his patient, a research chemist who conducted high-pressure liquid chromatography with hazardous materials, was no longer disabled by her depression and was fit to return to work. Upon inquiry by an independent evaluator, however, the social worker indicated that he had no idea of the duties and the potential dangers. In a similar case, a treating psychiatrist argued that his psychotic patient could return to her job in government, in spite of her active paranoia and lack of compliance with medication, because he felt that no one could force her to take the medication.

SUMMARY

The evaluation and treatment of individuals with work-related disabilities provide a number of challenges to clinicians. The role of an independent psychiatric evaluator is not

interchangeable with that of a treating psychiatrist. When undertaking an evaluation, psychiatrists should specifically identify their role and remain within its bounds. The importance of work to individual and societal well-being, the moral valence we attach to it, and the diverse motivations for entering and leaving the workforce all combine to make this an emotionally charged area with many clinical challenges. The clinician and patient are best served when clinicians are honest with themselves and the patient about the limitations on their knowledge and ability and the constraints these limits impose. Utilization of psychological testing appropriate to the case may contribute meaningfully to objectivity and the avoidance of unconscious bias. Paying attention to detail, and understanding the task involved and the techniques for completing it, is likely to lead to more consistent and reliable treatment and assessments.

CLINICAL PEARLS

- Functional *impairments* are limitations to specific functions that may impair the patient's ability to perform the essential duties of particular occupations.
- The actual determination of *disability* results from either an *administrative* or a *judicial decision* that weighs evidence and expert opinions, including those provided by psychiatrists; the adjudicators are the "finders of fact."
- Definitions of disability imply that disability is an "either-or" condition—i.e., someone is disabled or they are not. The reality is more complex, and in this chapter we take the approach that "disability determination" should be approached taking into account the *diagnosis*, its *severity*, and the life *context* of the person being evaluated.
- An evaluator is obligated to be a seeker of truth, whereas a treater's primary duty is to the patient as a seeker of cure and comfort.
- For evaluations that require assessment of causation, credibility, and severity, where necessary and when circumstances allow, an enhanced *dimensional* method for assessing psychiatric impairment that incorporates formal psychological testing combined with a comprehensive medical record (chart) review and examinee/patient may contribute to greater reliability in diagnosis, causal attribution, and severity ratings. This method, which includes partially quantitative elements, utilizes a *cross-reference grid* that incorporates various rating scales with definitions for five levels of impairment that enable the rater to "triangulate" the rating by cross checking one scale against the others (Williams 2006; 2010). Psychological testing, including the Minnesota Multiphasic Personality Inventory-2 (MMPI-2, 1989), can also be added to this comparison grid.
- *Disability* relates to interaction between specific impairments and adaptive capacity.

- The SIRS-2 can serve as a useful adjunct to the MMPI-2 (RF) in the detection of feigned mental disorders, particularly for malingering of major psychiatric disorders.
- The examiner frequently encounters situations in which it is difficult to determine the relative balance of depression, anxiety, somatization, and character pathology. In these situations, the additional information supplied by the MMPI-2 can be of significant benefit.
- An individual with a *disorder* may or may not have an *impairment*, and that impairment may or may not amount to a *disability*. The ADA prohibits discrimination against individuals who have disabilities, or who are perceived as having disabilities, if they can perform the essential functions of the job with or without reasonable accommodation (Langer, 1996; Zuckerman, 1993).

ACKNOWLEDGMENTS

The author would like to acknowledge contributions by the following colleagues. Ronald Schouten, MD, JD, director of the Law and Psychiatry Service at Massachusetts General Hospital and associate professor of psychiatry at Harvard Medical School, wrote the section on disability and the Americans with Disabilities Act and introduced the author to academic scholarship, beginning with the *Psychiatric Care of the Medical Patient*, 2nd edition published in 2000. Charles Mangham, Sr., MD, clinical professor of psychiatry at the University of Washington School of Medicine and training analyst at the Seattle Psychoanalytic Society and Institute, helped the author learn how to listen to patients over 25 years of consultation. Paul Arbisi, PhD, professor, Department of Psychiatry, University of Minnesota, helped introduce the author to the MMPI-2 and MMPI-2 RF and reviewed the chapter in detail, greatly contributing to accuracy and clarity in the discussion of the MMPI-2 and MMPI-2-RF. Arian Kidder, PhD, provided quick and expert editing of this manuscript under pressure, adding to its readability. Of course, any errors or shortcomings are the responsibility of the author.

DISCLOSURE STATEMENT

Dr. Williams reports that in 2013, after completion of the original draft of the chapter, Pearson Assessments and the University of Minnesota Press provided software resources to enable the transformation of archival MMPI-2 reports from his practice to MMPI-2-RF profiles in support of an ongoing research project.

TELEPSYCHIATRY

Terry Rabinowitz

INTRODUCTION

Some medical conditions may make it difficult or impossible for affected individuals to receive necessary psychiatric care because they may be unable to come for appointments or to participate in their care as required. In addition, psychiatric treatment may not be possible because large distances separate a patient from his or her potential care providers, with few physicians willing to spend uncompensated time in travel and few patients with significant medical comorbidity able to make long trips without costly assistance and a significant investment in time. A videoconference approach for these persons may be a realistic, cost-effective, and acceptable solution to this problem that makes it possible to deliver quality psychiatric care to some who could not otherwise receive it.

TELEMEDICINE AND TELEPSYCHIATRY

As defined by the American Telemedicine Association (ATA),

Telemedicine is the use of medical information exchanged from one site to another via electronic communications to improve patients' health status.... Videoconferencing, transmission of still images, e-health including patient portals, remote monitoring of vital signs, continuing medical education and nursing call centers are all considered part of telemedicine and telehealth.... (American Telemedicine Association, 2011)

Thus, *telepsychiatry* may be defined as the use of telemedicine to deliver psychiatric care or education across distances, using any available technologies. Other equivalent or related descriptors include *tele-psychiatry*, *telemental health*, *tele-mental health*, *telepsychology*, and *tele-psychology*.

BACKGROUND AND HISTORY

The first published articles about telemedicine were in the field of telepsychiatry (Baer, Elford, & Cukor, 1997) and are attributed to Cecil Wittson and colleagues, who, in the 1950s and 1960s, studied the use of a videoconference approach to provide psychotherapy, comparing it to face-to-face (FTF)

care, and found that the technique used had no significant effect on the quality of the sessions, but that therapist choice and group member selection were important predictors of outcomes (Wittson, Affleck, & Johnson, 1961). Later, Wittson and Benschoter reported on the use of a two-way closed circuit television system between the academic medical center, Nebraska Psychiatric Institute (NPI), and the Norfolk State Mental Hospital, separated by 112 miles. They reported improved patient services at the state facility as a consequence of increased NPI specialist availability through telemedicine. In addition, staff members at both locations used the system to discuss research investigations, and overall interaction and collaboration increased between the two facilities (Wittson & Benschoter, 1972).

The first reports of psychiatric consultations using telemedicine began to appear in the 1970s. In general, these reports described consultations to primary care providers by psychiatrists at academic medical centers using two-way interactive television. For example, Solow et al. used a psychiatric consultative model that comprised a referring provider briefly describing his or her patient to the consulting psychiatrist (CP), interview of the patient by the CP, and CP discussion of findings and recommendations with the referring provider. This model had high patient and provider acceptance (Solow et al., 1971). Later, Dwyer reported the successful use of this modality to provide psychiatric consultations from Massachusetts General Hospital (the *hub* or *distant site*) to a medical station (the *spoke* or *origination site*) in Boston (Dwyer, 1973). Dwyer reported that about 30 psychiatrists and 30 psychiatry residents and medical students responded positively to telepsychiatry, and suggested that, for some patients, this modality might be preferable or superior to an FTF approach—similar findings were reported more than three decades later (Rabinowitz et al., 2006). The greatest impediments to acceptance and implementation of telepsychiatry were the relatively high costs of transmission; cumbersome equipment; technical problems such as sound pick-up, dropped calls, and camera operation; lack of reliability compared to the FTF condition; and so-called *technophobia*, an irrational fear and avoidance of new technologies (Grady, 2002; Yellowlees, 1997; Yellowlees, 2001; Yellowlees, 2005).

Beginning in the 1980s, affordable videoconferencing enabled widespread use of this technology. Early videoconference costs were prohibitive, and picture and sound quality were not always satisfactory, but with the use of digitized audio and

video data, it is now possible to expect and obtain acceptable high-quality transmissions (even for images that require very accurate reproduction) at low cost. For example, Kldiashvili and Schrader reported that digital images are appropriate substitutes for glass slides for telecytology applications, particularly when used for quality assurance programs (Kldiashvili & Schrader, 2011), and Urness et al. reported generally high levels of satisfaction (equivalent to those for FTF) of patients using telepsychiatry (Urness et al., 2006). In addition, Doolittle and colleagues reported a steady decrease in per-visit costs and increased use of an established teleoncology service from 1995 to 2005: from 103 visits at \$812 per visit, to 235 visits at \$251 per visit (Doolittle, Spaulding, & Williams, 2011).

DOES TELEPSYCHIATRY WORK?

Although it seemed obvious that telepsychiatry applications were useful in a number of domains (e.g., cost-savings, effectiveness, acceptability), clinicians and researchers set out to demonstrate that this was the case by using a scientific approach that included experimental and control subjects, larger samples, and more carefully controlled environments. However, although there still is a paucity of large, well-controlled studies that show equivalence (or superiority of) telemedicine/telepsychiatry vs. the FTF condition (Rabinowitz et al., 2008; Whitten et al., 2002; Williams, May, & Esmail, 2001), the accumulated data from many smaller studies and the experience of many clinicians suggest that telepsychiatry is effective, saves money, and is an acceptable alternative to FTF care (Mair et al., 2000; Kennedy & Yellowlees, 2003; Frueh et al., 2004; Modai et al., 2006; Antonacci et al., 2008; Hailey, Roine, & Ohinmaa, 2008). In the late 1990s, evidence-based telepsychiatry reports began to appear. Searching the MEDLINE and PubMed databases using keywords *telemental*, *tele-mental*, *telepsychiatry*, *tele-psychiatry*, *telepsychology*, and *tele-psychology* reveals a steady increase in telemental health-related publications over the past several decades. In addition, there are many more telemedicine publications that do not “trigger” on these keywords but that directly or indirectly address psychiatric issues.

TECHNICAL AND LEGAL ASPECTS AND NOMENCLATURE

While it is possible for a psychiatrist to use telemedicine equipment without having any appreciation of its actual functioning, a better understanding of the technology is likely to lead to less anxiety about its use and more widespread acceptance and implementation of the technique by clinicians and patients (Yellowlees, 2005; Whitten & Kuwahara, 2004; De Las Cuevas et al., 2003). In addition, because of advances in communications technology, it is now possible to videoconference using compact, inexpensive, user-friendly devices such as webcams, tablet computers, and smartphones, though some of these technologies may not be adequate or appropriate for a telepsychiatry consultation; each clinician and patient is likely to have specific

preferences regarding picture and sound quality as well as ease of use of videoconference equipment. Therefore, when contemplating using a telemedicine approach, potential users are advised to perform some “test runs” of different equipment to determine if it meets their individual needs. For example, a smartphone may be an acceptable device for a short, focused patient “visit” but may not be especially comfortable for a 50-minute psychotherapy session for reasons including its inability to pan, tilt, or zoom, leading to user/patient fatigue, and its adequate but not excellent audio and video features.

To better understand how telemedicine applications are described, evaluated, and implemented, and to help readers evaluate telemedicine publications, a few telemedicine-related definitions follow.

Bandwidth (or Digital Bandwidth): A rate of data transfer, bit rate or throughput, measured per second in bits (bps), kilobits (10^3 bits; kbps), or megabits (10^6 bits; mbps). Typical free-standing telemedicine apparatuses may function reasonably well at bandwidths as low as 128 kbps (kilobits per second) but generally work better at rates of 364 kbps and higher. See Table 87.1 for bandwidth comparisons of different equipment.

It may be helpful to think of different bandwidths as analogous to different pipe diameters; larger pipes allow greater flow rates; that is, more data transferred per second. Therefore, greater bandwidth is a desirable feature of any telemedicine system. However, increased bandwidth is costlier and often requires more sophisticated (i.e., more complicated) technology.

Codec: This is a device or computer program capable of encoding or decoding a digital data stream or signal. A codec encodes a data stream or signal for transmission, storage, or encryption, or decodes it for playback or editing. Codecs are

Table 87.1 TYPICAL OPERATING BANDWIDTHS OF DIFFERENT COMMUNICATION EQUIPMENT

APPARATUS	APPROXIMATE BANDWIDTH
Typical dial-up telephone	28 kbps
Faster dial-up telephone	56 kbps
<i>Telemedicine minimum:</i>	128 kbps
Basic DSL (Digital Subscriber Line)	768 kbps
T-1 / DS1	1.5 mbps
3G	2.4 mbps
Over-the-Air (OTA) television	4–20 mbps
T-3	44 mbps
Maximum FiOS (Fiber Optic Service)	50 mbps
4G (long-range) or WiFi (<i>Wireless Fidelity</i>) (short-range)	>100 mbps
Cable television	50–1000 mbps

used in videoconferencing, streaming media, and video editing applications. Audio and video files are compressed with a certain codec when they are saved, and then decompressed by the codec when they are played back.

Encryption is the conversion of data into a form called a *cipher text* that cannot be easily understood by unauthorized persons. *Decryption* is the process of converting encrypted data back into its original form, so it can be understood. Some or all videoconference data may be encrypted, potentially enhancing their security, but encryption itself is no guarantee that these data are entirely safe. Thus, when considering using telemedicine, it is important for each provider to be familiar with the data security practices in effect at his or her telemedicine (i.e., “proximate”) site as well as those in use at the distant or “patient” site, keeping in mind that: (1) not all encryption methods are equally effective; (2) some software applications used for videoconferencing may not be Health Insurance Portability and Accountability Act (HIPAA)-compliant even though data are encrypted (see: U.S. Department of Health and Human Services Health Information Privacy website): <http://www.hhs.gov/ocr/privacy/hipaa/understanding/coveredentities/index.html>; and (3) some software producers may fully disclose neither the limitations of their encryption technology nor what data might be accessed or made available to third parties during or after a videoconference session. When in doubt, consultation with appropriate (e.g., risk management, information technology) services is recommended before a telepsychiatry consultation is performed. Although data security, including patient confidentiality, is an important issue, it has been our experience that, if providers take reasonable steps to protect sensitive information, there is a very low risk of data breaches. Therefore, we recommend a prudent but not over-cautious approach to data security: Do not let concerns about data security be the *deal breaker* when considering using telemedicine.

There are no universally accepted or mandated standards or guidelines for telemedicine or, more specifically, for telepsychiatry. However, *Practice Guidelines for Videoconferencing-Based Telemental Health* were published in 2009 by the American Telemedicine Association (ATA) and may be accessed at their website: <http://www.americantelemed.org/i4a/pages/index.cfm?pageid=3311>. These guidelines provide a useful set of “bare minimum” requirements for a telemental health service. In addition, the publication includes a useful glossary of telemedicine/telehealth terms.

TELEPSYCHIATRY CONSULTATIONS

Using telemedicine to provide psychiatric treatment for persons with co-occurring non-psychiatric conditions may be an especially helpful approach for several reasons:

1. Patients may live or be hospitalized in rural or other underserved areas where no psychiatrists with the necessary skills are available;
2. Patients may not be able to travel to obtain care where a medical psychiatrist is available;
3. The medical psychiatrist may be unwilling or unable to travel to where the patient is;
4. A local psychiatrist may be qualified to treat the patient but may want advice from a more specialized psychiatrist or simply one outside their usual medical community;
5. Some patients (e.g., those with avoidant or paranoid personalities; those who do not wish to be in public because of disabling or disfiguring conditions; those with autism spectrum disorders) actually would prefer a remote to an FTF consultation; and
6. Psychotherapeutic and psychoeducational groups are easier to convene when it is not necessary to coordinate simultaneous travel for all of the group members.

In addition, telepsychiatry is particularly adaptable to training and supervision of residents and fellows, because it avoids the potentially intimidating effect of having several doctors in the patient’s room at once, and making recordings of salient moments is easy.

Urness et al. evaluated patient satisfaction and outcomes for telepsychiatry compared to in-person consultations using the Short Form 12-Item (SF-12) Health Survey and a satisfaction survey. At the one-month follow-up, 48 of 62 subjects (77%) were evaluated. Telepsychiatry patients showed significant improvements on mental health measures compared to controls. Ninety-three percent felt they could present the same information that they could in-person, 96% were satisfied with their telepsychiatry session, and 85% were comfortable talking with their provider; these rates were similar to those for in-person encounters (Urness et al., 2006). Boydell and colleagues reviewed 100 pediatric telepsychiatry consultations to determine whether the recommendations made during each session were actually implemented and found that neither the technology used nor technological difficulties were barriers to implementation (Boydell et al., 2007; Pakyurek, Yellowlees, & Hilty, 2010).

Pakyurek et al. suggest that telepsychiatry may actually be a superior method of psychiatric assessment for children and adolescents compared to the face-to-face approach, due to four factors associated with telepsychiatry: (1) the novelty of the consultation, (2) the capacity to provide direction, (3) the extra distance involved (both psychological and physical), and (4) the authenticity of the interaction (Pakyurek, Yellowlees, & Hilty, 2010). Rabinowitz and colleagues reported similar results for a cohort of nursing home residents ages 44–100 years and in addition found that some patients (e.g., those who were paranoid or avoidant) expressed a preference for telepsychiatry (Rabinowitz et al., 2006; Rabinowitz et al., 2010; Rabinowitz et al., 2006).

Yellowlees et al. assessed the feasibility of using an asynchronous (also called *store and forward*) approach to providing telepsychiatry consultations. This involved the examination by two psychiatrists of video-recorded assessments of 60 adult patients followed by recommendations to their primary care

providers. They concluded that asynchronous telepsychiatry consultations were possible and that they would be a helpful additional procedure that enhances access to care (Yellowlees et al., 2010). A follow-up study of asynchronous telepsychiatry (ATP) by Butler and Yellowlees found that the cost savings of the approach was due in large part to the substitution of lower-cost providers for specialists (i.e., psychiatrists) at the patient sites (Butler & Yellowlees, 2011).

We have provided psychiatric consultations to rural nursing home residents since 2002, saving both time and money, as well as avoiding the need to transport frail residents over long distances. Virtually all of these residents had non-psychiatric medical comorbidity, and without telepsychiatry, many would have received no psychiatric care at all because of psychiatrist unavailability. We reported estimated time savings of more than 843 hours that would have been spent for patients traveling to the psychiatrist and vice versa, and potential cost savings of as much as \$253,000 (for round-trip physician travel time) for 278 telepsychiatry encounters for 106 nursing home residents (Rabinowitz et al., 2010).

Lending further support to using telemedicine to perform psychiatry consultations for persons with medical illnesses are several reports of its use in treating many medical conditions or patient groups frequently encountered by medical psychiatrists. In a study of 80 patients with head and neck cancer whose tumors were examined both face-to-face and by simulated telemedicine consultations, Stalfors et al. found that tumor classification and treatment planning were the same for both conditions in 73 (91%) of the patients (Stalfors et al., 2001).

Heath and colleagues performed and analyzed 63 pediatric critical care telemedicine consultations from their tertiary care facility to ten rural emergency departments. They used this approach to make 236 specific recommendations and to supervise the critical care transport team in 25 (40%) of the cases. Both the consulting intensivists and the referring providers thought that telemedicine consultations improved patient care and provided good to very good provider-to-provider communications (Heath et al., 2009).

Magann reviewed the telemedicine literature for obstetrics and reported its use to read ultrasounds, interpret non-stress tests, counsel patients, manage diabetes, manage postpartum depression, and to support parents and children postpartum from remote sites, with potential benefits that included reductions in time lost from work, decreased transportation costs, greater efficiency for providers, and reduced medical costs (Magann et al., 2011). An analysis of telemedicine data from the Milwaukee Veteran Affairs Medical Center (VAMC) pulmonary telemedicine clinic, where pulmonary physicians delivered care via telemedicine to patients 215 miles away, found that consultation led to a change in management for 41% of patients, and only 8% of patients required an in-person clinic visit following a telemedicine encounter (Raza et al., 2009).

According to Barneveld Binkhuysen and Ranschaert, teleradiology was first developed for military purposes in the 1980s (Barneveld Binkhuysen & Ranschaert, 2011). Since then, its implementation has become remarkably widespread,

with applications reported for nearly every radiological specialty and subspecialty. A search of the MEDLINE database using the single keyword *teleradiology* found 1,373 articles published between 1972 and 2011; for comparison, 255 citations were found using the search term *telepsychiatry* for the same period.

THE TELEPSYCHIATRY ENCOUNTER

Most telepsychiatry consultations are performed by a remote psychiatrist who consults on a patient at one of several locations that might include: the patient's home, a general hospital, a physician's or another provider's office, a community health center, or another venue equipped for videoconference consultations. Regardless of the site, meeting a common set of minimal requirements will help ensure an optimal encounter and acceptance of the technology (Table 87.2).

Grady (Grady, 2002) identifies the importance of the "seven A's" when implementing and maintaining a telepsychiatry service and to assure its success:

Alliance is the consultant's relationship with the remote site's administrative, support, and provider staff.

Assessment includes identifying needs and resources of the satellite site, capabilities and resources of the hub site, and the interest/investment of both sites.

Approach describes how to get the "telepsychiatry word" out to others. Grady recommends that clinicians be the individuals first contacted (i.e., approached) as they will have the greatest insights into the needs of clinicians and patients at the satellite sites.

Improved *access* for patients may be the single most important reason for telepsychiatry. This also refers to where the teleconferencing equipment is located: putting it where it is most easily accessed at the distant site (e.g., a community mental health clinic, a primary care provider's office) and at the hub (e.g., within a telemedicine department, within the medical psychiatry unit) will increase the likelihood that it will be used.

Accountability refers to responsibilities of the provider and facility, including physical safety of the patient, security of patient records, and a plan for performance evaluation and improvement.

Apprehension may be felt by the telepsychiatrist, patient, or clinicians and support staff at the satellite site. It is the responsibility of the telepsychiatrist to be sufficiently comfortable and adept with the equipment that he or she can use it with confidence and allay the concerns of others.

Anticipation of equipment malfunctions, patient refusals, staff worries, and other problems will help the provider develop contingency plans. Bear in mind that it is impossible to anticipate all types of equipment malfunctions or when they might occur. This is especially true given the increased use of low-cost, easily accessed videoconference equipment such as smartphones and tablet computers. Therefore, it is recommended that users become familiar and proficient with one or a very small number of apparatuses rather than try to master every available technology.

Table 87.2 SOME BASIC REQUIREMENTS FOR TELEPSYCHIATRY ENCOUNTERS

PARAMETER	REQUIREMENT/GOAL	ACTION
Safety	Ensure safety of a suicidal or otherwise unsafe patient	Establish a reliable and rapid system of communication other than the telepsychiatry apparatus (e.g., cellular or other telephone, pager) to contact an onsite person in case assistance is needed.
Usability	Conditions and apparatuses must be user-friendly and reliable	Take time to learn about equipment by having a few practice sessions with technical assistance available; make sure venues are well-lighted, quiet, secure, and easily accessible; have back-up plan for communication (e.g., cellular or other telephone) in case of equipment malfunction; know how to access technical staff during any time a telemedicine encounter might occur—24/7 if necessary. If using at home, make sure there is someone with some experience using, e.g., webcams, FaceTime, Skype, etc., who is readily available for quick technical assistance.
Acceptability	Increased likelihood that telepsychiatry will be used	Provider must be comfortable with equipment; acknowledge to patient and/or staff at distant site any limitations/benefits of approach (e.g., saves travel time and money, there may be a slight delay in audio portion of signal); assistance may be needed to position patient or to physically examine for some conditions such as extrapyramidal syndromes; headphones may be useful for some patients with hearing problems.
Education	To better understand how telepsychiatry can be used	Consider recording of telepsychiatry encounters: These can be used to show others how telepsychiatry works, for second opinions, and for provider education (i.e., for the provider to observe his/her “telepresence” and to make adjustments if indicated). Make sure appropriate permissions are obtained. Recordings of encounters may be considered part of the permanent medical record.

LEGAL, REGULATORY, AND FINANCIAL CONSIDERATIONS

Although telemedicine has been available since the 1960s, there are few laws regarding its use. For example, the U. S. Centers for Medicare and Medicaid Services (CMS) have published data regarding what telemedicine services will and will not be reimbursed, but there are no national standards for telemedicine use and more specifically, no laws that dictate how telemedicine in general shall be practiced nor how specific telemedicine specialty services should operate. To address this deficiency, the American Telemedicine Association has published a number of standards and guidelines for the use of telemedicine (see <http://www.americatelemed.org/practice>). Although this collection does not cover every aspect of telemedicine or every telemedicine specialty, it is a reasonably comprehensive database and an extremely useful resource. Moreover, these various standards and guidelines should be considered as representing the *de facto* standard of care for the covered telemedicine applications.

Two common questions regarding telemedicine are: (1) Does malpractice insurance cover this approach? and (2) Is it necessary to be licensed in the state where the telemedicine service is provided? The answers are not simple.

Each malpractice insurer approaches telemedicine differently, and there are no universal rules or regulations governing its coverage. Therefore, it is strongly recommended that each clinician know and receive confirmation in writing *before a telemedicine consultation is performed*, whether his or her policy covers telemedicine and if not, what must be done for coverage to be in effect. Many, but not all, carriers provide coverage around the clock for their subscribers, regardless of venue or technology, as long as the clinician practices within

the “boundaries” of the specialty. However, this is not a universal behavior, and ignorance of the terms of one’s coverage might lead to an undesirable outcome that could have been easily prevented.

If the originating and distant sites are in the same state, questions of licensure do not apply; we are not aware of any state medical licensing board that prohibits the practice of telemedicine between an in-state provider and patient. However, *interstate* telemedicine practice is more complicated. For example, some states with common borders allow providers from either state to practice medicine and telemedicine without requiring licensure of the “hub” physician in the “spoke” state, provided such practice is a rare occurrence. Other states require in-state licensure for even a single telemedicine consultation from an out-of-state physician. Therefore, it is recommended that each clinician learn what the state licensing board requirements for telemedicine practice are in the state to which the telemedicine services will be delivered, before any service is provided. In addition, it is important to know whether the spoke state has different licensing requirements or rules with respect to *medical consultants vs. primary providers*. It is equally important to know if the out-of-state clinician will have any trouble with prescriptions called in to or sent out to a pharmacy in another state.

Obtaining reimbursement for telemedicine services is becoming easier. For example, when telemedicine was in its infancy, neither private insurers nor CMS covered telemedicine services. However, with clear and convincing evidence that care delivered using a telemedicine approach is, in many cases, as good as (or better than) care delivered face-to-face, insurers, lawmakers, and laypersons have come to realize the benefits of telemedicine and are willing to reimburse accordingly or to ask their representative to enact laws requiring appropriate reimbursement for telemedicine services.

For example, on October 1, 2012, the state of Vermont enacted a telemedicine law (<http://www.leg.state.vt.us/docs/2012/Acts/ACT107.pdf>) that states in part:

...All health insurance plans in this state shall provide coverage for telemedicine services delivered to a patient in a health care facility to the same extent that the services would be covered if they were provided through in-person consultation....

Some other states have enacted similar laws, and some states have more inclusive ones. This is good for patients and for telemedicine and portends greater acceptance of and reimbursement for telemedicine services moving forward.

MORE INFORMATION

The best source for general information about telemedicine is the American Telemedicine Association (ATA) website: <http://www.americantelemed.org>. Once at this website, a few clicks will bring the interested searcher to the Telemental Health Special Interest Group (SIG), a very active SIG that is an excellent source of information for budding telepsychiatrists as well as those who are already familiar with the technology. More specific information about telepsychiatry as it relates to medical-psychiatric affairs can be gleaned by joining the Telepsychiatry SIG of the Academy of Psychosomatic Medicine (APM) (at <http://www.apm.org/>). This SIG was formed in 2010 to promote the use of telepsychiatry among medical psychiatrists. The two key telemedicine journals are *The Journal of Telemedicine and Telecare* (<http://jtt.rsmjournals.com/>), and *Telemedicine and E-Health* (<http://www.liebertpub.com/TMJ>).

SUMMARY

Using telemedicine to perform psychiatric consultations will benefit patients, providers, and communities. It will bring psychiatric care to many who would not otherwise receive it; it will save time and money; and it will expand the range of options for consulting psychiatrists. In addition, telemedicine has the potential to create new opportunities for research, to provide unique ways to treat patients, and to make the practice of medical psychiatry more enjoyable and fulfilling.

CLINICAL PEARLS

- When contemplating using a telemedicine approach, perform some test runs of different equipment to determine if it meets one's individual needs.
- Some software applications used for videoconferencing may not be HIPAA-compliant, even though data are encrypted (see <http://www.hhs.gov/ocr/privacy/hipaa/u7nderstanding/coveredentities/index.html>).

- We recommend that users become familiar and proficient with one or a very small number of apparatuses.
- The American Telemedicine Association has published a number of standards and guidelines for the use of telemedicine (see <http://www.americantelemed.org/practice>).
- Before a telemedicine consultation is performed, each clinician should know and receive in writing information as to whether his or her malpractice insurance policy covers telemedicine, and if not, what must be done for coverage to be in effect.
- It is important to know policies that apply across state lines for telepsychiatry and for prescribing medications.

PRACTICE GUIDELINES, PERFORMANCE MEASUREMENT, AND INCENTIVES

Daniel P. Hunt

INTRODUCTION

Clinical practice guidelines summarize and rate the evidence to support recommendations for the care of patients. Ideally, guidelines should make it easier for clinicians to provide high-quality, current-standard care that is evidence-based and patient-centered. This chapter describes the methodology for producing trustworthy guidelines and provides a framework for practitioners to assess the validity of guidelines.

Clinical practice guidelines (CPG) provide the underpinnings for performance measurements that have become commonplace for hospitals, practice groups, and individual practitioners. Financial incentives or pay-for-performance programs are aimed at quality improvement in medicine, often by promoting implementation of guideline recommendations. The evidence for efficacy and cost-effectiveness of pay-for-performance programs lags behind the widespread adoption of these programs. In simplest terms, clinical practice guidelines drive performance measurement, which drives performance-based incentive programs.

Clinical practice guidelines proliferated during the past two decades, driven by rapidly expanding medical research and literature that is overwhelming for the practitioner. The hope and promise of clinical practice guidelines has been that they would speed translation of clinical research to the care of patients, reduce variability in clinical care, and ultimately improve the health of individual patients while easing information overload for practitioners. During the same time period, large medical systems, insurers, patients, and physicians began to measure performance, often using guidelines to help define and justify individual measures.

This chapter will define clinical practice guidelines (CPGs), explain the process for producing valid guidelines, provide a framework for critical appraisal of guidelines, assess the use of performance measures, consider the impact of physician/system incentives in the implementation of guidelines, and address circumstances in which optimal patient care requires deviation from guidelines.

CLINICAL PRACTICE GUIDELINES

DEFINITION

The medical literature is replete with papers that purport to be guidelines. A simple Pub Med search of the term “guideline” in July of 2011 yielded 204,862 citations that could be loosely titled “guidelines.” For the purposes of this discussion, a much more specific definition for clinical practice guidelines is required in order to identify guidelines that are more likely to be valid and useful for clinical care. The Institute of Medicine (IOM), in its 2011 publication *Clinical Practice Guidelines We Can Trust*, provided the following definition:

Clinical practice guidelines are statements that include recommendations intended to optimize patient care that are informed by a systematic review of evidence and an assessment of the benefits and harms of alternative care options.

The IOM report outlines characteristics of trustworthy guidelines, which are listed in Box 88.1.

DEVELOPMENT OF CLINICAL PRACTICE GUIDELINES

The development process for trustworthy clinical practice guidelines is arduous and rigorous. Development generally begins with identification of a topic area that is worthy of attention for practicing clinicians. Table 88.1 provides a sequence of steps in development of a CPG and uses a hypothetical example of perioperative medication management to detail the process. The next step in producing a guideline is obtaining support, primarily financial, for the process, which requires a considerable investment of time by experts for intensive literature review, consensus meetings, writing, external review, and editorial input.

Once the topic area is defined and support for the process is assured, the convening individual or organization chooses guideline panel members. The panel should be

**Box 88.1 CHARACTERISTICS OF TRUSTWORTHY
CLINICAL GUIDELINES**

- Based on a systematic and critical review of the existing evidence.
- Developed by a knowledgeable, multidisciplinary panel of experts and key affected groups.
- Consider important patient subgroups (e.g., elderly patients)
- Incorporate patient preferences as appropriate, defined by patients involved in the formulation of guideline.
- Constructed through a transparent and explicit process that minimizes distortions, biases, and conflict of interest.
- Provide clear explanations of alternative care options and the expected outcomes.
- Provide ratings for both the quality of the supporting evidence and the strength of the resulting recommendations.
- Are reconsidered and revised as appropriate (and presumably on a regular basis) as new evidence becomes available.

Derived from the IOM report (Institute of Medicine [U.S.], & Graham, 2011).

multidisciplinary, including specialists and generalists along with methodological experts (epidemiologists, statisticians, guideline development experts, implementation experts, among others) as needed. The panel usually includes 10 to 20 members who represent three to five disciplines (Burgers, Grol, et al., 2003). A heterogeneous panel is more likely to produce better panel performance and more balanced guidelines (Murphy, Dingwall, et al., 1998). The panel requires a strong leader who is skilled in facilitating balanced discussion.

In addition to medical and methods experts, it is desirable to have patient representation on the development panel, although this presents its own challenges, given the technical nature of many deliberations.

The initial focus for the guideline panel is developing interpersonal relationships, establishing goals for the group, and defining the process. Bales and Strodtbeck identified the following three phases of group decision-making:

1. Orientation, or defining the problem;
2. Evaluation and discussion of the alternatives to address the problem; and
3. Control, or deciding which alternatives should prevail (Bales & Strodtbeck, 1951).

Before beginning deliberations, the panel and the panel members should declare and manage potential conflicts of interest. Scott and Guyatt outline issues to help address potential or real conflicts of interest, summarized in Table 88.2 (Scott & Guyatt, 2011). Although there is considerable concern about individual conflicts of interest, convening organizations may have a subtler but more pervasive potential conflict of interest. For example, an organization representing pulmonary specialists who derive practice income from pulmonary function testing would potentially be influenced by the vested interests of its members when convening a panel to develop guidelines for perioperative pulmonary care.

The next step in developing a CPG is to generate specific clinical questions. Clearly, these questions should be relevant to practicing clinicians and to their patients and should encompass major management decisions for the particular condition. The clinical questions form the framework for identifying and synthesizing the evidence that supports the recommendations.

Table 88.1 PROCESS FOR GUIDELINE DEVELOPMENT

STEP IN PROCESS	KEY STEPS OR CHARACTERISTICS	EXAMPLE
Identify topic area	Generally should be of interest to practicing clinicians, although may affect a small number of patients. Should generate specific clinical questions that can be answered by evidence.	Perioperative management of medications
Obtain resources for producing the guideline	Financial support in bringing all appropriate stakeholders together. Resources needed to produce review of the evidence, to write the guideline itself, and to disseminate the guideline. Critical that source of support not have conflict of interest in generation of guideline.	Collaborative of specialty societies might agree to provide resources (e.g.: national organizations for surgery, anesthesiology, medicine, hospital medicine would have potential interest in guideline)
Choose guideline panel members	Broad, multidisciplinary representation.	Surgery Anesthesiology Medicine Family Medicine

(continued)

Table 88.1 (CONTINUED)

STEP IN PROCESS	KEY STEPS OR CHARACTERISTICS	EXAMPLE
		Obstetrics/Gynecology Hospital Medicine Patients Epidemiologists Pharmacologists Pharmacists Nursing Guideline writing experts
Choose panel chair(s)	Chair needs skill in managing group dynamics and discussion.	Elect from within the group
Declare and manage potential conflicts of interest	Conflicts may include financial, academic, intellectual conflicts. Chair must determine if the participant with a conflict of interest must be excused from portions of the discussion or should not serve on this panel.	Physicians who have financial interests in the drugs that are discussed should be carefully considered and potentially excluded.
Generate clinical questions	Should identify clinical problems within the topic area that require guidance. Should generate focused questions. Panel must reach consensus on the final questions.	How should antihypertensives (and each class of antihypertensives) be managed during the perioperative period? How should diabetes treatment (oral agents, insulin) be managed around the time of surgery? Anti-platelet agents? Anticoagulants?
Identify outcomes critical to the recommendations the guideline will formulate	Identify all important patient outcomes. Explicitly rate the importance of the outcomes.	For example (within this guideline): Anticoagulants Serious bleeding New thrombosis Surgical complications Mortality
Systematic review of the current evidence addressing each question	May draw on existing systematic reviews, but often must commission new systematic reviews of the literature. Preferable to have the reviews done by groups independent of the guideline panel. Transparently summarize the review process and the evidence.	Systematic review of all studies of warfarin and surgery, other anticoagulants and surgery.
Guideline panel reviews prepared summaries of the evidence based on systematic review	Assess the quality of the evidence for each question.	Use a simple rating system for strength of evidence
Formulate recommendations and rate the strength of recommendations	Recommendations should be actionable and should employ active voice rather than passive voice. Should avoid ambiguous or vague statements such as "Physicians may offer. . ." Recommendations should be actionable and ideally should be easily incorporated in clinical decision-support tools.	For example: For patients at high risk of bleeding during the surgery and during the immediate post-operative period, but at low risk of thrombosis, the clinician should stop warfarin five days before surgery.
External review	Before submitting the guideline for publication, it should be critically reviewed by potentially affected parties who are independent of the guideline panel.	Review by a broader audience of surgeons, surgical subspecialists, internists, hematologists, cardiologists, etc.
Final formulation	Taking into account the external reviewers' comments, should finalize recommendations.	

Table 88.2 CONFLICT OF INTEREST IN DEVELOPMENT OF CLINICAL PRACTICE GUIDELINES

	ISSUES	SPECIFICS
Panelists	<p>Must disclose all industry-related professional activities.</p> <p>For the duration of guideline development, must divest themselves of direct financial interests in commercial companies with interest in any of the guideline's recommendations.</p> <p>Identify all sections of the draft for which they have a conflict of interest.</p>	<p>Research grants, speaker support, stock ownership, board positions, consultancy agreements should be documented by the chair of the panel</p>
Panel	<p>Identification and recruitment of panelists should be an open, transparent process.</p> <p>Should include methodologists who share responsibility for the process but have no financial or intellectual conflicts of interest.</p> <p>Explicit processes must be used to assess evidence quality and link this to recommendations.</p> <p>Only conflict-free panelists should determine the recommendations, including the strength of the recommendations.</p>	<p>Panels generally should include broad representation.</p> <p>Lack of consensus around the evidence or limited evidence should be resolved by explicit democratic process such as Delphi rounds.</p>

Adapted from Scott and Guyatt (2011).

Systematic reviews of the available evidence are the critical next step. The systematic review should result in a grading of the evidence, which is generally done using a fairly simple ordinal scale (I, II, III; A, B, C; *good, fair, poor*; or a numerical scale). Simple systems, such as that originally proposed by the Canadian Task Force on the Periodic Health Examination, may be based solely on study design, classifying randomized controlled trials (RCTs) as *good* (or Level I); cohort or case control studies as *fair* (or Level II), and expert opinion as *poor* (or Level III) (Spitzer, Bayne, et al., 1979). More recent evidence-classification schemes assess the methodological details of the included studies, but generally distill this to a simple classification. Some guideline-writing committees employ an independent group to perform the systematic review of the evidence for each clinical question, arguing that this reduces bias.

The guideline panel then links the available evidence and its strength to specific recommendations that address the original clinical questions. The recommendations themselves are also rated for strength using dichotomous or ordinal scores (strong recommendation, weak recommendation; A, B, C) after careful consideration of the potential benefits and weaknesses of a clinical management strategy.

The writing group for the panel then produces a draft CPG. The American College of Cardiology Foundation/American Heart Association (ACCF/AHA) recommends that guideline drafts include the following elements (ACCF/AHA, 2010):

1. Statement of the clinical question.
2. Recommendation that answers the clinical question and provides a classification of the strength of the recommendation and a classification of the level of evidence supporting the recommendation. (The ACCF/AHA uses the classification schemes outlined in Table 88.3.)

3. Explanatory text that provides a summary of the evidence.
4. References.
5. Evidence table.
6. Diagrams, tables, or graphic summaries that emphasize the key points regarding the question.

The draft of the CPG should be distributed to external reviewers and interested parties for comment before the document is finalized for dissemination or publication.

CRITICAL APPRAISAL OF PUBLISHED GUIDELINES

Clinical practice guidelines should be subjected to critical appraisal before implementation by practitioners. There are many systems available to grade the quality of the evidence and the strength of recommendations contained within CPGs. A useful example is the AGREE II instrument, which contains 23 items across six domains (Brouwers, Kho, et al., 2010). The items comprised in this instrument are available online, including a table from the original paper that is available at the website of the *Canadian Medical Association Journal*, <http://www.cmaj.ca/content/182/10/1045/T4.large.jpg>. As with most critical appraisal tools for CPGs, this system assesses the process of guideline development and the reporting of this process, but it does not assess the clinical content or the quality of the evidence within the guideline (Cluzeau, Burgers, et al., 2003).

The IOM report identified the challenge for practicing clinicians to independently assess the quality of relevant CPGs. This is particularly difficult when there is more than one CPG, often produced by different specialty societies that

Table 88.3 ACCF/AHA CLASSIFICATION OF RECOMMENDATIONS AND LEVEL OF EVIDENCE

RECOMMENDATION CLASSIFICATION		LEVEL OF EVIDENCE	
I	Conditions for which there is evidence and/or general agreement that a given procedure or treatment is useful and effective	A	Data derived from multiple randomized clinical trials or meta-analyses. Must provide citations with the recommendation.
II	Conditions for which there is conflicting evidence and/or a divergence of opinion about the usefulness/efficacy of a procedure or treatment	B	Data derived from a single randomized trial, or nonrandomized studies. Must provide citation(s).
IIa	Weight of the evidence/opinion is in favor of usefulness/efficacy	C	Consensus opinion of experts, case studies, or “standard of care.”
IIb	Usefulness/efficacy is less well established by evidence/opinion		
III	Conditions for which there is evidence and/or general agreement that the procedure/treatment is not useful/effective and in some cases may be harmful		

Derived from *Methodology Manual and Policies from the ACCF/AHA Task Force on Practice Guidelines* (ACCF/AHA, 2010).

address the same or similar clinical questions. The IOM recommended that certification of trustworthy CPGs should be a goal, although there is no current authoritative body to provide assessment and certification of individual guidelines. In the United Kingdom, the National Institute for Health and Clinical Excellence (NICE) takes the approach of certifying *organizations* that produce guidelines. The IOM proposed that certification of organizations based on their development procedures would be the most efficient method for assuring quality in guidelines. This certification might be based in the National Guideline Clearinghouse (www.guideline.gov), the National Quality Forum (NQF), the National Committee for Quality Assurance (NCQA), the Patient-Centered Outcomes Research Institute, or in NICE.

PRACTICAL ISSUES WITH USING GUIDELINES

For some problems, there are numerous high-quality CPGs available, and the specific recommendations contained in these guidelines may differ for each specific patient situation. This poses a challenge for the practitioner who must decide between the guidelines, weighing the apparent rigor that went into the development of each guideline, but finally deciding a course of action based on clinical experience and judgement. Sound clinical judgement should never be supplanted by a CPG.

The vast majority of CPGs address single diseases or conditions. Many patients, particularly those who are older, have multiple conditions, concerns, or diseases. There may be more than one high-quality guideline for each disease or condition, and these guidelines may be in full agreement. An illuminating 2005 paper considered applicable CPGs in the care of a hypothetical 79-year-old woman with hypertension, diabetes mellitus, osteoporosis, osteoarthritis, and chronic obstructive pulmonary disease (COPD) (Boyd, Darer, et al., 2005). Adherence to the guidelines would result in prescription of a

complicated regimen of 12 medications, recommendation of a complex (and somewhat conflicting) non-pharmacological regimen, while not accounting for potential adverse interactions between treatments and not accounting for patient preferences. This hypothetical case points out many reasons that CPGs may not be appropriate for some patients and should prompt the physician to deviate from standard recommendations. Table 88.4 includes additional challenges to full application of CPGs for individual patients.

Patients with unusual conditions may fall outside clinical practice guidelines. Patients with multiple comorbid conditions make the application of multiple CPGs unwieldy and potentially dangerous. Some patients and their physicians may have exhausted all conventional, CPG-supported options, yet wish to proceed with physiologically sound, yet unconventional, treatment. In each of these cases and in those identified in Table 88.4, the treating physician risks a worsened performance score, yet their patients might be receiving outstanding care and achieving positive health outcomes. This is one of the great challenges in the use of CPGs and performance measurement: to appropriately use evidence-based medicine while not missing out on the benefits of innovative care that falls outside such guidelines. The medical psychiatrist can play a pivotal role in helping to identify patients who would benefit from less reliance on CPGs, while carefully documenting the rationale in order to avoid negative performance measurement.

IMPLEMENTATION OF PRACTICE GUIDELINES

The intention of CPGs is to improve the care of individual patients and, as a consequence, to improve the care of populations. In order to fulfill this intent, recommendations contained in practice guidelines must be implemented by practitioners and patients at the point of care. CPGs affect the work of multiple members of a health care team, including

Table 88.4 CHALLENGES TO THE USE OF PRACTICE GUIDELINES IN CLINICAL CARE

ISSUE	APPROACH
Patient needs and preferences	Understanding patient circumstances, particularly social contexts. Thoughtful negotiation with patients regarding options.
Obscure diagnoses	There may be no guidelines, therefore requiring physician judgement. May limit use of guidelines for the patient's other conditions.
Complex comorbidities	Requires physician judgement regarding medical priorities. (For example: a life-threatening cardiac condition would take priority over routine screening or management of a more chronic condition.) Patient priorities are extremely important to consider in addressing multiple comorbidities.
Difficult personality traits or psychosocial factors	May dramatically reduce the realistic application of CPGs.
Conflicting high-quality guidelines	Acknowledge the existence of conflicting guidelines, discuss with the patient, and document rationale for decisions. Obtain expert opinion from colleagues or consultants to resolve the decision conflict for the individual patient.

nurses, physicians, clerical staff, case managers, and allied health providers. Implementation strategies must identify and target all active users of the CPG. A number of steps must be accomplished for successful implementation of guidelines for the individual patient. These steps are outlined in Table 88.5.

First, the practitioner must be aware of the existence of the CPG and must have ready access to it. The applicable recommendations of the guideline should fit within the time constraints of an efficient clinical encounter. The IOM report states that CPG characteristics that promote use include “clarity, specificity, strength of the evidence, perceived importance, relevance to practice, and simplicity” (Institute of Medicine [U.S.] & Graham, 2011). Many patients have multiple complex and interrelated medical conditions that make the application of disease-focused CPGs challenging. Guidelines that provide concise summaries of recommendations and key messages are more likely to be used.

In addition, translation of guidelines to electronic decision-support systems may help clinicians employ recommendations in real time and may be helpful for applying multiple guidelines in the management of complex patients. For example, physician order entry for radiological studies may incorporate CPG recommendations within the order set, in order to improve the value of testing.

As mentioned above, clinicians must first be aware of relevant guidelines in order to implement the contained recommendations. There are several potential ways to inform clinicians about the existence, importance, and relevance of CPGs. Traditionally, clinicians learned about advances in medical care through educational materials or journals, but the impact of printed materials has been limited at best (Farmer, Legare, et al., 2008). Didactic lectures and workshops given as part of formal continuing medical education (CME) courses have small effects on clinician practice and have particularly limited effect in promoting complex practice changes (Forsetlund, Bjorndal, et al., 2009). Mass-communication techniques (web-based, television, radio, newspapers, pamphlets, posters) influence practitioner behavior, although

there is little evidence to determine their degree of influence and little to determine the most effective means of mass communication.

The IOM report and a number of individual studies indicate that local opinion leaders are effective in influencing the practice of healthcare providers and therefore may be effective in implementation of CPGs (Institute of Medicine [U.S.] & Graham 2011). The opinion leader should combine the respect of his or her colleagues in the community with effective communication skills. Dissemination of trustworthy CPGs through local opinion leaders, while potentially very effective, also carries the risk of introducing the individual biases and distortions of an individual physician, thereby lessening the power of CPGs for driving care consistency across broad care systems.

A related approach is termed “academic detailing,” in which a knowledgeable person, who is usually a clinician with expertise in the area of concern, provides interactive face-to-face education for individual clinicians. In a fashion similar to that employed by pharmaceutical houses, the detail person visits target practitioners in order to explore their problems and potential local solutions, to discuss practitioner questions and concerns, and to provide written information on the CPG that may help in its acceptance and implementation. Although costly, academic detailing appears to consistently promote improvement in clinical practice and, by implication, would promote adherence to guidelines (O’Brien, Rogers, et al., 2007).

Audit and feedback (a continuous process in which performance is measured, data are collected in focused reports, and findings are discussed with practitioners) may promote practitioner adoption of CPG recommendations. Audit and feedback may incorporate either external or internal systematic and critical analysis of the quality of medical care. It may focus on the process of care, but more importantly should focus on patient outcomes. Direct discussion of audit results with practitioners appears to be a critical component of successful audit and feedback (Institute of Medicine [U.S.] &

Table 88.5 STEPS AND METHODS IN IMPLEMENTATION OF PRACTICE GUIDELINES

STEP	BARRIERS	IMPLEMENTATION STRATEGIES
Awareness of guideline	Overwhelming amount of medical literature	Traditional continuing medical education (CME) Print or online announcement of guideline Mass media dissemination to increase patient awareness in addition to practitioner awareness
Familiarity with guideline	Large, unwieldy documents Information overload in general	CME that focuses on specific recommendations from the guideline Executive summaries of guidelines
Agreement with guideline	Competing guidelines Advancing evidence Perception that guideline does not apply to "real-world patients"	Opinion leaders Broad representation in guideline development Specialty society endorsement of the guideline
Self-efficacy of guideline end user	Practitioner skills in need of updating Infrastructure to support implementation of guideline	CME focusing on skills development, interactive learning Audit and feedback of individual performance Electronic decision support
Expectation of positive outcomes	Skepticism about interventions Previous negative experience with guidelines	Audit and feedback of practice-wide performance Benchmarking for outcomes Citation of previous published success at improving outcomes through implementation of guidelines
Overcome practice inertia	Resistance to change	Motivational strategies that include audit and feedback Opinion leaders
Insure appropriate organizational support	Poor staff support for the guideline Poor reimbursement for guideline adherence Lack of electronic support systems, including reminder system	Institutional buy-in and strong leadership

Adapted from Cabana, Rushton, et al. (2002).

Graham, 2011). Audit and feedback may be perceived as punitive by the receiving practitioner unless it is actionable and clearly focused on improvement. For audit and feedback to be effective, practitioners must perceive that the performance data are important, derived from a valid data source, and provided in a timely manner. Benchmarking, physician leadership, and sustained feedback over an extended time period improve the impact of audit and feedback. Individualized feedback may be more effective than broader group feedback, provided this is not seen as punitive.

The practice environment plays a major role in determining whether or not CPGs are implemented. Large healthcare organizations that include well-differentiated departments and decentralized decision-making seem better able to incorporate new innovations such as CPGs than are individual practitioners.

Tailored interventions incorporate needs-assessment for practitioners and organizations and then employ various implementation strategies to address identified needs or barriers. Naturally, this would generally lead to a multifaceted approach that includes two or more interventions targeting specific needs. For example, a practice that is challenged by

clinical inertia might employ opinion leaders to influence the organization, along with motivational strategies based on audit and feedback.

The literature suggests that individual implementation methods meet with varying degrees of success, depending on the characteristics of the practice, the prevailing practice environment, and the needs of patients and practitioners. Medical psychiatrists may detect deviations from CPGs by other practitioners when their patients present with distress from adverse clinical or financial outcomes.

ELECTRONIC INTERVENTIONS

Electronic health records offer the opportunity to integrate CPGs through the use of clinical decision support. The IOM report on clinical practice guidelines recommends that "guideline developers should structure the format, vocabulary, and content of CPCs to facilitate ready implementation of computer-aided clinical decision support" (Institute of Medicine [U.S.] & Graham, 2011). This should enable practitioners to provide more personalized, guideline-based care in

a timely fashion. Ideally, clinical decision support embedded within the electronic health record would obviate the need for intensive implementation programs discussed in the previous section. A recent study of the clinical decision-support system within a large integrated healthcare network found that four functional categories encompass the interaction between a clinical decision-support system and the clinical system itself: triggers, input data, interventions, and offered choices (Wright, Goldberg, et al., 2007). These functional categories are elaborated on in Table 88.6.

Unfortunately, the data necessary to allow clinical decision-support tools to consistently provide guideline-based recommendations are often lacking, or the systems may be unable to handle complex patient situations. Clinical decision-support tools may be aggravating for clinicians to use if they interrupt work flow or are simply unhelpful. For example, a report of a computerized physician order entry–based decision-support tool for evaluation of patients with possible pulmonary embolism found that the tool increased the yield of computed tomography (CT) angiography, but the physicians found the tool so cumbersome that they asked that it be removed from the system (Drescher, Chandrika, et al., 2011).

While computerized clinical decision support may ultimately offer reliable point-of-care application of recommendations from clinical practice guidelines, there are still many obstacles to overcome. In fact, some have argued that the volume of routine documentation required to comply with billing regulations limits the ability of electronic health records to provide decision support (Berenson, Basch, et al., 2011).

PERFORMANCE MEASUREMENT

Performance measurement is presumed necessary to improve quality of care and for meaningful implementation of CPGs. Quality of care has been defined as “the degree to which

health care services for individuals and populations increase the likelihood of desired health outcomes and are consistent with current professional knowledge” (Institute of Medicine [U.S.], Lohr, et al., 1990). Clinical performance measurement, a subtype of quality measurement, assesses the degree to which a provider competently and safely delivers clinical services appropriate for the patient in the optimal time period. Such a measurement may include patient access, outcome of care, patient experience, process of care, or structure of the care unit. Clinical performance measurement has several purposes, including identifying poorly performing physicians, guiding professional development to help all physicians improve, and facilitating external validation for healthcare stakeholders (Scott, Phelps, et al., 2010). Performance measurement may be done at the practitioner level, at the hospital level, at the integrated healthcare systems level (e.g., Partners HealthCare in Massachusetts, Geisinger Health Systems in Pennsylvania), or at the geographic delivery area level. Physician clinical performance assessment is defined as “the quantitative assessment of physician performance based on the rates at which their patients experience certain outcomes of care and/or the rates at which physicians adhere to evidence-based processes of care during their actual practice of medicine” (Landon, Normand, et al., 2003).

Many performance measures have been proposed for many medical and surgical problems. The Agency for Healthcare Quality and Research (AHRQ) maintains an online, fully searchable database of quality measures accessible through the AHRQ website (www.ahrq.gov). The National Quality Forum (NQF; www.qualityforum.org) also provides an extensive database of quality measures.

Physicians have expressed concern about the validity and reliability of performance measures. This is particularly of concern at the individual physician level, where the number of patients with a condition considered for measurement may not be sufficient to produce reliable performance scores (Fung,

Table 88.6 FUNCTIONAL CATEGORIES IN CLINICAL DECISION SUPPORT

CATEGORY	DESCRIPTION	EXAMPLES
Triggers	Events in the clinical system that cause a decision-support rule to be invoked	Prescription of a drug Ordering a laboratory or radiological test Entering a new problem on the patient problem list
Input data	Data elements used by a rule to make inferences	Laboratory results Patient demographics Patient problem list
Interventions	Possible actions that the clinical decision support module can take	Send a message to the clinician Display a guideline or the relevant portion of the guideline Log that an event occurred
Offered choices	Provides the user with appropriate choices based on the clinical information and the clinical decision support algorithm	Allow clinician to cancel a medication order if patient allergies are detected in the clinical data Provide the clinician with alternative medications and ask for a choice

Adapted from Wright, Goldberg, et al. (2007).

Schmittiel, et al., 2010). A study of primary care physicians, for example, found that relatively few primary practices include enough patients with specified conditions to allow reliable measurement of 10% relative differences in quality measures among fee-for-service Medicare patients (Nyweide, Weeks, et al., 2009). None of the practices in this study had caseloads that would allow reliable detection of 10% relative differences in preventable hospitalization or 30-day readmission after discharge for congestive heart failure. Additionally, the quality of data in electronic health records may not be robust enough to allow valid performance measurement (Pronovost & Lilford, 2011). Performance measurements of clinical care capture only a small percentage of overall patient care and may ignore the clinical judgement required to care for complex patients (Scott, Phelps, et al., 2010).

The Agency for Healthcare Research and Quality (AHRQ) recommends five questions to decide the validity of performance measurements:

1. How strong is the scientific evidence supporting the validity of this measure as a quality measure?
2. Are all individuals in the denominator (patients with the condition of interest) equally eligible for inclusion in the numerator (patients who experience the process or outcome)?
3. Is the measure result under the control of those whom the measure evaluates?
4. How well do the measure specifications capture the event that is the subject of the measure?
5. Does the measure provide for fair comparisons of the performance of providers, facilities, health plans, or geographic areas?

The final question above implies risk-adjustment for case severity and complexity, but the methodologies for risk-adjustment generate substantial controversy, potentially undermining the trust of practicing physicians and medical organizations. Pronovost and Lilford (2011) made five recommendations intended to improve performance or quality measurement, as follows:

1. *Ensure validity and transparency.* Measurement algorithms and risk adjustment formulas, which to date have often been proprietary and somewhat secretive, should be transparent and open to scrutiny. Measures should have “face validity,” meaning that the measure appears to measure what it says it will measure. Measures should also demonstrate “criterion validity,” meaning that they are related to real-world experience; and they should demonstrate “convergence validity,” in that separate measures for a disease process would be highly correlated across a patient panel.
2. *Develop standard surveillance.* Systems should enable consistent and reproducible identification of events and of those at risk for events. The effort to identify these

numbers should be equivalent across institutions or practices. This is a critical issue, as (for example) a study focused on breast cancer screening in community health centers pointed out by demonstrating marked variation in screening rates, depending on the definition of eligible patients (Landon, O'Malley, et al., 2010).

3. *Evaluate performance change over time.* This recommendation requires sophisticated statistical expertise to risk-adjust for disparities among populations of patients.
4. *Build tools to prioritize measures.* These tools should take into account the concerns of the public and of healthcare stakeholders, the magnitude of problems, and the views of clinicians regarding available measures.
5. *Create an independent agency.* The agency would encourage the development and dissemination of measures and the collection of data independent of hospitals.

Specific to quality measures for processes of care, Chassin et al. argued for four criteria to be met in order to apply these measures on a broad scale (Chassin, Loeb, et al., 2010). First, and as emphasized above, there must be a strong evidence base showing that the care process leads to improved outcomes. Measures that lead to improved rates of “checking the right boxes” but that have no discernible benefit in patient outcomes or patient sense of well-being are to be avoided. A large quality-improvement study at community health centers demonstrated improvement in *processes* of care (e.g., use of asthma management plan, assessment of smoking status, assessment of hemoglobin A1C for diabetics, checking lipid profile in hypertensives), but it failed to demonstrate improvement in intermediate clinical *outcomes* (e.g., urgent care or hospitalization for asthma, control of hemoglobin A1C in diabetics) (Landon, Hicks, et al., 2007). In this study, it seemed apparent that simply “checking the box” that the patient had been given a management plan for their asthma did not affect the disease process itself and did not affect triggers for asthma exacerbations.

Second, the performance measure must accurately capture the actual delivery of evidence-based care (Chassin, Loeb, et al., 2010). For example, a quality measure of discharge teaching might be fulfilled by simply documenting that discharge teaching for heart failure self-management has been done when the “discharge teaching” consists solely of a printed handout’s being given to the patient. This is far less effective than intensive instruction (Phillips, Wright, et al., 2004).

Third, the process measure should address a process that is close in time to the desired outcome, and there should be a limited number of intervening processes between the measured process and the outcome (Chassin, Loeb, et al., 2010). This criterion should be applied more strictly in the hospital setting because of the time course of acute illness, while in ambulatory settings the care process may well be further removed from the desired outcome (e.g., mammography and reduction in breast cancer mortality).

Fourth, and of great importance, the process measure should not lead to unintended adverse consequences (Chassin,

Loeb, et al., 2010). A classic example of this problem has been the quality measure aimed at the timely administration of antibiotics for community-acquired pneumonia, which led to many patients without pneumonia being treated with antibiotics (Houck, Bratzler, et al., 2004; Kanwar, Brar, et al., 2007). The pressure to beat a deadline on administration of antibiotics caused physicians to prescribe antibiotics based on inadequate evaluations, such as clinical presentation with productive cough only to determine later that there was no radiological evidence of pneumonia. Use of beta-blockers for perioperative cardiac risk reduction provides another example of a process measure leading to unintended adverse events (Auerbach & Goldman, 2002; Lindenauer, Pekow, et al., 2005). In this situation, early, small randomized trials suggested a reduction in cardiac adverse events among patients given beta-blockers, but subsequently, a large cohort study and large randomized trials failed to show benefit (Lindenauer, Pekow, et al., 2005; Devereaux, Yang, et al., 2008). In this situation, the process measure was adopted by many hospitals before there was truly sufficient clinical evidence to back it. The unintended consequences of performance measures cannot be reliably predicted and require continuous updating from accumulating evidence and updated CPGs.

The American College of Cardiology Foundation, American Heart Association, American Medical Association (ACCF/AHA/AMA) performance measurement set for patients with coronary artery disease (Drozda, Messer, et al., 2011) is provided in Table 88.7 as an example of the types of measures that might be monitored for a physician caring for patients with a single disorder, or for a system caring for a population of patients with a disorder. Multiple CPGs support this set of performance measurements (Chobanian, Bakris, et al.,

2003; Gibbons, Abrams, et al., 2003; Eagle, Guyton, et al., 2004; Anderson, Adams, et al., 2007; Mosca, Banka, et al., 2007; Antman, Hand, et al., 2008; Douglas, Khandheria, et al., 2008). Although some of the measures require chart-review to collect the data (e.g., symptom and activity assessment, symptom management, cardiac rehabilitation), most of the measures could be produced by combining data from pharmacy and diagnosis databases. Although small practices are challenged in measuring these parameters across the practice (Landon & Normand, 2008), increasing adoption of electronic health records holds promise that such performance measure sets can be produced efficiently and consistently.

Employing performance measures in a rigid and non-critical fashion threatens to undermine the health of the substantial minority of patients who would benefit from creative and innovative care. It seems very likely that the majority of patients, who have relatively straightforward problems and concerns, will benefit from greater consistency in the delivery of care. An unintended systems consequence may be the dampening of innovation among specialists and tertiary care centers as these providers strive to meet performance targets even though the complexity of their patients demands deviation from regimented care. In fact, tertiary centers and their consulting physicians should be caring for atypical and complex patients to justify the high cost of care in these centers.

INCENTIVES

In an attempt to overcome resistance to practice changes recommended in clinical practice guidelines, insurers,

Table 88.7 ACCF/AHA/AMA PERFORMANCE MEASURES FOR CORONARY ARTERY DISEASE

MEASURE	DESCRIPTION	TYPE OF MEASURE
Blood pressure (BP) control	% patients who have BP in target range <140/90 or have BP >140/90 but were prescribed two or more antihypertensives	Treatment outcome
Lipid control	% patients who have LDL cholesterol <100 mg/dL or who have LDL > 100 mg/dL and documented plan of care, including at minimum prescription for a statin	Treatment outcome or process
Symptom and activity assessment	% patients with documentation in the medical record of activity level or presence or absence of angina	Patient-centered outcome, process measure
Symptom management	% patients with evaluation of level of activity AND evaluation of anginal symptoms with documented and appropriate plan of care	Patient-centered outcome
Tobacco-use screening and intervention	% patients screened for tobacco AND received counseling if using tobacco	Process
Antiplatelet therapy	% patients prescribed aspirin or clopidogrel	Treatment
Beta-blocker therapy	% patients with prior myocardial infarction or left ventricular ejection fraction (LVEF) < 40% who are prescribed a beta-blocker	Treatment
Angiotensin converting enzyme (ACE) inhibitor/ Angiotensin receptor blocker (ARB) therapy	% patients with diabetes or LVEF <40% who are prescribed an ACE inhibitor or ARB	Treatment
Cardiac rehabilitation	% cardiac patients (broadly defined) who were referred to a cardiac rehabilitation program	Treatment, process

governmental payors, and healthcare systems employ physician or practitioner incentives. These incentives are generally financial and include so-called pay-for-performance (P4P). The incentives may take the form of a bonus for achieving target goals in performance measurement or for demonstrating improvement in performance. Bonus programs may dictate competition between providers, resulting in winners and losers (Rosenthal, Fernandopulle, et al., 2004). In competitive programs, an arbitrarily set percentage of providers receives a bonus for performance, or there may be graduated performance bonuses based on relative performance rank. Alternatively, the practitioner or healthcare delivery system may receive a bonus for simply reaching the predetermined performance target. It is thought that the competitive incentive system is more effective in implementing change, although at a cost to morale and self-esteem of the lower performing providers. In a deterrent approach to incentives, the practitioner may be penalized for failure to achieve quality, process, or outcome goals.

Many incentive programs have evolved and have been widely adopted during the past 15 years, despite a remarkably sparse evidence base to support their use. In fact, a systematic review of P4P programs found positive or partially positive effects on measures of quality, but also found unintended adverse outcomes, and found no argument for cost-effectiveness (Petersen, Woodard, et al., 2006).

Pay-for-performance programs may seek to influence care at any of the following levels: individual practitioner, practice group, or hospital. Table 88.8 summarizes advantages and disadvantages at each of these levels.

INDIVIDUAL PRACTITIONER INCENTIVES

Financial incentives for individual physicians seem to be a reasonable approach to improving performance or meeting quality targets. Ideally, these P4P programs would incentivize

quality measures that are well validated by guidelines, can be reliably measured, and are important to patient outcomes. Although there are clearly advantages to focusing P4P on the individual practitioner, challenges include much less precision in measurement given smaller numbers of patients, and the potential burden imposed on a practice by reporting requirements. Additionally, rewarding practitioners for a limited number of quality metrics may result in the unintended consequence of diverting their focus from other important patient problems, or prompting physicians to avoid “high-risk” patients in their practice.

Studies of practitioner-level P4P have shown mixed results. For example, a study of the effect of financial incentives on the outcomes of hypertension management in the United Kingdom found that even generous financial rewards had no effect on processes of care or hypertension-related clinical outcomes (Serumaga, Ross-Degnan, et al., 2011). In contrast, a P4P program aimed at improving care for cardiovascular disease patients in a large health plan in Hawaii found that a program incentivizing individual practitioners with approximately 3.5% of their base professional fees (to a maximum of \$16,000 per year) resulted in improved rates of low-density lipoprotein (LDL)-cholesterol testing and prescription of a statin for this patient group (Chen, Tian, et al., 2011). Although these quality measures seem simple and relatively easy to fulfill, the most impressive finding in this program was that patients who received high-quality care as judged by LDL testing and statin prescription experienced fewer new coronary events and were less likely to be hospitalized.

A P4P program in a large group practice that changed from group-focused to physician-specific incentives for nine process and clinical-outcome measures in primary care showed significant improvements during the year after implementation (Chung, Palaniappan, et al., 2010). The incentive in this program was a relatively modest maximum of \$5,000 per year, but it was not clear that the incentive produced the

Table 88.8 PAY FOR PERFORMANCE (P4P)

LEVEL	ADVANTAGES	DISADVANTAGES
Practitioner	<p>Individual accountability</p> <p>Clearer link of incentive to individual patient care/outcomes</p> <p>Local decision-making, tends to be more “nimble with change”</p>	<p>Potential individual burden for data collection</p> <p>Smaller patient numbers reduces precision of measurement</p> <p>Greater impact of “adverse patient characteristics”</p> <p>Less resources to implement change</p>
Practice group	<p>Increased numbers of patients improve the precision of measurements</p> <p>Greater resources to implement change, but need for consensus</p> <p>Shared burden for data collection</p>	<p>Less individual motivation; temptation for “coasting by individuals”</p> <p>Competing priorities within the group</p>
Hospital	<p>Many more patients to facilitate meaningful measurements</p> <p>More resources and expertise for measurement</p> <p>Administrative support for P4P</p> <p>Adverse patient characteristics more broadly distributed, “averaging” advantage</p>	<p>Greater heterogeneity of patients may make measurements less targeted</p> <p>Slower response to change unless very strong administration</p> <p>Limited individual motivation on the front lines (“What’s in it for me?” phenomenon)</p>

positive results, as two comparator physician groups achieved similar improvements in the same time period without P4P incentives.

A systematic review of P4P studies found that programs aimed at the individual provider level or at the team level tended to report positive results (Van Herck, De Smedt, et al., 2010). Reporting bias may distort the perception of effectiveness of these programs.

PRACTICE GROUP INCENTIVES

A P4P scheme at the practice group level in England focusing on the care of patients with asthma, diabetes, and coronary heart disease found improvement in asthma and diabetes care early in the program (Campbell, Reeves, et al., 2009). However, the improvement in quality of care was not sustained, and continuity of care actually declined during the incentive program.

A systematic review found that medical groups performed better in P4P programs than independent practice associations (Van Herck, De Smedt, et al., 2010). This may reflect better-organized practices that incorporate multidisciplinary approaches, utilize clinical pathways, and deploy greater resources both for quality improvement and for quality measurement.

HOSPITAL-BASED INCENTIVES

A hospital-based P4P program implemented through Massachusetts Medicaid (MassHealth) in 2008 provided incentives to hospitals for quality of care for patients with pneumonia and for prevention of surgery-associated infections (Ryan & Blustein, 2011). The measures for pneumonia care included oxygenation assessment, blood cultures performed before antibiotics, smoking-cessation counseling, initial antibiotic given within six hours of arrival at the hospital, and appropriate antibiotic selection for immunocompetent patients. Measures for surgical infection prevention were prophylactic antibiotic within one hour of surgical incision, appropriate antibiotic selection, and prophylactic antibiotic discontinuation within 24 hours after surgery end time. The financial incentives in 2008 averaged \$40,000 per hospital, with the 75th percentile incentive being \$57,447. The potential payout at the 99th percentile was \$331,000. These incentives were labeled “generous.” A subsequent study of the program found no evidence that it improved quality during the first two years after it began (Ryan & Blustein, 2011). It seems very likely that the incentives, on a hospital level, were insufficient to effect change, and in fact, providing resources to simply manage the data required for the program would cost much more than the average payout.

The Premier Hospital Quality Incentive Demonstration project, sponsored by the Centers for Medicare and Medicaid Services (CMS) and studying the 260 hospitals in the Premier, Inc., hospital system, examined the effect of P4P on quality at these hospitals (Werner, Kolstad, et al., 2011). This program was competitive, with the top 20% of hospitals receiving payouts during the first two years of the program, while hospitals

performing below a threshold had to pay penalties beginning in the program’s third year. This study found that performance in care of acute myocardial infarction, heart failure, and pneumonia improved under P4P during the first three years the program compared to hospitals not participating in the P4P program. However, by the fifth year of the program, the control hospitals caught up in quality measures, leading the study to conclude that the effect of P4P was not sustained. Not surprisingly, the hospitals that were the largest, best financed, eligible for the largest bonuses, and operated in regions with less competition for bonuses fared the best in this program.

OPTIMIZING INCENTIVES

Based on the results of the systematic review of P4P studies, Van Herck et al. recommend the following for incentive programs (Van Herck, De Smedt, et al., 2010):

1. Targets for P4P programs should be those for which there is room for improvement. This should lessen the impact of a ceiling effect in which high-performing practitioners or systems have no real room for improvement.
2. Target measures should use process and clinical outcome measures. Although outcome measures are preferred for reasons previously discussed, these require adequate risk adjustment.
3. Involvement of stakeholders in development, implementation, and evaluation of the P4P program is key to full engagement.
4. If multiple payors are funding similar P4P programs, design should be uniform across the programs.
5. The P4P program should focus on quality improvement and achievement. This recommendation addresses the issue of achieving a performance threshold that tends to be motivating for high-performing providers, while recognizing that low-performing providers may have difficulty meeting a high threshold, but may be motivated by improvement goals.
6. The P4P program should distribute incentives at the individual level or at the team level, as this appears to be more effective than institutional incentives.
7. The P4P should be refocused once goals are achieved, although it is important to continue to monitor old targets.
8. Incentive size needs to be sufficient to motivate active participation and improvement. Unfortunately, the studies of this issue are conflicting, and there is not yet good guidance on the “dose–response” relationship for P4P.
9. Quality improvement requires adequate infrastructure support and education on quality-improvement tools. Evidence is conflicting on whether or not this is adequate to effect improvement without the addition of P4P.

In summary, incentives or “pay-for-performance” programs may have the potential to speed implementation of clinical practice guidelines, but the evidence for their impact and cost-effectiveness is somewhat limited and conflicting. Petersen et al. (2006) posed a series of research questions regarding financial incentives in health care, which are included in Table 88.9. Although the literature is growing, these questions need further consideration.

PRACTICAL APPLICATION OF GUIDELINES

How does the internist actually use guidelines? Obviously, there is no way to refer to a guideline for every active problem for each patient during every patient encounter. In general, internists use guidelines to answer discrete management questions. For example, a patient with an upper-extremity (UE) deep venous thrombosis (DVT) in association with a percutaneously inserted central catheter (PICC) presents management issues. Should the patient be anticoagulated? For how long? Should the catheter be removed?

An early 2012 PubMed search using the search term “Upper extremity deep venous thrombosis” and the limits *Practice guideline, English language, published within five years*, yields a single citation: *Antithrombotic therapy for venous thromboembolic disease: American College of Chest Physicians evidence-based clinical practice guidelines* (8th edition) (Kearon, Kahn, et al., 2008). This guideline fulfills the criteria for a trustworthy CPG. The relevant recommendations for one particular patient appear as follows in the guideline:

8.1. INTRAVENOUS UNFRACTIONATED HEPARIN (UFH) OR SUBCUTANEOUS LOW MOLECULAR WEIGHT HEPARIN (LMWH) FOR THE INITIAL TREATMENT OF UPPER-EXTREMITY DVT

8.1.1. For patients with acute upper-extremity DVT (UEDVT), we recommend initial treatment with therapeutic doses of LMWH, UFH, or fondaparinux as described for leg DVT [Grade 1C].

8.4 ANTICOAGULANTS FOR THE LONGTERM TREATMENT OF UEDVT

8.4.1. For patients with acute UEDVT we recommend treatment with a Vitamin K Antagonist (VKA) for ≥ 3 months (Grade 1C).

Remark: A similar process as for lower-extremity DVT should be used to determine the optimal duration of anti-coagulation.

8.4.2. For most patients with UEDVT in association with an indwelling central venous catheter, we suggest that the catheter not be removed if it is functional and there is an ongoing need for the catheter (Grade 2C).

8.4.3. For patients who have UEDVT in association with an indwelling central venous catheter that is removed, we do not recommend that the duration of long-term anticoagulant treatment be shortened to < 3 months (Grade 2C).

The answers for the clinical questions for this patient are clear. The patient should be anticoagulated with low-molecular-weight heparin followed by warfarin. Anticoagulation with warfarin should be continued for at least three months. The catheter does not need to be removed.

For many situations, recommendations are less definitive, and even with definitive recommendations, there may be

Adapted from Petersen, Woodard, et al. (2006).

coexisting medical issues, psychosocial issues, financial considerations, and patient preferences may require tailoring the recommendations for the individual patient. Ideally, reasons for deviations from evidence-based recommendations should be carefully documented.

Patients may present their physicians with CPGs gleaned from electronic searches. In fact, some professional societies provide patient-oriented distillations of CPGs for particular problems. For example, the American Society of Clinical Oncology (ASCO) provides a series, *What to Know: ASCO's Guideline on...*, for a number of topics of interest to patients. The physician should welcome open discussion of guidelines discovered by patients, but should also address issues of their validity with patients, as well as discussing the utility of particular guidelines for the patient's individual circumstance.

If the simple patient scenario were expanded to include a recent history of life-threatening gastrointestinal hemorrhage of obscure origin despite extensive evaluation, the recommendations from the guideline may no longer apply. Clearly, physician judgement would supersede rote application of the guideline in this circumstance.

Performance measurement evaluating a physician group's management of UEDVT points out inherent challenges. The majority of patients would benefit from anticoagulation for UEDVT, as recommended by the guideline. However, patients at risk for hemorrhage might incur greater risk with anticoagulation. The physician then faces a dilemma of whether or not to push for anticoagulation, thereby improving her performance score, particularly if the performance measure focuses solely on whether or not anticoagulation was administered, not on the patient's outcome. Additionally, performance measurement may focus the physician's attention more intently on the measured aspect of care to the exclusion of other equally important clinical issues.

If we increase the complexity of the scenario, further limitations for CPGs and performance measurement emerge. Suppose that the patient has a patent foramen ovale (PFO), placing them at risk for systemic emboli and stroke from the evolving upper extremity deep venous thrombosis. Suppose also that the thrombosis is extensive and has resulted in marked swelling of the upper extremity. There are no guidelines for this situation. Management would require careful consideration by experienced clinicians and multidisciplinary consultants. Guidelines, no matter how nuanced and evidence-based, will never supplant the judgement of physicians in managing complex medical, surgical, and psychiatric problems. CPGs should be considered a starting point for management, not the final "cookbook" solution for problems.

SUMMARY

Trustworthy clinical practice guidelines should distill burgeoning clinical research into valid recommendations that can be implemented by practitioners in the care of individual patients. This chapter provided a framework for assessing

the trustworthiness of CPGs. Effectively translating CPG recommendations requires performance measurement. Numerous metrics, many derived directly from CPGs, have been proposed, but they require substantial commitment and resources for useful measurement. Financial incentives may facilitate more rapid and effective implementation of CPGs, but they depend on valid performance measurement. While CPGs may facilitate more efficient and appropriate care of patients, they should never supplant the clinical judgement of a careful, thoughtful physician.

CLINICAL PEARLS

- Clinical practice guidelines (CPG) provide the underpinnings for performance measurements that have become commonplace for hospitals, practice groups, and individual practitioners.
- The IOM definition of CPGs is: "Clinical practice guidelines are statements that include recommendations intended to optimize patient care that are informed by a systematic review of evidence and an assessment of the benefits and harms of alternative care options."
- The medical psychiatrist can play a pivotal role in helping to identify patients who would benefit from less reliance on CPGs, while carefully documenting the rationale in order to avoid negative performance measurement.
- Sound clinical judgement should never be supplanted by a CPG.
- Medical psychiatrists may detect deviations from CPGs by other practitioners when their patients present with distress from adverse clinical or financial outcomes.
- Employing performance measures in a rigid and non-critical fashion threatens to undermine the health of the substantial minority of patients who would benefit from creative and innovative care.
- Ideally, reasons for deviations from evidence-based recommendations should be carefully documented.
- Measures that lead to improved rates of "checking the right boxes" but have no discernable benefit in patient outcomes or patient sense of well-being are to be avoided.
- The physician should welcome open discussion of guidelines discovered by patients, but should also address issues of validity with patients as well as discussing the utility of particular guidelines for the patient's individual circumstance.
- The unintended consequences of performance measures cannot be reliably predicted and require continuous updating from accumulating evidence and updated CPGs.
