This material is not intended to be, and should not be considered, a substitute for medical or other professional advice. Treatment for the conditions described in this material is highly dependent on the individual circumstances. And, while this material is designed to offer accurate information with respect to the subject matter covered and to be current as of the time it was written, research and knowledge about medical and health issues is constantly evolving and dose schedules for medications are being revised continually, with new side effects recognized and accounted for regularly. Readers must therefore always check the product information and clinical procedures with the most up-to-date published product information and data sheets provided by the manufacturers and the most recent codes of conduct and safety regulation. The publisher and the authors make no representations or warranties to readers, express or implied, as to the accuracy or completeness of this material. Without limiting the foregoing, the publisher and the authors make no representations or warranties as to the accuracy or efficacy of the drug dosages mentioned in the material. The authors and the publisher do not accept, and expressly disclaim, any responsibility for any liability, loss or risk that may be claimed or incurred as a consequence of the use and/or application of any of the contents of this material.

the new generation just walking.*

CONTENTS

Preface

Acknowledgments

Contributors

PART I

DIAGNOSTIC METHODS

1. Principles of Medical Psychiatry
Donna B. Greenberg and Barry S. Fogel
2. Physical and Neurological Examination
Barry S. Fogel
3. Neuropsychological Assessment
Aaron P. Nelson and Stephanie Assuras
4. Rating Scales and Screening Tests
Barry S. Fogel
5. Laboratory Tests
Kimberly Stoner
6. Laboratory Evaluation of Endocrine Disorders in Patients with Neuropsychiatric Symptoms
Fernando A. Rivera, Shirlene Sampson, and Christopher L. Sola
7. Neuroimaging in Psychiatry:
The Clinical–Radiographic Correlate
David L. Perez, Laura Ortiz-Terán, and David A. Silbersweig
8. Clinical Neurophysiology in Medical Psychiatry
Rani A. Sarkis and Shahram Khoshbin
9. Neuropsychiatry of Primary Sleep Disorders
Amit Chopra and Jarrett W. Richardson

PART II

THERAPEUTIC MODALITIES

10. Psychotherapeutic Principles and Techniques:
Principles of Medical Psychotherapy
Stephen A. Green
11. Family Therapy in Chronic Medical Illness
Gabor I. Keitner

12. Parent Guidance for Medically Ill Parents
Vaughn L. Mankey and Cynthia W. Moore
13. Group Psychotherapy for Medically Ill Populations
Cheryl Gore-Felton and David Spiegel
14. Cognitive Behavioral Therapies
Lara N. Traeger and Joseph A. Greer
15. Nonadherence to Treatment
Joseph A. Greer, Paul J. Helmuth, Jeffrey S. Gonzalez, and Steven A. Safren
16. Hypnosis in Psychosomatic Medicine
José R. Maldonado
17. Mind–Body Medicine
Gregory L. Fricchione
18. Spiritual and Religious Issues in Medical Illness
Gregory L. Fricchione and John R. Peteet
19. Technology in Treatment and Physician–Patient Communication
Steven E. Locke and Tristan Gorrindo
20. Psychiatry and Physical Medicine and Rehabilitation
Nasser Karamouz, Richard T. Goldberg, Lucienne A. Cahen, and Seth D. Herman

PART III

PHARMACOLOGIC AND OTHER SOMATIC TREATMENTS

21. Psychopharmacology in the Medical Patient
Thomas Markham Brown, Alan Stoudemire, Barry S. Fogel, and Michael G. Moran
22. Pharmacokinetics of Psychotropic Drugs in the Context of General Medical Illness
Cynthia A. Gutierrez and Barry S. Fogel
23. Medically Significant Side Effects of Psychotropic Drugs
Thomas Markham Brown
24. Neurostimulation: ECT, VNS, rTMS, and DBS
Lawrence Park
25. Acute Pain Management and Psychopharmacology in the Medically Ill
Robert J. Boland, Monique V. Yohanan, and Richard J. Goldberg

26. Pharmacologic and Other Somatic Treatments of Nausea and Vomiting <i>Danielle N. Ko and Eva H. Chittenden</i>	526
27. Pharmacologic and Other Somatic Treatments of Dyspnea <i>Pedro E. Pérez-Cruz and Eva H. Chittenden</i>	536
28. Therapeutic Nutrients, Herbs, and Hormones <i>Patricia L. Gerbarg and Richard P. Brown</i>	545

PART IV

MAJOR SYMPTOMS AND SYNDROMES

29. Grief, Complicated Grief, and Bereavement-Related Depression <i>Alana Iglewicz and Sidney Zisook</i>	611
30. Acute and Chronic Reactions to Trauma <i>T. H. Eric Bui, M. Alexandra Kredlow, Meredith E. Charney, Mary C. Zeng, and Naomi M. Simon</i>	620
31. Anxiety in the Medically Ill <i>Richard J. Goldberg and Donna B. Greenberg</i>	635
32. Eating Disorders <i>Megan Moore Brennan, Caitlin M. Nevins, and Jennifer J. Thomas</i>	656
33. Primary Sleep Disorders in Medical and Neurological Patients <i>Amit Chopra and Jarrett W. Richardson</i>	678
34. Medical and Psychiatric Aspects of Chronic Fatigue Syndromes and Apathy <i>Linda L. M. Worley and Donna B. Greenberg</i>	691
35. Sexual Dysfunction <i>Barry S. Fogel and Donna B. Greenberg</i>	708
36. Chronic Pain <i>David Borsook</i>	731
37. Excessive Illness Behavior <i>James C. Hamilton, Krystal A. Hedge, and Marc D. Feldman</i>	743
38. Treatment of Addictions and Related Disorders <i>Robert Swift</i>	756
39. Evaluating and Managing Suicide Risk and Violence Risk in the Medical Setting <i>Phillip M. Kleespies, Douglas H. Hughes, Sarah R. Weintraub, and Ashley S. Hart</i>	781
40. Personality Disorders in the Medical Setting <i>Barry S. Fogel</i>	801

PART V

NEUROPSYCHIATRIC DISORDERS

41. Delirium: Neurobiology, Characteristics, and Management <i>José R. Maldonado</i>	823
42. Dementia: Diagnosis and Treatment <i>Scott McGinnis</i>	908
43. Epilepsy and Seizures <i>W. Curt LaFrance, Jr. and Andres M. Kanner</i>	935
44. Diagnosis and Treatment of Headache <i>Elizabeth W. Loder</i>	963
45. Traumatic Brain Injury: Evaluation and Management for the Psychiatric Physician <i>Gregory J. O'Shanick, George T. Moses, and Nils R. Varney</i>	984
46. Frontal Systems and Dysfunctions <i>Kimiko Domoto-Reilly, Paul Malloy, Deborah A. Cahn-Weiner, and Thomas Markham Brown</i>	999
47. Movement Disorders <i>Shreya Raj and Jeremiah M. Scharf</i>	1007
48. Neuropsychiatric Aspects of Focal Neurological Disease: Cerebrovascular Disease and Multiple Sclerosis <i>Ruchi Aggarwal and Mario F. Mendez</i>	1019
49. Brain Tumors <i>Donna B. Greenberg</i>	1034
50. Attention-Deficit Hyperactivity Disorder in Medical Illness <i>Anna M. Georgiopoulos and Craig B. H. Surman</i>	1045

PREFACE

This third edition of *Psychiatric Care of the Medical Patient* reflects changes in medicine, psychiatry, and the healthcare system over the two decades since the first edition was published. Medical psychiatry—the medical subspecialty that applies psychiatric knowledge and skills to the problems of patients with general medical problems—is continually evolving. What remains constant is the primacy of the sacred relationship between the patient and the physician, and the psychiatrist's knowledge and experience of medicine as a basis of that relationship.

Medical psychiatrists like general psychiatrists have expertise in the diagnosis and treatment of primary mental disorders, appreciating the relevance to health of patients' developmental histories, family relationships, and social and occupational environments, and understanding how the physician–patient relationship can be an aid or an impediment to a favorable outcome of medical care. In addition, medical psychiatrists have detailed knowledge of one or more specific general medical or surgical specialties, as well as familiarity with aspects of neurology, endocrinology, and clinical pharmacology that are particularly relevant to the interaction of mental disorders with general medical conditions and their respective treatments. In addition medical psychiatrists are highly aware of healthcare system issues and relationships among different physicians, specialties, and disciplines.

These differences can be seen as a matter of degree, as all good general psychiatrists should have some of the knowledge and skills we attribute to medical psychiatrists. General psychiatrists can become medical psychiatrists, beginning by focusing their practices on patient populations with general medical issues. Even so, there really is a qualitative difference in the attitudes and professional identity of medical psychiatrists. Medical psychiatrists view themselves as physicians above all, not as mental health professionals with medical training. Their aims are not limited to diagnosing and managing primary mental disorders or differentiating between “functional” and “organic” etiologies for symptoms. When they evaluate patients they aim to understand patients' adaptations to their existential predicaments, which include whatever diseases afflict them or threaten them, be those categorized as “mental” or otherwise. This understanding often is accompanied by the psychiatrist's empathy and the patient's trust. Along these lines, a motivated physician who is not a psychiatrist but who is psychologically minded and emotionally intelligent can effectively function as a medical psychiatrist for many of his or her own patients with the aid of ongoing consultation and mentorship from a psychiatrist.

The patient who sees a medical psychiatrist might begin the relationship with tentativeness, skepticism, or ambivalence. Ideally these feelings give way to trust and confidence. Highly specific knowledge of the medical issues the patient faces can be an important factor in bringing about the change. It can be transformative when a patient senses—or concludes—that the medical psychiatrist can grasp without excessive explanation the details of the patient's symptoms and functional impairments, drug side effects, burdens in adhering to treatment, difficult treatment-related decisions, and more.

We believe there are many patients who need what medical psychiatrists can offer and who don't get it, usually because the need isn't recognized and sometimes because resources don't permit it. The need is greater than ever because of specific changes and trends in medicine and the healthcare system. We offer an illustrative and far from exhaustive list:

1. People are living longer and accumulating more chronic diseases and impairments. These conditions make increasing demands for adaptation at the same time as patients' physical and/or mental capacity to adapt can be diminished by illness.
2. The healthcare system demands more standardization, care according to evidence-based practice guidelines, and rules-based recordkeeping that severely limits discussion of subjective, synthetic, speculative, and holistic perspectives. At the same time we are increasingly recognizing how different patients can be, based on their age and gender, their genetics, their ethnic origins and family environments, their personalities, their social and economic circumstances, their personal preferences, and their particular combination of comorbid conditions. It is a sometimes daunting challenge to respect this diversity and effectively advocate for appropriate individualization of care within the current context.
3. Electronic health records, rapidly becoming the norm, can be an impediment to patient care. When a physician's eyes and attention are focused on a screen, they are not focused on the patient. When records are full of cut-and-pasted routine information, and when medical notes are filled-in templates, auditors can check boxes to ensure that coding rules are followed—but it can be difficult for physicians to see what is distinctive about a patient, to convey important subjective perceptions, and to effectively message their colleagues through the record. Alerts about potential drug–drug and drug–disease

- interactions can be triggered too often—or not often enough—for physicians to depend on them. The time spent dealing with the electronic record may not be offset by the time saved or adverse events averted—with the patient thus losing valuable face time with the physician or the physician losing time for reflection, research, and recreation. (As information technology advances, these issues eventually will be resolved: better voice recognition, better processing of free text and other unstructured data, more intelligent machines, and effective deployment of hypertext will help.)
4. The Internet has had profound—and mixed—effects on patients' health and their adaptation to illness. Patients are better informed but sometimes misinformed by what they find online. Through social media patients can find others with similar problems, but time spent online is time not spent in direct face-to-face interaction. It remains to be seen for whom online social support works as well as the traditional kind.
 5. Hospitalizations are shorter, and people now receive care in community settings who would not have just 20 years ago. Care rendered in a hospital for a serious illness involves many people of different specialties and disciplines, whose efforts often are not optimally coordinated. The team of physicians and other health professionals who get to know a patient in the hospital or emergency room is different from the team caring for the patient outside the hospital. The outpatient team has different resources and a different time frame for action, and it may have different goals and incentives. Communication failures are common—and even with good communication there can be failures of coordination of care.
 6. Patient autonomy has become a dominant principle—usually but not always for the best. Competent patients are expected to give or withhold informed consent for medical procedures and to give advance directives for their care in hypothetical life-or-death circumstances. Despite current pressures to “get advance directives” or “get informed consent” from patients, taking informed consent and advance directives seriously requires much more than getting patients' signatures on long and detailed printed forms. How questions are asked, when they are asked, and who asks them all will affect answers to the questions on those forms.
 7. While physicians have less control over what happens to their patients, they are no less accountable for medical outcomes. Physicians must teach and persuade, suggest and motivate, rather than simply order and prescribe.
 8. Patients' expectations for care are greater because more conditions can be treated. Because of the Internet and direct-to-patient advertising, patients know what is available and may request or even demand particular treatments. At the same time costs are escalating and physicians are pressed to limit the use of expensive treatments.
 9. Consumption of psychotropic drugs—mostly by people who have never received even an evaluation by a psychiatrist—is endemic in the United States. For example, the *point*—not lifetime—prevalence of antidepressant use in a recent Mayo Clinic community survey was 13%, and among women aged 50–64 years the rate was 24%. By the time patients see psychiatrists they usually have experienced one or more psychotropic drugs, or they currently are taking one or more. This alters the presentation of mental disorders to psychiatrists as well as often affects the attitude a patient has when a new psychotropic drug prescription is proposed.
 10. Attention to pain as “the fifth vital sign” has increased, with mixed effects. While fewer patients are suffering from untreated severe pain, the misuse, abuse, and ineffective use of prescription opiates clearly has increased. Pain research has advanced, with better understanding of neuropathic pain, more specific treatment for many painful conditions, greater recognition of unusual pain syndromes, and improved methodology for rehabilitation. All chronic pain is now appreciated as having a neuropathic aspect. Tools for recognition of addiction and new treatment options such as buprenorphine have evolved as well. Dissemination of these advances to date has been uneven, as is typical of medical innovations.
 11. Cognitive impairment disorders have increased in prevalence with the aging of the population, and there is much greater differentiation of the diseases that cause them. The distinctions among dementia syndromes and their underlying neurodegenerative diseases are widely appreciated in the neurological community. Symptomatic treatments are used both for neurodegenerative diseases and for their neuropsychiatric complications such as depression and psychosis. Diagnostic practice, which just a few decades ago was typically the identification of a “chronic organic brain syndrome” and “ruling out a treatable dementia”, has moved toward broader appreciation of distinct neurodegenerative diseases that elicit physicians' intellectual interest.
 12. Some highly prevalent mental disorders including depression, generalized anxiety, and ADHD are less stigmatized than they once were. Nonetheless, many disorders including schizophrenia, borderline personality, and drug dependence continue to carry stigma. An unfortunate consequence is a tendency toward diagnosis of nonstigmatized conditions when the diagnosis of a stigmatized condition, either as an alternative or as comorbidity, would be more accurate and helpful in planning treatment.
 13. Brain imaging has captured the public's imagination with positive effects like broader public support for brain research. There are, however, some prevalent misconceptions. For example, some patients believe that normal brain imaging rules out neurodegenerative disease. In cases of traumatic brain injury, defense lawyers have essentially argued that normal anatomic brain imaging means that an injury will not lead to prolonged disability, while plaintiffs' lawyers have argued that abnormal functional brain imaging means that it will; neither inference is necessarily correct.

14. Complementary and alternative medicine (CAM), including the use of herbal remedies and nutritional supplements, has moved toward the mainstream of practice, but it is not quite there. Many popular treatments have weak evidentiary support, and the use of complementary and alternative treatments can delay access to evidence-based conventional treatments or can interact adversely with them. For specific patients the consideration of evidence-based CAM treatments that are potentially superior to conventional treatments is almost random, depending on the physician's personal knowledge and experience.
15. Perceptions are changing of what is normal function later in life and what losses of function are acceptable. More people than in the past believe that they should continue in their occupations, remain as athletic as they were when they were younger, and have an active sexual life well into their 70s and 80s.
16. There are an ever-increasing number of circumstances where medical situations that once had to be accepted are now potentially changeable, although often with pain, inconvenience, and/or expense. For example, an aging face can be made to look younger with Botox or aesthetic surgery. A postmenopausal woman can conceive and bear a healthy child with the aid of IVF, using donor eggs or her own eggs or embryos frozen at an earlier time. Bionic devices can partially alleviate losses in vision or hearing; prosthetic limbs can be attached to nerves and function more like natural ones.
17. Long-term psychodynamic therapy is not as central to general psychiatric practice as it once was. At the same time, the evidence base supporting psychodynamic concepts of defense mechanisms, attachment styles, and personality organization has increased. Psychodynamic understanding has particular value in helping patients adapt to general medical illnesses, their symptoms and impairments, and the demands of their treatments. Ironically, psychodynamic theory and practice might find broader application in medical psychiatry than in the treatment of primary mental disorders.
18. Organized religion is important to a smaller proportion of the population, but it is essential to the lives of believers. Many people are "spiritual but not religious," and many have deeply felt ethical principles and transpersonal motivations not based on belief in a higher power or transcendent being. Faced with illness-related existential challenges, patients turn to their principles, but without conventional religious affiliations they may not have an obvious source of assistance in applying them. Medical psychiatrists sometimes can help patients discover and utilize their spiritual or religious resources.
19. The population in the United States—and in several other upper-income and middle-income countries—is getting fatter, with steadily increasing rates of overweight and obesity and the syndromes associated with excessive weight, including Type 2 diabetes and obstructive sleep apnea. Medical, surgical, and cognitive-behavioral therapies for obesity have an increasing evidence base, but the majority of people with medically significant overweight and even morbid obesity are not effectively treated.
20. Sleep disturbance, sleep disorders, and sleep deficits are highly prevalent, and their pervasive impact on physical and mental health is increasingly recognized. Even so, sleep does not yet get the attention it deserves, and therapies for sleep disorders that are efficacious in controlled studies are less effective in actual practice. Principles of sleep hygiene are known to the field but not necessarily taught to patients or followed by patients even when they are known. The critical sleep-related questions are changing. Where two decades ago the question might have been, "Could this patient have obstructive sleep apnea?" it might now be, "Is this patient using his CPAP machine, and if not, why not?"
21. Questionnaire-based screening tests and patient-reported outcome measures have become mainstream and in some contexts mandatory.

The editors of this volume have selected chapter authors whom we regard as medical psychiatrists or as key members of medical-psychiatric teams. Many of them have training in neurology, internal medicine, obstetrics and gynecology, or another nonpsychiatric specialty. In our editorial dialogue with them we have asked them questions from our own medical-psychiatric perspective. This perspective, and, implicitly, the attitudes and identity of the medical psychiatrist, are conveyed by the first three sections of this book, which describe the evaluation of medical-psychiatric patients and a comprehensive approach to assessing major symptoms and syndromes.

The potential of healthcare to prolong life and to enhance the quality of life has never been greater. Yet, there often are gaps between the potential of 21st-century medicine, patients' expectations from their healthcare, and the reality of patients' healthcare experiences, clinical outcomes, and health-related quality of life. Medical psychiatrists participate in efforts to identify and close such gaps. In doing so they begin with the legacy of the physician–patient relationship; they draw upon know-how and wisdom developed and articulated by 20th-century psychiatrists, and they apply 21st-century medical knowledge. The editors' hope is that this third edition of *Psychiatric Care of the Medical Patient* will support—and memorialize—this effort.

April 2015

ACKNOWLEDGMENTS

We deeply appreciate the work of our contributing authors, whose chapters reflect the time and care given to this project. In the academic world book chapters may not ‘count’ as much as peer-reviewed journal articles, but in the real world the clinical wisdom found in a good medical textbook can stick in a physician’s mind and durably improve practice.

We acknowledge David D’Addona, our editor at Oxford University Press. He’s the best of the many editors we have worked with in over 30 years of writing for medical publications. David has a great sense of what would make someone want to read—or even buy—a medical textbook when so much information is instantly and freely available online. In addition, no one could do a better job of making a tardy contributor—or editor—feel guilty and understood at the same time.

We remember our late colleague Dr. Alan Stoudemire, a wonderful physician, prolific writer, and tireless proponent of medical psychiatry, who collaborated with us and inspired us from the early 1980s until his death shortly after the second edition of this book was published. We also remember Dr. W. Victor (“Vic”) Vieweg, a cardiologist-psychiatrist who co-wrote our cardiology chapter. Vic was an outstanding teacher and scholar of both psychiatry and cardiology, whom we were honored to have as a contributor to this volume.

BF: Above all I must acknowledge the contribution of my wife, Xiaoling Jiang, PhD. Xiaoling is a trilingual literary

scholar who has lived in China, Japan, and the United States; she has observed the changes of the last two decades in medicine and psychiatry from outside the medical profession and from a global perspective, deconstructing them with her usual acuity. Answering her many questions about the content of the book and my own contributions to it evoked many new insights. She encouraged me to pursue the project and helped me protect the time to complete it. And, she inspires me in general.

I also would like to thank the many fellows and junior faculty in neuropsychiatry and behavioral neurology whom I have mentored over the past 17 years at the Brigham and Women’s Hospital. Several have contributed chapters to this volume; all have contributed to the evolution of my thinking about how neurological, psychiatric, and general medical perspectives can be better integrated. It has given me joy to see them succeed in their scientific and clinical work.

DG: I am indebted to many of my medical and psychiatric colleagues at Massachusetts General Hospital. They set a high standard of clinical reasoning, dedication, and curiosity, and their passion for medicine is infectious! Further inspiration comes from the psychiatrists and psychologists, nationally and internationally, who express their creativity at the bedside of the medically ill, challenging all of us to do better.

PART I

DIAGNOSTIC METHODS

PRINCIPLES OF MEDICAL PSYCHIATRY

Donna B. Greenberg and Barry S. Fogel

INTRODUCTION

Medical psychiatry is a medical specialty concerned with patients' mood, thinking, and behavior in the context of general medical or neurological conditions, surgery, and/or trauma. Medical psychiatrists view the longitudinal course of a medical illness in a full context of genetic, developmental, social, and environmental factors, and as a chapter in a life narrative. It is concerned with patients (1) who have medically unexplained physical symptoms or physical symptoms disproportionate to apparent pathology, (2) who have pain or other distressing symptoms that remain after their underlying medical condition has been treated, (3) who do not adhere to medically prescribed treatment, (4) whose high risk for medical conditions or complications can be reduced by behavioral changes, (5) whose chronic medical conditions have a course that is influenced by emotional factors, or (6) who have primary mental disorders concurrently with general medical conditions, where the treatment of the mental disorder must be modified in consideration of the medical conditions and their treatments or the general medical treatment must be modified in consideration of the mental disorder and its treatment. In all of these situations an integration of the perspectives of psychiatry, behavioral neurology, internal medicine, and health psychology can be useful.

THE CULTURAL ENVIRONMENT OF MEDICAL PSYCHIATRIC PRACTICE

Over the past few decades, general psychiatry has become more "medical," cognitive and behavioral neurology has burgeoned as a neurological subspecialty that shares a common certification process with the psychiatric subspecialty of neuropsychiatry, and general internal medicine has increasingly focused attention on behavior change and treatment adherence to close the gap between treatment efficacy and treatment effectiveness. Neuropsychologists have become essential partners to neurologists in the practice of cognitive and behavioral neurology, and psychologists specializing in behavioral medicine have established an important role in medical clinics. Thus, many disciplines have concerns overlapping with those of medical psychiatrists, and many individual practitioners in those disciplines have overlapping skills. However, medical psychiatrists have a distinctive combination of knowledge,

skills, and perspectives drawn from general psychiatry, general internal medicine, neuropsychiatry and behavioral neurology, and health psychology. They have the capacity to take into consideration the biological implications of medical treatment and to consider the existential and moral issues faced by the patient and family as well as the neuropsychiatric elements of the patient's presentation. This book embodies the perspectives of the editors: one is a psychiatrist and neurologist and the other a psychiatrist and internist.

The advent of the serotonin reuptake inhibitor (SSRI) antidepressant drugs and second-generation neuroleptic drugs has made it easier for nonpsychiatrist physicians to undertake treatment of major depression and even some psychotic conditions. Tricyclic antidepressants, monoamine oxidase inhibitors, first-generation antipsychotic drugs, and lithium all have side-effect profiles and/or dosing issues that made their use especially challenging for nonpsychiatrists. At this time, the patients seen by medical psychiatrists often are already taking a psychotropic drug when they come for their first consultation. The medical psychiatrist becomes the specialist evaluating the therapeutic and adverse effects of already-present psychotropic agents in the context of medical illness. The dynamic is somewhat different in the medical-psychiatric context than it might be if the patient were independently coming to the psychiatrist for psychiatric diagnosis and treatment.

Advances in diagnostic technology, including new blood tests and new imaging procedures, have reduced the number of grossly missed diagnoses in patients with medically unexplained symptoms. It is now unusual to find patients diagnosed as hysterical who turn out to have their symptoms totally explained by a missed diagnosis like multiple sclerosis, lupus, or a slow-growing brain tumor. We more often encounter symptom amplification, a patient's nonacceptance of a diagnosis that is supported by valid diagnostic data, a patient's attachment to a diagnosis not supported by scientific evidence, or valid disagreements between the physician and the patient about how a known condition should be managed.

Advances in brain imaging, genetics, and psychopharmacology have brought about a change in the perception of mental disorders in the general population and among nonpsychiatric physicians. It is now widely accepted that most mental disorders are related to brain dysfunction, even in cases when they are initiated by or exacerbated by life events. Nevertheless, the psychiatrist is not yet seen by the general

public as a type of clinical neuroscientist. Psychiatrists' training still emphasizes the ability to listen with empathy to patients' narratives, to perceive subtle emotional communication, and to understand patients' existential predicaments as well as their diagnoses. Nonpsychiatrists—both patients and health professionals—still perceive psychiatrists as in some way different from other physicians. These perceptions may include the attribution of esoteric skill, as well as less admirable attributes.

As more medical conditions are treatable, as life expectancy has increased, and as the cost of care escalates, the medical profession and the healthcare system in general have focused more on quality of life. Function and well-being are more often now explicitly described and measured. A focus on the patient's quality of life in the face of chronic illness or disability fits well with the tradition of integrating humanistic and physiologic perspectives on illnesses of all kinds. The medical psychiatrist asks, "How can I be helpful to this patient?" in the broadest sense, to increase function and quality of life as well as life expectancy and freedom from distressing symptoms. Some medical psychiatrists even venture to touch upon the meaning of life in their interactions with patients.

Ironically, another tradition in twentieth-century psychiatry—one that has been codified in the *Diagnostic and Statistical Manual* of the American Psychiatric Association and in the *International Classification of Diseases*—gives primacy to the classification of mental disorders by characteristic symptoms. This allows treatment, research, and reimbursement for care to be based on categorical diagnosis. This tradition of diagnostic classification by characteristic symptoms was motivated in part by the aim of making psychiatric diagnoses more reliable and thereby improving the quality of psychiatric research. This methodology is necessarily reductionist; in the absence of definitive biologic markers, it can convey specious precision in diagnosis. Nevertheless, formal psychiatric diagnosis by consensus criteria is essential to evidence-based practice. It is necessary but rarely sufficient for optimizing the overall outcomes of care in patients with multiple comorbidities.

Electronic medical records, the adoption of which in the United States has been heavily promoted by the federal government, have increased the standardization of clinical data and have improved the availability of such data to consultants. These records also permit the systematic application of decision support tools and predictive analytics at the point of care. At the same time, the use of such records for documenting physician services for billing and compliance purposes has filled electronic records with content of little clinical interest or professional perceptiveness; promiscuous cutting and pasting can propagate errors. Decision-making prompts such as drug interaction warnings, if generated too frequently and without priorities, tend to be ignored by busy clinicians. The care of patients with multiple and complex chronic conditions will generate huge volumes of data which can be opaque without systematic, intelligent data reduction and summarization. It frequently falls to the medical psychiatrist to put a surfeit of data into a patient-centered context, summarizing the present and past history in a way that acknowledges its meaning and

import to the patient, sets priorities for action, weeds out erroneous and obsolete data, and highlights what is most important going forward.

The Internet has profoundly changed medical practice in ways that are especially relevant to medical psychiatrists. Getting information about medical conditions is now very easy for patients and families. Patients and families frequently come to visits with preformed ideas about the clinical situation rather than with completely open minds. In order to provide information about treatment options, the physician often must start with correcting misinformation. Sometimes online clinical information relieves patients' anxiety, but often it increases it. Specialists, including medical psychiatrists, are no longer gatekeepers controlling access to arcane knowledge. Instead they are interpreters, critics, and expert users of information that increasingly is available to all. Medical psychiatrists have an important role in summarizing and clarifying the data that exist and in using their expert communication skills to elicit and address patients' beliefs, including those arising from online self-study.

THE EVOLVING ROLE OF THE MEDICAL PSYCHIATRIST

Other aspects of the contemporary environment of medical practice affect what medical psychiatrists do and the challenges they face. These include (1) a trend toward institutional medical practice, with most physicians employed by hospitals, clinics, or group practices; (2) greater reliance on practice guidelines and other explicit and usually evidence-based standards of care; (3) greater use of screening tests and rating scales in routine practice, with quantitative measurement of care outcomes; (4) greater legitimacy of complementary and alternative medicine, with wider use of vitamins, herbs, and bodywork; and (5) devolution of most psychotherapy and psychosocial treatments to nonmedical disciplines.

The current system of physician payment in the United States has complex effects on medical-psychiatric practice. The current regulatory requirement that health plans cover mental health and substance abuse services potentially increases the supply of services. However, as long as such services are managed separately ("carved out") from general medical services, they create barriers to the integration of psychiatric and general medical care. Physician payment schedules do provide more compensation for longer visits with patients, but the requirements for documentation of longer visits bias the use of the physician's time toward broader scope rather than greater depth of interaction. Medicare and some other health plans pay individual physicians for coordination of care but don't usually cover interdisciplinary conferences. Some health plans engage in "gain sharing" with physician groups who make the care of chronic diseases more efficient; the physician group receives a percentage of the amount by which the total cost of caring for a clinical population was less than expected. Integrating medical and psychiatric care for patients with complex medical and psychiatric comorbidities can reduce overall costs

and improve outcomes, but health systems have difficulty attributing benefits and rarely pay for medical-psychiatric services based on their economic value to the healthcare system. Overall, there is increasing recognition that patients with a combination of medical and psychiatric issues tend to be high utilizers of healthcare services, and that there would be financial as well as clinical benefits from more intensive management of their care. The editors believe that medical psychiatrists should have a major role in designing solutions for managing such patients, and that they will always have a direct role in finding individual solutions for the most complex and difficult of them.

The foregoing circumstances imply that the medical psychiatrist plays a range of different roles, addresses a range of different questions, and operates within a range of financial and organizational constraints. The traditional roles of the medical psychiatrist are (1) consulting to the patient's attending physician; (2) serving as a liaison between the psychiatry service and a nonpsychiatric specialty service, typically assisting with mental health screening, training of clinic staff on relevant psychiatric issues, program development, and interdisciplinary rounds and conferences; (3) engaging in ongoing treatment of individual patients' mental disorders, concurrent with the referring physician's treatment of the nonpsychiatric condition; and (4) when the medical psychiatrist is also fully trained in a general medical specialty, providing principal care to patients with problems within both psychiatry and their other specialty. More recently, some additional roles have emerged: (5) providing principal care to patients with comorbid psychiatric and medical problems when the latter are relatively stable and are less complex and demanding than the mental disorder(s); (6) managing and/or training multidisciplinary teams treating patients with medical-psychiatric comorbidities, especially those with depression and general medical illness (von Korff, 2011); and (7) serving as utilization reviewers or care managers on behalf of health plans or other payer organizations.

THE MIND-BODY PROBLEM

Throughout the entire literature of medical psychiatry, psychosomatic medicine and related disciplines, there is a residue of dualistic thinking. For example, major depression, which clearly comprises significant disturbances of brain metabolism, neurotransmission, endocrine regulation, and chronobiology, is called a "mental disorder," while migraine, a condition with no greater physiologic disturbance than major depression and equally great emotional accompaniments, is called a (general) medical condition. Major depression frequently is associated with physical pain. Stress and sleep problems contribute to migraine attacks and to relapses of depression. Primary care physicians treat both depression and heart failure. The former is nonetheless called a "psychiatric problem," but the latter is not called a "cardiologic problem"; heart failure is described in relation to an organ system affected and not in relation to a specialty that frequently treats it.

There is some utility in grouping conditions in which disturbances of mood, thinking, and/or behavior are the exclusive or greatly predominant expressions of disease, such as obsessive-compulsive disorder or schizophrenia. Yet these conditions are not purely "mental" either. Neurologists do not treat them—not because they are not brain diseases but because historically they were not viewed as brain diseases and because caring for such patients requires skills not ordinarily taught in neurology residency. These conditions might usefully be viewed as "brain diseases with predominant behavioral symptoms" or as "brain diseases that typically present with behavioral symptoms."

The characterization of chronic pain illustrates further problems of nomenclature. In patients with chronic pain, the central nervous system has "learned to feel pain." Is the condition neurological if the learning takes place in the spinal cord and psychiatric if it takes place above the tentorium?

George Engel, by teaching medical students and physicians to focus on the patient's personal story and the experience of illness, highlighted the psychological and social context in the practice of medicine. With appreciation for the interaction of the psychological with the somatic, he described the "biopsychosocial" model of medical practice (Engel, 1977). More than 30 years later, "biopsychosocial" would be viewed for the most part by nonpsychiatric physicians as a psychiatric term of art. References to "psychiatric comorbidity" would be widely understood, but such terminology does not overcome the dualism of separating the psyche and the soma, the brain and the mind.

Nevertheless, diagnoses must be made and coded even when they rest on a shaky philosophical foundation. In this volume, contributing authors will refer to psychiatric illnesses, (primary) mental disorders, "mental and behavioral symptoms and syndromes," and "disorders of mood, cognition, and/or behavior." These are distinguished from "general medical illnesses," which are conditions typically within the ambit of nonpsychiatric specialties. Medical psychiatrists must be aware that patients, families, nonpsychiatric physicians, and nonmedical health professionals might think that "mental" illness is somehow in the mind rather than in the brain, or think of chronic pain that exceeds visible pathology as usually and primarily due to emotional disturbance. These viewpoints should be recognized as the prejudices that they are—ones to be elicited and then challenged if they interfere with a more constructive understanding of a patient's clinical problem.

THE MEDICAL-PSYCHIATRIC ENCOUNTER

CONTEXT

In its classic form a clinical encounter begins with a chief complaint, followed with a history of the present illness, prior medical history, developmental history, social and occupational history, family history, review of systems, and finally

a physical examination. However, the medical-psychiatric encounter always takes place within a specific context and under specific constraints and expectations that will critically affect how the clinical work is done. The following outline describes what should be considered—explicitly or implicitly—prior to the first encounter with a medical-psychiatric patient.

1. Define the context of the encounter:
 - a. Who are the interested parties?
 - b. Will there be collateral sources of information?
 - c. Are there caregivers, and how will they be involved?
 - d. What is the purpose of the encounter?
 - e. What is the definition of success?
 - f. Is this a single encounter or the beginning of a relationship?
 - g. How much time is available for the encounter, including both time with the patient and time needed for documentation and communication activities?
2. Assemble relevant background data:
 - a. From the clinical record
 - b. From outside clinical records
 - c. Nonclinical data relevant to the problem
 - d. Primary data (e.g., diagnostic images) rather than interpretive reports
3. Determine constraints on follow-up:
 - a. Organizational (e.g., related to the site of care)
 - b. Financial (e.g., related to what a health plan covers and what a patient would be willing to pay for uncovered services)
 - c. Circumstantial (e.g., how long a patient will be in the hospital; where the patient usually lives)
4. Specify the work products:
 - a. A note in the medical record
 - b. A specific oral or written communication with a specific person or agency
 - c. A specific oral or written communication with the patient
 - d. Prescriptions, test requisitions, and other direct orders

While these considerations should precede the encounter with the patient, most of them need not be documented. In fact, more precise conception of the purpose of a medical-psychiatric encounter and the audience for the record of it sometimes can inspire shorter but more effective clinical records and communications.

DISTINCTIVE ASPECTS OF THE MEDICAL-PSYCHIATRIC HISTORY

The medical-psychiatric history contains the same elements as a general medical history, but there are different points of emphasis and differences in the scope and depth of the interview. It is most detailed in the areas necessary for the success of the clinical encounter.

Chief Complaint

The *chief complaint* in medical psychiatry often is not a complaint of the patient. In this situation someone else—for example, a physician encountering noncompliance with treatment or a family member unable to manage a patient's care at home—is the person with a problem to be solved with the medical psychiatrist's help. When the chief complaint is from the patient, it may be a complaint about the treatment rather than a complaint of a symptom of disease. It is perhaps best to replace "chief complaint" with an alternative term like "presenting problem" or "main issue"—implicitly if not explicitly.

History of the Present Illness and Its Three Dimensions

The *history of the present illness* in medical psychiatry has three dimensions. One dimension is the *history of the presenting problem*—one typically related to mood, cognition, and/or behavior, including health-related behavior. A second dimension is the history of the *patient's known general medical conditions* and how they are related in time to the presenting problem. The third dimension concerns the *impact of the predicament*—both the presenting problem and medical conditions—on the patient's life. This includes changes in functional capacity, in actual life activities, and in the meaning and enjoyment of life.

Past Medical History and Life History

The *past medical history* describes discrete illnesses, surgeries, and traumatic events as well as chronic or relapsing-remitting medical conditions. The special focus in medical psychiatry is on the *interaction* between general medical conditions, symptoms related to mood, cognition, and behavior (whether or not diagnosed as mental disorders), and functional performance. General medical conditions can be precipitated or aggravated by emotional stress. On the other hand, general medical conditions are themselves sources of emotional stress. General medical illness can precipitate or aggravate mental disorders, either via emotional stress or via direct physiological effects of the illness or its treatment. The general medical illness, the mental disorder, or the combination of the two can impair physical, instrumental, and/or social function. Functional impairment in turn can have both physical and emotional consequences, both directly and indirectly. The medical-psychiatric history comprises at least parallel histories of the patient's general medical, behavioral, and functional problems; at best it describes the interplay of the three (Viederman, 1984).

The *life history* is the biographical sketch on which the history of illness is superimposed. Relating the history of illness to the life history is relevant both for objectively gauging the severity of the patient's illness and for appreciating the subjective meaning of the illness to the patient. For example, a highly educated person with a neurodegenerative disease will fail simple bedside memory tests at a more advanced stage of brain disease than one with poor education and below-average

intellect. And the loss of memory, when it comes, can be a more fundamental blow to the former individual's self-concept. Similarly, a talented athlete with a general medical illness who is now capable of only an average physical performance may be showing disease-related functional impairment, and the emotional impact of that impairment may be great if the patient's self-esteem or income are related to his athletic prowess.

The life history typically surveys family background, formal education, work, avocations, friendships, intimate relationships, current family relationships, and episodes of trauma, illness, financial problems, or other challenges and how they affected physical health, mental health, and relationships. It also touches on areas of success and accomplishment, and on what gives meaning and joy to the patient's life.

The agenda of obtaining a comprehensive life history can help the physician–patient relationship develop. A full life history is rarely obtained in an initial clinical encounter; it tends to be filled in gradually as a relationship develops between the clinician and the patient. Some elements come to the foreground on their own schedule when there is greater trust. As the relationship develops, the clinician “listens with the third ear” (Reik, 1948) for the emotional dimension of the patient's experience.

Social History: Relationships and Work

The *social history* places the patient in a nexus of relationships—intimate and nonintimate, related and unrelated to the care of the patient's illness. The medical psychiatrist is interested in (1) positive relationships that enhance the patient's life, (2) relationships that cause trouble for the patient, (3) relationships that have changed for the better or the worse in the time period of interest for the evaluation, and (4) relationships that are potential resources for helping the patient. Changes in relationships can be causes or effects of illness or can be unrelated.

The *occupational history* can be conceived in terms of time scales. The lifetime occupational history with information about finding and losing work, moving or changing jobs, relationships with employers, and so forth, can in many cases provide a “personality biopsy,” particularly if the patient provides information about his health, activities, and emotional state while doing various jobs and while undergoing job transitions. The occupational history provides evidence related to all five major personality factors: extraversion, neuroticism, openness to experience, conscientiousness, and agreeableness (Costa & Widiger, 2002).

The *recent occupational history* can shed light on how the patients' illnesses have affected their occupational performance and how they have or have not adapted to their symptoms and impairments in physical and/or mental function. Discrepancies in severity between biological markers of disease, symptoms, functional impairments, and occupational performance lead to identification of both diagnostic issues and therapeutic opportunities.

The patient's *current work situation* should be considered as a physical environment, a social environment, and a set of performance requirements. The medical psychiatrist should

attempt to build a mental picture of the patient's workplace. Exposure to toxic substances should be considered, although often the toxic personality of a boss or coworker is more relevant to the patient's health. The physical demands of the patient's work should be elicited by detailed questions if the clinician is not highly familiar with the patient's job. People with similar job titles can face different physical and emotional demands. Overtime, shift work, frequent travel across time zones, and other chronobiologic stresses are important given the medical significance of sleep quality and quantity. Falling asleep on a day job is likely to be noticed and is a virtually pathognomonic sign of excessive daytime sleepiness.

All patients should be asked if they have traveled abroad. A *geographical history* should be taken if there is any reason to believe the patient has traveled to places where unusual infectious diseases or parasitic infestations are prevalent. Patients involved in international business, those in the military, immigrants, family members of immigrants, and patients with international travel as an avocation fall into this category. In this context it is noteworthy that the anxieties of undocumented immigrants and their families about the risk of deportation can impede the development of trust and full disclosure of relevant information.

Substance Use History

The *substance use history* in general medicine usually comprises a few questions about alcohol and tobacco and a perfunctory question about illicit drugs. Medical psychiatrists can bring greater precision to the substance abuse history by considering the following:

1. Misuse of prescription drugs, especially opiates but also stimulants and benzodiazepines, is common. Medical patients, including those receiving concurrent psychiatric treatment, often are prescribed drugs that can be misused. Patients who have been prescribed these drugs should be questioned about how they use them, how frequently they refill their prescriptions, and whether more than one doctor or pharmacy is involved in providing their prescriptions. Suspicious, guarded, evasive, or inconsistent replies should be followed up with a fact check.
2. *How* substances are used, and not just the quantity used, matters. This is particularly important in medical-psychiatric patients, who can be more sensitive—or more tolerant—to the pharmacological effects of particular substances than an average person with no medical illness. Patients should be asked about the physical and mental effects of their usual dose of a substance and whether the substance is used in order to get a particular effect.
3. The illicit drugs most commonly used, the route of administration, and what the drugs are called vary between communities. Inquiry about illicit drugs is more productive when the questions asked are more specific.

4. Patients often come to medical settings having recently discontinued or cut down on their use of a substance, or having been forced to do so once they have begun medical treatment in an institutional setting. They may have given up a substance because they no longer tolerate it, because a physician told them to, or because they fear its adverse effects on their medical condition. Or, illness-related disability interferes with their ability to obtain their former drug of choice. Patients should be asked about discontinuation of substance use or changes in substance use as well as what they are using currently.

Functional History and Activity History

The *functional history* and *activity history* are concerned with what the patient is able to do—either alone, with supervision, with assistive devices, or with human assistance—and with what the patient actually does. Questions in this area, to be time efficient, should be centered on functions that are threatened by the patient's medical conditions. Functions reviewed comprise the following: (1) basic physical activities of daily living (ADLs) such as eating, bed mobility, transferring, walking, using the toilet, dressing, bathing, and grooming; (2) instrumental activities of daily living (IADLs) such as shopping, driving or using public transportation, communicating by telephone, mail, texting, or email, paying bills and managing money, and household maintenance; (3) parenting and caregiving activities appropriate to the patient's age and family situation; (4) social activities both individual and group; and (5) recreational activities.

The history often will include corroborating history from a collateral source such as a family member, friend, or nurse. Discrepancies between the patient's report and a collateral source report of functional capacity raise the issue of potential cognitive impairment or of minimization or amplification of symptoms—either by the patient or by collateral source. Discrepancies between what the patients can potentially do and what they actually do raise concerns about apathy, fatigue, or impaired executive cognitive function (see chapter 86).

Sexual History

The *sexual history*, like the occupational history, can be taken in relation to different time scales. The *lifetime sexual history* provides insight into gender identity and gender preference and into personality. It gives an indication of the patient's overall level of libido and in general how important sex is in the patient's life. It can indicate whether the patient's sexuality is oriented toward emotional intimacy, physical pleasure, or procreation, whether the patient has used sex manipulatively, and whether there are themes of dominance and submission or unusual sexual interests.

The *recent* or *illness-related* sexual history focuses on how the patient's sexual life has changed or not changed in connection with the illness and with contemporaneous changes in life situation and relationships. Illness-related changes in

sexual activity can be either causes or effects. Given the wide variability of baseline sexual activity in the general population, the sexual history should include both the patient's current sexual activity and whether it represents a change from baseline. Also, how the patient feels about any change should be explored.

Medication History

The *medication history* should include details of nutritional supplements, herbs, and other complementary and alternative treatments. It should include any medications or supplements recently discontinued or changed in dosage, why the medications or supplements were changed, and whether there were symptoms associated with the change. It should include the history of any adverse reaction to a drug or supplement, especially adverse reactions that were either medically serious or emotionally disturbing. In addition to adverse reactions, patients should be asked about unusual reactions to medications even if they were not adverse; for example, did they have a euphoric reaction to a drug, or find that a tiny dose of a particular medication was nonetheless effective. Finally, the medication history should elicit differences if any between how medicines were prescribed and how they actually were taken. Patients frequently adjust dosages of medications to optimize effects and minimize side effects. They also may reduce the dosage or frequency of a medication if they cannot afford it. And, patients can think they are taking a medication as prescribed, while a subsequent pill count may show they were not.

Family History

An essential *family history* includes the health history and salient behavioral facts about all first-degree relatives, often expressed as a genogram. Because many mental disorders are not diagnosed, it is important to know if family members have had unusual symptoms or impairments that are potentially due to mental disorders, particularly focusing on familial mental disorders with symptoms related to those displayed by the patient. Hypomanic behavior often is recognized but not diagnosed as a mental disorder if it has some adaptive aspects. Likewise, depression that is apparently reactive to life circumstances may be viewed as normal by the patient or other informant. Also, nonprofessionals may lump chronic mental disorders with personality traits; a patient with generalized anxiety disorder may be seen as a nervous and worried person rather than someone with a chronic mental illness.

The timing of deaths in the family and the causes of death are data that can suggest a genetic predisposition to a disease that can shorten life expectancy. The early death of a parent can be a strong influence on a patient's emotional development. The death of a family member just before a new medical problem or flare-up of an old one suggests a potential causal relationship—typically one of contribution rather than sole causation. Concerns for children are an important dimension of the experience of illness for parents and grandparents. Family histories can change over time, with new diagnoses arising in family members as time passes.

Review of Systems

The *review of systems* in medical psychiatry differs from a generic review of systems in two ways. First, it explores the details of sleep and the details of eating in greater depth. Second, it reviews the status of chronic or relapsing-remitting conditions that are not actively symptomatic at the time of the interview. Such conditions are relevant to a holistic understanding of the patient and to comprehensive treatment planning. One common example is when a patient has no symptoms in a particular system because he avoids activities that provoke symptoms. The patient with COPD who stops walking outside the home because of fear of dyspnea can be more impaired by COPD than one who continues an active life but frequently complains of respiratory symptoms.

The review of systems conducted as a rapid series of closed-ended questions is not, in general, a good use of clinical time. When patients' cognitive and behavioral status permits, screening questionnaires followed up by targeted questions may be a more efficient route to the relevant facts. This topic is discussed at length in chapter 4.

Physical and Neurological Examination

The next chapter describes in detail the *physical and neurological examination* of the medical-psychiatric patient. Emphasis is placed on selected elements of the examination that will screen for dysfunction in an important system, quantify the severity of dysfunction by challenging the patient, or test diagnostic hypotheses.

Formulation and Intervention

The *formulation* builds toward a conclusion of how to be helpful to the patient. It begins with the listing of known and probable diagnoses and the current status of the patient's diseases and disorders. Current treatment, treatment options, and expected treatment results are delineated in the areas relevant to the presenting issue. Functional limitations are defined, and there is an appraisal of the severity of critical symptoms. These are understood in the context of the life history and coping strategies of the patient. With this background, the medical psychiatrist suggests *interventions* to address the presenting problem and, to the extent relevant in the given context, to improve the patient's function, well-being, symptom control, and medical prognosis. In moving from the assessment to a suggested intervention, the medical psychiatrist draws upon the base of specific knowledge and therapeutic principles described throughout this volume. Some principles are specific to particular medical specialties and clinical contexts, while some concepts apply to a range of settings and situations. These concepts are now described.

EXCESSIVE ILLNESS BEHAVIOR

Contemporary medical psychiatry has moved away from dichotomizing patients into those with "legitimate" or "organic" conditions and those with primarily "mental" problems. The concept of *excessive illness behavior* makes room for

the complexity of person–disease interactions and medical–psychiatric comorbidity. It also comprises behavior ranging from normal expressions of distress to florid somatization. Principles of assessing and treating excessive illness behavior are similar across the spectrum of severity and complexity (see chapter 37).

Begin with Communication and Building Trust

In treating excessive illness behavior, the first principle is good communication. This begins with an interview that builds trust with the patient. The medical psychiatrist aims to understand who the patient is, what he cares about, and the meaning of the illness to the patient as a human being. The clinician must, to some extent, join the patient's reality as a precondition for leading him out of it.

Understand the Medical Realities

In order to engage productively with a patient who is displaying excessive illness behavior, medical psychiatrists must be personally satisfied that they know what is true about their patients' general medical conditions. This often requires assembling, reviewing, and if necessary reassessing the data; communicating with other physicians; and pursuing additional data and/or expert opinions. They can then clarify for the patient and/or concerned caregivers what is true, what is uncertain, and what is simply not so.

Facilitate Tolerance of Uncertainty

Since uncertainty provokes anxiety, the medical psychiatrist must acknowledge and facilitate the patient's coping with uncertainty. How this is done will depend on the actual level of uncertainty, the consequences of being wrong, the patient's personality, and the interpersonal context. Sometimes it is appropriate for a physician to act as an authority and be unequivocal; on other occasions it may be more useful to acknowledge uncertainty and to commit to close follow-up and frequent communication.

Link Stressors and Symptoms When Supported by the Data

Often the optimal intervention for a medical-psychiatric patient involves educating the patient about the connection between physical symptoms and psychosocial stressors. While this often appears obvious to clinicians, it is surprising how often patients do not make the connection until it is pointed out.

Apply Systematic Behavioral Analysis

For patients with excessive illness behavior, the behavior itself may amplify and sustain chronic illness or interfere with adherence to medically appropriate treatment and thus the chance of cure. Psychological, interpersonal, social, economic, and even political factors affect how episodes of illness are precipitated, sustained, experienced, and reported. In order to interrupt

vicious circles of illness and maladaptive illness-related behavior, clinicians must first identify them, analyzing the antecedents and consequences of illness-related behavior and applying the results of the analysis to planning treatment—or, in some cases, to inform a decision *not* to pay attention to particular symptoms, complaints, and requests for help. This book's chapters on treatment adherence, on excessive illness behavior, and on personality and the physician–patient relationship present specific tactics for implementing this strategy.

Don't Expect the Patient to Accept a Psychiatric Diagnosis

Patients with excessive illness behavior can have obvious depression or anxiety but be resistant to seeing themselves as having any “mental disorder.” The medical psychiatrist often sees clearly how depression or anxiety produce actual physical symptoms in addition to worsening the emotional experience of whatever other physical symptoms the patient might have. While psychiatrists can easily see the value of treating depression or anxiety if it is present, patients who view such treatment as delegitimizing their complaints will just say no—or perhaps find any treatment offered to be intolerable, inconvenient, or otherwise undesirable. Resolving the problem with empathic connection and a trusting physician–patient relationship is nice work if one can get it, but open-ended psychotherapeutic engagement often is not feasible in a busy clinical setting. For this reason it is well worth considering techniques for overcoming patients' resistance to treatment that have shown effectiveness in everyday practice settings, including motivational interviewing techniques, structured patient education, regularly scheduled general medical appointments not contingent on having complaints, and treatments with antidepressant drugs for an explicitly recognized nonpsychiatric indication.

Be Alert to Potentially Inappropriate Treatments

Patients with excessive illness behavior often get inappropriate treatments with adverse effects that cause or provoke a new illness or condition. In evaluating such patients and reviewing their medication lists, diagnostic procedures, hospitalizations, and surgeries, the medical psychiatrist should begin with skepticism and curiosity. After satisfying themselves as to the accuracy of the information provided, they should consider whether particular interventions were medically necessary or were deviations from standard practice. Such deviations can arise not only from direct or indirect pressures from patients, but also from countertransference. Physicians sometimes do too much when confronted with patients whom, in their hearts, they would prefer not to treat at all.

CIRCULAR PROCESSES

In most general medical conditions, and particularly those with frequent psychiatric accompaniments, the patient's behavior influences the course of illness. In addition to

treatment adherence, the patient's diet, activities, and sleep patterns may affect clinical outcomes. These relationships can give rise to circular processes—positive feedback loops that make matters ever worse until the processes are interrupted by events, circumstances, or therapeutic interventions. These processes include:

1. Pain → Inactivity → Physiologic changes due to inactivity (e.g., cardiovascular deconditioning, joint contractures) → Increased pain
2. Pain → Treatment with opiates → Opiate tolerance and dependence → Increased pain
3. Chronic general medical disease → Nocturnal symptoms → Sleep disruption → Physiologic changes due to inadequate sleep → Worsening of general medical illness
4. Chronic general medical disease → Depression → Increased cortisol secretion, decreased sleep, irregular food intake, decreased physical activity → Worsening of general medical illness
5. Chronic general medical disease → Apathy → Nonadherence to treatment → Worsening of general medical disease
6. General medical disease → Toxic-metabolic encephalopathy → Cognitive impairment → Nonadherence to treatment → Worsening of general medical illness
7. Alcohol addiction → Alcohol-related diseases and conditions (e.g., cirrhosis, pancreatitis, traumatic brain injury) → Impaired executive cognitive function → Poor judgment → Increased drinking
8. Excessive illness behavior → Inappropriate tests, procedures, and treatments → Adverse reactions → Iatrogenic diseases and conditions → Increased illness-related behavior
9. Hostile, suspicious, and potentially litigious behavior → Defensive medicine → Anger over cost, inconvenience, discomfort and/or adverse effects of unnecessary or excessive procedures or treatments → Increased hostility and mistrust
10. General medical illness → Moods and behavior difficult for significant others → Deterioration or loss of important relationships → Emotional and physiological changes related to separation and to loss of social support → Worsening of general medical illness or its symptoms

NEUROPSYCHIATRIC PERSPECTIVES

Neuropsychiatry is a subspecialty distinguished both by the kind of patients and conditions it treats and by its perspective on symptoms and conditions—one that is particularly attentive to alterations in brain function associated with

symptoms and conditions that are subjective or historically viewed as “mental.” Since the late 1990s the neuropsychiatric perspective has been increasingly evident in medical psychiatry, applied not only to the psychiatric aspects of neurological diseases but also to the psychiatric aspects of other general medical illnesses. This neuropsychiatric perspective is applied not only to mental disorders but also to pain and to such symptoms as sleep disturbance, apathy, and fatigue.

As basic neuroscience progresses and the general public is more aware of the brain, physicians of all specialties are more open to the idea that chronic distress can change the anatomy, physiology, and chemistry of the brain in a way that contributes to future suffering. What is recurrent or persistent can become chronic, whether it be anxiety, depression, pain, the experience of trauma, or the craving for a mind-altering substance. Understanding this impels clinicians to intervene vigorously to reduce distressing symptoms and addictive behaviors. The medical psychiatrist keeps the hypothesis of persistent changes in brain function in mind when considering the patient’s history of illness. The full story of a patient’s illness, including what goes on when symptoms are not at their worst, is a basis for inferring that persistent changes in the brain have taken place. Reduction of symptoms and full remission of symptoms can have very different prognostic implications. With these considerations in mind, we introduce a neuropsychiatric viewpoint on some specific symptoms and syndromes that will be recurrent topics throughout this volume.

LONGITUDINAL PERSPECTIVE IS ESSENTIAL FOR ACCURATE DIAGNOSIS AND FORMULATION

Many neuropsychiatric conditions can only be accurately diagnosed by reference to their course over time; the choice among diagnostic alternatives cannot be made based on a single examination of the patient. These include the degenerative dementias, the spectrum of schizophrenia, and the spectrum of bipolar disorder. The medical psychiatrist may have the role of reminding other physicians of remaining diagnostic uncertainty or of seeking information about patients’ past histories from outside records or collateral sources. Alternatively, they sometimes have to clarify for patients or families that a lack of diagnostic certainty is not the same thing as diagnostic ignorance or lack of useful understanding.

Consider the patient who presents with mild cognitive impairment, who probably has frontotemporal degeneration or Alzheimer-type pathology and whose cognition is getting worse but has not yet reached the point of frank dementia. When talking to the patient and family, the conclusion should not be “we’re not sure what’s wrong” or “we’ll need to follow the patient over time to make a diagnosis.” The patient and family need to know that the patient has a degenerative brain disease and has a prognosis of progressive loss of function. Life decisions and care decisions need to be made at a point where the prediction of prognosis is more certain than the prediction of postmortem brain pathology.

Conversely, a pathological diagnosis can be certain—as it would be in a case of Huntington’s disease—yet there might be considerable uncertainty about prognosis in areas of great importance to life decisions and needs for care. The estimation of prognosis will combine data from genetic analysis with assessment of the rate of change in the signs of disease, comparing multiple data points. A question like “Will I need institutional care 2 years from now?” or “When will I have to stop driving?” has no definite answer. But medical psychiatrists, by integrating multiple longitudinal observations—clinical, imaging, neuropsychological—can do better than “I don’t know.”

When a patient with a general medical illness presents with a specific symptom or syndrome such as difficult-to-treat pain, excessive illness behavior, anxiety, depression, or resistance to treatment, it is useful whenever feasible to review the patient’s response earlier in life to stresses similar to the current one. These stresses might be previous flare-ups of the current active medical problem, a different illness, or physical or psychological trauma. Some patients get anxious when they are physically sick, others get depressed, and still others get angry. Such dispositions are likely to be “hard-wired.” Time relationships and potential causal relationships are variable and go well beyond a naïve concept of emotional reaction to illness. Episodes of clinical depression can precede and perhaps trigger episodes of relapsing-remitting general medical conditions; they can accompany them and possibly share an underlying neuroimmunologic basis or they may follow them, linked in various potential ways. Emotional reactions to the symptoms of illness, to the prognosis of the illness, or to actual or feared illness-associated functional, social, or occupational consequences, all are possible—as are psychiatric side effects of general medical treatments. There can be much to disentangle; knowing what happened on other similar occasions can be a guide.

DEPRESSION IS A DISEASE AND REMISSION IS THE GOAL OF TREATMENT

We view clinical depression as a relapsing condition that involves neurologic, endocrine, and chronobiologic dysfunction, and often has a somatic presentation. The longitudinal course of that disorder may track with the ups and downs of a comorbid chronic general medical disease, making everything less bearable. As further chapters document, a trial of antidepressant medication is appropriate in patients with chronic pain and/or distress from chronic unexplained symptoms whether or not they meet diagnostic criteria for major depression or they accept a diagnosis of depression. Optimal care of clinical depression entails the serious pursuit of remission of symptoms—not merely a measurable reduction in them. Before accepting that patients must reconcile themselves to chronic depression, a psychiatrist should ensure that the patient has had adequate trials of several different pharmacologic regimens—some of which involve multiple drugs, concurrent psychotherapy when feasible, and consideration of electroconvulsive therapy and repetitive transcranial magnetic stimulation. Medical psychiatrists specifically should

add consideration of whether concurrent general medical conditions or their treatments, issues with treatment adherence, or genetic variations imply that an apparently adequate trial of a treatment actually was not adequate, or that a promising treatment was aborted for reasons that could have been avoided if the patient's specific circumstances had been appreciated. For example, patients might not tolerate an antidepressant drug at a usual dose because they are slow metabolizers of that drug. If the drug were given at a lower dose, it might be tolerated and effective. Medical psychiatrists' experience gives them a profound understanding of how bad depression can be—especially when combined with general medical illness—and how seriously its treatment must be taken.

ANGER CAN BE A CLINICAL PHENOMENON

A state of excessive and dysfunctional anger can accompany general medical illness in some patients. While it can be an enduring personality trait manifesting clinically because the patient is in a clinical setting, it also can truly be an illness-linked affect just like sadness or worry. While clinical anger in general medical populations can be measured by rating scales, it has been much less well studied than depression and anxiety. Anger can be part of the syndrome of depression, or, like apathy, it can occur independently of it. It is worsened by physiological arousal—sympathetic activation—and by conditions that impair inhibition. Because it impairs patients' relationships with both clinical professionals and informal caregivers, anger deserves the medical psychiatrist's systematic consideration. The psychiatrist should consider whether the anger is a new problem or an old one; whether it is synchronized in some way with fluctuations in the general medical course; and whether it is associated with another neuropsychiatric syndrome. Also, clinicians should consider whether anger is part of an unfortunate circular process, where the physiologic accompaniments of anger, its impact on treatment adherence, and/or its impact on caregiving relationships make the medical outcome worse—and the patient angrier.

CHRONIC PAIN IS A CENTRAL NERVOUS SYSTEM DISORDER

The central nervous system (CNS) is altered by chronic exposure to a painful stimulus in ways that can sustain the experience of pain when the noxious stimulus is no longer present. For this reason chronic pain can be viewed as a disorder of the CNS. This disorder involves chronic sensitization—changes in neurons and synapses that make them more excitable by normal, nonnoxious stimuli (Woolf, 2011). These changes are persistent but not necessarily irreversible. Furthermore, long-term exposure to painful stimuli causes changes in limbic and cerebellar circuits that can give rise to depressive symptoms and avoidance behavior. Persistent pain impairs executive cognitive function, with consequences for organization, planning, resistance to distraction, persistence, judgment, and self-awareness. Sleep architecture and endocrine function can be disrupted as well. The depressed mood and apparently self-defeating behavior of many patients with

chronic pain is rooted in widespread alterations in brain function. Effective treatment and restoration of normal health and function will require far more than analgesics, and problems with treatment adherence early in the process can be anticipated.

ADDICTION IS A BRAIN DISEASE THAT AFFLICTS THE WILL

The neuropsychiatric viewpoint on addiction is that it is a chronic disorder of brain function with frequently severe social complications. Addressing addiction requires that the physician face and make peace with the duality of mind and brain. Addicts are afflicted by a condition that is not entirely under their control, but at the same time they must exert their will to do something about it. Like people with many other kinds of maladaptive behavior, addicts have trouble “bringing the future into the present”—being aware at the point of temptation of the future harm of indulging their addictions and being able to translate that awareness into effective inhibition of the addictive behavior. Medical conditions and their symptoms can increase motivation for addictive behavior—for example, pain can lead to a desire to take narcotics—and they can decrease self-awareness or inhibitory capacity, especially when the conditions or their treatments impair the function of the frontal lobes or their connections. Completing a potentially vicious circle, addictive behavior—especially the abuse of alcohol or drugs—can cause or exacerbate medical conditions that increase the patient's vulnerability to future addictive behavior (see chapter 38).

Given the potential harm that addiction to narcotics can bring, physicians treating persistent pain can face a conflict between the imperative to take pain seriously and the imperative to prevent the suffering of addiction. As there is no definitive test for determining vulnerability to addiction, analysis of the patient's biography—how the patient has adapted to illness, stress, and other challenges over the life course—can aid in the judgment of which reports by the patient can be trusted and which must be independently verified. Instruments for measuring cognitive, instrumental, social, and occupational functioning can have a role, as can the critical review of records and timely interviews with collateral sources. All of this data gathering and consideration typically falls between the acute phase of pain treatment—when relief is the highest priority—and the commitment to longer-term therapy with or without agents that can become substances of abuse.

CHRONIC FATIGUE AND APATHY ARE MAJOR SYMPTOMS SEPARABLE FROM DEPRESSION

Fatigue and fatigability are subjective experiences. Apathy, a tripartite phenomenon comprising a lack of concern, a lack of feeling, and a lack of motivation, is more directly apparent in its more severe forms. Both have the objective consequence of decreased activity—a consequence that can worsen the prognosis of many diseases and conditions via physical deconditioning, decreased treatment adherence, and/or direct metabolic consequences such as insulin resistance. Both fatigue

and apathy reflect neurophysiological disturbances, apathy being exclusively a CNS phenomenon while fatigue has a neuromuscular dimension as well. Gross brain diseases, neuromuscular diseases, and the indirect effects of endocrine dysfunction, systemic inflammation, and sleep disturbance can cause apathy and/or fatigue. Drugs prescribed for either psychiatric or general medical indications can have apathy and/or fatigue as side effects.

Depression and anxiety can have apathy and/or fatigue as accompaniments. However, many patients have the latter without the former and might reject the diagnosis of depression or anxiety if it were proposed by the physician. Treatment directed at relieving fatigue generally is well received by patients. Identifying apathy and/or fatigue as a focus of intervention stimulates the exploration of the underlying causes, which usually include physiologic as well as strictly emotional factors (see chapter 34).

SLEEP DESERVES MORE ATTENTION THAN IT OFTEN GETS

People sleep for between a quarter and a third of their lives. The quality and quantity of a patient's sleep is strongly related to his overall well-being, and sleep has—like several of the other cardinal neuropsychiatric symptoms—a reciprocal relationship with health, function, activity, and well-being. Detailed inquiry about the subjective and objective features of sleep is always relevant and sometimes crucial to optimal formulation and treatment planning. Both primary and secondary sleep disorders are common in the medical-psychiatric population; a typical situation is the obese patient with depression, hypertension, the metabolic syndrome, and obstructive sleep apnea. Recognition and effective treatment of the sleep apnea is crucial to a favorable long-term outcome.

While an adequate amount of restful sleep is essential, helping medical-psychiatric patients obtain it often is difficult. For example, many patients with obstructive sleep apnea do not wear their continuous positive airway pressure (CPAP) masks all night. The key point is that it is really worth trying to get the patient's sleep right because doing so will necessarily help many other things, and finding the reasons for poor sleep is likely to be otherwise useful. Furthermore, patients find inadequate sleep to be unacceptable, and forming an alliance with a physician around sleep improvement can be easier than forming one that is explicitly *psychotherapeutic* (see chapters 9 and 33).

COGNITIVE IMPAIRMENT IS EVERYWHERE

It is increasingly appreciated that cognitive impairment without delirium or frank dementia is widespread in general medical contexts. Examples include patients with prolonged stays in intensive care units, those who have had open heart surgery with hours on cardiopulmonary bypass, those who have had intensive cancer chemotherapy, and those with persistent attention deficit hyperactivity disorder; there are dozens more. The nondementia cognitive impairments seen in general medical contexts are more evident on

neuropsychological testing or on high-sensitivity bedside examinations than they are on brief informal mental status testing or on instruments like the Mini-Mental State Examination (Folstein et al., 1975) interpreted with its usual cutoff scores. They are functionally significant—causing patients and their families concern and sometimes distress, affecting performance in work both at formal occupations and at home, and altering the quality of interpersonal relationships. The medical psychiatrist is often the first physician to appreciate the extent and relevance of illness-associated cognitive impairment. A factually informed empathic connection with the patient and/or caregivers concerning the cognitive impairment and associated changes in mood and behavior can be a great relief to those who are worried. Follow-up includes steps to limit the adverse effect of the cognitive impairment on treatment adherence and to promote the avoidance (when feasible) of treatments that might make it worse. Depending on the severity of the impairment and its prognosis, the medical psychiatrist might need to help with issues ranging from disability status to driving safety to legal competence.

As in other medical-psychiatric contexts, the cognitive impairments associated with general medical illness occur on top of a “cognitive life story.” Lifelong learning disabilities or intellectual gifts can affect the relationship between the magnitude of the insult to the brain and clinically observed performance; they also change the meaning and significance of cognitive impairment to the patient. A mathematician who loses the ability to calculate because of a brain disease is likely to have far more brain damage than a patient with the same current impairment who had difficulty with math before dropping out of high school. And, the former patient probably will have greater awareness of the loss and will suffer more from it. Patients in an early stage of a degenerative brain disease with at most mild cognitive impairment can suddenly become demented when illness-associated cognitive impairment is superimposed. Sometimes the syndrome is one of delirium evolving into dementia, but in other cases the patient never has an altered sensorium. When an older patient develops obvious cognitive impairment from a medical illness or treatment-related brain insult that usually causes mild or minimal cognitive symptoms, the pre-illness history should be reviewed in depth for evidence of prodromal dementia.

PHYSICIAN–PATIENT RELATIONSHIPS AND TREATMENT ADHERENCE CAN BE NEUROPSYCHIATRIC ISSUES

Optimal physician–patient relationships require that the patient show active participation, attention, concentration and memory, expressive language and accurate comprehension, short-term memory, and executive cognitive function, along with the ability to trust, to confide, and to accept care. Adherence to treatment requires the same things, with the added challenge in most cases of carrying out the plan of treatment amidst all of the distractions of real life in an environment that may lack cues and controls that reduce

executive demands. There are many ways in which these prerequisites for optimal treatment relationships can be disrupted by a wide range of gross brain diseases and by primary mental disorders. An attention deficit, a paranoid psychosis, a subtle deficit in comprehension of orally presented material, or amnesic mild cognitive impairment (and these are just a very few examples) can cause a patient to miss an appointment or not to take medication as prescribed. Personality conflicts, miscommunication, and practical barriers also play a role, but these have always been considered by psychiatrists asked to assist when general medical treatment is not working. What is new is a greater emphasis on the neuropsychiatric possibilities.

DISABILITY SHOULD BE DECONSTRUCTED

Neuropsychiatric conditions can interact with general medical illness to produce functional disability; the combination of the two can disable a patient when neither the general medical illness nor the neuropsychiatric problem would be disabling in itself. Because of their perspective, medical psychiatrists often are effective advocates for such patients when they are seeking disability benefits, accommodations at the workplace, or simply the understanding of their loved ones (see chapter 86).

While explanation and advocacy are useful, they occasionally conflict with the agenda of treatment, particularly when the goal is to eliminate or mitigate the disability. For example, the clinician may want to convince an insurance company that a bad back plus a major depression make a full day's work impossible, while at the same time wanting to convince the patient that effective treatment of the depression and progressive mobilization can restore function even if the anatomy of the lumbar spine doesn't change.

THE IMPORTANCE OF SPECIALIZED MEDICAL KNOWLEDGE

Many chapters of this book educate readers about specific medical conditions, their usual treatments, and what patients with them suffer. When doing psychotherapy with patients going through rigorous treatments of serious medical conditions, it is essential to know what the treatments are like and what experiences the patient might still have in store. When working with patients with somatoform disorders or excessive illness behavior, it is essential to know the details of the symptoms, diagnosis, and treatment of the "organic" medical disease along with the symptoms that are amplified or mimicked.

KNOW THE MEDICAL FACTS AND APPRECIATE THE SUBJECTIVE EXPERIENCE OF THE ILLNESS

For example, the neurological evaluation of patients with nonepileptic seizures (NES) is much like the evaluation of patients with epileptic seizures. Once NES has been diagnosed and a

decision has been made to discontinue antiepileptic drugs now thought unnecessary, the approach to discontinuing the antiepileptic drug is much like the one that would be taken in a patient with epilepsy. Since many patients have both epileptic and nonepileptic seizures, medical psychiatrists treating patients with NES must be equipped to detect any emerging evidence for epilepsy—or other neurological disorders—even as they help patients to identify and deal with stressors differently and to accept diagnosis and treatment for any primary mental disorder they also have. Familiarity with electroencephalography and its limits, antiepileptic drugs and their pharmacology, side effects, interactions with psychotropic drugs, and the symptomatology of unusual types of epileptic seizures are all needed to provide optimal *psychiatric* care for such patients.

The discussion of NES illustrates a perspective that applies to many other medical specialty contexts. Whether it is working with burn victims or patients with end-stage renal failure, an effective medical psychiatrist must understand the symptoms and the treatments the patient with the illness will experience—the subjective dimension—as well as the objective facts of how the disease and its treatments affect the brain and how psychotropic medications affect the disease and interact with its treatments.

COMPREHENSIVELY ANALYZE MEDICATION ACTIONS AND INTERACTIONS

Comprehensive review of the medication list has always been critical in medical-psychiatric consultation. The medical psychiatrist may be the first physician to collect all of the relevant data—especially when complementary and alternative treatments, borrowed medications, or drugs taken not as prescribed are involved, or when there are issues of substance abuse. Psychiatrists may be more assiduous in pursuing collateral source information or in gaining their patients' confidence so that they disclose additional facts; the greater legal protection for the confidentiality of psychiatric data can be relevant as well. Medications recently discontinued can have as much impact on the brain as those recently started—so the recent history of medication changes must be included when the medication list is considered. Information about potential drug interactions and side effects is extremely easy to obtain over the Internet or through databases linked to electronic medical records, but deciding what information is truly significant is nontrivial. The time sequence of medication changes and symptom changes helps, but the medical psychiatrist can bring some additional assets: (1) consideration of individual differences, such as differences in the genetics of drug metabolism and differences in the tolerability of different types of side effects; (2) elicitation of the patients' subjective experience of medications and of the meaning to them of relying upon—or simply of taking—certain medications; (3) detailed and structured observation of the patient's cognitive and affective mental status—often a sensitive indicator of medication toxicity; and (4) collaborative dialogue about the relative importance of taking, risks of taking, and risks of not taking particular medications.

CONSIDER FUNCTION AS WELL AS SYMPTOMS

A recurrent theme in medical psychiatry is that in chronic diseases, the goal of treatment cannot be presumed: once cure is off the table, goals may differ among patients and between patients and their physicians. For some patients relief of particular symptoms is paramount, but for others the preservation of particular functions or continuation of particular activities matters more. Physical and mental activity promotes health, as does positive emotional engagement in both intimate and nonintimate relationships. Functional impairments can lead to changes in social and/or economic status that worsen the prognosis for both physical and mental conditions. The issue of functional versus symptomatic outcomes is salient for some patients with chronic pain: inactivity and narcotic analgesics can bring them short-term reduction in pain at the cost of greater chronic impairment.

HELP PATIENTS ADDRESS GENETIC INFORMATION

As the cost of genotyping falls rapidly and the association of genes with diseases is better understood, patients and their families will get ever more information about their genetic differences and their genetic risks. For major conditions determined by a single gene or chromosomal abnormality, it is likely that genetic testing will be clinically motivated, the results will be unambiguous, and genetic counseling will be readily available. The task of genetic counselors has been to interpret family and medical histories to assess the chance of a disease, educate about inheritance, genetic testing, management, and prevention and to promote informed choices about the condition (see chapter 64). The broad availability of genotyping will necessarily change what genetic counselors do, as they will increasingly have to help patients make sense of their genotypes in situations where there are statistical associations of genes with diseases, but the precise pattern of inheritance isn't known. Analysis of the family tree will provide an initial estimate of risk of a condition that does not manifest until later in life, such as vulnerability to cancer or dementia; knowing the genotype will help refine it. Knowing that one is at risk for a particular disease may be least emotionally burdensome when it points the way to an action that will reliably prevent the disease, even if that action is an unpleasant one. It is most burdensome when nothing can be done to prevent an awful illness like Huntington's disease. At all points on the continuum, powerful emotions like fear, guilt, anger, and the pain of loss can occur and can be helped by the medical psychiatrist's informed empathy; and here, as elsewhere, the clinician can help patients tolerate unavoidable uncertainty. Realizing that misconceptions and overinterpretation of genetic data are always possible, solid knowledge of the specialized medical facts is the point of departure. In clinical genetics, the facts will change from year to year as the big data from widespread genotyping are successfully analyzed, challenging clinicians to stay informed about the genetic issues relevant to their long-term patients.

PUT PRACTICE GUIDELINES IN THEIR PROPER PLACE

Evidence-based practice guidelines are rapidly finding a place in American medicine, moving from statements of ideals to criteria for performance evaluation and payment of clinicians. For many years physicians have resisted practice guidelines because of a conviction that medicine is an art as well as a science, and that patients can have crucial individual differences from statistical norms on which the much of the evidence behind guidelines is based. However, most patients are *not* outliers, and a universal and generic objection to practice guidelines is merely an excuse. Most patients will do better if their physicians follow guidelines rather than improvise (see chapter 88).

Medical psychiatrists, however, specialize in seeing exceptions to rules. Medical-psychiatric patients have multiple comorbid conditions, and the guidelines for one condition can be incompatible with the guidelines for another. Drug interactions, genetic variations, and behavioral differences, all can make a guideline inappropriate for a particular patient.

The broad multispecialty perspective of medical psychiatry is useful in framing the case that a particular patient should be treated outside of guidelines and excluded from the calculation of aggregated outcomes. Nonetheless, medical psychiatrists encounter patients treated outside of practice guidelines who would clearly do better if their physicians followed the guidelines and did not view them as exceptions. Whether the reason for the physician's inappropriate deviation from standards is related to countertransference, misdiagnosis, or lack of skill, the medical psychiatrist can effectively advocate for patients to get the standard treatment they need and to avoid the ill effects of inappropriate treatment. For medical psychiatrists working in smaller medical communities where physicians must get along even when they disagree, advocacy of this kind calls upon skills in diplomatic and tactful communication. On occasion it is helpful to suggest that a practice guideline be followed "to relieve the patient's anxiety."

UNDERSTAND WHY SPECIALIST OPINIONS MAY DIFFER

Medical psychiatrists can become adept at recognizing when patients are outliers or special cases who will need nonstandard treatment or modification of how standard treatment is delivered. In addition to patients with complex comorbidities and genetic differences, mental and behavioral factors including personality can also be good reasons for deviation from guidelines. When medical psychiatrists suspect that the treatment of a general medical condition needs to change to improve its outcome—whether the change is toward greater or lesser compliance with practice guidelines and local customs—a second opinion is likely to be part of the strategy. Whether they give, receive, or interpret second opinions, medical psychiatrists should appreciate that when the second opinion does not confirm the first there is a conflict to be resolved, and they can assist with that resolution. A tie-breaking third opinion usually is not the answer.

A basic approach to reconciling conflicting second medical opinions is to begin with the question of whether the two physicians were working with the same facts—for example, accessing the same set of records, images, laboratory results, and medical history. Next is the question of whether particular facts were interpreted differently—for example, whether a particular image was read as normal or abnormal. If facts and their interpretations are aligned, the medical psychiatrist questions whether different inferences and judgments from the facts are based on different supplementary information and different principles of inference, for example, whether the two physicians applied different diagnostic criteria. Finally, different recommendations for action may be based on different presumptions about the goals and constraints of treatment or different knowledge about the patient's preferences. When the reasons for a difference of opinion are elucidated, it often becomes clear which opinion is more applicable in the given case (see chapter 82).

THE RELATIONAL PERSPECTIVE

Just as a patient's illness occurs within a life story, it occurs within a nexus of relationships—intimate and nonintimate, familial, social and professional. A vast literature of social psychology has established the relevance of adequate and healthy social relationships to optimal physical health. While the main focus of most medical psychiatrists—like most general psychiatrists—is individual patient encounters, it has always been known that changes in the social network can greatly help or harm patients.

Not only are social relationships important to health and to healthcare, but function within relationships is an essential expression of human existence that can be altered for better or worse by illness. Relevant factors include (1) the predicament of illness, with issues ranging from financial stress, disruption of daily routines by caregiving, competing loyalties and obligations, and the fear of loss; (2) changes in cognitive function due to the illness or its treatment, which in turn influence interpersonal communication and social behavior; (3) the patient's emotional reaction to illness; (4) empathy or the lack of empathy on the part of others for the patient or on the part of the patient for others; (5) where the patient is in the course of life; and (6) the expectations and needs of others from the patient.

Direct intervention in family and other interpersonal relationships—for example, family or couples therapy or a caregivers' support group—is an appealing option when it is obvious that such relationships are a locus of distress or are adversely affecting treatment outcomes. However, one can only treat nonpatients when they agree to be treated. Referrals to nonmedical family therapists or to support groups may not be accepted even when offered very appropriately.

In general medical settings it is routine for physicians to talk with concerned family members, and it is usual for this to be done with the informal assent of the patient, especially if the patient is acutely ill. When medical psychiatrists are knowledgeable about the patient's general medical issues and

have a strong working relationship with the patient's principal physician or specialty service, they can be in a particularly strong position for engaging family members in dialogue. If medical psychiatrists are a regular part of a specialty service team, they might even be sought out spontaneously by family members interested in their advice and opinions. In all circumstances when the patient is competent, it is essential to seek the patient's unambiguous consent first and to define both with the patient and the family the scope and the aims of the conversation.

In formulating a case and contemplating intervention, consideration should be given to several types of relationships and how they might facilitate a better outcome or relieve the patient's distress: physician–patient relationships, family relationships, nonfamilial social relationships, and spiritual/religious relationships whether with clergy, other believers, or the divine.

The medical psychiatrist should consider how the patient's illness affects what he does for others. When illness makes a patient less able to care for a spouse or a child, feelings of anxiety and guilt can be more distressing to the patient than physical pain. Similarly, while impaired occupational function due to illness can cause distress because of its financial implications, the more salient loss for many patients is the social context of work and the existential meaning of being productive.

PHYSICIAN RELATIONSHIP TO PATIENT—FORMS A CONTINUUM FROM EXPERT TO HEALER

The role of a medical psychiatrist ranges from that of a technical expert to that of a healer. Physical illness and its discomforts, losses, and threats can induce psychological regression and intensify transference, for better or for worse. In typical medical-psychiatric contexts, transference is recognized and managed or utilized but rarely interpreted. In particular the discussion of negative transference is interpreted only to the extent helpful in reducing disruption of treatment. Medical-psychiatric consultations in the hospital are intense brief encounters, where positive transference, if present, can be used to promote a better adaptation to illness. Ongoing involvement of the medical psychiatrist in the care of a chronic disease is a less intense but more open-ended relationship in which, at best, the patient feels the psychiatrist is a part of his life and potentially available to help at times of distress or challenge, offering empathic companionship and expert advice as the patient faces the existential challenge of illness. In long-term treatment, medical psychiatrists build the patient's trust through repeated demonstrations of skill and empathy. Once trust is established, clinicians can positively influence even those patients who did not have a positive transference to them at the outset.

Medical psychiatrists can make therapeutic use of the power of positive transference only when such transference is present and when their own feelings toward a patient are positive. When either transference or countertransference is negative, it is usually best to assume the role of the technical expert and aim to limit the intensity of the physician–patient

relationship. Referral to another psychiatrist sometimes is an option; when it is not, one should consider whether there is a preexisting positive relationship with a general medical physician that could be an effective psychotherapeutic channel if that physician is willing and is appropriately advised.

BRIEF INDIVIDUAL PSYCHOTHERAPY IS POWERFUL

A significant part of many medical psychiatrists' practices comprise patients without major Axis I or Axis II disorders, who, under the extraordinary stress of general medical illness or physical trauma, develop mental and behavioral symptoms and seek psychotherapeutic help. Many such patients get great benefit from relatively brief psychotherapy. The therapist's activities include some combination of educating the patient on the facts of the general medical condition, identifying and explaining the patient's emotional and behavioral responses to the sick role, analyzing changes in important personal relationships, and assisting the patient in solving life problems associated with the illness. The medical psychiatrist is flexible and pragmatic, deciding at any given time whether introspection, empathy, emotional support, or practical assistance is most appropriate. Negative transference is addressed only when it directly interferes with treatment and is interpreted in a circumscribed manner so as to overcome the patient's resistance without mobilizing intense affects that could be potentially disorganizing. The conceptual framework and therapeutic language can be that of psychodynamics or that of cognitive-behavioral therapy; the essential work is the same either way. Patients are helped to understand their situations more clearly, to face them with less anxiety and more thoughtfulness, and to identify and utilize their inner and external resources (see chapter 10).

FAMILY THERAPY CAN HELP FAMILIES MEET THE CHALLENGE OF ILLNESS

Serious general medical illness or trauma challenges families to face new practical demands while coping with their emotional reactions to the illness or injury of someone they love. Families' habits of communication, ways of dividing work, and consensus (or lack of consensus) about familial obligations that may have been acceptable prior to the medical event can emerge as dysfunctional in the new context. If a family didn't see their usual ways as a problem before the medical event, they are unlikely to suddenly become introspective and self-aware just because there is a medical crisis. The medical psychiatrist's identification of issues of problematic family functioning must be gradual and tactful when the family has not yet granted the psychiatrist a license to treat anyone except for, possibly, the patient with the medical illness. Often the most acceptable place to start is by providing information to the family if this is acceptable to the patient. Assessing and attempting to improve communication within the family around illness-related issues is a relatively nonthreatening next step. Moving on to more sensitive issues concerning obligations, loyalties, and conflicts is conditional on establishing

trust and family consensus on a common agenda. If the latter do not develop after a few meetings with a family, it is probably better to focus on the individual rather than attempt to persuade or entice a family into conjoint treatment (see chapter 11).

CONSIDER THE PATIENT'S ROLE AS A PARENT

When patients are parents of dependent children, the parental role is almost always one of their most important concerns along with their occupation and their intimate relationships. It is thus curious that while physicians virtually always ask patients about their work, they sometimes do not ask them about their children and parental relationships. Even when a medical-psychiatric patient does not present with a problem related to parenting, the medical psychiatrist should routinely ask all adult patients if they are parents and, if so, to try to learn a bit about each of their children in terms of age, temperament, functioning, coping abilities, specific challenges, and so forth. Parents usually like discussing their children. An open-ended inquiry such as "Tell me about your children" often can enhance the relationship between the clinician and the patient while eliciting important information. When the patient is a less-experienced parent of children under the age of 6 years, the clinician might make the point that very young children feel more secure and cope better with stress when routines and nonparental caregivers are as consistent as possible. Clinicians can think creatively with parents about how to engage supports and utilize resources to increase consistency for their children.

When children are old enough to understand the parent's illness and anticipate potential future events such as medical emergencies, the clinician can help parents plan how they will talk with their children about what is wrong and what might happen. When the children are adolescents or young adults, they can be of significant practical help to their parents; helping a sick parent can be a positive experience if it is not so demanding as to completely disrupt other aspects of the child's life. In this situation the clinician can help parents figure out what it is reasonable to ask of their children and how to effectively communicate their condition, their needs, and their concerns for their children's welfare (see chapter 12).

GROUP THERAPY HAS A SPECIAL PLACE IN MEDICAL PSYCHIATRY

Group therapy, which actually had its origins in support groups for patients with general medical illness, can be preferable to individual psychotherapy for some medical-psychiatric patients. These include patients who are anxious and uneasy with the one-on-one context of individual psychotherapy, preferring to hear others talk about their issues before speaking up about their own. They also include patients who see individual psychotherapy as stigmatizing or as a sign of weakness, but who wouldn't have the same negative view of a "support group" for people with the same illness. Group therapy for patients with general medical illness and associated emotional issues has empirically

demonstrated benefits for mood, pain, and life adjustment. While evidence that group therapy affects longevity or the course of a major medical illness like cancer is inconclusive (though suggestive), there is better evidence for psychiatric benefits. The greatest constraint on the effectiveness of group therapy for medical-psychiatric patients is the availability of a suitable group at the point in a patient's course of illness when emotional concerns are in the foreground and the patient is motivated to accept the referral. In a large metropolitan area there is likely to be a suitable group when it is needed, but if it is not associated with the same hospital, doctors, or provider network, a referral might not be feasible. It is not known whether groups for people with varied medical conditions are as effective in general as groups for people who all have the same illness, but more homogeneous groups are more likely to provide patients with practical suggestions for coping with the specific challenges of an illness like breast cancer or lupus. In the end, starting with the belief that group therapy for medically ill patients is a good idea and using local experts and online social networking, the patient or the physician often can find a resource. Those who believe in the special virtues of group therapy for the medically ill note the following: (1) group therapy allows patients access to emotional support, and to learn new interpersonal and coping skills without identifying themselves as abnormal; (2) patients discover they are not unique in their predicaments, and this can relieve feelings of existential isolation and personal misfortune; (3) as patients see how others cope with the challenges of illness they come to respect others' efforts, leading to greater respect for their own; (4) listening to others' accounts of their experiences, patients may feel that their own experiences are understood and validated; and (5) patients have the opportunity to help others, an activity that is intrinsically satisfying and meaningful. Some patients will be comforted by knowing that others are worse off. Meeting and getting to know and coming to care about another patient with a worse case of the same illness can have a different and more positive emotional effect than merely knowing that such patients exist.

SPIRITUAL EXPERIENCE IS UNIVERSAL AND WORTH EXPLORING

All human beings are capable of an experience and viewpoint that might be called "spiritual"; the experience of spirituality does not require religious belief or affiliation. The spiritual state of mind is a peaceful one of secure attachment and "remembered wellness"; some patients can attain it despite current pain, anxiety, and actual separation from or loss of loved ones. Medical psychiatrists work with their patients to find internal and external resources for facing the emotional challenges of illness. In this context they should elicit information about patients' spiritual experiences and orientation. The clinicians who simply show openness to and interest in their patients' spirituality can encourage them to make use of it; shared belief is not necessary (see Waldfogel & Wolpe, 1993, and chapter 18).

SUMMARY

Medical psychiatry might be described as a specialty in which outliers are the norm and exceptions are the rule. While general medical illness and ultimately mortality are universals of the human condition, most people cope with illness without psychiatric assistance. Patients come to us—or are sent to us—because they are different in some way. The differences medical psychiatrists encounter in the practice comprise a broad range that includes comorbid primary mental disorders, gross brain lesions in regions that affect emotional experience or emotional communication, CNS side effects of general medical drugs, genetically based variations in drug metabolism, challenging family circumstances, past trauma, substance abuse, and personality traits that impede coping with a particular illness. Beginning with the differences that create problems, we then look for differences that might help with solutions, a search that also covers a broad range.

The specialty requires that clinicians know at the outset a little bit about a lot of things—so they can quickly grasp the gist of the patient's problem and formulate the right questions. The clinician also must know about the patient's specific conditions and treatments in great detail, with appreciation of their nuances and subjective aspects.

The perspective of medical psychiatry is simultaneously episodic and longitudinal. The problem at hand usually is related to the patient's present coping with a current medical situation, but both the problem and the solution are best understood in relation to the patient's course of illness and personal biography. The patient's history and examination are never complete, as new information emerges and new observations are made with every clinical encounter. The top priority for treatment can change in response both to medical events and to life events.

Medical psychiatrists live in a real world of preemptive medical events, a complex and imperfect healthcare system, changing psychiatric nosology, and the continuing stigma of mental illness and the psychiatric profession. What enables us to be effective is that we are *physicians* above all.

Overall, the healthcare system is in the process of moving from *delivering services* to *pursuing outcomes*. Diagnosing and treating diseases, and the procedures and services used to do that, increasingly are viewed as means to an end. Medical psychiatry has *always* focused on the outcomes of care, attending to functional and subjective dimensions of medical illness.

Medical psychiatrists face a challenge similar to the one faced by many of our patients: how to be confident and calm in the face of uncertainty. Evidence-based medicine teaches us rules, but we see exceptions every day. Whether following guidelines or intentionally deviating from them, we are rarely certain in advance whether the treatment we choose will work as we hope and expect. Even so, we want our patients to know and to feel that the decisions we have made were good ones: well informed, rational, and responsive to their individual differences and specific circumstances and

preferences. This challenge of combining confidence and humility, extensive and detailed knowledge, curiosity, and skepticism in appropriate proportions is faced by all good physicians at times; medical psychiatrists face it more often than most.

Medical psychiatry is an especially satisfying specialty to practice, for two main reasons. The first is that medical psychiatrists have more time with their patients than most other specialists. The second is that the field brings rigor, discipline, and specialized knowledge to the psychological and relational aspects of medical care, while also assimilating the detail and precision of its biomedical aspects.

PHYSICAL AND NEUROLOGICAL EXAMINATION

Barry S. Fogel

INTRODUCTION

In general medical patients, the physical examination typically comprises a combination of *hypothesis testing* driven by the chief complaint and medical history and *screening for physical signs* related to various organ systems. The latter is driven by customary practice and often by the need to comply with practice guidelines and/or billing regulations, and it may be perfunctory. In any case, it would not be feasible to routinely examine each organ system at the level of completeness and detail typical of a specialist in that system. This is often the case with the neurological examination, as a complete neurological examination is time consuming, and the level of neurological knowledge and skill can vary considerably among accomplished physicians who are not neurologists. Furthermore, examinations of other organ systems often are abbreviated when the system is outside the scope of the presenting complaint. The generalist's examination of the skin often is less meticulous and complete than that of a dermatologist; physicians outside of orthopedics, physical medicine, or rheumatology tend to be less complete and quantitative in their examination of joints.

No physician would regard a computed tomography (CT) scan of the brain as ruling out all brain disease, though it could be definitive in ruling out hydrocephalus, or a sufficiently large brain tumor or intracerebral hemorrhage. If demyelinating disease were suspected, magnetic resonance imaging (MRI) would have fewer false negatives than a CT scan. Different types of physical examination are like different imaging procedures or different laboratory test panels—their sensitivity and specificity and ultimate diagnostic value depend on what conditions are to be diagnosed or ruled out and on the prior probability that the patient has one of the conditions of interest. If a physical examination is done purely for screening or for “medical clearance” without any diagnostic hypothesis or list of conditions to be excluded, it is likely to have many false negatives if considered in the light of specific diagnostic hypotheses formed after careful consideration of the patient's presenting problem, its context, and findings on laboratory tests and diagnostic imaging.

PURPOSES AND TYPES OF PHYSICAL EXAMINATIONS

There are several situations in which physical examinations conducted by medical psychiatrists—or at their behest—can add special value to the care of the patient:

1. *Narrowing a differential diagnosis prior to ordering diagnostic tests and imaging procedures.* For example, patients with depression, anxiety, fatigue, multiple somatic complaints, and weight loss frequently will have both a chronic general medical disease and a mood disorder. In this situation, characteristic physical findings suggestive of adrenal hyperactivity or adrenal insufficiency would trigger the measurement of plasma cortisol and follow-up provocative tests if there were even a borderline abnormality. In the absence of physical findings or a history of endocrine disease, it is unlikely that a plasma cortisol level would be obtained as part of a general “medical screen” in such a patient.
2. *Looking for physical signs supporting the diagnosis of a specific condition that often has symptoms or functional impairment in excess of findings on a nonfocused, general physical examination.* Conditions ranging from vulvodynia to many of the focal neuropathies due to nerve entrapment or compression have characteristic physical findings that would not be detected or not be adequately characterized without a specialized examination.
3. *Quantifying the severity of a known physical condition to better assess its relationship to the patient's subjective distress and functional impairments.* For example, measuring changes in vital signs and auscultating the heart and the chest following mild exertion can help the clinician understand why a patient with cardiac or pulmonary disease might be unmotivated to exercise. Anxiety about exercise might be commensurate with changes in vital signs and objective signs of dyspnea or be disproportionate to them, and the approach to the psychological dimension of rehabilitation will differ accordingly.

4. *Getting a subjective sense of the patient's condition to better understand its emotional impact.* This is most obvious in the case of skin lesions or physical deformities, or when the patient is in evident distress from pain or dyspnea, but it is also helpful when the patient is asked to perform a task during the physical examination and does it with unusual effort or excessive timidity.
5. *Enhancing positive transference through appropriate touching of the patient.* Patients who are dying, patients with a poor prognosis, patients in pain, and patients with stigmatized conditions can in many cases be comforted and reassured by the physician's touch during the examination. Psychiatrists are well aware of the potential problem of boundary violations and evocation of anxiety or negative transference in individuals predisposed by their history or their diagnosis. Notwithstanding, even the limited touch involved in taking vital signs can have positive effects in contexts where a more extensive physical examination by the psychiatrist would be unwise.
6. *Communicating across disciplinary lines to stimulate a fresh look at a patient's problem.* Citing a specific physical sign that is unequivocally present yet not previously noted on another physician's examination can be an effective way to request a second look at the patient with a fresh perspective. Many specialists find an inquiry about a physical sign more welcome and less meddlesome than the medical psychiatrist's expressing a concern that there might be a missed or underappreciated diagnosis.

Physical examinations by medical psychiatrists are of four general types (see Table 2.1). The *first type* is essentially

the same as the examination by a primary care physician. A patient, for example one with delirium, is thought to have an acute medical illness, which, if present, is likely to show manifest physical signs that will be found on examination, such as the signs of heart failure, pneumonia, or an acute abdomen. Or, a homeless and medically neglected patient with chronic mental illness is admitted to hospital and screened for comorbid medical conditions that, though apparent when a general medical history and physical are done, went unrecognized because the patient was not receiving regular medical care. The *second type* of examination is performed when a patient has medically unexplained symptoms or an obscure diagnosis after examination by a primary care physician, examination in an emergency room, or even examination by other medical specialists. In this case, *specialized, focused examinations of greater depth and scope* than typical of a general medical examination are needed. These are *hypothesis-driven*, based on the patient's symptoms, medical history, context, and results of prior diagnostic investigations and laboratory tests. This type also includes a careful redo of a screening examination that might have been done rapidly and with low sensitivity in the context of "medically clearing" a patient for admission to a psychiatric inpatient service. The *third type* of examination is performed when a patient has a known disease—such as an autoimmune disease, cancer, or chronic organ failure—that is relapsing-remitting, progressive, or subject to recurrence, and the medical psychiatrist aims to determine *whether the disease has relapsed or progressed*, as this will have impact on the interpretation of symptoms and on treatment planning. In this situation the examination is focused on assessing the *presence and severity—the latter sometimes quantitatively—of specific*

Table 2.1 TYPES OF PHYSICAL EXAMINATION IN MEDICAL PSYCHIATRY

EXAMINATION TYPE	PURPOSE	SCOPE AND DEPTH	SPECIAL FEATURES
Screening for general medical diseases	Identify conditions missed because of lack of recent medical care or brevity of recent medical visits	Similar to a primary care physician's comprehensive examination	Focus on acute diseases or chronic diseases depending on context and setting
Investigating poorly explained symptoms	Determine cause of symptoms not well explained by diagnoses to date; identify potentially missed diagnoses	Focus on conditions that could better explain the patient's symptoms; deep and detailed examination of relevant organ systems	Hypothesis-driven; methodology similar to subspecialist examination
Assessing status of a known disease	Assess current activity (e.g., exacerbation, remission, or relapse) and severity; screen for complications of the disease and its treatments	Organ system focus; thorough assessment of disease-specific signs	Quantitate results using specialty-specific scales
Functionally-focused examination	Evaluate for disability and/or assess for symptom amplification or excessive illness behavior	Do simultaneous physical examination, functional assessment, and observation of patient behavior during the examination	Quantitate physical findings, functional impairments, and symptoms; note inconsistencies

physical signs. The methodology is that of the relevant medical specialty. Further, if the patient is receiving treatments such as immunosuppressive drugs known to predispose to serious adverse effects or complications, the examination might also include screening for such problems. The *fourth type* of examination focuses on *physical function* and is typical of the examinations done for disability evaluation and for assessment of suspected symptom amplification and excessive illness behavior. The examination specifically aims to observe function and to relate physical signs and other measures of disease severity to the symptoms and impairments reported by the patient and to observed performance. Examination methodology draws from several specialties, notably including physical medicine, geriatrics, neurology and orthopedics.

The analysis of physical examinations by type is applicable not only to the examinations conducted personally by medical psychiatrists but also to medical psychiatrists' reviews of the examinations done by other physicians. It aids in recognizing when a particular part of an examination should be repeated or expanded, either by the medical psychiatrist or by another specialist whose examination will be responsive to the issues raised by the medical psychiatrist.

With this background we offer suggestions for the examination that take into account the organ system and the purpose of the examination.

SETTING OF THE EXAMINATION AND DEMOGRAPHICS

Examination findings in hospitalized patients and other acutely ill patients can change from hour to hour, and neurological symptoms, especially mental status findings, can be context-dependent. These considerations are of particular relevance in the assessment of delirium. If it will not be self-evident from the medical record, the examiner should note the time and place of the examination and, if applicable, whether there was anything unusual about environmental conditions, such as an unusually high environmental temperature or a particularly noisy and distracting environment such as that of a busy emergency room or intensive care unit (ICU).

The age and gender of the patient will of course be indicated on every page of the medical record, but it is worth noting whether the patient looks younger or older than his or her chronological age. Many of the diseases and impairments associated with aging correlate more strongly with biological rather than chronological age. While there is a no generally accepted definition for biological age, experienced clinicians usually will agree when a patient looks significantly older or younger than his or her years. The holistic perception of age by clinicians integrates diverse items including rate of movement, mental acuity, skin condition, and oral health. A Danish longitudinal study of 1826 same-sex twins aged 70 or older examined the relationship between age as perceived by assessors of various backgrounds looking at passport-style photographs and a range

of health outcomes including physical function, cognitive function, and mortality; some twin pairs also had analyses of leukocyte telomere length. Perceived age was correlated in the expected direction with all of the health outcomes and was inversely associated with leukocyte telomere length (Christensen et al., 2009). Judgments of apparent age by people without clinical training had nearly as strong an associations with health outcomes as judgments of apparent age by geriatric nurses.

Primary care physicians' judgments of apparent age significantly exceeding chronological age, although relatively insensitive to patients' health status, can be remarkably specific. In a primary care population of patients aged 30–70, Hwang et al. (2011) showed that a physician's judgment of apparent age 5 or more years older than chronological age was 82% specific for poor general health as assessed by the SF-12 questionnaire; apparent age 10 or more years greater than chronological age was 99% specific for poor health.

Note also should be made of the patient's ethnicity, which is not always evident from the patient's surname. Particular nationalities are associated not only with genetic diseases but also with a higher prevalence of cytochrome P450 variants that imply slow or fast metabolism of commonly prescribed psychotropic and general medical drugs, or a greater vulnerability to particular medically serious drug interactions.

GENERAL APPEARANCE, HEIGHT AND WEIGHT

The general appearance of the patient, including how the patient is dressed and groomed, can give important clues to the patient's functional capacities and to whether there is impairment of executive cognitive function due to problems with the frontal lobes and/or their connections. These clues will be absent if the patient has been dressed and groomed by caregivers prior to the examination. Note should be taken of signs of physical abuse; often bruises will be covered by garments, and so the entire skin should be checked at some point in the examination. Muscle bulk should be noted; its significance will depend on demographics. Increased muscle bulk due to athletic activities will be associated with an increased serum creatinine; this can lead to underestimation of renal function if it is not taken into account. Disproportionately increased muscle bulk associated with excessive hair and testicular atrophy raises a suspicion of anabolic steroid use. Diminished muscle bulk has a broad differential diagnosis including deconditioning due to immobility, nerve or muscle disease, and catabolic states such as those due to cancer. In addition, patients with diminished muscle bulk can have a serum creatinine level within normal limits in the presence of moderate renal insufficiency.

The distribution of body fat should be noted. Excess abdominal fat is more strongly correlated with the metabolic syndrome than excess fat in the buttocks, hips, and thighs; a patient with a waist circumference of 40 inches or

more has an increased risk of the metabolic syndrome even if he or she has a normal body mass index (BMI) (Chen et al., 2013). Neck circumference is an independent risk factor for the metabolic syndrome; it is significantly associated even when waist circumference and BMI are taken into account (Zhou et al., 2013). Central obesity with peripheral wasting is typical of hypercortisolism, whether the latter is associated with adrenal hyperplasia or with exogenous corticosteroids.

A medical outpatient's height should be measured on the first encounter and his/her weight measured at the first and subsequent visits. Height should be measured on admission and weight should be measured on a regular basis for patients in hospitals or institutional settings, and the BMI should be calculated and recorded. Changes in weight are of obvious diagnostic relevance and often can be detected earlier with routine weighing than with casual observation alone.

VITAL SIGNS

Vital signs comprise temperature, pulse, blood pressure, and respiratory rate. The measurement of each has nuances that are relevant in medical-psychiatric contexts.

TEMPERATURE

People with depression, apathy, delirium, or subacute cognitive impairment can have systemic diseases—for example, infection, cancer, or autoimmune disease—that are associated with low-grade fever. If the fever is recognized it triggers a medical assessment, and the involvement of the psychiatrist usually is limited to managing symptoms and the psychiatric comorbidities of the medical problem responsible for the fever. However, low-grade fevers can be missed, or erroneously diagnosed, because of errors in the measurement or interpretation of body temperature data. The normal range for mean oral temperature is $98.2 \pm 0.7^{\circ}\text{F}$ ($36.8 \pm 0.4^{\circ}\text{C}$). Axillary temperatures are lower; rectal and tympanic temperatures are higher; the difference in temperature between sites is not consistent either within or between individuals (Sund-Levander & Grodzinski, 2013). Circadian variation in body temperature is approximately 1.4°F (0.77°C) between the daily minimum (typically in the early morning hours) and the daily maximum (typically in the early evening). Twenty-four-hour monitoring of body temperature in hospitalized patients with recent fever showed that 16% had temperatures exceeding 38°C at some point during the day that were not detected by routine monitoring of vital signs (Varela et al., 2011).

Older people tend to have baseline body temperatures toward the lower end of the normal range; those who are obese or who are impaired in cognitive and/or physical function are more likely to have low baseline body temperature (Lu et al., 2009). Physiologic amounts of progestins—whether endogenous or exogenous—raise body temperature by 1.1°F (0.6°C). While it is obvious that hot and cold foods and drinks can influence oral temperature, it is less appreciated that mouth breathing, such as that due to nasal obstruction

or sleep apnea, can reduce oral temperature. In patients who habitually mouth breathe a rectal or tympanic temperature measurement may be more accurate.

A patient with a baseline oral temperature of 97.5°F could be febrile with an oral temperature of 98.9°F taken in the morning. On the other hand, a young woman taking oral contraceptives could have an evening oral temperature of 99.8°F without fever. This is another reason why the time of the physical examination is important to record.

A baseline body temperature usually can be found in a patient's primary care record or hospital chart. A record of the baseline body temperature should be sought when the patient has a high normal temperature and the clinical setting suggests a significant probability of a condition associated with a low-grade fever.

PULSE

In the physician's office and at the bedside, the patient's pulse often is measured by a nurse or medical assistant using the same automated device used to measure blood pressure. However, valuable additional data are obtained by determining the pulse by traditional palpation of an artery. Irregularity of the pulse suggests cardiac arrhythmia; excessive regularity of the pulse, without the expected variation in rate associated with respiration, suggests cardiopulmonary disease. Palpation of the pulse for a full minute is far more sensitive to these abnormalities than the 15-second palpation that is commonly done at the bedside. Changes in pulse with changes in posture—or the lack thereof—give insight into hydration status and autonomic function. When a patient changes from the supine to the standing position there is a transient increase in pulse associated with the transient drop in venous return to the heart. The absence of this increase suggests autonomic dysfunction. A large increase in pulse associated with a drop in blood pressure is seen in dehydration and also in the presence of drugs that cause orthostatic hypotension by alpha-adrenergic antagonism; lower-potency first-generation antipsychotic drugs lower blood pressure by this mechanism. Checking the pulse when the patient is experiencing acute anxiety can identify patients whose anxiety is associated with significant tachycardia. Complete lack of variability of the pulse rate in a patient with tachycardia suggests paroxysmal atrial tachycardia or atrial flutter, which can be either the primary cause of the anxiety or a complication of anxiety related to an anxiety-induced increase in sympathetic tone and decrease in vagal tone. Tachycardia with some variability but not pronounced irregularity is more likely to be sinus tachycardia, and in that case the anxiety is more likely primary and the tachycardia secondary. Tachycardia with an irregularly irregular rhythm most often is due to atrial fibrillation; paroxysmal atrial fibrillation can either trigger anxiety or be triggered by it. In patients with paroxysmal arrhythmias, a careful palpation of the pulse when the patient is symptomatic is diagnostically useful and is feasible not only in inpatient settings but in outpatient settings when there is an observer—potentially a family member—at hand. If the examiner or the patient has one, a mobile phone attachment (e.g., one marketed by AliveCor)

can be used to record a one-lead ECG rhythm strip up to 5 minutes long, sufficient to allow a more confident assessment of the heart rhythm accounting for a rapid or irregular pulse palpated at the bedside.

BLOOD PRESSURE

The accurate measurement of blood pressure is essential to the accurate diagnosis of numerous conditions of medical-psychiatric interest, beginning with hypertension—a widely prevalent condition that is both a risk factor for cardiovascular and cerebrovascular disease and a sign of endocrine disorders or medication side effects. The American Heart Association publishes extremely detailed guidelines for measuring blood pressure; actual practice in clinics deviates from guidelines, yielding different results that often lead to different conclusions about diagnosis and the need for treatment (Pickering et al., 2005; Ray, Nawarskas, & Anderson, 2011; Minor et al., 2012). Because a number of commonly prescribed psychotropic drugs can raise blood pressure, the detection of hypertension can be critical for management of treatment-related cardiovascular risk. A borderline blood pressure on a prior examination deserves follow-up using rigorous methodology. Several points are relevant:

1. The patient's arm should be supported at the level of the patient's right atrium when the blood pressure is taken. This is halfway between the bed or examining table and the sternum if the patient is supine. If the arm is lower, the measured pressure will be higher, and if it is higher, the measured pressure will be lower, by approximately 2 mmHg per inch above or below the ideal level.
2. A cuff of adequate size must be used; given the high prevalence of obesity, many patients will require a "large adult" cuff for an accurate reading. Using a cuff that is too small is a common cause of erroneously high blood pressure measurements. Specifically, if the arm circumference is 35 cm or greater the standard adult size cuff is too small; in this situation a large adult cuff should be used if the arm circumference is between 35 cm and 44 cm, and an adult thigh cuff should be used if the arm circumference is 45 cm or greater.
3. The cuff must be deflated slowly—not faster than 2 mmHg per second. If the cuff is deflated too rapidly the systolic blood pressure will be underestimated and the diastolic blood pressure will be overestimated.
4. Blood pressure is influenced by the patient's position. Diastolic pressure is approximately 5 mmHg higher sitting as opposed to supine; systolic pressure is approximately 8 mmHg higher supine as opposed to standing. Sitting with the back unsupported—as on an examining table—can increase the diastolic pressure by approximately 6 mmHg.
5. Ambulatory patients typically have higher blood pressures when measured by the physician than when

measured by a nurse; the mean difference in one large study was 6.3 mmHg in the systolic pressure and 7.9 mmHg in the diastolic pressure.

6. 24-hour ambulatory blood pressure recording is the most reliable and valid way to determine whether a patient has high blood pressure.
7. Normal blood pressure is lower at night than in the daytime. A nighttime blood pressure of greater than 125 mmHg systolic or 75 mmHg diastolic is abnormal.
8. Orthostatic hypotension, whether due to dehydration, autonomic dysfunction, or an endocrine disorder, can present as anxiety or panic when standing or walking, as phobic avoidance of standing or walking, or as a tendency to fall. This is especially true in older patients with cognitive impairment or in others who cannot precisely describe their problem. Orthostatic hypotension due to dehydration usually is immediate, but orthostatic hypotension due to autonomic dysfunction can be delayed, coming on a few minutes after the patient stands up. If a patient with suspicious symptoms does not show a blood pressure drop immediately on standing up, the blood pressure should be measured again after he or she has been standing for at least five minutes.
9. The standard context for measuring blood pressure in the clinic is after five minutes at rest. Exercise or anxiety can raise the blood pressure, and recovery with relaxation can take a few minutes.

RESPIRATORY RATE

Respiratory rate can be accurately measured by counting breaths over a minute or more; in the authors' experience this is not consistently done by clinicians, despite evidence that in adults an abnormally high respiratory rate (over 20 breaths per minute) is a valid indicator of illness severity and poor prognosis (Cretikos et al., 2008; Bianchi et al., 2013). Periodic breathing—breathing that cyclically oscillates between shallow and deep with a cycle length of 1–2 minutes—should be noted; it can reflect a primary problem either in the cardiovascular system or in the central nervous system (CNS). Its most severe form is Cheyne-Stokes respiration, in which there is actual apnea at the nadir of the cycle. Periodic breathing is worse with exercise in patients with heart failure. In heart failure patients, periodic breathing both correlates with severity of disease and carries independent weight as an indicator of poor prognosis (Dhakal et al., 2012; McGee, 2013).

Patients with recurrent functional hyperventilation—with or without associated panic attacks—do not necessarily have tachypnea; their breathing may be deeper than normal rather than more rapid than normal; this pattern is common in younger patients (Han et al., 1997). Thus, a normal respiratory rate, even during a panic attack, does not rule out episodic functional hyperventilation as the basis of somatic symptoms of anxiety.

SKIN, HAIR, AND NAILS

The critical question concerning skin examination in medical psychiatry is whether the entire skin was examined. Outpatient physical examinations and emergency room triage examinations that do not include a complete examination of the skin can miss valuable and occasionally critical diagnostic information. Many of the systemic diseases that can present with psychiatric symptoms have early dermatologic manifestations; lupus and Addison's disease are two examples. The medical psychiatrist can promote earlier diagnoses of such conditions by suggesting that psychiatric and dermatologic conditions might have a common cause and make (or suggest) a referral to a dermatologist. (For a comprehensive review of the topic see Goldsmith et al., 2012.) Skin diseases, including those that signify systemic diseases, can look different in patients of color (Kelley & Taylor, 2009). For example, while lupus is more common in people of color, the characteristic facial rash is more difficult to see on a dark skin. The skin findings of greatest interest in examining a patient with a psychiatric presentation depend, as usual, on the clinical context and the prevalence of particular diseases in the population from which the patient comes. For example, a subacute mental status change with multiple somatic symptoms would warrant a careful look for a rash in any case, but one might think of Lyme disease in a hiker from New England, lupus in an African-American woman with a positive family history, and syphilis in a sex worker. Hair pulling (trichotillomania) and skin picking (dermatillomania) are impulse-control disorders with a number of associated psychiatric comorbidities including obsessive-compulsive disorder and depression. Hair pulling and skin picking can occur in areas ordinarily covered by clothing. For example, patients may pull underarm hair or pubic hair. Trichotillomania can be distinguished from alopecia areata by testing hair adjacent to the bald area; in trichotillomania this hair has normal resistance to being pulled, while in alopecia areata the hair can be easily pulled out. The differential diagnosis of hair loss is facilitated by trichoscopy, the examination of the scalp and hairs with a surface microscope with 10x to 70x magnification (Pedrosa, Morais, Lisboa, & Azevedo, 2013). "Tele-trichoscopy" would be a consideration for physicians with microscope attachments for their mobile phones; such attachments are widely available with magnification in a suitable range. Patients sometimes use cosmetics, style their hair, or cover their heads in order to conceal areas on the scalp or the face where hair has been pulled out. Concealment measures of this kind will be noted on a careful examination of the integument that considers the possibility.

Skin picking that meets diagnostic criteria for a mental disorder—including subjective distress or functional impairment as well as skin damage not explained by a general medical condition—affects 1%–2% of the general population. Patients with the disorder can pick at the skin virtually anywhere they can reach—so only a complete skin examination can rule out the condition (Grant et al., 2012).

Nail biting (onychophagia) can be distinguished from intrinsic nail disease and, like other self-inflicted dermatologic problems, it should be noted because of its association

with other psychiatric disorders including anxiety disorders, attention deficit-hyperactivity disorder (ADHD), and Tourette syndrome.

In patients with impaired mobility and/or impaired somatic sensation, including frail and debilitated patients with poor nutrition, there is a high risk of skin breakdown in areas subjected to pressure or shearing forces; in patients near the end of life there can be "skin failure," with skin breakdown in the face of trivial and unavoidable stresses to the skin. Patients at risk for skin breakdown should be examined frequently, focusing on areas such as the sacrum, buttocks, and heels that are subject to pressure when the patient lies in bed. Abnormal erythema of the skin often precedes actual breakdown of the skin, though this may be difficult to see in people with dark skins. Abnormal skin temperature—either warmer or cooler than the surrounding skin—is another sign of impending skin breakdown. This phenomenon sometimes can be appreciated on palpation; it can be confirmed using a noncontact infrared thermometer (Sprigle et al., 2001; Rapp et al., 2009). The clinical reality is that pressure ulcers, which can develop literally in hours, frequently are missed by clinicians at their early stages and then present with involvement of subcutaneous tissues or even damage to underlying muscle. One reason they are missed is that the physicians and nurses involved in the patient's care don't examine skin areas at risk with sufficient frequency. When patients are acutely ill, the clinician's focus usually is elsewhere than the skin. The issue of unnoticed skin breakdown can present to medical psychiatrists when they evaluate patients for delirium; if there is a significant area of skin breakdown, the associated inflammation (and often infection) can be a factor that causes or contributes to delirium. Skin breakdown in areas where more attention (e.g., frequent repositioning and pressure-relieving devices) could easily have prevented the problem raises questions of quality of care and/or the appropriateness of the setting of care relative to the patient's vulnerabilities and functional impairments. Several other observations on complete skin examination of special interest to psychiatrists are presented in Table 2.2. In practice, they may not be recorded or even noticed on physical examinations that do not pay special attention to the skin.

Typically the write-up of a general physical examination with no detail about the skin leaves the medical psychiatrist uncertain whether skin conditions of interest were present but not seen, seen and not noted, or simply not looked for. If any of the above diagnostic considerations are applicable to the patient, skin condition is not fully described, and the examiner's usual procedures are not known, the medical psychiatrist must consider recommending (or personally conducting) a new, complete, and hypothesis-driven examination of the skin.

HEAD, EYES, EARS, NOSE, AND THROAT

HEAD

The examination of the head in an adolescent or young adult with a history suggestive of a developmental disorder should include notes on the shape of the head and a measurement of

Table 2.2 SKIN FINDINGS OF MEDICAL-PSYCHIATRIC INTEREST

SKIN CONDITION	PSYCHIATRIC SIGNIFICANCE
“Tracks”	Intravenous drug use
Tattoos, piercings, and other body art	The nature, location, and content of the body art can reveal psychodynamic or psychosexual issues. Poorly implemented body art can raise concerns of infection.
Unexplained (or non-credibly explained) bruises, cuts, scratches or burns, particularly in atypical places for accidental injury	Differential diagnosis includes abuse by a caregiver or intimate, impulsive or deliberate self-injury, and sadomasochistic sexual behavior
Razor cuts on the arms, legs, or trunk	Self-injurious behavior; often associated with borderline personality disorder
Unusually heavy makeup, particularly when visiting a physician	Differential diagnosis includes histrionic personality and efforts to conceal a revealing skin lesion.

head circumference. Specific congenital and developmental conditions are associated with microcephaly, macrocephaly, and/or abnormalities of the shape of the head. Pediatricians routinely note head circumference, but this is not the rule with their nonpediatric colleagues. When a patient has chronic cognitive impairment, either developmental or acquired, and the patient has had a recent change in behavior or mental status, the head should be carefully checked for *signs of trauma*. Signs of head trauma without a credible history to explain them raise the issue of abuse.

EYES

Examination of the eyes offers a window into the body's interior. General ophthalmology texts extensively cover ocular manifestations of systemic diseases (e.g., Friedman et al., 2009). Systemic conditions with psychiatric presentations can have eye signs at presentation; on occasion the eye signs are diagnostic (like Kayser-Fleischer rings in Wilson's disease) or point to a category of disease (like dry eyes in Sjögren's syndrome). Other systemic conditions with prominent psychiatric accompaniments, for example diabetes or lupus, can be complicated by eye involvement that increases the challenge of illness by threatening a loss of vision. A typical general physical examination will look for evident disease of the conjunctiva and sclera, measure the pupils and test them for reactivity to light and accommodation, test extraocular movements, look for cataracts, confirm that the optic nerve head is not swollen, and assess the retina and its blood vessels to the extent that these are visible without dilating the eye. Visual fields, if tested at all, typically will be tested with moving fingers for gross intactness of peripheral vision in four quadrants. This should be done separately for each eye. In the author's experience, visual acuity is not consistently tested.

The hypothesis-driven examination of the eyes has broader scope and addresses specific questions. Visual acuity is tested in good light with a pocket vision screener, with patients wearing glasses or contact lenses if they ordinarily do so to read. Visual acuity of 20/200 or worse in the better eye, with optimal correction of refractive error, is regarded as functional blindness. Patients with poor cognitive function or with poor communication due to psychotic illness can have severe visual impairment but not complain of it. Instead they can display avoidance behaviors, have falls or other accidents, or experience hallucinations and visual misperceptions. Identifying the presence of significant visual impairment leads to ophthalmologic consultation, diagnosis, and intervention. If the patient is unable to participate in bedside visual acuity testing, a visual evoked potential study can be done.

More detailed evaluation of the visual fields is indicated when the clinical history, the mental status examination, or the sensorimotor examination suggests a tumor, stroke, or other focal cerebral lesion. A reasonable bedside evaluation can be done by confrontation testing with the examiner 18–24 inches away from the patient, looking at the patient eye-to-eye, and testing each eye separately. Testing with small finger movements—about 2mm—at the extreme periphery of the visual field, checking both outer quadrants, is a highly sensitive screening test for temporal field defects. Testing with both eyes open the patient's ability to perceive simultaneous movements in the left and the right visual fields screens for extinction, a phenomenon that is a sign of contralateral parietal lobe disease. Extinction is present when the patient can see a stimulus when it is presented alone, but fails to see it when it is presented simultaneously with a stimulus on the opposite side. Confrontation testing with a small object such as the tip of a cotton swab, one eye at a time, can approximately map the visual field and can, in a cooperative patient, measure the patient's blind spots. A red pinhead is more sensitive to subtle defects than a white object. As with the testing of visual acuity, the aim of testing visual fields is to identify defects suggesting primary diseases of the eye or the brain that require diagnostic follow-up, as well as to identify visual problems of significance to the patient's everyday function, safety, and well-being.

A very quick, simple test for gross visual field defects and for the extinction phenomenon is the finger counting test. The examiner tests one eye at a time, having the patient block the other one with his or her hand. The examiner simultaneously presents one or two fingers at the periphery of the right upper quadrant and one or two fingers at the periphery of the left upper quadrant and asks the patient to state the *total* number of fingers the examiner is holding up. The process is repeated with fingers at the periphery of the left lower quadrant and the right lower quadrant. If the patient has a quadrant or more of field defect in either or both eyes, or has extinction in any quadrant, he or she will undercount the sum of fingers. This identifies a potential defect that can be examined further (Anderson et al., 2009).

Evidence of conjunctivitis is obvious when the entire conjunctiva is involved; the condition can be missed or underestimated if there is disproportionate involvement of the

conjunctiva of the eyelids (the palpebral conjunctiva). If the patient complains of a foreign body sensation or of eye irritation, and the conjunctiva are not obviously inflamed, the examiner should flip the eyelid and look at the palpebral conjunctiva.

In the medical-psychiatric context, abnormally small or abnormally large pupils most often are due to the effects of drugs: opiates give small pupils, and anticholinergic and sympathomimetic drugs give large ones. However, some patients with anticholinergic side effects, including many patients of advanced age, do not show widely dilated pupils but instead show medium-sized pupils that are poorly reactive to light and accommodation. Patients with large pupils due to sympathomimetic drugs typically do not show impaired pupillary reactivity. Patients with diseases affecting the optic nerves, such as glaucoma or retinitis pigmentosa, can have impaired function of the afferent limb of the pupillary light reflex (an “afferent pupil”): both pupils react normally to light shined into the unaffected eye while both pupils react slowly, incompletely, or not at all to light shined into the affected eye. A practical bedside procedure for identifying an afferent pupillary defect in the presence of an intact efferent limb of the reflex is the swinging flashlight test. The examiner shines a flashlight into each eye, alternately. When the flashlight shines into the eye with the afferent defect, the pupil dilates since the afferent stimulus from the affected eye is less than the afferent stimulus from the unaffected eye. The defect can be quantitated by determining what density of neutral-density filter placed in front of the better eye will make the test negative. A meta-analysis of studies of pupillary light reflexes in glaucoma diagnosis showed that the swinging flashlight test was highly *specific* for optic nerve disease, though not as *sensitive* as infrared pupillometry (Chang et al., 2013). Patients with autonomic disorders, including those with Parkinson’s disease or Lewy body dementia and also including some adults with autism spectrum disorders, can show pupillary light reflexes that are slow and delayed in onset (Giza et al., 2012). These findings, when present, can help in differential diagnosis.

Screening examination of ocular movements attempts to verify that extraocular movements are full and conjugate. When they are not, there is either a primary problem with the extraocular muscles, a cranial nerve palsy, or dysfunction of the brainstem oculomotor control system. Patients with myasthenia gravis—another condition of medical-psychiatric interest because of its sometimes delayed diagnosis and puzzling symptoms—can have a breakdown of full and conjugate movements on an intermittent basis; in untreated patients, eye movements get worse with fatigue. In patients treated for myasthenia with cholinesterase inhibitors, eye movements will get worse as their drugs wear off. Having a patient with ocular myasthenia open and forcefully close their eyes repeatedly for a minute or more sometimes can elicit weakness in one or more of the ocular muscles. Full and conjugate movements, of course, do not rule out all impairments of oculomotor control. Patients with fully normal oculomotor function are able to shift their gaze from one target to another rapidly and accurately without overshooting or undershooting the target. The inability to generate a targeted eye movement at

all implies significant cerebral dysfunction. Recurrent overshooting or undershooting the target—ocular dysmetria—indicates impaired function of the cerebellar motor control system. The most common neurological conditions in which ocular dysmetria is encountered are multiple sclerosis and cerebellar stroke, particularly a stroke due to occlusion of the posterior inferior cerebellar artery (Grimaldi & Manto, 2012). Eye movements are discussed further below in connection with the examination of the cranial nerves.

EARS

Physical examination of the ears might reveal impacted ear wax, important as an indicator of neglect or self-neglect as well as an explanation for communication problems. The eardrums once visualized might show evidence of prior trauma or infections. Most important from the medical psychiatric standpoint is the ears’ functional performance in hearing and balance.

Hearing loss of over 25 dB (mild loss) if the speech frequencies are involved and, even more, any hearing loss of over 40 dB (moderate to severe loss) can impair communication and social functioning and can worsen the functional consequences of cognitive impairments. Functionally significant hearing loss has greater than 40% prevalence in the population over 65 (Gates & Mills, 2005) and a similarly high prevalence among younger people with excessive noise exposure. The latter include people who regularly listen to loud music and those who work in noisy environments or use noisy machines without wearing ear protection. Because of the stigma associated with hearing loss and with wearing hearing aids, many patients do not complain of their hearing loss. Screening at the bedside is simple, but, as with other elements of the physical examination, the medical psychiatrist should know—either from the documentation or from personal knowledge of the examiner’s practice—how the examiner did the screening. Two well-validated bedside tests of hearing are the rubbing finger test (hearing two fingers rubbed together 6 inches away from each ear) and correctly repeating a sequence of three digits whispered two feet away from each ear (Chou et al., 2011). The tests have similar sensitivity and specificity for detecting hearing loss of 30 dB or more; repeating digits is sensitive to impaired speech discrimination as well as pure tone loss in the speech frequencies. Selective low-frequency or high-frequency hearing loss will not be detected by these screening procedures, but it may be relevant to auditory symptoms like tinnitus. Quantitative screening of hearing loss between 500 Hz and 4000 Hz is feasible with a bedside otoscope/audiometer (e.g., the Welch-Allyn AudioScope®); evaluating hearing loss outside that range requires formal audiometry.

Perception of an auditory signal conducted through the air versus through the bone is tested using a 512Hz tuning fork and comparing the hearing threshold when the tuning fork is held a few inches from the ear with that when it is held against the mastoid process. Normally the sound will be louder when presented to the ear than to the bone, because the former presentation takes advantage of the amplification of sound by the middle ear. Reversal of the normal pattern implies middle ear

disease such as otosclerosis or a perforated eardrum, or blockage of the ear canal. Comparing air with bone conduction using a 128Hz tuning fork (the kind used to test vibration sense) can give a false-positive result; low frequencies are conducted better by bone and are amplified less by the middle ear than are higher frequencies. Testing of vestibular function is addressed in the section on the neurological examination.

NOSE

Examination of the nose focuses on allergic rhinitis and nasal obstruction. Nasal allergy often is associated with other allergic phenomena including asthma, and nasal obstruction leads to snoring and mouth breathing and sometimes to obstructive sleep apnea. Swollen, boggy mucosa over the turbinate cartilage is a characteristic sign, which can be seen with or without erythema. Damage to the nasal septum from cocaine or other snorted drugs of abuse should be looked for in appropriate contexts, though it is not necessarily seen on a general physical examination even when it is present on a specialist examination because the damage may be further up the nose than can be seen with an otoscope speculum. Testing of the sense of smell, discussed further below, has a role in the assessment of traumatic brain injury, dementia, limbic epilepsy, and multiple sclerosis, and in the assessment of nasal damage due to snorted drugs of abuse.

MOUTH

The mouth warrants a systematic look for signs of oral cancer and precancerous changes in patients who smoke; those patients' risk is even higher if they also abuse alcohol. The oral cancer examination includes grasping the tongue with a gloved hand or piece of gauze and flipping the tongue over to see its underside and the floor of the mouth. This step, routine in the dentist's office, often is omitted on physicians' screening physical examinations. Loss of lingual papillae is associated with vitamin deficiency. The mouth is a usual site of candidiasis and other mycotic infections in immunosuppressed patients. Oral mycoses can take a variety of forms; acute candidiasis can be erythematous or pseudomembranous; chronic candidiasis can present as leukoplakia, a hyperplastic condition (Muzyka & Epifanio, 2013). Patients with serious systemic illness may not complain of symptoms when they have oral candidiasis, especially when there is impairment of cognition or communication; the condition manifests instead with diminished oral intake. Also, the brunt of the condition may be in the inferior pharynx so that a cursory look in the oral cavity may miss it. Nonspecialists usually do not carry mirrors or fiberoptic devices for fully visualizing the pharynx; what is important is considering when the condition is likely in a given context of disease, drug therapy, and symptoms, and knowing that looking in the mouth and only the part of the throat that is visible without aids can lead to a false negative.

The condition of the teeth and gums tends to be mentioned in passing if at all, unless the patient has a gross problem like a dental abscess or multiple missing teeth. If problems typically in the domain of dentistry are not mentioned in

the report of a physical examination, it does not mean they were not present. The common lack of attention to dental and periodontal status is unfortunate, because periodontal disease is endemic worldwide and has both general medical and neuropsychiatric implications. Periodontal disease can (1) cause a systemic inflammatory state, (2) increase blood levels of C-reactive protein, and (3) increase the risk of coronary artery disease. The increase in proinflammatory cytokines associated with periodontal disease can contribute to neuropsychiatric symptoms including depression and apathy (Kronfol & Remick, 2000; Van Dyke, 2008). There is a reciprocal relationship as well: depression worsens the prognosis and treatment outcome of periodontal disease (Rosania et al., 2009). When a patient has significant periodontal disease on a screening examination assessment, the medical psychiatrist often can find valuable information by asking whether the patient is aware of it and if so, what if anything is being done about it. Lack of awareness and/or lack of apparent concern about obvious gum disease can be evidence of apathy, denial of illness, dental phobia, or problems accessing or paying for dental care.

Halitosis—clinically significant “bad breath”—is a condition that affects approximately 25% of the world's population. It has implications for patients' social and marital interactions, and ultimately for their self-confidence and self-esteem. Even patients who are generally self-aware may be unaware of their halitosis, especially if they live alone. However, lack of awareness of *severe* halitosis can be clue to defects in self-awareness and self-monitoring.

The differential diagnosis of halitosis is of medical-psychiatric interest. Approximately 85% of cases are of oral origin—due to periodontal disease and/or to coating of the posterior tongue by a film rich in anaerobic bacteria. In about 10% the foul odor originates from the nose or the oropharynx (e.g., from rhinosinusitis or tonsillitis), and in the remaining 5% the source is gastrointestinal or systemic. Of the latter type, fruity odors due to diabetes probably are the most common; end-stage liver failure and end-stage kidney failure also have characteristic odors. Halitosis due to systemic conditions or nasal conditions can be differentiated from the more usual oral cases because they give a foul odor to breath expired through the nose; the latter cause a foul odor from the mouth only.

Halitosis is common in patients with mouth breathing because it is made worse by a dry mouth; thus it is associated with sleep apnea. It is exacerbated by drugs with anticholinergic effects because the latter inhibit saliva production (Bollen & Beikler, 2012).

NECK AND SPINE

The ability to feel the contents of the neck depends in part on its size and shape. It is easier to palpate a thyroid gland, appreciate the filling of neck veins, or hear a carotid bruit in a long and thin neck. When the patient has a short thick neck, the absence of a sign on neck examination related to the thyroid, vascular system, or lymph nodes is more likely to be a false

negative. In addition, patients with short thick necks are more likely to have obstructive sleep apnea, and, as noted above, abnormally high neck circumference is a risk factor for the metabolic syndrome that adds incrementally to the risk associated with increased waist circumference and elevated BMI.

Careful auscultation for carotid bruits—at multiple locations along the carotid arteries—is worthwhile in patients at high risk for atherosclerosis affecting large blood vessels. While carotid bruits are not always present in patients with large vessel disease, there are few false positives.

The neck is a good place to check for rigidity in patients who may have extrapyramidal motor disease or extrapyramidal side effects of psychotropic drugs. Neck rigidity can be unequivocal in patients who lack “cogwheel rigidity” of the upper extremities. Evaluation of the passive range of motion of the neck can show limitations related to degenerative disease of the cervical spine—a highly prevalent condition in later life that can be associated with cervical radiculopathy (and often neck or arm pain) as well as with impairment in gait and balance due chronic spinal cord impingement.

The spine examination is of evident relevance to understanding back pain, the most common type of disabling chronic pain of benign cause. Generalized spasm of the lumbar paravertebral muscles can be seen with back pain regardless of its cause; but localized, unilateral, segmental spasm of lumbar muscles points to impingement on the corresponding lumbar nerve roots, or pain in a body part innervated by those nerve roots. When there is disease of the vertebrae themselves, for example, from bony metastases or from osteoporosis of the spine with compression fractures, palpation or general percussion of the spinous processes in the midline can show localized tenderness. If vertebrae have collapsed, the spinous processes will be unusually close together, and review of long-term medical records may show that the patient has lost height.

Posture should be noted; abnormal posture can be the cause of muscle strain, and it can be a characteristic sign of a disease. Patients with Parkinson’s disease are stooped; those with progressive supranuclear palsy stand erect. Significant scoliosis in a young or middle-aged adult typically is due to a neurodevelopmental problem, and the presence of one such problem increases the likelihood of another one—making it more likely that there will be data in the developmental and educational history potentially relevant to a presenting psychiatric issue.

CHEST

In the medical-psychiatric context the most common reasons for examination of the chest are (1) as part of a general screen for systemic diseases that can affect mood or cognition, (2) to understand the cause of shortness of breath, and (3) to assess the severity of a known pulmonary disease. The question often arises whether an individual’s disease-related emotional distress and his or her impairments in physical, social, and/or occupational function are commensurate with the objective

severity of pulmonary disease. When symptoms or disabilities are disproportionate to findings on pulmonary examination it suggests that psychiatric or non-pulmonary medical comorbidities are contributing to the distress and dysfunction.

Dyspnea is of particular interest to medical psychiatrists because of its circular relationship with anxiety. Dyspnea often is the most distressing symptom experienced by a patient with heart or lung disease, and its presence can trigger anxiety even when the patient knows its cause and is not worried about it. Anxiety attacks, regardless of their cause, can present with subjective shortness of breath and/or with sighing or hyperventilation. Frequent sighing and greater reliance for breathing on the chest wall muscles rather than the diaphragm suggest that anxiety is contributing to tachypnea and/or dyspnea, in the absence of disease that directly affects the muscular function or the range of motion of the diaphragm. A contribution from anxiety does not, of course, rule out the simultaneous presence of pulmonary disease, since both dyspnea and the lack of oxygen can induce anxiety.

The chest examination should include observation of the qualitative aspects of respiration, particularly in patients who suffer from anxiety, dyspnea, or both. These qualitative aspects include the apparent effort the patient makes to breathe, retractions of the intercostal muscles, changes in position the patient makes to improve breathing, and the relative involvement of the chest wall muscles in comparison with the diaphragm in respiration.

When observing the patient’s breathing and counting respirations, sighing should be noted. Sighing in a social context typically implies frustration or boredom, while private sighing is more often associated with sadness (Teigen, 2008). Deep sighing is strongly correlated with depression in patients with chronic disease, as was shown rigorously in a recent study of patients with rheumatoid arthritis (Robbins et al., 2011). When dyspnea is associated with frequent sighing, it is likely that anxiety contributes to the subjective perception of dyspnea and that relief of anxiety will at least partially relieve the dyspnea.

Recurrent attacks of dyspnea in a person without known or apparent lung disease raises the issue of panic attacks with prominent respiratory symptoms or of a functional hyperventilation syndrome. However, the differential diagnosis also includes recurrent small pulmonary emboli. In that condition a meticulous examination of the chest, listening systematically in many locations, sometimes reveals friction rubs or other abnormal breath sounds, *if the examination is done when the patient has recently become short of breath*. A standard auscultation of the chest when the patient is not symptomatic is unlikely to be positive. When chest examination findings together with the patient’s history suggest the diagnosis of recurrent pulmonary embolism, the medical psychiatrist’s response will depend on the context of his or her practice. In some contexts the medical psychiatrist will directly order a timely lung scan; in others the order must come from the patient’s primary care doctor or general medical specialist. When the psychiatrist communicates with a general medical physician, mentioning a localized friction rub or abnormal

breath sounds can facilitate the latter's consideration of the diagnosis and willingness to order an imaging procedure to confirm it or rule it out. Mentioning that a patient does not have prominent anxiety despite significant dyspnea can similarly motivate a more intensive evaluation by the general medical physician.

HEART

As diagnostic technology for evaluating cardiac disease has advanced, the diagnostic importance of physical examination of the heart has diminished. Nonetheless, by finding abnormalities on physical examination of the heart, the medical psychiatrist can motivate a further evaluation of cardiac disease by laboratory, physiological, or imaging procedures, and can prompt reconsideration of heart disease by a cardiologist or general medical physician who has seen the patient in the past. Further, by recognizing the limitations of physical examination of the heart, medical psychiatrists can better appreciate what cardiac conditions might still be present in a psychiatric patient who has been "medically cleared" utilizing a routine physical examination and a non individualized battery of laboratory tests.

The limitations of physical examination of the heart are greater in obese patients. The accumulation of fat in the chest wall attenuates abnormal heart sounds and also makes it harder to estimate the size of the heart by percussion.

A full cardiac examination includes an assessment of the size of the heart by percussion (if feasible given the patient's anatomy), palpation of the cardiac impulse at the apex, and auscultation at the base of the heart and the apex of the heart, in the sitting and supine positions—and in some contexts with the patient lying on the left side—both at rest and after vigorous exercise. Auscultation around the entire area of the heart would be added if pericarditis were under consideration. Attention is paid to the splitting of the second heart sound and the variation of the two components of the second heart sound with respiration, whether there is a third and/or fourth heart sound, and whether there are murmurs, clicks, or friction rubs. Murmurs are characterized by their amplitude, pitch, location, variation in amplitude with body position and with exercise, and whether they are constant throughout systole or diastole or rapidly diminish in amplitude.

The cardiac component of a typical physical examination—even one by an internist or cardiologist—typically includes a proper subset of the above observations, although the written record examination typically does characterize any abnormal sounds that were heard. In reviewing the record of a physical examination of the heart, the medical psychiatrist should consider whether some part of the ideal full examination was omitted and whether the missing part would be specifically relevant to a current diagnostic hypothesis. If medical psychiatrists do their own examinations, the scope and focus should be hypothesis-driven—for example, when the hypothesis is one of heart failure, they should listen carefully for a third heart sound and examine

the patient lying down and after exercise. The interpretation of examination findings should consider whether they are inconclusive or potentially falsely negative for the suspected condition. The documentation of the hypothesis, the physical findings, and their interpretation, all are useful in communicating diagnostic concerns to a primary care physician or cardiologist and in prompting more conclusive diagnostic studies.

When a chronically ill patient has heart failure among his or her diagnoses, it may be known to—or at least knowable by—the medical psychiatrist how the findings on physical examination of the patient's heart differ when the heart failure is optimally compensated and when it is decompensated. While physical signs elsewhere in the body, such as those of pulmonary edema or venous congestion, might also be present when the heart failure is decompensated, there may be consistent cardiac findings such as a loud third heart sound or a palpably enlarged heart. If the medical psychiatrist knows, from the medical record or from discussion with the primary care physician or cardiologist, the patient's personal "signature" of heart failure, the psychiatrist can utilize this perspective to improve his or her assessment if the particular patient shows an acute change in mental status or loss of function. A brief cardiac examination focusing on the patient-specific signs will suggest whether a change in mood, cognition, behavior, or physical functioning is likely to be associated with worsening heart failure.

The limitations of the bedside cardiac examination can be reduced greatly with technology. Electronic stethoscopes that both amplify and record heart sounds bring consistency to the description of murmurs; applications are available for mobile devices that offer graphical representation of heart sounds that can be transmitted online to a consultant. Point-of-care pocket-sized ultrasound devices enable even internal medicine residents with only 2 or 3 hours of training to make highly specific diagnoses of left ventricular dysfunction or pericardial effusion (Alexander et al., 2004; Ruddox et al., 2013).

ABDOMEN

The main issue for medical psychiatrists on the abdominal examination is the problem of false negatives. It is unlikely that a finding of an acute abdomen will turn out to be a false positive; specialist examination and diagnostic procedures will virtually always make possible a specific diagnosis. An optimal abdominal examination—something that can be impossible if the patient has significant abdominal obesity or if a patient is delirious and agitated—would provide information on:

1. The presence or absence of peritonitis and, if present, whether it is localized or generalized;
2. The presence or absence of ascites, and, if present, the amount
3. The approximate size of the liver, whether the liver is tender, and whether the liver is unusually hard or soft

4. Whether the spleen is enlarged
5. Whether there is an abdominal aortic aneurysm
6. Whether there are normal bowel sounds
7. Whether there are any abnormal masses or areas of localized tenderness
8. Whether there are any hernias or defects in the abdominal wall
9. Whether there is lower abdominal fullness suggesting fecal impaction

When a patient is cooperative and sufficiently thin, it is possible for an experienced examiner to provide this information. If the patient's behavior, body type, or corpulence prevents a confident answer in any of these areas and the patient is acutely ill, the physician typically must resort to laboratory tests and diagnostic imaging to settle any outstanding questions. The medical psychiatrist, reviewing the findings of the physical examination of the abdomen in a chronically ill patient, can identify what is not known by keeping in mind the limitations of the abdominal examination as performed and recorded. Together with diagnostic hypotheses, this guides the orders for further investigations and/or the communication with the general medical physician(s) involved.

When the patient has a relapsing-remitting or fluctuating gastrointestinal condition with known and variable physical signs, a targeted abdominal examination by the medical psychiatrist can help establish the contribution of the medical condition to an acute change in mental status. For example, in an institutionalized patient with moderate dementia and a tendency toward fecal impaction, discovery on examination that the patient's lower abdomen feels full but soft—as it did the last time the patient had fecal impaction—would identify fecal impaction as a likely cause of an acute agitated delirium superimposed on the dementia. Or, in a patient receiving palliative chemotherapy for widely disseminated ovarian cancer, the examination finding of a reaccumulation of ascites might help link an increase in depressed mood and pain complaints to progression of the cancer rather than to an emotional reaction to the cancer diagnosis.

On occasion, the medical psychiatrist will attend to an abdominal sign that is particularly meaningful in the medical-psychiatric context. An borderline-enlarged spleen can prompt a more thorough search for chronic low-grade infection or autoimmune disease in a patient with a syndrome of chronic fatigue thought most likely to reflect a somatoform disorder. A small, hard liver typical of alcoholic cirrhosis can encourage the medical psychiatrist to further question the validity of a patient's denial of a drinking problem, and to order or suggest additional diagnostic tests such as a coagulation panel, an ammonia level, or an abdominal ultrasound. Further, the physical finding of a grossly abnormal liver might be mentioned to a patient and family when confronting a denial of alcoholism.

PELVIS AND GENITALS

The examination of the pelvis in women, and of the external genitalia in patients of either gender, usually is not done directly by the medical psychiatrist because of concerns about perceived boundary violations. This can create a problem, however, if the general medical physician responsible for “medical clearance” has omitted or deferred the physical examination of the pelvis and genitals. Patients presenting with recent-onset medical–psychiatric issues, such as depression or anxiety with prominent somatic symptoms, need thorough evaluation for infectious diseases and for cancer, and there are both common infections and common neoplasms that affect the reproductive system. Some specific conditions that can be diagnosed by physical examination and have important medical-psychiatric dimensions include polycystic ovary syndrome, ovarian cancer, pelvic inflammatory disease, testicular cancer, and testicular atrophy due to anabolic steroid abuse; in addition, several common sexually-transmitted diseases (STDs) have characteristic physical findings on genital examination. Thus an essential point for the medical psychiatrist is that someone should examine the reproductive system in connection with the current evaluation if it hasn't been done recently and at a time when the patient was symptomatic.

The qualitative dimension of the pelvic examination is valuable information not necessarily recorded in the medical record but potentially available through the medical psychiatrist's directly communication with the examiner. The medical psychiatrist should consider inquiring in greater detail about a female patient's history of sexual and intimate relationships if it is known that she had intense discomfort during the pelvic examination or had an intense emotional reaction to the examination. In this situation there could be a history of trauma or abuse, or the patient might suffer from a primary gynecologic condition that causes significant dyspareunia that is secondarily affecting sexual relationships, marital satisfaction, and/or self-esteem.

ANORECTAL REGION

The same considerations about potential boundary issues and the risk of missing important diagnoses apply to the examination of the perianal skin and to the digital rectal examination (DRE), and they are applicable to general medical physicians, many of whom omit the DRE when they do general physical examinations because of concerns about patients' modesty or a feeling that the DRE is too invasive for a routine examination (Wong et al., 2012). Medical psychiatrists will at times encounter patients who have not had a DRE even when they saw a general medical physician for a condition such as chronic constipation for which a DRE would obviously be informative.

Diagnoses that are potentially detectable on DRE include prostatic hyperplasia, prostate cancer, and rectal cancer; hemorrhoids, anal fissures, perianal abscesses, anal cancer, and other anal pathology; and fecal impaction. In female patients DRE can aid in the diagnosis of pelvic inflammatory disease.

Of particular medical-psychiatric interest is the sensitivity of the DRE to disorders of anal sphincter control and to pelvic floor dysfunction. Abnormally low anal sphincter tone suggests autonomic neuropathy or sacral cord injury. A missing anal wink reflex suggests sensory or autonomic neuropathy. Pelvic floor dyssynergia is a major cause of chronic constipation that responds in the majority of cases to biofeedback training, eliminating the need for long-term laxative use.

A complete DRE comprises the following 10 steps (Talley, 2008): (1) reassuring the patient and explaining the purpose of the examination; (2) positioning the patient in the left lateral decubitus position; (3) inspecting the perineum; (4) asking the patient to strain while watching the perineum; (5) testing the anal wink reflex; (6) beginning palpation of the anus itself to assess tenderness and prompt relaxation of the sphincter; (7) assessing resting sphincter tone; (8) palpating the rectal walls, including palpation of the prostate gland through the anterior wall; (9) evaluating pelvic floor function; and (10) removing the finger and examining the feces for blood, pus, or mucus. To evaluate pelvic floor function the examiner asks the patient to strain and push the examiner's finger out; when function is normal the anal sphincter relaxes and the perineum descends by 1 cm to 3.5 cm. Nondescent of the perineum coupled with external anal sphincter contraction implies pelvic floor dyssynergia. The patient is then asked to squeeze the examiner's finger. If the pelvic muscles and anal sphincter are functioning properly the finger will be squeezed and lifted toward the umbilicus. This tests the muscle functions needed to ensure fecal continence.

In patients with delirium or dementia with agitation, the diagnosis of acute anal disease may explain a recent change in mental status. In cognitively intact patients with chronic mental illness and no constipation or specific anal or pelvic complaint, the main function of DRE is screening for prostate cancer and colorectal cancer. While DRE is underutilized as a tool for identifying dysfunction of the anal sphincter and pelvic floor, the historical emphasis on the DRE in prostate cancer screening has not been supported by rigorous studies. DRE identifies few prostate cancers that have not already caused elevated levels of prostate-specific antigen. Those that are found by DRE alone are not necessarily aggressive ones, and there is no convincing evidence that finding prostate cancers on DRE (or on PSA screening) reduces prostate cancer mortality (Ilic et al., 2013). As to screening for colon cancer, fecal occult blood testing is less sensitive than colonoscopy, and testing for blood at the time of a DRE is less sensitive than testing spontaneously passed stool. In particular, bleeding from an advanced premalignant lesion is more likely to be detected by testing of spontaneously passed stool (Ashraf et al., 2012). Notwithstanding, testing stool from a DRE is better than no testing at all, so it should be considered when examining patients unlikely to comply with home-based stool collection or to have a screening colonoscopy. As with women and pelvic examination, when a man shows unusual discomfort or emotional distress related to a rectal examination it raises the issue of history of sexual trauma or physical abuse—a topic to be explored sensitively at an appropriate time. There may be relevance to ongoing intimate relationships when the patient is a man who has sex with other men.

Finally, as noted in the discussion of the abdominal examination, fecal impaction sometimes is the explanation for acute changes in behavior or mental status in institutionalized, cognitively impaired patients. Rectal examination can be the key to this diagnosis in some cases, though when the impaction is higher in the colon an imaging procedure—sometimes just a plain abdominal X-ray—will confirm the diagnosis even though the rectal examination is negative.

NEUROLOGICAL EXAMINATION

There are three overlapping purposes of the neurological examination: (1) to detect deviations from normal function, (2) to test hypotheses about the systems or anatomic loci responsible for the deviation from normal function, and (3) to measure the severity of dysfunction. Most of the neurological examination involves stimulating the patient in some way and observing a response. An absent or abnormal response can result from impaired perception of the stimulus, failed execution of a response, or ineffective linkage between the perception of the stimulus and execution of the response. A neurological examination can be incomplete for diagnostic purposes when it fails to detect dysfunction that is present, when it does not convincingly rule out dysfunction that is not present, or when it gathers insufficient data to explain whether the problem is with perception, execution of the response, the connection between the two, or some combination.

NEUROLOGICAL MENTAL STATUS EXAMINATION

In contrast to the psychiatric mental status examination, which aims to detect and characterize disorders of mood, thought process and content, and behavior, the neurological mental status examination focuses on detection and characterization of disorders of the level of consciousness, cognition (including attention and orientation, memory, language, and learned cognitive skills such as calculation), perception, executive function, and praxis (execution of skilled motor performances). The neurological mental status examinations performed in general medical contexts for screening purposes typically are brief and limited, leaving several domains of mental status unexamined. The medical psychiatrist's neurological mental status examination should be broader in scope; but to be practical, it must be focused and hypothesis-driven. Hypotheses are suggested by some combination of the history, findings on the general physical and neurological examination, laboratory and/or imaging abnormalities, and demographic and environmental circumstances such as coming from an area in which an infectious disease that frequently causes brain dysfunction is endemic. In bedside or office assessment for the presence of cognitive or perceptual dysfunction, the critical concern is test *sensitivity*. The two most common reasons for insensitivity of such assessments are that (1) functions that ought to be evaluated are not tested at all, and (2) the items covering an area of function are too easy to detect

abnormality in patients with high baseline function and/or mild impairment. An example of the former is not testing visual memory in a patient with temporal lobe lesion of the right hemisphere; an example of the latter is testing memory in an alcoholic practicing lawyer by asking him to recall three common words after three minutes.

Both types of test insensitivity can be avoided by beginning with a hypothesis about how a specific impairment would be likely to affect the specific patient. In tests to *characterize* or *measure the severity* of a cognitive or perceptual impairment, the clinician should aim for a level of difficulty that will put the patient's performance in the middle of the range, avoiding both the "floor" and the "ceiling." The components of the neurological mental status examination are now discussed in detail.

General Behavior

The patient's comportment, attention to the examiner's questions, effort devoted to answering them, and response to potential distractions in the environment should be described unless they are normal throughout the entire examination. Lack of engagement in the examination, if not obviously reflecting conscious or intentional refusal to be examined, can be a sign of a diminished or fluctuating level of consciousness, impaired executive function, or apathy. A lack of persistence in answering questions can indicate impaired attention. Distraction during the examination by ordinary environmental stimuli (e.g., a nurse walking past on her way to another patient) can be a sign of impaired attention or impaired executive function. Undue silliness and jocularity during the examination is usually due to defective inhibition, a form of executive impairment.

Orientation and Attention

The phenomenon of orientation is related to level of consciousness, perception of the environment, and memory; being oriented is expressed by behavior as well as by the spoken word. A hospitalized patient calling the nurse "waiter" and demanding that the dinner menu be brought at 3:00 a.m. is disoriented in a different way than one who behaves appropriately and knows the day, time, and name of the hospital but doesn't know what county the hospital is in. Orientation to place is indicated in one way by behavior typical of being in that place; in another way it is indicated by verbalization of the location's complete address. The latter depends on memory and language in addition to knowing where one is. Orientation to day and time similarly is expressed both by behavior and by verbalizations, the latter dependent partially on memory and language. Disoriented behavior is common in delirium and in the later stages of dementia; patients with mild cognitive impairment might misstate the date but behave in a way that shows awareness of the season, day versus night, and so on.

A severely inattentive person would be unable to focus on the task of a formal mental status examination and be unable to consistently answer the examiner's questions.

The record of the examination should cite an example of the patient's distractibility and/or lack of persistence. Less severe impairment in attention often can be demonstrated by having a patient count backwards from 20 to 1, recite the months of the year in reverse, or repeatedly take 7 or 3 from 100. Doing the second task requires sufficient language function to retrieve the names of the months; doing the third task requires basic ability to calculate. The indicator of impaired attention is the inability to complete the task even if it is begun correctly. A typical way for a patient to fail the months in reverse task is to get part way through the months and then complete the task by naming the months in forward order.

Another option for bedside testing of attention is having the patient alternate numbers and letters, for example, 1-A-2-B-3-C, and so on. If the patient's attention wanders, he or she may continue the task by simply counting or reciting the alphabet. The requirement for maintaining mental set is greater for the alternating condition than for a simple count. For patients unable to talk, a similar test of attention would be asking them to tap an alternating rhythm with their fingers: one tap, two taps, one tap, two taps, and so on. An inattentive patient would be likely either to stop tapping or to tap without alternating.

Visual attention can be impaired when simple attention is intact. Since visual attention is critical to driving or operating dangerous machinery, it is an important function to test when the examiner might be asked to comment on the patient's ability to drive or to return to work. A simple bedside task is to give the patient a sheet of paper full of randomly oriented and randomly spaced letters and numbers, and to ask them to cross out a defined subset of them—for example the even numbers and the vowels. A specific problem with visual attention is suggested if the patient misses the targets in one half or one quadrant of the page, or if targets are missed that are oriented in a particular direction. When visual fields are tested by confrontation, visual inattention might be shown by the patient's missing some but not all small finger movements at the periphery of vision but not larger movements or larger static objects. The fact that the stimulus is seen some of the time rules out a gross visual field defect.

Auditory attention can be tested by presenting a series of numbers and asking the patient to signal when he or she hears an odd number or hears one specific number. Or, a patient can be presented with a series of tones that may be either high or low and asked to signal when he or she hears a high tone but not a low one.

People with more severe general impairments of attention will have trouble with both tests of visual and of auditory attention; people with milder impairments may show problems with one sensory modality or type of task but not with another. When the purpose of the examination is to show that attention is not intact, any unequivocally abnormal test result will suffice. Giving several tests of different types makes sense when the goal is to determine the scope and severity of impairment or to identify areas in which function is relatively preserved.

Memory

When the objective in memory testing is to identify delirium or dementia—the latter as a syndrome diagnosis as distinct from the diagnosis of a neurodegenerative disease that will eventually produce the syndrome of dementia—the typical procedure of testing recall of three or four unrelated words after a five minute delay usually is sufficient. Memory testing as part of the clinical neurological examination acquires subtlety when the question is one of memory loss *from the patient's baseline*, or when the disease or condition suspected can have differential effects on a particular kind of memory such as visual memory or memory for spoken as opposed to written language. The medical psychiatrist who evaluates previously obtained information on the patient's memory must determine what exactly was tested, decide whether the testing was sufficient to address the current hypothesis, and consider whether the patient's memory performance might be different now from what it was when last tested by a prior clinician.

A cognitively intact, literate adult should be able to accurately repeat four unrelated words after the words are presented no more than three times; once they have been accurately repeated (registered) the patient should be able to recall, after a few minutes, at least three of the four words without aid, and the fourth with a cue (e.g., the first letter of the word or the category to which the word belongs). If the patient cannot register the words, there is likely a problem with motivation or cooperation, attention, or language. If the patient cannot recall even three of four correctly registered words without aid but can recall all four with cues or with multiple choice, there is a memory problem that involves the recall process but does not involve complete forgetting of the material. Verbal memory deficits that disappear with cueing and/or multiple choice questions are likely to involve problems with executive function (frontal lobes and their connections) and/or with language (e.g., word-finding problems). Complete forgetting of material that was accurately registered suggests dysfunction of the primary memory circuits that comprise the hippocampus, medial thalamus, and mammillary bodies and their connections. Regardless of the specific memory test done or the modality of presentation, comparison of registration (repetition), free (unaided) recall, and cued recall helps to identify the nature of memory loss when it is present.

For detecting subtle deficits or mild impairment in individuals with high premorbid functioning, two alternative bedside tests of verbal memory should be considered. These are more difficult than recalling four unrelated words yet not too difficult for a literate adult of normal intelligence, even one with limited formal education. The first is the two-sentence logical memory test. The patient is given two unrelated sentences to remember, and is asked to recall as many details of each as possible, without mixing them up. The two sentences are presented three times, stopping after the first or second trial if the patient recalls the sentences perfectly. Then, after a few minutes of intervening activity—for example, testing other cognitive functions—the patient is asked to recall the details of the first sentence and then the details of the second one. If the first sentence has five details and the second has

eight, a normal adult will be able to recall at least 10 of the 13 details by the third try, and will be able to keep the sentences separate. On recall five minutes later, the patient should lose no more than two of the details that were recalled on the last attempted repetition of the sentences.

For example, the first sentence is "A hunter killed a wolf at the edge of the forest," and the second is "In an orchard, behind a tall fence, there were trees with many ripe apples." The five details from the first sentence would be hunter, killed, wolf, edge, and forest, and the eight details from the second sentence would be orchard, behind, tall, fence, trees, many, ripe, and apples.

If the two-sentence memory test does not show definite abnormality, but a deficit in verbal memory is suspected from the patient's history or other clinical data, the possibility of a verbal memory deficit can be further investigated with a six-item paired associate learning task. Here the patient is presented with six pairs of words—five of which are not obviously associated with each other. For example, the six pairs might be rain–clouds, hammer–stairs, up–left, shoe–right, blanket–car, wood–dress. The examiner then presents the first word in each of the six pairs and asks the patient to recall the second. The word pairs are presented up to three times with the words presented in the recall condition in a different order each time; if the patient gets all six pairs correct on the first or second try, the pairs are not presented again. If the patient is able to learn at least four of the six pairs by the third try, recall is tested one more time after a few minutes with an intervening distraction. An adult of normal intelligence without a verbal memory deficit should be able to learn at least five of the six pairs by the third try and should lose no more than one of the associations after a five minute interval with an intervening distraction. When the two-sentence memory test and the six paired associates were used to test verbal memory as part of a 20-minute high-sensitivity bedside cognitive screening test, qualitative judgments of the nature and severity of memory impairment from the bedside assessment were highly correlated with those based on comprehensive neuropsychological testing (Faust & Fogel, 1989). Patients with hearing loss or with central auditory processing problems may require words to be presented in writing rather than spoken. Patients with impaired speech but intact writing should be asked to perform memory tasks in writing. Those with impairments of expressive language can be asked to point to pictures of items to be recalled. A neuropsychologist or behavioral neurologist can assist with the distinction of memory deficits from other types of cognitive impairments when there are multifocal cognitive deficits such as might be found in patients with multiple strokes, multiple sclerosis, or multiple brain metastases.

Patients suspected of having with selective impairment of visual memory must be tested in the visual modality. The direct equivalent of the typical verbal memory test is having the patient copy three simple shapes, then draw the same shapes immediately after the originals have been removed, and finally to draw them from memory after a few minutes delay with an intervening distraction. As with verbal memory, multiple choice can be used to identify patients in whom

memory loss is due to executive cognitive dysfunction rather than true forgetting. A simpler yet face-valid bedside or office test of visual memory is hiding three dollar bills around the bedside or the office while the patient watches, having him or her immediately point to where they were hidden, and then having the patient point out after a delay where the money was hidden. A cooperative patient with normal visual memory should have no problem finding the money.

Language

Language functions include spontaneous speech, comprehension, repetition, naming and word finding; in addition, there are nonverbal aspects related to transmitting and receiving emotion through the rate, rhythm, volume, and intonation of speech. Because of the complexity of language, there are several ways in which it can fail. The distinctions are psychiatrically relevant as well as helpful in localizing the brain dysfunction within the dominant hemisphere, and in determining whether there is a contribution of nondominant hemisphere dysfunction to the patient's communication impairment. Anatomic brain imaging, despite its ever-improving spatial resolution and wide availability, does not necessarily answer all relevant questions about impairment of function, so precision and specificity in the assessment of language is neurologically as well as psychiatrically useful.

The detailed examination of language goes beyond the scope of this chapter, but several fundamental points related to specific language disorders will be mentioned:

1. *Transcortical motor aphasia.* Patients with left-hemisphere medial frontal dysfunction, including those with hypotensive infarcts at the border zone of the anterior cerebral and middle cerebral arteries, can show transcortical motor aphasia, a disorder in which there is very little spontaneous speech and in which speech is initiated with great difficulty, but comprehension and repetition are intact. In addition to being able to repeat sentences, patients with this type of aphasia can complete familiar phrases such as "Roses are red, violets are (blue)." Such patients are of special interest to medical psychiatrists for three reasons. First, their occurrence with border zone (aka "watershed") infarction means that they will appear in intensive care units and in acute medical-surgical environments where they might be seen by a consulting psychiatrist before they are seen by a neurologist. Second, because of their difficulty initiating speech they can appear uncooperative, apathetic, or electively mute before the language disorder is appreciated. Third, patients with transcortical motor aphasia have an especially good prognosis for recovering language function within 18 months when the aphasia was caused by a stroke (Cauquil-Michon et al., 2011; Flamand-Roze et al., 2011). If a comprehensive language examination confirms the diagnosis of transcortical motor aphasia, the patient and family can be offered realistic hope of improvement that can improve morale and enhance motivation for speech therapy.
2. *Broca's aphasia.* Patients with Broca's aphasia (aka *non-fluent aphasia*), typically due to a left middle cerebral artery stroke, have a lesion in the frontal lobe anterior to the part of the motor strip that controls the movements of the mouth. They speak with great effort and poor accuracy and are not better with repetition. Comprehension is relatively intact. The typical emotional response is depression but not suspiciousness or paranoia.
3. *Wernicke's aphasia.* Patients with Wernicke's aphasia (aka *fluent aphasia*), typically due to an embolic infarction of the posterior superior temporal lobe, easily generate large amounts of abnormal speech and continually misunderstand what others are saying to them. They are often unaware of their deficit, particularly early on, and this contributes to suspiciousness or even frank paranoia. The abnormal speech is on occasion misdiagnosed as a manifestation of delirium or of a primary psychosis; demonstration of markedly impaired comprehension and repetition should be sufficient to differentiate the condition.
4. *Anomia.* Patients with *nominal aphasia* or *anomia* due to a dominant posterior parietal lesion cannot accurately name items, whether they are presented visually or they are described in words; their spontaneous speech can show word substitutions, letter substitutions, or circumlocutions, the latter including elaborate descriptions of things for which the patient cannot find the right word. Impaired naming is seen not only in focal lesions but also in diffuse or multifocal processes such as toxic encephalopathy, encephalitis, or neurodegenerative diseases. Impaired naming can show a circular relationship with anxiety. Patients become anxious because they cannot find the words they are looking for; as anxiety increases, they have more trouble finding a suitable alternative for conveying their thought.
5. *Impairment of prosody.* Patients with lesions or dysfunction in the nondominant hemisphere can show problems with the production and/or interpretation of prosody: the tempo, rhythm, pitch, and loudness of speech that convey emotion, distinguish statements, questions, and commands, and indicate whether speech is to be taken seriously or ironically or facetiously. Varieties of aprosodia—expressive and receptive, with and without impairment of repetition—parallel the varieties of aphasia. Posterior lesions such as those involving the non-dominant posterior superior temporal region impair comprehension of prosody, and anterior lesions such as those involving the non-dominant anterior perisylvian region or the medial frontal region impair expression of prosody (Heilman et al., 2004; Wildgruber et al., 2006). Prosodic impairment is of obvious medical-psychiatric interest because of its functional implications; it can be occupationally disabling, and it can bring conflict and frustration to caregiving relationships. Testing for prosodic impairment parallels testing for aphasia. The patient is asked to name the emotions conveyed by sentences spoken by the examiner and to say

whether sentences are meant as questions, statements, or commands; to read sentences to convey different emotions and intentions; and to repeat sentences with the same words that differ in prosody.

The examiner can assess prosody at the bedside by giving the following tests: (1) asking the patient to read a sentence—for example, “My friend is moving to a beautiful new house”—in an angry, sad, happy, ironic/facetious, or questioning tone; (2) reading a sentence to the patient with prosody conveying different emotions or meanings and asking him or her what emotion or meaning is conveyed; and (3) asking the patient to repeat sentences presented by the examiner with prosody expressing the same emotion or meaning.

6. *Dyslexia and dysgraphia.* Almost all dominant hemisphere brain lesions that significantly affect spoken language will also affect reading and/or writing. Thus, having the patient hand-write a one-paragraph summary of his or her own recent illness can be a time-efficient and sensitive (albeit nonspecific) way to screen for language problems in those with medical or epidemiologic risk factors for brain diseases that might affect language. The converse is not true; focal brain lesions in certain specific locations can impair writing and/or reading without impairing spoken language.

Understanding the precise nature of a patient’s language dysfunction is useful in determining the relationship of that dysfunction to the patient’s mental and behavioral symptoms—causal, concurrent, or coincidental. If the language dysfunction has not been previously characterized, there may be opportunities to improve the patient’s relationships with caregivers by doing so and explaining the findings to them.

Calculation

Questions about very simple arithmetical facts are more a test of long-term memory than of calculation itself. Obviously wrong answers to over-learned arithmetical facts—for example, “two plus two equals five”—suggest malingering, conversion, or elaboration of cognitive symptoms. Multistep calculations or calculations involving numbers with two or more digits are true tests of calculation. When they are failed, they suggest dysfunction of the dominant parietal lobe. However, the usual principle of analysis of cognitive deficits applies. To ascribe a cognitive deficit to a specific brain region or system, one must establish that the input pathway and output pathway are not cause of the problem: the patient must be sufficiently motivated and attentive, must understand the calculation to be done, and must be able to express the answer verbally, in writing, or by indication of a choice among alternatives.

Visual-Spatial Functions

Visual-spatial functions involve the visual association areas in the anterior occipital lobes, posterior inferior temporal lobes, and the parietal lobes, the latter especially on the

nondominant side. These functions are sometimes neglected in routine bedside mental status examination, and in themselves they contribute so little to the score of standard bedside cognitive screening instruments that patients can get passing scores despite severe impairment in the visual-spatial domain.

The quickest and most practical bedside test of visual-spatial function is the clock drawing task (CDT). The patient is given a sheet of paper and is asked to draw the face of a clock and to set the hands at a specific time, commonly “ten after eleven”. Patients with disturbances of visual-spatial functions may draw a circle that is not round, that is incomplete, or that is too small to accommodate the numbers of the clock. The numbers may be misplaced, either found outside the circle or incorrectly distributed within the circle. If there is neglect of half of the visual field (typically the left half) or of a quadrant (typically the left upper or left lower quadrant), this will be reflected by the absence of numbers in the given half or quarter of the clock. Hands may be misplaced or of the wrong length.

If the clock drawing is not executed perfectly, the patient can be asked to copy a clock that is correctly drawn. The copying task rules out contributions of memory impairment and/or poor planning to errors in the drawing—continued failure suggests problems either with visual perception, with the task of drawing (constructional praxis), or both. Impairment in visual perception can be distinguished from impairment in drawing performance by having the patient distinguish correctly from incorrectly drawn clocks, stating what is wrong about the ones that are incorrect.

There are more than 20 published systems for administering and scoring the CDT, but none has been accepted as a standard. They were comprehensively reviewed by Mainland et al. (2014). They concluded that for *identifying* cognitive impairment, simpler systems using only a spontaneous clock drawing worked as well as more complex and time-consuming ones. More complex systems can help determine whether CDT errors are related to visual-spatial deficits, impaired praxis, impaired executive function, impaired attention, and so forth. Specific types of errors on the CDT deficits have been correlated with specific regional abnormalities on functional brain imaging. Regardless of the administration procedure and scoring system, impairment on the CDT has been shown by numerous studies to correlate with impairment on longer and more systematic tests of visual-spatial function and with functional impairment such as poor driving ability (Freund et al., 2005).

A basic scoring system for the CDT applied to 536 patients in a memory disorder clinic identified dementia with 71% sensitivity and 88% specificity; patients were scored abnormal if they had any of the following errors on the spontaneous CDT: (1) refusal to do the drawing, (2) inaccurate time setting, (3) no hands, (4) missing numbers, (5) number substitutions, or (6) number repetitions (Lessig et al., 2008). The CDT has been successfully applied as a brief cognitive screener in general medical patient populations ranging from those with cancer to those with fibromyalgia, and it has been used to identify which elderly patients undergoing femoral fracture repair were at highest risk for postoperative delirium

(Meziere et al., 2013). *Minor* errors on the CDT are commonly seen in elderly patients without cognitive impairment; these have been systematically characterized (Hubbard et al., 2008).

In addition to its remarkable psychometric properties, the CDT has practical utility in communicating the physician's concern about a patient's cognitive impairment. A badly drawn clock has face validity in making the case with a caregiver or other physician that there is a functionally significant problem.

Another test of visual perception that is feasible whenever language is intact is scene analysis. A picture with rich content in both the background and the foreground is shown to the patient, who is asked to describe what is seen. As a follow-up, the patient can be asked to point out specific details or identify particular elements in the picture. Like the clock drawing, scene analysis tasks have appealing face validity. Caregivers can easily understand there is a problem when the patient looks at a picture and neglects its left half or is unable to distinguish the main figure from the background.

Praxis

Praxis refers to the ability to execute a complex motor activity, assuming gross motor and sensory function adequate to physically complete the task. Apraxia typically results from parietal lobe and/or frontal lobe dysfunction. One or both hemispheres may be involved depending on the task. To test for praxis the patient is asked to demonstrate how he or she would do various tasks, usually involving a tool, such as cutting with scissors, hammering a nail, or swinging a baseball bat. The patient with intact praxis will demonstrate the use of the imaginary tool; one with impaired praxis either will use the body part as if it were the tool or will fail to do the task at all. A patient who fails an initial test of praxis can be asked to imitate the action when it is performed by the examiner. If the action can be copied accurately, the patient's ability to organize and execute the motor performance is intact but the ability to conceive it is impaired. It is unusual to see apraxia without other cognitive and/or perceptual problems.

Medical psychiatrists sometimes are asked to evaluate patients who claim to be—or who are said to be—unable to do certain physical tasks despite apparently intact motor function. This problem, when due to apraxia, occasionally is misunderstood as reflecting malingering, conversion, or symptom amplification. A more detailed neurological examination with an extended cognitive evaluation will resolve the issue.

Executive Function

Executive functions comprise goal-setting, organization and planning, persistence, resistance to distraction, understanding the significance of environmental cues, self-regulation and self-control, inhibition of socially inappropriate behavior, abstract reasoning, insight, and judgment. They are often thought of as “frontal lobe” functions; however, the neural circuits involved in executive functions also include the basal

ganglia, thalamus and cerebellum, and they are influenced by neuromodulators originating in brainstem, thalamus, and basal forebrain nuclei. The tasks used to test executive function rely upon inputs from and outputs to other brain regions. Executive functions are the last cognitive functions to reach maturity and usually the first to be impaired by diffuse encephalopathy or neurodegenerative disease.

Executive functions can be classified into three groups with anatomical associations. Inhibition and self-control are related to the orbital frontal region and its connections; abstract reasoning, organization and planning, judgment, and interpretation of environmental cues are associated with the dorsolateral frontal lobe and its connections; initiation, motivation, and persistence are associated with the medial frontal lobe and its connections. The frontal lobe functions that typically are tested as part of a neurological examination in the office or at the bedside are mainly—or entirely—those of the dorsolateral frontal systems. Thus, typically, dysfunction of the orbital frontal or medial frontal system is inferred from the history and from observation of the patient's behavior during the examination. A well-documented neurological mental status examination describes any elements of the patient's behavior during the examination that offer remarkable evidence of apathy or disinhibition, a typical example of the latter being the production of vulgar language when the patient is asked to list words beginning with the letters f, a, and s. Patients with impairment in executive function perform better on cognitive tests when the patient's executive function is augmented by cues from or the physical or social environment, and when there are few potential distractions. Thus, a patient with impaired executive function might be well oriented and pass basic bedside memory tests when at home, but be disoriented and fail memory tests when examined in the setting of an intensive care unit. For this reason the context of the examination is especially relevant when assessing executive function. When the findings on cognitive examination are unexpected given the patient's diagnosis and condition, documentation of mental status should note the time and place of the examination and anything remarkable about the environment at that time.

The CDT is an excellent screening test for dorsolateral frontal function when visual-spatial function is intact. When visual-spatial function is intact and executive function is impaired, a free-drawn clock is incorrect but a copied clock is correct. The free-drawn clock typically shows poor planning and organization. Numbers may be poorly spaced, duplicated, or omitted. If the clock is to be set at “ten after eleven” the patient might point the large hand toward the ten rather than the two. If the patient can copy a clock drawing perfectly, a poor performance on the free clock drawing cannot be attributed to visual-spatial dysfunction or to impaired praxis.

Other useful and common bedside tests of dorsolateral frontal function include:

1. Listing items that belong to a given category, such as vegetables, fruits, tools, or pieces of furniture. This task requires organization and persistence and the ability to maintain the mental set to stick with a single category.

2. Listing words that begin with a specific letter of the alphabet, such as a, f, s, or t. A person with intact frontal lobe function and intact naming will be able to name at least eight items in 30 seconds that begin with any of those letters. Production of vulgar language on this task suggests impaired orbital-frontal function.
3. Explaining what pairs of words have in common when there is something obviously different about them: for example, hammer and screwdriver, school and prison, president and dictator, love and hate. The patient with intact language and dorsolateral frontal function will easily name the common category; patients with impaired function will be unable to shift their mental focus from the differences. Patients with impaired orbital frontal function occasionally will produce bizarre responses that they have failed to inhibit.
4. Sorting cards by color, by number, and by shape. Patients with impaired dorsolateral frontal function can have difficulty shifting from one sorting rule to another.
5. Writing a short account of the present illness. Patients with impaired frontal function but no language impairment will write grammatical sentences but will give an incomplete, poorly organized, or perseverative account or one that includes irrelevant or even inappropriate content.

Formal testing of orbital frontal inhibitory functions has been done in the neuropsychology laboratory, for example, using the Iowa Gambling Task (IGT; Bechara, 2010). The Executive Interview Test (Royall et al., 1992) is a bedside screening test with several items related to inhibitory functions. For example, the examiner asks the patient not to shake his hand and then stretches his hand out to the patient. Patients with impaired frontal lobe functions often are unable to inhibit their response to the cue and will reach for the examiner's hand. However, the test can be failed because of either dorsolateral frontal dysfunction or orbital frontal dysfunction. Findings that point more specifically to the orbital frontal system are those related to lack of inhibition of inappropriate responses to emotionally salient cues.

The following points concerning executive function are of special interest to the medical psychiatrist:

1. Deficits in executive function underlie functional impairment in many cases of brain diseases or traumatic brain injury, and they can be disproportionate to other kinds of cognitive impairment.
2. Schizophrenia, bipolar disorder, and severe depression all are associated with impaired executive function, and this feature can contribute to disability they cause.
3. Drugs and alcohol can impair executive function disproportionately to other cognitive functions.
4. Patients with impaired executive function may present with complaints about their memory; their caregivers' initial complaints often concern inappropriate or irresponsible behavior, bad judgment, or resistance to care.

Metacognition

Metacognition—"knowing about knowing"—comprises patients' awareness of their own cognitive and mnemonic capabilities and defects, and also their judgments about whether particular judgments or memories are valid or should be questioned. Dementing diseases affect both cognition and metacognition, but cognitive and metacognitive dysfunctions need not be highly correlated early in the course of illness. Some drugs, notably alcohol and benzodiazepines, impair cognition and metacognition in parallel, so that individuals are unaware of the extent of their drug-induced impairment. Others, notably anticholinergic agents, can impair cognition to a similar extent while leaving the patient aware that his or her cognition has been affected by a drug (Mintzer & Griffiths, 2003). This may account for a greater propensity of patients to complain of the cognitive side effects of anticholinergic drugs than to complain of the cognitive side effects of benzodiazepines. Patients with relatively intact metacognition will be less disabled for a given degree of cognitive impairment. For example, if metamemory is intact, a patient with an early dementia will take notes, use technology-based reminders, and ask for directions rather than forget important tasks, miss appointments, or get lost while perhaps blaming others for their mistakes. Metacognition can be assessed by asking the patient to evaluate his/her own cognitive performance and comparing the patient's self-evaluation with the examiner's observations and history provided from collateral sources.

GAIT AND BALANCE

The observation of gait and the testing of gait and balance can reveal much about CNS function, but they sometimes are omitted when the patient is examined in bed. Impaired gait and balance are related to the risk of falls with injury, a significant threat to patients in hospitals and in long-term care settings. Fear of falling is an important factor in social withdrawal and functional decline in frail old people. And, determining the underlying reason for impaired gait and/or balance can lead to a new, psychiatrically relevant neurological or general medical diagnosis.

The basic observation of gait requires simply that the patient get up from a chair or from a bed, stand in place briefly, then walk across the room, turn around, return to the bed or chair, and finally sit down or lie down. The examiner observes the speed and the difficulty with which the steps are executed and whether movements are symmetrical, steps are of normal length, and the arms swing as expected. Unusual postures or hand positions are noted, as are any adventitious movements of the hands, fingers, or face.

If the patient feels faint and must sit down shortly after arising from bed or chair, orthostatic hypotension should be suspected. If the arm does not swing on one side but it does on the other, the patient should be examined for hemiparesis and for lateralized spasticity or rigidity. Very small steps with a stooped posture and difficulty stopping and/or turning

around suggest a diagnosis of Parkinson's disease. A shuffling gait with feet "glued to the floor" suggests hydrocephalus. While difficulty turning around is typical of Parkinson's disease the sign is nonspecific.

A specific gait-related performance—getting up from a chair and walking 10 feet—can be timed with a stopwatch and used as a repeatable measure for tracking a patient's response to a treatment such as physical therapy, levodopa therapy of Parkinson's disease, or the placing of a shunt to treat hydrocephalus.

When basic observations of gait are normal but problems with the motor system (including coordination) are a concern, there are several options for making walking more difficult and thereby unmasking asymmetries, coordination problems, or adventitious movements. These include walking on heels or on tiptoes, walking on the sides of the feet, or walking on a narrow line touching heel to toe. In some contexts asking the patient to hop in place on one foot may be appropriate. When observations of gait are normal but the history suggests a concern about gait stability, the examiner should try to reproduce conditions associated with the reported problems, such as dim lighting or the need to circumvent obstacles.

Standing balance can be given a stress test in order to assess balance-related complaints or to test hypotheses about the systems for standing balance—the vestibular system, the midline cerebellum and its connections, the visual system, and the proprioceptive system. If the patient can stand stably with eyes open, he or she can be asked to close the eyes; this removes the stabilizing effect of visual input and can cause a loss of balance if lower-extremity position sense is impaired. Standing on the toes or on the heels, or with one foot in front of the other heel to toe, makes an additional demand on balance-related systems. A patient who is stable on two feet can be asked to stand on one foot; marked asymmetry of performance is abnormal.

When gait is said to be normal on a reported examination, or no comment at all is made about gait in the report of an office examination of an ambulatory patient, it can be inferred that casual observation of the patient's walking into and out of the office showed no evident abnormality. If there are open hypotheses that can be tested by a more thorough examination of the patient's gait, the patient should be reexamined with those hypotheses in mind. Abnormalities are documented; if the patient is normal on all bedside tests of gait that were given, the examiner should indicate which tests were done unless the examination was done in a clinic specializing in gait and balance problems that follows a consistent and known routine.

CRANIAL NERVES

The examination of the cranial nerves is interwoven with the physical examination of the head, eyes, ears, nose, and throat. The items most often omitted on routine screening neurological examinations are testing of the senses of smell and taste. When cranial nerves II through XII are reported

as intact, it is explicit that smell was not tested, and it can be assumed that taste was not tested if taste was not mentioned specifically.

CRANIAL NERVE I: OLFACTORY NERVE

The primary pathway for the sense of smell—the olfactory tract—begins in the olfactory bulb and ends in the ipsilateral medial temporal lobe. The olfactory bulb can be damaged by trauma to the nose or inhalation of toxic substances. The olfactory tract can be damaged by traumatic brain injury, particularly when the injury affects the orbital frontal region; the tract can be demyelinated in multiple sclerosis. The olfactory cortex and its connections are vulnerable to a broad range of brain diseases, including both Alzheimer's disease and Parkinson's disease. Loss of olfactory sense implies diminished ability to discriminate tastes. It entails safety risks, particularly for individuals who live alone; a person with complete anosmia cannot smell smoke in case of fire or tell by smell that food has spoiled. Several types of patients encountered by medical psychiatrists have specific indications for olfactory testing: (1) patients with complaints of memory loss, (2) patients with a history of traumatic brain injury, (3) patients with suspected multiple sclerosis, (4) patients with motor symptoms suggesting Parkinson's disease, (5) patients with complaints of altered taste or smell, and (6) patients who have weight loss and/or diminished appetite.

Loss of olfactory function in degenerative brain diseases can occur early in their course—even before the other characteristic signs of the disease are fully manifest. Unequivocal defects in olfactory function are seen in patients with very early Parkinson's disease and in patients with mild cognitive impairment who will go on to develop Alzheimer's disease (Casjens et al., 2013; Sun et al., 2012). The finding of an olfactory deficit raises the risk of dementia incrementally after controlling for findings on neuropsychological testing and brain imaging. Loss of olfaction helps distinguish early Parkinson's disease from motor symptoms due to vascular disease or severe depression. Olfactory testing determines three features of olfaction: olfactory thresholds, discrimination of different scents, and identification (naming) of scents. Comprehensive formal testing of olfaction is time consuming and requires relatively expensive standardized olfactory stimuli. The University of Pennsylvania Smell Identification Test (UPSIT) (Doty, 1995) and Sniffin' Sticks (Hummel et al., 1997) are the two olfactory test kits most often cited in the neurological and ear, nose, and throat literature; they deserve consideration when there are research issues or forensic issues that warrant the time and expense of quantifying and fully characterizing deficits. For clinical diagnostic purposes, practical bedside tests usually suffice.

For quantitative determination of olfactory threshold at the bedside, the following procedure can be followed using a standard alcohol wipe as the stimulus (Davidson & Murphy, 1997). One nostril is tested at a time; the patient closes the eyes and mouth and occludes one nostril. A metric ruler is held touching the open nostril at one end and pointing straight down. The stimulus is placed 30 cm from the nostril and

moved one centimeter closer to the nostril with each breath. The patient signals when he or she can smell the stimulus; the distance in centimeters from the nostril is the threshold. A variation of the test using a 14g cup of peanut butter as the stimulus was used by Stamps et al. (2013) to identify patients in a memory clinic who had probable Alzheimer's disease. In contrast to normal controls or patients with mild cognitive impairment (MCI) or non-Alzheimer dementias, the patients with probable Alzheimer's disease showed marked asymmetry of the olfactory threshold, at least 5 cm worse on the left in all cases and >10 cm worse on the left in all of the mild cases.

Testing of olfactory discrimination and olfactory naming can be done, one nostril at a time, using commonly recognized and easily available odorants such as instant coffee, extracts of vanilla, almond, or lemon, and common spices like cinnamon or clove. Patients with bilaterally occluded nostrils can be tested retronasally by presenting the stimulus orally, having the patient rinse the mouth after each odorant is presented (Croy et al., 2013). Three or four different scents are sufficient to screen for olfactory discrimination and olfactory naming deficits. Patients are asked to name each scent presented; if unable to do so, they are asked to pick from among four choices. Scratch-and-sniff screening cards with three scents are commercially available.

CRANIAL NERVE II: OPTIC NERVE

The neurologist's examination of the optic nerve focuses on the appearance of the optic nerve head, visual acuity, and the visual fields. A pale, flat optic disk is a sign of optic atrophy, most often as a result of a prior episode of optic neuritis. A swollen optic disk with fuzzy margins, accompanied by absent venous pulsations, is a sign of increased intracranial pressure from hydrocephalus, an intracranial mass, or pseudotumor cerebri. Visual acuity usually is tested with a pocket screening card; to be meaningful, patients must be tested with corrective lenses or reading glasses if they are ordinarily used. Geriatric psychiatrists who frequently must assess visual acuity in patients who need reading glasses but don't have them at hand can benefit from keeping a few different strengths of reading glasses in their examining rooms or medical bags. Visual fields are tested at the bedside by confrontation. Peripheral fields are tested using minimal finger movements at the extremes of the fields. This procedure can easily identify loss of peripheral vision, or the loss of a half or a quarter of the visual field from damage to an optic tract or occipital cortex. Using a red or white push pin a few millimeters in diameter (or the tip of a long cotton swab), it is possible to map the patient's blind spots and thus determine whether they are enlarged, as they might be by glaucoma. The optic nerve is the afferent limb of the pupillary reflex response to light. Shining a light in one eye normally leads to constriction of both pupils. If either pupil constricts, the afferent limb is intact. If one pupil does not constrict but the other does, there is a problem with the non-constricting pupil or with its innervation. For example, if the right pupil constricts when a light is shined into the left eye but then dilates when the light is shined into the right eye the function of the right optic

nerve is impaired. This might be seen following optic neuritis on the right. If the right pupil constricts when the light is shined into the right eye but not when it is shined into the left eye, and the left eye constricts when light is shined into the left eye, the two optic nerves are intact and the nerve supply to the right pupil is intact, but the connection across the midline from the left pretectal region to the right Edinger-Westphal nucleus nucleus is impaired. This situation might be seen with demyelinating disease or small-vessel cerebrovascular disease that is damaging white matter tracts in the midbrain.

Pupils, although reactive, can be larger or smaller than normal because of drug effects. Large pupils despite bright light suggest a cholinergic deficit. The examination of the optic fundus and testing of the pupillary light reflex should be done in dim light. Excessively small pupils in dim light suggest a sympathetic deficit; they also can be due to the use of opiates. The fact that a patient has normal peripheral vision does not imply a quick and consistent response to a stimulus anywhere in the patient's field of vision—especially an unexpected stimulus or one embedded within a field of distractors. The useful field of view (UFOV), defined as the visual field over which information can be rapidly extracted without head or eye movements, can be markedly smaller than the visual fields as assessed by confrontation. When this is the case there can be major functional consequences, notably a significant impairment in the ability to drive safely. Reduction in UFOV has been linked to an increased rate of at-fault motor vehicle crashes (Ball et al., 2006). The test, which is computer-administered, evaluates the patient's ability to perceive a centrally presented visual stimulus while simultaneously attending to a peripheral one and to identify a target stimulus amidst distractors (Visual Awareness, 2013). When UFOV is impaired despite normal visual fields, the cause of the problem is impairment in the cortical processing of visual information rather than in the eyes, optic nerves, optic tracts, or primary visual cortex. While UFOV is not tested routinely, the literature on the test highlights an important limitation of bedside visual field testing—or even traditional optometry—in testing a dimension of visual function of great importance to everyday life.

CRANIAL NERVES III, IV, AND VI—OCULOMOTOR, TROCHLEAR AND ABDUCENT NERVES

The third cranial nerve innervates the pupillary muscles as well as the extraocular muscles apart from the superior oblique and lateral rectus. The fourth cranial nerve innervates the superior oblique muscle, and the sixth cranial nerve innervates the lateral rectus. The routine examination tests the extraocular motor functions of cranial nerves III, IV, and VI by having the patient follow a moving finger up, down, left, and right. The third cranial nerve's control of the pupil is assessed by observing the size of the pupils at rest, and the reactions of the pupils to accommodation and to a light shined separately into the right eye and the left eye. The pupillary light reflex is discussed above in connection with testing the optic nerve. Accommodation is tested by having the patient focus on the examiner's finger as it is moved in from a distance

toward the patient's nose. The normal response is brisk constriction of the pupils as both eyes move medially to maintain focus on the examiner's finger. Accommodation depends on the cholinergic innervation of the pupil and is disrupted by the anticholinergic effects of drugs; impaired accommodation is a common reason for a complaint of blurred vision when it occurs as a medication side effect. Even without a complaint of blurred vision, impairment of accommodation supports a suspicion of anticholinergic excess as a reason for or contributor to an alteration of mental status.

The function of the third cranial nerve apart from controlling the pupil, and the sole function of the fourth and sixth cranial nerves, is eye movement. The examination of eye movements is an extensive subject beyond the scope of this chapter. We will, however, mention three eye movement disorders with special interest to medical psychiatrists:

1. *Internuclear ophthalmoplegia.* To turn the eyes to the left, a signal from the left paramedian pontine reticular formation goes to the nucleus of the left abducent nerve and, via the right medial longitudinal fasciculus (MLF), to the nucleus of the right oculomotor nerve. If the right MLF is disrupted by infarction, demyelination, or inflammation, the effect of the patient's attempting to look left will be that the left eye will abduct, the right eye will not adduct, and the left eye will show nystagmus with a quick component to the left, as if the abducting eye were returning toward the midline again and again to coax the recalcitrant right eye to move. Lesions of the left MLF will have the corresponding impact on attempted rightward gaze. Because the third nerves and medial rectus muscles themselves are unaffected in this condition, both eyes will adduct when accommodation is tested. Causes of internuclear ophthalmoplegia include multiple sclerosis, brainstem strokes, and spirochete infections including neurosyphilis and neuroborreliosis.
2. *Ocular dysmetria.* Precisely and rapidly shifting one's gaze from one point to another requires accurate saccades (rapid conjugate eye movements between fixation points). When medial cerebellar structures (or their connections) that are associated with eye movements are disrupted the result is ocular dysmetria, a condition where saccades are either too short or too long. The eye undershoots or overshoots the target and there must be a corrective saccade to bring it to the correct fixation point. The bedside test is having the patient rapidly shift gaze from a finger on one of the examiner's hands to a finger on the other hand; this is done repeatedly, with the examiner repositioning the target finger before each shift in fixation point. Ocular dysmetria is an unambiguous sign of cerebellar system dysfunction, unlike nystagmus which has several alternative explanations.
3. *Diplopia.* Subjectively experienced double vision can occur any time the patient's gaze is not conjugate, but it does not necessarily do so because patients can suppress the image from one of the two eyes. Diplopia can be fixed or can be variable according to the direction of gaze or the

level of fatigue or CNS drug side effects. Diplopia present only when looking in specific directions can arise from monocular weakness or impairment of gaze in a particular direction, whether on a muscular or neural basis, or from intranuclear ophthalmoplegia. Diplopia dependent on the level of fatigue can occur when the patient has a phoria (latent mal-alignment of binocular vision that is suppressed by fixation of gaze). In this situation the eyes are not aligned if one eye is covered, but binocular fixation is sufficient to line them up. When the patient is fatigued or the CNS is depressed by medications, the eyes may be unable to attain full alignment even when binocular vision is attempted. Drugs such as anticholinergics that impair accommodation can cause diplopia when the patient looks at near objects because the eyes do not converge sufficiently. Ocular myasthenia gravis causes diplopia that first appears or gets worse after the patient exercises the eyes; repeated forceful blinking may be enough to provoke diplopia in many patients with ocular myasthenia.

CRANIAL NERVE V: TRIGEMINAL NERVE

One of the thickest nerves in the body, the trigeminal nerve provides sensory innervation to the face and motor innervation to the muscles of mastication. It has three branches—ophthalmic, maxillary, and mandibular. Testing of its sensory functions typically is limited to testing light touch with a cotton swab, pain with a sharp object like a toothpick, and temperature with a cool object like a tuning fork. Position and vibration senses in the face usually are not tested. Sensation is tested in areas served by each of the three branches of the nerve, since diseases around the skull and face can disrupt branches of the nerve selectively. The ophthalmic branch of the trigeminal nerve is the afferent limb of the corneal reflex—blinking of the eyes when the cornea on one side is stroked lightly with a wisp of cotton. The cotton is presented from the side to avoid confounding of the tactile stimulus with visual threat. The motor functions are tested by palpating the masseter muscles while the patient clenches the teeth, then having the patient move the jaw from side to side against resistance.

From the medical-psychiatric viewpoint, the trigeminal nerve is important because of its role in facial pain: trigeminal neuralgia, or tic douloureux, is the classic example of paroxysmal neuropathic pain. Like other types of neuropathic pain, trigeminal neuralgia can present with symptoms disproportionate to signs, thus sometimes raising the issue of a somatoform disorder. Signs are not entirely absent, however, sensory examination of one or more branches of the trigeminal nerve on the affected side will be abnormal. As a large nerve, the trigeminal nerve is more likely than smaller ones to be affected by systemic diseases that cause cranial nerve damage, such as chronic meningitis or autoimmune vasculitis. These conditions also are potential causes of mental status changes.

Assessment of the trigeminal nerve is important in evaluating cases of dizziness or vertigo because of the proximity of the trigeminal nerve to the acoustic nerve at the cerebellopontine angle. Tumors of that region can present with vertigo—a

condition in which psychosomatic factors sometimes are suspected. A tumor of that region large enough to cause vertigo often is large enough to impinge on the trigeminal nerve and cause either partial unilateral facial sensory loss or a unilaterally decreased corneal reflex.

CRANIAL NERVE VII: FACIAL NERVE

The facial nerve provides motor innervation to the muscles of the face and also is the afferent pathway for the sense of taste from the anterior two-thirds of the tongue. The facial nerve is tested by having the patient move the face in various ways—close the eyes forcibly, smile, or blow through pursed lips. Asymmetry of the face is observed as well; total dysfunction of the facial nerve on one side—Bell's palsy—causes a drooping of the face on one side, incomplete eye closure, and a widened palpebral fissure. The input to the facial nerve motor nuclei from the cerebral hemispheres is bilateral; specifically, the upper motor neurons for upper face are bilateral while the upper motor neurons for the lower face are contralateral only. A hemispheric stroke will affect the lower face and not the forehead—immediately indicating facial weakness of central origin as distinguished from facial weakness due to a facial nerve lesion. Asymmetry of the face when smiling spontaneously can occur in patients whose deliberate smile is symmetrical; this finding points to dysfunction of the contralateral temporal lobe. This is of medical-psychiatric interest because acquired temporal lobe lesions, such as those due to embolic stroke or tumor, can present with changes in mood or behavior without changes in motor function that would immediately suggest gross brain disease.

Testing the sense of taste often is omitted from general physical examinations. However, the sense of taste is of special medical-psychiatric interest because its impairment can influence appetite, weight, and eating behavior. Some patients with a loss of taste lose their appetite. Others increase their salt or sugar intake because they cannot adequately taste the saltiness or sweetness of their food; this can adversely affect patients' general medical conditions. The sense of taste usually is tested using a salt or sugar solution on a cotton swab, testing on the front of the tongue, one side at a time. Sour, bitter, and umami (savory) stimuli are less consistently available at the bedside, and many of the potential choices have smells that potentially confound the testing process. However, non-odorous sour and umami stimuli are readily available at a grocery store, namely citric acid (sour salt) and monosodium glutamate. Most common causes of taste loss affect all of the primary tastes, although not necessarily equally; small lesions of the brainstem can produce dissociation of sensation for different primary tastes. Anatomical lesions of the facial nerve usually affect both taste and motor function, although a selective lesion of the chorda tympani nerve can impair taste without producing facial weakness. When weakness in the face is accompanied by a loss of the sense of taste it confirms a neural rather than (or in addition to) a muscular or cerebral cause for facial weakness. Loss of the sense of taste also can occur as a side effect of medication (notably cancer chemotherapy

agents) or due to zinc deficiency; in this case the loss of taste is bilateral and applies to the posterior as well as the anterior tongue, and there is no associated facial motor deficit.

CRANIAL NERVE VIII: VESTIBULOCOCHLEAR OR AUDITORY VESTIBULAR NERVE

The vestibulocochlear nerve runs from two parts of the inner ear—the labyrinth and the cochlea—through the petrous bone to join the brainstem at the cerebellopontine angle. Dysfunction of the eighth nerve and/or its connections can present with any combination of hearing loss, tinnitus, impaired balance, and/or vertigo (a subjective sensation of motion). The bedside or office examination of the eighth nerve comprises testing of hearing, testing of balance, and observation for nystagmus on testing of extraocular movements. The testing of hearing was discussed above in connection with the examination of the ears, and the testing of balance was discussed in connection with testing of gait. Intactness of the vestibular division of the eighth nerve and its connections can be assessed by caloric testing; irrigating the ear canal with cold water produces lateral nystagmus with a quick component moving away from the stimulated ear; irrigating it with warm water produces nystagmus with a quick component toward the stimulated ear. The Barany maneuver (see below) can be used to evoke the characteristic nystagmus of benign positional vertigo—nystagmus that typically is unidirectional (or at least asymmetrical) and has both a lateral and a rotatory component.

Abnormalities on testing of the vestibulocochlear nerve can be related to dysfunction of the sensory organ, a lesion in the nerve (most often an acoustic neuroma), or problems with the central connections of the nerve, of which the most common causes are brainstem strokes and demyelinating disease. While brain imaging procedures, especially MRI, are the mainstay of differential diagnosis, brainstem auditory evoked potentials can provide complementary information that is at times essential, because small lesions of the central auditory pathways can be beneath the resolution of MRI.

Several issues concerning testing of the eighth nerve are of special interest to medical psychiatrists:

1. Hearing loss can significantly increase the functional impairment associated with mild cognitive impairment or early dementia. Even when a patient has a neurodegenerative disease, identifying and mitigating hearing loss can in effect improve memory, and it can increase the executive functional resources available for instrumental activities by reducing the cognitive demand associated with resolving ambiguous auditory perceptions. Since adaptation to the use of a hearing aid requires memory and executive function, and adaptation is most effortful at the beginning, hearing aids are more likely to be useful when started at the stage of mild cognitive impairment rather than later in the course of a dementing illness. Auditory misperceptions can contribute to suspiciousness and paranoid ideation as well. However, remediation of hearing loss is rarely

useful in reversing paranoid delusions once they are established, even if misheard communications have contributed to them.

2. Because by age 80 more than half of all individuals have hearing loss, every elderly patient should be screened for it.
3. Younger patients who present with mental or behavioral symptoms but have no complaint of hearing loss should nonetheless be screened for hearing loss if have any of the following: (a) tinnitus, (b) vertigo, (c) a family history of deafness, (d) a developmental disorder associated with hearing loss, (e) a history of multiple ear infections, (f) severe head injury, and/or (g) occupational or avocational exposure to loud noise (barotrauma). People working on construction sites, at airports, and at rock concerts are all exposed to potentially injurious levels of noise, and they will develop hearing loss in time if they do not wear ear protection. Similarly, people who spend several hours a day listening to loud music using headphones are at risk for barotrauma-related hearing loss. Hearing loss from barotrauma disproportionately affects the perception of higher frequencies, with maximum loss around 4000 Hz. Audiometry or audioscopy can demonstrate the characteristic pattern of barotrauma-induced hearing loss, thus supporting a specific etiology as well as confirming the presence of impairment.
4. Patients with tinnitus may have the condition on a cerebral basis or because of dysfunction of the cochlea, the eighth nerve, or the brainstem auditory pathways. When a patient with tinnitus and episodic vertigo has unilateral hearing loss that disproportionately affects lower frequencies, the diagnosis of Meniere's disease is likely (Stapleton & Mills, 2008). This is a condition of particular interest to medical psychiatrists because it is associated both with depression and with autoimmunity (Gasquez et al., 2011).
5. Dizziness, usually a lightheaded feeling but occasionally true vertigo, can be an expression of anxiety of any cause. In old age the symptom can present with reluctance to walk or fear of falling, or with an actual history of falls. Among the medical conditions to be excluded before ascribing dizziness to anxiety are disorders of the vestibular system and its connections via the eighth nerve to brainstem nuclei associated with balance and eye movement. The standard neurological examination includes observation for nystagmus on gaze in different directions. The nystagmus associated with vestibular dysfunction, which usually has some rotatory component, can escape casual observation if it is of low amplitude. It can help the examiner to focus attention on a scleral blood vessel while having the patient look up, down, left, and right; the high contrast of the red blood with the white sclera highlights the rotatory movement.

If the patient's history suggests vertigo or dizziness greatest with changes in position, the examination should include efforts to provoke nystagmus by movements of the head and

body such as the Barany maneuver (aka Dix-Hallpike test), which tests for benign positional vertigo due to dysfunction of the posterior semicircular canal of the inner ear on one side (Fife et al., 2008). The patient sits on an examination table positioned so that he or she can be moved into the supine position with the head hanging down over the edge of the table. As the patient is moved from the sitting to the supine position with the head extended, the head is gently rotated 45 degrees toward the side of the ear that will be tested. The patient's eyes are kept open and observed for combined vertical and torsional (rotatory) nystagmus that is accompanied by reproduction of the patient's symptoms of vertigo. Nystagmus begins after a latency of a few seconds, decreases and stops within a minute, reverses direction when the patient is returned to the upright seated position, and fatigues and ultimately disappears on repeated trials. The facts that the positional nystagmus can reliably be provoked by a well-defined maneuver and that it diminishes with repetition of the maneuver supports the diagnosis of a condition that is both physiologically based and of benign significance. Nystagmus and vertigo of other, less benign causes also can be provoked by the Barany maneuver. However, in most of these cases the nystagmus will not diminish with repetition and/or there will be other neurologic or otologic signs.

There are several other useful bedside tests of neuro-vestibular function, which are helpful in evaluating dizziness, vertigo, and unsteady gait, which frequently are caused by disease of the inner ear or eighth nerve, but also can reflect injury to the pons or the cerebellar system by a stroke or demyelinating disease. They are thoughtfully reviewed by Newman-Toker (2014), whose syllabus on neuro-vestibular testing is available for download on the Internet. One valuable example is the horizontal head impulse test, which evaluates the vestibulo-ocular reflex (VOR), in particular the function of the horizontal semicircular canals of the inner ear and their connections in the brainstem. Patients with acute onset imbalance and vertigo due to cerebellar strokes have a normal VOR, while those with an eighth nerve lesion or inner ear disease usually have an abnormal one. A normal VOR raises concerns about a central cause of vertigo and imbalance, potentially one involving the cerebellum and/or its connections, such as MS or a posterior circulation stroke. Two other unequivocal signs that vertigo is central rather than peripheral are pure vertical nystagmus and pure rotatory nystagmus with no lateral component.

The horizontal head impulse test requires a patient to maintain fixation on the examiner's finger while the examiner rapidly rotates the patient's head 10–20 degrees laterally with a "flicking" motion. The patient should be told in advance what the examiner plans to do, and the examiner should rotate the head slowly once or twice to illustrate. When the head is rapidly rotated toward the side of a vestibular lesion the patient will be unable to maintain fixation and will require a corrective saccade after the head movement stops. This test has been nicknamed "dolls eyes on steroids": It serves much the same purpose as caloric testing but is more convenient. Adaptations to test the other semicircular canals and the utricle and saccule of the labyrinth have been described (Halmagyi et al., 2001).

CRANIAL NERVE IX: GLOSSOPHARYNGEAL NERVE

The glossopharyngeal nerve supplies sensory innervation to the posterior oral cavity and pharynx and the sense of taste to the posterior third of tongue. It is the route to the brainstem for signals from carotid body baroreceptors and carotid glomus chemoreceptors. It is the afferent limb of the gag reflex. On the efferent side it supplies parasympathetic (cholinergic) innervation of the parotid gland. On screening examinations the ninth nerve is evaluated by testing the gag reflex; this is done by stimulating the posterior palate with a tongue blade or cotton swab. Ideally this is done one side at a time, to enable detection of unilateral ninth nerve lesions. Similarly to the blink reflex, stimulation of the gag reflex on one side produces contraction of the palatal muscles bilaterally. Thus, if the context suggests the possibility of a unilateral ninth nerve lesion and a screening neurological examination described the ninth nerve as intact, it would be worth rechecking the gag reflex, one side at a time. If the gag reflex is absent or markedly hypoactive, which it can be on a central basis, finding intact taste on the posterior third of the tongue supports the cause being central and not peripheral.

Of particular interest to medical psychiatrists is that lesions of the ninth nerve can produce unusual and distressing symptoms that are easily diagnosed if, and only if, the physician is familiar with the syndrome. Glossopharyngeal neuralgia, a syndrome similar to trigeminal neuralgia, presents with paroxysmal lancinating pains at the base of the tongue or around the palate. Attacks can be accompanied by vagally mediated syncope.

CRANIAL NERVE X: VAGUS NERVE

The vagus nerve provides motor and sensory function to the gastrointestinal tract from the palate and pharynx through the ileum, and also innervates the respiratory tract—larynx, trachea, and lungs—and the heart. It is the afferent pathway for the baroreceptors and chemoreceptors of the aorta and the carotid artery. Autonomic symptoms—cardiovascular or gastrointestinal—frequently accompany vagus nerve lesions. On the screening neurological examination, the tenth nerve is tested in its role as the efferent limb of the gag reflex. If the soft palate is stimulated on either side, the palatal muscles should contract on both sides. The palate will fail to contract and rise normally on the side of a tenth nerve lesion; complete paralysis of the palate is more likely to occur with nuclear or infranuclear lesions. Lesions of the recurrent laryngeal nerves—the branches of the vagus nerves that supply the larynx—present with hoarseness, but visualization of the vocal cords with a mirror or fiberoptics is necessary to confirm which side is affected. The vagus nerve—one of the longest in the body—is vulnerable to any of the systemic diseases that cause polyneuropathy, such as diabetes or amyloidosis, and to toxins such as lead or solvents that cause polyneuropathy. Many of these conditions also have neuropsychiatric dimensions and can present with prominent mental and behavioral symptoms.

Identification of a previously unsuspected neuropathy can significantly affect the differential diagnosis of the presenting symptoms.

CRANIAL NERVE XI: ACCESSORY NERVE

The accessory nerve is the motor nerve supplying the trapezius and sternomastoid muscles. It is tested by having the patient shrug the shoulders and turn the face to the side, against resistance. Medical psychiatrists evaluating patients for suspected motor conversion symptoms can, on occasion, note nonphysiological patterns of weakness that arise from patients being unaware that contraction of a sternomastoid muscle turns the face to the opposite side, or being unaware that the trapezius muscle has a different nerve supply than the other muscles of the shoulder area. Trapezius weakness on a central basis is on the opposite side from sternomastoid weakness; when caused by an accessory nerve lesion, the weakness of the two muscles obviously is ipsilateral.

CRANIAL NERVE XII: HYPOGLOSSAL NERVE

The hypoglossal nerve is the motor efferent to all but one of the intrinsic muscles of the tongue. It is tested by having the patient protrude the tongue with the mouth open and by having him or her push the tongue against each cheek against external resistance. Because contraction of the tongue muscles pushes the tongue forward, unilateral weakness of the tongue will cause the tongue to point toward the weak side. When the weakness is due to upper motor neuron dysfunction—for example, when it is due to a cerebral stroke—the tongue will not be atrophic. Prominent atrophy of the tongue is indicative of disease of the lower motor neuron—either in the twelfth nerve nucleus or the hypoglossal nerve itself. Fasciculations of the tongue indicate disease affecting the hypoglossal nerve nuclei, most often amyotrophic lateral sclerosis (ALS). ALS can present with neuropsychiatric symptoms, and fasciculations of the tongue may precede more prominent bulbar signs and symptoms. Careful inspection of the tongue for fasciculations is particularly relevant in patients suspected of having frontotemporal dementia, as this is the type of dementia specifically associated with ALS.

MOTOR FUNCTIONS

The basic motor examination comprises assessment of muscle tone and bulk, testing of muscle strength, observation of involuntary movements including tics, tremors, dystonia and dyskinesia, and noting of fasciculations if they are present. Because it is not practical to test every muscle in the body, the screening motor examination typically tests a set of proximal and distal muscles bilaterally, looking for asymmetry and for a proximal–distal gradient—proximal weakness being typical of myopathy and distal weakness typical of polyneuropathy. While examiners do not typically record exactly which muscles they have screened, a conservative assumption for the medical psychiatrist is that a nonspecialized examination

of the motor system might have a “blind spot,” with positive examination findings to be found if one looks in the right place. In particular, the motor aspects of damage to a specific nerve—whether from trauma, entrapment, or another cause such as vascular or autoimmune disease—can only be assessed by testing the muscles innervated by the nerve involved.

Motor disorders can be of neuropsychiatric import but go unnoticed or be minimized by the patient; tardive dyskinesia is a poignant example. In these cases the patient might not complain of the problem, and the physicians might not notice it unless they are looking for it. In addition, involuntary movements, tremors, and fasciculations can fluctuate in intensity over time and simply not be present at the time of a specific neurological examination. Thus they cannot be ruled out for all time by a single examination, no matter how expertly performed and carefully documented. Some specific points deserve mention:

1. Increased muscle tone in limbs can be thought of as unidirectional (spastic) or bidirectional (rigid), the latter implying simultaneous contraction of agonist and antagonist muscles. The former is a sign of pyramidal tract dysfunction, the latter of extrapyramidal dysfunction. Rigidity can be accompanied by tremor; this is a characteristic finding in Parkinson's disease, drug-induced parkinsonism, and malignant extrapyramidal reactions to neuroleptics. Parkinsonian tremor, whether due to Parkinson's disease or due to antipsychotic drugs, has a lower frequency than the tremor of patients with malignant neuroleptic reactions. Tremulous rigidity need not feel like a cogwheel or ratchet, and for this reason the author prefers the term “tremulous rigidity” to “cogwheel rigidity.”
2. In addition to spasticity and rigidity, medical psychiatrists often encounter two other types of abnormality of muscle tone. The first one, *paratonia*, can take one or both of two forms: oppositional paratonia (“gegenhalten”) and facilitatory paratonia (“mitgehen”). In the former condition the patient resists passive movement of a limb by the examiner. In the latter condition the patient assists, augments, or extends the passive movement. Both types of paratonia are associated with cognitive and motor signs of frontal lobe dysfunction (Beversdorf & Heilman, 1998). The examiner can test for both types of paratonia by holding the patient's arm, asking him or her to relax, and then holding the patient's hand and passively flexing and extending the elbow three times, ending with the elbow extended, then letting of the patient's hand. If oppositional paratonia is present, the patient will resist passive movement in both directions; if facilitatory paratonia is present, the patient will flex the elbow after the hand is released.

The second type of abnormal tone of special interest is the *waxy flexibility of catatonia*. The syndrome of catatonia involves multiple behaviors, one of which is offering slight and even resistance to passive movement of the patient's limbs by the examiner. (The mildness of the resistance distinguishes it from most cases of oppositional paratonia.) Waxy flexibility often is accompanied by

catalepsy, the maintenance against gravity of the limbs in a position into which they were placed by the examiner. The other motor phenomena of catatonia are stereotypies (frequent repetitive non-goal-directed movements), mannerisms (caricatures of normal behaviors), and grimacing. Catatonia, once associated primarily with schizophrenia, has increasingly been recognized as a syndrome that can also arise from mood disorders and even from general medical conditions (Tandon et al., 2013). It is important to recognize because it responds to treatment with benzodiazepines and/or electroconvulsive therapy, and it is potentially dangerous if not treated. In a case series of patients with catatonia in the ICU, Saddawi-Konefka et al. (2014) reported two patients with premorbid chronic anxiety who developed catatonia in the ICU in the context of benzodiazepine withdrawal. This calls attention to yet another potential cause of catatonia in the medical-psychiatric context, important because long-term benzodiazepine treatment often is discontinued, either deliberately or inadvertently, when patients are hospitalized.

3. The rigidity of malignant catatonia or neuroleptic malignant syndrome feels more intense than the rigidity of Parkinson's disease or drug-induced Parkinsonism.
4. Loss of muscle bulk can be disproportionate to loss of strength. For example, atrophy of the thenar eminence in carpal tunnel syndrome or of the hypothenar eminence in ulnar nerve entrapment can be noted even when the strength of the intrinsic hand muscles is near normal.
5. Loss of muscle strength, like loss of cognitive function, should be assessed with respect to the patient's pre-illness baseline. Athletes and patients with highly physical occupations can have strength that is within normal limits for the general population despite their having had a significant loss of function due to neuromuscular disease.
6. Myasthenia gravis, an autoimmune disease of the neuromuscular junction, is characterized by maximal muscle strength at the beginning of exercise followed by loss of strength as exercise continues and reserves of acetylcholine are depleted. While patients with severe myasthenia will have weakness at the outset, those with less severe disease can have a normal motor examination unless they are tested following exercise of the muscles involved.
7. Tremors should be characterized by frequency, amplitude, the most involved muscle groups, and the circumstances that bring them out; essential tremor is made worse by action, while the alternating or “pill-rolling” tremor of Parkinson's disease is worse at rest. Many psychotropic drugs can cause or worsen tremors; neuroleptics and antidepressants (of all classes) can produce fine tremors and can exacerbate action tremors or the rest tremor of Parkinsonism. The distinction between drug-induced tremors is clinically important because they should be treated differently. A beta blocker can help an action tremor, but it is of no use for Parkinsonian tremor.

8. The predominant frequency of a tremor in Hz is the single most useful quantitative datum in differential diagnosis. It can be reliably measured at the bedside using the built-in accelerometer of a smartphone, employing the iSeismo application, one originally developed to measure and report seismic activity (www.iseismometer.com; the application is available for both iOS and Android operating systems). The phone is strapped to the tremulous limb; the application records motion on three axes, plots the motion on a graph with time markers, and calculates the frequency spectrum of the motion (Joundi et al., 2011). Another smartphone application for monitoring tremor, the Lift Pulse (www.liftlabdesigns.com) assesses the fluctuation in tremor amplitude over time as well as measuring its predominant frequency.
9. An unusual tremor syndrome, orthostatic tremor, is a high-frequency (13 Hz–18 Hz) tremor in the leg muscles elicited by standing up and relieved by sitting or walking. Patients with this rare disorder sometimes are misdiagnosed and are seen by psychiatrists because of their secondary depression and anxiety. Confirming a high-frequency tremor in the legs, for example by using a smartphone app, can expedite a correct diagnosis. Many movement disorders—including tics and dyskinesia—fluctuate over time and are responsive both to the environment and to what the patient is doing at the time. It is thus possible to judge an involuntary movement as mild or even absent, when at a different time it is moderate or even severe. The history in these situations is one of flurries or attacks of involuntary movements alternating with quiet periods with few or no involuntary movements. The clustering of involuntary movements shows fractal symmetry; clusters of discrete involuntary movements within a flare-up of the movement disorder are spaced proportionally to the pattern of flare-ups over the course of time.
10. Environmental responsiveness of involuntary movements does not imply a “psychogenic” origin. In neuroleptic-induced vacuous chewing movements (VCM), a rat model of tardive dyskinesia, higher levels of environmental noise are associated with a significantly greater frequency of abnormal movements.
11. There are a number of movement disorders in which involuntary movements are associated with or triggered by voluntary ones. Chief among these are the occupational dystonias such as writer’s cramp. These conditions are regarded as involuntary and based in dysfunction of motor control systems. Patients with these conditions usually have subtle abnormalities of somatic sensation as well; patients with writer’s cramp have an impaired ability to localize touch on the affected and the unaffected hand. (Lin & Hallett, 2009). This movement disorder and other occupational dystonias will be found on neurological examination only if the patient is asked to perform the action that ordinarily triggers it; the sensory disorder will be found only if it is looked for specifically, as touch localization is not part of the screening sensory examination.
12. Some common movement disorders, notably tardive dyskinesia and Tourette syndrome, have multiple and varied manifestations. For such patients, a video recording of the patient’s typical involuntary movements is a valuable supplement to a verbal description of them. Video recording is standard in many movement disorder clinics. Informal video recording with the medical psychiatrist’s smartphone can capture essential features of a movement disorder that then can be reviewed with a neurologic subspecialist.
13. The clinical import of involuntary movements can be great even when the movements themselves are mild and functionally insignificant. For example, a patient born to a parent with Huntington’s disease has a 50% chance of getting the condition. Such a patient showing even very mild chorea—if there is no other explanation for it—establishes that he or she has inherited a neurodegenerative disease.
14. While mild fasciculations can be seen in normal individuals and in patients with nerve root inflammation, pronounced fasciculations strongly suggest disease of motor neurons, most often due to ALS. ALS is associated with neurodegenerative conditions that can present with changes in mental status, particularly one of the variants of frontotemporal degeneration (FTD). Fasciculations can occur at a point in the disease where weakness and atrophy are still mild. When the fasciculations are themselves mild, they may be seen only if specifically sought. The small, discrete movements of fasciculations are best detected in the examiner’s peripheral vision. As in the examples just given for chorea and dyskinesia, fasciculations of little functional consequence in themselves can be clinically important in a context of suspected ALS.

COORDINATION (CEREBELLAR FUNCTION)

Coordination is disturbed by dysfunction—whether due to a drug or metabolic state or due to an anatomical lesion—of the cerebellum and its connections in the brainstem, thalamus, frontal lobes, and spinal cord. Impaired coordination in the limbs is associated with dysfunction of the lateral cerebellum—the cerebellar hemispheres—while impaired gait and impaired standing or sitting balance are associated with dysfunction of the midline cerebellum—the cerebellar vermis. The standard screening examination for limb coordination is done on the left and the right separately, in the upper and the lower extremities. The patient puts the index finger on the nose, then touches the examiner’s finger, then touches the nose, and then touches the examiner’s finger, which has moved to a different location. If the patient significantly overshoots or undershoots the mark when touching the examiner’s finger, cerebellar dysfunction is suspected. The other usual test of upper extremity coordination is the performance of rhythmic alternating movements, typically having the patient tap the knee, the thigh, or a tabletop with, alternately, the palm of

the hand and the back of the hand. Clumsiness or irregular rhythm in performing the task is a sign of impaired coordination, with an irregular rhythm particularly suggestive of cerebellar system dysfunction.

The lower extremity is tested by having the patient touch the heel to the contralateral shin just below the knee, and then slide the heel straight down the shin toward the ankle. If the heel wobbles from side to side, impaired coordination is suspected. Rhythmic alternating movements are tested by having the patient alternately tap the floor with the heel and with the toes.

The interpretation of failure on tests of coordination should take into account vision, position sense, and noncerebellar aspects of the motor system. A particularly common issue in interpretation is whether a wobble on heel-to-shin testing or missed targets on finger-nose-finger testing is due to an action-induced tremor rather than to the inaccurate targeting of directed movement—dysmetria—that is characteristic of cerebellar system dysfunction. Follow-up observations can help make the distinction. Action tremors are present any time the patient makes an intentional movement, so they will be present if the patient slowly tracks the examiner's finger movement with his or her own finger—an activity that would not require precise targeting of a single movement. Having the patient move his or her fingertip quickly back and forth between the examiner's left index finger and right index finger requires precise targeting of the upper extremity movement and can reveal undershooting or overshooting that can be clear-cut even if there is an action tremor superimposed upon it. The same tasks carried out with the patient's big toe touching the examiner's index finger(s) can be useful in making the same distinction.

SENSORY FUNCTIONS

The sensory examination evaluates the patient's perception of light touch (typically tested with a wisp of cotton), pain (typically tested with a sharp object like a pin or toothpick), temperature (typically tested with a cool metal tuning fork), vibration (typically tested with 128 Hz tuning fork), and position sense (typically tested with small movements of the fingers and toes). Less consistently tested is discriminative sensation, such as touch localization, two-point discrimination, stereognosis (the ability to identify an object placed into the hand when the eyes are closed), and graphesthesia (the ability to identify a letter or number traced on the skin). Obviously, an exhaustive examination of all forms of sensation is not feasible; screening and hypothesis testing are the realistic options.

Sensory screening most often fails because of insensitivity when the examiner presents stimuli too strong to reveal the deficit, which is usually a partial loss of sensation rather than total anesthesia. For example, a defect in position sense in the feet is missed because the toe movements made by the examiner are too large. The other main error on sensory testing is not doing the specific testing needed to assess the relevant diagnostic hypothesis. For example, a patient with a parietal lobe lesion may have marked deficits in discriminative

sensation without any deficit in the primary sensation of touch, pain, temperature, position, or vibration. Such a patient must be specifically tested for touch localization, stereognosis, graphesthesia, and/or extinction of the stimulus on the affected side when both sides are stimulated simultaneously.

Sensory thresholds can be quantitated using specialized instruments. Quantitative sensory data can be used to assess the course of a disease affecting the peripheral nerves and to measure treatment response.

Several points on the sensory examination are of particular interest to medical psychiatrists:

1. Many toxic, metabolic, and autoimmune conditions that also cause neuropsychiatric symptoms are accompanied by polyneuropathy. Polyneuropathy is a common neurological side effect of drugs and is virtually universal with cisplatin and carboplatin, drugs commonly used in the chemotherapy of solid tumors. It also can be an early sign of nervous system damage from alcohol abuse, or of recurrent hyperglycemia that has not developed into frank diabetes. The early stage of polyneuropathy can be asymptomatic, or the patient can be unconcerned about symptoms of neuropathy because of the CNS effects of the disease. Careful testing of pain and temperature sense in the fingers and toes will detect early signs of axonal neuropathies, as these conditions first affect the small-diameter nerve fibers that carry pain and temperature sense. Moving from the toes or fingers proximally, there will be a gradient of increasing sensation. The sensory loss will be uniform across the fingers and across the toes.
2. Demyelinating neuropathies, most due to either autoimmune or vascular disease, differentially affect large-diameter myelinated nerve fibers. These conditions first affect position and vibration sense and, at the outset, pain and temperature sense can be relatively spared. This distinctive pattern of sensory loss aids in the differential diagnosis of the neuropathy.
3. A common reason for medical psychiatric consultation is pain in excess of apparent physical signs. One cause of this phenomenon is localized nerve or nerve root compression which, by differentially affecting large fiber signals that modulate pain sensation, can cause pain and dysesthesia disproportionate to motor weakness, muscle atrophy, or gross sensory loss. Of these conditions the carpal tunnel syndrome is the best known, but there are many other syndromes entrapment neuropathies, some of them occupational. Nerve root impingement by osteoarthritic bony deformities or by herniated intervertebral disks also can at times produce disproportionate pain and dysesthesia. The key to the diagnosis is precisely mapping the area of altered or diminished sensation—which, in the case of a nerve entrapment, should closely follow the known territory of a specific nerve. Some of these territories show minor variability, but for practical purposes they are consistent: the sensory territory of the median nerve might not split the fourth finger, but it will always include the middle finger and never include the fifth

finger. Corroborating data from the physical examination include atrophy of the muscles in the same territory—which can occur with or without obvious weakness—and tenderness of the nerve over the point of entrapment.

Occasionally an entrapment neuropathy will present with a well-defined trigger point that will reproduce the patient's pain if pressed on but without a well-defined zone of sensory loss. These neuropathies are particularly likely to be misdiagnosed because of the almost negative neurological examination. A prime example is the anterior cutaneous nerve entrapment syndrome (ACNES) of the abdomen (Akhnikh et al., 2013; van Assen et al., 2013). In this condition the anterior cutaneous branch of one of the intercostal nerves (most often T11) gets entrapped as it passes through the rectus abdominis muscle just medial to its lateral edge. Patients have episodic abdominal pain—sometimes severe enough to provoke surgical consultation, imaging procedures, or even laparoscopy—or chronic abdominal pain misdiagnosed as irritable bowel syndrome or a somatoform disorder. The disorder can be diagnosed with great confidence by a targeted physical examination alone. When ACNES is present, there is a tender spot over the rectus

abdominis muscle point no more than 2 cm in diameter, pressure on which produces the characteristic pain. The patient, lying supine on the examination table, is asked to lift his or her head off the examining table. This tenses the rectus abdominis and exacerbates the pain; if the cause of the pain were visceral no increase in pain would be expected. There might be some sensory alteration in the vicinity of the trigger point, but clear-cut sensory loss with a well-defined boundary is not the rule. The majority of patients with this disorder respond well to local injections with a local anesthetic and a corticosteroid. If injections are not sufficient, surgery to release the entrapment usually will permanently alleviate the pain.

In addition to getting entrapped by normal anatomic structures, cutaneous nerves can be entrapped by scar tissue. In the inguinal region, entrapments of the ilioinguinal and genitofemoral nerves are a common cause of persistent postoperative pain. Patients with these disorders can be misdiagnosed as having psychosomatic problems or analgesic dependency. The presence of sensory loss in a pattern consistent with the territory of the entrapped nerve supports the diagnosis; blocking the pain with an injection of local anesthetic at the presumed site of entrapment will confirm it. Table 2.3 lists some

Table 2.3 COMMON ENTRAPMENT NEUROPATHIES

NEUROPATHY	EARLY SYMPTOMS	MOTOR SIGNS	SENSORY SIGNS
Median nerve at the wrist (carpal tunnel)	Pain in wrist radiating proximally; paresthesias in thumb and index finger	Thumb weakness and/or atrophy of thenar muscles (later than symptoms and sensory signs)	Sensory loss on palmar side of medial 3.5 fingers; palm is spared
Ulnar nerve at the elbow (cubital tunnel)	Deep ache around the elbow; tingling in ring and little fingers	Grip weakness and/or hypothenar atrophy (later than symptoms and sensory signs)	Sensory loss on <i>both palmar and dorsal</i> sides of ulnar 1.5 fingers; palm is spared
Ulnar nerve at the wrist (compression in Guyon's canal)	Pain and numbness of ulnar 1.5 fingers, or painless atrophy of hypothenar and interosseous muscles	Hypothenar and interosseous weakness and/or atrophy	Sensory loss on palmar side of ulnar 1.5 fingers
Radial nerve in proximal forearm (posterior interosseous nerve syndrome)	Dull aching pain over front of elbow	Weakness of extension of third and fourth fingers early; weakness of extension of all fingers and of thumb adduction later	None
Suprascapular nerve entrapment	Poorly circumscribed dull aching pain in posterior shoulder	Supraspinatus and/or infraspinatus weakness and/or atrophy	None
Lateral femoral cutaneous nerve (meralgia paresthetica)	Numbness, tingling, and painful hypersensitivity in anterolateral thigh	None	Decreased pinprick sensation accompanied by hypersensitivity to light touch
Common peroneal nerve entrapment	Pain radiating from knee to dorsal foot; sensory loss on dorsum of foot	Foot drop (may come later than sensory symptoms)	Sensory loss on dorsum of foot
Tarsal tunnel syndrome	Burning pain and tingling of plantar region; pain triggered by pressing or rubbing plantar surface of foot	Weak flexors of great toe; clawing of other toes due to weak flexors (later than sensory symptoms)	Sensory loss over one or both sides of the plantar surface of the foot, depending on site of entrapment
Lower trunk of brachial plexus (thoracic outlet syndrome)	Pain and paresthesia of ulnar aspect of forearm, hand, and ulnar two fingers	Usually none; rarely atrophy and weakness of intrinsic hand muscles	None

common entrapment neuropathies encountered in patients with localized pain and an unremarkable routine physical examination. The common entrapment neuropathies illustrate several important points relevant to the problem of missed or inaccurate diagnoses by physicians unfamiliar with them:

- a. Pain can be disproportionate to findings on sensory and motor examination.
- b. Pain usually comes before muscle weakness, even when the nerves involved have primarily motor functions.
- c. Pain can be poorly localized.
- d. Decreased pinprick sensation can be accompanied by *hypersensitivity and discomfort* with light touch stimulation.
- e. Muscular weakness and muscle atrophy are *partially* correlated; one can be much more prominent than the other.
- f. Patterns of motor and/or sensory findings are highly specific; findings *not* present help distinguish entrapment neuropathies from nerve root lesions such as those associated with herniated disks.

There are many rare entrapment neuropathies; many are associated with particular occupations, hobbies, or sports, or with pregnancy. When patients present localized nonvisceral pain or sensory symptoms unexplained, or unconvincingly explained, by the physicians they have seen to date, it is worth considering whether the pattern of symptoms fits one of the entrapment neuropathies and whether the history suggests activities, injuries, or systemic risk factors that would predispose to that particular entrapment.

Closely related to entrapment neuropathies, and raising similar diagnostic issues, are compression neuropathies; like entrapment neuropathies, these involve a localized insult to a peripheral nerve. These are of particular medical-psychiatric interest because they can be caused by pressure from medical devices and can occur in the context of anesthesia, surgery, and/or rehabilitation. Crutches, walkers, and self-powered wheelchairs all are associated with compression neuropathies, which can be due to pressure directly from a device or from muscle hypertrophy related to using it.

4. Nerve root impingement ideally would produce sensory loss precisely following a dermatome from the associated spine around to the front of the body. However, the sensory dermatomes of adjacent nerve roots overlap somewhat, so the width of the band of sensory alteration is variable.
5. The finding of a sensory loss in a dermatome also can aid in the diagnosis of herpes zoster and post-herpetic neuralgia, conditions that can cause severe pain with minimal physical signs apart from the sensory examination, since these conditions are based on infection of dorsal root ganglia and do not affect motor function at all. The diagnosis is obvious when the acute attack of herpes zoster is

accompanied by a prominent rash, but this is not always the case, and on occasion the rash was present and not noticed by the patient.

6. Limb weakness or paralysis are common neurologic conversion symptoms. Patients with conversion weakness or paralysis often also show sensory changes in the affected limbs, just as do patients with weakness or paralysis on an “organic” basis. However, the sensory changes, if carefully mapped, often are incompatible with those expected from the lesion location inferred from the pattern of motor deficits. Dermatomes on the arms and legs follow precise patterns that the patient may not know; for example, the territory of S1 goes from the low back down the back of the leg but does not include the anterior leg, and the territory of L5 includes the big toe but not the little toe.
7. Patients with traumatic spinal cord injuries or spinal cord infarcts usually have clear-cut “sensory levels” below which there is absent or diminished sensation and above which sensation is intact. However, in patients where the spinal cord is impinged upon by a slowly progressive extrinsic mass or is affected by an intramedullary tumor, there may not be a clear-cut sensory level, and the areas of normal and diminished sensation can follow an irregular pattern. This can happen because the lesion does not totally destroy normal spinal cord neurons and axons and/or because it extends up and down the cord for several levels. These patients are ones in whom neurological conversion symptoms may be suspected. Notwithstanding, the patient with a genuine spinal cord lesion will have some areas of diminished sensation below the lowest level of the lesion and no areas of diminished sensation above the highest level of the lesion.
8. Patients with parietal lobe damage, most often due to a tumor or stroke but occasionally due to other conditions such as demyelinating disease, arteriovenous malformations, or parasitic infestation, can show a combination of sensory and motor symptoms suggestive of neurological conversion because primary sensory modalities may be relatively intact, and motor strength on direct testing may be normal as well. Nonetheless, the patient may be incapable of many simple voluntary motor actions because of apraxia and may *experience* grossly abnormal sensation in the affected areas because of the lack of discriminative sense. In this situation a sensory examination that includes testing of stereognosis (identification of an object placed in the hand without looking at it), two-point discrimination, discrimination of textures, graphesthesia, and extinction on simultaneous bilateral stimulation will identify “parietal lobe” sensory loss. Formal testing of praxis will also support the diagnosis of parietal lobe dysfunction. If the lesion is on the nondominant side, there will be impaired visual-spatial function; if it is on the dominant side, there usually will be an impaired ability to calculate.

REFLEXES

The reflex examination has always had particular interest for psychiatrists because, in contrast to the sensory and motor examinations, it requires less patient cooperation and because it is difficult for patients with malingered illness or conversion symptoms to precisely mimic abnormal reflexes. Apart from their continued utility in assessing potential symptoms of conversion or malingering, abnormal reflex findings continue to be valuable despite advances in brain imaging for several reasons. First, in progressive brain diseases like tumors, dementing diseases, and hydrocephalus, focal abnormalities in the function of the nervous system can appear before there are changes visible with the usual anatomic imaging procedures. Second, reflexes provide evidence as to whether anatomic or biochemical abnormalities seen on testing are functionally significant. Third, in relapsing-remitting diseases like multiple sclerosis, abnormal reflexes can provide evidence of disease activity prior to obvious changes in the patient's symptoms.

A typical screening neurological examination tests the deep tendon jerks at the biceps, triceps, brachioradialis, patellar, and Achilles tendons, and tests the plantar reflex by stroking the lateral sole from the heel towards the toe. When brain disease is suspected, this is augmented by testing primitive reflexes or "frontal release signs"—reflexes present in normal infants but not usually present in adults without frontal system dysfunction. These are discussed below.

Reflexes can be scored on a scale of 1+ to 4+ or a scale of 0.5+ to 5+. The four-point scale is encountered more often; the six-point scale adds the score of 0.5+ to indicate that reflexes are present only with facilitation and the score of 5+ to indicate the presence of sustained clonus. Reflexes are scored zero only if they are absent even when something is done to enhance them (facilitation)—typically the voluntary contraction of other muscles, as when the knee jerks are enhanced by clenching the fists. On the four-point scale, reflexes are scored 1+ if they are spontaneously present but of low amplitude or if they are present only with facilitation. Brisker than average reflexes that are possibly (but not necessarily) abnormal limits are scored 3+; those viewed as unequivocally beyond normal limits are scored 4+. Any reflex accompanied by unsustained clonus would be at least 3+, and one accompanied with sustained clonus would always be 4+.

Markedly increased reflexes suggest a central nervous system problem that affects the pyramidal motor system; something prevents descending inhibition of reflex loops in the spinal cord. When reflexes are *extremely* increased, with sustained clonus, dramatic extensor plantar responses and proximal spread of reflex muscle contractions, brainstem or spinal cord rather than purely cerebral dysfunction should be suspected. *Mild* reflex asymmetry can potentially reflect a longstanding developmental variation; for this reason, finding a record of a single reliable and complete baseline neurological examination can be very helpful diagnostically. The presence of mild reflex asymmetry in the past when the patient was well can reassure the clinician that its current presence doesn't necessarily signify new CNS disease; on the other hand, if

reflexes were unequivocally symmetrical at an earlier time, present mild asymmetry suggests an acquired neurological disorder. A significant asymmetry in the size of the extremities suggests a congenital or early acquired reason for a mild asymmetry in reflexes. Such asymmetries can be present and yet never be noted on recorded physical examinations until they are specifically sought.

Generalized hyperreflexia can be due to bilateral anatomic lesions of the brain or upper cervical spinal cord; in general medical settings, it more often represents increased CNS excitability or lack of inhibition on the basis of a toxic-metabolic encephalopathy or withdrawal from drugs or alcohol. Patients with generalized hyperreflexia from toxic-metabolic causes may or may not have extensor plantar reflexes.

The range of normal for deep tendon jerks is broad. Present but hypoactive (1+) reflexes can be seen occasionally in people without neurological disease; they are seen commonly in patients with cerebellar disorders and patients with systemic or muscular conditions that cause generalized weakness without significant CNS dysfunction. Hypothyroidism is classically associated with a delayed relaxation phase of the ankle, knee, and biceps reflexes; the *intensity* of the delayed reflex can be normal, increased, or decreased in this situation. Relaxation time over 320 msec is abnormal; this time interval of approximately one-third of a second is long enough to be judged clinically. While hypothyroidism is the most common cause of delayed relaxation of deep tendon jerks, and 75% of patients with clinical hypothyroidism will have it, there are other diagnostic possibilities with medical-psychiatric implications including anorexia nervosa, pernicious anemia, and sarcoidosis (Marinella, 2004). While patients with truly *subclinical* hypothyroidism would not be expected to have them, the presence of such "hung-up" reflexes would increase the likelihood that thyroid dysfunction, despite only borderline abnormal laboratory tests, was contributing to the patient's mental condition, as it would be direct evidence of altered CNS function due to the endocrine disease. When a specific deep tendon reflex is totally absent, the usual reason is damage or dysfunction of a nerve or nerve root involved in the reflex; for example, a missing ankle jerk usually is due to dysfunction of either the sciatic nerve or the first sacral root.

Polyneuropathy—as opposed to mononeuropathy multiplex—affects the longest nerves earliest and most severely. Patients with polyneuropathy can lose both ankle jerks, have diminished knee jerks, and have normal biceps and triceps reflexes. The particular relevance of polyneuropathy to medical psychiatrists is that polyneuropathy is a common expression of neurotoxicity that also can affect the brain, and patients can have polyneuropathy demonstrable on examination without complaining of symptoms.

Deep tendon reflexes can aid in identifying neurological conversion symptoms or in demonstrating neuropathology in a patient with an obvious mental disorder who also has a complaint of pain or sensorimotor dysfunction. Deep tendon reflex responses are not as subjective as sensory testing,

they are less dependent on patients' cooperation than motor testing, and they are difficult to simulate by volitional movements. In addition, they should bear a consistent relationship to the putative anatomy of the neurological condition that the patient would have if his or her complaints were based a neurological disorder. In this connection, some reflexes seldom tested routinely occasionally can be diagnostically valuable. For example, neither the knee jerk nor the ankle jerk test the L5 root, but the less-known medial hamstring reflex does, and a study correlating surgical findings with the preoperative neurological examination showed the medical hamstring reflex to be as accurate in localizing the level of a herniated lumbar disk to L5 as the ankle jerk is in localizing it to S1 (Esene et al., 2012). The report of the study presents the psychometric properties of the different lower extremity deep tendon jerks and describes the technique for eliciting the reflex.

The extensor plantar reflex, or Babinski sign, is regarded by many physicians as virtually pathognomonic of CNS dysfunction involving the pyramidal motor system. The finding is accepted by physicians of all specialties as evidence that there is "something organic" and as such, it is of particular use to the medical psychiatrist lobbying for consideration or reconsideration of a patient's general medical diagnosis. Unlike voluntary withdrawal in response to noxious stimulation of the sole, the Babinski sign is consistent and repeatable. When the extensor plantar reflex is due to cortical disease, it typically involves only the big toe. Lesions lower down the neuraxis usually also involve extension and sometimes abduction of the other toes, and spinal lesions virtually always do so (Deng et al., 2013). Inter-rater reliability of the Babinski sign is highly dependent on examiners' skills, which can be improved by education and training (Morrow & Reilly, 2011). The latter authors provide excellent guidance in eliciting and interpreting the plantar response:

1. Correct interpretation of the response is more important to reliability than the precise details of stimulation of the sole. When it is not feasible to stimulate the sole because of either impaired access or excessive ticklishness, the sign can be elicited by other forms of stimulation, including firmly stroking the medial surface of the tibia from proximal to distal (Chaddock sign), firmly compressing the lower calf muscles (Gordon sign), or firmly stroking the skin beneath the lateral malleolus from proximal to distal (Oppenheimer sign).
2. Extension of the big toe due to contraction of the extensor hallucis longus (EHL) muscle is essential to the extensor response. Extension or abduction of the other toes need not be present. Extension of the big toe should be synchronous with activity of other flexor muscles of the lower extremity, usually as the flexors of the knee and/or the ankle. (This synchronous muscle flexion need not be accompanied by joint movement.)
3. Extension of the big toe relative to the other toes can mimic the appearance of an extensor response, but if it does not involve contraction of the EHL such an event

is not a Babinski sign. For example, this can occur if all toes might flex followed by the big toe relaxing before the other toes, or if all of the other toes flex while the big toe remains motionless.

It is well-recognized that toxic-metabolic encephalopathy can produce extensor plantar reflexes. Less frequently, the extensor reflex is unilateral even though the cerebral dysfunction is bilateral. Notwithstanding, the most likely cause of a unilateral extensor plantar response is unilateral or at least asymmetrical pyramidal tract disease, and an assessment for anatomical lesions is warranted.

Equivocal or absent plantar reflexes do occur and generally are uninterpretable unless reflexes are markedly asymmetrical. An equivocal plantar response sometimes can be converted into a clear-cut extensor response by stroking the sole more laterally, or converted into a clear-cut flexor response by stroking the sole more medially.

Primitive reflexes, otherwise known as frontal release signs, involve more complex responses to stimulation than the deep tendon jerks. The method for eliciting and interpreting the primitive reflexes has been nicely reviewed by Schott and Rossor (2003).

Two groups of primitive reflexes—grasping reflexes and primitive oral reflexes—are familiar to generalist physicians. When properly assessed, they can contribute incrementally to neuropsychiatric diagnosis.

GRASPING REFLEXES

There are two types of grasping reflex, one elicited by movement of the examiner's fingers across the palm and the other elicited by prolonged touch in one spot. The first grasping reflex is elicited by first applying deep pressure to the palmar surface of the hand and then stroking distally toward the fingers. When the reflex is present, the hand will grasp the examiner's fingers and will continue hold on firmly as the examiner moves his or her fingers. The grasp will persist as long as the examiner pulls the fingers away; stroking the dorsum of the patient's hand may release the reflex. The second grasping reflex is initially elicited by light, static pressure (rather than movement) by the examiner's fingers on the radial part of the hollow of the hand. This elicits a gradual closing of the patient's hand on the examiner's fingers. When the second grasping reflex is strong the stimulus can be given anywhere on the patient's palm; the patient will reposition his or her hand to get a good grasp. In severe cases, the examiner can remove his or her fingers from the patient's hand and the patient will pursue the examiner's moving fingers, attempting to grasp them again, demonstrating a "groping reflex". Both types of grasping reflex suggest frontal system dysfunction; they are especially common in degenerative dementia. A unilateral grasp reflex implies unilateral or at least asymmetrical disease; however, a bilateral grasp reflex sometimes can be seen with unilateral lesions. Two examples of interpreting the sign are as follows: (1) the occurrence of a new unilateral grasp reflex in a patient with multiple sclerosis can be a sign of disease relapse or progression, or (2) the

occurrence of a grasp reflex in a patient with mild cognitive impairment would increase the probability that the impairment will evolve into dementia.

PRIMITIVE ORAL REFLEXES

Primitive oral reflexes represent vestiges of infant feeding behavior. The suck reflex, when present, can be elicited by putting something into the mouth—typically a tongue depressor. The rooting reflex is a turning of the mouth toward a stimulus that gently strokes the cheek; in more severe cases the mouth moves toward anything nearby brought into the field of view. The snout reflex is a puckering of the lips elicited by gentle pressure on the nasal philtrum. It should be distinguished from the pouting reflex, which is elicited by pressure on the lips or around the mouth and reflects pyramidal tract dysfunction rather than specifically frontal system dysfunction. The primitive oral reflexes are not lateralized. Their occurrence is diagnostically nonspecific beyond suggesting cerebral disease. The presence of two or three of the primitive oral reflexes could be helpful in distinguishing between a degenerative dementia and a dementia syndrome due to conversion or to another primary mental disorder.

THE EVOLVING ROLE OF THE PHYSICAL EXAMINATION

Increasingly, imaging and laboratory tests have become the primary standard for diagnosis in general medicine with the physical examination acquiring a less central role. While in some primary care settings the traditional general physical examination will remain relevant, the physical examination in secondary and tertiary care will continue to evolve. The authors expect several trends to continue:

1. The physical examination will be more hypothesis-driven and more individualized.
2. Individual components of the physical examination will be approached from a psychometric viewpoint, with population-specific and examiner-specific assessments of reliability, validity, and sensitivity and specificity for specific diagnoses.
3. Clinicians will make greater use of point-of-care technology to augment their senses when examining patients. Electronic stethoscopes are now common; handheld ultrasound units may become standard tools for bedside (or at least emergency room) cardiac and abdominal examinations.
4. The ubiquity of smartphones implies that digital images and audio and video recordings will become a standard way to record physical findings and share them with specialist colleagues. Smartphone accessories such as magnifying lenses and couplers to diagnostic instruments (e.g., ophthalmoscopes and stethoscopes) will facilitate this process. Devices intrinsic to smartphones, such as

accelerometers and cameras, will be used to collect physiologic information. Ultimately, the ease of transmitting physical findings between physicians and obtaining near real-time specialist advice may alter patterns of referral and payment for subspecialty care.

5. Specific parts of the physical examination will be the focus of structured training and objective competency assessment.
6. During the transition toward a more individualized, psychometrically informed, hypothesis-driven, and technologically assisted physical examination, there will be considerable variation in examination technique and in the validity and value of findings. The medical psychiatrist will need to consider the qualitative and methodological aspects of the physical examinations a patient has had to date—not just their nominal scope—to decide whether they answer the diagnostic questions at hand.

CLINICAL PEARLS

- The physical exam has a number of distinct purposes: (1) narrowing a differential diagnosis prior to ordering diagnostic tests; (2) looking for physical signs to support the diagnosis of a specific condition that often has symptoms or functional impairment in excess of findings on a nonfocused, general physical examination; (3) quantifying the severity of a known physical condition to better assess its relationship to the patient's subjective distress and functional impairments; (4) getting a subjective sense of the patient's condition to better understand its emotional impact; (5) enhancing positive transference through appropriate touching of the patient; and (6) communicating across disciplinary lines to stimulate a fresh look at a patient's problem.
- If a patient with suspicious symptoms for orthostatic hypotension due to autonomic dysfunction does not show a blood pressure drop immediately on standing up, the blood pressure should be measured again after the patient has been standing for at least 5 minutes.
- Patients with recurrent functional hyperventilation—with or without associated panic attacks—do not necessarily have tachypnea; their breathing may be deeper than normal rather than more rapid than normal. This may be the case more often in younger patients (Han et al., 1997).
- *Visual* attention can be impaired when simple attention and (static) visual acuity are intact. Visual attention is critical to driving or operating dangerous machinery. A simple bedside task is to give the patient a sheet of paper full of randomly oriented and randomly spaced letters and numbers and ask the patient to cross out a defined subset—for example, the even numbers and the vowels.
- The patient with transcortical motor aphasia, associated with border zone infarcts and paucity of speech, can

repeat sentences and can complete familiar phrases such as “Roses are red, violets are (blue).”

- Patients with Wernicke’s aphasia may be suspicious and paranoid early on, before they are aware of their deficits. Lack of comprehension and inability to repeat support the diagnosis.
- Almost all dominant-hemisphere brain lesions that significantly affect spoken language will also affect reading and/or writing. Thus, having the patient hand-write a one paragraph summary of the recent illness can be a time-efficient and sensitive (albeit nonspecific) way to screen for language problems in patients with medical or epidemiologic risk factors for brain diseases that might affect language.
- The clock drawing test (CDT) is an excellent screening test for dorsolateral frontal function when visual-spatial function is intact. When visual-spatial function is intact and executive function is impaired, the spontaneous drawing of the clock typically shows poor planning and organization. Numbers may be poorly spaced, duplicated, or omitted; if the clock is to be set at “ten after eleven” the patient might point the large hand toward the ten rather than the two. If the patient can then copy a clock drawing perfectly, the poor performance on the spontaneous clock drawing cannot be attributed to visual-spatial dysfunction or to impaired praxis.

DISCLOSURE STATEMENT

Dr. Fogel is Chief Scientific Officer of Synchronuron Inc., Managing Director of Anal-Gesic LLC, and Executive Vice President of PointRight Inc. He is the sole inventor or lead inventor on several pharmaceutical patents. In his opinion these affiliations do not entail any conflict of interest with regard to the editing of this book or his personal contributions to it. NEUROPSYCHOLOGICAL ASSESSMENT

Aaron P. Nelson and Stephanie Assuras

INTRODUCTION

Neuropsychology is the science of human behavior based on the function of the brain. Clinical neuropsychology is an applied discipline that uses principles of brain–behavior relationships to evaluate and diagnose abnormality in the realm of behavior and cognition. This process of evaluation and diagnosis, termed *neuropsychological assessment*, involves obtaining information about an individual’s history and current functioning as well as administering a variety of behavioral measures designed to probe specific cognitive functions. A clinical neuropsychologist analyzes and integrates information collected during the assessment process with the aim of providing diagnostic clarification or helping to guide treatment planning.

HISTORICAL PERSPECTIVE

Clinical neuropsychology traces its roots to the confluence of three major tributaries of psychological science: psychophysics, the psychometric method, and the lesion method in behavioral neuroanatomy. New methodologies for viewing the brain, both structurally and functionally, continue to illuminate the everyday miracles of thought, memory, and emotion. The integration of clinical work with experimental discoveries has reached a new zenith in cross-fertilization of both endeavors. The phenomenal growth of clinical neuropsychology over the past half century owes much to contemporaneous work in clinical neuroscience.

Although it is not possible to pinpoint the date of its establishment as a discipline, Arthur Benton points out that clinical neuropsychology lacked the usual trappings of a coherent specialty prior to 1960 (Benton, 1992). There were no professional organizations, journals, or training programs. In its earliest form, neuropsychology was practiced in medical settings in association with departments of neurology and neurosurgery. Psychologists with expertise in psychological measurement and a special interest in behavior effects of brain injury designed tests to assess various abilities in their patients.

Although theories of brain function can be traced back to the writings of the ancients, the term *neuropsychology* came into use only relatively recently. The ancient Egyptians originally localized the seat of human thought in the heart. This

notion remained largely unchallenged until some 3000 years later, when a Greek student of Pythagoras proposed that the brain was responsible for sensation and thought and advanced the notion that specific aspects of mental function were represented in specific regions of the brain. This approach to thinking about the brain was later termed *localization* and became the center of great controversy 2000 years later. Hippocrates, writing in the fourth century BC, claimed the brain as the organ of intellect, sensation, and emotion. Furthermore, he posited that mental illness was rooted in abnormal brain function. Along this line, he advanced the hypothesis that epilepsy was not the result of demonic possession but rather an organic ailment.

Beginning in the middle of the 19th century, psychophysics comprised a refined approach to the precise measurement of various human attributes. Galton’s studies of individual differences in sensory and psychomotor responses epitomized this approach, as did the early work of Ebbinghaus on “individual memory curves of retention” (Ebbinghaus, 1885/1913). At the beginning of the 20th century, Binet and Simon (1916) and others introduced the revolutionary concept of measurable intelligence, a notion that continues to have a profound and controversial impact on human society. The psychometric method was employed to design and construct measurement methods possessing validity and reliability, which are crucial underpinnings of all psychological and neuropsychological tests.

The lesion method has its origins in early case reports of brain–behavior effects in injury and illness. The famous case of Phineas Gage in 1848 involved a railroad worker who survived a catastrophic injury in which an iron spike was blasted through his head, essentially disconnecting the anterior portion of his brain (Harlow, 1868). The resulting pattern of spared and affected functions in Gage gave rise to an early understanding of the functional role of the frontal lobes in human behavior. The pioneering work of Paul Broca, a French neurologist who described his patient “Tan” in 1861 (Broca, 1861), was instrumental in unveiling the role of the dominant hemisphere in human language function. In the 1950s, Scoville and Milner’s studies of patient “HM” shed new light on the role of the limbic system in anterograde memory function (Scoville & Milner, 1957).

The advent of World War I saw the first period in history when modern American medicine had to cope with the tragedy of “industrial” warfare. Legions of combatants returned

from Europe with life-altering brain injuries. Assessing the cognitive consequences of such injuries spurred the growth of early assessment methodologies. The aftermath of World War II marked the establishment of modern clinical psychology, with an emphasis on the special skill of psychological testing. Measurement of intelligence was the venue in which early testing applications were most significant.

The earliest codification of neuropsychological examination methods can be attributed to Dr. Ralph Reitan. A pioneering neuropsychologist, Reitan and his colleagues assembled a battery of test measures in which specific patterns of scores were linked to dysfunction of associated brain regions (Reitan & Wolfson, 1993). Later approaches diverged from a reliance on a set battery of tests and instead used a more dynamic method, the “process” approach to neuropsychological assessment developed by Dr. Edith Kaplan in her work at the Boston Veterans Administration Hospital (Kaplan, 1990). This technique entails ongoing *in situ* hypothesis testing in which particular attention is paid to the qualitative aspects of a patient’s test response. Although quantitative data are also important, the patient’s route to solving a particular cognitive problem often reveals an underlying process that can be reflective of spared and affected brain regions. In contemporary practice, both of these methods rely on a vast body of knowledge about characteristic syndromes that are associated with underlying disease states.

The current practice of clinical neuropsychology concerns itself with assessment of cognitive functions, through the use of test instruments, for the purpose of understanding the functional integrity of the brain. By relying on knowledge of brain–behavior relationships and characteristic syndromes, the results of assessment are useful for diagnosis and treatment of brain-related injuries and illness.

FUNDAMENTAL ASSUMPTIONS

The study of clinical neuropsychology is firmly rooted in the larger field of neuroscience and therefore rests on the assumption that the nervous system impacts behavior and cognition. Conversely, inferences can be made about the integrity of the brain based on observable behavior. The ability to make accurate and meaningful inferences is predicated on a thorough understanding of two streams of knowledge: (a) the neural infrastructure underlying normal human cognition and behavior, and (b) the characteristic profiles of neurocognitive and neurobehavioral syndromes.

Observable behavior is frequently the most sensitive manifestation of brain pathology. Such behavior can range from subtleties of social comportment to performance on a specific neuropsychological test. A competent neuropsychologist will sample multiple domains of behavior. Observable behavior, including “test behavior,” reflects an interaction between the domains of person and environment. Variables from each domain must be considered in order to arrive at an understanding of the clinical significance of a given behavior.

Individual tests used in neuropsychological practice focus on measurement of particular cognitive processes. In order to

be useful, each test must be constructed according to sound psychometric principles and possess adequate validity and reliability. In addition, there must be appropriate normative data with which to compare a single patient’s performance. The neuropsychologist relies on a comprehensive understanding of test construction and standardization in order to select and interpret measures for a given clinical context. This includes choosing tests with normative data derived from subjects of similar age, education, and nationality to the patient currently being tested (Attix et al., 2009).

The interpretation of test results depends on an understanding of the component processes involved in any given test response. For example, the ability to name an object to visual confrontation depends on multiple processes that are mediated by different brain systems. The individual must first orient and attend to the stimulus. Second, the stimulus must be accurately registered at the level of visual perception. Third, the neural pathway that links the visual percept to meaningful recognition must be patent. Fourth, the ability to assign a phonemic/lexical label to the object must be intact. Finally, the individual must be able to convey a response through speech. Because a complex cognitive action, such as naming a simple object, can be undermined by perturbation at any point within the network linking multiple functions, a neuropsychologist must understand the component processes involved in each behavior. By examining the patient’s function in multiple domains with multiple measures, the neuropsychologist can determine which processes and associated neural circuits are functioning abnormally.

Performance on a single test is not sufficient to make a diagnostic inference. A common misconception is that a poor score on a particular test denotes an impairment in the domain that the test is nominally designed to assess. For example, if a patient performs poorly on a “memory” test, this does not necessarily signify impairment in memory but could indicate difficulties with attention or language. A neuropsychologist will evaluate a profile of test results in a dynamic, interactive fashion in order to arrive at a diagnostic formulation.

Neuropsychological testing is simply one means of obtaining a sample of behavior. A neuropsychologist must proceed with caution in using test data to predict behavior. The testing environment is, by necessity, contrived to promote a standard approach to test administration. This contrivance constitutes a challenge in understanding how test performance corresponds to “real life” behavior. For example, a patient who complains of difficulty with concentration and memory at work may perform quite normally in the context of the quiet, distraction-free examination room. Discrepancy between “test behavior” and “real-life” behavior is the source of ongoing challenge for the design of an ecologically valid assessment environment.

CLINICAL APPLICATIONS

The overall purpose of the neuropsychological evaluation is the creation of a dynamic portrait of the patient in cognitive, psychological, and functional terms. Characterizing

cognitive strengths and weaknesses is a critical goal of the neuropsychological evaluation, as this contributes to an understanding of the underlying etiology and clarification of the differential diagnosis. Precise quantitative measurement of cognitive functions also yields data that can be useful for establishing a baseline of cognitive functioning against which to calibrate degree of change in patients over time. This involves systematically monitoring cognitive functioning to determine response to a specific treatment intervention, or to characterize the course of a symptomatic pattern for the purpose of further clarifying a diagnosis or prognosis. For example, with objective quantitative data, neuropsychologists are in a unique position to evaluate the efficacy of treatment interventions (e.g., pharmacotherapy, electroconvulsive therapy, neurosurgery) by reevaluating after initiation of therapy.

As Americans live longer and become more aware of the relationship between aging and dementia, they are more likely to notice subtle changes in cognitive function in themselves and in family members. This awareness is particularly heightened in individuals with a family history of neurodegenerative disease. Detection of subtle cognitive dysfunction in aging is even more challenging in individuals of high baseline intellectual ability. Neuropsychological assessment can be useful in identifying abnormalities of cognitive function that may not be evident on casual observation, within a standard office mental status examination, or through the use of common brief screening measures (e.g., Mini Mental State Examination, Montreal Cognitive Assessment).

Because of its knowledge base in behavioral neuroscience, neuropsychology has an important role in treatment planning. Enumeration of cognitive strengths and intact abilities can be used to design real-world adaptive or compensatory strategies that a patient may employ to circumvent deficits. Neuropsychologists make specific and detailed recommendations for rehabilitation in cases of brain injury, tumor, and stroke, and are central to the planning process for patients and families confronting dementing illnesses. Recommendations for supplementary diagnostic procedures (e.g., imaging, electroencephalogram, polysomnography) and/or referral for additional specialty consultation (e.g., neurology, ophthalmology) can be indicated to round out the diagnostic process. Referral to psychiatry may be indicated for consideration of the potential benefits of pharmacological intervention (e.g., treatment with antidepressant, stimulant, cognitive-enhancing, or mood-stabilizing medication).

Prescribed treatment recommendations may include compensatory strategies and skill acquisition programs to address cognitive weaknesses. Behavioral strategies to enhance planning and organization can be implemented via post-evaluation consultation with the neuropsychologist or through the use of structured workbooks and guides. If more intensive or ongoing treatment is indicated, a referral can be made to a clinician or program specializing in cognitive rehabilitation. Health-related behavioral modifications are often recommended. For example, a patient with insomnia resulting in suboptimal daytime cognitive function will benefit

from learning about sleep hygiene factors that can lead to improved, restorative sleep. Modification of environmental factors can be effective for enhancing patient safety and caregiver confidence; the use of tracking devices for wandering patients (e.g., GPS-enabled shoes and bracelets) can be practical solutions for a common problem in elderly individuals with neurodegenerative illness.

The neuropsychological exam can be “negative” in a range of scenarios. The “worried well” may be relieved to learn that their occasional word-finding hesitancy does not bespeak the onset of a dementia; recommendations for maintaining optimal brain health going forward are often appreciated. Interestingly, not all patients are relieved to learn that their cognitive symptoms do not have an underlying organic etiology. Discussion of this type of patient is beyond the scope of our chapter. However, a recommendation for individual psychotherapy is often more “acceptable” to the patient after he or she has been through a comprehensive evaluation process or if it is contextualized as a means of enhancing cognitive health.

Neuropsychological assessment can delineate the potential impact of brain pathology on venues of real-life functioning, ranging from the most rudimentary human activities (bathing and dressing) to work life and the complexities of intimate relationships. Neuropsychologists can provide an explanatory context for a patient’s cognitive, social, or behavioral difficulties. In addition, in the case of progressive disease, neuropsychologists can provide education about how the patient’s changing condition will impact day-to-day functioning differently over time. It is not unusual for an otherwise sensitive spouse to blame an affected husband or wife for a particular behavior, which had been assumed to be under voluntary control. Learning that the behavior is part and parcel of a disease process dramatically alters this attribution and allows both patient and spouse to work together on the problem.

Neuropsychological consultation is frequently pivotal in cases involving adjudication of criminal or civil matters. Neuropsychologists with special training and experience in forensics play an important role in determination of competency in matters ranging from criminal responsibility to guardianship. There has been significant increased appreciation of the utility of neuropsychological knowledge for assisting the courts in understanding functional consequences of neurological disorder in personal injury cases ranging from product liability to accidental injury. Neuropsychology is becoming central to determination of competency and medical decision making in end-of-life care. Neuropsychologists have pioneered the development of specialized and embedded measures of effort and symptom validity for use in cases in which motivational factors are important (cf., Bianchini et al., 2001).

APPROACH TO NEUROPSYCHOLOGICAL ASSESSMENT

Three major approaches to neuropsychological assessment have emerged during the last half century.

FIXED BATTERY APPROACH

The fixed battery approach to neuropsychological assessment was developed primarily by Ralph Reitan and his colleagues (cf., Reitan & Wolfson, 1992). This approach to assessment was formulated in the 1950s, two decades before the advent of widely available structural brain imaging. At that time, this type of assessment was relied upon as a first-line diagnostic method in patients with stroke, brain tumor, or traumatic injury. Relying strictly on quantitative scores and indices, the Halstead-Reitan battery yields information regarding lesion laterality, localization, and extent of overall neuropsychological impairment. As the name suggests, practitioners of this approach typically utilize a standard set of tests in the context of assessment and do not vary this battery, if possible. The battery is designed to assess each major cognitive domain and therefore ensure a comprehensive assessment of every patient. A clear advantage of this approach is the ability to detect deficits that are unsuspected or not otherwise evident. Another advantage is that practitioners of this method become very familiar with the subtleties of the battery and develop a greater sensitivity to slight variations in the performance of component tasks. Disadvantages of this approach include inefficiency (i.e., a time-consuming battery is administered in all cases, including those for whom more focused assessment would be sufficient) and lack of flexibility. Some have also criticized the most widely used fixed-battery approach for insufficient assessment of key functions, including memory (Lezak, 1995).

PROCESS APPROACH

Another major neuropsychological methodology is the Boston Process approach, primarily developed by Edith Kaplan and colleagues (Milberg et al., 1986). This approach proceeds in a hypothesis-driven manner and uses the patient's test performance to guide and inform an evolving and dynamic assessment strategy. The process-oriented evaluation is individually tailored to each patient and uses specific tests for the purpose of answering particular questions. As answers to these questions emerge during the evaluation, the neuropsychologist moves through a series of decision points, probing particular cognitive functions as needed; test selection occurs in real time. In addition, this approach stresses qualitative aspects of test performance, examining the process by which the patient solves a problem rather than exclusively relying on test scores as quantitative data. Tests are administered in a standardized fashion but can also be modified to test the limits of cognitive function and to produce richer qualitative data. Task performance is analyzed across multiple measures to parse out component processes and identify specific cognitive deficits.

FLEXIBLE BATTERY APPROACH

In current practice, most neuropsychologists utilize the so-called "flexible battery" approach (Sweet et al., 2001). Just as the name implies, a select battery of tests may be the starting point for assessing a particular case type. For example, a

specific set of test measures is used for evaluating elderly individuals referred with a question of dementia. However, the clinician can modify the battery either beforehand or during the course of the assessment depending upon specifics of the case, including questions that emerge during the administration of other test measures. This approach has the virtue of generating a substantial repository of core common data on similar cases that can be pooled for both clinical and academic benefit, while allowing for latitude in the individual case.

CLINICAL METHOD

Clinical neuropsychological assessment comprises a series of activities during which information is elicited and analyzed in the service of diagnosis and treatment planning. This process is illustrated in Figure 3.1. Although test administration is the most time-consuming component of the process, it is often the case that some of the most valuable information emerges while discussing a patient's history and current life situation. The information obtained during the initial interview is important for differential diagnosis and frequently guides the remainder of the assessment.

REFERRAL QUESTION AND CHIEF COMPLAINT

The first task of a neuropsychological assessment is to clarify the reason for referral. Patients are typically referred for neuropsychological assessment by other clinicians involved in their care, often for assistance in diagnostic clarification and treatment planning. After the referral question is ascertained, the patient is seen and a chief complaint is elicited including a clear description of the onset and course of the complaint (e.g., symptoms, concerns) as well as information regarding the medical and social context in which the problem(s) emerged. The patient's overall understanding of the rationale for the consultation and appreciation of his/her current circumstances is also sought.

HISTORY

Information is obtained from a variety of sources including the patient's self-report, observations of family members or close friends, medical records, and prior evaluations from academic or work situations. Information is obtained regarding (1) past medical history including illnesses, injuries, surgeries, medications, hospitalizations, substance abuse, and relevant family medical history; (2) past psychiatric history including hospitalizations, medications and outpatient treatment; (3) developmental background including circumstances of gestation, birth and delivery, acquisition of developmental milestones, and early socialization skills; (4) social development including major autobiographical events and relationships (a three-generational geneogram is highly useful in gaining relevant family information); (5) educational background including early school experiences and academic performance during high school, college, postgraduate study, and other educational and technical training (the presence of

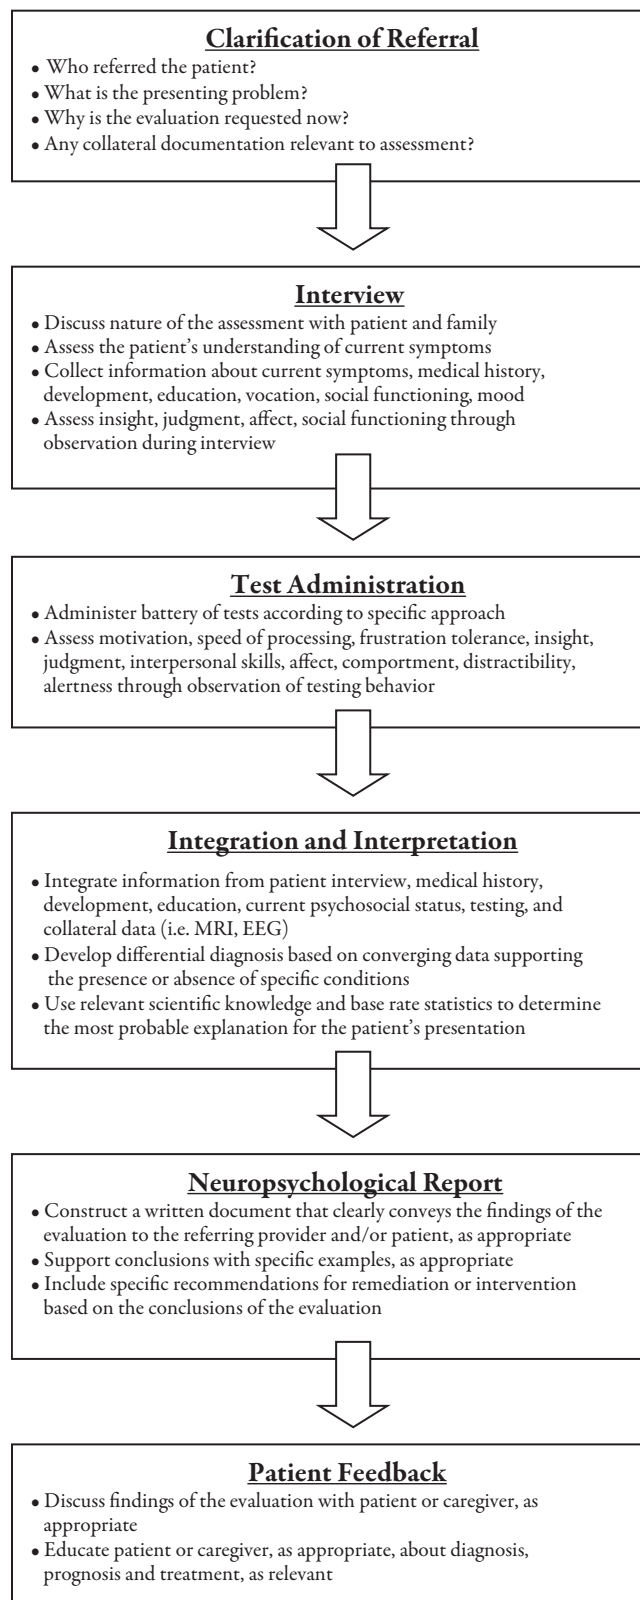

Figure 3.1 Schematic of Neuropsychological Evaluation.

a learning disability should be assessed); (6) vocational history including work performance, work satisfaction, and relationships with supervisors and coworkers; and (7) recreational interests and hobbies.

BEHAVIORAL OBSERVATIONS

Physical appearance is inspected including symmetry of anatomical features, facial expression, manner of dress, and attention to personal hygiene. The patient is asked specific questions regarding unusual sensory or motor symptoms. Affect and mood are assessed with respect to range and modulation of felt and expressed emotions and their congruence with concurrent ideation and the contemporaneous situation. Interpersonal comportment is assessed in the context of the interview. Specifically, attention is paid to whether the patient's behavior reflects a normal awareness of self and other in the interaction, along with whether the patient is motivated and complies with examination requests, instructions, and test procedures. An appreciation of the patient's level of motivation to participate in the evaluation and comply with examination instructions is crucial to assessing the validity of the test data. General level of arousal or alertness is determined by observing the patient's degree of drowsiness, tendency to yawn or fall asleep during the interview, level of interpersonal engagement, and speed of response in conversation. Environmental and diurnal factors can modify arousal, and an attempt should be made to assess whether this is relevant in the case of a particular patient by inquiring about consistency of arousal level and any fluctuations that the patient or caregiver has observed.

EXAMINATION

A sufficiently broad range of neuropsychological functions is evaluated using tests and other assessment techniques. The major domains to be surveyed include general intellectual ability, attention, executive function and comportment, memory, language, visuospatial abilities, motor functioning, and mood/personality. As a prelude to test administration, it is imperative to establish the integrity of sensation and perception because impairments in these areas can invalidate the results of examination. For example, it would be incorrect to conclude that a patient has a receptive language impairment when, in fact, there is a primary hearing deficit.

DIAGNOSTIC FORMULATION

Data from the history, observation, and testing of the patient are analyzed collectively to produce a concise understanding of the patient's symptoms and neuropsychological diagnosis. A configuration of abilities and limitations is developed and used both diagnostically and as a framework through which to address the goals of treatment. When possible, the diagnostic formulation should identify the neuropathological factors that give rise to the patient's clinical presentation, including underlying anatomy and disease process.

RECOMMENDATIONS AND FEEDBACK

Consultation concludes with the process of feedback, through which the findings of the evaluation and treatment recommendations are reviewed with relevant individuals (i.e., referring physician, the patient, family, treatment team members). As discussed earlier in the chapter, a variety of treatment plans

may be advised including neurological evaluation, psychiatric consultation, psychotherapy, cognitive/behavioral remediation, and vocational guidance. Recommendations should be pragmatic and individually tailored to each patient’s specific needs. Strategies for optimizing performance in personal, educational, occupational, and relational spheres are identified and discussed in lay language that the patient and family member(s) can understand. When possible, the clinician outlines concrete strategies to facilitate remediation of identified problems. Appropriate neuropsychological follow-up is also arranged when indicated.

DOMAINS OF NEUROPSYCHOLOGICAL FUNCTION

The fractionation of neuropsychological functions into specific domains is a somewhat arbitrary organizational contrivance. In reality, there is considerable overlap within and between cognitive domains. For example, working memory shares much common ground with aspects of attention and language.

GENERAL INTELLECTUAL ABILITY

Determining an individual’s level of intellectual functioning is a fundamental component of the neuropsychological assessment. Intelligence encompasses a broad range of capacities, many of which are not directly assessed in the traditional clinical setting. The estimate of general intellectual ability is based on both formal assessment methods and a survey of demographic factors and life accomplishments. Information regarding the patient’s educational background and longstanding

difficulties (e.g., learning disability, repeated grades), occupational history, and special abilities is used to establish an estimate of baseline intellectual functioning. Once established, general level of intelligence serves as a point of reference from which to evaluate performance in other domains. Test performance should always be compared with an estimate of premorbid level of functioning, which is critical in establishing whether there has been a change in cognitive status. However, it is important to note that an individual’s profile of cognitive abilities can range considerably from domain to domain; variable capability across diverse neuropsychological functions is often the rule rather than the exception in normal human development (Schretlen, 2003). While superior intelligence may obscure the detection of cognitive deficits, low baseline intelligence may appear to represent a cognitive decline when no change from a previous level of functioning has occurred.

Formal measures of general intellectual function typically assess a broad range of functions through multiple subtests (e.g., WAIS-IV, WASI-II, WISC-IV) and yield an “intelligence quotient” as well as other derived index scores. Other test instruments obtain high correlations with IQ measures and have been used to estimate overall intellectual ability (e.g., Ravens Progressive Matrices). In cases of known or suspected impairment, premorbid ability can also be surmised from performance on measures presumed less sensitive to cerebral dysfunction (e.g., vocabulary). Single-word reading tests (e.g., WTAR) have been used to estimate baseline verbal intelligence in patients with early degenerative conditions. In addition, so-called “best performance methods” can be used. This method assumes that the patient’s highest level of performance can be used to set a reference point for optimal baseline ability (Table 3.1).

Table 3.1 GENERAL INTELLECTUAL ABILITY

TEST NAME	DESCRIPTION
Wechsler Intelligence Scales	<p>The Wechsler Adult Intelligence Scale (WAIS-IV) is composed of 13 individual subtests. Administration of all subtests generates Full-Scale IQ and four different performance indices: Verbal Comprehension Index, Perceptual Reasoning Index, Working Memory Index, and Processing Speed Index.</p> <p>The Wechsler Abbreviated Scale of Intelligence (WASI) is designed to be a short and reliable measure of intelligence that produces Indices that are similar to those obtained with the WAIS-IV.</p> <p>The Wechsler Intelligence Scale for Children (WISC-IV) is used for testing children and adolescents ranging in age from 6–17 years.</p> <p>The Wechsler Preschool and Primary Scale of Intelligence (WPPSI) is used for testing children ranging in age from 4–6.5 years.</p>
Wechsler Test of Adult Reading (WTAR)	<p>The WTAR is a measure of recognition vocabulary requiring oral reading of 50 phonetically “irregular” words. It is used to estimate premorbid baseline intellectual ability in patients with known or suspected dementia. Similar measures include the NART, NART-Revised and ANART. Errors consist of word mispronunciations.</p>
Raven’s Standard and Colored Progressive Matrices	<p>These are standardized measures of nonverbal analogical reasoning widely used both within and outside the United States as a “culture fair” measure of general intellectual ability. Both tests require the patient to demonstrate an understanding of the logic underlying visual patterns by selecting the missing component of the pattern from a series of choices. The Standard Matrices contain 60 black and white items ranging from simple to extremely difficult, while the Colored Matrices consist of 36 colored items that span a limited range of complexity. Errors consist of incorrect identification of the missing component of the visual pattern.</p>

Table 3.2 ATTENTION AND EXECUTIVE FUNCTIONING

FUNCTION	TEST	DESCRIPTION
ATTENTION SPAN	Digit Span	The examiner reads increasingly long strings of numbers aloud. The examinee must repeat the numbers aloud in the same order, first forward and then in the reverse order.
	Spatial Span	The examiner taps a series of blocks in fixed locations. The examinee must repeat this series in the same order, and then in the reverse order.
SUSTAINED ATTENTION & VIGILANCE	Auditory & Visual Continuous Performance Test (CPT)	Basic auditory vigilance is tested by having the patient listen to a series of letters read serially and responding to a single target letter or series of letter configurations. Visual vigilance can be tested by showing a series of single numbers on a computer screen and requires responding to a target stimulus, but not to nontarget stimuli.
	Paced Auditory Serial Addition Test (PASAT)	The patient hears a tape-recorded voice reading numbers at various rates, ranging from every 2.4 seconds to every 1.2 seconds. The objective of the task is to sum the last two numbers heard and voice the sum aloud (e.g., if the numbers from the tape were “5, 2, 8, 4”, the patients responses would be the following (in italics): “5, 2, 7, 8, 10, 4, 12,” etc.). The process of voicing the sum aloud serves as interference, which must be overcome in order to attend to the following number. In total, 60 numbers are read in each of the four trials and every subsequent trial is faster than the one preceding it.
SET-SHIFTING	Trail Making Test A & B	This measures of visual scanning, visuomotor tracking, and response set flexibility. Trails A involves connecting consecutively numbered circles, from 1 to 25. Trails B requires the patient to continually shift set, alternating between letters and numbers (i.e., 1, A, 2, B, etc.). Both tasks must be performed as quickly as possible and without lifting the writing utensil from the paper.
	Wisconsin Card Sorting Test	A measure of nonverbal concept formation, response set flexibility, sustained attention, and ability to integrate corrective feedback. The patient must sort cards according to underlying principles (color, form, number), which must be deduced and which are shifted at set intervals.
	Luria Graphomotor Sequencing	Involves using a pencil to copy a series of patterns (i.e., m-n-m-n, peaks and plateaus, and multiple loops) without lifting the pencil. Errors consist of failing to alternate (i.e., m-n-m-m-m)
	Luria Motor Sequences	Involves performing repeated sequences of hand movements. Errors consist of failure to maintain the order of movements within each sequence.
RESPONSE INHIBITION	Stroop Color-Word Interference Test	Composed of 3 parts that require (1) reading a series of black and white color words (red, blue, green), (2) identifying the color of red, blue and green 'Xs', and (3) identifying the ink color of incongruent color words (i.e., the correct response to the word 'red' printed in blue ink would be 'blue'). In all conditions the patient is asked to perform as quickly as possible.
	Motor Go-No-Go	Involves responding to a target signal (1 loud knock) by lifting a finger, but not to a second signal (2 loud knocks). The tendency to respond to the second signal must be inhibited. The examiner produces a series of 1 or 2 knocks and observes the patient's responses. Each hand is tested separately.
PLANNING	Delis-Kaplan Executive Function System (DKEFS) Tower Test	Involves ordering 4 colored beads within a set of constraints. Only one bead may be moved at a time, and beads moved from their initial placement may not be returned. Similar tests include Tower of Hanoi and Tower of London.
PERSEVERANCE	Verbal & Design Fluency	Letters: the examinee must recite as many words as possible that start with a particular letter, with the exception of proper nouns, numbers, and more than one iteration of the same root word. This is repeated with three different letters in total. Categories: the examinee must recite as many words as possible from a particular category. This is repeated with three different categories in total. Design: the examinee must create as many unique designs as possible by connecting lines between dots laid out in a grid.

ATTENTION AND EXECUTIVE FUNCTION

Attention

Many cognitive capacities are inherently predicated on a fundamental ability to attend to the surrounding environment. For example, an individual cannot effectively name an object if the object is not first attended to and visually processed. Because attention is a prerequisite for other aspects of cognitive function, disruption of attention can generally skew the results of a neuropsychological assessment. Early assessment of attention is vital for informing the scope of the examination and the analysis of test data (Table 3.2).

Attention is a general term that encompasses a number of different component processes. Attention span refers to the number of unrelated “bits” of information that can be held on line at a given moment in time. Assessment of attention span is typically accomplished through the recall of progressively longer series of information bits, such as numbers (digit span) or spatial locations (spatial span). Sustained attention, also called vigilance, refers to the capacity to maintain active attention over time. The most common method of assessing vigilance utilizes a target detection paradigm. Here the patient is instructed to respond to an infrequently occurring target stimulus. For example, on a measure of auditory vigilance, the patient hears a series of letters of the alphabet and must signal by pressing a response key each time a particular target is presented (see CPT, PASAT). Selective attention is similar to sustained attention, but requires a response only to a particular class of stimuli and not other stimuli. Set-shifting refers to the capacity to relinquish an existing procedural strategy in favor of a new response, based on recognition of a change in reward contingencies. It is typically measured with tasks requiring the patient to shift focus among stimulus features of a test display (see Trail Making A and B, Wisconsin Card Sorting Test, Luria Graphomotor Sequences). Resistance to interference, also called response inhibition, refers to the ability to sustain a given response even in the face of a salient distraction designed to undermine the target response. This is assessed with tasks requiring the patient to inhibit overlearned responses or other distractions that could undermine a desired response (see Stroop Interference Test, Trail Making Test).

Executive Functioning

Executive functions require the capacity to process information in a planful, organized, and contextually appropriate manner. Formal tests of executive function assess a number of different capacities including some functions mentioned above (set-shifting, overcoming interference, response inhibition) and also planning, perseverance, initiation, reasoning, and abstraction. Planning involves thinking several steps ahead of one’s current circumstances for the purpose of informing and altering a course of action. Tests measuring planning ability often require subjects to determine the correct series of steps needed to successfully reach a particular goal (see DKEFS Tower Test). Perseverance is the ability

to sustain a particular course of action, even in the absence of an external prompt. Measurement of perseverance often begins with both examiner and subject performing the same task, but involves the subject continuing the task even after the examiner has stopped (see Luria Motor Sequences, Verbal and Design Fluency). Initiation refers to the ability to spontaneously commence an action in the absence of a direct prompt from the external environment. This function is measured with presentation of a task followed by a period of time during which the subject is expected to respond independently (see Verbal Fluency, Go-No-Go). Reasoning involves using a system of logic to solve a particular problem or task. This can be measured in a variety of ways, including using visual puzzles and verbal analogies (see Ravens Progressive Matrices, WAIS-IV Comprehension). Abstraction is the ability to articulate shared attributes of dissimilar objects (e.g., WAIS-IV Similarities, Wisconsin Card Sorting Test) (Table 3.2).

COMPORTMENT, INSIGHT, AND JUDGMENT

Although few tests probe these functions in a formal manner, they are important components of neuropsychological function and are frequently disturbed in cases of neurological and neuropsychiatric illness. Comportment refers to the ability to behave in a contextually appropriate manner. Disturbances often manifest as socially inappropriate behaviors that suggest insensitivity to accepted cultural norms. Examples might include making offensive comments, crossing interpersonal boundaries, interrupting during conversation, or failing to attend to personal hygiene. In the context of neuropsychological assessment, insight involves an accurate perception of one’s mental and physical condition as well as appreciation of the impact of one’s behavior on others. Cognitively impaired individuals often lack one or both of these components of insight. Judgment involves the capacity to perceive and assess one’s environment accurately and to make decisions that reflect sensitivity to preserving the safety and integrity of oneself, one’s resources, and one’s environment.

A neuropsychologist can assess these functions informally through naturalistic observation, reports from individuals familiar with the patient, and also by inquiring about any accidents or legal infractions involving the patient. Formal measures of these functions exist primarily in the form of questionnaires that quantify the degree to which the patient manifests disturbances in these general areas. The Frontal Systems Behavior Scale (FrSBe) comprises descriptions of various behaviors that are characteristic of patients with frontal lobe damage. Each behavior is assigned a severity rating by the patient and by a family member, and the overall severity rating is thought to reflect the degree of behavioral disturbance present. The Neuropsychiatric Inventory (NPI) is another self-report rating scale that is completed by a family member or caregiver. Both the extent of the patient’s behavior and the degree of subsequent familial distress are rated.

LEARNING AND MEMORY

The assessment of learning and memory function is perhaps the most complex endeavor of the neuropsychological examination. Working memory involves holding a stimulus or set of stimuli in mind in order to either produce it after a delay (e.g., looking up a telephone number and remembering it until it is successfully dialed) or use it in a mental procedure involving manipulation of information (e.g., carrying out mental arithmetic). The simpler aspect of working memory, also called maintenance of information, can be tested by requiring a subject to hold information in mind and reproduce it after a short delay (see Digit Span Forward). The more complex component of working memory can be tested in a number of ways, all of which entail online maintenance and manipulation of information (see Tests of Mental Control, WAIS-IV Letter-Number Sequencing, WAIS-IV Arithmetic, PASAT). Memory is assessed with respect to modality of presentation (auditory vs. visual), material (linguistic vs. figural), and locus of reference (personal vs. nonpersonal). Also important is the time of initial exposure, namely whether information was learned before the onset of brain damage (retrograde memory; see Boston Retrograde Memory Test, Transient Events Test) or after (anterograde memory; see WMS-IV, RAVLT, Bushke SRT, Three Words/Three Shapes, Warrington RMT). The evaluation of memory should include measures that allow the dissociation of component processes entailed in the acquisition and later recall of information,

namely encoding, consolidation, and retrieval. To this end, measures are used to assess performance with respect to length of interval between exposure to information and demand for recall (immediate vs. short vs. long delay) and extent of facilitation required to demonstrate retention (free recall vs. cued recall vs. recognition). The assessment of retrograde memory function poses a special problem insofar as it is difficult to know with certainty what information was previously registered in the remote memory of a particular patient. Although there are a number of formal tests that can be used for this purpose (e.g., Boston Remote Memory Battery, Transient Events Test), we also assess this aspect of memory function by asking for personal information which presumably is well known, or had been well known at one time, by the patient (i.e., names of family members, places of prior employment). In these instances it is helpful to obtain confirmation of the accuracy of this information from family members or friends, if possible (see Table 3.3).

LANGUAGE

Language is the medium through which much of the neuropsychological examination is accomplished. Language function is assessed both opportunistically, as during the interview, and via formal test instruments (Table 3.4). Conversational speech is observed with respect to fluency, articulation, and prosody. The patient's capacity to respond to interview questions and test instructions provides an

Table 3.3 LEARNING AND MEMORY

FUNCTION	TEST	DESCRIPTION
WORKING MEMORY	Tests of Mental Control	The examinee is asked to recite familiar sequences such as the alphabet, days of the week, months of the year, and numbers from 1–20 as quickly as possible. The examinee then must recite all sequences, except the alphabet, in reverse order. Serial subtractions involve subtracting a particular number until a predetermined point is reached.
	WAIS-IV Letter-Number Sequencing	The patient hears a series of alternating numbers and letters and is required to reconfigure them so that all of the numbers are recited first, in ascending order, and then letters in alphabetical order.
	WAIS-IV Arithmetic	Involves mental calculation of aurally presented arithmetic problems of increasing difficulty.
See also Digit Span Forward and PASAT in Table 3.2.		
RETROGRADE MEMORY	Boston Retrograde Memory Test	Involves showing a series of black and white photos of famous persons from the 1920s to the 1980s. If the patient cannot spontaneously generate the correct name, the examiner can give a semantic cue (i.e., “he was a singer in the 1920s”) and then a phonemic cue (i.e., first name). This test assumes that the patient has been exposed to the information in the first place.
	Transient Events Test (TET)	This is a measure of memory for popular news events from the 1950s through the 1990s. Items were selected by way of the <i>New York Times</i> index according to the criteria that they were mentioned at least 250 times during a particular year and less than five times over the subsequent 2 years. Hence, all items were of transient notoriety thereby minimizing confounding effects of overexposure. Free recall and recognition are tested.

(continued)

Table 3.3 (CONTINUED)

FUNCTION	TEST	DESCRIPTION
ANTEROGRADE MEMORY	Wechsler Memory Scale (WMS-IV)	This is a composite battery of tests assessing orientation, attention, learning, and memory for verbal and visual information across immediate and delayed intervals. It yields a series of index scores.
	Rey Auditory Verbal Learning Test	This measure of verbal encoding, learning, and retention involves drilling the examinee on a series of 15 unrelated words over five successive trials. Learning is followed by an interference trial, immediate recall, and 30-minute delayed recall and recognition. Various comparisons yield information regarding sensitivity to proactive and retroactive interference and rate of forgetting.
	Bushke Selective Reminding Test	This is a special type of list-learning test that is most helpful in cases where encoding is intact, but there may be a question of impairment at the level of consolidation or storage. A list of 12 words is read, and the patient must repeat as many words as possible. However, different from the previous list-learning tasks, the examiner then reads only the words that the patient did not recall. This continues across 6 trials, and each time the patient must try to recite as many words as possible but only hears the words not recalled on the preceding trial. There are immediate and delayed recall trials followed by visual multiple choice recognition paradigms.
	Three Words Three Shapes Memory Test	The patient is instructed to copy three words and three shapes, after which incidental recall is tested. The patient is drilled on the words and shapes until criterion is reached, and recall is tested after intervals of 5, 15, and 30 minutes. Recognition is tested using distracter shapes and words.
	Warrington Recognition Memory Test	Involves the visual presentation of single words and faces at the rate of one every 3 seconds. The patient is instructed to reach each word silently and make and report a judgment regarding his association (pleasant or unpleasant) to it. Immediately afterward, the patient is shown a pair of words, each containing a target word and a distracter, with the instruction to identify the one presented previously. Memory for faces is tested in the same way.

informal index of receptive language ability or comprehension. Visual confrontation naming is carefully assessed so that word-finding problems and paraphasic errors may be elicited. Repetition is measured with phrases of varying length and phonemic complexity. Auditory comprehension is evaluated by asking the patient questions that range in length and grammatical complexity. Reading measures include identification of individual letters, common words, irregularly spelled words, and nonwords, as well as measures of reading speed and comprehension. Spelling can be assessed in both visual and auditory modalities. A narrative handwriting sample can be obtained by instructing the patient to describe a standard stimulus scene.

VISUOSPATIAL FUNCTIONS

After establishing the integrity of basic visual acuity, the spatial distribution of visual attention is evaluated. The presence of visual neglect is assessed through the use of tasks that require scanning across all quadrants of visual space. Assessment of left/right orientation involves directing patients to point to specific body parts, either on themselves or the examiner. Topographical orientation can be tested by instructing the patient to indicate well-known

locales on a blank map. Graphic reproduction of designs and assembly of patterns using sticks, blocks, or other media are used to assess visual organization and constructional abilities. Facial recognition represents a special component perceptual process and can be measured using Benton's Facial Recognition Test. The Judgment of Line Orientation Test assesses perceptual accuracy in judging the angular displacement of lines. Warrington's Visual Object Space Perception Battery is an example of a collection of measures designed to assess various aspects of perceptual function (see Table 3.5).

MOTOR FUNCTIONS

Naturalistic observations of the patient's gait and upper and lower extremity coordination are an important part of the motor examination. Hand preference should be assessed either through direct inquiry or a formal handedness questionnaire (Table 3.6). Motor speed, dexterity, and programming are tested with timed tasks, some of which involve repetition of a specific motor act (e.g., finger tapping, peg placement) and others that involve more complex motor movements (e.g., finger sequencing, sequential hand

Table 3.4 LANGUAGE FUNCTION

TEST NAME	DESCRIPTION
Boston Diagnostic Aphasia Examination (BDAE)	This is composed of measures that assess all aspects of expressive and receptive language function including naming, comprehension, repetition, reading, writing, praxis, and prosody.
Boston Naming Test	One component of the BDAE, this measure of confrontation naming is often administered independently. It consists of a series of 60 black and white line drawings of objects. Naming difficulty increases as the objects progress from high frequency to low frequency. Stimulus cues are provided in the event of perceptual difficulty. Phonemic cues are used to distinguish between retrieval difficulties and lack of knowledge of a particular object name.
Nelson Denny Reading Test	This test contains two multiple-choice measures that assess vocabulary and reading comprehension. Reading speed is also computed. Reading comprehension can be scored on the basis of both a standard and extended length of time.
Wide Range Achievement Test (WRAT-4)	This standardized battery of acquired scholastic skills includes measures of spelling, written arithmetic, and single word reading.
Wechsler Individual Achievement Test (WIAT-II)	This Wechsler test assesses the academic achievement of children, adolescents, and adults, aged 4 through 85 years. The test enables the assessment of a broad range of academic skills or only a particular area of need within the areas of reading, written language, oral language, and math.

Table 3.5 VISUOSPATIAL FUNCTIONING

TEST NAME	DESCRIPTION
Benton Facial Recognition Test	This task is composed of two parts. The first involves matching a target face with one of six faces. The target stimulus is always identical to the correct answer. The second part of the task involves choosing the three photographs, out of the array of six, that contain the same face as the target photograph. Increasing use of camera angle and shadow contribute to the progressive difficulty of the task.
Benton Line Orientation Test	This task involves judging the spatial orientation of sets of line segments by comparing them to a grid composed of 11 radii. It is sensitive to visuo-perceptual deficits associated with posterior right hemisphere lesions.
Visual Object Space Perception Battery	This battery contains eight individual tests that each probe a specific component of object or space perception. Individual subtests are untimed and can be given in isolation or within the context of the full battery. Normative data are based on healthy control subjects as well as patients with right- and left-hemisphere lesions.
Visual Cancellation	The objective of this task is to circle each instance of a target letter or symbol from among a field of similar stimuli. There are a total of 60 targets evenly distributed among the four quadrants of the 8-1/2 × 11 inch page. Errors of omission involve failing to respond to the target stimulus. Errors of commission involve responding to stimuli other than the target stimulus.
Hooper Visual Organization Test	This task involves examining line drawings of objects that have been broken into fragments and rotated. The objective is to mentally reorganize each set of fragments and subsequently identify the corresponding coherent whole.
Complex Figure Drawing	This task involves copying a complex line drawing, usually the Rey-Osterreith complex figure or Taylor complex figure. Ability to reproduce the gestalt as well as the internal details of the design facilitate the detection of various perceptual deficits. Significant distortion of or failure to copy one side of the figure can indicate the presence of hemispatial neglect.

Table 3.6 MOTOR FUNCTIONING

TEST NAME	DESCRIPTION
Finger Oscillation Test	Finger tapping speed is measured by having the patient tap a key as quickly as possible over a period of 10 seconds, using the index finger. Each hand is tested a number of times and trial totals are averaged. Poor performance consists of slow tapping speed. Unilateral motor weakness can be assessed by comparing tapping speeds of each hand. Bilateral weakness is assessed through comparison with age-matched norms.
Hand Dynamometer	Grip strength is measured in each hand by having the patient squeeze a pressure-calibrated instrument. Unilateral motor weakness can be assessed by comparing performance with each hand. Bilateral weakness is assessed through comparison with age-matched norms.
Grooved Pegboard	Measures of fine motor speed and dexterity, entailing placement of pegs in a pegboard, are obtained with each hand separately. Poor performance consists of difficulty grasping and manipulating the pegs, resulting in slowed performance.
Reitan-Klove Sensory-Perceptual Examination	Collection of measures of tactile, auditory, and visual perception using unilateral and double simultaneous stimulation. Fingertip number writing, visual fields, and tactile finger recognition are tested.

positions). Manual grasp strength can be assessed with a hand dynamometer.

syndromes and proceed with caution when evaluating psychiatric symptoms in the presence of neurological or medical illness.

AFFECT, MOOD, AND PSYCHOLOGICAL FUNCTIONING

Standardized measures of mood, personality, and psychopathology can be used to assess the contribution of psychiatric illness to the patient's presentation and diagnosis (Table 3.7). However, it is important to understand that many neurological illnesses can cause disorders of affect and mood. In addition, certain neurological illnesses can produce symptoms that overlap with particular psychiatric disorders. Therefore, neuropsychologists must possess a thorough understanding of the psychiatric profiles associated with various neurobehavioral

DEMENTIA SCREENING TOOLS

Because detection of age-related cognitive impairment and dementia plays a significant role in neuropsychological evaluation, a number of specific screening tools have been developed (Table 3.8). Many of these measures are designed to quickly assess gross level of functioning in major cognitive domains and can be administered in a matter of minutes (see Blessed Dementia Scale, MMSE). The Mattis Dementia Rating Scale is a more comprehensive set of items designed to stage severity of impairment in patients with known dementia.

Table 3.7 PSYCHOLOGICAL FUNCTIONING AND MOOD

TEST NAME	DESCRIPTION
Beck Depression Inventory	This instrument is used to assess depression severity based on self-reported ratings of a number of different relevant symptoms. Higher scores indicate greater severity of symptoms.
Beck Anxiety Inventory	This instrument is used to assess anxiety severity based on self-reported ratings of a variety of somatic, cognitive, and psychological symptoms of anxiety. Higher scores indicate greater severity of symptoms.
Personality Assessment Inventory (PAI)	This test contains 344 questions with a scale ranging from false, not at all true, to very true. It consists of 22 non-overlapping scales that assess constructs relevant to personality and psychopathology. Validity, treatment, and interpersonal scales are also included.
Minnesota Multiphasic Personality Inventory-2 (MMPI-2)	This series of 537 true/false questions load on to a number of different subscales that correspond to various personality traits or types of psychopathology. Scores on each subscale are standardized. Combinations of high and low scores on individual subscales correspond differentially to the presence or absence of various psychopathologies. Careful interpretation of subscale scores is crucial to the accurate use of this measure.

Table 3.8 DEMENTIA SCREENING TOOLS

TEST NAME	DESCRIPTION
Blessed Dementia Scale	Consists of two parts: (1) a rating scale of Activities of Daily Living to be completed by a caregiver other independent rater, and (2) a brief screening measure of orientation, concentration, and memory. Higher scores indicate greater severity of dementia.
Mini Mental Status Exam (MMSE)	This is a set of brief tasks that can be administered at the bedside and used to screen for obvious cognitive impairment. Includes items that assess attention, orientation, language, memory, and construction. Lower scores indicate greater severity of dementia.
Montreal Cognitive Assessment (MoCA)	This brief screening measures assesses multiple cognitive domains, including short-term and long-term memory recall, visuospatial abilities, language, attention and concentration, and aspects of executive functioning.
Mattis Dementia Rating Scale (DRS-2)	This scale assesses a wide range of neuropsychological domains including attention, initiation and perseverance, construction, conceptualization, and memory. It is used for grading and tracking overall degree of dementia. Lower scores indicate greater severity of dementia.

CONTENDING WITH SPECIAL CIRCUMSTANCES

EXAMINING THE PATIENT WITH SENSORY OR MOTOR DEFICITS

Patients with limitations in primary sensory or motor function present special challenges for assessment. Visual problems are highly common within the aging population, including presbyopia, glaucoma, and cataracts. Since a considerable amount of typical testing procedures entails visual processing of various stimuli and materials, patients should be examined while using their usual corrective lenses. Keeping several pairs of reading glasses of varying diopter strength on hand as part of testing equipment is always a good idea. When evaluating the blind patient, tests requiring visual processing are simply excluded from the test battery.

Acquired visual impairment is often observed in individuals with traumatic brain injury, stroke, tumor, or different types of neurodegenerative disease. It is important to distinguish between peripheral and central causes of impaired performance in the neuropsychological examination, as these etiologies have different diagnostic significance and will respond to different types of treatment interventions. This determination can be difficult in some cases and require additional specialty evaluation by ophthalmology or neuro-ophthalmology.

As is the case with visual impairment, diminished hearing is an exceedingly common problem in the elderly patient.

Interestingly, many older patients are either reluctant to acknowledge or unaware of problems with diminished hearing acuity. Furthermore, a significant number of patients with identified hearing loss are unwilling to utilize hearing aids. When examining the hearing-impaired patient, the clinician must speak clearly, slowly, and loudly. It can be helpful and informative to have the patient repeat back questions to ensure apprehension. Ideally, a clinician with American Sign Language (ASL) expertise will be available to examine patients with congenital or acquired deafness. As this is frequently not possible, the neuropsychologist will adapt testing methods to the situation.

Adaptation of patient response modality is necessary in individuals with disorders of expressive speech or motor function. Various forms of assistive technology have been developed for use with both aphasic and paralyzed patients. However, it is often advantageous to utilize tests in which recognition responses (as opposed to expressive language, figure drawing, or motor enactment) are required. It is important to consider both the efficiency and tolerability of a testing method with the patient in the service of establishing and maintaining an empathic connection throughout what can be an emotionally arduous process.

Lateralized sensory deficits can be partially accommodated by presenting information to the relatively spared side. For example, directing spoken instruction to the preferred ear or presenting visual information to the relatively spared hemifield. Using visual stimuli in vertical arrays can be helpful as well. Various authors have considered the sensory and/or motoric demands of many commonly used neuropsychological tests and proposed alternative administration approaches (cf., Caplan & Schechter, 1995).

Hill-Briggs et al. (2007) provide a comprehensive review of issues pertaining to neuropsychological test administration, accommodations, modifications, specialized test development, and disability-related factors that influence test interpretation across the spectrum of disabled individuals. Bylsma and Doninger (2004) review the assessment of individuals with significant visual loss.

EXAMINING PATIENTS FROM DIVERGENT LINGUISTIC/CULTURAL BACKGROUNDS

Neuropsychologists are increasingly involved in the evaluation of individuals from divergent cultural backgrounds and for whom English is not the primary language. It is naïve to assume that simply translating the examiner's instructions and test items from standard English to the native language of the examinee will overcome a huge gulf in cultural experience and all that comes with it. People from different parts of the world are acculturated with widely varying attitudes toward the very notion of testing and assessment. Neuropsychologists must be highly sensitive to these deeply ingrained and pervasive differences and take them into account when endeavoring to examine individuals of different nationality.

The optimal approach is to have access to a network of practitioners with varying cultural and linguistic competencies, armed with tests that have been developed and standardized

within the cultural/linguistic context of patients of different nationality. Although neuropsychology is making headway in this regard, we are truly only at the beginning of the beginning in this work. Given realistic constraints extant in most healthcare settings, it is usually necessary to compromise by using professional interpreters and adopt a highly conservative approach to test data generated in this fashion.

SUMMARY

Although clinical neuropsychology is a relatively new discipline, it traces its roots back to the ancients who wondered about the “seat of the soul” and the source of human thought. Drawing from the earliest studies of brain–behavior relationships in patients with naturally acquired lesions, and the accumulating body of literature in cognitive neuroscience, neuropsychologists have created a diverse collection of test instruments and other assessment methods which permit the precise measurement of specific components of human thinking. Together with a comprehensive knowledge of neuropathologic syndromes and functional neuroanatomy, the results of neuropsychological examination provide both descriptive and diagnostic information regarding the condition of the brain. As in all venues of medicine, diagnostic precision is a prerequisite for sound therapy. Because of its relative newness as a clinical discipline, several applied paradigms currently exist and there is some debate regarding preferred methods. Neuropsychologists in the 21st century face the challenge of establishing and promulgating an approach to assessment and treatment that unifies clinical practice and embraces the need for progressively refined normative information suited to diverse patient populations.

CLINICAL PEARLS

- A competent neuropsychologist will sample multiple domains of behavior. Observable behavior, including “test behavior,” reflects an interaction between the domains of person and environment. Variables from each domain must be considered in order to arrive at an understanding of the clinical significance of a given behavior.
- Performance on a single test is not sufficient to make a diagnostic inference
- Discrepancy between “test behavior” and “real life” behavior is the source of ongoing challenge for the design of an ecologically valid assessment environment.
- Neuropsychologists have pioneered the development of specialized and embedded measures of effort and symptom validity for use in cases in which motivational factors are important.
- The Boston Process approach proceeds in a hypothesis-driven manner and uses the patient’s test performance to guide and inform an evolving and dynamic assessment strategy. The process-oriented evaluation is individually tailored to each patient and uses specific tests for the purpose of answering particular questions. Test selection occurs in real time.
- The information obtained during the initial interview is important for differential diagnosis and frequently guides the remainder of the assessment.
- The first task of a neuropsychological assessment is to clarify the reason for referral.
- The fractionation of neuropsychological functions into specific domains is a somewhat arbitrary organizational contrivance. In reality, there is considerable overlap within and between cognitive domains. For example, working memory shares much common ground with aspects of attention and language.
- Variable capability across diverse neuropsychological functions is often the rule rather than the exception in normal human development (Schretlen, 2003).
- Premorbid ability can also be surmised from performance on measures presumed less sensitive to cerebral dysfunction (e.g., vocabulary). Single-word reading tests (e.g., WTAR) have been used to estimate baseline verbal intelligence in patients with early degenerative conditions.
- Early assessment of attention is vital for informing the scope of the examination and the analysis of test data.
- Sustained attention, also called vigilance, refers to the capacity to maintain active attention over time. The most common method of assessing vigilance utilizes a target detection paradigm. Here the patient is instructed to respond to an infrequently occurring target stimulus, for instance a sound or word, as a measure of auditory vigilance.
- Resistance to interference, also called response inhibition, refers to the ability to sustain a given response even in the face of a salient distraction designed to undermine the target response.
- Planning involves thinking several steps ahead of one’s current circumstances for the purpose of informing and altering a course of action. Tests measuring planning ability often require subjects to determine the correct series of steps needed to successfully reach a particular goal (see DKEFS Tower Test).
- Perseverance is the ability to sustain a particular course of action even in the absence of an external prompt.
- Comportment refers to the ability to behave in a contextually appropriate manner.
- Working memory involves holding a stimulus or set of stimuli in mind in order to either produce it after a delay (e.g., looking up a telephone number and remembering it until it is successfully dialed) or use it in a mental procedure involving manipulation of information (e.g., carrying out mental arithmetic).

RATING SCALES AND SCREENING TESTS

Barry S. Fogel

SUMMARY

Rating scales and screening procedures derived from them have become an essential component of medical-psychiatric practice. Familiarity with the psychometric properties of a rating scale and understanding of the specific construct the scale was designed to measure can protect the clinician against misinterpretation of scores. Medical psychiatrists make daily use of widely-known scales for anxiety, depression, cognition, and functional status; important differences between commonly-used measures for these constructs are noted. Beyond these general-purpose scales there are instruments designed to measure psychiatric constructs specific to medical conditions such as fear of movement or fear of hypoglycemia; these have a special role in assessing patients who have no primary mental disorder but who have cognitive or behavioral issues significantly affecting general medical treatment outcomes. In a multidisciplinary or multi-specialty context rating scales can provide an efficient and effective common language. Simultaneous monitoring of multiple scales can help in the management of patients with multiple interacting comorbidities, impairments, and treatments. Systematic use of self-rated scales can make medical psychiatrists more efficient. Online test administration and computerized adaptive testing are enabling ever more subtle assessments to be convenient and scalable. At best, rating scales can enable assessments to be more complete and reliable, can improve communication between clinicians, can allow more objective and quantitative assessment of treatment outcomes, and can permit a more rigorous analysis of tradeoffs between wanted and unwanted effects of treatments. On the other hand, over-reliance on a handful of specific rating scales can lead clinicians to neglect important symptoms because they are not measured well by their customary instruments.

INTRODUCTION

As medical practice increasingly becomes evidence-based, quantitative rating scales and standardized screening tests that once were common only in research settings have become customary in clinical care. Symptom rating scales were adopted early in psychiatric research because for most primary mental disorders there are no generally accepted physiological measures of disease severity and treatment response. Screening

tests to help general medical physicians and other clinicians identify mental disorders have been widely promoted because such conditions historically have been underdiagnosed in general medical practice. Rating scales have also been employed to *screen out* patients who are *not* at significant risk for particular adverse events: for example, patients with very low suicide risk may not need intensive observation even though they are severely depressed. Screening tests—especially those that involve self-rating or rating by a briefly trained nonclinician—take up little physician time. Utilization of rating scales and screening tests in routine clinical practice has evolved from the exception to the norm during the author's career in medicine.

The existence of a generally accepted rating scale for a symptom or syndrome has become an essential prerequisite for the symptom or syndrome to be a focus for clinical attention. All clinical trials of drug treatments must have measurable, quantitative end points to be acceptable to the Food and Drug Administration (FDA). Furthermore, if a medical psychiatrist wants to focus the attention of a general medical physician on a specific mental, behavioral, or functional issue, mentioning a rating-scale score (or its verbal equivalent) can be a very efficient way to do it.

This chapter aims to make the medical psychiatrist a better-informed user of screening tests and rating scales. After reviewing some basic psychometric terminology, it will focus on how the clinical populations and settings of medical psychiatry should affect the selection and interpretation of these instruments. Specific rating scales are discussed to illustrate particular issues in the selection, use, and interpretation of such scales in medical psychiatry. The reader is referred to standard references for full reviews of psychiatric rating scales and general health rating scales (Rush et al., 2008; McDowell, 2006). Websites that provide resources for measurement of health status and health-related quality of life, and, where applicable, websites operated by scale authors or publishers, offer further details. For example, cdc.gov/hrqol describes health-related quality of life scales that currently enjoy wide acceptance in the United States. The National Institutes of Health maintains a website entirely devoted to its Patient Reported Outcome Measure Information System (PROMIS). The instruments described, which include measures of medical-psychiatric interest, take advantage of contemporary methodologies of item response theory and computer adaptive testing (National Institutes of Health, 2014).

WHAT MEDICAL-PSYCHIATRIC RATING SCALES MEASURE

General psychiatric rating scales measure mental and behavioral symptoms and syndromes. In medical-psychiatric settings, general psychiatric rating scales have their place—but they are complemented by scales relevant to the relationship and interaction of psychiatric and general medical conditions. These include (1) scales for rating specific symptoms and syndromes like pain, sleep disturbance, or sexual dysfunction that can reflect either primary mental disorders, general medical disorders, or the combination of the two; (2) scales that directly assess cognitive function; (3) scales that measure general health status; (4) scales of functional performance; and (5) scales for quantifying the psychosocial impact of general medical illness.

In acute medical-psychiatric contexts, scales for risk assessment—specifically of the risks of suicide or violence—have a special place. In the care of chronic general medical conditions, scales that measure impediments to treatment adherence or to optimal treatment outcomes are especially relevant.

RELATIONSHIP OF RATING SCALES TO SCREENING TESTS

Rating scales can be used as screening tests for specific diagnoses. Based on a rating scale score, a patient is identified as probably having a particular disease, disorder, syndrome, or condition. The actual diagnosis is made by a clinician, who combines the data from the rating scale (often the items and not just the score) with some combination of elements from the medical history, clinical examination, and diagnostic tests. Psychometric properties like sensitivity and specificity are applied to the concept that patients with scores above a threshold have the diagnosis, and all others do not. In practice, patients with scores near the cutoff score often are viewed probabilistically—more likely than not to have the diagnosis, but not as certainly as those well above the threshold (or well below it, when the diagnostic criterion is a low score on the rating scale). Less commonly, a rating scale is made into a screening test by applying Boolean logic, a regression equation, a decision tree, or a neural net algorithm, using individual item scores as the independent variables.

In the context of general medical illness, psychiatric rating scale items that are typical of a particular primary mental disorder might instead be attributable to a general medical illness. The diagnosis of a syndrome (e.g., clinical depression) is independent of the attribution of specific symptoms, but the diagnosis of a *primary* mental disorder (e.g., major depressive disorder) is not. The attribution issue reduces the certainty of a diagnosis of a *primary mental disorder* made using a rating scale criterion. Nonetheless, using rating-scale item responses as a point of departure in a psychiatric interview can make the interview more productive. Furthermore, summing scale items, or applying a validated algorithm for combining relevant items, complements the more subjective clinical process

of synthesizing clinical data, and in some situations the standardized approach is superior. Once a diagnosis is made, rating scales—if they are sufficiently sensitive to changes—can be used to track the course of illness and measure the patient's response to treatment.

TYPES OF RATING SCALES

Rating scales measure the severity of a disease, syndrome, condition, symptom, functional impairment, or disability. They are quantitative and usually ordinal rather than truly continuous. Points on an ordinal scale can be represented as words and/or pictures; the 0–10 rating scale for pain (Fig. 5.1) is a familiar example. Rating scales can have a single factor or dimension, or can be multifactorial. The score on a single dimension is the sum of a specific subset of item scores.

Rating scales are completed by the patient, by a caregiver or other collateral source, by a trained rater who is not a clinician, or by a clinician who might or might not require specialized training on the scale. Some patient-completed scales require only that the patient answer specific factual questions, while others require the patient to make judgments or self-assessments. The latter type of scale will be insensitive in the face of impaired metacognition or denial of illness. Patient-completed scales that refer to a time other than the immediate present rely on the patient's memory, and if they ask the patient to count events or summarize experiences during an interval, some degree of executive function is required as well. For this reason the validity of such scales decreases in the face of cognitive impairment. Note in this connection that scales of binary items like symptom checklists impose less cognitive demand than scales with ordinal items, and frequency-based ordinal items impose a greater cognitive demand on the patient than severity-based ones.

Some clinician-rated scales require the clinician to have specialized training in psychology or psychiatry. Clinician-rated scales that draw heavily on clinical expertise will be less reliable with less experienced clinicians. All of the above issues deserve consideration when determining whether a published measure of scale's reliability is applicable in a specific clinical situation.

When there are self-rated, caregiver-rated, and clinician-rated versions of the same scale, agreement of scores among the versions strengthens confidence in the rating. On the other hand, disagreement between self-ratings and caregiver/family ratings and/or clinician ratings is diagnostically valuable information. Disagreement between self-ratings and clinician ratings can represent impaired metacognition, unawareness of deficits or denial of illness, symptom amplification by the patient, clinician underestimation of the patient's distress, or, if the self and clinician ratings are done at different times, fluctuation of the condition. When ratings of symptoms by family members or other caregivers are more severe than patients' self-ratings, the discrepancy can reflect patients' denial or families' distress. Discrepancies between family/caregiver ratings and clinician ratings have implications similar to those of

discrepancies between self-ratings and clinician ratings. Ultimately, reconciling the difference between the clinician's ratings and the patient's ratings can be an important part of building a therapeutic relationship.

Symptom rating scales assign a numerical score to one specific physical or emotional symptom such as pain, dyspnea, or anxiety. The symptom can be either reported by the patient or inferred from observations.

Disease and syndrome rating scales are sums—often weighted by severity and/or frequency over a specified time period—of the symptoms and signs that are characteristic of a disease or syndrome. Getting a scale score by summing item scores is most reliable and valid if all items are measuring the same underlying construct, items are scaled similarly, and the clinical significance of the items is similar. These assumptions do not necessarily apply to scales commonly used in clinical practice. For example, most clinicians would agree that a patient's having mild and intermittent depressive symptoms of four different kinds is of lesser concern than having severe and persistent suicidal ideation alone. Yet, both might contribute 4 points to the total score on a depression rating scale comprising items that rate the severity of individual depressive symptoms on a 4-point scale and sum the item scores to get an overall depression rating.

Functional assessment scales assess patients' level of independence in performing each of a set of physical, instrumental, and/or social activities. Functional assessment scales sometimes include an indication of how much help is required by a patient who is not independent in an activity. Results can be reported as a description of the dependencies identified, a count of activities in which the patient is dependent, or a score that weights dependencies according to how much help is required to do each activity requiring assistance. Functional ratings can refer either to capabilities at the time of the rating or to activities actually performed or attempted over a specified time interval. The result of a functional assessment scale that refers to a specific period can be different if the rater is asked to describe the patient's worst function, best function, or usual function during the period. When the functional assessment is done to assess improvement in a patient getting rehabilitation, it is important to track the patient's best level of function and usual level of function; when it is done to assess caregiving needs, an assessment of the patient's worst function is essential.

Functional assessments can either be historical—based on reported observations or on the patient's recall—or can be based on direct observation of the patient attempting to do each activity being rated. Observed functioning will be no worse than the patient's worst functioning and no better than the patient's best functioning, but it may not be representative of the patient's usual functioning. In particular, the circumstances of observation are important for patients with brain dysfunction who have become reliant on environmental cues to carry out activities properly. When such patients are tested in an unfamiliar hospital or clinic environment, they may appear more impaired than when tested in a home full of cues.

Cognitive performance scales are sums of item scores, where each item tests a specific cognitive capability and

gives the patient's performance a binary or ordinal score. When something as complex as cognition is reduced to a single dimension, there necessarily will be tradeoffs between sensitivity and specificity, and important areas of function will be assessed perfunctorily or not at all. For patients with severe cognitive impairment, there are scales that test residual cognitive capacity based on inference of cognitive function from observed behavior. Cognitive performance scale scores usually are reported as a single number, although clinicians often characterize cognitive deficits by adding a note about specific test items missed, or about the patient's approach to the item. For example, on a cognitive rating scale patients' scores on memory items might depend only on whether they can recall all of the words on a list previously presented to them. A clinician's note—for example, that the words could be recalled by a patient when he was cued with the categories to which the words belonged—would be valuable in interpreting the score, because it would indicate that memory storage was intact even though free recall was impaired. This could help in the differential diagnosis of the cognitive impairment identified by the scale.

Behavior rating scales and psychopathology rating scales rate patients for the presence and severity of each of a list of symptoms and signs applicable to many different psychiatric diagnoses. As with functional assessment, results can be reported qualitatively or quantitatively—which specific items were present, or the sum of scores across all items. The former is more commonly done when the scale is used primarily as a structure for conducting and reporting a clinical assessment; the latter is done when the scale is used to characterize illness severity or measure treatment response.

Burden of illness scales are designed to quantify the overall load of disease carried by a patient. These are especially relevant in populations like frail elderly people, those with severe developmental disorders, and victims of severe trauma in which patients typically have multiple disease diagnoses, several of which are severe enough to cause distress, impair function, or shorten life expectancy. Such scales typically are counts of diseases or conditions weighted by their severity, symptomatic or functional impact, or implications for life expectancy or future healthcare utilization.

Predictive scales are sums of item scores, or results of algorithms applied to item scores, that are designed to predict a specific health outcome such as a fall or other injury, hospitalization, mortality, or service utilization. They are based on predictive models. They are used to identify patients at risk, to assist with making prognoses, to risk-adjust outcome-based healthcare performance measures, and to identify addressable risk factors in high-risk patients.

Adverse event or side-effect rating scales can be either general or specific to a particular drug or class of drugs. The latter are particularly relevant when a useful drug has a very high incidence of side effects; and quantifying the burden of side effects helps assess the risk versus the benefit for the treatment. For example, the Columbia Suicide Rating Scale

(C-SSRS; Posner et al., 2011), discussed further below, was originally developed to measure suicidal ideation as a potential side effect of initiating antidepressant drug treatment.

Global assessment scales are single-item scales that ask a clinician or other expert assessor to assign a numerical score to how sick, how symptomatic, or how impaired a patient is. The most useful global assessment scales are *anchored* by detailed descriptions of cases that would get various specific scores along the scale.

Generic rating scale items—which by themselves can serve as single-item rating scales—include the following:

1. *The simple one-directional ordinal scale.* For a 5-point scale, several examples are:
 - a. 0, 1, 2, 3, 4
 - b. None, minimal, mild, moderate, severe
 - c. A, B, C, D, E
 - d. Poor, Fair, Good, Very Good, Excellent
 - e. Never, rarely, occasionally, frequently, all the time

An ordinal scale will be more comparable between patients if all raters are given a common set of examples corresponding to the different possible responses to the item. Without such anchors, an ordinal scale can still be valuable in comparing the condition of the same patient from one time to another, if the ratings at the two different times are performed by the same person.

2. *The bidirectional, symmetric ordinal scale* (aka Likert scales, after the psychologist Rensis Likert, who described them). There are several items, usually eight or more. Items are ordinal, bidirectional, and typically expressed in words: for example, patients are given a statement and is asked whether they strongly agree, agree, neither agree nor disagree (or are not sure), disagree, or strongly disagree. Positive or negative numerical scores are assigned to each item; the assignment of scores to responses can differ by item. The sum of the numerical item scores is the scale score. Likert scales in which item scores have five options and those in which item scores have seven options are the most common. One species of Likert scale utilizes items with an even number of response choices, forcing patients to choose to either agree or disagree with each item, even if their agreement or disagreement is mild.
3. *The visual analog scale.* In this scale, the patient is asked to mark on a line segment a place corresponding to the severity of the symptom being assessed. The line segment can be either horizontal or vertical. If the segment is horizontal, the left end means the symptom is absent; the right end means the symptom is present with maximum possible severity. If the segment is vertical, the bottom means the symptom is absent and the top means the symptom is present with maximum severity. A common set of anchoring examples make scores more comparable between patients. The visual analog scale can be converted into a numerical 0–100 scale by measuring the distance

from the left (or bottom) of the line segment to the patient's mark, dividing that distance by the length of the entire segment, and multiplying by 100.

4. *A numerical scale.* The usual range is 0–10 or 0–100. In contrast to ordinal scales, there usually is a presumption that the scale is homogeneous—that for example the difference between a 10 and a 20 and that between a 60 and a 70, have similar clinical significance.

Frequency-severity or duration-severity scales are combinations of two or more single-item ordinal scales that together capture the time course of a symptom (or syndrome). Patients typically are asked to rate how often (or for how long) they have the symptom and what is the average severity (or the worst severity). The combination of scales often is valuable in understanding a patient's experience of the symptom. However, simply adding frequency and severity scales to make a single score requires an assumption that severity and duration are of equal weight in determining the overall negative valence of the symptom.

USES OF RATING SCALES

The potential medical-psychiatric uses of a rating scale include the following:

1. Framework for structuring a clinical assessment;
2. Screening test;
3. Support for a diagnosis;
4. Aid to treatment-related decisions;
5. Aid to prognosis;
6. Measurement of clinical course;
7. Measurement of treatment response;
8. Aid to prediction of future course or treatment response;
9. Rigorous measurement of an area of function that is important to the understanding of medical-psychiatric conditions but is poorly covered by routine medical and psychiatric histories (e.g., measurement of sleepiness/wakefulness and measurement of apathy/motivation);
10. Communication between clinicians, including communication across disciplines and standardization of medical records;
11. Broadening the scope of patient assessment within practical time constraints, by facilitating reliable and structured input from patients, family caregivers, and clinicians of various disciplines; and
12. Inquiring via patient questionnaires about areas patients might be reluctant to discuss in face-to-face interviews, including sexuality and substance use.

CONSIDERATIONS IN CHOOSING RATING SCALES AND SCREENING TESTS

A rating scale or screening test should be considered in relation to the patient population being rated, the purpose of the scale, who will be obtaining the data, who will utilize the score, and the direct and indirect costs of utilization. Specific considerations include the following:

1. *The patient population.* The scale should be easy to administer within the contexts in which the patients are usually treated. If the scale involves self-rated items, the questions should be appropriate to the educational and cultural background of the patients. The time needed to do the rating should be compatible with the typical length of the clinical encounter, and the procedure for rating should be compatible with the typical process of the clinical encounter and with the usual environment in which the patient is seen. The scale should be sensitive enough to detect variability within the patient population. Cutoff scores for identifying cases should be adjusted if necessary for differences in population norms for non-cases.
2. *The purpose of the scale.* If the scale will be used to follow longitudinal course or treatment response it must be suitable for repeated administration. For scales that measure cognitive performance, learning effects must be taken into account and alternate forms used if necessary. If the scale is used as a screening test in a non-psychiatric setting it should be easily utilized by people without training in psychiatry or another mental health profession.
3. *Who will be receiving and utilizing the score.* If the score will be placed in a common medical record used by various disciplines, widely known scales usually are preferable even if they are not optimal. When using a scale likely to be unfamiliar to most users of the medical record, a brief explanatory note on the scale should be included in the record that describes what the scale measures and whether there is a cutoff score for identification of a case. If the score will be used within a multidisciplinary service where there are joint conferences or rounds at which a scale can be introduced and explained, it usually is better to select the scale with optimal characteristics for the patient population treated and the specific purpose.
4. *Direct and indirect costs of utilization.* Some rating scales are explicitly in the public domain. However, many of the most useful and most broadly accepted scales are subject to copyrights held by a copyright owner that requires a fee to be paid for each test administration. Intermediate between them are tests subject to copyrights held by a copyright owner who permits free clinical use of the scale but charges a licensing fee when the test is used in funded research. When scales are used in funded clinical research the cost of licensing a specific proprietary scale usually is negligible in relation to the cost of the study as a whole. When this is the case, one should choose the scale with the optimal characteristics for the patient population and the purpose of the study.

The main indirect cost of administering a scale is the professional time involved; this gives a big advantage to brief scales and to scales based on patient or caregiver questionnaires, those that can be administered by non-clinical staff, and those that can be administered by computer. Most third-party payers do not pay clinicians extra for using rating scales, so the net financial effect is negative unless the rating scale can replace some part of the traditional clinical history and examination and/or the test score or item responses can replace text in a medical record that would take the clinician significant time to write.

5. *Psychometric optimality versus regulatory requirements and clinical custom.* When a rating scale is rarely used in clinical practice, clinicians reading study results based on measurements with that scale might be reluctant to rely upon them to guide treatment decisions. When a scale is used to measure the outcome of treatment with an investigational drug or device, the FDA may mandate the use of a particular standard scale for measuring the primary endpoint, and other standard scales for measuring potential adverse events. Researchers may need to compromise between a practical need to use a standard, commonly accepted rating scale for a particular purpose and the scientific ideal of a using a less-familiar rating scale that is optimal from a the point of view of content, psychometric properties, and adaptation to the specific patient population and clinical context at hand. The usual solution is to use both scales if this can be done without excessive burden on study subjects. In the case of a treatment trial, the score on the standard scale is used to define the primary endpoint of the study and the optimal scale is used to define a secondary endpoint. Both primary and secondary endpoints are reported when the study results are published.

GENERIC VERSUS SPECIALTY-SPECIFIC RATING SCALES

Medical psychiatrists are concerned with the interrelation of general medical conditions, trauma, and surgery; the patient's mood, thinking, and behavior; and the patient's functional status and well-being. Most of the variables of medical-psychiatric interest can be measured by instruments like depression rating scales, cognitive screening tests, and assessments of physical and instrumental function, that are applicable to patients with a wide range of diseases and conditions. Specialty-specific tests, or tests applicable only to patients with specific underlying medical conditions, are most useful when the pattern of psychiatric symptoms or functional impairments seen in a particular context differs significantly from those seen in relation to medical illness in general. For example, military veterans who have suffered repeated blast injuries can show a characteristic combination of neuropsychiatric and general medical complaints that differ from those of patients who have suffered other kinds of trauma. Similarly, patients with spinal cord injuries or with radical pelvic surgery have distinctive types of sexual problems. In specialty clinics for blast injury survivors, or for patients with spinal

cord injuries, symptom rating scales tailored to these patient populations might be more useful than general-purpose instruments. When a medical psychiatrist begins working in a liaison capacity with a medical, surgical, or rehab specialty service, the use of specialized rating scales should be part of a discussion of how different specialists will work together.

SOME BASIC PSYCHOMETRIC TERMINOLOGY

Several terms are ubiquitous in discussions of rating scales and screening tests. Their definitions are straightforward, but their usage in the medical-psychiatric context raises specific issues that will be noted.

RELIABILITY

Reliability refers to the consistency of a scale score or categorical test result between two different raters (inter-rater reliability) or between two different ratings or test administrations (test-retest reliability).

Reliability Issues

Inter-rater reliability for many scales is high when both raters are highly trained and experienced, but considerably lower when raters do not have scale-specific training and experience. The incorporation of a rating scale within the clinical routine of a specialty service tends to increase its inter-rater reliability (when used on that service, with its typical patient population). When scales are based on a clinical assessment by interview or examination, there can be high inter-rater reliability for the *scoring* of assessment—for example, how two different raters would score the same video recording of an interview—but lower inter-rater reliability when two raters separately interview or examine the patient. Furthermore, when each rater does a separate interview or examination, there is confounding with test-retest reliability.

Test-retest reliability depends on the interval between the two test administrations and what is being rated. When there is circadian variation in the thing being measured, ratings a few hours apart can be significantly different. Learning effects and fatigue can change scores if two ratings are done on the same day. If the raters are different for the first and second rating, there is confounding with inter-rater reliability.

For these reasons test-retest reliability is context-dependent. It is valuable to confirm reliability of a rating scale within one's specific clinical context before using it in research or relying upon it for important clinical decision making. In addition, steps can be taken to improve the reliability of a rating scale to be used for a specific purpose. For example, consider the use of the Abnormal Involuntary Movement Scale (AIMS; see (Munetz & Benjamin, 1988) to assess a young female patient's response to a new drug treatment of tardive dyskinesia (TD). It is known that inter-rater reliability of the AIMS is lower with inexperienced raters, and that TD can

show circadian fluctuation and fluctuation linked to the menstrual cycle. To improve the reliability of the AIMS, the investigator could perform the AIMS procedure during morning clinic visits scheduled during the first week of the patient's menstrual cycle each month. The standard examination for AIMS scoring would be videotaped, and all recordings would be scored by the same experienced rater. With this strategy, reliability of measuring TD would be maximized, as would the likelihood of seeing therapeutic effects of the new drug if they were indeed present.

INTERNAL CONSISTENCY

Internal consistency refers to the extent to which the different items of a multi-item scale, test, or questionnaire are measuring the same construct. If a rating scale counts symptoms that are not consistently associated with one another, internal consistency will be lower. Internal consistency is measured with specialized statistics, of which *Cronbach's alpha* is the most widely used. An alpha of 0.9 or greater is excellent; one between 0.7 and 0.9 usually is acceptable.

Internal Consistency Issues

Cronbach's alpha can be inflated when a test has many items that are very similar to each other; it will be spuriously low if the scale is tested on a clinical population in which there is little variation in the construct to be measured. When rating scales are used as screening tests to identify potential cases of a condition, their internal consistency may be less important than when they are used to measure the condition's severity or to track its response to a treatment. For example, if the goal of an alcohol use disorder rating scale is to identify patients with drinking problems of any kind, it may not matter that the various manifestations of problem drinking included in the scale are not highly correlated with one another.

VALIDITY

Validity refers to the relationship between the scale score or screening test result and some other determination of the same construct—typically one that is widely recognized and accepted. Types of validity include the following:

Face validity—obvious association of scale items with the thing being tested;

Criterion validity—correlation of scale scores with a “gold standard” measure of the same thing, such as a laboratory test result or the score on a rating scale that is deemed more definitive, for example because it is more detailed, broader in scope, and/or obtained under more rigorous conditions;

Convergent validity—correlation of scale scores with other scales that measure the same construct;

Divergent validity—lack of correlation of the scale with scales thought to measure a distinct construct;

Predictive validity—ability of the scale score to predict a clinical outcome or other future event; and

Construct validity—an integrated judgment of whether the scale measures the underlying concept of interest. A judgment of construct validity includes consideration of the other types of validity.

Validity Issues

When a scale measuring a mental or behavioral construct is used to communicate with patients and families, the *face validity* of scale items helps in convincing them that the scale score is meaningful as the basis for a diagnosis, a treatment decision, or medical advice. For example, if a patient with dementia failed a test of reading and understanding road signs, it would be relatively easy to convince a family that it was time for the patient to stop driving; this might be more convincing than a score on a test of calculation or word-list memory that has no direct relationship with driving ability, even if the latter actually is more highly correlated with the likelihood of car crashes over the coming year. When a rating scale is used for communication with a non-psychiatric physician, it will work better if the scale has validity with respect to a *criterion* the physician already accepts, or *convergent validity* with respect to a scale the physician already uses. Thus it is helpful to know whether the recipient of a communication is familiar with the construct that the scale measures, and to know what he or she currently understands as appropriate ways to assess it.

SENSITIVITY, SPECIFICITY, AND RELATED CONCEPTS

When evaluating a screening test, which may be a rating scale used in conjunction with a specified cutoff score for identifying a case, the ideal is a test that identifies all patients with the condition and rules out the condition in everyone else. A test can fall short of the ideal either by failing to detect the condition when it is present, or by misidentifying unaffected patients as cases, or both. Which of the two potential shortcomings of a test is the greater problem depends on the purpose of the test, on the costs and consequences of different types of error, on the rate of the condition of interest in the patient population to be tested, and on the way the condition of interest manifests in the population to be tested. How closely a screening test attains the ideal is captured by two ratios: sensitivity and specificity. These two ratios are determined by the combination of the properties of the test *and* the specific population to which the test is applied. The ratios are defined in terms of the counts of patients in each of four mutually exclusive and comprehensive categories:

True Positive (TP): Patients who are positive on the screening test and has the condition of interest;

True Negative (TN): Patients who are negative on the screening test and do not have the condition of interest;

False Positive (FP): Patients who are positive on the screening test but do not have the condition of interest; and

False Negative (FN): Patients who are negative on the screening test but have the condition of interest.

Sensitivity ($TP/(TP+FN)$)

Sensitivity is the proportion of patients with the condition of interest that are positive on the test. While sensitivity often is thought of as a property of a test, it is really a property of a test *in a specific clinical context*. For example, a screening test for dementia might be highly sensitive when applied to detect moderate dementia in a population of high school graduates, but insensitive when applied to detect mild dementia in a population with graduate degrees.

Sensitivity Issues

When a screening test is based on applying a cutoff score to the summary score on a rating scale, sensitivity can be increased simply changing the criterion used to determine whether the test is “positive”. Taken to the extreme, it is true for any rating scale used as a screening test that the criterion for identifying cases can be set so that everyone who takes the test will meet the criterion and the test is 100% sensitive. In this case there are no false negatives because there are no negatives at all. However, sensitivity is meaningless without simultaneous consideration of specificity, which in the extreme case just given would be quite low unless most or all of the population had the condition, making the screening test unnecessary in the first place. A measure of a test’s sensitivity is most meaningful if it is calculated on a sample of patients typical of the clinical population in which the test will be used, the sample contains a sufficient number of patients with and without the condition of interest, and the patients in the sample who have the condition are representative of the clinical population with respect to the severity of the condition of interest and the range of symptoms and signs they display.

High sensitivity is essential in situations where the test is used to rule out a condition which, if present, would urgently require management or treatment. For example, screening tests for the risk or suicide or violence must be highly sensitive if they are used to determine when a psychiatric inpatient is safe to discharge. Furthermore, to be useful such tests should show high sensitivity *in the specific population in which they will be used*, for example a chronically-disabled population, a population of combat veterans, or an incarcerated population of violent offenders.

SPECIFICITY ($TN/(FP+TN)$)

Specificity is the proportion of patients who don’t have the condition of interest who are negative on the test. In other

words, specificity is the sensitivity of the test for detecting *non*-cases.

Specificity Issues

The considerations mirror those for sensitivity. When a screening test is based on reaching a threshold score on a rating scale, raising the threshold will increase the test’s specificity at the expense of its sensitivity. High specificity is desirable in situations where being wrong about calling a patient a “case” entails unnecessary cost, risk, or stigma. The diagnosis of psychogenic non-epileptic seizures (PNES) offers a useful medical-psychiatric example; the diagnosis of HIV infection is a good general medical one. A common approach to clinical situations where both high sensitivity and high specificity are needed is a two stage screening approach, where a highly sensitive and moderately specific test is given first, and those who screen positive are given a more specific test to validate the diagnosis—often one that is more expensive or less convenient.

PREDICTIVE VALUE

Positive Predictive Value (PPV) is the proportion of patients who test positive that actually have the condition of interest. Expressed as a formula, $PPV = TP/(TP+FP)$.

Negative Predictive Value (NPV) is the proportion of patients who test negative test that in fact not have the condition of interest. Expressed as a formula, $NPV = TN/(TN+FN)$.

Predictive Value Issues

Like sensitivity and specificity, PPV and NPV are attributes of *a test and a population*, not attributes of a test in itself. A test with high sensitivity and high specificity can have a low PPV if the condition of interest is very rare in the population tested. For, example, suppose a test is 99% sensitive and 95% specific for a condition with a prevalence of 1% in the population tested. Its PPV will be approximately 20%, since out of every 100 people in the population approximately 1 will be a true positive and 4 will be false positives (that is, negatives to which the test was insensitive). In this situation five patients who “screened in” would have to undergo further evaluation to identify one patient who truly had the condition of interest. When the implications of a diagnosis are weighty and the condition of interest is relatively rare in the population to be tested, a test must have very high specificity to be clinically useful.

Like PPV, NPV is always relative to a specific population, and the considerations for NPV mirror those for PPV, just as the considerations for specificity mirror those for sensitivity. A very high prevalence of the condition of interest in the test population will imply a low NPV unless a test is extremely sensitive.

The relationship of sensitivity, specificity, PPV and NPV is illustrated in Figure 4.1.

Figure 4.1 Wong-Baker FACES® Pain Rating Scale.

RECEIVER OPERATING CHARACTERISTIC

The receiver operating characteristic (ROC) is a curve that illustrates the tradeoff of sensitivity and specificity for a screening test that is based on a rating scale with various options for the cutoff score (criterion level) for determining that a patient has the condition of interest. The ROC curve is drawn within a box where the x-axis is the rate of false positives and the y-axis is the rate of true positives. Each point on the curve is determined by a cutoff score for the test on the underlying rating scale. Note that the cutoff scores themselves do not appear on either the x-axis or the y-axis. It sometimes makes an ROC curve more comprehensible to label a few points on the curve that correspond to specific cutoff scores.

Figure 4.3, from an article on diagnostic test interpretation (Tape, 2013) illustrates the ROC curve for serum T4 as a screening test for hypothyroidism, the latter diagnosed clinically. The three points on the curve represent three different cutoff points for the serum concentration of thyroxine (T4): 5, 7, and 9 µg/dL.

The ROC curve for a test with no predictive value would be a line with slope 1—the diagonal of the square in which the ROC curve is drawn. When a test has such a ROC curve, higher sensitivity can only be had by reducing specificity. The ROC curve for an ideal test would be a vertical line along the y-axis plus a horizontal line at y = 100%. With an ideal test there is a cutoff score at which false positives are zero and true positives are 100%. With a very good but not ideal test the rate of true positives will approach 100% at a cutoff score that implies only a very small number of false positives.

ROC Issues

A test of no value whatever would have an ROC of 50%; a test with an ROC of 90% or higher would have outstanding value;

		Condition (as determined by "Gold standard")		
		Condition Positive	Condition Negative	
Test Outcome	Test Outcome Positive	True Positive	False Positive (Type I error)	Positive predictive value = $\frac{\sum \text{True Positive}}{\sum \text{Test Outcome Positive}}$
	Test Outcome Negative	False Negative (Type II error)	True Negative	Negative predictive value = $\frac{\sum \text{True Negative}}{\sum \text{Test Outcome Negative}}$
		Sensitivity = $\frac{\sum \text{True Positive}}{\sum \text{Condition Positive}}$	Specificity = $\frac{\sum \text{True Negative}}{\sum \text{Condition Negative}}$	

Figure 4.2 Relationship of Test Attributes.

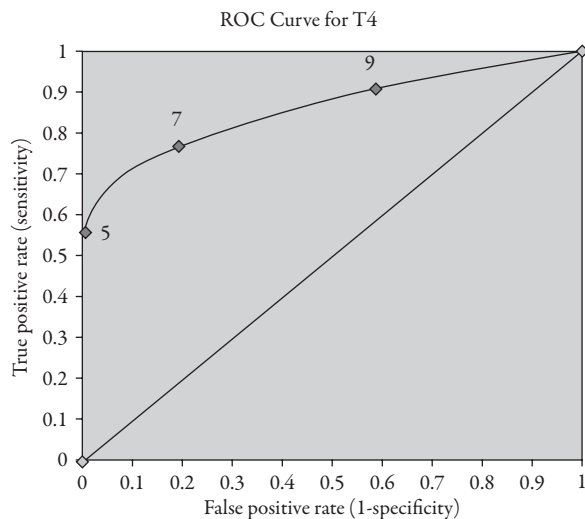

Figure 4.3 ROC Curve for Serum T4 as a Test for Hypothyroidism.

most clinical purposes require an ROC of at least 70%. The usual tradeoff is between the cost of a test (including burden on clinicians and patients) and the ROC.

One way to attain high specificity while maintaining high sensitivity is to utilize a two-stage testing procedure where the first screening test, one with high sensitivity, identifies patients with high risk of having the condition, and the second test, one with high specificity, is used to determine whether a high-risk patient actually does have it. In psychiatric contexts, the usual two-stage procedure begins with a scale based on a patient or family/caregiver questionnaire. A subset of patients is identified as comprising probable cases based on application of a cutoff score to the questionnaire-based scale. Each probable case undergoes an examination by a clinician to rate him or her on a second scale. Only patients that meet a specified criterion for the clinician-rated scale score are identified as positive (probable cases) by this two-stage screening procedure.

BIAS IN SELF-RATINGS

All self-rating scales are subject to various types of *response bias*. Some patients will tend to answer yes/no questions positively and to agree more often than they disagree; this is called *acquiescence bias*. The reverse bias—a tendency to answer negatively and to disagree—is less common in the general population, but can be shown by angry or hostile patients. Acquiescence bias and its reverse can be mitigated by balancing the wording of scale items equally as positive and negative statements.

Social desirability bias is shown when patients answer questions in a conventional, “proper” way. Patients may be reluctant to honestly answer questions related to alcohol or drug use, tolerance of unlawful behavior, personal prejudices, or symptoms commonly associated with mental illness.

Central tendency bias is shown when patients rarely show strong agreement or disagreement with statements and rarely

characterize a symptom as severe. It is common in the general population, and its prevalence may vary by ethnicity, family background, and personality type.

Acquiescence bias can be mitigated by test design; social acceptability bias can be more difficult to resolve if the condition being rated is stigmatized and widely viewed as unacceptable. Central tendency bias can be adjusted for at the individual patient level when a scale is used to follow the course of illness or measure the effects of treatment. In theory, central tendency bias could be assessed with a set of nonclinical items and the bias estimate used to adjust the interpretation of the clinical self-rating (e.g., choice of a cutoff score for identifying a patient as probably having a particular disorder). However, this is not done in practice.

Response biases have cultural correlates; specific ethnic groups may be less willing to express strong opinions or to admit to having socially undesirable attitudes or behavior. Cultural issues should be considered when using rating scales in multicultural clinical populations and when choosing from among rating scale options for use in a specific cultural group.

Clinicians can increase the utility of serial self-ratings of a particular symptom or syndrome by doing one or more simultaneous clinician ratings early on to “anchor” the scale. For example, a clinician might note that a self-rating of 10 on a depressive symptom questionnaire such as the PHQ-9 (Kroenke et al., 2001) corresponds to a rating of 15 on the clinician version of the same scale given on the same occasion, and that a self-rating of 20 corresponds to a clinician rating of 30. The patient would be regarded by the clinician as someone who tends to under-rate symptoms of depression, and the clinician might then interpret a subsequent self-rating of 5 as equivalent to a clinician rating of 7 or 8.

Visual analog scales (VAS) and ordinal scales for same condition yield similar results and they have similar clinical utility. However, the continuous nature of the VAS pain scale and its lack of intermediate anchoring points can produce paradoxical results when the scale is used to measure day-to-day changes in acute pain. In the short term, scores on the VAS and on an ordinal pain scale can even change in opposite directions (DeLoach et al., 1998). The visual analog scale can be problematic for neurological patients with impaired visual perception; this is most dramatic for patients with right-hemisphere lesions and left hemineglect, where a horizontal visual analog scale will always be marked toward the right side. Arranging the visual analogue scale vertically mitigates the problem of hemi-inattention, but other visual perceptual difficulties can make the test less valid nonetheless. On the other hand, scales that rely on verbal definitions can be affected by language problems—a virtue of a visual analog pain scale that is anchored by emoticons depicting pain and suffering is that it works without regard to language; it can be valid even for patients with aphasia.

The continuous nature of scores on a visual analog scale facilitates the use of parametric statistics in analyzing outcomes in the research context. This can increase statistical power to capture a significant difference in outcomes between patient groups.

An underlying tacit assumption of many ordinal scales is that there is uniform scaling; for example, a score of 20 is twice as bad as a score of 10 on a scale measuring a distressing symptom or syndrome. However, this assumption is impossible to prove because there is no standard criterion of “badness” of symptoms. Of greater concern is that when using rating scales with many items of diverse content, there can be major clinical differences between patients with the same summary score. Often it is important to know which specific items on a scale the patient endorsed. For this reason it is useful for clinicians to review item-level responses and for staff to keep self-rating forms together with the clinical record, at least until they can be reviewed by the clinician. Of particular importance to medical psychiatrists is the review of patients’ responses to items describing physical symptoms that can be either due to the patient’s general medical illness or due to depression, anxiety, or another disorder conventionally viewed as “mental.” If symptoms of general medical illness account for much of a patient’s score on a rating scale for depression or anxiety, this should be noted in the medical record to help future readers of the record to understand the meaning of the score.

RATING SCALES AND COGNITIVE IMPAIRMENT

Many rating scales rely on the patient’s recall of thoughts, behavior, and mood over a specified period such as the past week, the past month, or the interval since the last visit. Patients with impairment of memory may be unable to recall accurately their mental state and behavior in the recent past, reducing the validity of the scale. Other cognitive impairments that can alter rating scales based on patient interviews or questionnaires include impairments of attention and concentration, impairment of comprehension, and impaired self-awareness. When cognitive impairment limits the validity of scales based on patient interview or questionnaires, alternatives are scales based on caregiver interviews or questionnaires, or on observation of the patient’s behavior by clinical staff. Discrepancies between self-ratings and observer-based ratings can raise the suspicion of cognitive impairment, or denial or unawareness of symptoms. Several of the scales designed for rating mental and behavioral symptoms in patients with gross brain diseases come in self-rated, caregiver-rated, and clinician-rated versions.

THE COPYRIGHT ISSUE

While some well known and very useful rating scales are in the public domain, for example, the Hamilton Depression Scale and the Visual Analog Scale for pain, many standard psychiatric rating scales are copyrighted. In some cases a test will be in the public domain but a particular way of scoring the test will be copyrighted: the CLOX scoring system for the neuropsychological interpretation of clock drawings (Royall et al., 1998) is an example. When scales or scoring systems are copyrighted, the copyright owner must be paid a royalty if the test is used in sponsored research. Whether use of a scale in an

individual physician’s clinical practice constitutes “fair use” or requires payment of a fee depends on the scale. The obligation to pay a significant fee per use for a rating scale makes it less appealing for routine clinical use unless the administration and interpretation of the test is a billable procedure—as it is for some tests designed for use by clinical psychologists—or the use of the test is subsidized by a care management organization such as a health plan. In the medical-psychiatric context, it usually is not feasible to charge a separate fee for a rating scale that is incorporated into a clinical evaluation; for this reason, most clinicians will prefer tests that either are in the public domain or are usable royalty-free under fair use conditions. Some widely used rating scales with enforced copyrights offer the offsetting benefit of extensive support of the scale by the copyright holder. Support for scales may include online training, user groups, durable educational materials, test administration forms, and maintenance of databases of references and norms for various populations.

A REPERTOIRE OF RATING SCALES

Medical psychiatrists tend to encounter a similar set of problems regardless of the underlying general medical condition: depression, anxiety, cognitive impairment, pain, apathy, sleep disturbance, sexual dysfunction, and so on. Ratings of mental and behavioral symptoms, syndromes, and conditions that are based on questioning a patient—whether by a questionnaire, via computer, or by a clinical interview—can be complicated in the medical-psychiatric context by the effects of general medical illnesses and their treatments on self-awareness, memory, cognition, and communication. When this is the case, scales based on direct observations by a family member or professional caregiver may be more valid. A more subtle point is that mental and behavioral symptoms that are consistently associated in patients with a particular primary mental disorder may not be consistently associated in patients with the same major symptom in the context of a general medical condition. A rating scale designed for a primary psychiatric population can have different psychometric properties when used in a medical-psychiatric population. For example, in primary major depression, vegetative symptoms, apathy, anhedonia, depressed mood, and depressive thoughts tend to be correlated; in depression due to some general medical conditions the correlation does not apply. A patient with mood changes due to a frontal lobe glioma might have severe apathy and anhedonia but have few depressive thoughts. The patient’s summary score on a standard depression rating scale would understate the severity of the patient’s mental disorder, because the usual thoughts associated with severe depression would be absent or minimized.

Pragmatic considerations of time and cost are relevant to the choice of rating scales for use in general medical settings. Finally, the time available for psychiatric activities—including doing rating scales—can be tightly constrained in general medical settings, so even a few minutes’ difference in time to complete a scale can be decisive in choosing it over one with similar psychometric properties.

With these considerations in mind the author offers a basic repertoire of rating scales with proven feasibility and clinical utility in medical-psychiatric settings.

DEPRESSION RATING SCALES

The *Patient Health Questionnaire-9 Questions* (PHQ-9) has emerged as a widely accepted screening test and rating scale for depression in general medical and in community settings. Based on the *Diagnostic and Statistical Manual of Mental Disorders-IV* (DSM-IV) diagnostic criteria for depression, the test sums the scores of nine ordinal items rated 0–3 based on how often in the past 2 weeks the patient has experienced various symptoms of depression. A tenth question, not included in the summary score, is a 4-point ordinal self-rating of impairment due to depressive symptoms. The PHQ-9 takes less than 5 minutes to complete, even when patients take time to consider their answers. A modified version—the PHQ-9-OV (observational version)—is designed to be completed by a caregiver familiar with the patient, in situations where cognitive or communication problems preclude the use of a questionnaire-based scale (Saliba et al., 2012). Pfizer holds a copyright on the scale but permits it to be used by clinicians royalty-free. It is available in over 30 languages.

In a validation study of the PHQ-9, the authors studied 580 patients in community primary care settings who both completed a PHQ-9 and had structured diagnostic interviews by mental health professionals (Kroenke et al., 2001). The study report includes an ROC analysis that shows the sensitivity–specificity tradeoff for different choices of cut point. In the reported primary care population, with a cutoff of ≥ 9 the test is 95% sensitive and 84% specific for a diagnosis of major depression. To attain 95% specificity, a cutoff of ≥ 15 is needed; at that level the sensitivity drops to 68%. Overall, the ROC curve supports the value of the PHQ-9 rating scales as the basis of a screening test in community primary care settings for major depression as defined by DSM-IV. The PHQ-9-OV was tested with dementia patients in skilled nursing facilities and was shown to be highly correlated with the Cornell Scale for Depression in Dementia (Phillips, 2012).

The PHQ-9 is both *scored* and *interpreted*; it is possible to exceed the cut point on the test but yet not receive a clinical diagnosis of major depression. Making a diagnosis of any depressive disorder requires both a total score greater than or equal to the cut point, and either loss of pleasure, depressed mood, or both, at least half of the days in the past 2 weeks. A diagnosis of *major* depression requires that five or more items were present on at least half of the days in the past 2 weeks, or that at four items were present on at least half of the days and that on several days the patient had thoughts of self-harm or of being better off dead.

Four of the PHQ-9 items concern symptoms that frequently accompany significant general medical illnesses in the absence of any primary or secondary mental disorder: sleep disturbance, altered appetite, decreased energy, and impaired concentration. The PHQ-9 is sensitive to depressive disorders that might respond to antidepressant treatment. As noted

elsewhere in this volume, medical psychiatrists usually find it more productive to focus on the choice of optimal treatment rather than on the question of whether to attribute symptoms to the general medical illness, to a comorbid primary mental disorder, or to a discrete process—“secondary depression”—that is different from the general medical illness in itself, but is not exactly the same as primary depression in its symptoms, course, prognosis, and/or treatment response. Patients scoring in the range of primary major depression on the PHQ-9 frequently will respond to treatment for depression.

THE BECK DEPRESSION INVENTORY

The Beck Depression Inventory (BDI; see Beck et al., 1988, 1996) is a 21-item questionnaire that, like the PHQ-9, asks the patient to rate individual items on a scale on a scale of 0–3. In keeping with the DSM-IV, the scale asks about symptoms in the past 2 weeks. However, the patient is asked to rate the *severity* of each individual symptom rather than its frequency. Like the PHQ-9, the BDI is copyrighted. The copyright owner, Pearson, does not grant royalty-free duplication rights, and it sells BDI test forms for approximately \$2.00 each. The test has been translated into numerous languages. The BDI takes 5–10 minutes if completed by the patient and somewhat longer if the questions are asked by an interviewer. Cut points for mild, moderate, and severe depression are ≥ 14 , ≥ 20 , and ≥ 29 , respectively.

While the BDI has been exhaustively validated, the additional time required for its administration, the cost of the test, and lack of an observer-based version favor the PHQ-9 over the BDI for routine clinical use. However, the BDI has special strengths relevant to the *understanding* of patients’ depressive symptoms in addition to measuring them, and to the measurement of change in symptom severity with treatment: (a) It has 21 items rather than 9; (b) Items measure symptom severity rather than symptom frequency, and (c) The BDI captures two discrete dimensions of depression—the affective (8 items) and the somatic (13 items; see Steer et al., 1999). While the two dimensions are moderately correlated (correlation coefficient = 0.57), one would expect the correlation to be weaker in patients with general medical illness, in whom some of the somatic items could be due to the medical condition.

HAMILTON DEPRESSION RATING SCALE

The Hamilton Depression Rating Scale (HAM-D or HDRS; see Hamilton, 1980) is a 17-item clinician-rated scale for depression that was specifically developed to measure the severity of the symptoms of primary depressive illness and to follow their change with treatment. It was not designed to be a diagnostic test, let alone a test to screen for depression in general medical settings. It takes 20–30 minutes to conduct the structured clinical interview upon which the scale scores are based (see Williams, 1988, for details of the interview). The 17 ordinal items all rate the *current* presence and/or severity of depressive symptoms; frequency of symptoms over an interval is not measured. Item scores range from 0–2 or from 0–4; the maximum score on the 17-item scale is 50 points. Cut points

for mild, moderate, and severe depression are ≥ 8 , ≥ 14 , and ≥ 19 , respectively. The 31-point range of scores associated with severe depression implies that the scale will not show ceiling effects and will thus be able to measure relative change even in patients who remain severely depressed. The items give considerable weight to somatic symptoms: scores indicating severe depression can be reached from symptoms of medical illness alone, and somatic improvements can substantially reduce the HDRS score even if a patient remains severely depressed and actively suicidal. Overall, the HDRS is not as well suited for use in general medical settings as the BDI or the PHQ-9.

GERIATRIC DEPRESSION SCALE

The Geriatric Depression Scale (GDS; see Yesavage et al., 1982) originally was 30-item questionnaire with yes–no items concerning the patient's symptoms at the present time; it is now most widely used in a 15-item version that comprises a subset of the original items (Sheikh & Yesavage, 1986). When the GDS refers to the recent past, the time frame is indeterminate—for example, “Are you in good spirits most of the time?” There are no items concerning the frequency or severity of particular symptoms. The scale is in the public domain, it is available in many languages, and there are smartphone versions for both the iOS and Android operating systems. It takes a typical patient about 5 minutes to complete the 15-item version. Items are phrased both positively and negatively, but the phrasing is not balanced; for the 15-item version, the answers to 10 questions are more likely to be answered “yes” if the patient is depressed. The scale's author recommends that if items are not completed, the sum on the items that are complete should be scaled up proportionally and rounded up to the next integer. A score 5 or greater on the 15-item version suggests that a patient should be evaluated clinically for depression. Wancata and colleagues (2006) concluded from a review of 42 publications on the GDS that with its usual cutoff scores (5 on the 15-item version and 10 on the 30-item version) and a validity criterion of a clinical diagnosis of major depression by a psychiatrist, the scale's sensitivity and specificity are, respectively, 0.805 and 0.750 for the 15-item version and 0.753 and 0.770 for the 30-item version. Marc et al. (2008) tested the 15-item GDS against a clinical consensus diagnosis of DSM-IV major depression in an ethnically diverse elderly homecare population in New York and found that with an optimal cutoff score of 5, the sensitivity and specificity were 0.718 and 0.782. The test performed equally well in men and women, and in various ethnic groups.

The GDS has some obvious benefits for screening in medical-psychiatric settings. It requires little time, the respondent burden is low, there are smartphone versions, and it can give valid information even about patients with moderate cognitive impairment. However, it is better for use as a screening test than as a tool for following the clinical course of a patient already diagnosed with depression, because the severity and frequency of the individual items are not rated. Also, it will not capture the severity of a depression in which two or three symptoms are very severe and others are not present or not acknowledged. It also should be noted that more

than 20% of cases of major depression will *not* be identified by the GDS with its usual cutoff score. Thus, it is more helpful in case-finding than it is in ruling out clinically significant depression.

Like the BDI, the GDS has a factor structure, although exploratory factor analyses give different results depending on the clinical population studied and the language in which the scale was administered. The most consistent factors to appear in factor analyses of the GDS are dysphoria, positive mood (or its absence), and a factor capturing apathy, cognitive impairment, and social withdrawal (Kim et al., 2013).

CORNELL SCALE FOR DEPRESSION IN DEMENTIA

The Cornell Scale for Depression in Dementia (CSDD; see Alexopoulos et al., 1998) is a depression rating scale optimized for use in patients with moderate to severe cognitive impairment. It is based on answers to interview questions that are given to a caregiver of the patient—typically a family member, nurse, or aide. Depressive symptoms identified by the caregiver interview are then confirmed in a brief interview with the patient, which uses questions that are phrased more simply. If the caregiver and the patient interviews are discrepant, the clinician is instructed to re-interview both and then make a clinical judgment. Ultimately the score on each item is a clinical judgment rather than the answer of either the caregiver or the patient to a specific question. Items on the CSDD refer to the week prior to the interview, and item scores range from 0–2, where 1 corresponds to mild or intermittent symptoms and 2 corresponds to severe and presumably persistent ones. There are 19 items covering five domains: mood (sadness, anxiety, irritability, and lack of emotional reactivity), behavior (agitation, retardation, multiple somatic complaints, and loss of interest in activities), physical symptoms (changes in appetite, weight, or energy), cyclic functions (diurnal variation and various attributes of sleep), and ideation (suicidal thinking, self-deprecation, pessimism, and mood-congruent delusions). Rating several of the items requires a judgment that the symptoms are not long-standing and due to chronic general medical illness. The CSDD requires administration by a skilled clinician and takes between 20–30 minutes to complete. The scale is copyrighted; permission for clinical use can be obtained from the scale's authors.

Both the CSDD and the PHQ-9-OV are suitable tests for quantifying depression in patients with moderate to severe cognitive impairment. The CSDD, with 10 more items and a medically oriented perspective on sleep disturbance, diurnal variation, and somatic symptoms, offers a better qualitative understanding of the patient's symptoms; but, asking the rater to judge whether somatic symptoms are due to chronic medical illness rather than depression can be problematic. Both the CSDD and the PHQ-9-OV can be used to follow change over time, although neither one includes an assessment of symptom severity not confounded by symptom frequency.

RATING SUICIDE RISK: THE COLUMBIA SUICIDE SEVERITY RATING SCALE

The assessment of suicide risk is a crucial part of the psychiatric assessment of any patient with depression. Notwithstanding, it is only recently that a standardized measure of suicide risk has emerged that has predictive validity and wide international acceptance. The Columbia Suicide Severity Rating Scale (C-SSRS; see Posner et al., 2011) was originally developed to screen adolescents in antidepressant clinical trials for suicide risk, after it was recognized that a significant minority of depressed adolescents treated with SSRIs developed suicidal ideation as a treatment-emergent side effect. The US FDA essentially mandated the use of the C-SSRS in antidepressant clinical trials, and soon it became a standard component of side-effect monitoring in all psychotropic drug trials. The C-SSRS is a copyrighted instrument that is available for clinical use without a fee; substantial royalties must be paid for the use of the scale in funded research. It has been translated into over 100 languages. A website, www.cssrs.columbia.edu, provides downloadable copies of the scale, links to references on the scale's psychometric properties, and links to training resources.

The C-SSRS is an interview-based scale that is administered by a person who has had basic training on how to conduct the interview; Columbia provides educational materials for this training. The interviewer need not be a mental health professional. The longest version of the interview takes no more than 10 minutes to administer, and the six-question screening version can be completed in about 2 minutes. It comes in several versions for clinical use: (1) lifetime and past month, (2) since last visit, (3) risk assessment, (4) clinical practice screener, (5) pediatric lifetime, and (6) pediatric since last visit. Items are either binary (yes/no or checklist), ordinal measures of severity or frequency, or counts of suicidal or self-injurious actions. All versions of the scale elicit history of death wishes, suicidal ideation, suicidal intent, and suicidal behavior. A risk-assessment version adds a clinical status checklist, a treatment history, and questions about potentially activating events and protective factors.

The count of "yes" answers to five questions on suicidal intent yields a score ranging from 0–5; suicidal behavior is scored similarly, and the sum of the two scores gives a score from 0–10 measuring suicidal intent or behavior. Higher scores on these scales have been shown to predict suicide attempts during antidepressant drug trials. The scale items concerning the severity of past attempts, clinical status, activating events, and protective factors are used qualitatively to guide further clinical assessment and decision making.

Neither the C-SSRS nor a psychiatric evaluation can predict whether or when a specific individual will attempt suicide. However, the C-SSRS can help guide decisions about the intensity of supervision needed to protect a patient and the level of psychiatric care that might be appropriate. When depressed patients have both a low lifetime C-SSRS score and a low recent C-SSRS score, they rarely will require hospitalization to mitigate the risk of self-harm. In the

medical-psychiatric context, a low C-SSRS score can be used to support a recommendation against an expensive and intrusive "suicide watch." The use of a well-recognized suicide risk scale can aid interdisciplinary communication and also can mitigate concerns about legal risk.

For distressed patients—whether the primary condition is depression or a painful somatic condition—monitoring of the C-SSRS from one visit to the next can aid in the determination of whether interventions such as antidepressant treatment or intensive pain management are working. The alleviation of suicidal thoughts and wishes to be dead is a face-valid indicator that a patient is in less overall emotional distress.

Prior to the C-SSRS, there were several other published suicide-risk rating scales, but none attained the broad acceptance of the C-SSRS, which has been administered to millions of patients. As previously existing scales are not psychometrically superior or more suitable for routine clinical use, the medical psychiatrist should consider using the C-SSRS if a suicide rating scale is going to be used at all. The brief screening version of the C-SSRS—which consists of only six yes/no questions with a follow-up on timing if the patient reports suicidal behavior—is sufficiently simple that it was successfully incorporated into the initial nursing assessment of *all* patients in a general hospital, and a version administered by telephone via an automated voice response system is under development (Mundt et al., 2010). When it is applied universally in this way, it will identify patients not previously suspected of having suicide risk, thus triggering a more timely psychiatric evaluation.

ASSESSMENT OF VIOLENCE RISK

Concern about the potential for violence is a common reason for psychiatric consultation in medical settings. There is an extensive literature on instruments and algorithms for assessment of violence risk, summarized in recent comparative reviews and meta-analyses (McDermott et al., 2008; Fazel et al., 2012). At this time, no rating scale for violence risk has attained the same level of broad acceptance as the C-SSRS has attained for suicide risk. This may be due in part to the fact that violence risk has different determinants in incarcerated or recently released criminals, chronically mentally ill patients, residents of long-term care facilities, general hospital inpatients, and medical or psychiatric outpatients. A critical distinction is among impulsive, predatory, and psychotic aggression. A clinician would be concerned about the former in a delirious patient and the latter in a paranoid patient, and violence risk assessment tools designed for predicting predatory aggression in prior offenders would be of relatively little value in either of those situations. A practical question faced by the medical psychiatrist is what must be done to ensure the safety of the staff and other patients during the clinical encounter, and what must be done to ensure the safety of others afterward. As with suicide, serious violent behavior is a relatively rare event, and many patients will require hospitalization or other intrusive treatment in order to prevent one bad outcome. However, employing standardized rating

scales for violence risk can make care more efficient and less intrusive by identifying patients very *unlikely* to be violent, because such scales do have reasonable *negative* predictive value.

Medical psychiatrists called upon to assess violence risk in general medical settings should consider five contributors to risk: (1) antisocial personality traits with an associated history of violence, paranoid ideation, anger, and/or coercive sexuality; (2) neurological conditions that can impair impulse control, such as delirium or frontal system dysfunction; (3) loss of inhibition due to the effects alcohol or drugs such as benzodiazepines; (4) increased arousal due to stimulant drugs or to withdrawal of alcohol or opiates; (5) current life circumstances such as financial, legal, or marital problems arousing strong negative emotions. Each of these factors can be rated, but there is no established algorithm for combining them into a validated summary index of risk. The extensive literature on prediction of violence has primarily concerned recidivism in individuals with a history of violence or criminal behavior, not the prediction of violence in general medical contexts. Nonetheless it can be valuable to know, in the longer-term management of patients with chronic general medical conditions, whether a patient has strong antisocial traits and to know whether they are “clinically angry.”

While personality inventories in general measure psychopathy as a dimension, the most valid evaluation of antisocial traits comes from synthesizing the patient’s documented history (and thus the observations of others) and the results of a structured interview. The Hare Psychopathy Checklist (PCL-R; see Hare, 2003) is a widely used instrument for doing this. Like the C-SSRS, it is supported with a website and extensive training materials. Unlike the C-SSRS there is a fee for its routine clinical use, and it is designed for use only by mental health professionals. The PCL-R comprises 20 items, each a 3-point ordinal scale rating how strongly various personality traits or historical descriptions apply to the patient. It can take over an hour to complete because of the need to collect and synthesize data. It is thus impractical for the assessment of the potential for violence in acute medical situations. Its potential value in medical psychiatry is a contribution to understanding why a patient with a chronic illness might have chronic problems in relationships with physicians and institutions, such as making unreasonable demands, seeking inappropriate compensation or disability status, and so on. It has two factors, one reflecting interpersonal style (e.g., manipulative, shallow, grandiose) and the other reflecting a history of antisocial behavior and lifestyle (irresponsible behavior, parasitic lifestyle). The inter-rater reliability of the test depends on the raters’ skill. The ability of the test specifically to predict violence depends on context. When the issue of psychopathy and the potential for violence is central to long-term treatment planning, the medical psychiatrist might consider requesting a PCL-R as part of a battery of psychological tests that would also include screening for psychotic phenomena and for executive cognitive impairment.

Anger is the affect most strongly associated with violence. Patients’ level of anger can be practically assessed and quantitated with the Clinical Anger Scale (CAS; see Snell et al., 1995). The CAS comprises 21 self-reported 4-point ordinal items; these are summed to produce a score of 0–63. Items cover both specific angry thoughts and the effects of anger on general health, sleep, appetite, sexual interest, and decision making. There is a specific question about the desire to hurt others because of anger. Most of the questions refer to how the patient is feeling at the time of the test; references to the effect of anger on health and function refer to an indefinite time period including the present. A score of 20 is the threshold for moderate clinical anger; 30 is the threshold for severe clinical anger. The scale has high internal consistency and positive correlations with other scales measuring anger. Of interest, the test authors’ research group found little effect of social desirability bias on the test score.

The CAS has not been extensively studied in general medical settings; it is worth noting that several questions concern physical symptoms, cognitive complaints, and functional impairments possibly due to general medical illness but also potentially due to the sympathetic arousal and neuropsychological effects of anger. While this can be viewed as confounding the interpretation of the test and limiting its usefulness, the CAS offers a valuable perspective on the patient’s attribution of symptoms. In fact, if a patient feels too angry to sleep it is likely that addressing the patient’s anger may improve sleep—even if there are also general medical conditions that also influence sleep onset or sleep quality. When a medical-psychiatric patient is preoccupied with anger, the clinician’s adopting anger as a focus of treatment can be more acceptable to the patient than labeling the problem as depression, even when antidepressants will be part of the prescription.

ANXIETY RATING SCALES

The distinctions between affective, cognitive, and somatic dimensions of anxiety, and between anxiety as a personality trait and anxiety as a symptom, can make the measurement of anxiety challenging. The overlap of anxiety symptoms with the symptoms of general medical illness adds a further complication. Conditions like phobias, obsessive compulsive disorder, and posttraumatic stress disorder (PTSD) have prominent cognitive aspects; generalized anxiety disorder and panic disorder have a more somatic emphasis. Finally, the symptoms of anxiety and those of depression appear to converge later in life; anxiety is often a prominent symptom of late-onset major depression. This phenomenon may explain the historical overutilization of antianxiety drugs in primary care as the sole treatment of patients with primary major depression and associated anxiety. Separately reviewing the lifetime history of anxiety symptoms and depressive symptoms with the patient can help deconstruct the problem.

Anxiety scales widely used in medical settings include the Generalized Anxiety Disorder Assessment, the Beck Anxiety

Inventory, the Hamilton Anxiety Rating Scale, and the State-Trait Anxiety Inventory. In addition, there are specialized scales used to rate the symptoms of obsessive compulsive disorder, PTSD, and phobias.

THE GENERALIZED ANXIETY DISORDER ASSESSMENT

The Generalized Anxiety Disorder Assessment (GAD-7; see Spitzer et al., 2006) is for generalized anxiety what the PHQ-9 is for major depression. The scale consists of seven questions about cognitive and emotional symptoms of anxiety (but not autonomic symptoms), each of which is self-rated by the patient according to the frequency with which it occurs: not at all (0), several days (1), more than half of days (2), or nearly every day (3). The total score is the sum of the item scores; it thus ranges from 0–21. Cutoff scores for mild, moderate, and severe generalized anxiety are ≥ 5 , ≥ 10 , and ≥ 15 , respectively. The threshold score of 10 gives 89% sensitivity and 82% specificity for generalized anxiety disorder. Scores of 10 or higher are seen in 74% of cases of panic disorder, 72% of patients with social anxiety disorder, and 66% of patients with PTSD. The GAD-7 is thus useful for screening and measuring symptom severity, but in itself it cannot serve as the basis for a diagnosis. Of particular interest to medical psychiatrists: the GAD-7 does not include somatic symptoms such as palpitations, dyspnea, dizziness, numbness and tingling, and so forth. It is thus very unlikely to be confounded by general medical conditions with symptoms that overlap those of anxiety-based autonomic arousal.

THE BECK ANXIETY INVENTORY

The Beck Anxiety Inventory (BAI; see Beck et al., 1988) is a 21-item self-report questionnaire concerning symptoms of anxiety. Each item is rated for severity and associated distress on a scale of 0–3; the overall scale score is the sum of the item scores. In its initial validation study in patients with anxiety disorders or depression the scale showed high internal consistency and test–retest reliability of 0.75 over 1 week. Patients with severe anxiety scored higher on the BAI than patients with primary depression, and, on a group basis, patients with a primary anxiety diagnosis (with or without depression) scored higher than patients with a primary depression diagnosis (with or without anxiety). The scale was decomposed into two factors: one measuring somatic symptoms of anxiety such as numbness and tingling, dizziness, and shakiness, and the other measuring subjective symptoms of anxiety and panic, such as feeling terrified, scared, or being afraid of dying. The BAI can be completed in a few minutes by a cognitively intact patient.

THE HAMILTON ANXIETY SCALE

The Hamilton Anxiety Scale (HAM-A or HARS; see Hamilton, 1959) is a clinician-rated scale comprising 14 ordinal items, each rated for severity on a scale of 0–4; the scale takes 15–30 minutes to complete. Unlike many of the

other commonly used anxiety rating scales, it is in the public domain. Items cover anxious mood, tension, fears, insomnia, concentration and memory problems, depressed mood, muscular symptoms, sensory symptoms, cardiovascular symptoms, respiratory symptoms, gastrointestinal symptoms, genitourinary symptoms, autonomic symptoms, and anxious behavior at the interview. The symptoms rated in each organ system are those that can be caused by anxiety alone in the absence of primary organ system pathology—for example, palpitations and sinus tachycardia but not atrial fibrillation, or dyspnea and sighing but not wheezing. The score on the HAM-A is the sum of items; it thus ranges from 0–56. Patients with scores of ≥ 14 are likely to have clinically relevant anxiety; those with scores of 30 or higher are severely anxious. While they may have clinically relevant anxiety, they do not necessarily have anxiety disorders, because patients with depression can have equally high scores on the HAM-A.

The emphasis of the HAM-A on somatic symptoms of anxiety is a mixed blessing for the medical psychiatrist. A patient with multisystem disease can have a high score on the HAM-A solely from symptoms of his or her general medical illness. On the other hand, if a patient has symptoms confined to a single organ system that could be due either to anxiety or to a general medical condition, and the HAM-A shows somatic symptoms potentially due to anxiety in multiple organ systems along with fear and anxious mood, anxiety is supported as a cause—or at least an aggravating factor—of the symptom of interest.

Because the HAM-A is heavily weighted on somatic symptoms that are not specific for anxiety, it is not well suited for diagnosis or screening, particularly in general medical patients. It is more appropriately used to measure change over time in symptoms of anxiety in response to psychiatric treatment or to changes in a patient's general medical condition.

SPIELBERGER STATE-TRAIT ANXIETY INVENTORY

The State-Trait Anxiety Inventory (STAI; see Spielberger et al., 1970) in its most commonly administered form is a 20-item self-rated scale that measures both long-term anxious traits and current anxious feelings (state). It produces two scores—one rating trait anxiety, and the other rating state anxiety. All items are 4-point ordinal items; the items measuring traits are bidirectional and related to frequency (“almost never” to “almost always”), while the state items are unidirectional and related to intensity. Items are balanced, with some indicating more anxiety and other indicating less anxiety. The STAI was originally developed on a non-patient population, and perhaps for this reason it is often used in studies of non-patients such as family caregivers and in studies of general medical patients without known anxiety disorders. The state anxiety scale is sensitive to changes in anxious mood with changes in circumstances or with treatment. The STAI takes about 5 minutes to complete and requires a sixth-grade reading level, making it suitable for a broad range of clinical populations.

Overall, the STAI is weighted less on the physical dimensions of anxiety and more on the emotional and cognitive

dimensions. Medical psychiatrists might find the test particularly useful in medical-patient populations with a high prevalence of general medical symptoms that can also be caused by anxiety alone. The STAI has the additional benefit of putting the patient's current anxiety in the context of the patient's past emotional style. A patient with high state anxiety and low trait anxiety might be facing more severe situational stresses than a patient with a similar level of state anxiety but high trait anxiety. The probability that an underlying medical condition is contributing to the anxiety symptoms is greater in the former case, as well. Further, when a patient with low trait anxiety develops high state anxiety in an acutely stressful situation, supportive psychotherapy can draw upon the defenses and coping skills that kept the patient's anxiety low in the past. The patient also can be reassured that antianxiety drug treatment is likely to be short term, as the state anxiety symptoms are likely to abate when the acute stress has resolved.

Like the HAM-A and the BAI, the state scale of the STAI can be used to monitor the response of anxiety symptoms to psychiatric treatment or to changes in the patient's general medical status. It offers the advantage of self-rating; however, the HAM-A would appear to be preferable for patients in whom the main issue is multiple somatic complaints linked to an anxiety disorder.

RATING SCALES FOR SPECIFIC ANXIETY DISORDERS

Obsessive-compulsive disorder (OCD), various phobias, and PTSD have historically been classified as anxiety disorders, though the latter clearly has many symptoms unrelated to anxiety that can account for much of the patient's distress and disability. These conditions all have characteristic mental and behavioral symptoms that can overshadow anxious mood and somatic manifestations of anxiety, and for that reason they are best rated with syndrome-specific scales. Following are selected examples of such scales, with comments on their use in medical-psychiatric contexts.

YALE-BROWN OBSESSIVE COMPULSIVE SCALE

The Yale-Brown Obsessive Compulsive Scale (Y-BOCS; see Goodman et al., 1989a, Goodman et al., 1989b) has, in the past 25 years, become the standard instrument for clinician assessment of symptom severity in OCD. Its particular virtue is that it works regardless of the specific obsessions and compulsions from which the patient suffers. It comprises 10 clinician-rated items, each rated on a 5-point ordinal scale from 0 (no symptoms) to 4 (extreme symptoms). Subscales for obsessions and for compulsions are defined. The administration of the Y-BOCS is a two-stage process. The patient and clinician first review a checklist of obsessions and compulsions and identify the ones from which the patient suffers; the patient then chooses the three that he or she finds most prominent or distressing. The 10 ordinal items then refer to the occurrence of the three target symptoms. The five items

related to obsessions are time occupied by obsessive thoughts, interference with activities due to obsessive thoughts, distress associated with obsessive thoughts, resistance against obsessions, and degree of control over obsessive thoughts. The five items concerning compulsive behaviors are homologous. The Y-BOCS has acceptable internal consistency and inter-rater reliability, and it has been shown to be sensitive to clinically relevant changes in OCD symptoms with treatment. A self-rated version and a computer-administered version are available.

Of particular interest to medical psychiatrists is the sensitivity of the Y-BOCS to obsessions and compulsions that can present as general medical problems or that can become impediments to medical treatment adherence. The former comprise somatic obsessions, contamination obsessions, and potentially self-injurious compulsions like excessive handwashing. The latter include checking compulsions, cleaning and washing compulsions, ritualized eating, and repetition compulsions. These specific symptoms are identified on the symptom checklist and then become the basis of the quantitative score.

THE OBSESSIVE COMPULSIVE INVENTORY

An alternative to the Y-BOCS specifically designed for self-rating of OCD symptoms in general medical contexts is the Obsessive Compulsive Inventory (OCI; see Foa et al., 1998). The full OCI comprises 42 items relating to different types of obsessions and compulsions, each rated on a scale of 0–4 for how much distress the symptom caused the patient during the previous month. Distress ratings are calculated for six domains: washing, checking, ordering, obsessions, hoarding, and neutralizing. An 18-item version has similar content and psychometric properties (Foa et al., 2002). The OCI provides less detail than the Y-BOCS on the patient's psychopathology; in particular, it focuses on distress caused by symptoms rather than frequency, ability to resist, and so on, and it combines ratings of obsessive thoughts and compulsive behaviors in its scoring. Its virtue is that it is a self-rated instrument that surveys all main types of obsessive compulsive symptoms, making it well suited for screening and initial diagnosis (Abramowitz & Deacon, 2006). Once a patient has been diagnosed and begun treatment, the Y-BOCS appears more suitable for measuring treatment response, because it assesses multiple aspects of severity and not just distress, and after the initial assessment all Y-BOCS scale items will focus on the obsessions and compulsions most relevant to the patient.

PHOBIA RATING SCALES

Clinically significant phobias involve a combination of two factors: physiological arousal (fear or anxiety) in the presence of or contemplation of the phobic stimulus, and avoidance behavior. Rating scales for phobia are either for phobias in general, or specific scales for specific phobias such as agoraphobia, social phobia, or blood injury phobia. The IAPT Phobia Scale (Improving Access to Psychological Therapies, 2013) is a 3-item self-rated screening test for phobias in general. Each item asks the patient

to rate on a scale of 0–8 how much they would avoid particular circumstance: The questions concern the following: (1) “Social situations due to a fear of being embarrassed or making a fool of myself”; (2) “Certain situations because of a fear of having a panic attack or other distressing symptoms (such as loss of bladder control, vomiting or dizziness)”; and (3) “Certain situations because of a fear of particular objects or activities (such as animals, heights, seeing blood, being in confined spaces, driving or flying)”. A score of 4 (marked avoidance) on any specific item suggests the clinical diagnosis of a phobic disorder.

Virtually all rating scales for specific phobias measure both arousal and avoidance behavior. In medical settings the most relevant phobias are of three kinds: (1) those that interfere with medical treatment, prominently including blood injury phobias (fears of injections, venipuncture, or surgery), dental phobia, and disease-specific fears such as fear of hypoglycemia in insulin-dependent diabetics; (2) those that interfere with patients coming to a hospital, clinic, or doctor’s office, including agoraphobia, severe social phobia, and specific fears of clinical settings; and (3) phobias with panic attacks or other autonomic symptoms severe enough to present as medical problems in their own right.

In addition to the usual benefits of rating symptoms, the quantitative rating of phobias can help in gauging the relative severity of physiological symptoms versus avoidant behavior. For example, premedication prior to a feared procedure is likely to be an effective solution when autonomic symptoms are severe and avoidant behavior is not.

Most commonly used phobia scales are self-rating instruments, although many of them could be completed by a proxy and give clinically useful scores. However, psychometric properties should not be presumed to be the same if an informant is filling out the questionnaire on the patient’s behalf.

The medical psychiatrist addressing issues of medical fears and associated avoidance can utilize either general scales for rating medical fears and avoidance or scales that are specific for a particular disease and clinical situation. Representing the former are two self-rated omnibus scales, the Medical Fear Survey (MFS) and the Medical Avoidance Survey (MAS) (Kleinknecht et al., 1996). The MFS comprises a set of 5-point ordinal items (originally 70, subsequently 50 or 25) on which specific feared situations are rated on a scale of 1 (no fear or concern at all) to 5 (terror); the shorter versions use 4-point items that eliminate “terror” as an option. Typical items are “giving blood” or “seeing wounds.” The MAS comprises 21 items relating to reasons why a person might avoid seeing a doctor or seeking treatment, ranging from fear that blood will be drawn to concern about cost; they are rated on an ordinal scale of 0 (“I wouldn’t avoid treatment for that reason”) to 4 (“I have avoided treatment for that reason in the past and I would continue to do so now”). The MFS can be decomposed into seven factors that are related to fears of mutilation, deformed persons, cutting objects, medical/dental examinations, hypodermic injections, blood draws, and physical symptoms. The MAS can be decomposed into three factors that are related to fear that serious illness will be discovered, fear of blood draws or injections, and concerns about logistics and costs. Both instruments have been used extensively in research, and,

notably, a subscale of the MFS specifically dealing with fears of blood and injections has been used as a brief and practical measure of blood injection injury phobia. Medical psychiatrists encountering patients who frequently miss, cancel, or reschedule appointments, or who do not follow through with medical treatment recommendations, might consider these scales as an efficient way to determine whether phobic avoidance is critical, instead of or in addition to logistical problems, personality issues, or problems with physician–patient relationships.

In addition to general fears related to medical care, patients can have *condition-specific fears* that involve both anxiety and avoidance behavior. These fears can have major effects on treatment adherence and on clinical outcomes. Three illustrative examples are *fear of falling* in people with disorders of gait or balance (e.g., vestibular disorders), *fear of movement* in people with painful musculoskeletal conditions (e.g., osteoarthritis or low back pain), and *fear of hypoglycemia* in patients with insulin-dependent diabetes. For each of these fears there is at least one widely accepted rating scale that is brief enough to be used in clinical practice and psychometrically sound enough to be used in research.

The Short Falls Efficacy Scale–International (FES–I) is a 7-item questionnaire assessing a patient’s fear of falling in connection with various activities. Each item is a 4-point ordinal scale ranging from 1 (not at all concerned) to 4 (very concerned). The seven activities are getting dressed or undressed, taking a bath or shower, getting in or out of a chair, going up or down stairs, reaching for something above the head or on the ground, walking up or down a slope, and going out to a social event. The scale, which has very high internal consistency (Cronbach’s $\alpha = 0.92$) nicely and efficiently captures, characterizes, and quantitates fear of falling.

The Tampa Kinesiophobia Scale (TSK; see Kori et al., 1990) is a self-rated questionnaire that measures fears and avoidance behavior related to body movement and pain. It comprises 11, 13, or 17 four-point bidirectional ordinal (Likert-type) items rated from 1 (strongly disagree) to 4 (strongly agree), referring to statements like “Pain always means I have injured my body” and “Simply being careful that I do not make any unnecessary movements is the safest thing I can do to prevent my pain from worsening”. The scale has gained wide acceptance by specialists in physical medicine and rehabilitation (Woby et al., 2005; Damsgard et al., 2007; Roelofs et al., 2011). Although it was developed for use with low back pain patients, it has subsequently been applied to diverse pain populations including those with neck pain, osteoarthritis (Shelby et al., 2012), fibromyalgia (Burwinkle et al., 2005), and chronic fatigue syndrome (Silver et al., 2002). For the medical psychiatrist, the TSK score offers a measurable target for improvement with cognitive-behavioral and/or pharmacological treatment that is not based on diagnosing a “mental disorder”.

The Hypoglycemia Fear Survey–II (HFS–II; see Cox et al., 1987; Irvine et al., 1994; Gonder-Frederick et al., 2011) is exemplary of a highly specific scale for a medical phobia that is prevalent, treatable, and relevant to medical outcome. It rates two dimensions of fear of hypoglycemia: worry about

hypoglycemia and behavior aimed at avoiding hypoglycemia. The test comprises 33 ordinal items, each self-rated or informant-rated, for frequency on a scale of 0 (never) to 4 (always) in reference to the past 6 months. There are 15 items concerning specific avoidant or precautionary behaviors and 18 items concerning specific hypoglycemia-related worries. Factor analyses of data from various diabetic populations have confirmed the distinctness and internal consistency of the two factors. Fear of hypoglycemia, as measured by the scale, is associated with having had hypoglycemic attacks requiring assistance; it is also associated with worse glycemic control. Diabetic patients' scores on the HFS-II can be used to compare the impact of different treatments on their health-related quality of life. Clinically, medical psychiatrists can identify patients with a disproportionate fear of hypoglycemia that *is in itself* a relevant mental health outcome that *can lead to* a worse general medical outcome.

Social phobia (social anxiety disorder) and *agoraphobia* clearly can affect patients' participation in medical treatment. Each is treatable and each is measurable. The reader is referred to textbooks and review articles on these disorders for details on available rating scales and screening tests.

RATING POSTTRAUMATIC STRESS DISORDER

Posttraumatic stress disorder (PTSD) appears frequently in medical contexts, where it sometimes is an unrecognized yet functionally significant comorbidity with a major impact on health-related quality of life. PTSD is especially prevalent following catastrophic medical events like burns, multiple trauma, and spinal cord injury, or following injuries associated with assault, abuse, rape, or combat (Roberts et al., 2010). These are all populations in which screening for PTSD would have a high yield and could, if followed up and treated effectively, improve ultimate clinical outcomes. Furthermore, medical and surgical treatments and hospitalization can, for individual patients, be traumatic events that give rise to subsequent PTSD. PTSD is amenable to self-rating, because patients with PTSD are painfully aware of their symptoms and usually do not deny them if asked about them specifically.

Two similar self-rated scales of PTSD symptoms have been used widely in general medical-surgical populations to assess posttraumatic symptoms both in patients and in family caregivers. One is the *PTSD Checklist—Civilian Version* (PCL-C; see Blanchard et al., 1996) and the other is the *Davidson Trauma Scale* (DTS; see Davidson et al., 1997). Both have 17 items corresponding to DSM criteria for PTSD. The PCL-C asks the patient to rate distress from each symptom over the past month on a 4-point ordinal scale (from 0–4). The DTS asks the patient to rate the frequency of each symptom over the past week and, separately, the severity of each symptom over the past week, on a 5-point ordinal scale. Both tests have excellent psychometric properties and can be used either for screening or for following patients' response to treatment.

Self-rated scales for PTSD are more practical for use as screening tests or tools for epidemiologic study than the

standard Clinician-Administered PTSD Scale (CAPS; see Blake et al., 1990 and Blake et al., 1995), which takes 45–60 minutes to administer and is viewed as the definitive instrument against which the self-rated scales are validated. The self-rated scales refer to the “event”. In most general medical contexts, the identity of the event is self-evident; if it is not, the clinician will need to clarify with the patient just what the event of interest is.

The CAPS has a two-stage structure much like the Y-BOCS. The patient first reviews a list of potentially traumatizing events and, together with the clinician, selects up to three based on their severity or how recently they occurred. Then, with these events in mind, the clinician questions the patient about the 17 symptoms covered in the PCL and the DTS, rating each on 5-point scales for severity and for frequency. The clinician can add specific behavioral descriptions and can note if he/she thinks the patient is amplifying or minimizing a symptom. As on the DTS, the total score is the sum of the frequency and severity scores for the 17 items. The CAPS can be utilized to assess PTSD symptoms over the past week, the past month, or the lifetime of the patient. The lifetime score can relate the symptoms of PTSD to up to three separate events.

Both the CAPS and the self-rated tests give not only an overall rating of the severity of posttraumatic symptoms but also establish whether criteria for a formal diagnosis of PTSD are present, and profile the qualitative aspect of the syndrome—whether, for example, intrusive reexperiencing phenomena predominate over emotional numbing and avoidance.

GENERAL AND NEUROPSYCHIATRIC PSYCHOPATHOLOGY SCALES

For the medical psychiatrist, a general psychopathology rating scale can serve several specific purposes: (1) It can organize the data collection and synthesis of a psychiatric evaluation and ensure that ever-important areas like psychotic phenomena are considered and recorded; (2) It can provide a quick quantitative measure of “how mentally ill is this patient”—potentially useful in communicating with other professionals and in making judgments about change over time or with treatment; and (3) It can provide a simple tool for monitoring whether a stressful or neurotoxic general medical treatment (e.g., cancer chemotherapy) is causing clinically significant mental and behavioral side effects.

The Brief Psychiatric Rating Scale (BPRS; see Overall & Gorham, 1962) is a venerable and still widely used general psychopathology measure that was originally developed to monitor the course of patients with schizophrenia. It is a clinician-rated scale that combines information obtained from the patient in a 15–30-minute diagnostic interview with observations made during the interview. It has 18 items, all rated on a scale of 1 (not present) to 7 (very severe), with the ratings referring to the 2 or 3 days immediately before the evaluation. The scale items cover somatic concern, anxiety, emotional withdrawal, conceptual disorganization, guilt

feelings, tension, mannerisms and posturing, grandiosity, depressive mood, hostility, suspiciousness, hallucinatory behavior, motor retardation, uncooperativeness, unusual thought content, blunted affect, excitement, and disorientation. The BPRS is in the public domain.

For rating psychopathology related to dementia and other gross brain diseases, the Neuropsychiatric Inventory (NPI; see Cummings, 1997) serves a purpose similar to that of the BPRS for general psychopathology. The NPI comprises 10 or 12 items that are scored by the clinician after interviewing a caregiver of the patient. For each item the clinician asks a yes/no question to determine whether a particular symptom has been observed over the past 4 weeks. If yes, the clinician asks follow-up questions to rate frequency on a scale of 1 (less than once a week) to 4 (every day) and severity on a scale of 1 (mild) to 3 (severe). The item score is the product of the frequency and severity scores. In addition, the caregiver's distress about the patient's symptom is rated on a scale of 0 (no distress) to 5 (very severe or extreme distress). The overall score on the NPI is the sum of the item scores; the sum of distress scores is reported separately. The NPI comes in three alternate versions: a questionnaire version for caregivers (the NPI-Q), a version based on a clinician interview of nursing home staff (the NPI-NH), and a version that incorporates direct observations by the clinician during a structured examination of the patient (the NPI-C). The NPI is a copyrighted instrument that is licensed royalty-free to clinicians; a fee must be paid to license the test for use in funded research.

The 12 symptom areas covered by the NPI are delusions, hallucinations, agitation/aggression, depression/dysphoria, anxiety, elation/euphoria, apathy/indifference, disinhibition, irritability/lability, aberrant motor behavior, sleep disturbance, and appetite and eating disorders.

Thus there are several salient differences in the NPI that make it more useful than the BPRS for assessing dementia patients and other medical-psychiatric patients with similar issues: (1) It makes use of input from caregivers; (2) It covers a four-week period, and therefore counts infrequently occurring but potentially severe symptoms; (3) It covers eating and sleeping-related problems; (4) It captures neuropsychiatric symptoms more precisely; the apathy and indifference seen in many patients with early Alzheimer's disease are not the same symptom as the emotional withdrawal and blunted affect seen in patients with schizophrenia; (5) It specifically measures caregiver distress, and (6) It separately measures the frequency and the severity of symptoms.

The broad coverage of the NPI makes it less sensitive than a more specialized scale for measuring and monitoring specific neuropsychiatric symptoms or syndromes that might be the focus of medical-psychiatric concern. An example is the syndrome of apathy. In neuropsychiatric disorders including Parkinson's disease, effects of medial frontal lesions, and vascular dementia, the syndrome of apathy—a pathological lack of motivation, affect, or interest—can be a prominent symptom that is distinguishable from depression. It is important to recognize it, because it can be treated specifically and because its misdiagnosis as depression can lead to its treatment with

antidepressants that in some cases make apathy worse. While behavioral neurologists have always distinguished apathy from depression, wider recognition of apathy as a discrete symptom clearly was facilitated by the development of rating scales specific for that condition. Apathetic patients can be unable to care for themselves yet be unconcerned about their disability; this is a challenge to clinicians and to family caregivers. Yet, even severe apathy might contribute only slightly to the total score on the BPRS and only modestly to the total score on the NPI.

The use of a specialized rating scale focused on apathy is best for measuring the severity of apathy and for following changes in apathy in response to treatment. Moreover, the use of an apathy rating scale sensitizes the user—and the consumers of scale scores—to the issue of apathy. After rating several patients with an apathy rating scale and seeing apathy scale scores reported by their colleagues, physicians will recognize more patients with apathy in their clinical practice.

The Apathy Evaluation Scale (AES; see Marin et al., 1991) is an 18-item instrument with self-rated, informant-rated and clinician-rated versions that covers all three aspects of the syndrome of apathy: cognitive (lack of interest), affective (lack of feeling or concern), and motivational (lack of will or drive). Each item describes an aspect of behavior. In the clinician version, the item is given a score from 1 (behavior not characteristic of the patient) to 4 (behavior very characteristic of the patient), all with respect to the patient's behavior over the past 4 weeks. The self-rated and informant-rated versions use a differently-worded description of the 4-point scale. The AES has been shown to measure apathy as a phenomenon distinct from depression and has demonstrated favorable psychometric properties in a range of medical and psychiatric patient populations (Clarke et al., 2011).

The AES can be especially useful in assessing and following patients who have lost their interest and drive in connection with severe general medical illness and its treatment—for example, patients with cancer who have just undergone rigorous and exhausting chemotherapy—but do not show the syndrome of major depression. It is also applicable to assessing apathy as a residual syndrome in patients who have been treated for depression with antidepressant drugs, yet remain passive and disengaged despite relief of their dysphoric mood. The AES was used in this way in a recent multicenter drug trial reported by Raskin et al. (2012). The investigators identified 483 patients who had been treated with an SSRI other than escitalopram for 3 months or more, with relief of depressive symptoms but persistence of apathy as indicated by AES scores >30. Eight weeks of treatment with a different antidepressant drug—either escitalopram or duloxetine—reduced apathetic symptoms by an average of 14 points.

For measuring behavioral symptoms of frontal systems dysfunction apart from apathy, and not mixing them with various symptoms of primary psychoses, the Frontal Systems Behavior Scale (FrSBe; see Grace et al., 2001) can serve similarly to the AES in the measurement of apathy. The FrSBe measures three factors, corresponding to executive dysfunction, disinhibition, and apathy (Stout et al., 2003).

FUNCTIONAL ASSESSMENT

Functional assessment scales rate patients' ability to perform physical activities (e.g., walking or dressing) or instrumental activities (e.g., shopping, handling money, or using public transportation). Patients are rated as to whether they can perform specific activities independently, with supervision, or with assistance, or cannot perform them at all. Depending on the scale, scores may also reflect *how much* assistance is needed; for example, if the assistance required involves weight-bearing or not, and if it requires one person or two. The physical activities of daily living (ADL) conventionally comprise eating, mobility in bed, transferring from bed to chair, walking, using the toilet, bathing, grooming, and dressing. The instrumental activities of daily living (IADL) include shopping, driving or using public transportation, keeping one's living quarters in order, managing one's money, taking medications, and communicating by telephone, by mail, or via electronic media. The most widely used scale for measuring ADLs is the Katz Index of Activities of Daily Living (Katz et al., 1963), and the most widely used scale for measuring IADL is the Lawton Scale of Instrumental Activities of Daily Living (Lawton & Brody, 1969). Both of these scales were originally designed to be clinician-rated, but the scale items permit rating by the patient or by the patient's informal caregivers. Performance on the ADL index frequently is reported as a count of dependencies rather than as a summary score. It is also common to simply indicate the specific activities in which the patient is not independent. When scored as originally described, the Lawton IADL scale does not distinguish subtle from severe dependencies in IADLs; a patient who could dial only a few familiar numbers would get full credit for use of the telephone. For this reason it is most helpful in answering questions related to the need for assisted living or supportive services rather than questions about decision-making competence.

A summary scale that comprises physical and instrumental functions, specifically adapted for measurement of rehabilitation outcome, is the Functional Independence Measure (FIM; see Granger et al., 1993; Granger, 1998). The FIM has become an international standard for its purpose; it is supported, much as the C-SSRS, by a large academically-affiliated organization that warehouses normative data, investigates the scale's psychometric properties in various populations, provides training materials, runs user groups, and so on. Its particular virtue is its sensitivity to the kinds of change that take place in post-acute rehabilitation programs following trauma, surgery, or stroke. The measure comprises 18 items, each measured on a 7-point scale. Thirteen items relate to physical functions of self-care, continence, transfers, and locomotion; five items relate to cognitive functions of comprehension, expression, social interaction, problem solving, and memory. A score of 7 corresponds to complete independence; 6 corresponds to independence using a device, 5 corresponds to requiring supervision only, and 4 through 1 correspond to a progressively greater need for physical assistance. The FIM has very

high inter-rater reliability when the two raters are comparably trained therapists. Its virtue is its high sensitivity to changes during rehabilitation, which mainly derives from its subdivision of physical dependence into four levels.

Ratings of ADLs and IADLs are used to assess clinical course and treatment response, as well as to determine eligibility for compensation or supportive services. ADL independence is a critical criterion for physical therapy outcome, and IADL independence is a critical criterion for occupational therapy outcome. Several considerations in the use of these scales are especially relevant to medical psychiatrists:

1. ADLs and IADLs may be rated differently by patients, caregivers, and clinicians. Overestimation of independence by patients can reflect denial of illness or bad judgment due to frontal systems dysfunction. Underestimation of independence can reflect depression, demoralization, or delusional beliefs. Overestimation of independence by a family member may reflect denial or simply a lack of familiarity with the patient's challenges, particularly when patient and the relative do not live together; underestimation of independence may reflect an overprotective attitude or a conscious or unconscious intent to infantilize the patient. In any case, discrepancies in judgments of dependence among clinicians, patients, and families can cause interpersonal conflicts that should be resolved to optimize the outcome of care. Medical psychiatrists can be helpful in these situations because they can appreciate the medical basis of a patient's disability as well as the cognitive, emotional, and interpersonal issues involved.
2. When neuropsychiatric factors strongly influence ADL performance, a patient can perform independently at one time in one context while requiring supervision or physical assistance at a different time in a different context. An 85-year-old patient with mild dementia, who is independent in basic self-care while living in her home of 50 years, might be unable to use the toilet or walk safely while in the hospital for an acute medical condition.
3. Ratings of ADLs are the usual basis of entitlements to supportive services, for example, reimbursements from long-term care insurance and eligibility for Medicaid-funded nursing home care or home care services. Patients with inconsistent ADL independence due to neuropsychiatric conditions can truly require residential care or supportive services, yet pass a specific one-time test of ADL performance. The medical psychiatrist who appreciates this point can at times be an essential advocate for such patients.
4. ADL and IADL performance are affected by motivational state. Drugs and mental disorders that affect motivation can affect ratings of function, often reversibly.
5. The FIM's sensitivity to incremental changes in performance during the early stages of rehabilitation enables therapists and other clinicians to know when patients are making progress toward independence even though they

still require help or supervision. The medical psychiatrist can infer from increasing FIM scores that a patient is making progress, and provide realistic encouragement to a patient or caregiver. In later stages of rehabilitation, instrumental function can be much more impaired than physical function. In these cases the score on the FIM might be near maximal while the patient is still functioning well below baseline. When this is so the medical psychiatrist often can provide useful information or advocacy. If cognitive, emotional, or behavioral factors prevent a patient from being truly independent in life, he or she usually will need continuing treatment that addresses those factors and a supportive environment in the interim.

6. In the author's experience, judgments of functional independence by clinicians vary by the clinician's role and training. Specifically, therapists tend to focus on patients' best performance and what proportion of a task they can do independently; nurses providing supportive care tend to focus on how much assistance patients need at the time they need the most help. For example, a patient might progress in rehabilitation from continually needing help with transfers to needing help just once a day, when getting into bed at night. If, however, that one transfer required a two-person assist and the patient lived alone, home care still might not be feasible. Discrepant views of the meaning of "improvement" among patients, family caregivers, therapists, and physicians can produce conflicts that present to the medical psychiatrist, just as do differences in perceptions of functional independence.

COGNITIVE RATING SCALES

Brief quantitative rating scales for testing of cognition during clinical encounters occupy a middle ground between the unstandardized assessment that is part of a psychiatric mental status examination and the extensive assessments performed by neuropsychologists. Cognitive rating scales are used to detect dementia and delirium, to quantify the scope and severity of cognitive deficits, and, to a lesser extent, to characterize the nature of any deficits found. Commonly used scales all have acceptable reliability, but their validity depends on the purpose for which they are used. This is especially the case when scales are used as screening tests for dementia or mild cognitive impairment, where the usual tradeoff between sensitivity and specificity exists. Relatively high cutoff scores will lead to some poorly-educated patients being misclassified as cognitively impaired. Relatively low cutoff scores will lead to missing actual cognitive impairment in patients with high premorbid intelligence or mild impairment. Another common feature of brief cognitive rating scales is their greater sensitivity to generalized, diffuse, or multifocal cognitive deficits than to focal cognitive deficits, particularly when the latter involve nonverbal functions.

As disease-modifying therapy for dementing illnesses become available, the emphasis on cognitive screening will

shift toward sensitivity rather than specificity. Clinicians will not want to miss opportunities to intervene in patients with borderline or mild dementia who have not yet lost their functional independence.

For many years the most widely used brief bedside cognitive rating scale has been the Mini-Mental State Examination (MMSE) (Folstein et al., 1975). While the drawbacks of the instrument are widely known, the enormous literature on the scale and its widespread familiarity among clinicians have maintained its place in clinical practice. In the author's view, however, the aims of the MMSE are better attained by the Montreal Cognitive Assessment (MoCA) (Nasreddine et al., 2005), a scale of similar length and scope that addresses several of the shortcomings of the MMSE.

Both the MMSE and the MoCA are clinician-administered scales of general cognitive performance that yield scores between 0 and 30 based on the patient's performance on a standardized clinical examination that tests attention, concentration, memory, language, praxis, and some visuospatial functions. Table 4.1 compares the two scales.

Medical psychiatrists should be aware that "normal" scores on the MMSE or the MoCA, or even perfect scores on those scales, can rule out delirium or frank dementia, but they cannot rule out cognitive impairment in general. Many patients with functionally significant deficits will have a normal MMSE because their deficits are in areas that the MMSE does not test, or that account for only a point or two of the MMSE score. A patient with a large right-hemisphere stroke could have left hemineglect and severely impaired visual memory and score 29 out of 30 on the MMSE, losing a point only for the drawing item. Furthermore, patients with degenerative brain diseases develop mild cognitive impairment (MCI) before they develop dementia, and, at the stage of MCI, total cognitive rating scale scores usually fall at the lower end of the "normal" range.

When either the MMSE or the MoCA is used to follow changes in patients' cognitive performance over time, the words used to test memory should be changed to mitigate potential learning effects. Both the MoCA and the second edition of the MMSE (MMSE-II) have alternate forms with different lists. If the clinician is using the original MMSE, the lack of alternate forms can be compensated by keeping at hand a set of different 3-word lists of comparable difficulty that can be substituted for the test's usual items each time the test is repeated.

The numerical score on the MMSE or the MoCA concisely conveys the degree of a patient's cognitive impairment to any clinician with training in the clinical neurosciences, as these tests are ubiquitous. The "message" of an MMSE score can be articulated further by noting the reason a patient lost points—for example, "the patient got 29/30 on the MMSE, losing a point on the drawing of the intersecting pentagons."

Two significant "blind spots" of the MMSE and, to a lesser extent, the MoCA are visuospatial functions and executive cognitive function. Relatively isolated deficits in visuospatial function can occur as a consequence of right hemisphere lesions. Executive cognitive dysfunction has a wide range of potential causes including degenerative brain diseases,

Table 4.1 COMPARISON OF THE MINI-MENTAL STATE EXAMINATION (MMSE) AND THE MONTREAL COGNITIVE ASSESSMENT (MOCA)

COGNITIVE FUNCTION OR TEST FEATURE	MMSE	MOCA
Attention and Concentration	Serial 7s <i>or</i> spelling “world” backwards	Repeating 5 digits forward and 3 digits backward, signaling to the letter “A,” serial 7s
Language	Naming a pencil and a watch; repeat “no ifs, ands, or buts”; following a 3-stage spoken command; following a 1-step written command	Naming of three pictured animals; listing words starting with “f” in 60 seconds (verbal fluency); repetition of two sentences
Orientation	Date, day, season, state, county, town, hospital, floor	Date, day, place, city
Memory	3-word list presented, immediate recall scored, list presented up to six times until learned, then delayed recall after an intervening test item	5-word list presented twice for immediate recall; delayed recall at end of test
Abstract Reasoning	—	Similarities: two word pairs are presented
Executive Function	—	Alternating trail-making (connecting 1-A-2-B, etc.)
Visual-Spatial	Copy intersecting pentagons	Copy 3-D cube, draw clock
Time to Administer	10 minutes	10 minutes
Alternate Forms	Examiner can change the three words for the memory test	Original plus two alternates
Copyright status	Publisher expects fees for clinical or research	Free for clinical use; license needed for commercial research

toxic-metabolic encephalopathy, medication side effects, and major primary mental disorders including bipolar disorder and schizophrenia. Establishing that executive cognitive function is impaired can be particularly useful when the medical psychiatrist is called upon to explain why instrumental function is much worse than physical function in a patient who otherwise has grossly intact memory, orientation, and so on.

Two practical and empirically validated bedside scales for executive cognitive function are the Clock Drawing Test (CDT; described in Chapter 2, with additional comments below; see also Royall et al., 1999) and the Executive Interview Test (EXIT; see Royall et al., 1992). The EXIT gives a score of 0–50 based on a 25-item structured clinical examination that takes about 15 minutes. Each item is an ordinal item scored 0 if the response is normal and scored 1 or 2 if the item is abnormal, according to severity of abnormality. The examination is designed to elicit signs of executive dysfunction including perseveration, imitation behavior, intrusions, lack of spontaneity, disinhibited behaviors, and utilization behavior; it also checks for the presence of a grasp reflex and a snout reflex. Mentioning which items were responsible for a high EXIT score adds to its value as a tool for communicating with other clinicians.

The unique value of the EXIT to the medical psychiatrist is that it contains items—and tests for signs—that are not usually included in other bedside examinations. For example, one item presents the patient with anomalous sentences (e.g., “Mary fed a little lamb”) and asks the patient to repeat them. The mildly impaired patient will spontaneously correct the phrase despite the examiner’s instructions; a grossly impaired one might continue with the second phrase in the

familiar verse. Either type of error shows impairment in working memory—the ability to keep an instruction in mind despite a distracting stimulus. Executive functions like working memory are provably important to self-care and occupational function, yet are not directly tested by typical brief cognitive screens.

The CDT has both literal and figurative “face validity”—when a caregiver or clinician sees a grossly disorganized clock face produced by an educated adult, it is not hard to convince the person that there is an issue with brain function. Moreover, neglect of the left half or one of the left quadrants of the clock strongly suggests a structural lesion of the right hemisphere. Though they perhaps communicate less than an image of the drawing, there are over 20 different ordinal rating scales for clock drawings that measure just how bad the drawing is. No specific scoring system has become a de facto standard. Royall, the co-developer of the EXIT, devised a scoring system for the clock drawing, the CLOX (Royall et al., 1998) that is especially focused on errors due to executive dysfunction. The CLOX comprises two tasks: CLOX1 is a free drawing of a clock, and CLOX2 is a copy of a clock drawn in front of the patient by the examiner. CLOX1 is highly sensitive to executive cognitive dysfunction; both CLOX1 and CLOX2 will be impaired in cases of constructional apraxia or global dementia.

The patient’s score on CLOX1 ranges from 0–15, with 15 representing a perfect performance and a score less than 10 suggesting executive cognitive dysfunction. The clock drawing task is presented in a way that increases the likelihood of failure if the patient has impaired executive function. The patient is shown a blank sheet of paper and is asked by the examiner to “Draw

me a clock that says 1:45. Set the hands and numbers on the face so a child could read them.” The opposite side of the blank sheet of paper has a circle printed in its left lower corner, and it is intended the paper be placed on a light colored surface so that the printed circle will slightly show through. The patient is thus presented with several confusing cues and distractors: the words “hands” and “face,” the number 45, and the circle showing through slightly from the opposite side. Patients with impaired executive function will make errors of organization and planning or errors related to distractibility and lack of inhibition; for example, drawing a hand or a face, pointing one clock hand to the 4 and one to the 5, writing the time in digits, or tracing the small circle showing through from the other side of the page.

Low scores on CLOX1 are strongly associated with poor scores on the EXIT25 and other tests of executive function (Royall et al., 1998). They are also associated with functional defects in brain areas associated with executive function (Shon et al., 2013).

SCALES FOR PAIN, SLEEP DISTURBANCE, AND SEXUAL DYSFUNCTION

Pain, sleep disturbance, and sexual dysfunction are three somatic expressions of general medical illness that often come to psychiatrists’ attention because of their relationship to mental symptoms, especially depression and anxiety. These symptoms are especially likely to cause emotional distress. They can be caused or exacerbated by mental disorders and by transient emotional states. And, they are often helped by cognitive-behavioral or other psychotherapeutic interventions.

With the exception of simple quantitative measures of pain intensity, the most useful rating scales for these three symptomatic domains involve multidimensional or qualitative characterization of symptoms as well as some form of quantitative summary. The former aspect of the scales guides diagnosis and choice of treatment; the latter aspect is used to categorize symptom severity and quantify the outcome of treatment.

PAIN

The 0–10 Numerical Rating Scale (NRS), the Pain Faces (Figure 4.3), and the Visual Analog Scale (VAS) are all simple one-dimensional measures of current pain intensity. The first two scales are explicitly ordinal scales; the last is continuous, but because the scaling is not uniform it is essentially an ordinal scale as well. (Uniform scaling means that a difference of a specific number means the same thing at any point on the scale. This is not the case: for most patients a difference between 10 and 30 does not have the same subjective significance as a difference between 60 and 80.) These scales are useful in an acute care setting to inform a decision as to whether acute pain treatment with an opiate or other major analgesic is necessary, and to decide whether such treatment has been adequate. They are, in the author’s opinion, less useful in evaluating and developing treatment strategy for chronic or recurrent pain.

Pain rating scales differ in the *process* of gathering information from the patient and in the breadth and specificity of scale *content*. Information about a patient’s pain can be elicited in a primarily verbal or primarily visual channel (e.g., verbal pain descriptors or the NRS versus Pain Faces or the VAS). It can be elicited from the patient, from a proxy such as a family member, or from a clinical observer, usually a nurse. It can be responsive to a fixed set of questions, or interactive with a software application that presents questions based on responses to previous ones. Content can comprise any combination of ratings of frequency, severity, and intensity, and it can include a checklist of qualitative attributes of the pain—for example, shooting, aching, burning, and so on. Some pain rating scales include measurements of pain-associated depression, anxiety, fear, catastrophic thinking, self-perceived coping adequacy, and/or other pain-associated emotions and cognitions. Pain-associated distress and pain-associated functional impairment can be rated.

Pain rating scales can be generic or can be designed for specific clinical populations such as those with low back pain, neck pain, or upper extremity pain. Pain rating scales for specific patient populations can be more sensitive to changes with treatment, because the scale consists entirely of items actually encountered in the clinical context for which the scale was designed. The medical psychiatrist working in liaison with a specific medical or surgical subspecialty should consider using such scales.

THE BRIEF PAIN INVENTORY

The Brief Pain Inventory (BPI) (Cleeland & Ryan, 1994) addresses the limitations of single-item pain ratings. It is a self-rated instrument that takes 5 minutes to complete in its short form and 10 minutes in its long form. It is copyrighted but is available royalty-free for clinical use (there is a charge for use in funded research). It has been translated into numerous languages and has been psychometrically validated in many of them.

The long form of the BPI rates pain on the 11-point NRS (i.e., 0–10), but asks four questions: the status of the pain now, at its worst in the past week, at its best in the past week, and on average in the past week. There are seven questions about different kinds of functional impairment, each rated on a similar 11-point scale. The use of analgesics is covered, including the frequency of use, the degree of relief obtained, and the duration of relief. There is a set of yes/no questions about the qualitative nature of the pain, e.g., shooting, throbbing. Finally, the patient is asked to what he or she attributes the pain. The short form of the BPI asks only about the past 24 hours and includes the same four questions about pain severity and seven questions about pain-related impairment. There is a single question about degree of relief obtained from pain medication.

The BPI has been accepted by the US Food and Drug Administration as a primary patient-reported outcome measure in studies of analgesic treatments. It frequently is included as the pain measure in controlled studies of treatments of conditions that cause pain. Pain issues typically encountered by

medical psychiatrists include functional impairment due to pain or the fear of pain, tolerability of pain, erroneous attribution of pain, emotional reactions to specific pain treatment modalities, and use of pain medications other than as prescribed. In addition, medical psychiatrists occasionally encounter intractable pain with a neuropathic origin that has not been appreciated or fully addressed. The qualitative description of the pain included in the long form of the BPI can provide clues to neuropathic mechanisms. Overall, the BPI is the pain questionnaire best suited for use in medical psychiatry.

Some additional points can be made:

1. Among patients with brain diseases, those with left hemisphere lesions may prefer to rate pain using a visual method; those with right hemisphere lesions may prefer a verbal method.
2. Ordinal pain scales such as the NRS can be calibrated for individual patients by anchoring the numbers with the patient's rating of nearly universal pain experiences such as muscle aches from a flu-like illness, heartburn, a muscle strain or sprain, menstrual cramps, or a tension headache.
3. Neuropathic pain often involves symptoms in excess of obvious signs, and thus can raise concerns about somatization until a correct diagnosis is made. Neuropathic pains have distinguishing characteristics like "shooting" and "burning" and association with unpleasant numbness. These will be picked up by a scale like the long form of the BPI, with its checklist of pain adjectives. The structured characterization of pain quality is done more extensively by the McGill Pain Questionnaire (MPQ), also available in long and short forms, which strongly emphasizes the qualitative characteristics of the pain (Melzack, 1987). For example, on the short form of the MPQ the patient is given 15 descriptors of pain - 11 sensory and 4 affective - and asked to rate each of them for intensity as 0 = none, 1 = mild, 2 = moderate or 3 = severe.
4. Rating scales like the BPI usefully distinguish pain intensity/severity from pain interference, the latter comprising the impact of the pain on mood, sleep, relations with others, daily activities, and enjoyment of life. They do not usually distinguish intensity of pain - a purely sensory dimension - from *severity* of pain, a dimension that comprises the unpleasantness (hurtfulness) of pain. While these are highly correlated they are not identical, Brain lesions and primary mental disorders can lead to dissociation of pain intensity from degree of hurt; treatments like hypnosis for pain control deliberately induce such a dissociation. When pain and hurt are dissociated in a given patient and pain is rated with a scale like the BPI that treats intensity/severity as a unitary construct, the patient should be instructed to rate "how bad the hurting is" rather than how strong the sensation is.

5. The distress and impairment ("interference") associated with pain often can be modified even when pain continues as a sensory experience. When distress and impairment become the focus of treatment, they should be separately measured. This can be done using the 7 interference items of the BPI.
6. Pain is a major factor in provoking agitation and other behavioral symptoms in individuals with moderate or severe dementia, especially when the patient is too cognitively impaired to describe the pain or request relief. Pain rating scales for patients with dementia rely on nonverbal expressions of discomfort and distress as observed by caregivers. An example of such a scale is the Pain Assessment in Advanced Dementia scale (PAINAD; see Warden et al., 2003). The PAINAD produces a pain score of 0-10 by summing five items, each rated on a 0-2 scale, that capture nonverbal signs of pain and discomfort: breathing (labored breathing or hyperventilation), vocalization (moaning, groaning, or crying), facial expression (sad, frightened, or grimacing), body language (tenseness of the body or agitation), and consolability. It has good psychometric properties and has been cross-validated with similar scales.

SLEEP DISTURBANCE

Sleep has both quantitative and qualitative dimensions. In the setting of general medical illness, patients often feel their sleep is inadequate because it is insufficiently restorative even though time spent asleep might be close to what it was when the patient was in better general health. Non-restorative sleep usually is due to disruption of sleep architecture, with insufficient time spent in the deeper stages of sleep. Another reason sleep can be qualitatively inadequate is that it comes at the wrong time, out of phase with the patient's schedule of activity. Two obvious consequences of nonrestorative sleep are fatigue and excessive daytime sleepiness. Impairment of daytime cognitive and motor performance is another, important because it can lead to poor occupational or academic performance and to motor vehicle accidents. Less obviously, poor-quality sleep can cause or exacerbate depression, and it can impede a patient's response to antidepressant treatment.

Rating sleep is valuable for determining to what extent poor sleep might be affecting a patient's physical and emotional health. If the rating scale has suitable dimensions of measurement, it also can screen patients for specific, treatable sleep disorders.

Sleep can be rated based on a patient and/or an observer's historical account, or it can be comprehensively recorded in a sleep laboratory. More recently, sleep quantity and quality can be measured by inexpensive and widely available technology. Home-based sleep measurement technology adds a quantitative and objective component to sleep ratings.

Sleep rating scales are of two general types: comprehensive scales, and scales designed for screening for specific sleep disorders such as obstructive sleep apnea.

PITTSBURGH SLEEP QUALITY INDEX

The Pittsburgh Sleep Quality Index (PSQI; see Buysse et al., 1989) is a 19-item questionnaire that probes seven domains related to sleep quality: subjective sleep quality, sleep latency, sleep duration, habitual sleep efficiency, sleep disturbances, use of sleeping medication, and daytime dysfunction. Each domain is rated on a scale of 0–3; the sum of domain scores gives an overall sleep quality index that ranges from 0–21. The PSQI is a combination of multiple choice and fill-in-the-blanks items. The scale has high internal consistency within each domain but only moderate correlation of domain scores with the overall scores, compatible with the clinical observation that poor sleep quality is a multidimensional issue. The scale is copyrighted but may be used by clinicians without a royalty; it has been used in over 500 published studies. Cognitively impaired individuals may find it difficult to complete the questionnaire, as the fill-in-the-blanks items require reasonably intact memory function and writing ability.

The PSQI is helpful in describing what is wrong with patients' sleep in a standardized, quantitative format. Its broad scope is useful when evaluating sleep in medical-psychiatric patients with multiple comorbidities that can affect sleep in a variety of ways and can cause daytime impairments that overlap with those caused by sleep disorders. However, it is not designed to screen for any specific sleep disorder or to distinguish between common causes of insomnia or excessive daytime somnolence.

THE INSOMNIA SYMPTOM QUESTIONNAIRE

The Insomnia Symptom Questionnaire (ISQ; see Okun et al., 2009) is a self-rated instrument that focuses on diagnosing and measuring the severity of chronic insomnia. It comprises 13 items, all referring to the patient's experience over the past month. The first five items ask about difficulty falling asleep, difficulty staying asleep, frequent awakenings, feeling that sleep is not sound, and feeling that sleep is unrefreshing. If the patient has any of these complaints, they are asked to rate its frequency on a scale of 1 (don't know) to 2 (less than once a week) to 5 (every night) and indicate how long they have had the problem in weeks, months, or years. If patients have any sleep problems, they complete the next eight questions, which refer to effects of sleep disturbance on daily life, including daytime sleepiness, irritability, fatigue, and so on. These are scored for severity on a scale of 0–4. The rule for identifying cases of insomnia is not a simple score, but rather an algorithm based on item response theory. Patients screen in for chronic insomnia if they have symptoms that include difficulty initiating or maintaining sleep or having nonrefreshing sleep, at least one of the symptoms occurs three or more times a week, symptoms have persisted for 4 weeks or more, and at least one of the eight aspects of daily life has been affected "quite a bit" (3) or "extremely" (4). With this scoring algorithm, the ISQ is more than 90% sensitive to a clinical diagnosis of insomnia, and cases identified with the ISQ show significant differences on polysomnographic indices of sleep quality from non-cases.

EPWORTH SLEEPINESS SCALE

The Epworth Sleepiness Scale (ESS; see Johns, 1991) is a patient questionnaire with eight ordinal items, all concerned with the likelihood of dozing off or falling asleep in particular situations like sitting and reading or riding in a car as a passenger. The patient rates each situation on a scale of 0–3, with 3 signifying a high probability of falling asleep. A score of 9 or higher implies a high probability of a diagnosable sleep disorder. The scale is available in several languages. It is copyrighted but can be used by clinicians without a royalty.

Medical psychiatrists should consider giving patients the ESS not only when they present with sleep complaints but also when (1) there is cognitive impairment that fluctuates during the day, involves mainly attention and memory, and is not explained by delirium or dementia; (2) the patient is taking a medication with the potential to cause sleepiness as a side effect, such as a benzodiazepine or opiate analgesic; (3) the patient has had an at-fault motor vehicle accident; or (4) the patient has had an otherwise-unexplained decline in occupational performance.

THE FATIGUE SEVERITY SCALE

Patients with poor quality sleep can suffer more from fatigue than from sleepiness; fatigue is also a prominent feature of many neurological, autoimmune and infectious diseases that have prominent medical-psychiatric dimensions. Treatment of comorbid or consequential anxiety or depression can alleviate some of the fatigue caused by these conditions; at the same time, many psychotropic medications can exacerbate fatigue.

The Fatigue Severity Scale (Krupp, 1989) is a validated self-assessment instrument for quantifying fatigue. It comprises 9 bidirectional Likert-type ordinal items such as "I am easily fatigued" and "Fatigue interferes with my physical functioning." These are rated from 1 (strongly disagree) to 4 (neutral) to 7 (strongly agree). It has excellent psychometric properties (Valko et al., 2008).

SCREENING FOR OBSTRUCTIVE SLEEP APNEA

Patients identified as having excessive daytime sleepiness or significant fatigue can have disordered nighttime sleep or can be sleepy or fatigued for other reasons. Screening tests for specific common conditions like obstructive sleep apnea (OSA) can aid in the diagnosis. The psychiatric and general medical benefits of treating OSA are large, but polysomnography, the gold standard for OSA diagnosis, is expensive and often difficult to arrange. Screening tests for OSA help avoid polysomnography in patients very unlikely to have the condition, while justifying the expense (and in some cases facilitating third-party payment) of polysomnography or a trial of therapy with continuous positive airway pressure (CPAP) for patients who screen in. Fortunately, screening for moderate to severe OSA utilizing information from the history and physical examination alone has both high sensitivity and high specificity. This can be done with the a four-item screening tool (Takegami et al., 2009). This tool utilizes only four variables: gender, BMI,

blood pressure, and the frequency of snoring (from the patient's history). Item scores are 4 if the patient is male, 0 if female; a score of 1–6 based on the patient's body mass index, a score of 1–4 based on the patient's blood pressure, 4 if the patient reports snoring every day or often, and 0 otherwise. The sum is thus between 2 and 18. The authors' screening strategy is interesting: patients with scores of 8 or below are screened out, as they have less than 9% chance of having moderate OSA and no chance of having severe OSA. Patients with scores of 14 or above are referred for polysomnography and CPAP titration because they have a greater than 91% chance of having severe OSA. Those with scores between 9 and 13 inclusive are referred for overnight home pulse oximetry, with a decision about polysomnography based on the results. The two-stage strategy adopted by the authors for OSA screening should be considered for use with other medical-psychiatric conditions where the clinician would like to be conservative, both about ruling out a diagnosis and about investing in an expensive or otherwise difficult diagnostic procedure or treatment.

REAL-TIME RECORDING OF SLEEP DATA

The Fitbit (www.fitbit.com), a personal monitor of sleep and activity that is worn as a wristband, synchronizes with a smartphone to produce a daily log of time in bed, sleeping and waking times, number of awakenings, total sleep time, and restless time during the night. It can be used to corroborate information obtained from rating scales like the ISQ, and to complement them in following the patient's response to treatment. Continuous nighttime pulse oximetry using a fingertip sensor is also available in the consumer market from multiple vendors; it can be utilized to make a decision about the need for polysomnography and sleep apnea treatment in borderline cases.

SEXUAL DYSFUNCTION

The prevalence of sexual dysfunction—and, more broadly, changes in sex life for patients and their spouses or partners—is extremely high in patients with serious chronic diseases. Loss of desire is common, with both endocrine and interpersonal mechanisms involved. Patients with heart disease and/or their sexual partners may fear that sexual activity will be harmful or even fatal. In patients with brain diseases that have altered personality or emotional communication, spouses or partners may feel that the person they once desired no longer exists, even while feelings of non-sexual attachment and caring are stronger than ever. Despite their prevalence and emotional importance, sexual issues often are avoided in physician–patient–caregiver dialogues. They are a routine part of the conversation when the patient is a young man with a spinal cord injury, but not as consistently in the case of a breast cancer patient in her 60s or a man in his 70s with mild Alzheimer's disease.

Incorporation of an adequate sexual history into a medical-psychiatric consultation can be difficult, either because of constraints of time or because of the timing of the interview. Self-rated scales of sexual function offer a way to cover

this important area outside of the interview, at a time that is suitable for the patient. Responding in private to a questionnaire evokes less anxiety than being questioned face to face, and responses are less confounded by the physician–patient relationship. The emphasis of sexual dysfunction scales ranges from the mechanical—focused on male erectile dysfunction—to the predominantly interpersonal. The medical psychiatrist using a sexual dysfunction scale should choose a scale with the appropriate emphasis for the patient and the clinical situation.

While there are special scales available for measuring sexual function in specific medical conditions, this chapter will describe three characteristic scales for use in general medical populations. One, the Arizona Sexual Experiences Scale (ASEX) (McGahuey et al., 2000), is a very brief, convenient tool for screening patients for sexual dysfunction and quantifying its change, applicable to both men and women. The other two scales are gender-specific scales that provide deeper insight into the nature of patients' sexual issues, separate objective from subjective dimensions, and give clues to diagnosis.

THE ARIZONA SEXUAL EXPERIENCE SCALE

The Arizona Sexual Experience Scale (ASEX; see McGahuey et al., 1990) comprises five 7-point unidirectional ordinal items constructed so that higher scores are associated with more difficulty. Four items apply to both men and women: overall sex drive, ease of sexual arousal, ease of reaching orgasm, and satisfaction with orgasms. There is a single question for men about ease of getting and maintaining erections and a single question for women about vaginal lubrication. Questions all relate to the prior week, and the questions about orgasm are to be answered only if the patient was sexually active in the prior week. The scale is copyrighted by the University of Arizona, which asks that clinicians seek permission for its use.

The virtues of the ASEX for medical psychiatrists are its brevity, its applicability to both men and women, and the 1-week time frame for recall, which makes it more relevant to patients with fluctuating sexual function, and less demanding on patients with cognitive or emotional issues that would make it difficult for them to accurately summarize a month's experience. The 7-point design gives the scale relatively high sensitivity to incremental changes associated with treatment for sexual dysfunction or the course of the patient's illness.

THE BRIEF SEXUAL FUNCTION INVENTORY

The Brief Sexual Function Inventory (BSFI; see O'Leary et al., 1995) is an 11-item survey of male sexual function comprising 5-point unidirectional ordinal self-ratings of sex drive, erections, ejaculation, the patient's subjective concern over his sexual function, and overall satisfaction. All questions refer to the prior 30 days. The scale, which is in the public domain, has acceptable psychometric properties. It separately measures the objective and subjective dimensions of specific symptoms, and provides more detail than the ASEX on specific functional issues. For example, it has four questions about erections: frequency of having them, their firmness, difficulty of getting them, and the extent to which

they are perceived as a problem. The BSFI is well suited for the assessment of male patients with relatively stable chronic conditions. Its focus on the prior 30 days makes it less useful for patients with sexual problems that fluctuate in connection with medical treatments or their level of general medical symptoms. While the BSFI screens for sexual dysfunction, measures it, and describes it, it does not diagnose its cause. Further, the subjective dimensions of sexuality are strongly influenced by a patient's intimate relationships; a sexual partner's response to a man's physical sexual dysfunction can make it a greater or lesser problem for the patient, with a greater or lesser effect on the patient's overall satisfaction.

THE FEMALE SEXUAL FUNCTION INDEX

The Female Sexual Function Index (FSFI; see Weigel et al., 2005) comprises 19 unidirectional ordinal items assessing female sexual function over the prior 4 weeks. Items have either five or six levels. Domains covered are frequency and intensity of desire; frequency, intensity, confidence, and satisfaction with physical and emotional arousal; frequency, difficulty initiating, and difficulty maintaining lubrication; frequency, difficulty reaching, and satisfaction with orgasm; satisfaction with emotional closeness during sexual relations, with sexual relations per se, and with overall sexual life; and pain during or after intercourse. A great virtue of the FSFI is its level of detail—dissecting the issues of frequency, intensity, and subjective experience, and its identification of sexually-associated pain when it is an issue. The 4-week recall period raises issues in patients with unstable medical status, changing treatments, or cognitive difficulties in summarizing 28 days of experience. On the other hand, the longer recall period increases the chances of capturing relevant information from patients who have sexual relations infrequently—a not-uncommon situation in people with significant general medical problems.

The first two questions in the FSFI concern sexual desire, and by themselves they can be used as a screen for hypoactive sexual desire. The first item asks how often the patient felt sexual desire or interest over the previous 4 weeks; the second asks how the patient would rate her level of sexual desire or interest over that period. The frequency and intensity items are summed, yielding a score between 2 and 10. A score of 5 or less identified women with Hypoactive Sexual Desire Disorder with >85% sensitivity and >90% specificity across four different validation studies (Gerstenberger et al., 2010). A particular benefit of this two-question screen is that it does not require that the patient have a sexual partner or be sexually active.

SCALAR SUMMARIES OF HEALTH, FUNCTION, AND THE NEED FOR CARE

Summary measures of the overall functional impact of physical or mental illness have been used in treatment outcome studies for decades. Such measures can be one-dimensional or multidimensional, clinician-rated or self-rated.

Medical psychiatrists can make use of scores on these scales in several ways. Clinician-rated, scalar measures of physical health, function, and the need for care are used to answer the question of “how sick is this patient.” They can also be used to provide a global judgment of the outcome of general medical or psychiatric treatment. Two examples are offered here, the Karnofsky Scale (Karnofsky & Burchenal, 1949) and the Global Assessment of Function (Endicott et al., 1976).

KARNOFSKY PERFORMANCE STATUS

The Karnofsky Performance Status (KPS) or “Karnofsky scale” (Karnofsky & Burchenal, 1949; Péus et al., 2013), widely used in palliative care, is a percentage between 0% and 100% that combines an assessment of disease severity and functional impairment due to disease. While it is expressed as a number between 0 and 100, it is not truly a continuous scale; it is better understood as three contiguous scales joined together. It is shown in Table 4.2.

Table 4.2 KARNOFSKY PERFORMANCE STATUS

Able to carry on normal activity and to work; no special care needed.	100	Normal no complaints; no evidence of disease
	90	Able to carry on normal activity; minor signs or symptoms of disease
	80	Normal activity with effort; some signs or symptoms of disease
Unable to work; able to live at home and care for most personal needs; varying amount of assistance needed.	70	Cares for self; unable to carry on normal activity or to do active work
	60	Requires occasional assistance, but is able to care for most personal needs
	50	Requires considerable assistance and frequent medical care
Unable to care for self; requires equivalent of institutional or hospital care; disease may be progressing rapidly.	40	Disabled; requires special care and assistance
	30	Severely disabled; hospital admission is indicated although death not imminent
	20	Very sick; hospital admission necessary; active supportive treatment necessary
	10	Moribund; fatal processes progressing rapidly
	0	Dead

The scale's apparent value is in its efficient communication among different clinicians and specialties when discussing patient populations such as those with pancreatic cancer or ALS that usually follow a progressive and ultimately fatal course, with potentially some periods of improvement or stabilization.

GLOBAL ASSESSMENT OF FUNCTIONING

The Global Assessment of Functioning (GAF; see Endicott et al., 1976; Hilsenroth et al., 2000) combines symptoms and functional impairment differently from the Karnofsky Scale, in keeping with its ultimate focus on the need for treatment and the outcome of treatment of mental illness. In the GAF, either more severe symptomatology or greater functional impairment implies a lower score; significant suicidal behavior implies a score of 20 or below, regardless of the severity of other symptoms or impairments. The GAF focuses on social, occupational, and, where applicable, academic functioning rather than on physical function, and on mental and behavioral symptoms both in themselves and as causes of functional impairment. The interpretation of a GAF score can be complicated by symptoms and impairments due to physical illness, since the GAF is based on the assumption that social and occupational impairments are due to mental illness (Yamauchi et al., 2001). The integration of symptomatic and functional aspects of the GAF is not standardized, and in general there are many open issues about how to optimize its value as a diagnostic tool. In any case, it is insufficiently sensitive to reliably measure small changes in a patient's mental health (Aas, 2011). Despite its very broad acceptance as a scalar summary measure of mental illness, the GAF will rarely be a scale of choice for the medical psychiatrist.

MULTIDIMENSIONAL HEALTH AND HEALTH-RELATED QUALITY OF LIFE MEASURES

Multidimensional scales of health and health-related quality of life usually are questionnaire-based and self-rated. In addition to their use in epidemiological and clinical research, they have clinical utility in two specific areas. By rating several dimensions of symptoms and function, they help clinicians see the tradeoffs of positive and negative effects of treatments, and secondary benefits of treatments for quality of life and well-being. And, by covering a broad scope of issues, they expand the scope of the medical psychiatrist's consideration beyond the issues that feasibly can be covered in an initial consultation. They can thus help direct the evaluation of the patient at follow-up visits. Multidimensional instruments like the World Health Organization Health Related Quality of Life Scale—Brief Version (WHOQOL-BREF) and the SF-36 have particularly broad scope and thus are especially useful for this purpose.

THE SF-36 (36-ITEM SHORT FORM HEALTH SURVEY)

The 36-Item Short Form Health Survey (SF-36; version 2 the SF-36v2) (Ware et al., 2000) is a brief but comprehensive self-rated questionnaire concerning a patient's overall health and function, developed by the RAND Corporation for use in the Medical Outcomes Study and subsequent epidemiological research. While it remains popular in outcomes research, it is less frequently encountered in routine clinical use. Its particular value is its focus on the *functional consequences* of physical and mental illness. Medical psychiatrists working in settings where time limitations make it infeasible to elicit the biographical narrative that puts the present illness into context can use the SF-36 as a shortcut to contextual understanding. The questionnaire takes 5–10 minutes to complete and refers to the patient's health status in the previous 4 weeks; there is a variant available that addresses health status in the past week. Individual items are of several different types: binary; unidirectional ordinal with three, five, or six points; and bidirectional ordinal with five points. Items relate variously to the presence, severity, and frequency of symptoms. Domains are (1) physical functioning, (2) role limitations because of physical health problems, (3) bodily pain, (4) social functioning, (5) general mental health, (6) role limitations because of emotional problems, (7) vitality, and (8) general health perceptions. While the RAND Corporation holds the copyright to the original SF-36, it allows it to be used without charge in both clinical and research contexts as long as any publication based on SF-36 data properly attributes the instrument and notes any modifications made by the user. The instrument is available in numerous languages and has an extensive literature establishing its construct validity, and its sensitivity to changes in health status and differing outcomes of different medical treatments and systems of care. The combination of minimal cost, self-rating with low respondent burden, extensive validation, and broad scope make the SF-36 an instrument of choice for the medical psychiatrist. A revised and somewhat improved version of the instrument is available from a private copyright holder and is subject to a licensing fee, even for clinical use.

THE WORLD HEALTH ORGANIZATION HEALTH RELATED QUALITY OF LIFE SCALE—BRIEF VERSION

The World Health Organization Health Related Quality of Life Scale—Brief Version (WHOQOL Group, 1998) consists of 26 items, each a unidirectional 5-point ordinal scale that covers a very broad range of health-related issues covering domains of overall health and quality of life, physical health, psychological health, social relationships, and environment. In contrast to the SF-36, it includes extensive coverage of social and environmental issues related to health and health care. It is available for clinical use without a fee. There are distinctive questions in the WHOQOL-BREF that can open up productive lines of inquiry concerning the patient's social and environmental history, an area of medical-psychiatric relevance that often has a

low priority in evaluations focused on diagnosing and treating acute conditions. Some examples of these questions are:

1. How satisfied are you with the support that you get from your friends?
2. How satisfied are you with the conditions of your living place?
3. To what extent do you have the opportunity for leisure activities?
4. How safe do you feel in your everyday life?
5. Do you have enough money to meet your needs?

COMPREHENSIVE ASSESSMENT INSTRUMENTS FOR POST-ACUTE CARE: THE MINIMUM DATA SET AND THE OUTCOME AND ASSESSMENT INFORMATION SET

Post-acute care, which comprises facility-based care in skilled nursing facilities (SNFs), independent rehabilitation facilities (IRFs), and assisted living facilities (ALFs), as well as formal and informal home health care, is partially reimbursed in the United States by the Medicare and Medicaid systems. With this reimbursement comes regulation, a key component of which is a requirement that the care provider electronically submit standardized clinical assessments as a condition of reimbursement. These standardized assessments are used both for determining reimbursement rates and for measuring the quality of care provided. The standardized assessment for SNFs is called the Minimum Data Set (MDS; see Center for Medicare and Medicaid Services, 2013). The standardized assessment for Medicare-covered skilled home care (as distinguished from home assistance with basic activities of daily living) is the Outcome and Assessment Information Set (OASIS; Center for Medicare and Medicaid Services, 2012). The MDS is of particular interest to medical psychiatrists because its scope includes assessments of mood, cognition, behavior, and pain, along with indicators of the use of psychotropic drugs—particularly antidepressants, antipsychotics, and antianxiety and hypnotic drugs. The neuropsychiatric section of the OASIS is mainly useful for identifying the presence of a mental or behavioral problem and roughly estimating its severity and/or frequency; it provides less support than the MDS for the diagnosis of depression, dementia, or delirium. Both the MDS and the OASIS have their origin in tools for assessing functional dependency and needs for care and supervision, rather than for medical diagnosis; this might explain why some items of natural interest to a psychiatrist are missing. For example, the MDS does not have items dealing with patients' sleep.

An SNF patient's first MDS is based on an assessment that must be completed by day 8 of the SNF stay for patients covered by traditional, fee-for-service Medicare, and by day 14 for all patients regardless of the source of payment. For traditional Medicare patients who remain in the facility less

than 8 days, the facility must submit a combined admission/discharge MDS. For patients with other payers who remain in the facility for less than 14 days, the facility must submit a combined admission/discharge MDS unless the patient had an "unplanned discharge." Patients discharged to the community would always have planned discharges unless the discharge was against medical advice. After the initial MDS, follow-up assessments must be submitted on a specified schedule if the patient remains in the facility. In addition, a significant change in a patient's condition, or the start or end of physical and/or occupational therapy, would be an occasion for a required MDS update. Thus, if a medical psychiatrist is called to consult on a patient in an SNF, there is likely to be an MDS available; and if an outpatient or hospital inpatient has recently been in an SNF, MDS data usually can be obtained, although not necessarily immediately.

The OASIS assessment must be completed for all home care patients—regardless of the payer—within 5 days of the start of care, if the home care agency is to be eligible for Medicare reimbursement for *any* of its patients. Thus, if a patient has received formal home care from a Medicare-certified agency for a least 1 week, there will be OASIS data available from the home care agency that cared for the patient. The only exceptions allowed are pediatric patients, obstetrical patients, and those who are receiving no nursing care but only support with instrumental activities such as housecleaning or shopping.

The medical-psychiatric content of the MDS comprises the following:

1. A cognitive assessment. This is done by interview using the Brief Interview for Mental Status (BIMS). If the patient is unable to complete the BIMS, the nursing staff perform an observation-based rating of the patient's memory and "cognitive skills for daily decision making"—essentially executive function.
2. Screening for delirium using the Confusion Assessment Method (Inouye et al., 1990).
3. Screening for depression using the PHQ-9 or PHQ-9-OV.
4. A single-item assessment of the risk of self-harm.
5. A pain interview; if a patient cannot complete the pain interview, there is a pain rating based on observation of behavioral signs of distress and discomfort.
6. Ratings of the frequency of each of several problem behaviors including wandering, verbal or physical abuse of others, and resistance to care.
7. Binary items concerning the presence of hallucinations or delusions.
8. The number of days in the past week the patient received any drug in each of several classes of psychotropic drug: antidepressant, antipsychotic, antianxiety, and hypnotic.
9. Whether the patient has a history of chronic mental illness or mental retardation; there are specific questions about

depression, bipolar disorder, schizophrenia, anxiety, substance abuse, and post-traumatic stress disorder.

Curiously, the MDS does not include a sleep history apart from the item on the PHQ-9 relating to changes in sleep pattern.

The OASIS provides a much smaller number of neuropsychiatric items, with the effect that it is a relatively nonspecific screen for psychiatric conditions not yet explicitly diagnosed. This is in contrast to the MDS, which actually can be used to make reasonably confident new diagnoses of depression, delirium, or cognitive impairment. OASIS item responses are clinical judgments based on all data available to the clinician, including medical records, interviews of the patient, observations of the patient, communications from other clinicians, and interviews of caregivers. The relevant content comprises the following:

1. A composite rating of level of consciousness, attention, orientation, comprehension, and immediate memory on the day of the evaluation, using a single-item 5-point scale ranging from 0 (intact) to 4 (totally dependent due to delirium, persistent vegetative state, stupor, or coma).
2. A single-item 5-point scale rating the temporal pattern of a patient's confusion over the last 14 days, ranging from 0 (not confused) to 1 (confused in new situations only) to 4 (constantly confused).
3. A single-item 5-point scale rating the frequency with which a patient has felt anxious (or shown signs of anxiety) during the past 14 days.
4. A complex item concerning depression screening. The item asks if the patient has been screened for depression by the agency using a standardized instrument—one that has been validated for use in a community-dwelling home care population—and if so, whether the instrument indicated a need for further evaluation for depression. One option is to complete the PHQ-2, a two-item version of the PHQ-9 with questions about the frequency of low mood and the frequency of loss of pleasure or interest in the last 14 days.
5. A checklist of six behavioral symptoms; items are checked if they occurred at least once in the prior week. The items are memory deficit, impaired decision making, verbal disruption, physical aggression, “disruptive, infantile, or socially inappropriate behavior,” and “delusional, hallucinatory, or paranoid behavior.”
6. A 6-point scale rating the frequency of disruptive or dangerous behavior.

While the medical-psychiatric content of the OASIS is much less rich than that of the MDS, it is still valuable in several ways. It is helpful in setting the context of the first encounter with a patient currently receiving home care. And, when a patient receiving home care has a change in mental, behavioral, or functional status, the scales of the OASIS provide a standardized way for the nursing staff to communicate what has changed.

WHAT'S NEXT: THE PATIENT-REPORTED OUTCOME MEASUREMENT SYSTEM

Over the years since many currently-used questionnaire-based rating scales were developed there have been substantial advances in psychometric theory and technology. The National Institutes of Health (NIH) in 2002 began an initiative to develop new methods for patient-reported healthcare outcome measurement—one that emphasized a rigorous and methodical approach to developing and validating new measures and that took full advantage of computerized adaptive testing. Computerized adaptive testing permits the patient's responses to current questions to determine the choice of future questions. This enables a scale to be simultaneously broader in scope and richer in detail, without compromising efficiency and user-friendliness. All scales developed under the initiative are in the public domain, though private entities are involved in developing related software and in providing fee-based services to users. Extensive information about the Patient-Reported Outcome Measurement System (PROMIS) initiative and the scales developed under it are available from the NIH website www.nihpromis.org.

Areas tested by PROMIS instruments include the following:

Emotional distress: anger, anxiety, and depression

Applied cognition: abilities and general concerns

Psychosocial illness impact: positive and negative

Alcohol: positive effects, negative effects, positive expectancies, and negative expectancies

Fatigue: general and cancer-specific

Pain: behavior, interference, and intensity, general and cancer-specific

Physical function: mobility and upper extremity, general and cancer-specific

Sleep: sleep disturbance and sleep-related impairment

Sexual function: satisfaction, interest, lubrication, vaginal pain, erectile function, orgasm, therapeutic aids, sexual activities, anal discomfort, and interfering factors

Social roles: satisfaction with social roles, ability to participate in them and actual participation in them; satisfaction with discretionary social activities; companionship, instrumental support, informational support, and emotional support; and social isolation

PROMIS is a source of forms for paper-based administration, items for constructing customized scales, and Web-based testing with automated scoring. It remains to be seen when and how the PROMIS resources will replace well-established scales. The familiarity of a scale can trump its psychometric properties, especially if one of the purposes of the scale is communication across specialties and disciplines.

COMBINING RATING SCALES TO ADDRESS PATIENT-SPECIFIC ISSUES: “THE INSTRUMENT PANEL”

Patients seen in medical-psychiatric contexts typically have multiple comorbid conditions—several medical conditions and at least one mental disorder—and are taking multiple medications. When efforts are made to treat one disease, syndrome, or symptom, it is not unusual to make another one worse. If the symptoms that get worse cause more distress or functional impairment than the ones that are relieved, the patient may feel globally worse and may reject the treatment—even if it is effective for its specific indication. Simply asking patients about side effects is not enough, since a treatment-induced problem might not be linked by the patient to that treatment, and because patients often do not complain about negative symptoms such as apathy or loss of function.

Patients in general are concerned about six goals, variably emphasizing one or another:

1. Longevity, including preventing disease and removing threats to life;
2. Relief of pain and other unpleasant symptoms;
3. Avoiding side effects of treatment;
4. Positive well-being, vigor, and ability to enjoy life;
5. Ability to function in physical, social, and occupational realms; and
6. Quality of familial and intimate relationships.

From the patient's viewpoint, the doctor's priority of diagnosing and treating diseases is merely a means to the above ends. And, when one of the six concerns must be traded off against another, different patients will have different preferences. For example, some patients would prefer to die sooner or to suffer cognitive impairment rather than live in severe pain, while others will tolerate great discomfort in order to live a bit longer and to retain their intellectual function.

The medical-psychiatric evaluation should give the psychiatrist a good picture of a patient's goals and their relative importance. Review of the medical history and knowledge of the patient's specific medical conditions and treatments inform the prediction of potential tradeoffs between desirable goals across the course of illness. The psychiatrist can then create an “instrument panel” of rating scales that can be followed from one visit to the next, helping to identify when improvement in one area is associated with decline in another and leads to an overall negative effect from the patient's viewpoint. When this happens, changes in either the psychiatric or general medical treatment strategy may be helpful.

A basic instrument panel might include a measure of the severity of symptoms of the patient's most important medical condition, with a second condition included if there are two of equal importance; a pain rating scale if pain has been a symptom of the general medical illness; a depression rating

scale; another psychiatric rating scale if there is a history of a specific psychiatric illness; a cognitive rating scale; and a broad-scope functional assessment measure such as the SF-36. If the patient's cognitive status and motivation permit the use of self-rated scales, he or she can be given a set of questionnaires to be completed prior to the next visit. The burden on the patient is relatively small, and the benefits are several. The visit is not excessively taken up by closed-ended questions, leaving more time for the patient's agenda and for answering questions. The scope of topics covered is more complete than would be feasible in an interview. Documentation is improved. And, patterns of simultaneous changes can be appreciated that might go unnoticed without seeing change in scale scores side by side.

RATING SCALES AS A TOOL FOR PATIENT EDUCATION AND ALLIANCE-BUILDING

When patients and their caregivers come to understand that mental disorders are well defined, that they have been extensively and rigorously studied, and that recommended therapies are evidence-based, they are more likely to accept the idea of psychiatric treatment and more likely to adhere to treatment once it is started. Prejudice and stigma persist, and while a rating scale may not be as stigmatizing as a blood test or a brain image, its quantitative nature can engage a more objective view by the patient. The Intelligence Quotient, which is a score on a psychometric rating scale, is widely accepted—perhaps excessively so—by the general public as a valid measurement of something real and important. Further, the Internet has widely disseminated quantitative collective consumer ratings of hotels, restaurants, films, and even prescription drugs. In the current social context, the performance of a rating scale and the discussion of the meaning of the items and the scores can enhance the relationship between the patient and the clinician.

USE OF RATING SCALES TO ESTABLISH REMISSION

In medical-psychiatric contexts it is common to encounter patients who have been started on psychotropic drugs—typically SSRI antidepressants or benzodiazepines—by nonpsychiatric physicians and have remained on them for months or even years while continuing to have significant mental symptoms. General medical physicians may not see complete remission of depression as realistic in the context of serious chronic medical illness—but in fact, many patients cope well with illness, maintaining a positive affect and taking pleasure in living. When a patient was not depressed prior to developing a general medical illness, the goal for antidepressant treatment should be remission, not merely relief, unless it becomes clear after serious and persistent treatment—including trials of different antidepressants and psychotherapy—that remission is not a feasible goal. A significantly

elevated score on a depression rating scale or an anxiety rating scale can establish—and effectively communicate to general medical physicians, patients, and caregivers—that psychotropic drug treatment to date has not resolved the problem and that the diagnosis, drug, and/or dosage need to be revisited. In this connection it is very helpful for all physicians practicing in a particular setting to be familiar with at least one common depression rating scale such as the PHQ-9 or the BDI.

CLINICAL PEARLS

- Rating scales and screening tests should be a routine part of the practice of medical psychiatry.
- Questionnaire-based tests—whether completed by the patient or by caregivers or other informants—are the most efficient way to quantify symptoms and to expand the scope of medical-psychiatric evaluation without increasing the length of clinical encounters.
- Impairment of cognition, metacognition, or self-awareness can reduce the validity of self-rated scales. Relationship issues—or neuropsychiatric issues in the informant—can reduce the validity of scales rated by a caregiver or other informant.
- Discrepancies between symptom ratings by the patient, the caregiver, and the clinician are valuable diagnostic data; the clinician should analyze them.
- Clinicians should select for routine use a set of rating scales that are well suited to the patient populations they usually see.
- Specialized scales for medical-psychiatric problems such as kinesiophobia or sleep apnea work better than generic rating scales developed primarily for patients with primary mental disorders without general medical comorbidity.
- The choice of a cognitive screening test should be patient-specific and selected to avoid floor and ceiling effects; the appropriate cut point for abnormality will vary according to the patient's educational level and premorbid functioning.
- For patients with multiple conditions and/or adverse effects of medications, the use of a multiscale “instrument panel” can help both the clinician and the patient to understand tradeoffs between the benefits and adverse effects of treatment, and to appreciate how psychiatric and general medical issues interact to affect function and well-being.
- Scores on widely known rating scales such as the Numerical Rating Scale for pain or the MMSE can be used to efficiently and effectively communicate the presence and severity of symptoms and syndromes across disciplinary lines.

- When rating scales are used as screening tests there is always a tradeoff between sensitivity and specificity. Criteria for identifying cases should be set according to the clinical purpose of the test, and results should not be over-interpreted. The C-SSRS with a low cut point can identify patients who definitely *do not* need intensive suicide precautions; those just above the threshold aren't necessarily at high risk, they just need further clinical assessment. Similarly, the MMSE with a cut point of 24 can identify patients who are cognitively impaired and definitely need further assessment for the cause, but it does not rule out cognitive impairment in patients with higher scores.
- A two-stage approach to screening can reconcile issues of sensitivity and specificity. One cut point is used to identify definite cases, and another one is used to definitely rule out the diagnosis. Patients with scores between the two cut points are assessed with a second method that has the power to discriminate cases from non-cases among patients with such intermediate scores. The use of night-time monitoring of PaO₂ in patients with intermediate scores on the four-question test for obstructive sleep apnea is an excellent example of this approach.

LABORATORY TESTS

Kimberly Stoner

INTRODUCTION

Nearly a century ago, William J. Mayo wrote in *Surgery, Gynecology, and Obstetrics*, “I have been surprised to note the readiness with which high-grade young men, graduates from medical institutions which are models of our time, yield to the temptation of machine-made diagnoses.” (Huth & Murray, 2000, p. 354). If Dr. Mayo was concerned about overreliance on technology in 1923, one can only imagine what he would think of medical practice today. Countless biomarkers of disease states have been discovered and are measured in laboratories daily. MRI centers have appeared in shopping malls and billboards encouraging drivers to come in for a variety of screening CT scans. Computer-savvy people search websites in an effort to find a diagnosis that explains their symptoms, albeit with a reported average success rate of only 22.1% (Siempas et al., 2008). “Machine-made diagnoses” are abundant.

Despite the increased availability, laboratory testing is not a substitute for a thorough patient history and physical exam for clinicians to diagnose and manage patients (Hampton, et al., 1975). Decades later this sentiment persists. While laboratory testing is important, reviewing the history thoroughly and conducting a clinical interview remain the “cornerstones” (Hendren & He, 2006) in the diagnosis and treatment of psychiatric conditions. Symptoms elicited during the history and physical exam findings allow clinicians to generate a differential diagnosis, with laboratory tests and imaging studies then confirming or refuting their hypotheses. Several factors have led to the shift away from widespread use of screening comprehensive metabolic profiles, toward more hypothesis-driven, selective testing. Skyrocketing healthcare costs have led some insurers to stop reimbursing for laboratory tests drawn without clear indication (Staver, 1979). Concerns have been raised about the risks of radiation exposure for patients who undergo repeated imaging studies (Hendrick, 2010). Research has led to the revision of clinical practice guidelines, upon the determination that not all patients will benefit from screening. In addition to the lack of survival benefit for certain age groups or the lack of cost-effectiveness of screening in low-risk populations, there is increasing recognition of potential harm to patients with false-positive test results (Salz, Richman, & Brewer, 2010).

While an increased emphasis on evidence-based medical practice and cost-containment measures have led to

more judicious use, patients continue to undergo many laboratory tests annually. It is critically important for psychiatrists who provide consultative or collaborative care to medical patients to be cognizant of the indications for laboratory testing and to be competent in the interpretation of test results. There are many clinically sound reasons for psychiatrists to order laboratory tests in medically ill patients. Diagnostic criteria for many psychiatric diseases require that general medical conditions be excluded as the primary cause of patients’ symptoms. Certain psychiatric populations are at higher risk for having lab abnormalities including geriatric patients, patients with alcohol dependence, and eating disorder patients. Some psychiatric medications may lead to lab abnormalities (see chapter 23, *Medically Significant Side Effects of Psychotropic Drugs*, to review these medications) or require monitoring for toxicities. Laboratory testing may help psychiatrists detect when patients with addiction have relapsed, or if patients have not been compliant with taking prescribed medications. This chapter reviews general principles of laboratory testing and identifies laboratory tests that may be part of an appropriate evaluation for patients presenting with some psychiatric syndromes.

PRINCIPLES OF LABORATORY MEDICINE

“NORMAL” VALUES AND THEIR SIGNIFICANCE

Laboratory test results are considered “abnormal” when they fall outside of the reference range employed by the laboratory performing the test. Normal values are usually established by determining the average value and including two standard deviations above and below the mean (Edwards & Baird, 2005). This statistical approach will identify 95% of test results as being “normal” with the 2.5% of highest values and 2.5% of lowest values deemed “abnormal.” However, statistical significance does not always portend clinical significance. The distinction between disease and health is seldom a well-demarcated line lying two standard deviations from the mean. A hypoglycemic patient with a blood glucose of 69 mg/dl may experience fewer symptoms of hypoglycemia than a poorly controlled diabetic patient with a “normal” glucose of 70 mg/dl. Similarly, a statistically insignificant lab test

result that falls within the reference range may still be clinically important. Patients who have a baseline creatinine of 0.6 mg/dl have acute kidney injury warranting intervention when their creatinine rises to a level of 1.2 mg/dl, but both of these values may fall within the normal reference range. Reference ranges themselves may vary in different patient populations. Most reference ranges are established by sampling healthy 20–40-year-olds (Edwards & Baird, 2005) and may not represent the true normal range for patients of different ages, gender, or ethnicity. Furthermore, what is statistically normal may not be physiologically normal. If there is a high prevalence of iron deficiency in a population, the reference range for mean corpuscular volume (MCV) in asymptomatic patients may be low relative to that in a typical Western population in which iron deficiency is less common.

PATIENT SAFETY AND SOURCES OF LABORATORY ERROR

Sometimes abnormal lab values are statistically and clinically significant but go unnoticed by providers. By convention, abnormal values are usually highlighted in some manner when documented. Despite efforts to flag abnormal lab results, it has been reported that physicians do not always note or respond appropriately to important laboratory findings (Nykanen et al., 1993). This may be due to an increasing amount of laboratory data generated by more efficient methodology and computer automation, without a corresponding increase in medical professionals' abilities to sort through a barrage of test results (Mayer et al., 1998). Abnormal laboratory results fail to elicit an appropriate clinical response in up to 30% of cases (Altshuler, 1994). Some laboratories have instituted reporting policies mandating that extremely abnormal values must be communicated directly to a care provider to decrease the risk of their being overlooked. However, the manner in which abnormal lab results are flagged continues to be potentially problematic. A value that is 20 units outside of the normal range may be highlighted no differently than a value that is 1 unit outside of the normal range. For tests such as gamma-glutamyl-transferase (GGT), an abnormally low value has no clinical significance, but the results are flagged in the same manner as an abnormally high value. By chance alone, 5% of laboratory test results will be abnormal, implying that a physician with a large patient panel who orders many tests will be overwhelmed with abnormal test flags. Many laboratories have responded to the problem with protocols for directly notifying physicians of abnormal test results that may imply serious short-term medical consequences, such as a potassium level >6 mEq/mL.

Laboratory errors are responsible wholly or in part for a significant proportion of diagnostic errors in medicine (Grabner, 2005). Laboratory errors can be divided into pre-analytical, analytical and postanalytical errors. Preanalytical errors occur prior to the sample being analyzed and include the timing of the phlebotomy, improper filling of the specimen tube, patient hydration status, duration of tourniquet application, and elapsed time before analysis of the specimen (Ritchie, Ledue, & Craig, 2007). Studies suggest most errors

occur in the preanalytical phase (Bonini, Plebani, Ceriotti, & Rubboli, 2002). Errors can also occur during specimen analysis, if reagents are degraded or a machine is improperly calibrated. Postanalytical errors occur after specimen analysis, such as the test result being entered with a missing decimal point or into a different patient's chart. These preanalytic, analytic, and postanalytic sources of error have been the focus of attention for personnel working in clinical labs. "Pre-pre" and "post-post" analytical errors have also been described (Laposata & Dighe, 2007) and are of concern to the ordering physician. "Pre-pre" analytical errors occur when a physician decides to order the wrong test for the clinical question at hand. "Post-post" analytical errors occur when the accurate test results are misinterpreted.

One reason patients see medical psychiatrists is that they have physical symptoms and a "negative work-up" for "organic causes." Sometimes the psychiatrist must function as an advocate to reopen consideration of a missed medical diagnosis. When the "normal" lab test results do not fit with the history, it is time to reconsider whether there is laboratory error using the framework above to distinguish different types of potential errors. One particularly common error of interpretation is to regard a single normal test result as ruling out a disease that tends to fluctuate—where lab values sometimes are normal and sometimes are not. This is the case, for example, in prediabetes or early type 2 diabetes, where the fasting plasma glucose may be normal but the postprandial glucose is not. In Hashimoto's thyroiditis, there may be euthyroid periods alternating with periods of clinical hypothyroidism (see chapter 6 on endocrine testing).

BIOSTATISTICAL TERMS USED IN EVALUATING DIAGNOSTIC TESTS

Characterization of test performance is helpful in interpreting test results. Standard terminology has evolved to describe the performance of tests utilized to make a yes/no decision about the presence of a disease or condition. This terminology is applicable to laboratory tests, physiological tests, imaging procedures, and psychological tests. Table 5.1 offers definitions of terms frequently used to describe the properties of diagnostic tests.

All test characteristics are a function of both the test and the clinical context in which it is applied. When the test involves converting a continuous quantity into a binary decision, the cut point for diagnosis may also affect test characteristics. Sensitivity and specificity are the best known test characteristics. 100% sensitivity means that every patient in the population examined who tests negative will not have the disease. 100% specificity means that every patient in the population examined who tests positive will have the disease. Typically, a test will approach 100% sensitivity only by sacrificing specificity, and conversely. For this reason a single laboratory test seldom suffices to make a definitive diagnosis. Likelihood ratios are an extension of the sensitivity and specificity concepts that specifically concern how test results modify diagnostic impressions formed without them (Lawrence & Gyorkos, 1996). By definition, likelihood ratios describe how

Table 5.1 TERMINOLOGY USED IN THE EVALUATION OF DIAGNOSTIC TESTS

TERM	DEFINITION
Clinical significance	Test results that are important enough to alter the management plan for a patient
False negative	Patients with disease who have a normal or negative test.
False positive	Patients without disease who have an abnormal or positive test.
Likelihood ratio of a negative test (LR−)	Calculated as $(1 - \text{sensitivity}) / \text{specificity}$ or false negative rate divided by true negative rate. The amount by which the pretest probability of disease is reduced in patients with a negative test.
Likelihood ratio of a positive test (LR+)	Calculated as $\text{sensitivity} / (1 - \text{specificity})$ or true positive rate divided by false positive rate. The amount by which the pretest probability is increased in patients with a positive test.
Mean	Mathematical average of a sample of test results.
Negative predictive value (NPV)	The proportion of people with a negative test result who do not have the disease.
Positive predictive value (PPV)	The proportion of people with a positive test result who have the disease.
Pretest probability	The probability of disease before a test is run which is equal to the prevalence of the disease.
Prevalence	Proportion of persons who have the disease at a specified time.
Receiver operator characteristic (ROC)	Curve generated by plotting sensitivity on the y axis vs. $1 - \text{specificity}$ (false positive rate) on the x axis to demonstrate a progressive trade off between sensitivity and specificity as a function of the decision level distinguishing disease and health.
Reference ranges or intervals	Values that are considered “normal” for a laboratory test, generally two standard deviations around the mean. 95% of values will fall within this interval.
Sensitivity	The proportion of people with the disease who test positive.
Specificity	The proportion of people without the disease who test negative.

much a positive test result increases or negative test result decreases the risk relative to the estimated risk prior to the test being done. A likelihood ratio value of 1 implies that a test is useless in improving the distinction of diseased patients from healthy ones (Mayer, et al., 1998). Tests with high likelihood ratios significantly improve diagnostic accuracy. When there is a low baseline suspicion of disease in a particular patient, a test must have a very high likelihood ratio to be the basis of a confident diagnosis. For example, if a patient’s baseline risk of

having HIV infection is less than 1%, the likelihood ratio for an HIV screening test would have to exceed 100 for it to be the basis of even a tentative diagnosis.

Receiver operating characteristic (ROC) curves provide a graphical illustration of the balance between sensitivity and specificity. ROC curves provide information on test performance at all cut points for determining abnormality (Obuchowski, Lieber, & Wians, 2004). A diagonal line with a slope of 1 going through the origin of the graph would be the ROC of a test result that had no value in discriminating disease—in other words, one where sensitivity can only be gained by sacrificing specificity to an equal extent. The area under the ROC curve is referred to as either the “area under the curve” (AUC) or as the “receiver operating characteristic” (ROC), and it represents the overall value of a test in distinguishing the presence or absence of a disease or condition. The AUC of the diagonal line representing a worthless test is 0.5; the AUC of a perfect test would be 1.0 (Klee, 2004; Mayer et al., 1998). Tests with AUC values of less than 0.7 are rarely useful in clinical contexts; those with values between 0.7–0.9 represent tests that may be useful in specialized contexts, and those with values >0.9 are candidates for more general clinical use (Wians, 2009). While generally tests with a higher ROC are better, other considerations are also relevant in selecting tests. The prevalence of the disease in the population to be tested, the cost of the test, and relative consequences of false-positive and false-negative test results can sometimes argue for the choice of a test with a lower ROC as the initial test for a disease in a specific clinical setting (Boyd, 1997).

DETERMINING WHICH LAB TESTS ARE INDICATED

Medical psychiatrists may be called upon to review laboratory tests already done or to suggest tests not yet done. The former case is typical when many physicians have already seen a patient for medically unexplained symptoms, or when a patient is emotionally distressed and disappointed with the care (McGorm et al., 2010). The latter case is typical when medical psychiatrists want to initiate a treatment with medical contraindications or precautions, or when they are encountering a patient with a psychiatric syndrome from a demographic group likely to have unrecognized or untreated medical comorbidity.

The increased morbidity and mortality of psychiatric patients compared to the general population was first described a century ago (Bonhoeffer, 1912) and it still persists (Green et al., 2003) despite advances in medical care. Some excess medical morbidity may be attributable to the difficulty that mentally ill persons have with access to care or with adherence to recommended medical treatment. Side effects of commonly prescribed psychotropic drugs—especially atypical antipsychotic drugs—also contribute. Nearly a quarter of psychiatric outpatients do not have a regular source of general medical care (Tanielian et al., 1999). Even after a patient has entered a general medical care setting, the stigma of mental illness may interfere with receiving

optimal care (Kim et al., 2007; Kuey, 2008). Even clinicians free from any biases against people with mental illness may find it difficult to do a comprehensive history and examination on a patient with cognitive impairment, agitation, or paranoid ideation. In a study of 102 psychiatric inpatients transferred to an acute medical ward, only 23% could communicate the nature of their illness or location of their pain, and 78% of the medical diagnoses that were ultimately made were unrelated to the patient's description of the problem (Bunce et al., 1982). It is important that medical psychiatrists review the medical evaluations of their patients and do not assume that all appropriate laboratory tests have already been ordered by other providers, or that the results have been correctly interpreted in context. One reason is that patients with serious mental illness often have undiagnosed or inadequately treated general medical conditions. The second reason is that patients—particularly those with primary mental disorders, personality problems, or tendencies toward symptom amplification and dramatic self-expression—may be perceived by nonpsychiatric physicians as having medically unexplained symptoms on the basis of false-negative laboratory tests. The false negatives may be due to any of the error types described above. Probably the most frequent false negatives in this context are conclusions based on tests insufficient to rule out the most likely medical diagnosis, or application of criteria for abnormal results that are inappropriate for the patient's demographics and/or clinical context. The first step in the process that leads to an interpretation of laboratory data is deciding which, if any, laboratory tests should be obtained on a particular patient. While clinicians are advised to “order the test for patients in whom it is indicated, not order it when it is not indicated, and interpret the test results appropriately in light of other clinical factors” (Jackson, 2007, p. 733), how to do this is not always obvious or simple in specific clinical situations. Ironically, studies aiming to determine the prevalence of inappropriate laboratory test utilization may use methodologically unsound criteria for “inappropriateness” (van Walraven & Naylor, 1998). Studies investigating the prevalence of lab abnormalities and the rates of significant undetected medical illness in patients with psychiatric conditions have yielded divergent results. While one reason is the wide variability in the demographics and settings in which psychiatric patients are seen, another is the variability in the choice of tests used to detect or to confirm particular medical conditions. Determining which laboratory tests to request may prove more difficult than interpreting their results.

THE PREVALENCE OF MEDICAL DISEASE IN PATIENTS WITH PSYCHIATRIC SYMPTOMS

As just noted, the prevalence of previously unrecognized medical illness in patients presenting to psychiatrists with mental and behavioral symptoms varies enormously between studies, and it depends upon whether the question concerns the presence of any undiagnosed medical illness or an undiagnosed medical illness *responsible for the*

psychiatric symptoms. Thirty-six years ago, a study of 636 psychiatric patients using the diagnostic methodology current at the time failed to find a single case in which an undetected medical illness was responsible for the patient's psychiatric symptoms (Willett & King, 1977). A recent review of 1340 psychiatric admissions in the Veterans Affairs system found that medical disease was responsible for causing the psychiatric symptoms in only 2.8% of cases (Reeves et al., 2010). In contrast, 63% of patients presenting to an emergency department with new psychiatric symptoms were found to have an organic condition responsible for them (Henneman, Mendoza, & Lewis, 1994). The prevalence of undiagnosed medical disease causing psychiatric symptoms has been reported to be 46% in state psychiatric hospital inpatients (Hall et al., 1981) and 16%–17% in outpatients at community health centers (Bartch et al., 1990; Koran et al., 1989). A 1992 review of 21 studies including different psychiatric populations concluded that about half of patients had significant medical disease, and the disease likely contributed to the psychiatric symptoms in over a quarter of them (Koranyi and Potoczny, 1992).

The literature thus provides estimates ranging from zero to 63% for “organic” etiology of mental and behavioral symptoms in clinical populations evaluated by psychiatrists. This extraordinarily wide range of estimates can be accounted for by several factors: (1) differences in the demographics of the samples and the prevalence of general medical conditions in the sampled populations; (2) differences in the presenting symptoms and syndromes—obviously, an acute change in mental status is more likely to have a general medical cause than a stable chronic psychosis; (3) differences in the patients' access to and utilization of general medical care; (4) sensitivity and scope of the medical evaluations performed; and (5) whether the estimate includes only medical conditions that are the primary or sole cause of the psychiatric problem, or also includes medical conditions responsible for aggravating the psychiatric problem or triggering a relapse of a previously stable mental disorder.

For the same reasons, it is difficult to prescribe a single universal standardized evidence-based medical evaluation of a patient presenting to a psychiatrist with mental and/or behavioral symptoms (Zun, 2005). However, standardized approaches to general medical evaluation of psychiatric patients can be created for specific clinical populations in specific treatment settings.

A RATIONAL APPROACH TO LABORATORY TEST SELECTION

The prevalence of the condition is a critically important factor in determining whether or not laboratory testing for the condition should be performed. Prevalence is the foundation of the concept of “testing threshold,” which is defined as the probability of disease above which physicians should test before initiating treatment for that disease, and below which physicians should neither treat nor test (Mayer, 2004). J. E. Hardison wrote in *The New England Journal of Medicine* in 1979, “The less the indication there is for a test, the more

likely a positive result is falsely positive” (cited in Huth & Murray, 2000, p. 354). The positive predictive value of a laboratory test increases considerably as the prevalence of the disease increases. (Wians, 2009).

Laboratory test results influence up to 70% of medical decision making (Forsman, 1996); and because they may be perceived as more objective than a history and examination, such tests can carry disproportionate weight in clinicians’ minds. Laboratory tests should be chosen thoughtfully, because tests can be harmful: false positives can lead to unnecessary and sometimes injurious treatments and procedures; false negatives can lead to delays in diagnosis and treatment; and waiting for irrelevant test results can delay the initiation of treatment.

The first question to ask in deciding whether or not to order a test is, *How likely is this test to be truly abnormal—a true positive—in this patient?* Factors that have been reported to increase the likelihood that a psychiatric symptom is attributable to a medical illness include lack of prior psychiatric history, very rapid onset, onset before age 12 or after age 40 years, disorientation, depressed level of consciousness, abnormal vital signs, focal neurologic deficits, and the presence of visual or tactile hallucinations (Reeves et al., 2000).

Of course, if the diagnosis is obvious and the test result is expected to be positive, the test might not be necessary.

Kamp and Rosse concluded in 1990 after reviewing over 2000 test results on a group of psychiatric inpatients that admission testing was not justified because the abnormal test results were “predictable.” A test with a result expected to be abnormal would be appropriate if it was useful in quantifying the severity of the disease or condition, and such quantification would be useful in planning treatment and/or following the outcome of treatment. Another situation in which a “predictably abnormal” test would be warranted is when the clinical diagnosis, though highly likely, could be wrong, the test in question would help rule out a diagnostic error, and the consequences of a wrong diagnosis would be costly, dangerous, and/or irreversible.

The second question to ask when deciding whether or not to order a laboratory test is, *How will the test result change the treatment plan for the patient?* If an intoxicated-appearing patient reports that he has been consuming vodka, it is not necessary to measure a blood alcohol level to diagnose alcohol intoxication. If the episode of intoxication represents a relapse in a patient known to be alcohol dependent, the blood alcohol level is unlikely to change the treatment plan. However, if the patient is new to the healthcare system, finding a blood alcohol level of 300 mg/dl in a patient who was awake and ambulatory would clinch a new diagnosis of alcohol dependence and thus be quite valuable in planning the next steps in treatment.

The third question to ask when deciding whether or not to order a laboratory test is, *When will the test results be available?* The required turnaround time for results should be considered when determining whether or not to order a test, because it impacts the clinical utility (Pannall et al., 1996). For example, ordering a carbohydrate deficient transferrin (CDT) to help confirm a diagnosis of alcohol dependence

in a recently admitted inpatient may not be rational if the report would take 10 days to arrive and the patient, if alcohol dependent, would start exhibiting symptoms of alcohol withdrawal on the second hospital day. When a test will be used to inform a decision on the treatment of a chronic disease, the turnaround time is less important.

LABORATORY TESTS USED IN THE EVALUATION OF PSYCHIATRIC SYMPTOMS AND THEIR INTERPRETATION

LABORATORY TESTS

There are over 3,000 laboratory tests currently available, and only a small fraction of them are described in the following section. For additional strategies on selecting and interpreting laboratory tests or for information on lab tests not covered in this chapter, a free website for physicians can be found at <http://www.arupconsult.com>. Following is a selection of commonly conducted laboratory tests, in alphabetical order, with guidelines for interpretation of particular relevance to medical psychiatrists.

Alanine aminotransferase (ALT) is found primarily in hepatocytes, but is also found in lower concentrations in cardiac and skeletal muscle. Elevated ALT may signify hepatitis, but inflammation or damage in other tissues may also cause ALT elevation. Clinicians monitoring ALT in patients taking potentially hepatotoxic drugs generally do not consider an ALT elevation clinically significant until it is at least 3 times above the upper limit of normal, with some physicians classifying an ALT elevation of up to 5 times the upper limit of normal as “mild” (Musana, Yale, & Abdulkarim, 2004). Low ALT values may signify starvation, but often patients with low ALT are asymptomatic. The take-home is that you don’t necessarily diagnose hepatitis or drug-induced hepatotoxicity if the ALT is 2–3x normal—you do monitor, and you may get consultation.

Albumin is synthesized in the liver and usually accounts for the majority of protein in the blood. Abnormal albumin levels are usually of clinical concern, since the action of many medications, hormones, and calcium levels are affected by protein binding. Low levels are associated with increased mortality. (Fried et al., 1998). Elevated albumin levels are generally due to volume depletion. Low albumin levels may be related to poor nutritional intake, impaired production in patients with cirrhosis, chronic inflammation or loss of albumin into the urine in nephrotic syndrome. **Prealbumin** has a shorter half life than albumin, making low levels a more sensitive marker of acute nutritional compromise (Beck and Rosenthal, 2002). Serum levels decline in protein malnutrition states such as malignancy or cirrhosis and with zinc deficiency. Production decreases after 14 days of consuming a diet that provides only 60% of required proteins (Le Moullac, Gouache, & Bleiberg-Daniel, 1992). Prealbumin has been used to assess nutrition in elderly patients admitted to the hospital. (Nutritional Care Consensus Group, 1995) While

alcoholics may have elevated levels of prealbumin after binge drinking, an assessment of nutrition by prealbumin level may be assessed after one week (Staley, 1984).

Alkaline phosphatase is found in liver, intestines, and bones, and elevated levels may occur in liver or gallbladder disease, healing fractures, or cancers involving bone. Laboratories can fractionate alkaline phosphatase in order to determine if the elevation is from a gastrointestinal source or bone. Low alkaline phosphatase levels are generally not of direct clinical concern but can occur in vitamin B12 deficiency, vitamin D intoxication, hypothyroidism, or hypophosphatemia (Chernecky & Berger, 2008).

Ammonia is a waste product of nitrogen breakdown in protein metabolism. Elevated levels are most often seen in patients with cirrhosis, but can also occur in patients on valproic acid or those who are consuming high-protein diets. Elevated ammonia has been associated with hepatic encephalopathy, but there is poor correlation between the level of ammonia and the degree of confusion in patients. This is perhaps because the concentration of ammonia in the brain may correlate poorly with the concentration of ammonia in the blood (Butterworth, 2002). Ammonia levels will be increased if the specimen is not on ice or there is a delay in processing the specimen (Chernecky & Berger, 2008). Low ammonia levels are generally not of clinical concern.

Amylase is found in the pancreas and salivary glands, so inflammation in either tissue can cause an elevated level. Laboratories can fractionate amylase to determine if it is from a pancreatic or salivary source, which may be useful in diagnosing—and in confronting denial in—eating disorder patients with frequent self-induced vomiting. (Please see chapter 32 for more information on eating disorders.) Low amylase levels are not clinically significant. Amylase is renally cleared, so levels can be falsely elevated in patients with renal failure (Chernecky & Berger, 2008).

Antinuclear antibodies (ANA) are produced by the immune system against one's own DNA in autoimmune diseases such as systemic lupus erythematosus, but can also occur with certain medications such as carbamazepine. The cut-off for distinguishing normal from abnormal is usually 1:20 dilution. Higher titers such as 1:320 are indicative of a more strongly positive test. Steroids and other immunosuppressive agents may cause false-negative results. The likelihood of having a positive ANA increases with age, and nearly a quarter of women over age 65 years will test positive in the absence of disease (Goroll & Mulley, 2009). One third of healthy first-degree relatives of lupus patients have a positive ANA (Chernecky & Berger, 2008). However, a high-titer ANA may be a clue to the physician that an autoimmune disease might develop, and the patient should be followed. A negative ANA in a patient without a clear pattern of symptoms of connective tissue disease argues against the diagnosis. In patients with systemic lupus erythematosus (SLE), 93% have a positive ANA; since ANA is nonspecific, antibody to double-stranded DNA would clarify the diagnosis (Reichlin, 2013). ANA is typically present many years before the diagnosis of SLE. In one sample of patients with SLE, 78% had a positive ANA at a dilution of 1:120 or more 2 years before symptoms and 9 years

before diagnosis (Arbuckle, 2003). Chapter 61 discusses rheumatic diseases.

Arterial blood gases (ABGs) measure oxygen and carbon dioxide content in arterial blood, as well as measuring pH. Carbon dioxide levels can be increased in patients with lung disease; they are decreased with hyperventilation. Hypercarbia has been associated with induction of panic symptoms, but either high carbon dioxide or low oxygen content can produce anxiety. The partial pressure of arterial oxygen (PaO_2) decreases with age and in lung conditions including pulmonary embolus and pneumonia. Oxygen and pH results will be lower if the specimen is not placed on ice and processed promptly (Chernecky & Berger, 2008). The patient's temperature must be recorded when the ABG is drawn, since fever raises the oxygen content. ABGs should be considered in patients with episodic dyspnea suggesting panic attacks when there is something atypical about the presentation. The patient who hyperventilates because of a panic attack will have a low PaCO_2 and a high PaO_2 ; the patient with recurrent pulmonary emboli will have a low PaCO_2 and a low PaO_2 . Estimating the PaO_2 by measuring oxygen saturation with a pulse oximeter is a noninvasive aid to diagnosis in situations where obtaining an arterial blood sample is not feasible. However, it will not offer information about low carbon dioxide or dangerous hypercarbia in chronic lung disease. Chapter 54 discusses pulmonary diseases.

Aspartate aminotransferase (AST) is found in liver as well as cardiac and skeletal muscle. Elevated levels may indicate hepatitis, but they can also signify a myocardial infarction or rhabdomyolysis. Alcoholic hepatitis is classically taught to cause elevations in both AST and ALT, with an AST to ALT ratio greater than 2 to 1. This pattern of enzyme elevation implies liver disease and is not present in heavy drinkers without liver damage (Nyblom et al., 2004). Low AST levels are not usually of clinical concern but are sometimes found in patients with cirrhosis. AST levels can be falsely decreased in patients with elevated blood urea nitrogen levels (Chernecky & Berger, 2008).

Bicarbonate regulates the pH of body fluids. Levels increase in patients with lung disease who have chronic retention of carbon dioxide. Levels fall in eating disorder patients with vomiting, or with abuse of laxatives and/or diuretics.

Bilirubin is the product of hemoglobin breakdown during red blood cell degradation in the spleen. The indirect bilirubin is then sent to the liver where it is conjugated to form direct bilirubin. Blood tests measure total and direct bilirubin levels, and indirect bilirubin is calculated by their difference. Direct bilirubin increases in biliary obstruction, while indirect bilirubin is increased in hemolytic anemias. The bilirubin must be significantly elevated before a jaundiced appearance becomes obvious. Scleral icterus is associated with bilirubin at 3 or above.

Blood alcohol level or blood toxicology screens (unlike urine toxicology screens) indicate a specific level of the substance such as alcohol, acetaminophen, or aspirin, rather than just the absence or presence of the substance or its metabolites (McPherson & Pincus, 2006). Knowing the blood level can be clinically important for the management of patients who

have overdosed. Also, unusually high levels of alcohol or a sedative-hypnotic drug in a patient who is awake imply pharmacologic tolerance, a useful fact in confirming a suspected diagnosis of substance dependence as opposed to episodic substance abuse.

Blood urea nitrogen (BUN) measures the concentration of urea nitrogen from the breakdown of protein in the blood. It is produced by the liver and eliminated by the kidneys. Increased levels (known as azotemia) may cause confusion, agitation or coma. Levels increase with renal insufficiency, volume depletion and upper gastrointestinal bleeding. Low BUN values typically occur in a setting of decreased muscle mass, protein-calorie malnutrition or volume overload.

Calcium is stored in bone and is involved in muscle contraction and nerve conduction. High levels of calcium are seen in volume depletion, vitamin D toxicity, hyperparathyroidism, cancer, immobilization, and fractures. Hypercalcemia can cause altered mental status; typically, mild to moderate hypercalcemia causes fatigue or depression while moderate to severe hypercalcemia is associated with cognitive impairment, delirium, and, at the highest levels, stupor or coma. Abnormally low levels of calcium occur in vitamin D deficiency, hypoparathyroidism, and with high pH (Haist & Robbins, 1997). Calcium is largely protein-bound in the blood. To correct the total calcium because of an abnormal albumin level, subtract 0.8 mg/dL from the total calcium for every 1.0 g/dL by which the serum albumin concentration is >4 g/dL. Conversely, when albumin levels are low, total calcium can be corrected by adding 0.8 mg/dL for every 1.0 g/dL by which the albumin is <4 g/dL. For a direct measure of calcium in the setting of high or low albumin, an **ionized calcium level** is the preferred test.

Carbohydrate deficient transferrin (CDT) is used to detect alcohol abuse, although in some institutions results may take 1–2 weeks to obtain, limiting its usefulness. CDT is best reported as percentage of transferrin. It has moderate sensitivity and specificity as a longer-term marker of heavy ethanol use (Ingall, 2012; Center for Substance Abuse Treatment, 2006). An elevated CDT level is best used in combination with other markers of alcohol abuse (Neumann & Spies, 2003). The specificity of the test is decreased in patients with liver disease, and false negatives may occur in patients with iron overload (Chernecky & Berger, 2008). It is especially useful as a marker of abstinence because it returns to baseline levels 2–5 weeks after ethanol cessation. Declining CDT values support abstinence (Ingall, 2012).

Carboxyhemoglobin forms in the blood when carbon monoxide binds to hemoglobin. Carbon monoxide (CO) binds to hemoglobin more strongly than oxygen. Carboxyhemoglobin levels are above 3% in nonsmokers, and levels of 10% in smokers are normal. Carbon monoxide poisoning leads to elevated carboxyhemoglobin levels with acute symptoms of headache, dizziness, fatigue, flu-like malaise, blurred vision, nausea, and vomiting. If the exposure is more severe, confusion, syncope, seizures, and stroke-like syndromes can be seen. When CO poisoning is suspected due to faulty furnaces, poor ventilation of flame-based heating sources, or exposure to internal combustion engine exhaust,

a carboxyhemoglobin level should be obtained immediately, performed by spectrophotometric CO oximetry. Pulse oximetry is unreliable to assess oxygenation, as most pulse oximeters cannot distinguish oxyhemoglobin and COHb (Guzman, 2012).

Ceruloplasmin is a protein involved in the transport of copper and iron. It is most often ordered to assess for Wilson's disease, which is distinguished by low ceruloplasmin levels and high urine copper levels (Czaja et al., 1987). Malabsorption, as in patients with celiac disease, can also cause low ceruloplasmin levels. The majority (85%–90%) of patients with Wilson disease have <20 mg/dL; however, in Wilson's disease, ceruloplasmin is sometimes normal or elevated. Low ceruloplasmin is also seen in liver disease (Cauza, Maier-Dobersberger, & Polli, 1997) or conditions of kidney or intestinal protein loss. Ceruloplasmin is an acute-phase reactant, and its synthesis is stimulated by estrogens (Brewer, 1992). Diseases associated with high ceruloplasmin levels are too numerous for the test to be specific enough to be of clinical value. In patients with neurological symptoms suggestive of Wilson's disease, low serum ceruloplasmin, bolstered by Kayser-Fleisher rings by slit lamp eye exam, and elevated urinary copper excretion suggest the diagnosis.

C peptide is formed in the pancreas when proinsulin is converted to insulin. Decreased levels are seen in type 1 diabetics. The test is most often performed for the evaluation of factitious hypoglycemia by surreptitious insulin injection. Patients who are hypoglycemic because of self-administration of insulin (factitious hypoglycemia) will have high serum insulin levels and undetectable C peptide (Threatte & Henry, 1996).

Creatine phosphokinase (CK or CPK) is found in cardiac and skeletal muscle and in the brain. Laboratories can measure myocardial and skeletal muscle CK, specifically helping to distinguish acute myocardial infarction from rhabdomyolysis; measurement of brain CK is not clinically relevant. Significant elevations of skeletal muscle CK imply skeletal muscle breakdown that is of clinical concern because of the renal toxicity of the myoglobin that is released at the same time as the CK (Sauret, Marnides, & Wang, 2002). Situations associated with such elevations of skeletal muscle CK include alcohol abuse, extreme exertion, immobility (e.g., due to stroke) with pressure injury to muscles, and the neuroleptic malignant syndrome or malignant catatonia. Low CK levels are seen in patients with reduced muscle mass and do not provide information of incremental diagnostic value. Elevations of CK occur after an intramuscular injection is administered.

Creatinine is produced in muscle and renally excreted. Elevated values are indicative of kidney failure. Values may be 20%–40% higher when drawn in the late afternoon (Chernecky & Berger, 2008). Low creatinine values are seen in patients with decreased muscle mass, including frail elderly people, malnourished patients, and those who have been immobile for prolonged periods. The significance is that when such patients develop renal insufficiency, the creatinine may not be elevated beyond the normal range for healthy young adults. Chapter 59 discusses kidney disease and dialysis.

Epstein-Barr virus antibodies (EBV ABs) develop and persist in patients who have been infected with the virus that causes infectious mononucleosis, whether or not they are clinically symptomatic. Twenty percent of patients with acute infection have a negative Monospot test, the heterophile antibody latex agglutination test to horse red cells (Chernecky & Berger, 2008). This test can be negative particularly in the first month, and once positive may persist for a year. Cytomegalovirus or toxoplasmosis are a consideration in heterophile negative patients with mono-like symptoms and signs (Ebell, 2004). High EBV antibody titers have been reported in patients with chronic fatigue syndrome, but there is poor correlation between titers and symptoms. EBV antibodies are common given the high prevalence of exposure to the virus and cannot be used reliably to diagnose chronic fatigue syndrome (Koo, 1989). See chapter 34 for a discussion of fatigue and chapter 60 for a discussion of EBV infection.

Folate or vitamin B9 is formed in the intestine, stored in the liver, and involved in blood cell function and neuronal function. Elevated levels may occur in patients taking supplements and in patients with hepatic insufficiency. Low levels occur in patients with protein-calorie malnutrition, patients with malabsorption syndromes, and in severe alcoholics who do not eat regularly. Clinically significant folate deficiency is usually associated with macrocytosis of red blood cells (elevated MCV). Some antiepileptic drugs, such as phenytoin, cause folate deficiency as indicated by a low serum folate. Other antiepileptic drugs interfere with the conversion of folate into tetrahydrofolate, its active form. These patients can have central nervous system (CNS) dysfunction due to folate deficiency without a decreased serum folate. Sulfasalazine and trimethoprim/sulfamethoxazole are also associated with folate deficiency.

Gamma glutamyl transpeptidase (GGT) is an enzyme found mainly in the cells of the biliary tract. Patients with even mild alcoholic hepatitis will show elevations of GGT, but elevation of GGT alone does not establish a diagnosis of hepatitis or of alcoholism (Neumann & Spies, 2003). A number of mildly hepatotoxic drugs can elevate GGT without affecting other “liver enzymes” or causing clinical symptoms. An isolated elevation of GGT is not a reason for discontinuing a drug that is clinically valuable, but it does imply a need for follow-up monitoring of the GGT, AST, ALT, and bilirubin to rule out a progressive problem that eventually will become clinically significant and require discontinuation of the drug.

Glucose is a monosaccharide that is the main source of cellular energy. Levels are elevated in diabetic patients and also increase with cortisol levels. Due to the brain's reliance on glucose, hypoglycemia can cause confusion, anxiety, and may even present with focal neurologic findings mimicking a stroke (Haist & Robbins, 1997). Hypoglycemia is most often a side effect of diabetic medications, but it can occur in fasting patients with severe liver disease due to impaired gluconeogenesis. Hypoglycemia can occur in patients with insulinomas or with self-administration of insulin to produce a factitious illness. Patients with prediabetes or mild diabetes can have a normal fasting glucose with an elevated 2-hour postprandial glucose, or an elevated fasting glucose with a normal 2-hour

postprandial glucose; the latter case is most likely to occur when the meal is not a standardized high-carbohydrate meal or glucose challenge.

Glycosylated hemoglobin (HbA1c) is proportional to the average plasma glucose over 4 weeks to 3 months, with more weight on the last 4 weeks. Once a red blood cell is glycosylated, it remains so for the remainder of its 120-day life span. While previously only approved to monitor glycemic control in diabetics, a high glycosylated hemoglobin level can now be used to make the diagnosis of diabetes or prediabetes (insulin resistance). Hemoglobin A1c does have some ethnic and racial differences and may be altered in the setting of shorter red cell survival.

In order to identify who is at risk for diabetes, the American Diabetes Association has set the threshold for prediabetes as HbA1c 5.7–6.4 and the threshold for full diagnosis of diabetes as HbA1c ≥ 6.5 . Parallel criteria for prediabetes are fasting plasma glucose of 100 to 125 mg/dl, or a 2-hour plasma glucose of 140 mg/dl (7.8 mmol/l to 199 mg/dl) after a 75 g oral glucose tolerance test. Parallel criteria for full diagnosis of diabetes is fasting plasma glucose ≥ 126 mg/dl or a 2-hour plasma glucose of 200 mg/dl during an oral glucose tolerance test. Classic symptoms of hyperglycemia or hyperglycemic crisis with a random plasma glucose >200 mg/dl also makes the diagnosis (Selvin et al., 2010; American Diabetes Association, 2013). In the psychiatric context, the HbA1c is useful in monitoring patients on second-generation antipsychotic drugs for the development of insulin resistance. Low levels are not clinically significant (American Diabetes Association, 2013).

Hemoglobin is the protein in red blood cells that carries oxygen. Blood hemoglobin is the concentration of the hemoglobin in gm/dL and **hematocrit** is the percentage of blood volume that consists of red blood cells. Levels of both are elevated when plasma volume is depleted and when there is an increased number of red blood cells produced, as when patients live at high altitude, smoke heavily, or have polycythemia vera. Both the hemoglobin and the hematocrit are decreased in anemia, whether due to bleeding, hemolysis, or a chronic disease such as chronic renal failure that is associated with decreased secretion of erythropoietin, the endogenous stimulant of red cell production.

Human immunodeficiency virus (HIV) testing is generally performed as two tests. A more sensitive enzyme immunoassay (ELISA) is performed first, and positive test results then are confirmed with a more specific Western blot or immunofluorescence test (Owen, Yang, & Spira, 2008). The rationale behind the two-step process of testing is that the risk of missing the diagnosis, as well as the risk of diagnosing a healthy patient with HIV, are both clinically unacceptable. When the two tests are used in conjunction, less than 0.1% of test results are inaccurate. However, false negatives can still occur if testing is performed soon after the infection occurs. A measure of viral load HIV RNA by the reverse transcriptase polymerase chain reaction test may be more informative in the first 6 weeks after exposure (Sax & Bartlett, 2013). The Centers for Disease Control (CDC) modified its recommendations for screening in 2006 to include all persons ages 13–64 years, rather than limiting the test to patients with

certain high-risk behaviors. Chapter 63 discusses HIV and sexually transmitted infections.

Lipase is a pancreatic enzyme that breaks down fats and triglycerides. Most often, elevated levels are a marker of acute pancreatitis, with levels of 3 times the upper limit of normal considered clinically significant (Lankisch, Burchard-Reckert, & Lehnick, 1999). Levels may not be elevated in patients with chronic pancreatitis.

Lyme IgG and IgM are antibodies to *Borrelia burgdorferi*. IgM levels peak about 1 month after infection, so a low level does not exclude disease. IgG rises 2–6 weeks after signs of illness and can remain elevated for decades after the infection has resolved. These tests have no value at the time of the tick bite. Many other infectious and autoimmune diseases will cause false-positive tests for Lyme disease, including infectious mononucleosis, syphilis, rheumatoid arthritis, and systemic lupus erythematosus. Serology testing does not make the diagnosis of Lyme nor does it exclude the diagnosis. It is not useful for screening asymptomatic individuals in endemic areas, as the false positives can be greater than true positives. These tests have a place for patients who may have been exposed to ticks and who have signs of disseminated disease. Diagnostic testing usually begins with an enzyme linked immunosorbent assay (ELISA). If the ELISA is positive, then a Western blot is sent. If Western blot is negative, the serology is deemed negative. The patient has not been exposed to *Borrelia burgdorferi*. Serum *Borrelia burgdorferi* C6 peptide antibody (VlsE C6 peptid ELISA) becomes positive earlier and has greater specificity—96% alone and 99% with two-step testing (Chernecky & Berger, 2008; Hu & Steere, 2013). Chapter 60 details infectious diseases.

Magnesium located in bone and cartilage and is found universally within the cells of the body. High levels occur in renal failure, and iatrogenically in pregnant women being treated for preterm labor or eclampsia with intravenous magnesium. Magnesium may be used orally in antacids or as an element of enemas in older patients. Hypermagnesemia can present with decreased consciousness and slurred speech; however, mildly elevated levels are usually asymptomatic. Hyperbilirubinemia will decrease magnesium levels (Chernecky & Berger, 2008). Hypermagnesemia with hyponatremia can follow intoxication with amphetamine or cathinones (Prosser & Nelson, 2012). Lithium overdose is associated with high levels of magnesium, as are tumor lysis syndromes and other catabolic states in the setting of renal insufficiency such as rhabdomyolysis, seen in neuroleptic malignant syndrome, and malignant catatonia.

Magnesium levels should be checked in patients with hypocalcemia, as the two typically are associated. Hypomagnesemia can occur in dehydrated patients, particularly those with diarrhea; in eating disorder patients who abuse laxatives and/or diuretics; and in malnourished chronic alcoholics. Repletion of body fluids and electrolytes with intravenous solutions that do not contain magnesium can aggravate the problem. Hypomagnesemia can present with psychosis, agitation, or depression, and is particularly dangerous in patients with prolonged QT intervals because of increased risk of cardiac arrhythmias (Haist & Robbins, 1997). One context in which

it is essential to check magnesium levels is antidepressant overdose. In this situation the risk of QT prolongation and associated arrhythmia is high, and either the depression itself or a period of stupor or coma due to the overdose can be associated with dehydration. Hypomagnesemia is a consideration whenever the QT interval is prolonged, particularly in the setting of medications that prolong the QT interval, due to the greater danger of serious arrhythmia. See chapter 52.

Mean corpuscular volume (MCV) is the calculated volume of erythrocytes. Elevated levels are seen in alcoholics, vitamin B12 and/or folate deficiency, patients with malabsorption, cigarette smokers, and patients with high reticulocyte counts. Because an elevated MCV can have diverse causes, it is unacceptably nonspecific with respect to the diagnosis of alcohol abuse or dependence, even in clinical settings where the baseline prevalence of alcoholism is high (Neumann & Spies, 2003).

Abnormally low MCVs occur in patients with iron deficiency anemia (commonly seen in menstruating females and in patients with chronic gastrointestinal bleeding) and in patients with inherited disease of the red blood cells such as sickle cell disease and thalassemia. In clinical contexts—for example, recent immigrants from countries with a high prevalence of parasitic diseases and travelers recently returned from such countries—parasitic infestations associated with blood loss should be included in the differential diagnosis.

Phosphate is stored in bones and is elevated in patients with renal failure. Patients with hyperphosphatemia should be evaluated for possible hypocalcemia. Low phosphate levels can lead to irritability, encephalopathy, and seizures if extreme. Most commonly, low levels occur in the setting of inadequate oral nutrition; but patients with alcoholism, vitamin D deficiency, and treatment for diabetic ketoacidosis are also at risk (Haist & Robbins, 1997). Hypophosphatemia can also develop in patients treated for dehydration with intravenous solutions that do not contain phosphate.

Platelets are produced in the bone marrow and are involved in blood clotting. Low platelets may be due to decreased production in patients with cancer, alcoholism, or nutritional compromise; destruction in autoimmune conditions; or sequestration in patients with an enlarged spleen. Thrombocytopenia is not associated with increased bleeding risk until the platelet count falls below 20,000 per microliter (Haist & Robbins, 1997). Thus, spontaneous bleeding with lesser degrees of thrombocytopenia implies an additional cause of abnormal bleeding such as a colon lesion, drugs or inherited diseases that impair blood clotting, impaired hepatic synthesis of clotting factors, or qualitative platelet dysfunction such as that seen in von Willenbrand's disease. Thrombocytosis can occur in patients with acute inflammation or infection, and is associated with an increased risk of thrombosis when the platelet count exceeds 1,000,000/microL (Buss, Stuart, & Lipscomb, 1985). Patients with thrombocytosis due to a clonal abnormality causing increased production are at risk for both bleeding and clotting (Schafer, 2006).

Potassium is an intracellular cation that affects cardiac repolarization and cardiac conduction, rendering it very clinically significant because it predisposes to cardiac arrhythmias.

It is excreted by the kidneys and by the colon via the stool. The most common cause of hyperkalemia is renal failure, but it can occur in other diseases such as Addison's and with medications such as ACE inhibitors and potassium-sparing diuretics such as amiloride (Haist & Robbins, 1997). Severe hyperkalemia can lead to cardiac arrest, especially if the onset is acute. Electrocardiogram changes associated with hyperkalemia are peaked T-waves and shortened QT interval. Hypokalemia usually occurs in patients with vomiting or diarrhea, or those taking diuretics. In collecting the blood sample, using a tourniquet and having the patient pump the hands can raise venous potassium levels by up to 20% (Chernecky & Berger, 2008). Potassium levels are higher in the afternoon and early evening and may be falsely elevated if the blood specimen hemolyzes prior to analysis.

Rapid plasma reagin (RPR) is a nontreponemal serologic test for syphilis in which the serum reacts to a cardiolipin-cholesterol-lecithin antigen. The test has greater sensitivity during the secondary rather than the primary stage of syphilis. Consuming alcohol within 24 hours prior to testing can lead to a false-negative result (Chernecky & Berger, 2008). False-positive results are very common in autoimmune and other infectious diseases. However, the RPR is still preferred over the nontreponemal Venereal Disease Research Laboratory test for syphilis, because it is more sensitive. If there is a history of previously treated syphilis, the nonreactive RPR suggests that no further treatment is warranted as there is no sign of active infection. A sign of new infection in someone who had been treated in the past would be a fourfold increase in titer. If there is no history of treatment, syphilis has a low prevalence, and the RPR is positive, then the next step would be the *Treponema pallidum*-particle agglutination assay, a specific treponemal test. For economic reasons, some laboratories are now beginning with a specific treponemal ELISA. The harm of potentially treating a patient with penicillin unnecessarily is much less than the harm of allowing the disease to progress to later stages and the risk of the patient transmitting infection to others. Chapter 63 discusses HIV and sexually transmitted infections.

Sodium is a cation in extracellular fluid which is elevated in patients with volume depletion and diabetes insipidus, and can be decreased for any of a wide range of conditions associated with increased secretion of antidiuretic hormone (ADH). Hypernatremia can present with depressed sensorium and disorientation; in fact, it often occurs because the patient who has lost water is not alert, responding to thirst, and replacing the losses. Diabetes insipidus—decreased secretion of ADH by the hypothalamus or insensitivity of the kidney to ADH—is the principal cause of hypernatremia. In psychiatric contexts, this side effect of lithium is an important consideration. Hyponatremia, particularly when acute, can cause psychiatric symptoms including anxiety, confusion, or sedation, and can cause seizures. A serum sodium of 110 mEq/L will cause CNS dysfunction in virtually all patients; a level of 125 can cause symptoms if acute, but may be asymptomatic if it has developed over several weeks. The list of possible causes of low sodium is lengthy,

and the differential diagnosis varies based on the volume status of the patients. Hypervolemic hyponatremia is due to heart, liver, or kidney failure. Euvolemic hyponatremia is due to hypothryroidism or the syndrome of inappropriate antidiuretic hormone (ADH) secretion. Hypovolemic hyponatremia occurs when both sodium and water are depleted because of vomiting or diarrhea, or renal tubular loss (Haist & Robbins, 1997). Volume status can be assessed by measuring orthostatic blood pressure changes and by noting an increase or decrease in the levels of blood constituents such as the hematocrit or BUN. A number of psychiatric medications have been reported to cause SIADH; a list of common ones is found in Box 5.1). Psychiatric patients with polydipsia, beer potomania, and eating disorder patients who water-load prior to a weigh-in are at risk for hyponatremia. Patients with severe hyperglycemia can have hyponatremia because the ADH system regulates serum osmolality, and glucose can substitute for sodium in determining serum osmolality. Chronic hyponatremia, particularly in patients who are not symptomatic, should be corrected slowly (e.g., over days) to avoid central pontine myelinolysis.

Thyroid stimulating hormone (TSH) is released by the anterior pituitary to regulate secretion of thyroxine (T₄) and triiodothyronine (T₃) by the thyroid gland. Elevated levels are seen in hypothyroidism—and rarely in patients with TSH-secreting pituitary adenomas—and low levels are seen in patients with hyperthyroidism, and rarely in patients with hypopituitarism or with suppression of TSH secretion by a prolactin-secreting or nonsecreting pituitary tumor. TSH will also become low in patients on levothyroxine who are taking excessive doses of thyroid replacement or are deliberately ingesting thyroid hormones to lose weight or produce a factitious illness. TSH levels take 6–8 weeks to reach a steady level after a levothyroxine dose is adjusted (Hueston, 2001). Patients with a TSH <10 micro units per milliliter do not have more physical or neuropsychiatric symptoms than healthy controls (Jorde et al., 2006); nonetheless, individual patients may have a history and other laboratory findings suggesting a clinically relevant disturbance of thyroid function. (This is discussed further in chapters 6 and 55, which deal with endocrine testing and endocrine diseases.) Current practice guidelines recommend screening all women over age 50 years for thyroid disorders because of the high prevalence

**Box 5.1 PSYCHIATRIC DRUGS ASSOCIATED
WITH SIADH**

amantadine, amitriptyline, aripiprazole, carbamazepine, chlorpromazine, clomipramine, desipramine, doxepin, duloxetine, escitalopram, fluoxetine, fluvoxamine, fluphenazine, haloperidol, imipramine, lorazepam, nortriptyline, olanzapine, paroxetine, perphenazine, pramipexole, protriptyline, sertraline, thioridazine, thiothixene, tranlycypromine, trimipramine, valproic acid, venlafaxine.

of primary hypothyroidism in that population. Secondary hypothyroidism due to lack of TSH release from the pituitary will present with low TSH and low free T4, but accounts for less than 5% of cases of clinical hypothyroidism (Hueston, 2001). Medical psychiatrists may see low TSH from a pituitary or a hypothalamic cause in patients who have had radiation to the brain.

Free thyroxine (Free T4) is a measure of active, nonprotein-bound thyroid hormone. Levels are high in hyperthyroidism and low in hypothyroidism. Free T4 also decreases with age (Kennedy-Malone, Fletcher, & Plank, 2004) and it may be transiently decreased in the context of acute, severe illness. Clinical situations of chronic inflammation in which there is an excess of thyroid-binding globulin can lead to spurious elevation of total T4, and situations of malnutrition or hepatic dysfunction with low levels of thyroid-binding globulin can lead to a spurious low value of total T4. Determination of free T4 is particularly helpful in these situations. Within the normal range of free T4, there is no association of low T4 levels with clinical depression (Williams et al., 2009).

Urinalyses are most often ordered to look for evidence of urinary tract infections, but can also reveal hematuria suggesting urinary tract cancer or a bleeding disorder, or proteinuria suggesting kidney disease. Diabetic nephropathy is the most common kidney disease associated with proteinuria. Urine specific gravity—which, when low, suggests low urine osmolality—can be a clue to SIADH, diabetes insipidus, or water intoxication. The urine dipstick has high sensitivity but poor specificity for hematuria and pyuria, while the microscopic evaluation of urine is both sensitive and specific (Simerville, Maxted, & Pahira, 2005). Weakly positive leukocyte esterase or nitrites on dipstick are not as reliable a marker for infection as increased white blood cell counts on microscopy.

Urine catecholamines are measured in the evaluation of patients for pheochromocytoma. Due to the infrequent incidence of this disease (less than 1% of hypertensive patients), this test is less valuable when suspicion is low. Fractionated metanephrines in a 24-hour urine can be used to rule out pheochromocytoma when suspicion is low, but is only part of an evaluation to make the diagnosis when clinical suspicion for pheochromocytoma is very high (Young & Kaplan, 2013). Suspicion would be high in a patient with headaches, generalized sweating, and tachycardia, or in patients with episodes of hypertension, resistant hypertension, an episode of hypertension during a procedure, history of familial syndromes like neurofibromatosis 1, von Hippel-Lindau disease, multiple endocrine neoplasia 2 (with medullary thyroid cancer and hyperparathyroidism), or an incidental adenoma. Fractionated catecholamines (dopamine, norepinephrine, epinephrine) and metanephrines (metanephrine and normetanephrine) in a 24-hour urine collection with creatinine measured to document adequate sample is a sensitive test. Fractionated plasma metanephrines can be added when suspicion is high. It is practical, and some feel a specific test for first-line diagnostic testing, as patients with pheochromocytomas can

experience panic attacks. Elevated urine catecholamine levels may also occur with heavy consumption of bananas, beer, chianti wine, cheese, walnuts, and coffee (Chernecky & Berger, 2008).

Human chorionic gonadotropin (HCG) is a highly sensitive and specific test for pregnancy. Within 2 weeks of conception, HCG is elevated in the blood but not necessarily in the urine; after 2 weeks a urinary HCG is as sensitive as a blood HCG. Urinary HCG is the basis of home pregnancy test kits (Haist & Robbins, 1997). HCG-secreting tumors are virtually the only reason for a false positive HCG-based pregnancy test. Blood HCG measurement is of particular value in psychiatric contexts when female patients of reproductive age have had unprotected sexual intercourse and are taking medications highly associated with birth defects.

Urine toxicology screens are used to check for suspected substance abuse. The sensitivity of the test relates to how long after ingestion of the substance the urine sample is obtained. The time limits for detection are as follows: alcohol, 3–10 hours; amphetamines, 24–48 hours; barbiturates, up to 6 weeks; benzodiazepines, up to 6 weeks; cocaine, 2–4 days but up to 10–22 days with heavy use; phencyclidine (PCP), 1–8 days (ketamine may cause a false-positive PCP test); tetrahydrocannabinol (THC), 6–11 weeks with heavy use (McPherson & Pincus, 2006). Opiate detection depends on the half life of opiate used, but not all opiates are tested for in a routine urine drug screen panel. While morphine is noted, oxycodone is not usually detected. Fentanyl is not found because it has no metabolites. It can be difficult to distinguish between heroin, codeine, or morphine use among patients with low morphine and codeine concentrations. Many panels do not routinely screen for methadone; verapamil metabolites can contribute to false positives (Moeller, Lee, & Kissack, 2008). Amphetamine assays are complicated by false positives attributed to many prescription stimulants, and bupropion, phenothiazines, and tricyclic antidepressants may interfere with the immunoassay (see Box 5.2).

Box 5.2 THE TIME LIMITS FOR DETECTION IN URINE TOXIC SCREENS

Alcohol: 3 to 10 hours
Amphetamines: 24 to 48 hours
Barbiturates: up to 6 weeks
Benzodiazepines: up to 6 weeks
Cocaine: 2 to 4 days but up to 10 to 22 days with heavy use
Phencyclidine (PCP): 1 to 8 days (ketamine may cause a false positive PCP test)
Tetrahydrocannabinol (THC): 6 to 11 weeks with heavy use

Box 5.2 reproduced by permission, from Moeller, 2008, Table 3. Summary of Agents Contributing to Positive Results by Immunoassay (p. 69).

Vitamin B12, or cyanocobalamin levels, reflect absorption of B12 from dietary sources. Normal B12 absorption requires gastric acid, intrinsic factor (secreted by the stomach), and normal ileal function. Levels are low in patients with B12 malabsorption due to ileal disease, lack of intrinsic factor on an autoimmune basis (pernicious anemia), or chronically low gastric acidity related to advanced age or to chronic use of proton pump inhibitor drugs or H2 blocking drugs that chronically suppress gastric acid secretion. Due to the amount of B12 stored in the liver, patients with impaired B12 absorption or with little or no B12 dietary intake (as in severely malnourished patients or in vegans who do not take B12 supplements) will not develop a deficiency for months to years after B12 intake and/or absorption is inadequate. In patients with borderline low levels, a **methylnmalonic acid** level that is abnormally high will confirm that the low B12 level is clinically significant (Antony, 2007). B12 levels can be elevated in patients taking large doses of B12 supplements or with acute hepatitis, since it is stored in the liver and released when hepatocytes are damaged.

LABORATORY TESTS USED IN THE EVALUATION OF PSYCHIATRIC SYNDROMES

Table 5.2 lists laboratory tests that physicians should consider ordering as a component of a comprehensive evaluation of a patient evaluated in a medical psychiatric context. As noted above, this panel of tests should be modified based on the clinical setting and the characteristics of the patient population to be evaluated. Medical psychiatrists might begin by

considering this panel of tests and then adding or subtracting tests based on the specifics of the case. Efforts should be made to obtain the results of tests recently done elsewhere. If the results of a recent test are normal and credible, and the patient's status with respect to the relevant condition has not changed, the test may be omitted. Borderline abnormal tests done elsewhere typically are repeated.

SUMMARY

A single abnormal test result may have no clinical significance, particularly when the abnormality is mild and the result has been obtained in the context of multiple screening tests. On average, one in 20 test results will be a statistical outlier in a completely healthy patient. Individual tests done to test clinical hypotheses and tests with markedly abnormal values with potentially severe clinical consequences should be treated differently, with the patient promptly evaluated for conditions related to the laboratory abnormality. Moreover, many laboratory abnormalities associated with CNS dysfunction will have much greater import if they develop rapidly than if they develop gradually. For this reason the degree of abnormality of test results must be interpreted in temporal context. Overall, physicians need to treat patients, not lab values, and should aim to confirm diagnoses through a convergence of history, examination, and laboratory tests and, where appropriate, diagnostic procedures. "Ruling out" diagnoses through individual laboratory tests and "ruling in" diagnoses through laboratory findings alone is frequently expensive and occasionally dangerous.

Table 5.2 SUMMARY OF LABORATORY WORKUP OF COMMON PSYCHIATRIC SYNDROMES

PSYCHIATRIC SYNDROME	LABORATORY TESTS TO INVESTIGATE POTENTIAL MEDICAL CAUSES OF PSYCHIATRIC SYMPTOMS	FOR FURTHER INFORMATION
Anxiety	Hgb & Hct, TSH and free T4, blood and urine toxicology screen, glucose, ABG, sodium, calcium, magnesium, phosphate, urine catecholamines	See chapter 33
Delirium	Glucose, ABG, sodium, phosphate, calcium, BUN, magnesium, urinalysis, blood and urine toxicology screen, electroencephalogram, brain imaging, liver function tests including ammonia, WBC, albumin and prealbumin	See chapter 31
Depression	Hgb & Hct, liver function tests, TSH and free T4, sodium, BUN, creatinine, urinalysis, cortisol	See chapter 29
Fatigue	WBC, Hgb & Hct, calcium, sodium, BUN, creatinine, potassium, phosphate, TSH and free T4, liver function,	See chapter 36
Mania/Psychosis	TSH and free T4, sodium, vitamin B12, ceruloplasmin and urine copper, RPR, HIV, blood and urine toxicology screen, WBC, BUN, creatinine, iron, liver function tests, urinalysis, calcium, phosphate, glucose, folate, cortisol	
Alcohol abuse and dependence	ALT, AST, CDT, MCV, GGT, blood alcohol level, albumin, lipase, glucose, bilirubin direct and total	
Dementia	ABG, blood & urine toxicology screens, Hgb & Hct, WBC, glucose, BUN, calcium, magnesium, TSH and free T4, vitamin B12, folate, urinalysis, RPR, heavy metal in 24 hour urine, sodium, liver function test, brain imaging, lumbar puncture, phosphate, creatinine	See chapter 32
Eating Disorders	Hgb & Hct, WBC, platelet, glucose, BUN, creatinine, calcium, magnesium, TSH and free T4, vitamin B12, folate, sodium, liver function test, cholesterol profile, FSH and LH, DEXA scan, amylase, potassium, bicarbonate, phosphate	See chapter 34

CLINICAL PEARLS

- A statistical approach will identify 95% of test results as being “normal,” with 2.5% of highest values and 2.5% of lowest values deemed “abnormal.” However, statistical significance does not always portend clinical significance.
- “Pre-pre” analytical errors occur when a physician decides to order the wrong test for the clinical question at hand.
- “Post-post” analytical errors occur when the test involves converting a continuous quantity into a binary decision. The cut point for diagnosis may also affect test characteristics.
- Sensitivity and specificity are the best known test characteristics. 100% sensitivity means that every patient in the population examined who tests negative will not have the disease. 100% specificity means that every patient in the population examined who test positive will have the disease. Typically, a test will approach 100% sensitivity only by sacrificing specificity, and conversely.
- Factors that have been reported to increase the likelihood that a psychiatric symptom is attributable to a medical illness include lack of prior psychiatric history, very rapid onset, onset before age 12 or after age 40 years, disorientation, depressed level of consciousness, abnormal vital signs, focal neurological deficits, and the presence of visual or tactile hallucinations (Reeves et al., 2000).
- The three questions to ask in deciding whether or not to order a test are as follows:
 1. How likely is this test to be truly abnormal—a true positive—in this patient?
 2. How will the test result change the treatment plan for the patient?
 3. When will the test results be available?
- Prealbumin has a shorter half life than albumin, making low levels a more sensitive marker of acute nutritional compromise (Beck & Rosenthal, 2002).
- Many laboratory abnormalities associated with CNS dysfunction will have much greater import if they develop rapidly than if they develop gradually.
- Medical psychiatrists may see low TSH from a pituitary or a hypothalamic cause in patients who have had radiation to the brain.
- Amphetamine assays are complicated by false positives attributed to many prescription stimulants.
- In patients with borderline low levels of B12, a methylmalonic acid level that is abnormally high will confirm that the low B12 level is clinically significant (Antony, 2007).

LABORATORY EVALUATION OF ENDOCRINE DISORDERS IN PATIENTS WITH NEUROPSYCHIATRIC SYMPTOMS

Fernando A. Rivera, Shirlene Sampson, and Christopher L. Sola

INTRODUCTION

Whether an endocrine disorder is contributing to the presentation of neuropsychiatric symptoms is an important question for medical psychiatrists. It has long been known that hormonal disorders include cognitive, affective, and behavioral changes. These symptoms often precede or present simultaneously with the somatic signs and symptoms of endocrine disease and may confuse even the most astute diagnostician. Hormonal symptoms may be mislabeled during early stages as neurotic or somatoform; during more advanced stages, endocrine disorders may be misdiagnosed as dementia or primary psychosis. Endocrine disorders are more likely to present with neuropsychiatric symptoms in older patients and in children, who may be more sensitive to disruption of brain function by hormones.

In this chapter we focus on endocrine evaluation of patients who present with neuropsychiatric signs and symptoms, either alone or in combination with other nonpsychiatric symptoms. Chapter 55 will provide further detail on the psychiatric dimensions of specific primary endocrine disorders. Here we will deal with testing of the endocrine functions of the thyroid, adrenal, pituitary, and testes, and also with diabetes mellitus, hypoglycemia, and pheochromocytoma. Female reproductive endocrinology is covered in chapter 67.

When patients with known endocrine disorders are referred to medical psychiatrists for concurrent psychiatric syndromes, they are likely to be treated specifically for psychiatric syndromes whether or not the symptoms are thought to be secondary to the endocrine condition or merely comorbid. Similarly, when an endocrine disorder develops during the course of treatment of a chronic psychiatric illness, treatment of the endocrine disorder typically will be added to the ongoing psychiatric treatment. When a patient newly presents with neuropsychiatric symptoms, and a previously undiagnosed endocrine condition is identified, many endocrinologists would suggest treating the endocrine condition and following the patient to see if the psychiatric disorder resolves. A more nuanced approach would draw on the experience of the endocrinologist and his or her colleagues with other patients who had the same endocrine disorder, to assess whether the presenting patient's psychiatric symptoms are disproportionate to the endocrine abnormality. If so, it is

likely that the endocrine condition is a contributing or provocative factor in the psychiatric disorder and not its sole cause. Concurrent treatment of the endocrine and the psychiatric condition would be preferable in such cases, as it would be when patients are suffering greatly from mental symptoms or when their behavior poses a risk to their health and safety or to the safety of other people.

LABORATORY TESTS OF THE THYROID

Thyroid disease can produce neuropsychiatric symptoms in two ways—through the effects of an excess or deficiency of thyroid hormones on metabolism and neurotransmission, and through autoimmune inflammatory processes affecting the brain directly. Autoimmune diseases can result in the release of cytokines with neuropsychiatric effects or can affect other endocrine organs such as the adrenals and ovaries. Hypothyroidism and hyperthyroidism are remarkable because neuropsychiatric symptoms can be their most prominent manifestation, so thyroid disease may be discovered in working up the symptoms of brain dysfunction. By contrast, the implications of antibodies directed at the thyroid are considered more often after a patient has already been diagnosed with thyroid disease.

A combination of two tests—the serum thyroid stimulating hormone (TSH) and serum free thyroxine (T₄)—is highly sensitive and specific in detecting thyroid hormone excess or deficiency. The test results often point to the underlying cause of the thyroid dysfunction, most often due to disease of the thyroid itself and much less often due to pituitary or hypothalamic dysfunction.

THYROID STIMULATING HORMONE

The serum TSH level should be performed (or checked if recently done) in all medical-psychiatric patients in whom there is any suspicion of thyroid dysfunction, and in all female patients over 50 with psychiatric disorders whether or not there are signs and symptoms specifically pointing to the thyroid. Thyroid dysfunction should be suspected when neuropsychiatric symptoms occur that are potentially due

to too much or too little thyroid hormone, in combination with typical physical symptoms or signs on physical examination. The neuropsychiatric and general somatic symptoms and signs of hypothyroidism and thyrotoxicosis are summarized in Table 6.1.

Like other pituitary hormones, TSH is released in a pulsatile manner, but its serum level varies smoothly because the serum half-life of TSH is 50 minutes. In normal individuals the serum level of TSH has a circadian rhythm, with a peak level at 2 a.m. to 4 a.m. and a nadir between 4 p.m. and 8 p.m. The recommended time for drawing a diagnostic TSH level is first thing in the morning (Sviridova, Fadeyev, Sych, & Melnichenko, 2013). A spot TSH level drawn in the late afternoon can be in the normal range, slightly higher than the morning reading—a false negative in patients with mild hypothyroidism. Apart from the circadian rhythm, changes in TSH from hour to hour and from day to day are relatively small, so that a single serum TSH drawn in the morning is sufficient for diagnostic purposes.

TSH IN MONITORING THYROID HORMONE REPLACEMENT FOR HYPOTHYROIDISM

TSH Is Elevated, Free T4 Is Low

TSH is elevated in primary hypothyroidism. Free T4 is low. After treatment for clinical hypothyroidism is initiated, the dose of levothyroxine is adjusted to bring TSH levels into the lower half of the normal range.

TSH responses to levothyroxine replacement are gradual and should be measured at about 2 months after initiating treatment and a similar period after any subsequent change in dosage.

Data from recent studies, including the National Health and Nutrition Examination Survey of the Centers for Disease Control (NHANES III, 2013), are challenging the validity of the traditional TSH reference range of 0.5 μ U/mL to 5.0 μ U/mL (0.5–5.0 mU/L). When patients with a family history of thyroid disease or the presence of thyroid antibodies are excluded from the reference population, the TSH normal range appears to be more narrow (0.5–2.5 μ U/mL

Table 6.1 CLINICAL SIGNS AND SYMPTOMS OF THYROID HORMONE EXCESS AND DEFICIENCY

CONDITION	NEUROPSYCHIATRIC SYMPTOMS AND SIGNS	OTHER SOMATIC SYMPTOMS AND SIGNS
Hypothyroidism	Apathy	Cold intolerance
	Depressed mood or depressive syndrome	Edema (nonpitting)
	Irritability	Weight gain
	Cognitive impairment	Constipation
	Delirium (in severe cases)	Amenorrhea or irregular periods
	Psychosis (in severe cases)	Hair loss
	Slow speech	Cool skin
	Mania (rarely)	Hoarse voice
	Fatigue	
	Weakness	
	Muscle stiffness	
	Hypersomnia or sleepiness	
	Worsening of sleep apnea	
	Delayed relaxation phase of reflexes	
	Increased sedative and anticholinergic effects of CNS drugs	
Thyrotoxicosis (usually due to hyperthyroidism)	Anxiety	Heat intolerance
	Increased activity	Warm skin
	Impaired attention and concentration	Weight loss
	Rapid speech	Frequent bowel movements
	Mixed affective state	Amenorrhea or irregular periods
	Psychosis (in severe cases)	Dyspnea
	Delirium (in “thyroid storm”)	Hair loss
	Fatigue	Tachycardia and palpitations
	Weakness	Lid retraction and lid lag
	Proximal myopathy with muscle wasting (in advanced cases)	Atrial fibrillation
	Insomnia	Heart failure
	Hyperactive reflexes

[0.5–2.5 mU/L]). Therefore, a target range of approximately 1.0 μ U/mL to 2.5 μ U/mL (1.0–2.5 mU/L) seems appropriate for patients with defined thyroid disease receiving replacement levothyroxine. Whether patients without known thyroid disease or risk factors whose serum TSH levels are between 2.5 μ U/mL and 5.0 μ U/mL (2.5–5.0 mIU/L) should be treated remains less clear, especially for older patients.

The mainstay of thyroid hormone replacement is levothyroxine therapy, which should always be taken on an empty stomach one hour before or 2 to 3 hours after intake food or other medications. Although much attention has recently been focused on therapy with liothyronine or combination T3/T4 therapy using either thyroid hormone extract or synthetic T3/T4 combinations, most evidence to date shows no clinical advantage of combined T3/T4 therapy over traditional levothyroxine treatment.

SUBCLINICAL HYPOTHYROIDISM

TSH Is Elevated, Free T4 Is Normal

Subclinical hypothyroidism is defined as the presence of an above-normal TSH with simultaneous free T4 and free T3 levels in the normal range (Surks et al., 2004). A patient with a TSH greater than 10.0 mIU/L would be treated for hypothyroidism despite a normal free T4 and free T3 and the lack of the typical clinical syndrome.

There are no generally accepted recommendations for subclinical hypothyroidism (Biondi & Cooper, 2008; Garber, 2012). While endocrinologists would not *routinely* treat *asymptomatic* patients with a TSH <10.0 mIU/L they might differ on whether to regard major depression poorly responsive to standard antidepressant drugs as a symptom of hypothyroidism for the purpose of deciding whether a patient was “asymptomatic.” The identification of additional non-psychiatric symptoms or signs of hypothyroidism—for example, cold intolerance or slow deep tendon jerks—would be relevant to a consulting endocrinologist and special effort to elicit them is worthwhile. Subclinical hypothyroidism may be associated with an increased risk of atherosclerosis and cardiac events, but reversal of these effects with T4 therapy has not been systematically studied (Kratzsch & Pulzer, 2008; Cooper, 2007).

TSH IN SECONDARY OR TERTIARY HYPOTHYROIDISM

TSH Is Normal, Free T4 Is Low

With rare exceptions a normal TSH rules out a primary abnormality of thyroid function. A TSH level with a free T4 level should be done when the clinical context and the combination of neuropsychiatric and other somatic symptoms increases the probability that secondary thyroid dysfunction is present; for instance, when there is a history of head trauma or brain radiation. The addition of a free T4 to TSH level will improve diagnostic sensitivity. When the TSH is normal or below the normal range and the free T4 level is low, the patient is diagnosed with hypothyroidism due to pituitary (secondary) or hypothalamic (tertiary) dysfunction

TSH IN DIAGNOSING AND MONITORING TREATMENT OF THYROTOXICOSIS

TSH Is Low, Free T4 Is High

The TSH levels currently available from clinical laboratories are determined by immunoradiometric assays. They are either third generation assays that can measure levels as low as 0.01 mIU/L, or fourth generation assays that can measure levels down to 0.004 mIU/L. Either one is sufficiently sensitive to the presence of hyperthyroidism, which is diagnosed when the level of TSH is below the normal range and a free T4 or free T3 is above the normal range. The normal range of TSH varies between laboratories; a range of 0.3 mIU/L–0.5 mIU/L on the low end to 4.00 mIU/L–5.00 mIU/L on the high end would be typical, although, as has been noted, below a range of 0.5 mIU/L–2.5 mIU/L might more accurately capture the range of values for individuals with no thyroid disease whatever (DeGroot et al., 2009).

With either the third-generation or fourth-generation TSH assay, the sensitivity is high enough to make unnecessary the TRH stimulation test for the diagnosis of hyperthyroidism, because in hyperthyroidism there is a very strong correlation between a low baseline TSH and a blunted TSH response to exogenous TRH.

TSH remains suppressed for several months after treatment for hyperthyroidism (Brent, 2008).

TSH Is Low, Free T4 Normal, Free T3 High

If TSH is low and free T4 is normal, free T3 should be checked. T3 may be elevated in certain cases of Graves’ disease or if T3 is given exogenously.

Central or Secondary Thyrotoxicosis

TSH Is Normal or High, Free T4 High, Free T3 High

When the TSH is normal or above the normal range and the free and total T4 and free and total T3 level is high—a rare situation—the patient may be diagnosed with secondary hyperthyroidism, which is usually due to a TSH-secreting pituitary adenoma (Nayak & Hodak, 2007).

Subclinical Hyperthyroidism

TSH Low, Free T4 Normal, Free T3 Normal

Subclinical hyperthyroidism is defined as the presence of a below-normal serum TSH with simultaneous free T4 and free T3 levels in the normal range. Specifically, a patient with a TSH <0.1 mIU/L would be treated for hyperthyroidism even if the free T4 and free T3 were normal and the patient did not show the typical clinical syndrome of thyrotoxicosis.

AUTOANTIBODIES AND AUTOIMMUNE DISEASE

There are two common autoimmune thyroid diseases: Hashimoto’s disease, which usually causes hypothyroidism, and Graves’ disease, which usually causes hyperthyroidism

(Pearce, Farwell, & Braverman, 2003; Brent, 2008). These conditions are associated with antithyroid antibodies, of which five specific types are measured by clinical laboratories: antithyroid peroxidase antibodies, antithyroglobulin antibodies, anti-TSH receptor antibodies, thyroid-stimulating immunoglobulins, and thyrotropin-binding inhibitory immunoglobulins.

Thyrotoxicosis means an abnormally high level of thyroid hormone in the serum. It is most frequently due to hyperthyroidism—overactivity of the thyroid gland (Nayak & Hodak, 2007). Other cases are due to extrathyroidal sources of thyroid hormone or due to consumption of exogenous thyroid hormone, the latter being much more common than the former. The most common cause of hyperthyroidism is Graves' disease; other common causes are subacute thyroiditis, postpartum thyroiditis, toxic (hormone-secreting) thyroid adenomas, and toxic multinodular goiter. In most cases of thyrotoxicosis, the free T₄ is elevated. The incidence is highest in women between 20 and 40 years old (Brent, 2008).

Graves' disease is a systemic autoimmune disorder that prominently involves the thyroid gland, but also affects the eyes and the skin. The thyroid in Graves' disease is diffusely enlarged. The diagnosis usually can be made clinically, and three of the five antithyroid antibodies mentioned above are characteristic of the disease. Their presence is diagnostically helpful when the patient has typical skin and/or eye changes of Graves' disease but does not have an elevated level of T₄ or T₃. These three antibodies are antithyrotropin stimulating hormone receptor (TSH-R), thyroid-stimulating immunoglobulin (TSI), and TSH receptor binding inhibitor immunoglobulin (TBII). TSH-R is seen in the large majority of patients with Graves' disease (Barbesino & Tomer, 2013). TBII misses milder forms of Graves' disease. While patients with Graves' disease can also have anti thyroid peroxidase antibodies (anti-TPO) and antithyroglobulin (anti-TG) antibodies, these are more common in Hashimoto's disease than Graves' disease and can occur in some patients without thyroidal illness.

The special relevance of anti-TSH-Rs, TSIs, and TBII to medical psychiatrists is that some patients with autoimmune thyroid disease alternate between hypothyroid and hyperthyroid states, producing a clinical picture that can be confusing, especially when the main symptoms of the thyroid disease are neuropsychiatric. Knowledge of the presence of antibodies that can stimulate or inhibit T₄ production by binding to T₄-secreting cells can explain a fluctuating clinical course and can prompt the clinician to consider that changes in neuropsychiatric symptoms could be due to a switch between thyroid hormone excess and deficiency.

These tests are not routine, and are generally reserved for the evaluation of the patient with typical ophthalmologic signs of Graves' disease but with normal or borderline thyroid function and minimal or no thyroid enlargement; pregnancy complicated by Graves' disease; or atypical fluctuating hypothyroidism (Pearce et al., 2003).

Patients with other systemic autoimmune diseases including rheumatoid arthritis (RA), systemic lupus erythematosus (SLE), and idiopathic thrombocytopenic purpura (ITP) have

one or more antithyroid antibodies in a minority of cases. These patients are at greater risk of developing hypothyroidism than patients with similar demographics who do not have antithyroid antibodies. These systemic autoimmune disorders are associated with neuropsychiatric symptoms. When new neuropsychiatric symptoms present in patients with RA or SLE, reevaluation of thyroid status and testing for anti-TPO and anti-TG should be considered.

FACTITIOUS THYROTOXICOSIS

TSH Low, Free T₄ High, Thyroglobulin Low or Low Normal

Factitious thyrotoxicosis due to self-administration of T₄ or T₃ can be established by measurement of the serum thyroglobulin (TG) level. In hyperthyroidism, the level of TG is elevated or high normal because it is secreted along with T₄ and T₃. When exogenous thyroid hormone is taken, secretion of T₄ and T₃ by the thyroid decreases and hence serum TG will be low or low normal. Thyroglobulin is a glycoprotein integral in follicular storage of thyroid hormone; it is normally present in serum, and the serum level is increased in hyperthyroidism, in some cases of thyroiditis, and in papillary and follicular cancer of the thyroid, where it is a useful marker of tumor recurrence following thyroidectomy or radiation therapy (Brent, 2008; Mariotti, Martino, Cupini, et al., 1982).

ELEVATED T₄ IN SEVERE PSYCHIATRIC DISORDER

TSH Normal, Free T₄ Transiently Elevated

Transient elevation of T₄ can be seen in patients with acute, severe psychiatric disorders such as acute schizophrenia or mania (Spratt, Pont, & Miller, 1982). In these patients, TSH is not suppressed and occasionally it is elevated. The T₄ level returns to normal in less than a month. The presumptive cause is a stress-related alteration in activity of the hypothalamic-pituitary-thyroid axis; if the cause were intrinsic, thyroid overactivity (hyperthyroidism) the TSH level would be decreased.

EUTHYROID SICK SYNDROME

TSH Normal, Free T₄ Normal or Low, Free T₃ Low

Any acute severe medical illness or trauma can cause a decrease in the level of T₃, and sometimes also T₄, in the absence of underlying thyroid gland pathology and with a normal TSH level. This condition is called the "sick euthyroid" or "euthyroid sick" syndrome. The more common form consists of a reduction in total T₃ and free T₃ with normal levels of TSH and T₄. The reduction of the T₃ level is proportional to the severity of the patient's medical illness, and it is thought to reflect impaired conversion of T₄ to T₃. Other very sick patients can present with significant reductions in total T₄ and free T₄ as well. This variant has a worse clinical outcome

than the one in which only T3 levels are low. The diagnosis can only be confirmed by resolution of the thyroid hormone abnormality when the patient recovers from the acute medical condition. The present consensus of endocrinologists is not to give supplementary thyroid hormone to euthyroid sick patients unless there is independent evidence to suggest they are actually hypothyroid.

The euthyroid sick syndrome is the result of complex mechanisms that combine the effect of some drugs, cytokines, nutritional, and endocrine factors at all levels of the thyrotropic axis from the hypothalamus to the cellular transporters and nuclear receptors of thyroid hormones. The pattern of this condition depends on the underlying disease and its severity. Thirty-five years after the initial description, the pathophysiological significance of these anomalies remains controversial. It remains unclear whether the hormone responses of the euthyroid sick syndrome represent an adaptive and normal physiologic response to conserve energy and protect against a catabolic state, or whether it is a maladaptive response contributing to a worsening of the patient's condition (Luca, Goichot, & Brue, 2010).

LITHIUM-INDUCED HYPOTHYROIDISM

TSH High, Free T4 Low

Among psychotropic drugs, lithium is the only one associated with alteration of thyroid function. Lithium induces a decrease in production of T4 from the thyroid gland, as well as interference with the conversion of T4 to T3. The American Psychiatric Association Practice Guidelines for the Treatment of Patients with Bipolar Disorder conclude that hypothyroidism will develop in 5% to 35% of patients with that disorder, usually within 6 to 18 months of lithium treatment initiation. The wide range of reported prevalence rates has been attributed to methodological differences across studies such as variable sample sizes, durations of lithium exposure, assays of varying sensitivity, and different cutoff points for diagnosis. The risk is higher in women (American Psychiatric Association, 2002).

Baseline thyroid function tests should be measured prior to starting lithium therapy to ensure that previously undetected thyroid dysfunction is not contributing to mood symptoms. Pertinent thyroid function tests include TSH and free T4 levels, as well anti-TPO and anti-TG antibodies if the TSH is elevated; presence of the latter implies a higher risk for clinical hypothyroidism and thus a need for closer monitoring. Subsequent monitoring of thyroid function tests is usually conducted 3 months after starting lithium and every 6–12 months thereafter; in addition, patients should be questioned regularly at outpatient visits about physical symptoms suggestive of hypothyroidism. The development of hypothyroidism in a patient on lithium is a reason to begin thyroid hormone supplementation, but not necessarily to discontinue lithium if the patient has done very well on it. Current practice guidelines do not specify criteria for managing thyroid

replacement therapy in patients with lithium-induced hypothyroidism; a reasonable target for T4 supplementation is bringing the TSH into the lower half of the normal range.

In the presence of elevated TSH levels without clinical signs of hypothyroidism, some societies recommend checking serum TSH levels every 3 months, without giving adjunctive thyroid hormone therapy unless TSH levels rise above 10 mU/L. Others advise thyroid supplementation whenever TSH levels rise above normal, particularly when mood symptoms are not in full remission. When lithium is discontinued, thyroid function can return to normal but it does not always do so, and even when it does it may take up to 2 years. If a patient is begun on T4 replacement and lithium is discontinued, the patient's need for thyroid replacement, and the appropriateness of the dose of T4, should be reassessed annually and whenever a change in symptoms suggests the possibility of thyroid excess or deficiency (American Psychiatric Association, 2002; Cowdry et al., 1983).

EFFECTS OF DEPRESSION ON THYROID FUNCTION TESTS

Depression can be accompanied by subtle thyroid dysfunction. Patients presenting with depression rarely have frank clinical hypothyroidism—the maximum reported prevalence is 4%; in a specific clinical population the rate will be higher if patients are relatively older and there is a higher proportion of women in the sample. However, subclinical hypothyroidism has been found in as many as 40% of patients presenting with depression, depending on the clinical population sampled. Depression has been linked to an abnormal diurnal TSH rhythm as well, with an absent nocturnal increase, and in one study, patients with major depression (as opposed to nonmajor depression) had a lower basal TSH. About 25%–30% of patients with depression have a blunted TSH response to exogenous TRH. A possible explanation is that chronic TRH hypersecretion associated with depression leads to downregulation of pituitary TRH receptors. Supporting this hypothesis are reports of elevated Cerebrospinal fluid (CSF) concentrations of TRH in depressed patients (Wolkowitz & Rothschild, 2003; Bauer, Goetz, Glenn, & Whybrow, 2008). The blunting of TSH response to TRH occurs in a minority of cases, making it unsuitable as a diagnostic test for depression. Subtyping patients with depression according to their response to TRH stimulation has not proved helpful in predicting patients' response to antidepressant treatments (Bauer et al., 2008).

LABORATORY TESTS OF THE ADRENAL

The adrenal cortex produces two types of steroid hormones which are regulated by two different feedback loops. Glucocorticoids, of which cortisol is most important; is

regulated by a hypothalamic-pituitary-adrenal loop involving corticotropin releasing hormone (CRH) from the hypothalamus and adrenocorticotrophic hormone (ACTH) from the pituitary. Mineralocorticoids, of which aldosterone is most important, is regulated by a feedback loop involving the kidneys and the lungs, renin and angiotensin.

While neuropsychiatric symptoms as the sole manifestation of adrenal disorders is a rare occurrence, excess or deficiency of glucocorticoids usually entails mental and behavioral symptoms. When patients present with a combination of neuropsychiatric symptoms and general somatic symptoms and signs compatible with excess or deficiency of adrenal hormones, the laboratory evaluation of adrenal function is indicated. Measurement of serum cortisol is not, however, part of the routine laboratory screening of patients who present with changes in mood, behavior, or cognition; the presence of general somatic symptoms or physical signs characteristic of an adrenal disorder is the prompt for laboratory investigation. If a serum cortisol level has been recently measured, and it is known that it was drawn between 8 a.m. and 9 a.m., it can be compared with a normal range of 7 µg/mL to 25 µg/mL. Values <7 µg/mL suggest adrenal insufficiency, and values >25 µg/mL raise a concern of glucocorticoid excess. Table 6.2 lists the neuropsychiatric and general somatic manifestations of glucocorticoid excess and of adrenal insufficiency.

CUSHING'S SYNDROME (GLUCOCORTICOID EXCESS)

Cushing's syndrome is the clinical disorder that comes from prolonged exposure to inappropriately elevated plasma glucocorticoid levels. While glucocorticoids are often administered chronically for the treatment of allergic, autoimmune, inflammatory, or neoplastic disorders, the causes of endogenous excess of cortisol are rare. The differential diagnosis of endogenous Cushing's syndrome includes (1) excessive pituitary ACTH secretion, usually due to a pituitary adenoma (Cushing's disease); (2) adrenocortical carcinoma and other adrenal tumors; and (3) ectopic production of ACTH by malignancies (most commonly, small-cell carcinoma of the lung). In adults, Cushing's disease accounts for 60% to 70% of all cases, adrenal tumors for approximately 20%, and the ectopic ACTH syndrome for the remaining 10% to 20% (Ioachimescu & Hamrahian, 2013; Loriaux, 1990; Nieman et al., 2008).

Laboratory diagnosis of Cushing's syndrome is based on a combination of three findings: (1) excessive secretion of cortisol over a 24-hour period as indicated by an above-normal value of a 24-hour urinary free cortisol; (2) loss of normal diurnal variation in cortisol secretion as indicated by an elevated late-night salivary cortisol level; and (3) loss of feedback inhibition of the hypothalamic-pituitary-adrenal axis as indicated by failure of exogenous dexamethasone given at 11 p.m. to reduce the morning cortisol level (the low-dose

overnight dexamethasone suppression test (DST)). The relevant threshold values are (1) urinary free cortisol >200 µg/24 hours (551nmol/24h); (2) midnight salivary cortisol based on assay norms; and (3) 8 a.m. cortisol >50 nmol/L (or >2 µg/dL) the morning after 1 mg of oral dexamethasone at 11 p.m. the

previous evening. Salivary cortisol is in equilibrium with the free cortisol in the circulation. Thus, the finding of an elevated midnight salivary cortisol level on at least two separate occasions should raise concern about the possibility of Cushing's syndrome if the saliva sample was taken on a quiet, restful night. When values are on the borderline, or in situations where one of the three tests is abnormal and another is normal, the diagnosis can be confirmed by a standard low-dose dexamethasone suppression test; this is done by giving 0.5 mg of dexamethasone orally every 6 hours for 2 days, then measuring the 8 a.m. cortisol on the third day. The threshold value for abnormality is the same.

Once hypercortisolism is established, further tests are needed to determine the cause. These begin with measurement of serum ACTH. If the ACTH level is low or undetectable, the cause is in the adrenal itself, usually an adrenal adenoma. If the ACTH level is elevated or normal (which would be inappropriate if cortisol were high) the cause is either hypersecretion of ACTH by the pituitary or ectopic ACTH secretion, as by a hormone-secreting cancer. Excessive secretion of ACTH by a pituitary adenoma usually can be suppressed by giving dexamethasone 2 mg every 6 hours for 48 hours (the high-dose dexamethasone suppression test). ACTH secretion by malignant extrapituitary tumors is not suppressible by dexamethasone even at a high dose.

Some patients with major depression and some alcohol-dependent patients have adrenal test profiles indistinguishable from those of patients with mild Cushing's disease (i.e., Cushing's syndrome of pituitary origin). They have elevated cortisol levels and show suppression of cortisol production with high-dose dexamethasone but not with low-dose dexamethasone. Their endocrine abnormalities resolve with remission of their depression or with abstinence from alcohol. Further workup to establish whether the patient has Cushing's disease is done in collaboration with an endocrinologist; identification of a pituitary adenoma by an imaging procedure establishes the diagnosis.

ADDISON'S DISEASE (ADRENOCORTICAL INSUFFICIENCY)

Inadequate production of adrenal corticosteroids may result from a variety of primary adrenal disorders (Addison's disease) or be secondary to inadequate ACTH secretion (secondary adrenal insufficiency) (Dorin, Qualls, & Crapo, 2003). Addison's disease refers to insufficiency of glucocorticoids and mineralocorticoids and the associated clinical syndrome, rather than to a specific cause of adrenal damage or dysfunction. Destructive inflammation of the adrenal gland on an autoimmune basis is the leading cause, accounting for the majority of cases in developed countries. Other causes of adrenal insufficiency include infiltration of the adrenal with metastatic cancer; infections such as TB, syphilis, HIV, or disseminated fungal infections; and drugs such as ketoconazole, fluconazole, rifampin, and megestrol. Adrenal insufficiency keeps company with other autoimmune endocrine disorders like hypothyroidism, premature ovarian failure, Type I diabetes mellitus, and hypoparathyroidism. The

neuropsychiatric and general somatic symptoms and signs of adrenal insufficiency are shown in Table 6.2 above. Most are due to deficiency of glucocorticoids. Hypokalemia, which is secondary to mineralocorticoid deficiency, would be seen only in cases of Addison's disease but not in cases of secondary adrenal insufficiency. Hyperpigmentation of the skin, due to secretion of melanocortin synchronously with ACTH, is also exclusively of Addison's disease, in which ACTH secretion is mainly decreased.

Initial laboratory screening for adrenal insufficiency begins with an 8 a.m. serum cortisol level. If this is $<7 \mu\text{g/dL}$, further assessment is warranted. If the 8 a.m. serum cortisol is borderline low, or if there is reason to suspect atypical chronobiology of cortisol secretion (e.g., night shift work), a 24-hour urinary free cortisol should be obtained. A value of $<4 \mu\text{g}/24$ hours suggests adrenal insufficiency. Other laboratory tests that can help define adrenal status are (1) plasma ACTH, which is low in primary adrenal insufficiency and high in secondary adrenal insufficiency; (2) serum aldosterone, which is low in primary adrenal insufficiency but normal in secondary adrenal insufficiency; (3) plasma renin activity, which is high in primary adrenal insufficiency but normal in secondary adrenal insufficiency; and (4) DHEA and DHEA-S, which are low in both primary and secondary adrenal insufficiency.

The definitive diagnosis of primary adrenal insufficiency is based on proving that the adrenal gland does not adequately secrete cortisol even when vigorously stimulated by the pituitary. To do this, the patient is challenged in the morning with an intravenous dose of 250 μg of synthetic 1-24 ACTH (generic name *cosyntropin*, trade name Cortrosyn®). Serum cortisol is measured prior to the injection and at 30 and 60 minutes afterward. A normal adrenal gland will secrete sufficient cortisol to raise the serum concentration to $>20 \mu\text{g/dL}$ (550 nmol/L) over baseline; if this does not happen the adrenal function is insufficient.

Confirmation of the diagnosis of secondary adrenal insufficiency and determination of its cause requires a specialist endocrine evaluation that includes anatomic imaging (MRI unless there is a contraindication) of the pituitary-hypothalamic region. Depending on the context, it may be important in cases of central adrenal insufficiency to determine that the adrenal would be normally responsive to ACTH if secretion of the latter were normal. This can be confirmed with a low-dose cosyntropin test, which is performed in the same way as the cosyntropin test for Addison's disease except with a 1 μg dose of cosyntropin rather than with a 250 μg dose. A normal adrenal gland that has been underproducing cortisol solely because of insufficient ACTH will immediately secrete cortisol, producing a significant rise in the serum cortisol from baseline.

Treatment of Addison's disease usually requires both glucocorticoid and mineralocorticoid replacement. A typical glucocorticoid replacement regimen would be hydrocortisone, 20 mg in the morning and 10 mg in the late afternoon. A single morning dose of a more potent, longer-acting glucocorticoid such as prednisone (5.0–7.5 mg) is also effective. The only available oral mineralocorticoid preparation is

fludrocortisone (Florinef); the dose of this agent is adjusted for the individual patient based on blood pressure and serum potassium determinations. Patients with secondary adrenal insufficiency require only glucocorticoid replacement.

LABORATORY ASSESSMENT OF ADRENAL SUPPRESSION BY EXOGENOUS GLUCOCORTICOIDS

Exposure to supraphysiologic doses of glucocorticoids—more than 20 mg per day of prednisone or equivalent—for 2 weeks or more can cause clinically relevant suppression of the hypothalamic-pituitary-adrenal axis. While frank Addison's disease is unusual when exogenous glucocorticoids are withdrawn, exposure to long-term high-dose glucocorticoids causes a loss of adrenal reserve. This can cause a relative deficiency of glucocorticoids if the patient is challenged by acute illness, surgery, or trauma. This relative deficiency can manifest as hypotension, hypoglycemia, weakness and cognitive impairment, or even life-threatening adrenal crisis. It is unknown whether an episode of acute psychosis represents a stress that can precipitate signs of adrenal insufficiency in this context.

Adrenal reserve is assessed in the laboratory with a cosyntropin stimulation test; the procedures are identical to those used in assessing a patient for Addison's disease. If serum cortisol does not increase with a 250 μ g dose of cosyntropin, the adrenal gland is virtually unresponsive to ACTH and exogenous glucocorticoids will be necessary to cover periods of severe physiological stress. If the serum cortisol increases with a 250 μ g dose but not with a 1 μ g dose, there is a lesser degree of adrenal suppression; this would be seen in a recovering adrenal gland. While glucocorticoid supplementation at times of stress would still be indicated, the cortisol increase with the higher dose of cosyntropin is a positive prognostic sign. A cosyntropin stimulation test should be repeated every 3 months in a patient with adrenal insufficiency caused by exogenous glucocorticoids who is no longer receiving supraphysiologic doses or who has been switched to alternate-day therapy to permit recovery of adrenal function. Once the test normalizes, the patient will no longer need glucocorticoid supplementation.

LABORATORY ASSESSMENT OF CALCIUM METABOLISM

Too much or too little calcium can alter mental status, all the more if the change in calcium is rapid. Because serum calcium is measured routinely as part of blood chemistry screening panels, it is unusual for diagnoses of parathyroid disorders to be missed in patients receiving regular medical care. Extreme values of calcium are encountered in two situations: (1) patients with rapidly increasing calcium, for example, cancer patients with multiple bony metastases; and (2) patients with hyperparathyroidism who have not received general medical care, for example, homeless patients with chronic mental illness who have deliberately avoided health professionals. Medical psychiatrists typically see patients with mild to moderate abnormalities of serum calcium and parathyroid hormone (PTH) and are asked to assess the

relevance of those abnormalities to the patient's current mental and behavioral symptoms.

Primary hyperparathyroidism is characterized by hypercalcemia and low phosphate due to excessive PTH secretion, usually due to a parathyroid adenoma, more often in women than men. Fifteen percent of cases are due to parathyroid hyperplasia. Cancer causes hypercalcemia when osteoclastic metastases leach calcium from bone or when a PTH-like substance is produced by the tumor. The most common cancers associated with hypercalcemia are lung, breast, multiple myeloma, renal, cervix, and head and neck.

Other causes include hyperthyroidism, sarcoidosis (and other granulomatous diseases), vitamin A and vitamin D intoxication, immobilization, drugs (thiazides, lithium), Addison's disease, familial hypocalciuric hypercalcemia, and acute renal failure with rhabdomyolysis (Inzucchi, 2004).

SYMPTOMS AND SEVERITY OF HYPERCALCEMIA

The severity of the symptoms of hypercalcemia parallels the severity of the serum calcium level, the rate of the increase, and the overall health condition of the patient. A screening serum calcium often calls attention to this diagnosis; there should be a low threshold in patients presenting with the symptoms and signs in Table 6.3.

The clinical symptomatology is minimal for most of the patients with mild hypercalcemia (levels greater than the normal serum calcium level but <12 mg/dL [3.0 mmol/L]), although some report mild fatigue, depression, constipation, mild polyuria, mild increase in thirst, or vague changes in cognition.

Typical manifestation of hypercalcemia are more common with serum calcium levels of 12 mg/dL to 14 mg/dL [3.0–3.5 mmol/L] and include anorexia, nausea, abdominal pain, muscle weakness, and depressed mental status.

At serum calcium levels greater than 14 mg/dL (3.5 mmol/L), lethargy, disorientation, and coma may occur.

EVALUATION OF ETIOLOGY OF HYPERCALCEMIA

The diagnosis of hypercalcemia would require a comprehensive medical history, physical exam, laboratory work and occasionally imaging studies. Blood tests include: serum calcium, serum PTH, ionized calcium, phosphorus, and serum creatinine levels (Sheppard & Smith, 2007).

Relation of Calcium to Albumin

It is always appropriate and standard of care to calculate serum calcium corrected for the hypoalbuminemia level, especially in patients with conditions such as malnutrition, nephritic syndrome, cirrhosis, chronic obstructive pulmonary disease, or chronic congestive heart failure. The measured serum calcium level should be corrected for a low albumin level by adding 0.8 mg/dL (0.2 mmol/L) of calcium for each 1 g/dL (10 g/L) of albumin that a patient's serum is <4 g/dL. An accurate ionized calcium measurement will help on these cases; however,

Table 6.3 NEUROPSYCHIATRIC AND SOMATIC SYMPTOMS/SIGNS OF HIGH AND LOW CALCIUM

CONDITION	NEUROPSYCHIATRIC SYMPTOMS	SOMATIC SYMPTOMS/SIGNS
<i>Hypercalcemia</i>

ionized calcium samples must be drawn under anaerobic conditions and kept on ice for accurate results. Additionally, the availability and cost of this test somewhat limit this decision.

calcium level is usually adequate; ionized calcium samples must be drawn under anaerobic conditions and kept on ice for accurate results.

FACTITIOUS HYPERCALCEMIA

Total Calcium Elevated, Ionized Calcium Normal

When an elevated serum calcium is detected, factitious hypercalcemia caused by elevated levels of the plasma proteins that bind calcium (such as in HIV infection, chronic hepatitis, and multiple myeloma) is a consideration. The ionized calcium level is normal on these patients.

FURTHER EVALUATION OF HYPERCALCEMIA

After the first test confirms hypercalcemia, the following recommendation is the simultaneously measurement of serum PTH and serum plasma ionized calcium levels. In the absence of plasma protein abnormalities, obtaining a total serum

Serum Calcium High, PTH High or Normal

With normal parathyroid glands, hypercalcemia will suppress PTH. If the serum calcium level is elevated and the PTH level is high or inappropriately normal, the diagnosis of PTH-mediated hypercalcemia or primary hyperparathyroidism is made.

There are indications for surgical intervention in patients with primary hyperparathyroidism: increase in serum calcium level >1 mg/dL (0.25 mmol/L) above upper limit of normal in otherwise asymptomatic patients; creatinine clearance <60 ml/min (0.06 L/min) in asymptomatic patients; T-score (Bone Density Scan [DXA] or bone densitometry) of -2.5 or worse at the lumbar spine, total hip, femoral neck, or distal radius; or age <50 years. Surgery is also indicated in patients in whom medical surveillance is neither desired nor possible, including

those with significant bone, kidney, gastrointestinal, or neuromuscular symptoms typical of primary hyperparathyroidism (Bilezikian, Khan, & Potts, 2009; Inzucchi, 2004).

HYPOPARATHYROIDISM

Low Calcium, High Phosphate, Low PTH,
Normal Albumin

Hypoparathyroidism occurs most commonly due to surgical damage to the parathyroids during surgery for head and neck cancer or thyroid surgery, or neck irradiation. Other causes are rare and include parathyroid aplasia; infiltration by amyloid, sarcoid, or hemochromatosis; and autoimmune disease.

Low Calcium, Low Magnesium

Magnesium facilitates function of the parathyroid hormone, so conditions associated with magnesium deficiency such as poor nutrition, malabsorption, alcoholism, or renal tubular wasting from cisplatin treatment may be contributing factors.

Low Vitamin D

Vitamin D deficiency contributes to hypocalcemia. The vitamin deficiency may be due to chronic renal failure, inadequate sunlight, or intake.

Acute Pancreatitis Is Associated with Low Calcium

Acute symptomatic hypocalcemia should be treated with intravenous calcium gluconate. Chronic hypocalcemia due to hypoparathyroidism is treated by administration of oral calcium and if unsuccessful, vitamin D supplementation.

DISORDERS OF GLUCOSE METABOLISM

DIABETES MELLITUS

Diabetes mellitus, a chronic metabolic disease characterized by increased circulating blood glucose levels, results from the inadequate supply or action of insulin. Several distinct types of diabetes mellitus are caused by a complex interaction of genetics and environmental factors. Diabetes mellitus is diagnosed in most patients on the basis of their fasting glucose level. The more sensitive oral glucose tolerance test is less frequently performed, although it remains a standard way to diagnosed diabetes during gestation. A diagnosis of diabetes also can be made if a random plasma glucose level equals or exceeds 200 mg/dL (11.1 mmol/L) in the setting of symptomatic hyperglycemia, such as polyuria, polydipsia, or blurred vision. The hemoglobin A1c value is a long-term (2–3 months) marker of glycemic control. The American Diabetes Association additional *criteria for diagnosis of diabetes* is A1c ≥ 6.5 , fasting plasma glucose ≥ 126 mg/dL. The patients at increased risk for diabetes who meet criteria for prediabetes have a fasting plasma glucose of 100 mg/dL to 125 mg/dL or a Hgb A1c

5.7–6.4. With an oral glucose tolerance test, prediabetes as defined by the plasma glucose may be 140 mg/dl (7.8 mmol/L to 199 mg/dL (American Diabetes Association, 2013).

HYPOGLYCEMIA

Hypoglycemia is a syndrome best defined by the following triad of clinical findings (Whipple’s triad): (1) characteristic symptoms, (2) plasma or serum glucose concentration <50 mg/dL, and (3) reversal of symptoms by glucose administration. As a general rule, this means glucose levels <55 mg/dL (3.0 mmol/L) with clinical symptomatology that is relieved promptly after the glucose level is raised (Cryer et al., 2009). The symptoms of hypoglycemia are described in Table 6.4.

FACTITIOUS HYPOGLYCEMIA

The presence of anti-insulin antibodies or low C-peptide levels at the time of hypoglycemia strongly suggests a factitious etiology like surreptitious injection of insulin (Horwitz, 1989). Insulin from the pancreas is secreted as proinsulin and broken into insulin and C-peptide. C-peptide has no biological activity. Screening of urine or blood for sulfonylureas is available for patients suspected of surreptitious oral hypoglycemic agent ingestion.

In the 1970s and 1980s, hypoglycemia was overdiagnosed (Cahill & Soeldner, 1974; Gastineau, 1983; Nelson, 1985). Reactive hypoglycemia became a fashionable diagnosis to account for a variety of poorly defined physical and psychological ills including depression, anxiety, fatigue, sexual dysfunction, and overall loss of vitality (Yager & Young, 1974).

Table 6.4 NEUROPSYCHIATRIC AND SOMATIC
MANIFESTATIONS OF HYPERGLYCEMIA AND
HYPOGLYCEMIA

Hyperglycemia	Neuropsychiatric Symptoms	Somatic Symptoms/ Signs
	fatigue, anorexia, weakness, cognitive impairment, blurred vision	Polyuria
	delirium, depression, neuropathic pain	Excessive thirst
	coma	Sweet craving
		Dehydration
		Infection
Hypoglycemia	Cognitive impairment, somnolence, anxiety, tremor, weakness, hunger, irritability, feeling faint, lethargy, confusion, dizziness, weakness, incoordination, bizarre behavior, change in personality, seizures, coma	Sweating
		Hyperventilation
		Palpitations
		Headache,
		Blurred Vision
		Slurred speech
		Hemiparesis

Although most common in type 1 diabetes mellitus, severe hypoglycemia also can occur in type 2 diabetes in patients who are taking insulin or drugs (such as sulfonylureas and meglitinides) that stimulate the release of insulin. Patients may be taking too large a dose of insulin, delaying or skipping a meal, eating fewer carbohydrates than normally, or exercising more than usual. The sulfonylureas vary mostly in dose and half-life. Those with long half-lives, such as glipizide extended release and glyburide, can cause profound, prolonged hypoglycemia, especially in older patients and patients with impaired renal function.

Hypoglycemia is rare in non-diabetic individuals because healthy persons have adequate mechanisms for maintaining glucose homeostasis (metabolism). Alcohol ingestion is a potential factor for hypoglycemia because affects hepatic glycogen stores directly. At the same time, alcohol intoxication can make the symptoms of hypoglycemia harder to recognize.

An important issue in the psychopharmacological management of patients with hypoglycemia is the risk of beta-blocker therapy. Early misdiagnosis of an anxiety disorder and treatment with agents whose action blocks the normal response to hypoglycemia may prevent subjective experience of potentially lethal hypoglycemia.

Fasting hypoglycemia has other less common causes including insulin-secreting islet cell tumors of the pancreas, large non-islet-cell tumors, severe liver or renal disease, adrenal insufficiency, hypopituitarism, severe inanition, autoimmune disorders associated with antibodies to insulin or to the insulin receptor, and drugs or toxins (Cryer et al., 2009).

DISORDERS OF PITUITARY FUNCTION

Both the excess and deficiency of pituitary hormones are associated with neuropsychiatric as well as general somatic symptoms. Disturbances in the secretion of ACTH have neuropsychiatric effects through an influence on adrenal hormones, and TSH has its influence on thyroid hormone secretion. Similarly, luteinizing hormone (LH) and follicle stimulating hormone (FSH) influence the production of sex hormones by the ovary and testis; growth hormone influences the production of IGF-1 (somatomedin C) by the liver. For this reason, laboratory testing of levels of pituitary hormones is typically accompanied by testing of the associated hormones in the target organs. Prolactin is the only exception.

The most common causes of pituitary hypersecretion are hormone-secreting tumors, mostly histologically benign adenomas. Adenomas secrete only one pituitary hormone; it is thus possible for a patient with a pituitary adenoma to have an excess of one pituitary hormone and a deficiency of another one. Nonsecreting pituitary adenomas can cause deficiencies in pituitary hormones by displacing normal secreting cells. Panhypopituitarism, a simultaneous deficiency of all of the pituitary hormones, can be caused by a vascular insult to the entire pituitary.

ACROMEGALY

Age-matched and sex-matched serum IGF-1 levels are elevated in acromegaly. Consequently, an IGF-1 level provides a useful laboratory screening measure when clinical features raise the possibility of acromegaly. Due to pulsatility of GH secretion, measurements of a single random GH level is not useful for the diagnosis or exclusion of acromegaly and does not correlate with disease severity (Molitch et al., 2006; Webb et al., 2012; Melmed, 2006).

HYPERPROLACTINEMIA

Prolactin, the pituitary hormone that stimulates breast development and lactation, is the hormone most commonly secreted by hormone-secreting pituitary adenomas. Prolactin secretion is tonically inhibited by dopamine; it is stimulated by TRH. Dopamine antagonist drugs raise prolactin levels, with first-generation antipsychotic drugs like haloperidol and fluphenazine having particularly potent effects and risperidone the most likely of the atypical antipsychotics to raise prolactin. Metoclopramide, a dopamine agonist used for gastrointestinal rather than psychiatric indications, also raises prolactin levels. Other drugs associated with increased prolactin levels include opiates, verapamil, cimetidine, and estrogen-containing oral contraceptives. In a minority of cases, primary hypothyroidism increases prolactin levels presumably because of increased hypothalamic TRH secretion. Moderate elevation of prolactin levels can be seen in liver failure and in renal failure.

Prolactin levels rise following convulsive seizures and may double from baseline in the 10–20 minutes after a suspected event. This test may be a useful adjunct to differentiate generalized tonic-clonic or complex partial seizure from psychogenic nonepileptic seizure among adults and older children. It does not distinguish seizure from syncope (Chen, So, & Fisher, 2005). Finally, prolactin levels are elevated during lactation (initially as high as 300 when the mother has maximum estrogen priming, but later in lactation only minimally elevated)—and can be elevated by frequent nipple stimulation even in the absence of lactation (Snyder & Cooper, 2013).

Although there are many potential causes of an elevated prolactin, extremely high prolactin levels are virtually always due to pituitary tumors. An increase in prolactin level beyond the range explainable by any of a patient's current drug and medical conditions, (about 200 mg/L) is strongly suggestive of a pituitary tumor and should trigger a full work-up including imaging of the pituitary and testing of the other pituitary hormones.

Hyperprolactinemia is considered the most common pituitary hormone hypersecretion syndrome in both men and women. The pituitary adenomas (prolactinomas) are the most common cause of elevated serum prolactin levels (PRL levels >200 ug/L). Other etiologies include pregnancy, lactation, sleep, stress, systemic disorders, and drug-induced hypersecretion. Hyperprolactinemia in women is manifested by galactorrhea, irregular menses, and infertility. Men usually have no physical symptoms but both genders may experience reduced libido, depression, and anxiety (Levenson, 2006).

The decrease in serum prolactin levels with treatment in women with prolactinomas is usually associated with a return of normal ovulatory menstrual cycles and cessation of galactorrhea. Fertility is generally restored, and many of these women experience perfectly normal term pregnancies. Careful monitoring for symptoms of pituitary expansion during pregnancy is essential, although complication rates in women with microadenomas are low. Normalization of serum prolactin concentrations in men similarly results in restoration of normal gonadal function, assuming there is no impairment of gonadotropin secretion from the primary pituitary tumor.

In most centers, initial therapy for prolactinomas is medical, with either bromocriptine or cabergoline. Transsphenoidal surgery is usually reserved for patients with rapidly enlarging pituitary tumors or patients not responding to or unable to tolerate the side effects of ergot alkaloid therapy.

GONADOTROPINS

Hormone-secreting pituitary tumors rarely secrete the gonadotropins LH and FSH; pituitary tumors are more likely to cause a decrease in these hormones. In women the most common reason for significant elevation of FSH is ovarian failure, whether due to menopause, surgical removal of the ovaries, or autoimmune disease. The most common reason for elevation of LH is the LH surge associated with ovulation. In men, elevation of FSH and elevation of LH occur together as a response to primary testicular failure, an age-associated condition. Low values of LH and FSH are seen in various conditions that affect fertility, including polycystic ovary syndrome. These conditions are discussed in detail in chapter xx. The neuropsychiatric and general somatic effects of these hormones are via their effects on the ovaries and testes rather than direct ones. Alterations in gonadotropin secretion are suggested by changes in the female menstrual cycle and by changes in libido and/or fertility in either sex.

When testing pituitary gonadotropins in menstruating women, it is optimal to draw the sample on day 5–7 of the menstrual cycle prior to the LH surge associated with ovulation. Levels of LH and FSH can be tested at any time in men or in postmenopausal women. In men, measurement of the LH and FSH should be accompanied by a free testosterone level. A low testosterone level with an elevated LH and FSH suggests primary testicular failure; if both LH and testosterone are low, there is dysfunction of either the hypothalamus or the pituitary. The distinction can be made by challenging the patient with a 50mg oral dose of clomiphene, a drug that stimulates the secretion of gonadotropin-releasing hormone by the hypothalamus. If pituitary gonadotropin secretion is intact, the LH level will rise significantly.

MALE HYPOGONADISM

The measurement of the serum total testosterone, free plus protein-bound and typically ranging from 300 ng/dL (10.4 nmol/liter) to 800 ng/dL, is the usual measure of this

hormone. It is best drawn at 8 a.m. and repeated once or twice if not declarative, in order to guide the evaluation of male hypogonadism (Brambilla, Matsumoto, Araujo, & McKinlay, 2009). Testosterone levels can vary quite a bit from day to day, and the level, especially in young men, is higher in the morning.

Free testosterone is suggested if the measurement is at the lower limit of normal or if there is a condition likely to alter sex hormone-binding globulin. Conditions which change the concentration of sex hormone-binding globulin and make the free testosterone level more valuable include liver disease, severe systemic illness, and corticosteroid treatment (Manni et al., 1985; Mayo, 2013). Testosterone binding is reduced in proportion to obesity. Older men may have slightly increased binding to sex hormone-binding globulins.

The equilibrium dialysis method in dedicated laboratories is the standard for measuring free testosterone. Free testosterone by an analog method, commonly offered in hospitals and commercial laboratories, is not reliable; and indirect calculations of free testosterone should be checked against norms of the measuring laboratory (Snyder, Matsumoto, Kirkland, & Martin, 2013).

An understanding of male hypogonadism requires a review of the two major functions of the testes: secretion of testosterone and production of sperm. Hypogonadism refers to a deficiency of either or both of these essential functions. Inadequate sperm production alone usually presents as infertility, whereas the consequences of testosterone deficiency depend on the stage of sexual development of the patient. An excellent review of this complex area has been published (Bhasin et al., 2006).

Hypogonadal disorders in men can generally be grouped into those associated with diseases involving the testes directly (primary hypogonadism) and those associated with disorders of the hypothalamic-pituitary axis (secondary hypogonadism). In teenage boys, testosterone deficiency is characterized by failure of normal secondary sexual characteristics to develop (i.e., delayed puberty). In postpubertal males, testosterone deficiency is accompanied by symptoms including decreased libido and energy, sexual dysfunction, and decreased body hair and muscle mass.

Primary gonadal failure is typically associated with elevated serum gonadotropin concentrations and is therefore referred to as hypergonadotropic hypogonadism. The testosterone is low, and FSH and LH are high. The most common cause of this disorder in young men is Klinefelter's syndrome, associated with an abnormal chromosomal constitution of 47,XXY. Other causes of primary gonadal failure include myotonic dystrophy, mumps orchitis, testicular trauma or irradiation, and autoimmune testicular failure. Uremia and chronic alcohol abuse have features suggestive of both primary and secondary hypogonadism.

Hypogonadotropic hypogonadism may be due to either primary pituitary or hypothalamic pathology. Pituitary causes include destructive pituitary tumors, prolactinomas (see above), hemochromatosis, sarcoidosis, therapeutic irradiation or surgery, and severe systemic illness. The classic hypothalamic cause of hypogonadotropic hypogonadism is Kallmann's

syndrome. This syndrome is characterized by a deficiency of the hypothalamic peptide gonadotropin-releasing hormone (GnRH). Patients with Kallman's syndrome present as prepubertal eunuchs with minimal development of secondary sexual characteristics. Associated features may include anosmia or hyposmia and cleft palate and lip. The treatment of prostate cancer with GnRH analogs such as leuprolide is another etiology for secondary hypogonadism. Hypogonadism can follow anabolic-androgenic steroid dependence.

Male hypogonadism of any etiology may cause significant psychological distress and impaired social adjustment. Low self-esteem and self-confidence and feelings of inadequacy, isolation and alienation are common. Male patients with recently acquired loss of libido and drive not explained by major depression or drugs deserve a screening testosterone level and attention paid to gonadal size on physical examination. If these screening measures suggest hypogonadism, further workup is indicated.

An appropriate *initial* diagnostic evaluation of a patient with suspected hypogonadism should include a careful history and physical examination, focusing on the disorders outlined above. The degree of sexual development, testicular size, and evidence of pituitary dysfunction should be the focus of the physical examination.

Laboratory studies should include a serum testosterone, gonadotropin levels (LH and FSH), and a serum prolactin level. The results of these studies should define the level of the primary pathologic disturbance (i.e., a primary testicular disorder versus a central abnormality in hypothalamic-pituitary function). Patients falling into the latter category usually require radiographic imaging of the pituitary either by CT scanning or MRI. All patients with hypogonadism should be referred for further endocrinologic investigation. Appropriate therapy for testosterone deficiency is either a long-acting injectable testosterone preparation such as testosterone enanthate, or one of the new transdermal testosterone patches, gel and buccal mucosa lozenges (Bolton, 2007). Oral androgens are not the agents of choice for hypogonadal men, as they are less effective in restoring normal virilization and have considerably greater toxicity (see below). Hypogonadotropic hypogonadal men desiring fertility should be treated with clomiphene, gonadotropins or pulsatile GnRH rather than with androgens.

Androgen/testosterone replacement therapy in men should be initiated only after the possibility of occult prostate cancer has been eliminated.

The amount of testosterone required to maintain lean mass, fat mass, strength and sexual function varies widely in men. The diagnosis of androgen deficiency had been based on a single laboratory criterion: a testosterone level more than two standard deviations below the mean in normal young men; however, the dose required to prevent adverse changes varies considerably. Most of the estradiol of men (80%) results from aromatization of testosterone. It turns out that both deficiency of testosterone and deficiency of estradiol contribute to decline of sexual function in men. Estrogen deficiency also contributes to an increase in fat accumulation (Finkelstein et al., 2013).

Recent guidelines for testosterone therapy in adult men with androgen deficiency syndromes by the Endocrine Society suggest that only men with consistent symptoms and signs and unequivocally low serum testosterone levels be treated. The treatment is based on an initial test of morning total testosterone level, and in some patients free testosterone level. Testosterone in these cases improves sense of well being, muscle mass and strength, bone mineral density, and sexual function. Contraindications are breast or prostate cancer, a prostate nodule or PSA greater than 3 ng/ml if without urologic intervention, erythrocytosis, hyperviscosity, obstructive sleep apnea, lower urinary symptoms, or class III or IV heart failure. The goal is a mid-normal range testosterone incorporating the patient's preference and managed with a standardize plan of follow-up (Bhasin et al., 2006).

The relationship between aging-related testosterone deficiency and late-onset hypogonadism has been unclear. A recent study has suggested that late-onset hypogonadism may be defined by the presence of at least three sexual symptoms associated with a total testosterone level of less than 11 nmol per liter (3.2 ng per ml) and a free testosterone level of less than 220 pmol per liter (64 pg per ml) (Wu et al., 2010). Psychological symptoms do not parallel testosterone level, but loss of physical vigor does. This study suggested that the requirement of the presence of at least three sexual symptoms with a total testosterone level of less than 11 nmol per liter and a free testosterone level of less than 220 pmol per liter was appropriate for testosterone replacement, as had been suggested in practice guidelines.

PANHYPOPITUITARISM

A number of medical conditions (tumor like craniopharyngioma, macroadenoma, breast metastases, infarct, infiltrative diseases such as hemochromatosis,) can cause diffuse damage to the pituitary gland, with decreased secretion of all of the pituitary hormones. This leads to hypothyroidism, hypoadrenalism, hypogonadism, and growth hormone deficiency all at once. Patients with panhypopituitarism have a chronically ill appearance and show the neuropsychiatric symptoms of apathy, dysphoric mood, and cognitive impairment. A presentation of a patient with multiple somatic symptoms and prominent apathy in the context of one of the predisposing conditions should lead to laboratory testing for panhypopituitarism. An adequate screening test panel would include serum levels of TSH and free T₄, cortisol (drawn at 8–9 a.m.), and, if the patient is male, a free testosterone. A low cortisol level would be followed up with an ACTH level, and a low testosterone would be followed up with an LH level to confirm a problem at the level of the pituitary or above. Anatomic imaging of the pituitary-hypothalamic region would then help identify the cause of the problem.

Hormone replacement in panhypopituitarism conventionally has included replacement of T₄, cortisol, and testosterone or estrogen. Replacement of growth hormone is done less consistently. Measuring the serum level of IGF-1 can be useful in making the decision about growth hormone

replacement. A very low or absent level of IGF-1 and residual mental and physical symptoms after replacement of thyroid, adrenal, and gonadal hormones suggests value in a trial of GH replacement with careful monitoring of symptoms potentially attributable to GH deficiency.

PHEOCHROMOCYTOMA

Pheochromocytomas are rare catecholamine-secreting tumors that arise most often from chromaffin tissue of the adrenal medulla. While most patients with pheochromocytomas are hypertensive, hypertension is endemic and pheochromocytomas are rare; routine testing of hypertensive patients for pheochromocytoma is not warranted. Patients with hypertension should have a laboratory evaluation for pheochromocytoma if they have one or more conditions that raise the likelihood of their having the condition well above the population base rate. These conditions are (1) hypertension refractory to standard, stepped antihypertensive drug therapy and not explained by renal artery stenosis or by another endocrine disorder; (2) paroxysmal hypertension accompanied by headache, sweating, tremor, and other signs of sympathetic overactivity; (3) hypertension associated with hypermetabolism (e.g., weight loss despite increased caloric intake); (4) a personal history of associated disorders such as neurofibromatosis, tuberous sclerosis, Sturge-Weber syndrome, or multiple endocrine neoplasia; or (5) pheochromocytoma or an associated condition in a first-degree relative. About 10% of patients with pheochromocytomas do not have hypertension at all but do have discrete episodes of symptoms of sympathetic overactivity, including paroxysmal sweating and paroxysmal atrial tachycardia or fibrillation or ventricular tachycardia.

The most sensitive test for pheochromocytoma is a random plasma free metanephrine level. Because it is less specific than 24-hour urine studies, it is best done in patients where the clinical suspicion is already high. A less sensitive but more specific test should be used when clinical suspicion is low, or to confirm the diagnosis when the plasma metanephrine level is somewhat elevated but is inconclusive. That test is a 24-hour urine for catecholamines and metabolites (Pacak et al., 2007).

Table 6.5 NEUROPSYCHIATRIC AND SOMATIC SYMPTOMS OF PHEOCHROMOCYTOMA

NEUROPSYCHIATRIC SYMPTOMS	SOMATIC SIGNS
Panic attacks	Refractory hypertension
Headaches	Orthostatic hypertension
Palpitations	Paroxysmal hypertension
Visual blurring	Pallor and flushing
Especially as episodes (Spells)	Atrial tachycardia or fibrillation

Once the chemical diagnosis of pheochromocytoma is made, the tumor(s) must be located. Most can be found on an MRI of the adrenal region. Tumors not found on MRI will be picked up on scintigraphy using radiolabeled metaiodobenzylguanidine.

ENDOCRINE SCREENING IN PATIENTS WITH WEIGHT LOSS AND FAILURE TO THRIVE

Weight loss in *hyperthyroidism* is due primarily to increased catabolism, but other causes include increased intestinal motility and malabsorption. Most patients have hyperphagia. In older patients, however, hyperthyroidism often causes anorexia with accelerated weight loss. The average weight loss in a patient with hyperthyroidism is 16% of usual body weight (Hoogwerf & Nuttall, 1984). Weight gain occurs quickly with treatment.

Uncontrolled diabetes mellitus is a common cause of weight loss with increased appetite, particularly with new-onset type 1 diabetes mellitus. There is a loss in lean body mass as well as loss of extracellular and cellular water due to the osmotic diuresis from glucosuria. The etiology of weight loss in uncontrolled diabetes is likely multifactorial—a combination of anorexia, depression, pain, malabsorption, gastroparesis, and enteropathy. Some reports describe persons who intentionally undertreat their diabetes in order to lose weight (Rodin & Daneman, 1992). Although patients with poorly controlled or undiagnosed type 2 diabetes can occasionally present with weight loss, weight gain is much more common. However, some patients with type 2 diabetes can occasionally present with diabetic neuropathic cachexia, an unusual and poorly understood syndrome characterized by profound weight loss (as much as 60% of body weight) and often severe neuropathic pain of the anterior thighs (Neal, 2009). The pathophysiology is not clear, especially since there is no strong relationship between glucose control and resolution of weight loss, which usually happens spontaneously after months or years.

Chronic *primary adrenal insufficiency* often presents with significant weight loss, although other associated signs and symptoms are more prominent: dehydration, anorexia, lassitude, fatigue, and weakness. Adrenal insufficiency that is acute or due to hypothalamic or pituitary dysfunction is usually not associated with weight loss (Dorin, Qualls, & Crapo, 2003).

Anorexia, nausea, constipation, and polyuria may account for weight loss in patients with the classic clinical manifestations of *hyperparathyroidism*. However, the majority of patients with primary hyperparathyroidism are asymptomatic and do not have weight loss (Bolland, Grey, Gamble, & Reid, 2005).

The hyperadrenergic state among patients with *pheochromocytoma* would theoretically cause weight loss with increased appetite, but only 5% of patients with pheochromocytomas report weight loss (Goldstein et al., 1999).

Table 6.6 BASIC PSYCHIATRIC SYNDROMES THAT CAN BE CAUSED BY ENDOCRINE ABNORMALITIES

	DEPRESSION	MANIA	PSYCHOSIS	DELIRIUM	DEMENTIA	WEIGHT LOSS
<i>TSH</i>	<i>X</i>	<i>X</i>	<i>X</i>	<i>X</i>	<i>X</i>	
<i>Calcium</i>	<i>X</i>	<i>X</i>	<i>X</i>	<i>X</i>	<i>X</i>	
<i>PTH</i>	<i>X</i>	<i>X</i>	<i>X</i>			
<i>Cortisol</i>	<i>X</i>	<i>X</i>	<i>X</i>	<i>X</i>		<i>X</i>
<i>ACTH</i>	<i>X</i>	<i>X</i>	<i>X</i>	<i>X</i>		<i>X</i>
<i>Glucose</i>	<i>X</i>	<i>X</i>		<i>X</i>		
<i>IGF-1</i>	<i>X</i>	<i>X</i>	<i>X</i>			
<i>Prolactin</i>	<i>X</i>					
<i>Testosterone</i>	<i>X</i>					

Delirium, depression, and dementia are the most common conditions affecting cognitive status in older adults. The evaluation of any patient with failure to thrive (FTT) should include an evaluation to identify signs or symptoms of delirium, dementia, and depression. These conditions may result from medical comorbidities and medication effects; each may also contribute to the development of disability, malnutrition, and frailty. Dementia and depression were among the five leading causes of FTT in a case series of inpatients admitted with FTT (Hildebrand, Joos, & Lee, 1997).

BASIC ENDOCRINE SCREENING TESTS

There is scant empirical cost-benefit evidence to inform the laboratory work-up for depression. For patients at higher risk of underlying medical illness, consideration should be given to assessing TSH sensitive level and fasting serum glucose level.

Psychosis could be secondary to a medical condition. A large number and variety of medical conditions (Patkar, Mago, & Masand, 2004) and endocrine dysfunctions may lead to psychotic symptoms, including thyroid, parathyroid, or adrenal abnormalities. Screening tests should include TSH sensitive, PTH, serum calcium level, cortisol and ACTH levels.

A number of endocrine laboratory tests may be considered in the patient with delirium. However, the desire for diagnostic completeness can increase costs and possibly delay the prompt treatment of more obvious disorders. Targeted testing is appropriate in most instances, especially in the elderly: glucose, calcium and thyroid function tests could be initially included in the preliminary assessment.

The American Academy of Neurology (AAN) recommends screening for hypothyroidism in patients with dementia (Knopman et al., 2001). There are no clear data to support or refute ordering “routine” laboratory studies such as a complete blood count, electrolytes, glucose, and renal and liver function tests. The cost effectiveness of obtaining multiple laboratory studies in all patients is questioned because the yield is low (Weytingh, Bossuyt, & van Crevel, 1995) (see Table 6.6).

CLINICAL PEARLS

- TSH responses to levothyroxine replacement are gradual and should be measured at about 2 months after initiating treatment and a similar period after any subsequent change in dosage.
- A patient with a TSH >10.0 mIU/L would be treated for hypothyroidism despite a normal free T4 and free T3 and the lack of the typical clinical syndrome.
- A TSH level with a free T4 level should be done when the clinical context and the combination of neuropsychiatric and other somatic symptoms increases the probability that secondary thyroid dysfunction is present; for instance, when there is a history of head trauma or brain radiation.
- A target range of approximately 1.0 μ U/mL to 2.5 μ U/mL (1.0–2.5 mU/L) seems appropriate for patients with defined thyroid disease receiving replacement levothyroxine.
- Factitious thyrotoxicosis due to self-administration of T4 or T3 can be established by measurement of the serum thyroglobulin (TG) level.
- Some patients with major depression and some alcohol-dependent patients have adrenal test profiles indistinguishable from those of patients with mild Cushing’s disease (i.e., Cushing’s syndrome of pituitary origin)
- The presence of anti-insulin antibodies or low C-peptide levels at the time of hypoglycemia strongly suggests a factitious etiology like surreptitious injection of insulin (Horwitz, 1989).
- The most sensitive test for pheochromocytoma is a random plasma free metanephrine level. Because it is less specific than 24-hour urine studies, it is best done in patients where the clinical suspicion is already high.

- Exposure to supraphysiological doses of glucocorticoids—namely, more than 20 mg per day of prednisone or equivalent—for 2 weeks or more can cause clinically relevant suppression of the hypothalamic-pituitary-adrenal axis.
- Hypogonadism can follow after patients stop anabolic-androgenic steroids taken for some time for body building.

NEUROIMAGING IN PSYCHIATRY

THE CLINICAL-RADIOGRAPHIC CORRELATE

David L. Perez, Laura Ortiz-Terán, and David A. Silbersweig

INTRODUCTION

Clinical psychiatry is a rapidly evolving field. Diagnostically, psychiatrists are trained to recognize symptoms such as negative affect, impulsivity, grandiosity, and thought disorder, and subsequently determine if symptoms “fit” into established diagnoses. Over the next few decades, structural and functional neuroimaging techniques currently used to research the neural correlates of psychiatric symptoms will likely identify adjunct neural biomarkers to confirm diagnosis and, more importantly, identify predictors of prognosis and treatment response. Furthermore, neuroimaging techniques help detect medical and/or neurological conditions that exhibit prominent behavioral, affective, and/or cognitive symptoms that resemble primary mental disorders.

In this chapter we review structural and functional neuroimaging techniques and discuss the clinical-radiographic correlates of common medical and neurological differential diagnoses with prominent neuropsychiatric symptoms. The neural circuits frequently implicated in psychiatric and neuropsychiatric conditions are also detailed, and the structural and functional neuroimaging abnormalities commonly found in schizophrenia, major depressive disorder (MDD), and posttraumatic stress disorder (PTSD) are briefly summarized. Lastly, the potential for neuroimaging to aid prognosis, treatment selection, and identify targets for neuromodulation are explored.

STRUCTURAL NEUROIMAGING TECHNIQUES

COMPUTED TOMOGRAPHY

Computed Tomography (CT) of the brain was the first modern neuroimaging technique, available for research in the late 1960s and used clinically by the 1970s. This technique utilizes an ionizing X-radiation tube that rotates axially around a patient with detectors positioned on the opposite side measuring the amount of radiation transmitted. Data acquired by the detectors is digitized to create an axial tomographic 2D image of the body. Importantly, bodily tissues have varying densities and differ in their ability to attenuate radiation. Distinct tissue densities are represented on a

black-and-white scale (see Table 7.1). The use of an iodinated contrast agent aids detection of vascular pathology and disorders that disrupt the blood brain barrier (i.e., metastatic tumors). Brain CT scans can be rapidly performed, are readily available, and may be particularly useful in identifying acute hemorrhage and bony lesions, but have limited spatial resolution, expose patients to radiation (0.5–8 mSv), and are prone to artifacts, particularly in the posterior fossa. Also, CT scans are relatively insensitive to acute ischemic stroke detection; a well visualized hypodensity may not be appreciable until more than 24 hours after symptom onset. Subtle ischemic changes such as sulcal effacement and loss of gray-white matter differentiation may be seen within the first few hours of stroke onset. Hyperdensity of the middle cerebral artery (MCA), known as a “dense MCA sign,” may indicate intra-arterial clot and provides supportive evidence of an acute ischemic stroke.

MAGNETIC RESONANCE IMAGING

The physical properties of hydrogen, one the most abundant elements in the human body, provide the basis for magnetic resonance imaging (MRI). Hydrogen has a single spinning proton with a positive charge that generates a magnetic field along its north/south axis. Normally the field surrounding a given hydrogen proton is oriented randomly in relation to neighboring hydrogen protons; however, when an external magnetic field (B_0) such as that from a MRI magnet is applied, protons align with the direction of the field in a parallel or antiparallel direction. In addition to this realignment, the individual hydrogen protons precess (change in the alignment of the rotational axis) at a frequency called the *Larmor frequency*. If a radiofrequency pulse is then directed into the tissue, spinning protons that are in a position of low energy or in parallel move into a position of high energy or antiparallel. This repositioning generates a transverse magnetic field. When the radio frequency pulse is switched off, protons reorient back to the original position and induce an electromagnetic field that is detected by a coil outside the tissue. This response is measured and analyzed to produce MR-based images. Variations in the Larmor frequency of individual protons enable the spatial characterization that distinguishes MRI from nuclear magnetic spectroscopy (Grossman & Yousem, 2003).

Table 7.1 BRAIN TISSUE CHARACTERISTICS ON COMPUTED TOMOGRAPHY (CT) AND MAGNETIC RESONANCE IMAGING (MRI)

	CT	T1	T2	DWI	FLAIR
Air	black	black	black	white (artifact)	black
Water/Cerebrospinal Fluid	black	black	white	black	black
Fat	black	white	black	**	black
Calcium	white	black	black	**	black
Blood (hyperacute <7 hours)	white	dark gray	light gray–white	white	light gray–white
Blood (acute 7–72 hours)	white	dark gray–gray	dark gray	dark gray	dark gray
Blood (subacute >72 hours)	light gray–gray	light gray–white	dark gray	dark gray	dark gray
Gray Matter	gray	gray	light gray	light gray	light gray
White Matter	dark gray	white	dark gray	gray	dark gray
Edema	dark gray–black	dark gray	white	white	white
Infarction hyperacute (0–6 hours)	*	gray	light gray	white	light gray
Infarction acute (6 hours–4 days)	dark gray	dark gray	white	white	white
Infarction subacute (4–14 days)	dark gray–black	dark gray	white	light gray–white	white
Infarction chronic	black	black	dark gray–black	gray	dark gray–black

DWI indicates diffusion weighted image; FLAIR, fluid attenuated inversion recovery.

*Indirect signs of infarction such as hyperdense arteries and loss of gray/white differentiation.

**indicates not consistently appreciated.

The appearance of the brain on MRI is dependent on acquisition properties that are described using parameters such as echo times and time repetition. These parameters create different sequences referred as *T1* and *T2* (see Table 7.2). On *T1* sequences, white matter consisting mainly of fat-rich myelinated axons appears white; gray matter structures such as cerebral cortex and the nuclei of the brainstem and diencephalon appear gray. *T2* sequences display as white brain regions with a high water content; a normal brain will show a pattern of gray and white inverse to that seen on *T1* sequences. Fluid attenuated inversion recovery (FLAIR) is a *T2*-based image that uses an inversion recovery pulse sequence to block cerebrospinal fluid signal. While *T2*-based sequences are useful at detecting parenchymal pathology such as prior infarcts, mass lesions, edema, and white matter demyelinating plaques, FLAIR images particularly aid the detection of periventricular abnormalities that may be obscured by cerebrospinal fluid signal on *T2* images. *T1* sequences are most useful in delineating brain anatomy (i.e., regional atrophy). The addition of gadolinium, a paramagnetic heavy metal that decreases the *T1* relaxation times of tissues when injected intravenously as a contrast agent, enhances lesions that disrupt the blood–brain barrier including acute demyelinating white matter lesions, vascular lesions, and high-grade glial tumors. In addition, susceptibility weighted imaging (SWI) is a magnetic resonance technique that employs a gradient echo pulse sequence that is particularly sensitive to venous blood, hemorrhage, and iron deposition (although insensitive to hyperacute blood). When

ordering a clinical MRI, while there are variations across institutions, standard brain MRI orders will almost always include *T1*, *T2*, and FLAIR sequences; however, the use of contrast, SWI, or diffusion sequences (discussed below) should be specifically requested based on the differential diagnosis.

Clinical radiologists, neurologists, and neuropsychiatrists mainly rely on visual inspection to identify pathology on CT or MRI brain scans. However, quantitative techniques for MRI interpretation originally devised for research are beginning to be used in clinical practice. *Manual volumetry* is a technique that combines manual tracing of regions of interest (ROIs) with calculations that estimate the volume of structures based on cross-sectional areas. While this technique is widely available, it is time consuming, operator dependent, and requires that operators have an exquisite familiarity with the neuroanatomy of the region(s) being imaged. A more convenient, automated approach is *Voxel-based morphometry* (VBM). In VBM, *T1*-based MRI sequences for a given cohort of subjects are spatially normalized to the same stereotactic space. During spatial normalization, distinct brains are deformed to correspond regionally to one another and enable cross-subject comparisons. Following normalization, an automated segmentation procedure subdivides the ROIs into voxels (cubes of brain tissue) and characterizes each voxel as comprised of gray or white matter. Thereafter, voxel-wise *statistical parametric mapping* (SPM) techniques are applied across groups to detect group differences (Ashburner & Friston, 2000). Analyses that label all of the voxels within a

Table 7.2 RELATIONSHIPS OF T1 AND T2 MRI SEQUENCES AND TIME REPETITION (TR) AND ECHO TIME (TE) ACQUISITION PARAMETERS

	TR	TE
T1	Short	Short
T2	Long	Long

brain image according to statistical test outcomes, called a *statistical parametric map*, may include whole brain comparisons or may be limited to a priori ROIs. In addition to volumetric analyses, techniques have also been devised to quantify variations in morphology (shape) as a complement to volumetric analyses (Csernansky et al., 1998). Clinically, since the specificity and sensitivity of these techniques are not yet well validated at the individual subject level, quantitative structural analyses currently only allow for the detection of significant group differences. However, technical advancements under investigation may allow these analyses to be applied to specific individuals in the future.

More recently, techniques have been developed to measure the cerebral cortex, a highly folded structure that does not lend itself well to manual tracings. Automated software aids the measurement of cortical gray matter thickness through the creation of inflated surface representations (Fischl & Dale, 2000) and has been validated against histological analysis (Rosas et al., 2002) and manual regional MRI measurements (Kuperberg et al., 2003; Salat et al., 2004).

DIFFUSION WEIGHTED IMAGING/DIFFUSION TENSOR IMAGING

Diffusion weighted imaging (DWI) and diffusion tensor imaging (DTI) are T2-weighted scans that rely on the detection and quantification of the random movement of water, also known as *Brownian movement*. While the displacement induced by one hydrogen molecule is not appreciable, their collective impact generates a significant and quantifiable displacement of a chaotic nature. In biological tissues, since molecular movement may be influenced by multiple variables including capillary microcirculation that cannot be readily measured, the term *apparent diffusion coefficient* (ADC) is used to describe diffusion-based images.

Diffusion weighted images are acquired in X, Y, and Z planes and are combined to produce DWI and ADC sequences. These sequences provide a diffusivity calculation without qualifying the direction of tissue water movement, termed *isotropic diffusion*. For example, decreases in ADC values (and corresponding increases in DWI) reflect restricted diffusion and serve as an indirect measure of gray or white matter disintegrity. DWI can be understood as an index of tissue permeability difference and is measured in terms of mean diffusivity (MD). DWI sequences aid the identification of acute ischemic strokes, and provide adjunct information in the radiographic evaluation of neoplasms, traumatic brain injury, and demyelinating processes (Schaefer, Grant, & Gonzales, 2000). Clinically, in cases of a

suspected acute stroke where a hypodensity is not well delineated on a CT scan, a brain MRI with diffusion sequences should be specifically requested. Furthermore, a hyperintensity on DWI should correspond to a hypointensity on ADC; otherwise, a T2-shine-through effect may cause false positive interpretations of an acute stroke if an abnormality is seen only on DWI. If a brainstem stroke is suspected, clinicians may also request thin sections through the brainstem to improve test sensitivity.

DTI-based imaging relies on the principle that when the diffusion in a structured system, such as the brain, is quantified, molecular displacement may be limited by physical barriers. Displacement that is direction dependent (i.e., axonal) is called *anisotropic*. The processing of diffusion values limited by structural anatomy (i.e., axons) in each voxel is called *tensor*. A tensor can be defined as a set of coexisting magnitudes dependent upon direction and coordinates (eigenvector and eigenvalues $[\lambda]$). DTI-enabled tractography permits the reconstruction and 3D visualization of the neural column structure. DTI maps are typically displayed as color maps representing the whole brain connectivity, with the direction of tracks indicated by distinct colors. Red typically indicates the X-axis, green the Y-axis, and blue the Z-axis. If applied to white matter axonal fibers, tractography provides structural connectivity information, including delineating pathology such as fiber deviation/destruction caused by tumors or infarctions.

An important DTI measurement to consider is the anisotropic fraction (AF). AF quantifies microstructure integrity of the white matter and is obtained by recording water diffusivity along white matter tracts (Ries et al., 2008). This measure has the advantage of detecting microstructural abnormalities with high sensitivity. Loss of tissue organization causes a decrease in anisotropy (and an increase in AF). It is theorized that reduced water diffusion parallel to axonal tracts, measured by the AF, is indicative of axonal degeneration, disruption and partial breakdown of cytoarchitecture (Beaulieu, 2002), or demyelination (Song et al., 2002).

At present, there is no consensus on the optimal method to analyze DTI data clinically. An early devised method was the *fiber assignment by continuous tracking* (FACT) technique using the selection of multiple ROIs. Using FACT, either voxels within a ROI are manually placed within a tract of interest, or every voxel above a certain threshold anisotropy value is examined. The latter method is considered superior, as it may find tracts omitted by only inspecting select ROIs; however, this approach is also more computationally demanding (Mukherjee, Berman, Chung, Hess, & Henry, 2008).

An alternative approach is the application of voxel-based analyses using SPM or similar techniques. Achieving adequate coregistration of DTI images across subjects, however, can be challenging given individual differences in brain shape, size, and white matter anatomy. *Tract-based spatial statistics* (TBSS) is an automated method to detect group-wise changes in diffuse metrics from the white matter of the entire brain (Smith et al., 2006). Anisotropic fraction (AF) images for each subject in a cohort are registered to construct a mean AF map. This map is skeletonized to identify core white matter

tracts containing the highest AF values. AF values from individual subjects are then projected onto the AF skeleton, and voxel-wise statistics are applied to identify significant differences. Importantly, the TBSS method can detect changes in AF simultaneously throughout the white matter of the brain, while DTI fiber tracking derives results only from preselected white matter tracts. At the present time, there is no specific routine clinical indication for DTI imaging; however, a DTI scan may be requested and used to augment and/or clarify radiographic findings.

MAGNETIC RESONANCE SPECTROSCOPY

Magnetic resonance spectroscopy (MRS) is used to measure the average amount of distinct metabolites in brain tissue over the duration of an approximately 15-minute scan. It detects and quantifies resonance signals of molecules present at much lower concentrations and differentiates molecules based on their magnetic resonance properties. This technique relies in part on chemical-shift imaging which takes into account the effect of the local chemical environment on particular nuclei. The metabolic profile of a region can be obtained through single voxel MRS (SVMRS) or multivoxel MRS imaging. SVMRS provides a metabolic average score within the selected voxel, while multivoxel MRS provides, within a unique image acquisition, various molecular images indicating the spatial distribution of different metabolites. The major limitation of SVMRS is the lack of spatial information due to limited sampling, although voxel size across single voxel and multivoxel MRS is typically similar.

The central nervous system metabolites measured with MRS are outlined in Table 7.3 and Figure 7.1. Commonly detected metabolites include N-acetyl aspartate (NAA), a marker of neuronal integrity; choline (Cho), an indicator of

Figure 7.1 Magnetic resonance spectroscopy illustration. The number of signals represented corresponds to the number of different metabolites sampled within a specified voxel. The position of distinct peaks on the horizontal axis is proportional to the intensity of the magnetic field, normally called *chemical-shift*, and measured in parts per million (ppm). The area under the curve for each signal provides a relative concentration of each metabolite. ml indicates Myoinositol; Cho, Choline; Cr, Creatine; NAA, N-Acetyl-Aspartate.

cell membrane synthesis; and creatine (Cr), associated with cellular energy metabolism. MRS, thus far, is the only readily available technique enabling in vivo sampling of metabolic information and is used clinically to aid diagnosis of metabolic disorders (i.e., leukodystrophies), distinguish neoplasms from other abnormal brain signals (high-grade brain tumors characterized by high Cho and low NAA), and assess the effects of chemotherapeutics on brain tumors by helping to distinguish between necrosis and neoplasm recurrence.

Table 7.3 COMMONLY DETECTED METABOLITES IN MAGNETIC RESONANCE SPECTROSCOPY (MRS)

METABOLITE	ABBREVIATION	ACTION
N-Acetyl-Aspartate	NAA	Neuronal marker
Choline	Cho	Membrane turnover marker
Creatine/Phosphocreatine	Cr/PCr	Index of energetic metabolism
Lactate	Lac	Product of anaerobic metabolism
Myoinositol	mI	Astrocyte marker
Lipids	Lip	Cell membrane/myelin sheath marker
Glutamine	Gln	Involved in synaptic processes
Glutamate	Glu	Involved in synaptic processes

FUNCTIONAL NEUROIMAGING TECHNIQUES

SINGLE PROTON EMISSION COMPUTED TOMOGRAPHY

Brain single proton emission computed tomography (SPECT) is a functional neuroimaging technique that detects gamma ray projections, produced as radionuclide decay, with a scintillation camera. The camera is rotated around a patient’s head 360 degrees over an approximately 20-minute period to gather whole brain data. This technique measures regional cerebral blood flow (rCBF), which indirectly reflects neuronal activity in different brain regions and allows for the detection of functional brain abnormalities. The injected tracers currently used in the clinical practice are ^{99m}Tc-hexamethyl-propylene-amine-oxime (^{99m}Tc-HMPAO) and ^{99m}Tc-ethyl cysteinyl dimer (^{99m}Tc-ECD). These tracers are lipophilic, cross the cell membrane, and remain intracellular following their conversion to hydrophilic compounds. Their incorporation is proportional to rCBF in the first few minutes after injection. The SPECT image does not change

following subsequent modifications in blood flow, since the tracer is “locked in” to the cells that have taken it up (Farid, Caillat-Vigneron, & Sibon, 2011). This characteristic has made SPECT imaging particularly clinically useful for seizure foci detection if the tracer is injected in close temporal proximity to seizure onset (Knowlton, Lawn, Mountz, & Kuzniecky, 2004). Of note, the tracer takes approximately 30 seconds to reach the brain, and the switch from ictal hyperperfusion to postictal hypoperfusion occurs approximately in 1–2 minutes following seizure termination in temporal regions and sooner in extratemporal regions. Ictal SPECT imaging thus requires tracer injection within seconds of seizure onset (Van Paesschen, 2004). SPECT tracers have longer half-lives and are less expensive to manufacture than those used in positron emission tomography (PET). The main limitation of SPECT imaging apart from exposing the patient to ionizing radiation (approximately 6–10 mSv) is its relatively limited spatial resolution, although recent technical advancements, including coregistration of SPECT images on MRI rather than CT scans, have improved resolution.

POSITRON EMISSION TOMOGRAPHY

Brain PET is a nuclear medicine technique for the visualization of physiological and biochemical brain changes by a scintillation camera that detects gamma rays produced when positrons released from a tracer compound collide with ambient electrons. The release of diametrically opposed gamma rays produces a more spatially accurate image compared to SPECT. This information is converted into a 3D brain image. There are several radionuclides commonly used, including carbon-11, nitrogen-13, oxygen-15, and fluorine-18. Fluorine-18 has the longest half-life, and fluorodeoxyglucose (^{18}F -FDG), an analogue of glucose labeled with fluorine-18, is used frequently as a marker of brain function. Measuring regional cerebral glucose metabolism via ^{18}F -FDG PET has become a standard technique to detect regional hypometabolism in neurodegenerative diseases (and often times the preferred technique to SPECT for regional hypometabolism detection, given greater spatial resolution). An example of a well-recognized regional hypometabolism finding is bilateral parietal-temporal hypometabolism in Alzheimer’s disease (Herholz, Carter, & Jones, 2007). PET can also be utilized with antibody-radionuclide compounds to determine the distribution of particular molecules in the brain, and with ligand-radionuclide compounds to determine the distribution of neurotransmitter receptors. Pittsburgh Compound B allows *in vivo* detection of amyloid in the diagnostic work-up of Alzheimer’s disease (Klunk et al., 2004). The radiolabeled dopamine receptor ligand ^{11}C -raclopride has been used to quantify dopamine receptors in patients with schizophrenia and early Parkinson’s disease (Brooks et al., 1992; Farde et al., 1990). Use of interictal PET (with ^{18}F -FDG) to detect regional hypometabolism aids in determining seizure foci in patients undergoing epilepsy surgery evaluations (Ho et al., 1995). While the need for a cyclotron to manufacture PET tracers increases test expense (approximately 1500–5000 USD for PET, roughly 1000 USD for SPECT)

and exposes subjects to radiation (4–8 mSv), the spatial resolution and the superior quantitative aspects of PET make it frequently the procedure of choice in most clinical situations requiring the aid of a nuclear medicine brain scan. To aid clinical-radiographic interpretations across functional neuroimaging techniques, particularly PET and SPECT, clinicians should provide specific clinical symptoms (and suspected affected brain regions if possible) in their test requisitions to guide neuroradiologists.

FUNCTIONAL MRI

Functional MRI (fMRI) is a noninvasive, non-radiation-based neuroimaging technique, which uses the inherent magnetic properties of hemoglobin to provide a proxy for neuronal activity. Red blood cells contain hemoglobin molecules with centrally positioned iron atoms. The binding and unbinding of oxygen to hemoglobin results in conformational changes, with oxyhemoglobin (diamagnetic) and deoxyhemoglobin (paramagnetic) having distinct magnetic properties. Deoxyhemoglobin configurations create a surrounding inhomogeneous magnetic field leading to decreased signal. In healthy individuals, regional brain activations coincide with local vasodilation so that venous blood draining from active neurons is *more* oxygenated than if the neurons were less active. Therefore, less deoxyhemoglobin (and more oxyhemoglobin) due to increased neural demand for oxygen and parallel compensatory blood flow that exceeds the regional metabolic demand in a given functionally active region leads to increased blood oxygen level dependent (BOLD) signal (Logothetis, Pauls, Augath, Trinath, & Oeltermann, 2001). While BOLD fMRI provides a proxy for neural activity based on venous blood flow patterns, more recently developed methods such as *arterial spin labeling* (ASL) provide an arterial phase measure of cerebral blood flow with the potential for improved spatial and temporal resolution. If the regulation of vascular tone in response to downstream neuronal demand is impaired, as with cerebral atherosclerotic disease, flow-related fMRI activation patterns may not change as expected in the context of increased neuronal activity.

Overall, fMRI provides high spatial resolution but has limitations in temporal resolution based on the hemodynamic response (1–2 seconds). Techniques combining fMRI with electroencephalogram recordings may provide complementary spatial and temporal information; similarly, dual use of fMRI and magnetoencephalography (MEG) may also serve as complementary techniques. fMRI is exquisitely sensitive to small head movements and respiratory artifacts. Compared to SPECT and PET, fMRI has improved spatial and temporal resolution and does not expose subjects to ionizing radiation. However, subjects with metallic implants, including surgically implanted devices such as cardiac pacemakers, are unable to participate in MRI-based investigations. The MRI environment itself is also confining and may cause patients with claustrophobia to not participate; fMRI technology has not yet been extended to the increasingly popular “open MRI” whereby data is acquired in a less confined environment.

FUNCTIONAL NEUROIMAGING METHODS

Functional neuroimaging evaluations probing neuropsychiatric symptoms have utilized a broad array of paradigm and nonparadigm experimental designs and analysis techniques. Most broadly, paradigm-based experimental design may be subdivided into techniques that naturalistically “capture” symptoms or techniques that ask subjects to participate in tasks in order to examine active neural circuits. The symptom capture method has been used to characterize neural activations in phenomena such as hallucinations in patients with schizophrenia and tics in patients with Tourette syndrome (Silbersweig et al., 1995; Stern et al., 2000). For example, in a study probing visual hallucinations in a cohort of patients with paranoid schizophrenia and prominent auditory verbal hallucinations, subjects were placed in a PET scanner following the injection of a $H_2^{15}O$ tracer and instructed to relax, close their eyes, and press a button each time auditory hallucinations were experienced. Group analyses identified activations in bilateral thalamus, hippocampus/parahippocampal gyrus, right ventral striatum, anterior cingulate cortex, and left orbitofrontal cortex. Furthermore, in a unique case study of an unmedicated patient with paranoid schizophrenia experiencing dual auditory and visual hallucinations (perceiving colored scenes with rolling, disembodied heads, and hearing the heads verbalize command instructions), hallucinations were associated with visual association and auditory-linguistic association cortex activations and relative absence of prefrontal cortex activity (see Figure 7.2). Studies

of this type approximate a naturalistic identification of neural circuits active during acute symptom occurrence.

The more commonly used method in functional neuroimaging studies of patients with psychiatric disease has been the use of paradigm-based tasks to probe underlying neural circuit differences. Examples include using working memory tasks to probe dorsolateral prefrontal cortex function in patients with schizophrenia (Callicott et al., 2000), the presentation of war-related images and sounds to patients with Vietnam War related PTSD (Bremner et al., 1999), and displaying affectively valenced faces to patients with major depressive disorder (Sheline et al., 2001). Task-based fMRI paradigms are currently used clinically in language and memory lateralization evaluations for presurgical planning in patients awaiting neurosurgical intervention, particularly those requiring epilepsy surgeries (Tharin & Golby, 2007).

The two major types of paradigm design are block and event-related designs. In *block designs*, similar conditions are grouped together to form discrete experimental blocks. Within each block, multiple stimuli of the same subtype are presented consecutively within each block, and an output of interest (i.e., BOLD signal) is averaged across the entire block. At a minimum, blocks are divided into control blocks and condition-of-interest blocks. An example of this would be the presentation of trauma-related words to patients with PTSD compared to healthy controls as the condition-of-interest block, and the subsequent presentation of neutral words during control blocks (Protopopescu et al., 2005; see Figure 7.3).

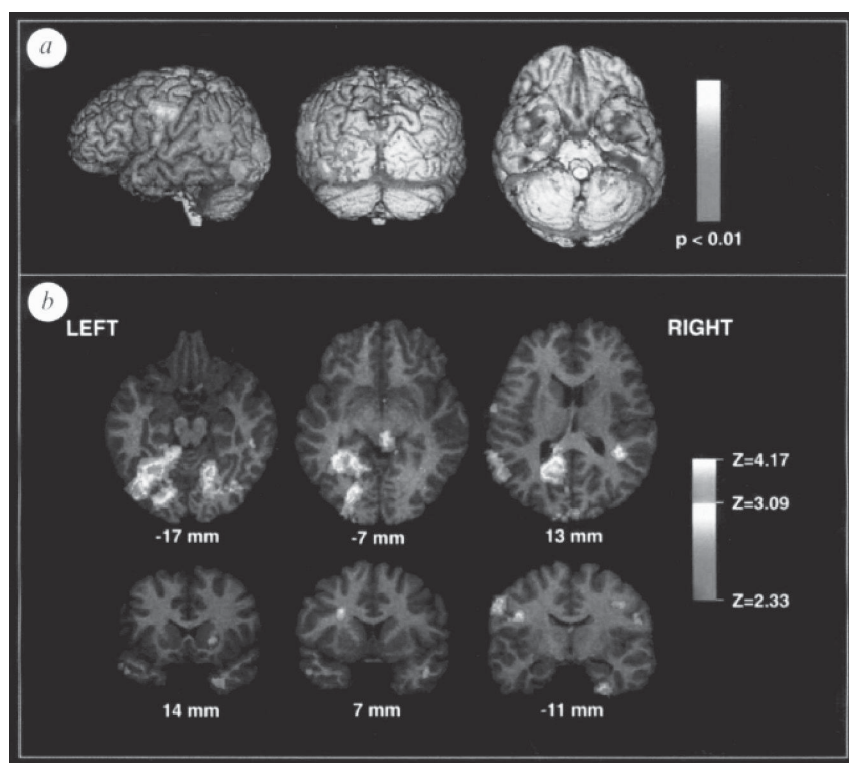

Figure 7.2 Functional activation pattern in a patient with schizophrenia experiencing dual auditory and visual hallucinations, recorded using a symptom capture paradigm with the patient also utilized as his own control. Reprinted by permission from Macmillan Publishers Ltd: *Nature*. Silbersweig DA, Stern E, Frith C, Cahill C, Holmes A, Grootenck S, et al. A functional neuroanatomy of hallucinations in schizophrenia. 1995;378:176–9.

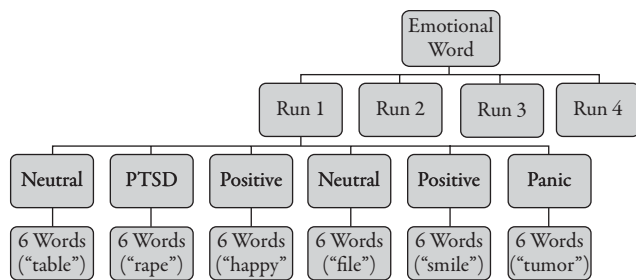

Figure 7.3 Sample diagram of a block design developed to probe the neural correlates of affective word processing. In this particular experiment, each run is composed of six distinct blocks, with each block containing six similarly affectively valenced words. Each affectively valenced block (i.e., PTSD-specific words) across runs would contain six different words that are similarly affectively valenced. The order of blocks across runs is typically randomized. Adapted from Protopopescu X, Pan H, Tuescher O, Cloitre M, Goldstein M, Engelien W, et al. Differential time courses and specificity of amygdala activity in post-traumatic stress disorder subjects and normal control subjects. *Biological Psychiatry* 2005;57:464–73.

Block design use improves signal detection power and simplifies analyses, but is limited by relative temporal insensitivity.

In *event-related designs*, stimuli are presented in discrete, short-duration events with the potential to randomize timing and stimuli order. Stimuli may be presented at intervals ranging from 2 and 20 seconds apart, depending on the specifics of the experiment. Also, stimuli across conditions (i.e., negative vs. neutral words) are randomized rather than consecutively displayed. While event-related designs lack the statistical power of block designs, this strategy enables the detection of changes in neural activity from baseline and allows for more sophisticated analytic methodology (Huettel, Song, & McCarthy, 2004).

In evaluating functional neuroimaging findings, it is important to also consider if “state” or “trait” characteristics are being evaluated at the time of the experiment. In state evaluations, disease-specific symptoms of interest are actively experienced by participants and probed during a functional neuroimaging study. An example is the previously described symptom capture experiment in hallucinating patients with paranoid schizophrenia. In trait investigations, the neural correlates of functions hypothesized to be related to disease pathophysiology are probed (i.e., fear conditioning and extinction learning experiments in PTSD patients), but the disease-specific symptomatology are not necessarily experienced during data acquisition.

Over the last decade, a shift has occurred in the exploration of functional activation patterns. Most early functional neuroimaging studies compared task-of-interest activation patterns to control conditions by performing subtraction-based analyses (“subtracting” out control or baseline activation patterns) to identify regions specifically implicated in task performance. This approach is also known as a *univariate* analysis. While this technique continues to prove useful in delineating structure–function relationships, brain function is now recognized as organized into spatially distributed regions that form discrete networks that coactivate (or deactivate) during task and rest (nontask) conditions. These functional connectivity investigations are *multivariate* analyses that probe coherent activation patterns within and across neural networks. In

multivariate analyses, distinct functional connectivity patterns across groups are descriptively detailed rather than the result of computed subtraction-based analyses. Functional connectivity may be examined during the performance of particular tasks, or while subjects rest and allow their minds to wander without focusing on any given thought or task. Resting state, task-free paradigms provide a powerful alternative approach to delineate neural circuit differences across psychiatric conditions (including default mode network disturbances), and may have an emerging role in a broad array of applications including presurgical mapping and the early detection of neurodegenerative disease (Greicius et al., 2007; Liu et al., 2009).

One commonly used method to probe functional connectivity are *regions of interest based methods* that select “seeds” and subsequently examine whole brain functional activation patterns in relation to these predetermined regions (Zhang & Raichle, 2010). *Component-based multivariate analyses* offer a distinct approach whereby advanced computational statistical methods decompose functional data into statistically distinct connectivity maps, or components. Components are suggested to represent functionally bound neural networks. Independent component analysis and principal component analyses are two of the more commonly used methods of this type. Advances in *graph theory* have also recently been applied to functional activation patterns to define the relationship between regions (nodes) based on their functional connectivity strengths. In particular, the brain’s functional connections exhibit small-world properties (Watts & Strogatz, 1998), whereby a limited number of temporally and spatially interconnected regions form distinct networks rather than being constructed as a network of random connections. Specific sites within a network that exhibit particularly robust connectivity are termed *modules* and *hubs*, and the strength of functional connections between nodes may be depicted by vectors of varying thickness (Pan, Epstein, Silbersweig, & Stern, 2011; Sepulcre et al., 2010; Zhang & Raichle, 2010).

NEUROIMAGING AND DIFFERENTIAL DIAGNOSIS

When evaluating a patient with behavioral, affective, and/or cognitive complaints, accessory features of the clinical history and physical examination help determine the need for neuroimaging. A history of previously diagnosed psychiatric disease, age of symptom onset, known neurologic and medical conditions, and family history all aid in determining if a patient’s psychiatric symptoms are primary or secondary to a medical/neurological condition. If psychiatric symptoms are suspected to be secondary manifestations based on aspects of the history, laboratory tests, and/or clinical examination, it is useful to systematically consider diseases across broad diagnostic categories including infection, cerebrovascular disease, oncologic, paraneoplastic, demyelinating, neurodegenerative, trauma-related, and rheumatologic/inflammatory conditions (see Table 7.4, Figure 7.4). Neuroimaging evaluations may either help refine the differential diagnosis, or guide diagnosis itself.

For example, a primary central nervous system (CNS) infection should be considered in a patient presenting with

Table 7.4 SAMPLE OF MEDICAL AND NEUROLOGIC CONDITIONS WITH POTENTIALLY PROMINENT PSYCHIATRIC SYMPTOMS

DISEASE CATEGORIES	SUPPORTIVE HISTORY	SELECT RADIOGRAPHIC SCANS OF PARTICULAR DIAGNOSTIC UTILITY
<i>Infection</i>		
Herpes Simplex Virus, Varicella Zoster Virus	Fever, meningeal irritation, delirium, seizures	MRI: High T2WI signal in the temporal lobe(s). Restricted diffusion/gyriform edema. Meningeal enhancement.
Human Immunodeficiency Virus (HIV) Dementia	Opportunistic infections, subcortical cognitive deficits	MRI: Generalized atrophy. Nonspecific T2WI WM lesions. CT: Generalized atrophy.
Neurosyphilis	Neuropsychiatric symptoms, meningeal irritation, focal deficits	MRI: Generalized cerebral atrophy and ventricular dilatation. Strokes. Meningeal enhancement.
<i>Cerebrovascular</i>		
Small Vessel Disease/ Binswanger's Disease	Subcortical cognitive deficits	MRI: Periventricular/subcortical T2WI hyperintense WM lesions. CT: Subcortical hypoattenuation.
Large Vessel Strokes	Cortical deficits: aphasia, neglect, visual field loss	MRI: T2WI hyperintensities. Mass effect. DWI high, ADC low. CT: Hypoattenuation.
Lacunar Strokes	Motor/somatosensory deficits	MRI: T2WI hyperintensities. DWI high, ADC low. CT: Punctate hypoattenuation.
Posterior Reversible Encephalopathy Syndrome	Hypertension, headache, seizures, vision loss	MRI: Posterior predominant T2WI hyperintensities. CT: Hypoattenuation.
Cerebral Amyloid Angiopathy	Dementia	MRI: Hypointense SWI lesions.
<i>Oncologic</i>		
Malignant Primary CNS Tumor	Headache, focal deficits, seizures	MRI (preferred) and CT: Mass effect +/- post-contrast enhancement.
Benign CNS Tumor (i.e. orbital groove meningioma)	Seizures, cognitive/affective deficits	MRI (preferred) and CT: Variable mass effect and post-contrast enhancement.
Carcinomatous Meningitis	Meningeal irritation, delirium	MRI: Sulcal enhancement.
Metastatic CNS Tumor	Focal deficits, headache, known malignancy	MRI (preferred) and CT: Enhancing mass lesions at the gray-white junction.
<i>Limbic Paraneoplastic</i>		
Anti-NR1/NR2 of N-methyl-D-aspartate (NMDA) receptor	Ovarian teratoma	MRI: High signal mainly in the temporal lobe(s) in T2WI. Restricted diffusion, gyriform edema.
Anti-Hu (ANNA-1)	Small cell lung cancer	MRI: High signal mainly in the temporal lobe(s) in T2WI. Restricted diffusion, gyriform edema.
Anti-Voltage-Gated Potassium Channels (VGKC)	Thymoma, small cell lung cancer	MRI: High signal mainly in the temporal lobe(s) in T2WI. Restricted diffusion, gyriform edema.
<i>Demyelinating</i>		
Multiple Sclerosis	Optic neuritis, relapsing-remitting deficits	MRI: T2WI WM hyperintense lesions, enhancing acute WM lesions.
<i>Neurodegenerative</i>		
Alzheimer's Disease	Progressive amnesia, anomia	MRI (preferred) and CT: Medial temporal lobe atrophy.
Frontal Temporal Dementia Behavioral Variant	Progressive impulsivity, apathy, personality change	MRI (preferred) and CT: Frontotemporal atrophy.

(continued)

Table 7.4 (CONTINUED)

DISEASE CATEGORIES	SUPPORTIVE HISTORY	SELECT RADIOGRAPHIC SCANS OF PARTICULAR DIAGNOSTIC UTILITY
Diffuse Lewy Body Disease	Visual hallucinations, fluctuating delirium, parkinsonism	MRI: Brain stem, substantia nigra, and cortical atrophy on T1WI.
Sporadic Creutzfeldt-Jakob Disease (CJD)	Myoclonus, ataxia, rapidly progressive cognitive decline	MRI: High signal on T2WI and DWI in the striatum and posterior cortical ribbon.
<i>Inflammatory</i>		
Systemic Lupus Erythematosus	Rash, arthritis, headache, constitutional symptoms	MRI: High T2WI signal in WM, non specific.
Primary Angitis of the CNS	Headache, focal neurologic deficits	MRI: Restricted diffusion on DWI and ADC. High intensity T2WI lesions.
Neurosarcoidosis	Cough, mediastinal adenopathy	MRI: Dural/leptomeningeal enhancement. Hypothalamus/pituitary and intraparenchymal lesions.
<i>Traumatic Brain Injury</i>		
Diffuse Axonal Injury	Variable deficits but includes coma	MRI: High intensity T2WI lesions +/- hemorrhage on SWI. CT: Focal high density with surrounding low-density edema.
Acute Subdural Hemorrhage	Brief lucid period prior to loss of consciousness, herniation	CT (preferred): Crescent-shaped high density fluid collection. MRI: Isointense on T1WI, hypointense on T2WI.
<i>Other</i>		
Toxic Leukoencephalopathy (i.e. Antineoplastic Drugs)	Subcortical cognitive deficits	MRI: Variable T2WI WM hyperintensities.
Thiamine Deficiency: Wernicke-Korsacoff Syndrome	Alcoholism, nystagmus, ataxia, confabulation, amnesia	MRI: mammillary body atrophy on T1WI, hyperintensity on T2WI. Enhancement.
Normal Pressure Hydrocephalus	Magnetic gait, urinary incontinence, subcortical dementia	MRI: Hydrocephalus, periventricular T2WI hyperintensities. CT: Hydrocephalus and periventricular hypoattenuation.

NOTE: CT scan abnormalities are delineated based on changes in "density" while MRI-based abnormalities are described by delineating lesional "intensity." Gadolinium may be used as an intravenous contrast for T1WIs and iodinated contrast is available for use in CT scans. Also, similar findings are typically denoted in both T2WIs and FLAIR sequences with the except that FLAIR sequences improve delineation of periventricular pathologies. T2WI indicates T2-weighted image; WM, white matter; DWI, diffusion weighted image; SWI, susceptibility weighted image; CSF, cerebrospinal fluid; CT, computed tomography.

acute-subacute mental status change, fever, and meningeal irritation (photophobia, nuchal rigidity). The additional presence of focal neurologic signs, including papilledema or lateralizing weakness, numbness or cortical deficits including aphasia, neglect, or visual field deficits, suggest parenchymal involvement and warrant a CT brain scan prior to cerebral spinal fluid sampling. FLAIR/T2 and T1 post-gadolinium MRI sequences can also help confirm if an infection extends to the brain parenchyma, as in a meningoencephalitis, or aid the diagnosis of a limbic encephalitis (i.e., herpes simplex virus) presenting with fever and mental status change without definitive meningeal irritation.

Patients with cerebrovascular disease may also present with underrecognized affective and behavioral symptoms. One such example is apathy in patients with an anterior cerebral artery stroke. If a detailed neurologic examination screening for corticospinal tract involvement (i.e., leg weakness, numbness, Babinski sign, increased reflexes) along with either a CT scan or DWI and ADC MRI sequences are not

performed, an anterior cerebral artery stroke could be mistaken for a hypoactive delirium.

Increasing characterized paraneoplastic phenomena may present with prominent limbic symptoms, and can be investigated using cerebral spinal fluid sampling, antibody testing, oncologic screening, and MRI brain imaging (Dalmau & Rosenfeld, 2008). A well characterized example is the case of anti-N-methyl-D-aspartate (NMDA) receptor antibodies presenting with psychosis, memory deficits, altered mental status, seizures, dyskinesias, and autonomic disturbances in young women with undetected ovarian teratomas. FLAIR, T2, and T1post-gadolinium sequences may identify medial temporal lobe and prefrontal cortical inflammation supportive of limbic encephalitis.

Screening for vascular disease, and particularly small vessel (microangiopathic) white matter disease, is an important component of the diagnostic work-up for geriatric patients presenting with progressive subcortical cognitive impairments (diminished processing speed, retrieval deficits with relatively

Figure 7.4 Sample diagnoses aided by radiographic findings. **A.** Computed tomography (CT) scan of an elderly man with impulsivity and disinhibition revealing hypoattenuation in the left frontal region consistent with a prior stroke. **B.** Noncontrast CT scan of a young woman with recent blunt head trauma demonstrating a right frontotemporal subacute subdural hemorrhage. **C.** Diffusion weighted image (DWI) of a woman with mood lability and myoclonus showing bilateral caudate and putamen restricted diffusion consistent with prion disease. **D.** Fluid attenuated inversion recovery (FLAIR) scan in an elderly woman with medically refractory seizures demonstrating increased left hippocampal FLAIR signal related to anti-HU paraneoplastic antibodies. **E.** T1 post-gadolinium scan of a woman with marked apathy demonstrating a heterogeneously enhancing intraparenchymal mass lesion consistent with a high-grade glioma. **F.** T1 post-gadolinium scan of a young man presenting with right-sided weakness found to have multifocal periventricular and subcortical enhancing white matter lesions consistent with an acute multiple sclerosis flare. **G.** T1 post-gadolinium scan of a middle-aged woman with alcohol dependence presenting with gait instability, amnesia, nystagmus, and bilateral gaze palsy, demonstrating bilateral mamillary body enhancement consistent with Wernicke-Korsakoff syndrome. **H.** T1 MRI of a man with progressive personality change and apathy revealing bilateral frontal, anterior temporal, and peri-insular atrophy with sulcal widening, consistent with frontotemporal dementia. Adapted from Perez DL, Larvic M, Acar D, Daffner K. Teaching NeuroImage: Apathetic variant of frontotemporal dementia, *Neurology* 2011;77(20):e117. Note: all images are displayed using radiographic conventions (i.e., right hemisphere displayed on the left side of the scan).

preserved retention/recognition on memory testing) and/or late-onset mood disturbance. Extensive hypoattenuation of the periventricular and subcortical white matter on CT scan, or T2/FLAIR hyperintensity on MRI, would support cerebrovascular disease, particularly in patients with a known history of hypertension, hyperlipidemia, and/or diabetes mellitus. Structural and functional imaging also aids in the diagnosis of neurodegenerative disorders through detection of lobar patterns of atrophy with associated sulcal widening (i.e., medial temporal or frontal) and focal hypometabolism (temporal/parietal or frontal/anterior temporal/insular) as present in Alzheimer's disease and frontotemporal dementia. Ventricular enlargement frequently accompanies neurodegenerative disease (hydrocephalus *ex vacuo*) and can be discerned from other forms of hydrocephalus, including normal pressure hydrocephalus, by concurrently detecting sulcal widening and a lack of periventricular signal abnormality suggestive of transependymal flow.

When evaluating potentially abnormal structural neuroimaging findings, it is also useful to consider the effects of normal aging (Fox & Schott, 2004). Assessing the extent to which atrophic changes are within the normal limits for age is a sophisticated clinical judgment, with the potential for differences of opinion even among experienced neuroradiologists;

unfortunately there are not yet well-accepted guidelines to assist clinicians in these determinations. Despite this, comparative analyses show that the aging brain loses volume in nonlinear and region-dependent fashion, and prefrontal cortical volume decreases more rapidly than other brain regions. Reductions in cortical volume, particularly in prefrontal and temporal regions, have been estimated to be approximately 0.5% per year in patients over 60 years of age (Fjell et al., 2009). Furthermore, volumetric reductions in aging populations are thought to reflect reductions in synaptic spine density rather than actual neuronal loss. Physical exercise and cognitively stimulating activities may also modulate the trajectory of normal age-related brain changes by promoting successful cognitive aging and enhanced neuroplasticity (Daffner, 2010). Thus, patient age is an important, heterogeneously presenting variable to consider when evaluating neuroimaging findings.

In general, a common problem in daily clinical practice is the extent to which brain imaging findings may be overinterpreted or underinterpreted. Radiographic misinterpretation can be partially avoided by familiarizing ordering physicians with the limitations of the individual neuroimaging techniques as previously discussed. Examples of this include the limitation of CT scans to appreciate even subtle ischemic stroke changes

only on the order of several hours post stroke, while DWI imaging may capture early ischemic change within 30 minutes of stroke onset. Therefore, when performing clinical-radiographic interpretations, particularly in diagnostically challenging cases, we urge ordering clinicians to collaborate closely with neuroradiologists and like-minded neuropsychiatrists.

NEURAL CIRCUITS IMPLICATED IN PSYCHIATRIC DISEASE

After obtaining structural and/or functional imaging in the neuropsychiatric evaluation of a patient, clinicians are left with the task of performing clinical-radiographic interpretations. A given radiographic finding (i.e., evidence of acute demyelination on T1-weighted post-gadolinium MRI imaging) may be incidental to a psychiatric complaint or may mediate, at least in part, the clinical symptomatology. An example of this clinical dilemma is increased anxiety in a patient accumulating lesions in prefrontal white matter pathways secondary to relapsing-remitting multiple sclerosis. An understanding of neural circuits mediating affect, behavior, and cognition helps determine whether particular neuroimaging findings are directly related to the patient's symptomatology (see Table 7.5).

Three nonmotor prefrontal-subcortical parallel circuits initially characterized by Alexander, DeLong, and Strick (1986) aid in understanding prefrontal neural circuits; these include orbitofrontal, anterior cingulate, and dorsolateral prefrontal cortex–subcortical pathways (see Figure 7.5). The orbitofrontal-subcortical pathway participates in inhibition of socially inappropriate behavior and in empathic behavior; its dysfunction is associated with personality change, impulsivity, utilization/imitation behavior, mania, and obsessive compulsive disturbances (Mega & Cummings, 1994). The anterior cingulate–subcortical pathway is involved in motivated behavior, affective regulation, and conflict monitoring, and dysfunction has been linked to akinetic mutism, apathy, and impaired response inhibition among other deficits (Devinsky, Morell, & Vogt, 1995; Etkin, Egner, & Kalisch, 2011). The dorsolateral prefrontal–subcortical circuit participates in higher order executive functions, and dysfunction may manifest as poor organization and planning, environmental dependency, working memory deficits, and impaired set shifting.

The amygdala and related prefrontal, ventral striatal, and brainstem connections are important in understanding the neural correlates of fear responses, emotional processing, and emotional memories (Cahill, Babinsky, Markowitsch, & McGaugh, 1995; LeDoux, 2007; Phelps & LeDoux, 2005). The amygdala, an almond-shaped structure in the anterior medial temporal lobe, is composed of distinct nuclei. Afferents from sensory thalamus and cortex, the hippocampal formation, and multimodal association cortices project to the lateral nucleus (LeDoux, 2007). Medial prefrontal regions project to the basal nucleus, intercalated cells, and central nucleus. The central nucleus, the major output structure of the amygdala, has efferent projections to brainstem structures including neuromodulatory systems (norepinephrine, dopamine, serotonin, and acetylcholine), periaqueductal gray, hypothalamus, and parasympathetic nuclei. The basal nucleus of the amygdala

sends efferent projections to the ventral medial prefrontal cortex, ventral striatum, and multimodal association cortices. These connections enable reciprocal interactions between the amygdala and the medial prefrontal cortex; the amygdala, in turn, functions as a major node in central autonomic pathways that are frequently dysfunctional in patients with affective disorders (see Figures 7.6 and 7.7). Disruptions of prefrontal efferents projecting onto the amygdala may result in unregulated amygdalar activity (impaired top-down inhibition) and subsequent heightened affective symptoms and fear responses.

The cortical-hippocampal system for declarative memory (including episodic and semantic memory) comprises a widely distributed neural network involved in the conscious recollection of past experiences and factual information (Eichenbaum, 2000). Neocortical association cortices, the parahippocampal region, and the hippocampus comprise three major components of this circuit. Neocortical regions including the ventromedial prefrontal, anterior cingulate, dorsolateral prefrontal, posterior parietal, and temporal cortices provide afferent cognitive, motor, or perceptual information to subregions of the parahippocampus. The parahippocampal region serves as a convergence site for cortical information and projects to the hippocampus, where subsequently individual elements of a memory are linked to one another. The outcome of hippocampal processing returns to the parahippocampal region and to neocortical regions via reciprocal connections. Additional regions in the declarative memory circuit include the fornix, mammillary bodies, and anterior nuclei of the thalamus; the thalamus projects to the anterior cingulate cortex as part of the previously described prefrontal–subcortical loop.

Circuits implicated in the modulation of reward, addiction, and pleasure involve both cortical and subcortical structures. Dopaminergic projections from the ventral tegmental area in the midbrain to the nucleus accumbens in the ventral striatum (mesolimbic pathway) are implicated in reinforcing the effects of drugs of abuse. Mesolimbic dopamine, while initially thought to encode reward, has been more closely linked to reward prediction and salience (Volkow & Li, 2004). Behaviors commonly seen in patients with addiction disorders, including compulsion and disinhibition, are associated with hypoactivity of the orbitofrontal and anterior cingulate cortices. Hypofunction of the ventral striatum has also been linked to anhedonia, particularly in patients with major depressive disorder (Epstein et al., 2006).

Another neural system of emerging importance in psychiatric and neuropsychiatric diseases is the brain's default mode network (DMN; See Figure 7.8). This widely distributed network consists of regions that co-deactivate during a broad array of task performances and subsequently coactivate when individuals are allowed to rest and self-reflect without specific instructions (Buckner, Andrews-Hanna, & Schacter, 2008; Raichle et al., 2001). The core regions associated with the DMN include ventral and dorsal medial prefrontal cortex, posterior cingulate cortex/precuneus, inferior parietal lobule, lateral temporal cortex, and the hippocampal formation.

Lastly, widely distributed neuromodulatory monoamine pathways should also be considered when deducing if clinical symptoms may be explained by radiographic findings. These

Table 7.5 COMMONLY IMPLICATED CIRCUITS IN PSYCHIATRIC AND NEUROPSYCHIATRIC CONDITIONS

include dopamine pathways (mesolimbic and mesocortical circuits), serotonergic projections from the raphe nuclei, norepinephrine projections from the locus coeruleus, and cholinergic output from the basal forebrain/Nucleus Basalis of Meynert. Having reviewed neural circuits implicated across psychiatric diseases, the following section briefly outlines the neural correlates of schizophrenia, MDD, and PTSD.

FUNCTIONAL NEUROANATOMY OF SCHIZOPHRENIA, MDD, AND PTSD

Schizophrenia is a chronic disintegrative thought disorder where patients frequently experience auditory hallucinations and bizarre or paranoid delusions. While a neural basis for schizophrenia has been suspected for over a century, advances in structural and functional neuroimaging techniques over the last 30 years have greatly advanced our understanding of this condition. Structural studies first using CT scans, and more recently utilizing automated methods such as VBM applied to T1 MRI scans, have commonly identified diminished whole brain volume, increased ventricular size, and regional atrophy in hippocampal, prefrontal, superior temporal, and inferior parietal cortices in patient with schizophrenia compared to control groups (Keshavan, Tandon, Boutros, & Nasrallah, 2008; Pearlson & Marsh, 1999; Shenton, Dickey, Frumin, &

McCarley, 2001; see Table 7.6). A reversal of or diminished hemispheric asymmetry has also been characterized. Functional neuroimaging studies have commonly identified hypoactivity of the prefrontal cortex (including the dorsolateral prefrontal cortex associated with executive dysfunction) and temporal lobe dysfunction (Brunet-Gouet & Decety, 2006; Keshavan et al., 2008). Also, while the clinical phenotype of schizophrenia only infrequently poses a diagnostic challenge, clinicians are not yet able to predict treatment response based on clinical phenotype. In promising preliminary research, a positive correlation has been identified between activity of the dorsolateral prefrontal cortex and response to atypical antipsychotic drugs or cognitive behavioral therapy (Kumari et al., 2009; van Veelen et al., 2011). Leftward shifts in frontal cortical asymmetry have also been associated with a positive response to atypical antipsychotic drugs (Szeszko et al., 2010).

MDD is a frequently encountered mental disorder characterized by depressed mood, diminished sense of self-worth, anhedonia, and apathy among other features. Structural studies in patients with MDD have frequently identified volumetric reductions in prefrontal regions including the subgenual anterior cingulate cortex, orbitofrontal cortex, hippocampus, and striatum. Functional neuroimaging studies using PET, SPECT, and fMRI-based techniques have demonstrated increased activity in the subgenual cingulate, amygdala, and mediodorsal thalamus, and diminished activity in dorsal anterior cingulate cortex, dorsolateral prefrontal cortex, and ventral striatum (Drevets, Price, & Furey, 2008; Lorenzetti, Allen, Fornito, & Yucel, 2009; Vago, Epstein, Catenaccio, & Stern, 2011). From a symptom domain perspective, specific neural circuit disturbances have been linked to particular symptoms of MDD (i.e., anhedonia and ventral striatum hypoactivity, impaired working memory and dorsolateral prefrontal cortex hypoactivity) but the neural systems mediating phenotypic subtypes, such as patients with or without suicidal ideation, are not yet well understood. Emerging research suggests increased anterior cingulate cortex activity/volume and hippocampal size may predict antidepressant treatment response (Chen et al., 2007; MacQueen, 2009; Mayberg et al., 1997).

PTSD is a disorder characterized by reexperiencing phenomena, hyperarousal, emotional numbing, and avoidance in the setting of previously experienced or witnessed life-endangering trauma. Volumetric analyses conducted in patients with PTSD compared to control populations have primarily identified hippocampal and anterior cingulate cortex atrophy (Karl et al., 2006; Woon & Hedges, 2009). Functional neuroimaging studies, mainly using univariate approaches to date, have identified prefrontal (anterior cingulate and orbitofrontal cortices) and hippocampal hypoactivity, and parallel amygdalar hyperactivity (Lanius, Bluhm, Lanius, & Pain, 2006; Liberzon & Sripada, 2008). In limited studies to date, rostral anterior cingulate cortex volume and diminished amygdala and ventral (subgenual) anterior cingulate cortex activity in response to an aversive visual task may predict a positive response to cognitive behavioral therapy (Bryant et al., 2008a; 2008b).

In addition to identifying neural predictors of prognosis and treatment response, delineating the neural correlates of psychiatric symptoms through neuroimaging techniques may

Table 7.6 COMMON STRUCTURAL AND FUNCTIONAL ABNORMALITIES IN PATIENTS WITH SCHIZOPHRENIA, MAJOR DEPRESSIVE DISORDER (MDD) AND POSTTRAUMATIC STRESS DISORDER (PTSD)

DISEASE	COMMON VOLUMETRIC FINDINGS	COMMON FUNCTIONAL FINDINGS	PRELIMINARY PREDICTORS OF TREATMENT RESPONSE
Schizophrenia	↓ Total brain volume ↑ Ventricular size ↓ Hippocampal volume ↓ Reversal of cerebral asymmetry ↓ STG, IPL, dlPFC ↑ Basal Ganglia (related to typical antipsychotic drugs) ↓ Basal Ganglia (related to atypical antipsychotic drugs)	↓ Prefrontal (i.e., dlPFC) activity during rest and cognitive challenge studies Temporal lobe dysfunction during rest and cognitive challenge studies	↓ dlPFC activity during a working memory task → ↓ atypical antipsychotic response ↑ dlPFC activity during a working memory task → ↑ CBT response ↑ Frontal structural asymmetry → ↑ atypical antipsychotic response
MDD	↓ Prefrontal (sgACC, OFC) ↓ Hippocampal volume ↓ Striatum	↑ sgACC ↑ AMG ↑ Mediodorsal thalamus ↓ dorsal ACC ↓ dlPFC Insular dysfunction	↑ ACC activity (during rest and affective challenge studies) and volume → ↑ antidepressant response ↑ Hippocampal volume → ↑ antidepressant response
PTSD	↓ Hippocampal volume ↓ ACC	↓ Hippocampus ↓ Medial prefrontal (ACC, OFC) ↑ AMG	↓ AMG and ventral ACC activity during an affective challenge task → ↑ CBT response ↑ Rostral ACC volume → ↑ CBT response

Preliminary structural and functional predictors of treatment response are also highlighted. Also, unless otherwise specified, functional findings reflect primarily task-driven abnormalities.

STG indicates superior temporal gyrus; IPL, inferior parietal lobule; dlPFC, dorsolateral prefrontal cortex; sgACC, subgenual anterior cingulate cortex; OFC, orbitofrontal cortex, ACC, anterior cingulate cortex; AMG, amygdala; CBT, cognitive behavioral therapy.

help identify potential targets for neuromodulatory interventions. Two of the more targeted neuromodulatory approaches are transcranial magnetic stimulation (TMS) and deep brain stimulation (DBS). Medication-resistant MDD has been the most well studied condition, with hypoactivity of the dorsolateral prefrontal cortex and hyperactivity of the subgenual cingulate cortex targeted using TMS and DBS respectively (Mayberg et al., 2005; Pascual-Leone, Rubio, Pallardo, & Catala, 1996). Ongoing research will likely broaden the use of these techniques for the treatment of additional affective and psychotic disorders.

SUMMARY

This chapter has outlined the emerging role for neuroimaging in the diagnosis and management of patients with psychiatric and neuropsychiatric conditions. Ongoing translational research endeavors will help link neuroimaging advances with genetic and epigenetic information to clarify endophenotypes

across psychiatric diseases. Furthermore, additional novel targets will be identified for neuromodulation and biofeedback techniques such as real-time fMRI. Overall, this endeavor will help clarify final common pathways through which medical/neurological disorders and primary psychiatric disorders produce behavioral, affective, perceptual, and cognitive symptoms.

In summary, physicians treating psychiatric disorders will increasingly make use of structural and functional neuroimaging techniques. Proficiency in the use and interpretation of neuroimaging findings will become the norm for psychiatrists, and a working knowledge of function–structure relationships will enable future advancement in the field.

CLINICAL PEARLS

- Computed tomography (CT) scans are relatively insensitive to acute ischemic stroke detection; a well visualized hypodensity may not be appreciable until more than 24 hours after symptom onset. Subtle ischemic changes such

as sulcal effacement and loss of gray/white matter differentiation may be seen within the first few hours of stroke onset.

- Hyperdensity of the middle cerebral artery (MCA), known as a “dense MCA sign,” may indicate intra-arterial clot and provides supportive evidence of an acute ischemic stroke.
- On brain MRI: while T2-based sequences are useful at detecting parenchymal pathology such as prior infarcts, mass lesions, edema, and white matter demyelinating plaques, fluid attenuated inversion recovery (FLAIR) images particularly aid the detection of periventricular abnormalities which may be obscured by cerebrospinal fluid signal on T2 images. T1 sequences are most useful in delineating brain anatomy (i.e., regional atrophy).
- The addition of gadolinium, a paramagnetic heavy metal that decreases the T1 relaxation times of tissues when injected intravenously as a contrast agent, enhances lesions that disrupt the blood–brain barrier including acute demyelinating white matter lesions, vascular lesions, and high-grade glial tumors.
- Clinically, in cases of a suspected acute stroke where a hypodensity is not well delineated on a CT scan, a brain MRI with diffusion sequences should be specifically requested.
- A T2-shine-through effect may cause false positive interpretations of an acute stroke if an abnormality is seen only on diffusion weighted images (DWI).
- If a brainstem stroke is suspected, clinicians may also request thin sections through the brainstem to improve test sensitivity.
- Anisotropic fraction (AF) quantifies microstructure integrity of the white matter and is obtained by recording water diffusivity along white matter tracts (Ries et al., 2008). This measure has the advantage of detecting microstructural abnormalities with high sensitivity.
- Magnetic resonance spectroscopy (MRS), thus far, is the only readily available technique enabling *in vivo* sampling of metabolic information. Clinically it is used to aid diagnosis of metabolic disorders (i.e., leukodystrophies); to distinguish neoplasms from other abnormal brain signals (high-grade brain tumors characterized by high choline, an indicator of cell membrane synthesis, and low N-acetyl aspartate, a marker of neuronal integrity; and to assess the effects of chemotherapeutics on brain tumors by helping to distinguish between necrosis and neoplasm recurrence.
- SPECT imaging is particularly clinically useful for seizure foci detection if the tracer is injected in close temporal proximity to seizure onset (Knowlton et al., 2004). Of note, the tracer takes approximately 30 seconds to reach the brain, and the switch from ictal to postictal hypoperfusion occurs approximately in 1–2 minutes

following seizure termination in temporal regions and sooner in extratemporal regions.

- Measuring regional cerebral glucose metabolism via 18F-FDG PET has become a standard technique to detect regional hypometabolism in neurodegenerative diseases.
- While increased blood oxygen level dependent (BOLD) signal (Logothetis et al., 2001) in fMRI provides a proxy for neural activity based on venous blood flow patterns, more recently developed methods such as *arterial spin labeling* (ASL) provide an arterial phase measure of cerebral blood flow with the potential for improved spatial and temporal resolution. In evaluating functional neuroimaging findings, it is important to also consider if “state” or “trait” characteristics are being evaluated at the time of the experiment.
- Reductions in cortical volume, particularly in prefrontal and temporal regions, have been estimated to be approximately 0.5% per year in patients over 60 years of age (Fjell et al., 2009).
- Diffusion weighted imaging (DWI) may capture early ischemic change within 30 minutes of stroke onset.
- Emerging research suggests increased anterior cingulate cortex activity/volume and hippocampal size may predict antidepressant treatment response (Chen et al., 2007; MacQueen, 2009; Mayberg et al., 1997).

CLINICAL NEUROPHYSIOLOGY IN MEDICAL PSYCHIATRY

Rani A. Sarkis and Shahram Khoshbin

Clinical neurophysiology comprises electroencephalography (EEG), evoked potential (EP) studies, electromyography (EMG), nerve conduction studies, and specialized investigations such as electrical testing of specific reflex arcs (e.g., the blink reflex). It can be critical in the differentiation of neurological conditions with similar phenomenology but different brain mechanisms, and its objective nature gives it a special place in the investigation of somatoform neurological symptoms. This chapter will describe the most commonly used procedures of clinical neurophysiology and highlight points of special interest to medical psychiatrists.

ELECTROENCEPHALOGRAPHY (EEG)

The surface electroencephalogram is a neurophysiological tool which measures brain activity with the aid of surface scalp electrodes. The exact source of this brain activity is the result of a complex interplay of large populations of neurons and surrounding glia, with the majority of the activity generated by dendritic synaptic potentials in gray matter pyramidal cells (Schaul, 1998). On a larger scale, the corticocortical and thalamocortical connections are also an important contributor to the EEG signal. For example, the thalamocortical connections are known to be essential in the generation of a number of sleep rhythms such as the sleep spindle (Speckmann & Caspers, 1979).

The standard EEG consists of electrodes placed according to the 10-20 international electrode system (Jasper, 1958). The 10 and 20 refer to the percentage of the distance, used to guide placement, from nasion (the craniometric point at the bridge of the nose where the frontal and nasal bones of the skull meet) to inion (the projecting part of the occipital bone at the base of the skull) anteroposteriorly, and then left to right preauricular points (Figure 8.1). In total, 19 electrodes are placed in addition to a ground and reference electrode. Electrode nomenclature consists of the following: C for central, F for frontal, Fp for frontopolar, O for occipital, P for parietal, T for temporal. Odd numbers refer to electrodes on the left and even numbers on the right. All central electrodes have a "z" subscript.

The electrical activity is then measured between 2 electrode pairs as a voltage difference. The electrodes can be paired in two different ways (montages) and then amplified. In the referential montage, all the electrodes are referred to the same electrode, for example, one attached to an earlobe. In contrast, the bipolar montage consists of pairs of successively numbered electrodes: electrode 1 linked to electrode 2, electrode 2 to 3, and so forth. With the current digital technology the EEG reviewer can easily switch between montages to better assess the brain activity in question.

The electrical activity once recorded can be characterized by its amplitude in microvolts (5-200 μ V) and its frequency. Surface EEG frequencies include Delta (0-4 Hz), Theta (4-8Hz), alpha (8-13 Hz), and beta (>13 Hz) (Table 8.1). By convention, any upward deflection on EEG is termed *negative* and any downward deflection is termed *positive*.

THE NORMAL EEG DURING WAKEFULNESS AND SLEEP

The "normal" adult EEG consists of a prominent alpha rhythm predominantly located in the posterior head regions, and low voltage faster frequencies (LVF) in the frontal regions (Figure 8.2). Alpha rhythm and posterior dominant rhythm are sometimes used interchangeably; however, under certain circumstances a person's posterior dominant rhythm may consist of lower frequencies. When the posterior dominant rhythm attenuates with eye opening and reappears with eye closure, it is considered *reactive*. The normal 8-13 Hz posterior background rhythm/alpha rhythm is achieved in the majority of cases at the age of 3 years. The normal alpha rhythm is reactive to eye opening and is maintained throughout life in healthy individuals. However, 10% of normal individuals do not have an appreciable posterior dominant rhythm on standard EEG, due to its having a very low amplitude when measured at the scalp (<15 μ V). The frequency of the rhythm seems to be closely related to cerebral blood flow.

As the person transitions to drowsiness (stage I sleep), slow roving eye movements are noted on EEG, the posterior alpha rhythm gradually disappears, and the brain activity consists of fronto-centro-temporal theta activity alongside prominent frontocentral beta activity (Figure 8.3). With deeper levels of

Figure 8.1 EEG electrode set up. Scalp EEG electrodes are placed according to the 10–20 system. Occasionally, extra electrodes are placed for monitoring of eye movements.

Table 8.1 FREQUENCY BANDS OF INTEREST CAPTURED WITH SCALP EEG

FREQUENCY TERM	RANGE
Alpha α	8–13 Hz
Beta β	>13 Hz
Theta θ	4–8 Hz
Delta δ	0–4 Hz

Figure 8.2 Normal adult EEG. A double banana montage is used with the left temporal chain on top, then left parasagittal chain, then midline electrodes, then right parasagittal chain, then the right temporal chain. A 10-second EEG sample is shown with the distance between each bar representing 1 second. The prominent positive deflections (downward) are due to artifact from the eye blink. During the first 2 seconds the patient has the eyes open, then upon eye closure an 11 Hz posterior alpha rhythm is seen; indicating that it is reactive. Lower voltage faster activity is noted in the anterior electrodes.

sleep, vertex waves appear. These waves are prominent negative waves, best appreciated in the midline electrodes, and can occur in isolation or in trains. Stage II sleep is characterized by the persistence of vertex waves and the appearance of 12–14 Hz frontocentral, sinusoidal rhythms termed *sleep spindles* (Figure 8.4). In addition to the sleep spindles, K complexes can also be seen, which are characterized by an initial

negativity, a slow positivity, and then another negativity seen prominently in the frontal or midline regions. Stages III and IV sleep are lumped together and termed *slow-wave sleep* and consist of higher voltage theta and delta activity. REM (rapid eye movement sleep) is characterized by rapid eye movements, intermittent alpha activity, and the appearance of sawtooth waves over the central regions.

Figure 8.3 Normal EEG during drowsiness. As the patient transitions to drowsiness (stage I sleep), roving eye movements are noted (white arrow indicates artifact due to roving eyes). The voltage of the background becomes attenuated and the alpha rhythm noted during wakefulness dissipates.

Figure 8.4 EEG during stage II sleep. The record consists of bilateral slowing predominantly in the theta range. In this EEG sample several vertex waves and sleep spindles can be seen, which are most prominent in the midline electrodes.

EEG ABNORMALITIES

EEG abnormalities can be broadly divided into slow-wave abnormalities and epileptiform abnormalities. Slow-wave abnormalities are documented when activity in the theta and delta range is seen (Figure 8.5) beyond what is expected for a normal EEG. For example, any slowing during wakefulness

is usually abnormal. Based on the location of the slowing on EEG, it can further be classified into focal or generalized. Other descriptors of the slowing also include whether it is continuous or intermittent. In general, focal cerebral abnormalities cause focal slowing on EEG, while more diffuse processes such as metabolic derangements cause diffuse slowing

Figure 8.5 EEG with focal slowing. EEG of a 68-year-old patient with a prior right middle cerebral artery stroke and a transient episode of confusion. The EEG during wakefulness shows focal slowing in the delta range in the right temporal chain, likely due to the prior stroke.

on EEG. Certain slowing patterns can be readily distinguishable. Continuous polymorphic delta activity is a pattern suggestive of a structural cerebral lesion with disruption of white matter tracts in the majority of the cases. In the absence of any structural lesion on imaging, continuous slowing may represent a postictal state and should resolve with time. Frontal intermittent delta activity (FIRDA) is a nonspecific pattern seen in metabolic encephalopathy and raised intracranial pressure. FIRDA can also be seen in normal drowsy individuals, and as a result is not necessarily pathological (Accolla, Kaplan, Maeder-Ingvar, Jukopila, & Rossetti, 2011).

Epileptiform abnormalities include spikes and sharp waves. A spike is defined as a transient (i.e., *transient wave*) that is distinguishable from the background activity, with duration of 20 to less than 70 milliseconds (Chatrian et al., 1974). A sharp wave is similar, but its duration is 70 to 200 milliseconds (Figure 8.6). Spikes and sharp waves are often followed by a slow wave, and can also be classified as focal or generalized.

When the spikes or sharp waves are periodic and lateralized to one hemisphere, they are termed *PLEDs*: periodic lateralized epileptiform discharges (Figure 8.7). PLEDs are seen under different circumstances; they can represent an injury pattern seen with an acute insult (Garcia-Morales et al., 2002) and resolve with time, or ongoing ictal activity (there are cases where clinical findings are correlated with each discharge, such as clonic movements), or a postictal state.

THE ROUTINE INPATIENT AND OUTPATIENT EEG

The standard routine EEG consists of 20–40 minutes of recording with the EEG technologist at bedside. During the procedure the patient is asked to open and close the eyes to assess for reactivity. Ideally, stage II sleep should be captured during the recording, as abnormalities may arise or become

more prominent during this stage. Slow-wave sleep and REM sleep are rarely seen during the routine EEG.

Other activation procedures are also performed depending on the circumstances. The purpose of the activation procedures is to “bring out” focal or epileptiform activity not apparent in the record. During the hyperventilation procedure, the patient is asked to hyperventilate for 3 minutes. Hyperventilation is of higher yield in young adults, and is contraindicated during pregnancy and in patients with asthma, cardiovascular disease, or cerebrovascular disease, due to theoretical concerns regarding bronchospasm or ischemia. Photoc stimulation is another activation procedure, where flickering lights of variable frequencies are shined into the patients’ eyes. In rare circumstances, the activation procedures themselves may trigger a nonepileptic seizure. In the inpatient setting, the activation procedures may not be performed unless specifically requested by the ordering physician. When dealing with a comatose individual, verbal and noxious stimuli are often given by the technologist to assess for reactivity on EEG.

THE EEG REPORT

A complete report should include the following:

- The patient’s posterior background and whether it is reactive
- A description and characterization of beta activity
- Stages of sleep noted
- Response to activation methods
- Single lead EKG rhythm
- Presence of any asymmetries
- Documentation of any slowing or epileptiform discharges
- A comparison of the current EEG to any prior EEGs

Figure 8.6. EEG with sharp wave. EEG of a 29-year-old woman with a history of epilepsy. The EEG shows stage II sleep with prominent sleep spindles and focal right temporal sharp waves (encircled).

Figure 8.7 EEG with PLEDs (periodic lateralized epileptiform discharges). EEG of a 72-year-old man with a history of head trauma, a left subdural hematoma, and altered mental status. The EEG shows periodic sharp waves (arrows) in the left hemisphere at a frequency of ~1Hz.

As can be clearly seen above, the EEG report includes important information not limited to epileptiform activity. The body of the report should always be scrutinized by the treating physician and not rely solely on the electroencephalographer's conclusions. For example, REM sleep noted on a routine EEG is suggestive of medication effect or possibly narcolepsy. Due to the complexities involved in EEG interpretation, it is always advisable to consult with the EEG reader when in doubt.

It also has to be kept in mind that an EEG is always interpreted in the context of the patient's age. Certain degrees of temporal slowing, for example, are allowed in the elderly.

Comparisons to prior EEGs are invaluable, as it may show new epileptiform activity or may establish the progression of an encephalopathy or degenerative brain disease. Finally, there are certain EEG waveforms that are suspicious but do not fulfill criteria for epileptiform activity; these may be labeled as "sharply contoured" discharges. When these are reported and the clinical suspicion of epileptic seizures is high, a repeat routine EEG, a more prolonged study, and/or a provocative procedure such as sleep deprivation is advised. In addition, a spike/sharp wave noted on EEG does not automatically mean a patient has epilepsy. In fact, studies

have documented the presence of interictal abnormalities in 0.3%–0.9% of healthy controls (Gibbs, Gibbs, & Lennox, 1943; Thorner, 1942).

A common dilemma facing the treating physician is the determination of the number and length of EEGs required in a given clinical setting. The first limitation is the number of machines available at the EEG lab, and the number of technicians. Under these circumstances it is best to consult with the EEG lab first. The other factors to consider are the level of consciousness of the patient and the question being asked. In the majority of cases a routine 20–30-minute EEG is usually obtained to rule out nonconvulsive status epilepticus, assess the level of encephalopathy, or screen for epileptiform abnormalities. However, it is known that comatose patients may require more than 24 hours of monitoring to capture subclinical seizures on EEG, while in awake patients with altered mentation 24 hours is usually enough. The yield of nonconvulsive seizure detection in the ICU rises from 61% in one hour to 88% by 24 hours in the noncomatose patient with altered mental status (Claassen, Mayer, Kowalski, Emerson, & Hirsch, 2004). The threshold should be low for undertaking longer EEG monitoring periods in any patient with a history of epilepsy for whom there is a question of current disease activity. In patients with suspected nonepileptic seizures, video with simultaneous EEG telemetry is the gold standard, and the time of monitoring to capture the event is variable depending on the patient. It should be long enough to capture at least one typical seizure. (See chapter 43 on epilepsy for further detail).

EEG IN THE AWAKE PATIENT WITH ALTERED MENTAL STATUS

The terms delirium and encephalopathy are often used interchangeably to describe the condition of the awake patient with altered mental status. When faced with this clinical scenario, the EEG can aid the physician with the differential diagnosis. The EEG is a very sensitive tool for the detection of encephalopathy; however, it has low specificity with regards to determining the etiology. The degree of EEG abnormality tends to correlate with the severity of the encephalopathy and tends to improve with its resolution.

A general rule of thumb is that abnormalities limited to the cortex will cause slowing of the posterior background frequency, while abnormalities involving subcortical structures lead to increased polymorphic delta activity, triphasic waves, or FIRDA.

EEG in Toxic and Metabolic Encephalopathies

A number of metabolic derangements can lead to abnormalities on EEG including electrolyte disturbances, hypo/hyperglycemia, osmotic changes, endocrine dysfunction, and organ failure (Kaplan, 2004). The degree of abnormalities is associated with the rate of change of the CNS level of the metabolite or toxin, with more acute changes causing the most severe abnormalities.

Hypoglycemia may lead to focal slowing on EEG, which goes along with focal neurologic deficits noted on examination. The EEG of a hyperthyroid patient may show a slight increase in the alpha frequency and excessive beta activity. Hypothyroidism shows lower alpha frequencies.

Other than patterns of slowing, hypoglycemia and hypocalcemia have been associated with epileptiform discharges on EEG, while nonketotic hyperglycemia may be a cause of PLEDs (Hennis, Corbin, & Fraser, 1992; Honigsberger, 1999).

Even at therapeutic levels certain medications may cause EEG abnormalities. Drugs such as carbamazepine, gabapentin, clozapine, lithium, and tricyclic antidepressants cause slowing of the background rhythm. Clozapine is notorious for causing spike and wave discharges in patients without a known history of epilepsy and is implicated in lowering seizure threshold (Freudenreich, Weiner, & McEvoy, 1997). Meanwhile, lithium can enhance epileptiform discharges in patients with known epilepsy.

At toxic levels lithium may cause a confusional state secondary to an encephalopathy or subclinical seizure activity; in this case the EEG is helpful to distinguish between the two, and to determine the need for benzodiazepines (Kaplan & Birbeck, 2006). EEG abnormalities noted in lithium toxicity include diffuse slowing, spikes, and triphasic waves. In general, at toxic doses, medications and toxins are expected to produce generalized slowing and a decrease in the frequency of the posterior background. Epileptiform discharges including PLEDs have been described with toxic doses of baclofen, mercury, manganese, isoniazid, tricyclics, penicillin, and aminophylline (Yamada & Meng, 2009). A different pattern, where generalized periodic epileptiform discharges with a low frequency <0.25 Hz are noted, can be seen with ketamine and PCP intoxication (Stockard et al., 1976).

Benzodiazepines, barbiturates, and cocaine cause increases in beta activity in the 20–25 Hz range termed *excessive beta* (Figure 8.8). The finding of excessive beta on EEG is suggestive of the patient using one of these drugs, and is clinically useful. Excessive beta is more pronounced in younger individuals and with acute intake of the drug.

One of the common abnormalities first described in hepatic and renal encephalopathy is the presence of *triphasic waves* (Figure 8.9). These are theta waves with an initial negativity, a large amplitude positivity, and then another negativity, providing it with the “tri-phasic” morphology. They occur in a periodic fashion with a frequency of 1–2 Hz. The occurrence of triphasic waves has been documented in up to 25% of patients with hepatic encephalopathy, and in some series has been associated with worse outcome and increased mortality (Karnaze & Bickford, 1984). They are frequently seen in patients with mild to moderate encephalopathy but have also been documented in patients who are awake with no apparent encephalopathy. Of note, in some instances it is difficult to distinguish triphasic waves from epileptiform discharges, and, in a patient with no clear etiology of altered mental status, a trial of benzodiazepines is warranted.

Although the triphasic waves were initially described in patients with liver disease, they were later found to occur in

Figure 8.8 EEG with excessive beta. A 27-year-old woman with anxiety and headaches, currently on diazepam. The EEG shows excessive beta activity throughout the record, which is a result of the diazepam.

Figure 8.9 EEG with triphasic waves. EEG of a 30-year-old patient with meningitis, renal failure, and agitation. The EEG sample during wakefulness shows bilateral, frontally predominant theta waves which have a triphasic morphology (arrow), commonly referred to as “triphasic waves.” The record also shows bilateral slowing in the theta-delta range.

patients with uremia, electrolyte imbalances, anoxic brain injury, and medication intoxications (Kaplan, 2004).

The EEG in chronic alcoholics is also nonspecific; however, a higher percentage of these patients have a low voltage EEG as compared to the normal population.

EEG in Autoimmune and Infectious Encephalopathies

Other important causes of alterations in mental status include the autoimmune and infectious encephalopathies. With acute viral or bacterial encephalitis, the EEG changes are nonspecific with diffuse slowing. Herpes encephalitis is an exception

where characteristic EEG findings can be seen. The virus has a predilection for the temporal lobes, and subsequently after a few days of clinical symptoms; characteristic PLEDs are noted in the temporal regions, sometimes independently, a phenomenon termed *bi-PLEDs*. The PLEDs are transient in nature and resolve within 3–4 days (Lai & Gragasin, 1988). Similarly characteristic EEG findings are also seen in subacute sclerosing panencephalitis (SSPE) and Creutzfeld-Jakob disease (CJD). SSPE is the result of chronic measles infection and is characterized by the appearance of high voltage spike and wave discharges occurring every 4–15 seconds. In CJD early changes on EEG are nonspecific, while later stages of the

disease are characterized by periodic discharges occurring at a frequency near 1 Hz. In patients with clinically suspected CJD these periodic discharges had sensitivity, specificity, and positive and negative predictive values were 64%, 91%, 95%, and 49% with respect to an autopsy diagnosis of the disease (Steinhoff et al., 1996).

In HIV infection the EEG is an early and sensitive indicator of HIV-associated encephalopathy. In a study published before anti-retroviral therapy was available, 30% of patients initially presenting with HIV infection and normal cognitive function had abnormal EEGs, showing slowing and diminished reactivity of awake background rhythms; follow-up EEGs six to nine months later were abnormal in 40% of patients (Koralnik et al., 1990). EEG abnormalities are reduced significantly by antiretroviral therapy, with benefits observed after as little as four weeks of therapy, with greater benefit in patients with more rapid normalization of CD4 counts (Babiloni et al., 2014). Patients with AIDS dementia or with opportunistic infections of the CNS display more dramatic EEG abnormalities, such as severe diffuse or focal slowing, or epileptiform abnormalities. Because of its high sensitivity to encephalopathies of various kinds the EEG is valuable in the differential diagnosis of HIV-positive patients with mental status changes, especially when there is potential confounding of the symptoms of primary mental disorder and the symptoms of gross brain disease due to HIV or associated with it.

Autoimmune encephalitides are another important category of causes leading to altered mental status. They can be broadly divided into paraneoplastic and nonparaneoplastic. The nonparaneoplastic group includes Hashimoto's encephalitis and systemic lupus erythematosus (Flanagan & Caselli, 2011). Patients with Hashimoto's encephalopathy findings typically show bilateral slowing, but there are case reports of focal temporal seizures (Arain et al., 2001). EEG slowing from this condition is expected to resolve with treatment (Rodriguez et al., 2006). EEG findings are also common in patients with SLE and seem to have a predilection for the left hemisphere (Glanz, Laoprasert, Schur, Robertson-Thompson, & Khoshbin, 2001).

Similar EEG findings are also noted in the paraneoplastic syndromes and are based on the area of the brain involved. With limbic encephalitis, all patients tend to have temporal abnormalities including slowing and/or epileptiform discharges. Clinically a high proportion of these patients also exhibit neuropsychiatric symptoms, and the disorder may present with such symptoms. (Rosenfeld & Dalmau, 2010). A recently described EEG finding in patients with limbic encephalitis is the *extreme delta brush*, which resembles a pattern seen in premature infants (Schmitt et al., 2012).

EEG in Nonconvulsive Status Epilepticus

One of the most important indications to order an immediate EEG in the inpatient setting is to rule out nonconvulsive status epilepticus (NCSE).

Nonconvulsive seizures have been documented in around 21.5% of patients with altered mental status admitted to the

hospital. Nonconvulsive status epilepticus is defined when the seizure activity is prolonged (there is no consensus on duration but a time period of >30 minutes is usually accepted). NCSE is difficult to diagnose because it is not accompanied by any tonic or clonic motor activity and is indistinguishable clinically from delirium or secondary psychosis not associated with NCSE. It is imperative to diagnose it early, as treatment has been associated with favorable outcomes. The EEG is the gold standard to diagnose NCSE and should be prioritized if the clinical suspicion is high. Circumstances where suspicion should be high include the abrupt onset of alteration in mental status, waxing and waning course, and clinical signs such as subtle automatisms (lip smacking, fumbling, etc.) (Chang & Shinnar, 2011). In those circumstances intravenous antiepileptic drugs (AEDS) are needed to try to abort the seizure activity (benzodiazepines, fosphenytoin, phenobarbital, levetiracetam, valproic acid, or lacosamide). Ultimately, any patient with altered mental status of unclear cause requires an EEG.

EEG in the Setting of Head Trauma

Traumatic brain injury (TBI) is classified into mild, moderate, and severe based on the duration of loss of consciousness or of posttraumatic amnesia. As discussed in detail elsewhere in this book, patients with mild traumatic brain injury do not necessarily have insignificant residual impairment in brain function, and a significant minority of such patients continue to experience neuropsychiatric symptoms months after the injury. In this patient population an acute EEG may reveal slowing with attenuation of the posterior background voltage. These changes tend to resolve with time as the patient recovers. However, most patients with residual symptoms following mild TBI will have normal EEGs, so the test is of limited diagnostic value except when the patient has symptoms suggestive of epilepsy such as episodic alterations of consciousness (Arciniegas, 2011). Patients with more severe degrees of injury may experience early posttraumatic seizures or late posttraumatic seizures. Early posttraumatic seizures may not necessarily recur, and, as a result, long-term antiepileptic drugs are not needed. The EEG is useful in aiding prognostication, as evidence of epileptiform activity would place the patient at higher risk of recurrence.

EEG in Patients with Cognitive Complaints

Before discussing EEG changes in dementia, one has to become familiar with EEG changes in normal aging. Common changes include a decrease in frequency of the posterior dominant rhythm by 0.5–1 Hz, although authorities in the field still consider any frequency less than 8 Hz during the waking state to be abnormal regardless of age. In addition, focal temporal theta slowing can be seen and may be a signature of subclinical cerebrovascular disease. There is no clear cutoff for how much theta slowing is allowed in the elderly, with quoted ranges between 10%–15% of the record. EEG changes in Alzheimer's disease are nonspecific and include slowing in the theta range and bursts of frontotemporal delta (Figure 8.10). In Parkinson's disease, theta and delta slowing

Figure 8.10 EEG in dementia. This EEG is from a 90-year-old woman with Alzheimer's disease and confusion. The white arrow shows an eye blink. The posterior background rhythm is in the theta range (6–7 Hz in this case).

may be seen over the posterior head regions. In frontotemporal dementia, the alpha seems to be preserved and frontotemporal slowing is expected (Jenssen, 2005).

The EEG can be useful in a patient who is exhibiting apparently severe cognitive deficits and has a history or examination atypical for dementia. In this setting a normal EEG would be evidence against the diagnosis of a dementing process (Holschneider & Leuchter, 1999). However, an EEG with a posterior background rhythm of 8–8.5 Hz—at the lower end of the normal range—could represent significant change from the patient's baseline. As such, it would be weaker evidence against a dementing process than one with an alpha rhythm between 10 Hz and 12 Hz.

EEG IN PATIENTS WITH ANXIETY DISORDERS AND PSYCHOSIS

Differentiating panic attacks from simple partial seizures can be difficult on clinical grounds due to the common symptomatology and similar brain regions involved (Hurley et al., 2006). The two conditions may also exist within the same patient (Mintzer & Lopez, 2002). There are also a few case reports of patients incorrectly diagnosed with panic disorder who in fact had a new onset of focal epilepsy (Gallinat, Stotz-Ingenlath, Lang, & Hegerl, 2003; Scalise, Placidi, Diomed, De Simone, & Gigli, 2006); the latter diagnosis would not only influence treatment but would be an indication to work up the patient to exclude a focal lesion such as a tumor. EEG in this clinical situation is most valuable when it shows an ictal pattern simultaneous with the patient experiencing his or her typical symptoms. Interictal epileptiform discharges suggestive of epilepsy are less diagnostically specific, but would support a trial of antiepileptic drugs. The caveat is that in some patients with only simple partial seizures, the scalp EEG may be negative both ictally and interictally; in these cases a high

clinical suspicion should drive more extensive neuroimaging and electrophysiologic testing.

The EEG in a patient with a history of diagnosed epilepsy who is presenting with new psychotic symptoms is useful in corroborating the clinical impression of the relationship of the psychosis to the seizure disorder. If discrete, repetitive, stereotypic mental or behavioral symptoms are ictal, one would expect the EEG to show seizure discharges coincident with the symptoms; video recording with EEG telemetry can demonstrate such a relationship. Psychotic symptoms occurring as part of recurrent episodes of delirium lasting minutes to hours at a time would most likely be postictal, and the EEG usually will show focal or diffuse slowing coincident with the symptoms. A persistent psychosis with gradual onset in a patient with several years' history of limbic epilepsy is likely to be an interictal psychosis—one related to the patient's persistent abnormal brain electrical activity, but with symptoms not synchronous with seizures or postictal states. In this case the EEG in the symptomatic patient usually shows temporal sharp wave or spike activity but not frank seizure discharges or focal slowing. On the other hand, EEG is not routinely recommended in the assessment of a patient with first-episode schizophrenia and no known history of epilepsy. Some studies have shown that patients with normal EEG were more likely to remit after one year of treatment (Freudenreich et al., 2007).

EEG IN EPILEPSY AND PSYCHOGENIC NONEPILEPTIC SEIZURES

Psychogenic nonepileptic seizures (PNES) are characterized by involuntary repetitive episodes of movement, behavior, and/or alteration of consciousness, sensation, or memory (Alsaadi & Marquez, 2005) without ictal or postictal changes on EEG consistent with the pattern of symptoms seen (Figures 8.11 and 8.12). Patients may present with generalized or unilateral

Figure 8.11 EEG of a seizure. This EEG of a 40-year-old man with a history of epilepsy shows a focal left temporal seizure during sleep. The seizure starts with rhythmic theta activity in the left temporal region, which changes in amplitude and morphology.

Figure 8.12 EEG in PNES (psychogenic nonepileptic seizures). A 30-year-old patient with spells of generalized shaking. At the beginning of the recording there is a lot of EEG artifact due to the shaking. A few seconds afterwards, a posterior alpha rhythm is appreciated after an eye blink.

shaking, unresponsiveness, bizarre behavior, weeping, pelvic thrusting, or forceful eye closure, among others. PNES is discussed in detail in chapter 43.

Patients with PNES frequently have genuine epilepsy as well. In this patient population, video EEG is the gold standard for diagnosis, as it is the best way to determine whether the mental and behavioral symptoms are simultaneous with seizure discharges or immediately follow them. Video EEG is definitive when the suspected PNES include loss or alteration of consciousness or bilateral tonic-clonic movements, as alterations in the EEG at the brain surface are inevitably present during epileptic seizures with such symptoms. More

complex but stereotyped and repetitive behavior, without major alteration of consciousness, can result from seizure discharges deep in the frontal lobe that do not spread to the brain surface. Seizures of this type can yield a video EEG suggestive of PNES—showing the typical symptomatic behavior with no coincident EEG change. Clinical suspicion should be high if the spells are stereotypic in nature, cluster, and tend to occur out of sleep. In rare circumstances, invasive electrode placements may be necessary to definitively settle the issue. They are undertaken when clinical suspicion of frontal lobe epilepsy is high because of the patient's history or findings of anatomic or functional brain imaging.

A NOTE ON QUANTITATIVE EEG AND EEG MODIFICATIONS

The standard EEG setup relies on electrodes placed on the scalp; however, there are a number of additional electrodes (Table 8.2) which are thought to increase the detection of epileptiform activity from the mesial temporal lobes, which is distant from the scalp. The placement of these electrodes should be discussed with the electrophysiologist, as different centers seem to favor different types of electrodes.

Advances in technology now permit the quantitative analysis of EEG signals in real time. In the ICU, quantitative EEG often is used in patients who are stuporous, comatose, or intubated. In these patients it provides semiautomated detection of changes in brain function related to hypoxia, ischemia, or seizure activity. Outside the ICU, quantitative EEG has as yet no established place in routine clinical practice. Applications of quantitative EEG have been limited to the research setting in psychiatric patients, and attempts have even been made to try to predict response to treatment (Coutin-Churchman et al., 2003; Hunter, Muthen, Cook, & Leuchter, 2010; Knott, 2000).

EVOKED POTENTIALS

An evoked potential (EP) consists of an electrical response elicited by presenting a patient with a sensory stimulus (auditory, sensory, or visual). Typically the stimulus is presented repeatedly and responses are summed, so that signals linked to the stimulus are augmented and background activity unrelated to the stimulus cancels out. Unlike the EEG, which captures spontaneous electrical activity, evoked potentials are dependent on the stimulus and are time-locked to it. Evoked potentials are used to assess the integrity of the sensory pathway, from the sense organ to the sensory cortex. In the medical-psychiatric context, EPs are used for two purposes: (1) to determine whether complaints of sensory loss are accompanied by and are proportionate to changes in the relevant parts of the nervous system; and (2) to detect demyelinating diseases that may not be diagnosable by anatomic brain imaging and that may have neuropsychiatric complications or comorbidities.

The setup of the test depends on the sensory stimulus being given. In general, a few scalp electrodes are placed to measure cortical responses if the stimulus is visual or auditory.

For visual evoked potentials (VEPs), electrodes are placed bilateral occipital, bilateral temporal, midline occipital, and midline frontal.

For auditory evoked potentials (AEPs), electrodes are placed on the left or right earlobes or mastoid process and vertex.

If the stimulus is sensory, then electrodes are placed at a location between C3 and P3 or C4 and P4, midline frontopolar, over Erb's point (angle between the clavicular head of the sternocleidomastoid muscle and the clavicle, thus placing it above the brachial plexus), cervical spine at C5, thoracic spine T12, and iliac crest.

VEPs assess the integrity of the visual system by stimulating each eye with a black and white checkerboard pattern repetitively (Figure 8.13). The expected signal is a positive wave measured by the occipital scalp electrodes at 100 milliseconds after the stimulus is given. The interval between the stimulus and the positive wave is the *latency* of the VEP. Normal ranges are determined by each laboratory, and are usually between 90–110 milliseconds. The finding of a prolonged latency is not specific for demyelinating disease, as it can also be seen in ocular disease (glaucoma), compressive lesions of the optic tract (tumors), and lesions of the occipital cortex. The test itself relies on patient cooperation and an experienced technologist.

VEPs are useful in confirming a diagnosis of hysterical blindness. If a patient has a visual acuity of 20/120 or better, the routine VEP stimulus will produce a definite positive wave at approximately 100 msec after the stimulus (Figure 8.14); this is true even if the patient does not focus on the stimulus, which a hysterically blind person obviously would not do (Howard & Dorfman, 1986). The VEP can be used in a more subtle way to diagnose patients complaining of impairment in visual acuity that is apparently disproportionate to ophthalmological and neurological findings. The stimulus for the VEP is a checkerboard of black and white squares that rhythmically alternates, black squares becoming white and white becoming black. If the patient's visual acuity is sufficient to resolve the squares, the alternation will be an effective repetitive stimulus and will produce a definite positive wave at 100 msec. If the acuity is too poor to resolve the squares, the patient will not perceive a changing stimulus and there will be no positive wave. Delay of the positive wave of the VEP suggests demyelination of the optic nerve or optic tract. This is most often due to optic neuritis; 30% of patients with optic neuritis will develop (or already have) multiple sclerosis (MS). Vitamin B12 deficiency also is associated with prolonged

Table 8.2 ADDITIONAL ELECTRODES WHICH CAN BE PLACED IN ADDITION TO THE STANDARD EEG SETUP

TYPE OF ELECTRODE	LOCATION	DEGREE OF INVASIVENESS
Anterior temporal	Between external auditory meatus and outer canthus of the eye	Noninvasive
Sphenoidal	Through mandibular notch	Minimally invasive, done at bedside.
Nasopharyngeal	Through nasal cavity	Minimally invasive, done at bedside.
Foramen ovale	Through foramen ovale	Invasive, placed by neurosurgeon

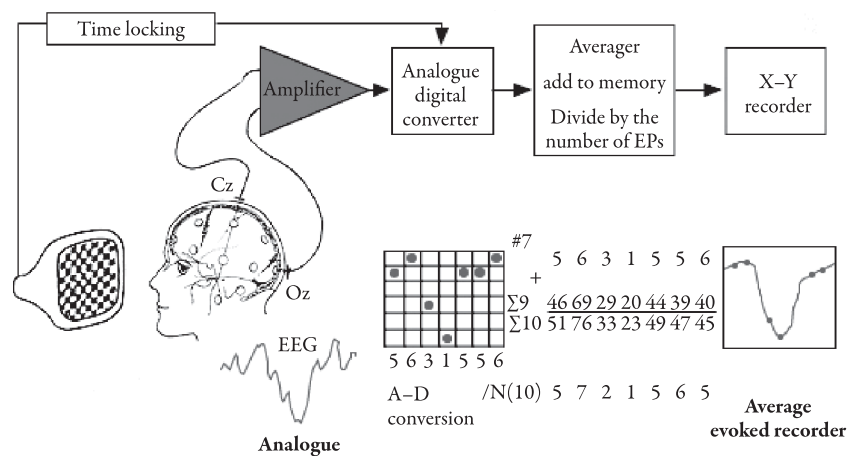

Figure 8.13 Diagram representing steps used in recording visual evoked potentials. The patient is asked to concentrate on a checkerboard pattern and the brain activity is then amplified and digitally converted. The repeated stimuli are then averaged.

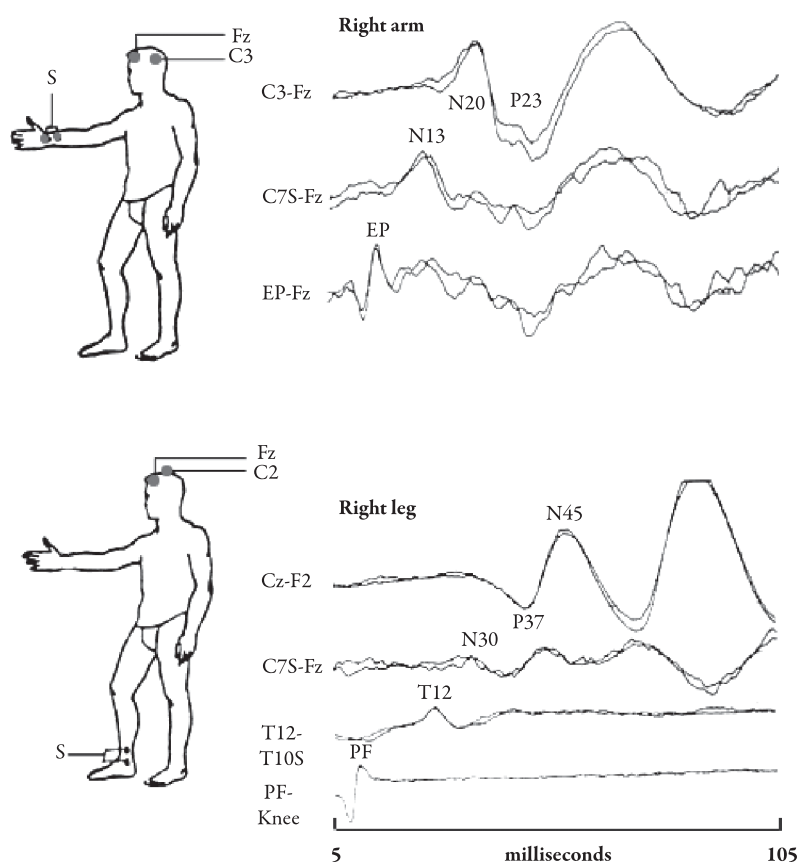

Figure 8.14 Examples of arm and leg somatosensory evoked potentials. Several stimulations of the median nerve (above), or posterior fibular (nerve below) are averaged between a pair of electrodes (C7S= 7th cervical spine, EP = Erb's point, T12: 12th thoracic spine, PF = popliteal fossa). The signals obtained are labeled P for positive and N for negative.

latency of the VEP. VEPs can be abnormal early in the course of MS at a time when the MRI is normal or nondiagnostic. The test should be considered when the patient is suspected of MS on clinical grounds, has a history of visual symptoms, and has a normal or nondiagnostic MRI.

AEPs, also known as *brainstem auditory evoked potentials* (BAEPs) assess the integrity of the auditory pathways, which connect the cochlea on each side with its primary auditory

cortex in the contralateral superior temporal lobe. In this test, a patient is presented with an auditory stimulus consisting of brief clicks. A complex signal of 6 waveforms is generated as the signal travels from the cochlear nerve, up the brainstem, and then reaches the cortex. Each wave represents a location on the way from the inner ear to the auditory cortex (Figure 8.15). If the time between one wave and the next is prolonged over the normal interval, there is demyelination

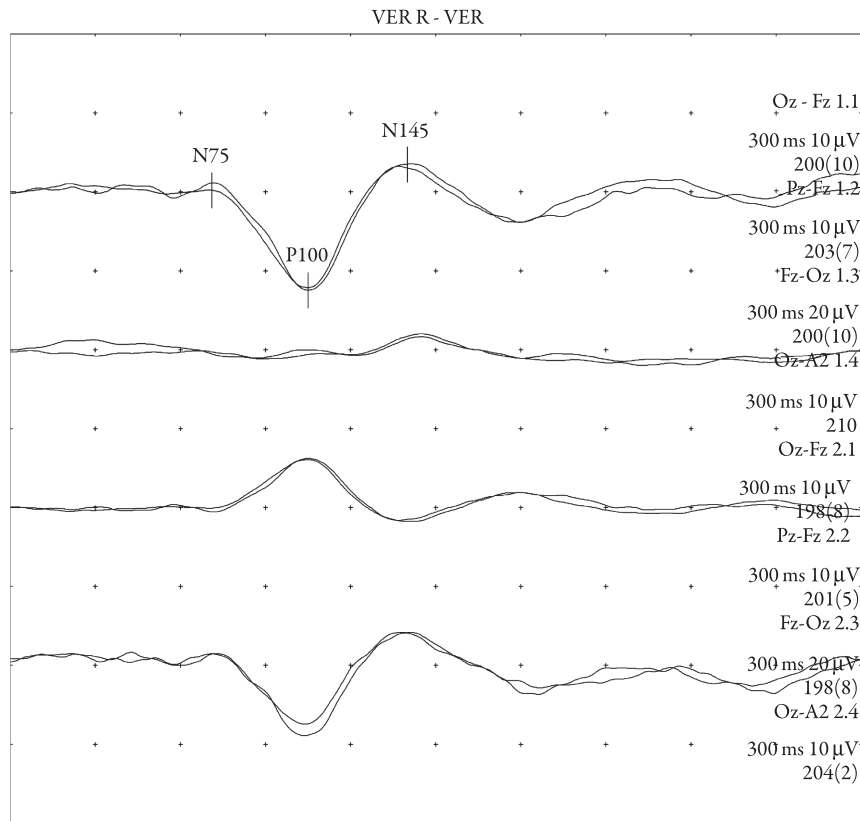

Figure 8.15 Normal visual evoked potentials tracing. The interval between crosses corresponds to 300 milliseconds. A positive deflection is noted at around 105 milliseconds corresponding to the P100 waveform.

of the auditory pathway between the two corresponding locations, a partial lesion of the pathway, or anatomic impingement on the pathway.

As with VEPs, the AEPs may provide evidence of demyelination in a patient clinically suspected of MS at a time when the MRI is normal or nondiagnostic. It would be particularly sensitive in this setting if the patient had complaints of vertigo or impaired balance, or if the neurological examination showed nystagmus or unsteady gait.

Just as the VEPs can be used to assess alleged loss of visual acuity, the AEPs can be used to assess the magnitude of genuine hearing loss. The stimulus for the AEP is a series of clicks. If the clicks are above the threshold for hearing they will produce an AEP; if they are below the threshold they will not. If a patient has a normal AEP at a volume at which they deny hearing, it can be concluded that the patient's deafness is of cerebral origin—due either to conversion, malingering, or a disorder of higher cortical function. In the last case there would always be evidence of cerebral cortical damage on an anatomic image.

Somatosensory evoked potentials (SSEPs) assess the transmission of a sensory signal from peripheral nerves to the contralateral somatosensory cortex (Figure 8.16). The three nerves stimulated in a standard SSEP test are the median nerves and, in the lower extremities, either the posterior tibial nerves (at the ankles), or the peroneal nerves at the fibular heads. The signal is then measured at the brachial plexus (for

the median nerve) and at the lumbar spine (for the posterior tibial or peroneal nerve), the cervical spine, and the contralateral cerebral cortex. Delayed latency of the SSEP is evidence for demyelination of the sensory pathway; the differential diagnosis includes demyelinating neuropathies and myelopathies as well as encephalopathies. Completely normal SSEPs would suggest a diagnosis of conversion in a patient complaining of severe sensory loss in a limb. An SSEP study would be appropriate when MS is suspected in a patient with prominent sensory symptoms but a normal MRI. Both the AEP and the SSEP can be used in confirming—or disconfirming—a diagnosis of brain death in a patient who might conceivably be “locked in”—alive and conscious but unable to respond to stimuli because of motor system damage. If a cortical potential can be evoked by an auditory or somatosensory stimulus, the patient is alive.

ELECTROMYOGRAPHY AND NERVE CONDUCTION STUDIES

Electromyography (EMG) is the study of the electrical activity of muscle fibers. This is typically done using a needle inserted into the muscle of interest, though the EMG is recorded on the surface of the skin in some contexts. It is useful in diagnosing three types of problems: (1) intrinsic diseases of muscle; (2) disturbances in the nerve supply to muscle;

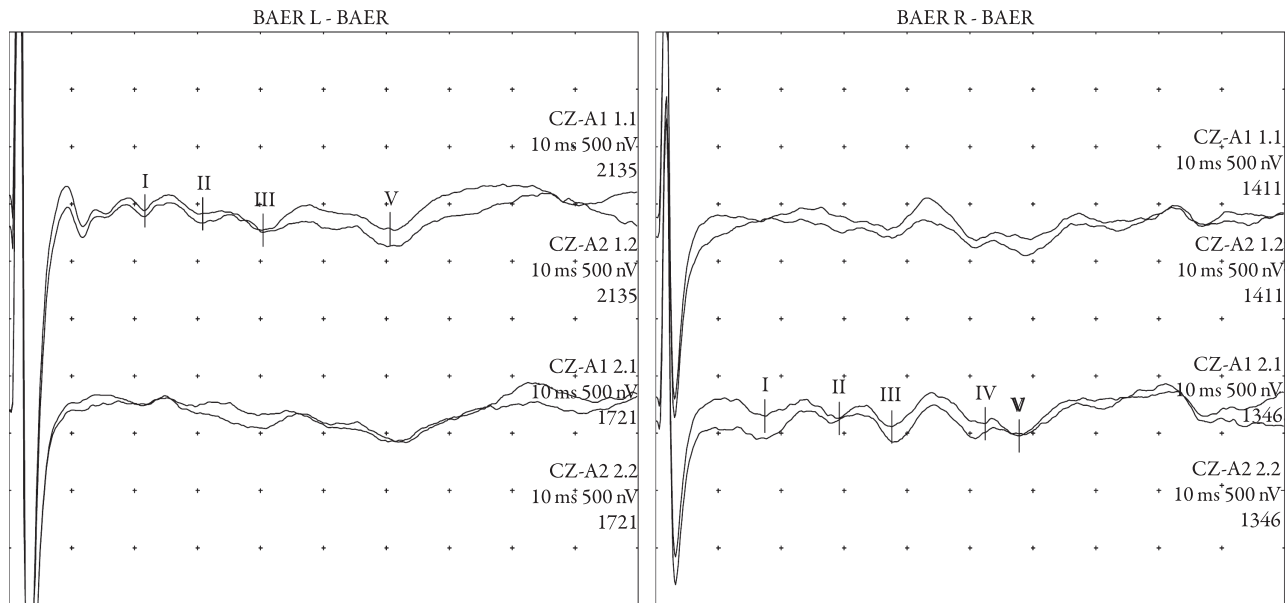

Figure 8.16 Left and right brainstem auditory evoked potentials showing the normal latency for waves I, II, III, IV, and V. The distance between the small crosses corresponds to 10 milliseconds.

(3) disorders of the neuromuscular junction; and (4) disturbances in motor control. Electromyography requires a skilled operator and can involve technical subtleties, depending on the muscles of interest. A medical psychiatrist would be most likely to initiate an EMG study in a patient with a complaint of weakness that is ascribed by the patient and/or other physicians to either systemic illness or depression, but might actually involve primary disease of muscle (e.g., polymyositis) or the neuromuscular junction (e.g., myasthenia gravis or Lambert-Eaton syndrome). Disproportionate involvement of proximal muscles is a clue to myopathy; dramatic decline in strength with continued exertion of a single muscle group is typical of myasthenia. Neither of these is typical of the general weakness and asthenia of systemic disease nor of the anergia and fatigability of depression.

Nerve conduction studies involve the application of a discrete, standardized electrical stimulus to a specific nerve distally and measuring the voltage over a specified proximal part of the nerve. There are well-established normal ranges for the amplitude of the proximal signal and for the interval between the distal stimulus and the proximal response—or, considering the distance as well as the time, the nerve conduction velocity. Nerve conduction tests can establish damage to specific nerves, as from trauma, demyelination, ischemia, compression, or entrapment, as well as polyneuropathy—diffuse damage to nerves throughout the body with the greatest effect on the long nerves to the extremities.

The second special use of nerve conduction tests in medical psychiatry is in establishing the diagnosis of an entrapment neuropathy with severe symptoms—usually of pain—that has been underappreciated or misdiagnosed by the patient's other physicians. In the medical-psychiatric context, nerve conduction studies have two special uses. One is to establish that

patient has polyneuropathy. This may be valuable when the patient's neuropsychiatric symptoms may be due to a drug or toxin that is known to affect the peripheral nerves as well as the brain. A patient with significant cerebral problems may not complain of neuropathic symptoms like numbness and tingling but may nonetheless have polyneuropathy, and the presence of the polyneuropathy may be useful in the differential diagnosis. For example, a patient with mental-status changes potentially due to heavy metal exposure would be expected to show polyneuropathy as well, if the heavy metal exposure were severe enough to explain their neuropsychiatric symptoms. A test proving neuropathy may be useful in confronting a patient who abuses alcohol or drugs; some patients are more effectively motivated by test results they find more "objective" than a psychological or psychiatric examination.

The second special use of nerve conduction tests in medical psychiatry is in establishing the diagnosis of an entrapment neuropathy with severe symptoms—usually of pain—that has been underappreciated or misdiagnosed by the patient's other physicians, leading to the patient's experiencing significant emotional distress. Entrapment neuropathies, which include the common carpal tunnel syndrome as well as some unusual entrapments, such as that of the infrascapular nerve associated with holding an infant when breastfeeding, can cause pain and dysesthesia disproportionate to any obvious physical sign. In such cases the nerve conduction study is virtually always abnormal, often markedly so. Specific treatment to decompress the nerve usually follows the nerve conduction study, frequently leading to relief of both physical and mental distress.

Special EMG techniques using repetitive nerve stimulation may also be used to assess the neuromuscular junction and diagnose myasthenia gravis. These patients may complain

of vague weakness, which at times is discarded as psychogenic. In the patient with chronic back pain, the EMG may reveal objective signs of radiculopathy and aid in the diagnosis. The test is also useful in assessing the integrity of the muscles and nerves in the setting of neurotoxins. Alcoholic patients may experience a sensory polyneuropathy in addition to thiamine deficiency, which in itself can cause a motor and sensory neuropathy as well (Morrison & Chaudhry, 2012). Unlike the previous neurophysiological tests, the EMG test may cause patients significant discomfort from the needle insertion or nerve stimulation. In addition, the EMG is a very dynamic test, as the examiner will have to decide which muscles to sample based on real-time findings; hence significant expertise is needed.

CLINICAL PEARLS

- Frontal intermittent delta activity (FIRDA) is a non-specific pattern seen in metabolic encephalopathy and raised intracranial pressure, but also in normal drowsy individuals and is not necessarily pathological (Accolla et al., 2011).
- A general rule of thumb is that abnormalities limited to the cortex will cause slowing of the posterior background frequency, while abnormalities involving subcortical structures lead to increased polymorphic delta activity, triphasic waves, or FIRDA.
- REM sleep noted on a routine EEG is suggestive of medication effect or possibly narcolepsy.
- Interpretation of EEG is related to age; certain degrees of temporal slowing, for example, are allowed in the elderly.
- When “sharply contoured” discharges are reported and the clinical suspicion of epileptic seizures is high, a repeat routine EEG, a more prolonged study, and/or a provocative procedure such as sleep deprivation is advised.
- EEG abnormalities noted in lithium toxicity include diffuse slowing, spikes, and triphasic waves.
- In the medical-psychiatric context, EPs are used for two purposes: (1) to determine whether complaints of sensory loss are accompanied by and are proportionate to changes in the relevant parts of the nervous system, and (2) to detect demyelinating diseases that may not be diagnosable by anatomic brain imaging and that may have neuropsychiatric complications or comorbidities.
- The test should be considered when the patient is suspected of MS on clinical grounds, has a history of visual symptoms, and has a normal or nondiagnostic MRI.
- The VEP should be considered when the patient is suspected of MS on clinical grounds, has a history of visual symptoms, and has a normal or nondiagnostic MRI.
- There are two special uses of nerve conduction studies in medical psychiatry. One is to establish that a patient has

polyneuropathy. This may be valuable when the patient’s neuropsychiatric symptoms might be due to a drug or toxin that is known to affect the peripheral nerves as well as the brain. The second special use of nerve conduction tests is in establishing the diagnosis of an entrapment neuropathy with severe symptoms—usually of pain—that has been underappreciated or misdiagnosed by the patient’s other physicians.

NEUROPSYCHIATRY OF PRIMARY SLEEP DISORDERS

Amit Chopra and Jarrett W. Richardson

INTRODUCTION

Sleep disorders are commonly observed in psychiatric populations, and detailed exploration of sleep complaints is key to comprehensive psychiatric evaluation. Primary sleep disorders must be differentiated from sleep disorders secondary to mental illnesses for appropriate referral and optimal treatment outcomes in psychiatric patients. This chapter covers clinical features, diagnosis, and treatment of common primary sleep disorders and their comorbidity with psychiatric disorders.

PHYSIOLOGY OF NORMAL SLEEP

Human sleep comprises alternating cycles of non-rapid eye movement (NREM) sleep and rapid eye movement (REM) sleep. NREM sleep is further divided into three stages of increasing depth of responsiveness including N1–N3 stages. Healthy young adults typically have four to six sequential cycles of NREM sleep followed by REM sleep. Approximately two-thirds of sleep time is spent in NREM sleep, and another quarter consists of REM sleep in adults. Table 9.1 summarizes the characteristics and percentage of the night spent in each sleep stage for healthy adults, which serves as a useful reference. In the elderly, the relative percentage of time spent in “deep sleep” decreases, and sleep is generally more shallow and fragmented.

During N1 sleep, a person can easily be awakened by environmental stimuli. N2 sleep is characterized by sleep spindles and K complexes on electroencephalogram (EEG). N3 is

referred to as *slow-wave sleep*, and it is characterized by more than 20% delta wave sleep on EEG. Environmental stimuli must be significant to awaken a patient from slow-wave sleep. The transition from NREM to REM sleep usually occurs through N2, and REM is characterized by high frequency EEG, episodic bursts of vertical eye movements, penile tumescence, and muscle atonia. The first REM episode is often only 1–5 minutes in duration and occurs 70–100 minutes after sleep begins. There is marked interindividual variability in arousal threshold in REM sleep. In general, slow-wave or deep sleep is more common early in the night and REM periods more common toward morning because of progressively longer REM episodes. Due to this phenomenon, people commonly better recall dreams that occur just before their morning awakening, and men experience morning erections. Patients with disrupted sleep often spend the majority of the night in stages N1 and N2, with little slow-wave or REM sleep. The exact role that slow-wave and REM sleep play in a refreshing night’s sleep is not well understood, but it is clear that significant reductions in either state lead to undesirable results including daytime somnolence, depressed mood, and cognitive impairment. In animal studies, prolonged absolute sleep deprivation has resulted in death attributed to sepsis (Bergmann et al., 1996).

SLEEP EVALUATION

Comprehensive clinical interview and physical examination along with appropriate investigations are key to diagnostic sleep evaluation. Clinicians need to focus on medical and

Table 9.1 SLEEP STAGES IN HEALTHY ADULTS

STAGE	PERCENTAGE	EEG CHARACTERISTICS	PHYSIOLOGIC CHANGES
Stage 1	2%–5%	Slow eye movements	Easy to arouse
Stage 2	45%–55%	Spindles, K complexes	More difficult to arouse
Stage 3\4	13%–23%	Slow EEG frequency	Difficult to arouse
REM	20%–25%	Rapid eye movements	Variable arousal threshold
		Muscle atonia	Penile engorgement
		Increased EEG frequency	

psychiatric history with a particular emphasis on sleep complaints. Acute and chronic pain should be assessed in the medically ill, as they are important causes of sleep disturbances. Questionnaires such as the Stanford Sleepiness Scale and Epworth Sleepiness scale should be used in patients to assess the severity of daytime somnolence. Box 9.1 lists the important areas of assessment for thorough evaluation and diagnosis of underlying sleep disorders.

Patients are often unaware of their nighttime breathing complaints, such as snoring, apneic spells, or behavioral events such as dream enactment behaviors. Therefore, collateral history from a bed partner is vital to gain information about nighttime respiratory and behavioral events. It is not uncommon for bed partners to have moved out of the bedroom because of intolerable snoring or dream-enactment behaviors, so collateral information may not be available. Further laboratory investigation should likely be pursued for adequate evaluation of sleep complaints in these circumstances.

The physical examination should focus on body mass index, neck circumference, nasal and oropharyngeal abnormalities, cervical/supraclavicular lymphadenopathy, and thyroid examination. Thorough pulmonary and cardiovascular examination allows assessment of the cardiopulmonary sequelae of sleep-disordered breathing. Neurological examination should be done to assess level of alertness, cognition, and to rule out neuromuscular disorders that may lead to

sleep-disordered breathing. Detailed mental state examination should be done to rule out psychiatric issues such as mood and anxiety disorders.

INVESTIGATIONS

OVERNIGHT PULSE OXIMETRY

Overnight pulse oximetry can be a useful initial screening tool to detect repetitive oxygen desaturations >4% in patients at risk of sleep-disordered breathing. It measures only one variable; without other data the clinician cannot correlate the oxygen saturation with the corresponding sleep stage, heart rhythm, or body position (Svanborg et al., 1990); therefore, it should not be used as a definitive diagnostic method. Normal findings on oximetry do not rule out sleep apnea, as younger patients may not have significant oxyhemoglobin desaturations with apneic episodes or, alternatively, the patient may not have slept during the oximetry study. Patients with positional (supine-dependent) apnea who happen to sleep on their sides may have normal oximetry study results.

POLYSOMNOGRAPHY

At present, the overnight polysomnographic (PSG) study conducted in an accredited sleep disorders center remains the state of the art diagnostic procedure for evaluation of sleep disorders. The standard procedure involves multiple monitors including electroencephalogram, surface electromyogram, electro-oculogram, electrocardiogram, pulse oximetry, respiratory airflow, and respiratory effort (Phillipson & Remmers, 1989). Continuous videotaping is helpful for assessing possible parasomnias or unusual nocturnal movements. Sleep technologists can record body position and describe snoring intensity. Under these circumstances patients are observed to sleep for at least one sleep cycle with NREM and REM sleep in the supine and nonsupine positions.

PSG is the gold standard for diagnostic investigations for assessment of sleep-disordered breathing (SDB) including obstructive or central sleep apnea syndromes. PSG is conducted in a split-night fashion where the first half of the night is utilized to assess the nature and severity of SDB and, during second half of the night, a positive airway pressure (PAP) trial is applied to determine optimal PAP pressure settings for adequate control of SDB. Other indications for PSG study include excessive daytime somnolence, parasomnias, and periodic limb movements of sleep. PSG is not indicated for diagnosis of restless legs syndrome.

Portable monitoring can be used to assess obstructive sleep apnea, and it is usually performed in the home without a sleep technician in attendance. Portable monitoring includes overnight oximetry, partial cardiorespiratory studies, and a fully portable PSG with monitoring of EEG, EOG, and EMG. Portable equipment that monitors EEG is often prone to malfunction due to displacement during sleep without sleep technologists available to rectify a faulty signal. The American Academy of Sleep Medicine recommends that

Box 9.1 ESSENTIAL ISSUES IN A SLEEP DIAGNOSTIC INTERVIEW OF PATIENTS AND BED PARTNERS

Presenting complaint
 Previous sleep evaluations
 Sleep schedule—parenting issues?
 Work schedule—rotating shifts?
 Nap schedule—frequent? prolonged?
 Exercise schedule—late in evening?
 Sleep environment—bright light? noisy? too hot/cold?
 Initial/middle/insomnia
 Nocturnal movements
 Sleepwalking/somnambulism/enuresis
 Excessive daytime somnolence
 Motor vehicle accidents
 Cataplexy/sleep paralysis/ hallucinogenic experiences
 Snoring
 Observed apneas
 Sleep position
 GI reflux—diagnosed? partially treated?
 Pain—chronic? acute? medications wear off?
 Erectile problems
 Alcohol/street drug/caffeine use/abuse/dependence
 Depression/mania/panic attacks
 Vivid dreams/nightmares
 Prescription drug use/abuse/dependence
 Family sleep history
 Childhood sleep history.

portable monitoring may be acceptable for assessment of OSA in certain carefully defined conditions, including patients with high pretest probability of moderate to severe OSA and absent medical comorbidities; nonambulatory or medically unstable patients; or to assess response to therapy in previously diagnosed OSA (Collop et al., 2007).

MULTIPLE SLEEP LATENCY TEST

The multiple sleep latency test (MSLT) is used to identify disorders of excessive daytime somnolence including narcolepsy. Patients must first have an overnight PSG study to exclude other sleep disorders causing disrupted nocturnal sleep. If patients have at least 6 hours of sleep, then an MSLT can be conducted the next day. Patients are asked to take four to five 20-minute scheduled naps, 2 hours apart. Patients wear electroencephalographic, electromyographic, electro-oculographic, and electrocardiographic leads. The MSLT test measures the initial sleep latency and REM latency if applicable. Patients are asked to stay awake between naps, refrain from stimulants like caffeine, and, if clinically indicated, undergo drug testing to detect occult sedative use.

Mean sleep latency over four or five naps is obtained, with a value <5 minutes suggestive of excessive daytime sleepiness; a value >10 minutes is considered to be normal. Values between 5 and 10 minutes should be considered on a continuum of sleepiness, with lower values indicating greater sleepiness. Patients with narcolepsy have sleep latency <8 minutes. Presence of REM sleep occurring within 15 minutes of sleep onset (SOREMP) during naps is also recorded. SOREMPs in two or more naps is considered abnormal and is thought to be neurophysiological marker of narcolepsy, although other causes, including abrupt withdrawal of REM-suppressant medications (antidepressants, stimulants), moderate to severe OSA, and sleep deprivation should be ruled out.

MAINTENANCE OF WAKEFULNESS TEST

The maintenance of wakefulness test (MWT) measures the ability of the patient to stay awake. This test is not used to diagnose sleep disorders, but it can be helpful in assessing the response to stimulants or a patient's fitness to drive. Patients are asked to sit in a comfortable recliner or bed in a dimly lit room and instructed to stay awake rather than to sleep. Each trial lasts until patient goes to sleep, or after 40 minutes if no sleep occurs. Normal sleep latency for this study is 30.4 minutes, and a sleep latency of 19 minutes or less correlates with driving impairment.

ACTIGRAPHY

An actigraph is a small watch-like device to be worn on the wrist of the nondominant hand that interprets periods of relative absence of wrist movements as sleep, and periods of high activity as wakefulness. There seems to be good correlation between total sleep time recorded by actigraphy and polysomnography. However, since this equipment counts limb movements and does not record EEG activity, specific

sleep stages cannot be identified. One distinct advantage of actigraphy is that the compact device is worn 24 hours per day for 1 to 2 weeks. This permits identification of irregular sleep/wake patterns in the patient's unique work/home environment. Actigraphy can be used to assist in diagnosis of sleep disorders including circadian rhythm disorders, insomnia, and hypersomnia.

DIAGNOSIS AND TREATMENT OF PRIMARY SLEEP DISORDERS

Primary sleep disorders can be broadly organized by the patient's most common presenting sleep complaint—excessive daytime sleepiness or insomnia. Many medical, neurological, and psychiatric conditions cause sleep disruption leading to insomnia or excessive daytime drowsiness (Boxes 9.2 and 9.3).

Box 9.2 CAUSES OF EXCESSIVE DAYTIME SOMNOLENCE
<i>Primarily Neurological</i> Idiopathic narcolepsy Narcolepsy caused by sarcoidosis Narcolepsy caused by lesion near the third ventricle Idiopathic hypersomnia Recurrent hypersomnia Traumatic brain injury Restless legs syndrome Periodic limb movement disorder Restless legs syndrome/periodic limb movement disorder caused by uremia Restless legs syndrome/periodic limb movement disorder caused by peripheral Neuropathy Restless legs syndrome/periodic limb movement disorder caused by Medication (tricyclic antidepressants, etc.) Sleeping sickness Increased intracranial pressure Delirium Kleine-Levin syndrome
<i>Primarily Medical</i> Obstructive sleep apnea Obstructive sleep apnea caused by acromegaly Obstructive sleep apnea caused by hyperthyroidism Central sleep apnea COPD Asthma Gastroesophageal reflux Hypoventilation syndrome Periodic limb movements caused by chronic renal failure Periodic limb movements caused by hyperthyroidism Periodic limb movements caused by hepatic encephalopathy

Primarily Psychiatric

Medication-induced (alcohol, hypnotic, sedative, etc.)
Stimulant withdrawal
Depression
Psychotic disorder
Altered sleep/wake cycle
Insufficient sleep syndrome
Inadequate sleep hygiene

SLEEP RELATED BREATHING DISORDERS

Sleep related breathing disorders (SRBD) describes a group of disorders characterized by apneas (complete cessation of airflow), hypopneas (partial cessation of airflow), or the quantity

Box 9.3 CAUSES OF INSOMNIA

Primarily Medical

Obstructive sleep apnea (less common than hypersomnia)
Central sleep apnea
COPD
Asthma
Gastroesophageal reflux
Peptic ulcer disease
Hyperthyroidism

Primarily Neurological

Fatal familial insomnia
Acute and chronic pain
Restless legs syndrome
Periodic limb movement disorder
Restless legs syndrome/periodic limb movement disorder caused by uremia
Restless legs syndrome/periodic limb movement disorder caused by peripheral neuropathy
Restless legs syndrome/periodic limb movement disorder caused by medication (tricyclic antidepressants, etc.)
Brainstem lesions/diseases
Dementia

Primarily Psychiatric

Medication-induced (xanthines, psychostimulants etc)
Withdrawal-related (alcohol, benzodiazepines)
Psychophysiological insomnia
Sleep state misperception
Anxiety disorders
Manic depressive disorders
Altered sleep/wake cycle

Primarily Environmental

Hospital routine (nocturnal X rays, blood draws, etc.)
Community noise (traffic, alarms, neighbors).

of ventilation during sleep. Apneic events are categorized as obstructive (inspiratory effort present during cessation of airflow), central (inspiratory effort absent during cessation of airflow), and mixed (both central and obstructive). The apnea/hypopnea index (AHI) refers to number of apnea/hypopnea events per hour, and it is used to quantify the severity of obstructive and central sleep apnea syndromes.

OBSTRUCTIVE SLEEP APNEA**CLINICAL FEATURES**

Obstructive sleep apnea (OSA) is the most common sleep-disordered breathing disorder. It is characterized by the repetitive collapse or partial collapse of the pharyngeal airway during sleep and the need to arouse to resume ventilation. Sleep apnea is defined as a period of 10 seconds or more with no respiratory movement. Hypopnea is a similar period of abnormally slow or shallow respiration, insufficient for normal gas exchange. OSA can occur at any age, with a greater prevalence in males than in females (4% vs. 2%). The steepest prevalence increase is in the transition from middle to old age. At younger ages it is more common in African-American patients.

High-risk patients for OSA include those who are obese or being considered for bariatric surgery, those with treatment-resistant hypertension, diabetes mellitus type II, atrial fibrillation, pulmonary hypertension, congestive heart failure, and stroke (Epstein et al., 2009). Box 9.4 summarizes

Box 9.4 AMERICAN SLEEP DISORDERS ASSOCIATION DIAGNOSTIC CRITERIA OF OBSTRUCTIVE SLEEP APNEA

Essential Signs/Symptoms

1. Excessive daytime sleepiness
2. Obstructed breathing during sleep

Associated Signs/Symptoms

1. Loud snoring
2. Morning headaches
3. Morning dry mouth

Essential Polysomnographic Findings

More than 5 apneas (.10 sec) per hour of sleep with evidence of respiratory muscle effort and one of the following:

- a. Apneas causing frequent arousals
- b. Apneas causing oxygen desaturation >4%
- c. Bradytachycardia

Adapted from American Sleep Disorders Association (1997), *The International Classification of Sleep Disorders, Revised: Diagnostic and coding manual*. Rochester, MN.

Renal

Nocturia

the diagnostic criteria of this common disorder. Box 9.5 outlines the medical complications of OSA.

DIAGNOSIS

Comprehensive sleep history in a suspected OSA patient includes assessment of symptoms including snoring, witnessed apneas, gasping/choking episodes, and daytime drowsiness. Subjective assessment of daytime sleepiness can be done by using scales including the Epworth sleepiness scale and the Stanford sleepiness scale. Physical examination findings in OSA patients include increased neck circumference, BMI >30 kg/m², modified Mallampati score on the oropharyngeal exam of 3 or 4, presence of retrognathia, macroglossia, enlarged tonsils, elongated/enlarged uvula, and nasal abnormalities (polyps, septum deviation).

The accepted objective measures of OSA diagnosis include in-laboratory polysomnography (PSG) and home testing with portable monitors (PM). PM is not indicated in patients with major medical comorbidities including, but not limited to, congestive heart failure, moderate to severe pulmonary disease, neuromuscular disease, and those with a comorbid sleep disorder such as narcolepsy or nocturnal myoclonus (Collop et al., 2007). Respiratory events in OSA comprise primarily obstructive apneas and hypopneas, which are characterized by cessation or reduction in airflow with ongoing respiratory effort. Based on the apnea/hypopnea index (AHI) derived from diagnostic study, OSA is divided into categories of severity: mild (AHI=5–15 events per hour), moderate (AHI=15–30 events per hour) and severe (AHI>30 events per hour).

TREATMENTS

OSA is a chronic disease which requires long term multidisciplinary management. Patients with OSA need to be treated because the cardiovascular complications of OSA are potentially fatal, excessive daytime sleepiness puts patients at risk of accidents, cognitive problems compromise daytime performance, and effective treatment exists. Treatment options should be discussed in the context of the severity of OSA, associated risk factors, and the patient's expectations. The treatments of OSA can be broadly classified under positive airway pressure (PAP) and non-PAP therapies.

POSITIVE AIRWAY PRESSURE THERAPY

PAP therapy is the treatment of choice for mild, moderate, and severe OSA and should be offered as an option for all patients. PAP may be delivered in continuous (CPAP), bilevel (BPAP), and auto (APAP) modes. PAP is applied through nasal, oral, and oronasal interface. The treatment for OSA has been revolutionized by the use of CPAP therapy in the last few decades. This treatment involves delivering pressurized air (ranging typically from 5 to 20 cm of water pressure) to the sites of upper airway blockage (generally oropharynx, less commonly nasopharynx) and forcing the airway open. Apneas and snoring are eliminated, allowing the patient to sleep continuously without arousals. The CPAP device is generally introduced during overnight polysomnography (PSG) study in the sleep lab, where staff can adjust the CPAP pressures appropriately.

Bilevel (BPAP) therapy represents a modification of CPAP where the positive pressure fluctuates depending on whether airflow is inspiratory or expiratory (Hillberg & Johnson, 1997). Bilevel pressure is considerably more expensive and is reserved for patients who cannot tolerate CPAP. Automated positive airway pressure (APAP) devices, which can continually optimize positive airway pressure, can be used in self-adjusting mode for unattended treatment of moderate to severe OSA in the absence of medical comorbidities (Morgenthaler et al., 2006). Supplemental oxygen alone is inadequate for OSA, and patients with both OSA and intrinsic lung disease who have persisting hypoxia despite CPAP may benefit from supplemental oxygen delivered via the CPAP mask.

PAP treatment ideally involves a multidisciplinary care team including a sleep specialist, referring physician, nursing staff, sleep technologist, and respiratory specialist. Patients should be educated about the function and the benefits of PAP treatment, care of the equipment, and potential problems including leakage through the PAP interface, claustrophobia due to the PAP interface, and dry mouth or nasal congestion which may lead to PAP noncompliance. Close follow-up in the first few weeks with trained healthcare providers is indicated to establish effective PAP usage patterns and remediate problems if needed. After initial PAP set up, long-term follow-up is recommended on a yearly basis and as needed to troubleshoot PAP-related issues (Kushida et al., 2006a).

CPAP effectively treats OSA in the majority of people, but despite its efficacy in ameliorating symptoms CPAP usage has been reported as 65%–80% in OSA patients. According to a review study, short-course educational interventions were not particularly successful, although cognitive behavioral therapy (CBT) led to a significant improvement in average nightly CPAP usage (Smith et al., 2009).

NON-PAP THERAPIES

Non-PAP therapies include behavioral treatments, oral appliances, nasal expiratory positive airway devices, and surgical treatments of OSA. Behavioral treatments for OSA include weight loss (BMI <25), exercise, positional therapy, and avoidance of alcohol or sedatives at bedtime. Weight loss through diet and exercise is an important element of the treatment plan for any overweight patient with OSA, which can be successful with motivated patients. For patients who develop apneas only when lying supine, positional therapy may be effective, and this may include having them use a device such as a t-shirt with an attached cloth tube of tennis balls that keeps them off their backs. Little data are available regarding long-term adherence with this practical intervention.

Promising studies examine the role of oral appliance devices that pull the tongue or the mandible forward in treatment of mild to moderate OSA (Kushida et al., 2006b). Patients with abnormalities of the soft tissue or skeletal structures surrounding the upper airway, or poor response to PAP therapy, may consider surgery. Surgical procedures that may be considered for management of OSA include tonsillectomy, uvulopalatopharyngoplasty, maxillary mandibular advancement (MMA) and tracheostomy. MMA improves PSG parameters comparable to CPAP in majority of OSA patients. Most of the other surgical treatments of OSA are rarely curative but may improve clinical outcomes (Caples, Rowley, & Prinsell, 2010). Tonsillectomy may be considered as the first line of treatment in children with moderate to severe OSA.

OSA AND PSYCHIATRIC COMORBIDITY

OSA needs to be included in the differential diagnosis of patients with mood and behavioral issues, since OSA patients may demonstrate symptoms including depressed mood, irritability, personality changes, and cognitive impairment. Studies have noted variable prevalence of depression from 17.6% to 45% in OSA patients.

A recent study of depression in OSA patients has reported a statistically significant correlation between Epworth sleepiness scale (ESS) scores and Hamilton depression rating scores (HDRS), suggesting that depression improves after improvement in daytime sleepiness in OSA patients (El-Sherbini, Bediwy, & El-Mitwalli, 2011). This finding supports the hypothesis that sleep fragmentation and daytime sleepiness due to OSA may have an important role in the generation of depression in these patients. Higher depression scores, and not the severity of sleep apnea, were predictive of daytime sleepiness and poor quality of life in patients with REM-related OSA in a recent study (Pamidi et al., 2011). Patients with OSA may

report improvement in their mood and energy within days, and this positive reinforcement leads to good CPAP compliance (Berthon-Jones, Lawrence, Sullivan, & Grunstein, 1996).

CENTRAL SLEEP APNEA SYNDROMES

Central sleep apnea syndromes are characterized by recurrent cessation of respiration due to apneas with no associated ventilatory effort. Different etiologies include primary CSA, Cheyne-Stokes breathing pattern, high-altitude periodic breathing, and CSA due to drug or substance use (long-acting opiates such as methadone, morphine, hydrocodone).

CLINICAL FEATURES

Recurrent apneas can lead to sleep fragmentation, excessive daytime sleepiness, or insomnia. A high ventilatory response to CO₂ seems to be a predisposing factor in development of CSA. Central apneas occur primarily during NREM sleep and less commonly during REM sleep. Oxygen desaturations are minimal in CSA, and arterial PaCO₂ less than 40 mmHg is typically observed during wakefulness.

Cheyne-Stokes breathing pattern is characterized by recurrent apneas/hypopneas alternating with prolonged hyperpneas, during which tidal volume waxes and wanes in a crescendo–decrescendo pattern. It is more commonly observed in elderly males with medical conditions such as congestive heart failure and stroke. CSA due to opiate use occurs due to respiratory suppression mediated through the action of opiates on mu receptors on the ventral surface of medulla, and it is typically seen after opiate use for at least 2 months.

DIAGNOSIS

Polysomnographic findings in primary CSA show five or more central apneas per hour of sleep. Cheyne-Stokes breathing pattern is characterized by at least 10 central apneas and hypopneas per hour of sleep in which hypopnea has a crescendo–decrescendo pattern of tidal volume during polysomnography study. Central apneas are associated with arousals from sleep leading to sleep fragmentation.

TREATMENT

After central sleep apnea (CSA) has been differentiated from obstructive sleep apnea by means of an overnight sleep study, treatments consisting of supplemental oxygen to reduce hypoxia and PAP therapies including CPAP, adaptive-servo ventilation (ASV) device, and BPAP (spontaneous timed-ST mode) can be effective in treatment of central sleep apnea syndromes (Aurora et al., 2012).

CSA AND PSYCHIATRIC COMORBIDITY

CSA has been found in 30% of the stable methadone maintenance treatment patients and in patients prescribed time-release opioid analgesic management (Wang D et al.,

2005). CSA symptoms tend to improve upon reduction of opiate dosage if possible.

RESTLESS LEGS SYNDROME AND PERIODIC LIMB MOVEMENTS

CLINICAL FEATURES

Restless legs syndrome (RLS) is a sensorimotor disorder characterized by an irresistible urge to move the legs, which is often accompanied by uncomfortable paresthesias felt deep inside the legs. These symptoms are made worse by rest (lying or sitting) and are at least partially and temporarily relieved by walking or moving the legs. The urge to move the legs worsens in the evening or night, with relative relief in the morning. The term *periodic limb movements* (PLM) describes the objective leg movements, while *restless legs syndrome* describes the subjective discomfort. PLMs occur in 80% to 90% patients with RLS but are not specific for RLS. Boxes 9.6 and 9.7 outline the diagnostic criteria of these overlapping disorders.

Between 5% and 15% of patients have RLS, with higher rates in those with uremia (15%–20%) and rheumatoid arthritis (30%). Periodic limb movements are more common with up to 34% of persons over 65 having this condition (Lugaresi et al., 1986). RLS occurs 1.5–2 times more commonly in women than in men. Clinicians need to carefully check whether the patient is taking any of the medications shown in Box 9.8 that can cause or exacerbate periodic limb movements (Ware et al., 1984). The differential diagnosis of RLS/PLMs is outlined in Box 9.9.

DIAGNOSIS

An overnight sleep study is not essential, since the diagnosis of restless legs syndrome can be made based on the patient's history. However, this approach can lead to a clinician overlooking possible periodic limb movements that are not associated with a restless feeling. A sleep study is valuable when a patient may have a coexisting sleep disorder like sleep apnea, or if the patient fails to respond to treatment for presumed restless legs syndrome. Helpful lab tests include complete blood count,

Box 9.6 DIAGNOSTIC CRITERIA: PERIODIC LIMB MOVEMENT DISORDER

1. Insomnia or excessive sleepiness. The patient can be symptomatic with the movements noted by an observer.
2. Repetitive, highly stereotyped movements usually involving extension of the big toe with partial flexion of the ankle, knee, and sometimes hip.

Adapted from American Sleep Disorders Association (1997), *The International Classification of Sleep Disorders, Revised: Diagnostic and coding manual*. Rochester, MN.

Box 9.7 DIAGNOSTIC CRITERIA: RESTLESS LEGS SYNDROME

Essential Signs/Symptoms

1. Unpleasant nocturnal sensation in the legs or difficulty falling asleep.
2. "Creeping" sensation of the calves often associated with generalized aches and pains.
3. The discomfort is relieved by movement of the limbs.

Essential Polysomnographic Findings

1. Repetitive episodes of muscle contractions (0.5–5 seconds in duration) separated by an interval of 20–40 seconds.
2. An arousal or awakening may be associated with the movement.

Adapted from American Sleep Disorders Association (1997), *The International Classification of Sleep Disorders, Revised: Diagnostic and coding manual*. Rochester, MN.

ferritin (since restless legs can be triggered by anemia), and low cobalamin and folate levels.

TREATMENT

The non-ergot dopamine (DA) agonists pramipexole (0.125–0.75 mg) and ropinirole (0.25–2 mg) are FDA-approved medications with proven efficacy in treatment of RLS. DA agonists are effective, but their use is limited by adverse effects—especially augmentation and impulse-control disorders (Early & Silber, 2010).

Augmentation refers to an earlier onset of symptoms in the evening following long-term treatment with dopaminergic drugs (mainly L-DOPA). Other characteristic features include an increase in symptom severity, a shorter latency to RLS symptoms while at rest, and an expansion of symptoms to other parts of the body. Among impulse-control disorders

Myoclonus

(ICD), pathological gambling, compulsive shopping, and hypersexuality have been noted in 7%–17% of RLS patients taking dopaminergic medications (Early & Silber, 2010). ICDs secondary due to dopaminergic medications usually resolve or substantially improve after discontinuation of these medications.

Alternative treatment options for treatment of RLS include clonazepam, gabapentin, pregabalin, and low and high potency opioids. Benzodiazepines and opioids are controlled agents that require monitoring for tolerance and addiction and are therefore not first-line treatment choices.

RLS AND PSYCHIATRIC COMORBIDITY

Studies have shown increased prevalence of depression and anxiety disorders in RLS patients. These patients can develop irritability, depressed mood, or cognitive disturbance due to disrupted sleep, although symptoms including anhedonia, loss of appetite, weight gain or loss, low self-esteem, and suicidal thoughts are not typical of RLS. Psychotropic medications including antipsychotics (both typical and atypical), antidepressants (TCAs, SSRIs, mirtazapine, venlafaxine) and lithium have been linked to exacerbation of RLS.

The pathophysiology of antidepressant-induced worsening of RLS remains unclear, but dopaminergic hypofunction combined with serotonergic and noradrenergic hyperfunction have been suggested as a possible etiology. In contrast, bupropion, due to primarily dopaminergic action, appears to reduce the periodic leg movements of sleep (PLMS) and RLS symptoms.

If poor sleep is a major factor in the depressive phenotype, then screening for RLS should be considered. A positive RLS screen warrants consideration of such nonpharmacological measures as physical exercise, sleep hygiene, and CBT along with optimization of RLS treatment. Such an approach may

eliminate or reduce depressive symptoms, but should be considered as an initial step only if depressive symptoms are mild (Chopra, Pendergrass, & Bostwick, 2011).

RLS patients already taking serotonergic antidepressants for treatment of depression may complain of the paradox of continued sleepiness and resultant fatigue, and poor motivation despite mood improvement and reduced irritability. RLS exacerbation should be suspected, and RLS and PLMS therapy optimized as the initial approach with a goal of achieving 6–8 hours of restful sleep per night. If the response is only partial, the serotonergic antidepressant medication may need to be reduced or switched to a different antidepressant drug. Alternatives to serotonergic agents include bupropion, with the addition of benzodiazepines or buspirone in patients with comorbid or persistent anxiety (Chopra et al., 2011).

PARASOMNIAS

Parasomnias are undesirable physical events during entry into sleep, within sleep, or during arousals from sleep (American Academy of Sleep Disorders, 2001; Vignatelli et al., 2005). Parasomnias can be broadly classified into NREM parasomnias (disorders of arousal) and REM parasomnias including REM sleep behavior disorder (RBD). Psychiatrists can be called to evaluate medically ill patients who have nocturnal agitation, sleepwalking, and unusual behaviors.

NREM PARASOMNIAS

The common disorders of arousal arising from NREM sleep include confusional arousals, sleep terrors, sleepwalking (somnambulism) and sleep-related eating disorders (SRED).

CLINICAL FEATURES

Confusional arousals consist of mental confusion or confusional behavior during or following arousals, typically from slow-wave sleep and usually in the first part of the night. Sleep terrors consist of arousals from slow-wave sleep accompanied by crying and behavioral manifestations of intense fear, with autonomic symptoms including tachycardia, tachypnea, diaphoresis, flushing of skin, and increased muscle tone. Amnesia for episodes of confusional arousals and sleep terrors is usually present, and these disorders tend to occur more commonly in children. Genetic factors play an important role in causation of 65% cases of sleepwalking.

Sleepwalking consists of complex behaviors that are usually initiated during slow-wave sleep and characterized by walking in an altered state of consciousness. Sleepwalking usually arises from first third or half of night, and amnesia is usually present for these episodes. Sleepwalking can involve routine behaviors, although inappropriate, agitated, belligerent, and violent behaviors can occur, particularly in men. The prevalence of sleepwalking in childhood has been noted to be as high as 17% (peaking at ages 8–13 years) and it is considered

to be normal developmental sleep phenomenon except in those patients with clinical consequences. However, if sleepwalking persists beyond adolescence or into adulthood, it may deserve clinical attention. Polysomnography findings of multiple arousals from slow-wave sleep can support the clinical diagnosis of sleepwalking.

Sleep-related eating disorders (SRED) consist of recurrent episodes of involuntary eating (multiple times per night), typically during partial arousals from sleep with subsequent partial recall. The problematic consequences of SRED may include consumption of peculiar forms or combinations of food or ingestion of inedible and toxic substances such as raw/frozen foods, animal food, and cleaning solutions. The patients complain of early morning anorexia and abdominal distension, along with adverse health consequences including weight gain and obesity. SRED is most commonly associated with sleepwalking disorder, and it is more prevalent in young females (up to 83% of the cases). Medication-induced SRED has been noted with psychotropic medications including zolpidem, triazolam and lithium carbonate. SRED must be differentiated from night eating syndrome (NES), which is characterized by overeating between the evening meal and nocturnal sleep onset, eating during complete awakenings from sleep with full recall, and absence of peculiar or bizarre eating behaviors.

DIAGNOSIS

In addition to detailed clinical history, polysomnography (PSG) findings of multiple arousals from slow-wave sleep with video recordings of accompanying sleep-related behaviors can help confirm the diagnosis of NREM parasomnias. PSG can be helpful to rule out other causes of arousals from sleep such as OSA and can also confirm REM with normal atonia to exclude REM sleep behavior disorder (RBD).

TREATMENT

NREM parasomnias deserve further clinical evaluation and treatment in cases where the behaviors are potentially injurious or violent or disruptive to others in the household, while mild cases may need reassurance only. Medications such as clonazepam or imipramine may be effective. Avoidance of sleep deprivation and techniques for self-hypnosis may be effective as well.

NREM PARASOMNIAS AND PSYCHIATRIC COMORBIDITY

There is no significant association between childhood sleepwalking and psychiatric disorders, although adults with sleepwalking may have a current or past history of nonpsychotic depressive and anxiety disorders. Violence and homicide leading to legal consequences has been reported, along with accidental self-harm and pseudo-suicides. Increased incidence of SRED has been noted in patients with eating disorders (inpatient group 16.7% and outpatient group 8.7%) as compared to 4.6% in controls (Winkelman, Herzog, & Fava, 1999).

REM PARASOMNIAS

CLINICAL FEATURES

RBD is the parasomnia of most interest to the medical psychiatrist. Patients with this condition appear to “act out their dreams,” as they lack muscle atonia during REM sleep. Patients and their bed partners can be seriously injured by hitting, kicking, rolling, and other more complex behaviors. Although no good epidemiologic data are available, REM behavior disorder is likely the most common parasomnia behavior.

RBD is a male-predominant disorder, and the major predisposing factors are male sex, age 50 years or older, and underlying neurological disorders—particularly Parkinson’s disease, Lewy body dementia, narcolepsy, and stroke. Idiopathic RBD is diagnosed in the absence of comorbid neurological conditions.

DIAGNOSIS

Polysomnographic findings in RBD include an excessive amount of sustained EMG activity, intermittent loss of REM atonia, or excessive phasic muscle twitch activity of the submental or limb EMG during REM sleep. Signs of autonomic nervous system activation such as tachycardia are uncommon during REM sleep activation in RBD as compared to the disorders of arousal.

TREATMENT

Treatment includes modifying the bedroom environment to reduce injury to the patient and bed partner. Recommended measures include placing a mattress on the floor, padding corners of furniture, window protection, and removing potentially dangerous items such as guns or sharp objects from the bedroom.

Clonazepam is suggested for the treatment of RBD but should be used with caution in patients with dementia, gait disorders, or concomitant OSA (Schenck & Mahowald, 1990). Its use should be monitored carefully over time, as RBD in some patients appears to be a precursor to neurodegenerative disorders with dementia. Clonazepam has been associated with reduction in sleep-related injurious (SRI) behaviors (Aurora et al., 2010). Melatonin may be considered due to fewer side effects (Aurora et al., 2010). RBD patients on psychotropic medications, particularly antidepressants, should be closely monitored for worsening of RBD symptoms.

REM PARASOMNIAS AND PSYCHIATRIC COMORBIDITY

An acute form of RBD emerges during intense REM rebound states, such as during withdrawal from alcohol and sedative-hypnotics or with drug intoxication. Use of most antidepressants with the exception of bupropion has been recognized as a precipitating factor for RBD. Psychiatric disorders are not considered as predisposing factors, with the exception of PTSD.

HYPERSOMNIAS OF CENTRAL ORIGIN

Hypersomnias of central origin include a group of disorders with the primary symptom of excessive daytime drowsiness when the underlying cause of the primary symptom is not due to circadian rhythm disorder, sleep-related breathing disorder, or another cause of disturbed nocturnal sleep. These disorders include narcolepsy, recurrent hypersomnia (Kleine-Levin syndrome), and idiopathic hypersomnia.

NARCOLEPSY

CLINICAL FEATURES

Narcolepsy is characterized by a pentad of symptoms including excessive daytime sleepiness, disturbed nocturnal sleep, cataplexy, hypnagogic hallucinations, and sleep paralysis; the later three are manifestations of REM intrusion into wakefulness. Narcolepsy can be associated with or without cataplexy, which is defined as abrupt muscle atonia associated with a powerful emotional trigger (such as laughing) without loss of consciousness. Cataplexy occurs in 70% of the patients, and its presence is virtually diagnostic of narcolepsy. The associated symptoms include REM sleep behavior disorder, automatic behaviors, and obesity.

The prevalence rate of narcolepsy is about 1 in 4,000 in North America and Europe with equal male to female prevalence. Symptoms usually appear in the teens or twenties, and onset after age 55 and before age 10 is rare.

DIAGNOSIS

Detailed clinical interview in combination with PSG (to rule out other causes of sleepiness) and MSLT remain the current gold standard in the diagnosis of narcolepsy in adults. Mean sleep latency <8 minutes with two or more SOREMPs are observed on MSLT following sufficient nocturnal sleep (minimum of 6 hours). HLA antigen DQB1*602 is specifically associated with narcolepsy (almost all patients) although it is positive in 12%–38% of the general population. Low CSF hypocretin levels <110 pg/ml have been found in more than 90% of the patients with narcolepsy and never in controls.

TREATMENT

Narcolepsy is a lifelong disorder, with chronic sleepiness being the most disabling symptom. General strategies include patient and family education, counseling regarding good sleep hygiene, discussion of safety issues including driving recommendations, and vocational counseling. Behavioral techniques that have been found to be helpful in treatment of narcolepsy include avoidance of sleep deprivation, maintaining a constant sleep/wake cycle, and taking two 15-minute scheduled daytime naps to reduce daytime drowsiness.

The main goal of pharmacological treatment is to improve daytime alertness and reduction in episodes of cataplexy in

narcolepsy patients. Treatment of excessive daytime sleepiness involves use of modafinil and stimulants. Modafinil at a starting dose of 200 mg in the morning is considered to be first-line treatment of excessive sleepiness in narcolepsy patients. An additional 200 mg can be added the morning dose or in the afternoon to extend the alerting effects of modafinil. Mild side effects of modafinil include headache, nervousness, insomnia, and dry mouth. Rare but serious side effects include Stevens-Johnson's syndrome, aggression, suicidality, and psychosis.

Psychostimulants including methylphenidate, amphetamine/dextroamphetamines, and methamphetamine have been used effectively to treat sleepiness in narcolepsy patients. Combination of sustained release stimulants in the morning, with additional immediate acting stimulants in the afternoon, have been found to be effective in patients complaining of sleepiness in the afternoon or late evening. There is little evidence of abuse and addiction of stimulant medications in narcolepsy patients.

Sodium oxybate, the sodium salt of gamma hydroxybutyrate (GHB), may be the drug of choice in patients with both excessive daytime sleepiness and cataplexy. It is only available in liquid form and is prescribed twice during the night, with the second dose taken 2.5–4 hours later than the bedtime dose. Mild to moderate side effects of sodium oxybate include dizziness, headache, nausea, pain, somnolence, sleep disorder, confusion, infection, vomiting, enuresis, and night terrors. Respiratory depression, bradycardia, delirium, myoclonus, hypothermia, and coma can occur in sodium oxybate overdose.

Stimulant medications often do not provide significant relief from cataplexy despite improvement in daytime sleepiness. Patients with significant cataplexy symptoms need additional medications with anticataplectic activity. REM suppressant medications including tricyclic antidepressants, SSRIs, reboxetine, and venlafaxine have efficacy in treating cataplexy associated with narcolepsy, but these medications do not improve excessive daytime sleepiness (Morgenthaler et al., 2007).

NARCOLEPSY AND PSYCHIATRIC COMORBIDITY

Higher levels of anxiety, depression, and impulsivity have been noted in narcolepsy patients with cataplexy as compared to controls (Dimitrova et al., 2011). Increased prevalence of binge-eating disorders and sleep-related eating disorders has also been noted in narcolepsy patients.

Due to the presence of hypnagogic or hypnopompic hallucinations, narcolepsy patients may be misdiagnosed with psychotic disorders such as schizophrenia. According to a recent case control study, no indication for an increased prevalence of schizophrenia or any other psychotic disorders has been reported in narcolepsy patients compared to population controls (Fortuyn HA et al., 2009). Stimulant induced psychosis may be a more likely diagnostic possibility in narcolepsy patients presenting with psychotic symptoms (Fortuyn et al., 2009).

IDIOPATHIC HYPERSOMNIA

CLINICAL FEATURES

Idiopathic hypersomnia is characterized by constant and severe day time sleepiness with features of nonrefreshing prolonged naps and post-awakening confusion (sleep drunkenness). It is categorized as idiopathic hypersomnia with (>10 hours) or without (<10 hours) long sleep time. The onset of idiopathic hypersomnia usually occurs before 25 years of age. This disorder is stable in severity and long lasting, with complications including social and occupational impairment.

DIAGNOSIS

Nocturnal polysomnography (to exclude other causes of daytime drowsiness) and MSLT are done to establish diagnosis of idiopathic hypersomnia. Mean sleep latency of less than 8 minutes and fewer than 2 SOREMPs are recorded on MSLT in patients with idiopathic hypersomnia.

TREATMENT

Idiopathic hypersomnia is usually a lifelong disease, although recent series suggest that hypersomnia may spontaneously disappear in 14% to 25% patients. Modafinil and stimulant medications are the mainstay of treatment of idiopathic hypersomnia (Morgenthaler et al., 2007).

IDIOPATHIC HYPERSOMNIA AND PSYCHIATRIC COMORBIDITY

A prospective cohort study of 75 patients with idiopathic hypersomnia, who were compared with 30 healthy controls, showed slightly higher but nonsignificant levels of anxiety and depression in patients as compared to controls (Vernet & Arnulf, 2009). During clinical assessment, depression (unipolar or bipolar) should always be considered in patients presenting with idiopathic hypersomnia.

RECURRENT HYPERSOMNIA: KLEINE-LEVIN SYNDROME

CLINICAL FEATURES

Kleine-Levin syndrome is characterized by recurrent episodes of hypersomnia, often associated with cognitive and behavioral symptoms, that typically occur weeks or months apart. Episodes usually last for a few days to several weeks and are often preceded by prodromal symptoms of fatigue and headache. Patients may sleep as long as 16–18 hours per day. Sleep and behavior are normal between episodes, which may occur 1–10 times per year. Kleine-Levin syndrome is a rare disorder, and approximately 200 cases have been reported to date in the literature with 4:1 male to female ratio. The frequency of HLA DQB1*02 has been noted to be increased in patients with Kleine-Levin syndrome.

DIAGNOSIS

Head imaging including CT and MRI scans are normal, although EEG findings are significant for generalized slowing of background with paroxysmal bursts of bisynchronous high amplitude theta-delta waves. CSF fluid cytology and protein are normal.

TREATMENT

Stimulant medications may be used to with some success in treating hypersomnia in patients with Kleine-Levin syndrome. Lithium treatment has not been shown to decrease the number of relapses, but it has been associated with shorter duration of recurrent hypersomnia episodes with absence of behavioral symptoms in a small case series (Poppe et al., 2003).

KLEINE-LEVIN SYNDROME AND PSYCHIATRIC COMORBIDITY

Associated symptoms may include cognitive symptoms such as feelings of unreality, confusion, hallucinations, and behavioral symptoms including hyperphagia, hypersexuality, irritability, and aggression. In a large case series of 339 patients with Kleine-Levin syndrome, depression was more frequently reported in women than in men. A few cases of recurrent hypersomnia have been reported to have an alternation between hypersomniac episodes and manic depressive episodes.

CIRCADIAN RHYTHM SLEEP DISORDERS

Circadian rhythm sleep disorders (CSRDs) are characterized by persistent and recurrent pattern of sleep disturbance caused primarily by alterations of the circadian timing system, misalignment between endogenous circadian rhythm, and exogenous factors that affect timing or duration of sleep. CSRDs are associated with insomnia and/or excessive daytime sleepiness leading to social or occupational impairment. CSRDs include advanced sleep phase disorder, delayed sleep phase disorder, free-running disorder, irregular sleep/wake rhythm, shift work disorder, and jet lag disorder.

CLINICAL FEATURES

Advanced sleep phase disorder (ASPD) is characterized by habitual sleep onset and wake-up times that are several hours earlier relative to conventional or desired times. Individuals typically complain of excessive evening sleepiness and early morning insomnia. The prevalence of ASPD is noted to be 1% in middle-aged and older adults and increases with age.

Delayed sleep phase disorder (DSPD) is characterized by habitual sleep/wake times that are delayed (usually >2 hours) relative to conventional or socially acceptable times. Individuals typically have difficulty falling asleep at socially acceptable times, and attempts to fall asleep earlier are often

unsuccessful, leading to secondary conditioned insomnia. Affected individuals prefer late wake-up times and report sleep drunkenness in the morning. The exact prevalence of DSPD in the general population is unknown, and it is more commonly noted in adolescents and young adults with a reported prevalence of 7%–16%.

Free-running disorder (FRD) is characterized by sleep symptoms that occur due to intrinsic circadian rhythm being not entrained to a 24-hour period (usually slightly longer), leading to quite variable sleep patterns that can be congruent to a free-running circadian pacemaker. Most individuals with FRD are totally blind due to lack of photic input to their circadian pacemakers. The actual incidence of FRD is unknown, and rare cases have been reported in sighted people.

Irregular sleep/wake rhythm disorder (ISWD) is characterized by lack of clearly defined circadian rhythm of sleep and wake. The sleep/wake cycle is disorganized so that sleep and wake are variable through out the 24-hour period.

Shift work disorder (SWD) is characterized by complaints of insomnia or excessive sleepiness that occur in relation to work hours that are scheduled during the usual sleep period. The sleep disturbances are most commonly noted in night shifts and early morning shifts. This condition usually persists for the duration of shift work.

Jet lag disorder (JLD) is a circadian rhythm disorder characterized by mismatch between the timing of the endogenous circadian clock and the sleep/wake pattern generated by a change in time zone. Affected individuals complain of disturbed sleep, decreased alertness, and impaired daytime function. The severity of symptoms is dependent on the number of time zones traveled and direction, with eastward travel being more difficult to adjust to than westward travel.

DIAGNOSIS

Thorough clinical interview, sleep diaries/logs, and actigraphy are used to confirm diagnosis of CSRD. Polysomnography (PSG) is not indicated in the diagnosis of CSRD; however, it may be helpful to rule out additional primary sleep disorders in patients with CSRD.

TREATMENTS

Recommended treatments of ASPD include sleep/wake scheduling and bright light exposure in the evening after 8 p.m. to phase-delay circadian rhythms and reduce evening sleepiness. Hypnotic medications may be used to maintain sleep in the early morning (Reid & Zee, 2011). Treatment of DSPD aims at shifting the affected individual to sleep at an earlier, socially acceptable time. The treatment modalities for DSPD include chronotherapy, timed exogenous melatonin administration, and morning bright light exposure.

The therapeutic approaches to FRD are focused on entraining the intrinsic pacemaker. Timed light exposure, fixed sleep/wake schedules, and timed exogenous melatonin administration can help entrain the intrinsic circadian pacemaker. Physical activity, behavioral techniques to improve

sleep hygiene, timed exogenous melatonin, and bright light exposure are available therapeutic options for ISWR.

Treatment of SWD aims to phase-shift (usually delay) the circadian clock so that the patient is alert at night and sleeps during the day. Different options include bright light exposure during the first part of the night shift (leading to phase delay) and avoiding bright light on the commute home from work (leading to phase advance). Timed light exposure is key to management of JLD, minimizing morning light and maximizing afternoon light on eastward flights and staying awake till the lights are out on westward flights. Medication options include melatonin (2–5 mg) before bedtime upon arrival (repeat up to 4 nights) or hypnotics (zolpidem 10 mg) up to 3 nights.

CSRD AND PSYCHIATRIC COMORBIDITY

CSRDs are chronic disorders associated with social/occupational impairment and psychiatric sequelae. DSPD has been associated with increased incidence of depressive symptoms, depressive disorders, and schizoid and avoidant personality disorders. Affected individuals' use of sedatives/hypnotics, alcohol, and stimulants to treat symptoms of insomnia and sleepiness may lead to substance use issues in ASPD and DSPD. ISWR is more commonly noted in children with mental retardation and institutionalized elderly with dementia, and FRD in sighted people is associated with increased incidence of psychiatric and personality disorders.

PRIMARY INSOMNIA

As outlined in Box 9.3, insomnia can be caused by a variety of medical, neurologic, psychiatric, and environmental conditions. If possible, any factors that cause or exacerbate insomnia can be corrected. However, in many patients with primary insomnia no specific trigger exists.

CLINICAL FEATURES

Primary insomnia disorder is defined as a subjective report of sleep initiation, duration, consolidation, or quality that occurs despite adequate opportunity for sleep, leading to some daytime impairment. Insomnia symptoms occur in approximately 33%–50% of the adult population, with specific insomnia disorders in 5%–10%. Risk factors for insomnia include increasing age, female sex, comorbid disorders (medical, psychiatric, primary sleep disorders), shift work, and possibly unemployment and lower socioeconomic status. Patients with chronic pain and psychiatric disorders have insomnia rates as high as 50%–75%.

Careful history including characterization of main complaint (difficulty with sleep initiation and/or sleep maintenance, poor sleep quality), past and current precipitants, duration, frequency (nights per week), daytime symptomatology and distress, course (intermittent, progressive), aggravating and alleviating factors, and previous treatments and responses are key to insomnia evaluation. The clinician must

ascertain that the patient's sleep and time complaints occur despite adequate time available for sleep, in order to differentiate insomnia from behaviorally induced insufficient sleep. Attention should be paid to sleep onset time, as unusual sleep onset and wake times may indicate circadian rhythm disorders such as delayed or advance sleep phase syndrome. Cognitive distortions and negative behaviors associated with insomnia should be explored, including use of alcohol, sedatives, and hypnotic medications. Common daytime consequences of insomnia include fatigue, sleepiness, mood and cognitive complaints, poor quality of life, and exacerbation of comorbid illnesses such as mood disorders.

Patients with primary insomnia can generally be subdivided into three major types. Those with "psychophysiological" or "conditioned" insomnia learn to associate sleeplessness with certain circumstances, like their own bedroom. These patients become progressively tense as bedtime approaches, which can be detected with surface electromyography (Hauri & Fisher, 1986). In contrast, patients with idiopathic insomnia typically have lifelong difficulties sleeping. The cause of this syndrome is unknown, although neurochemical abnormalities of the arousal or sleep-regulating areas have been suggested (Hauri, 1994). Sleep state misperception or paradoxical insomnia is a rare type of primary insomnia. Patients with this disorder complain of subjective sleep disturbance that is not consistent with objective data. In order to meet criteria for this diagnosis, polysomnography needs to demonstrate normal duration and quality of sleep.

TREATMENTS

Treatment of insomnia includes behavioral, psychological, and pharmacological therapies. The goals of insomnia treatment include reduction of sleep and waking symptoms, improvement of daytime function, and reduction of distress. Behavioral/psychological treatments and pharmacological treatments can be used alone or in combination to treat insomnia. Treatment outcome can be monitored longitudinally with clinical evaluation, questionnaires, and sleep logs.

SLEEP HYGIENE

Among the best studied and most readily available tools for improving sleep disturbance in medical patients are environmental and behavioral management (Hauri & Fisher, 1986; Hauri, 1994). More specific behavioral studies have led to some basic information about sleep habits that can be helpful to patients that have disturbed sleep. These sleep hygiene techniques have been found to have particular efficacy in patients who have chronic insomnia complaints.

Establishing a regular awakening time, essentially every day of the week, optimizes resetting the circadian clock. Unfortunately, the "clock" tends to drift rapidly back to the old schedule as soon as there is variability in rising times, so persistence and consistency are important. When regular exercise is an option, doing it in the late afternoon several hours before bedtime may improve sleep to some degree, because of the association of falling body temperature and

sleep. Avoiding clock watching can help reduce the arousal effects of becoming aggravated by checking the seemingly interminable hours through the night. Most people recall only the periods of wakefulness at night, so clock watching can reinforce the irritating perception that no sleep occurred.

Patients should avoid alcohol, nonprescribed sedatives, and stimulants (such as caffeine and nicotine any time during the day). They should not sleep on a full stomach (particularly if the patient is prone to gastroesophageal reflux). Introducing "unwinding" stimuli as pre-bedtime routines can be helpful to most patients with sleep complaints. Treating GE reflux with an antacid and H₂-blocking medication prior to the hour of sleep can be beneficial.

COGNITIVE BEHAVIORAL THERAPY FOR INSOMNIA

Cognitive behavioral therapy for insomnia (CBT-I) is a combination of cognitive therapy coupled with behavioral techniques (sleep restriction, stimulus control) with or without relaxation therapy. CBT-I uses a psychotherapeutic approach to reconstruct cognitive distortions with positive and appropriate concepts about sleep and its effects.

Stimulus control technique is designed to extinguish the negative association between the bed and undesirable outcomes such as wakefulness, frustration, and worry. These negative states are frequently conditioned, in response to efforts to sleep, as a result of prolonged periods of time in bed awake. The objectives of stimulus control therapy are for the patient to form a positive and clear association between the bed and sleep and to establish a stable sleep/wake schedule. Patients are instructed to go to bed only when sleepy, and use the bed for sleep only. If unable to fall asleep within 20 minutes, then patients are instructed to leave the bed and engage in a relaxing activity until drowsy, then return to bed—and repeat if necessary.

Sleep restriction is intended to improve sleep continuity by limiting time in bed to the total sleep time in order to enhance sleep drive. As sleep drive increases and the window of opportunity for sleep remains restricted, with daytime napping prohibited, sleep becomes more consolidated. When sleep continuity substantially improves, time in bed is gradually increased to provide sufficient sleep time for the patient to feel rested during the day, while preserving the newly acquired sleep consolidation. In addition, the approach is consistent with stimulus control goals in that it minimizes the amount of time spent in bed awake, helping to restore the association between bed and sleeping.

Relaxation training includes progressive muscle relaxation, deep breathing, or guided imagery, and it is designed to lower cognitive and somatic arousal states that may interfere with sleep. It can be especially helpful in patients with hyperarousal states, and it is often combined with cognitive therapy.

PHARMACOLOGICAL TREATMENTS

The pharmacological treatments for insomnia aim to improve sleep quantity and quality, reduce sleep latency and wake after sleep onset, and reduce daytime impairment. Current

FDA-approved medications for treatment of insomnia include benzodiazepine receptor agonists (BzRAs) and melatonin receptor agonist (Schutte-Rodin, Broch, Buysse, Dorsey, & Sateia, 2008). Other medications that are used off-label to treat insomnia include antidepressants and antiepileptic drugs. Over-the-counter drugs including antihistamines, melatonin, and valerian have been used to treat insomnia, although evidence regarding the efficacy and safety of these agents is limited (Schutte-Rodin et al., 2008).

BENZODIAZEPINE RECEPTOR AGONISTS

Examples of short/intermediate-acting benzodiazepine receptor agonists (BzRAs) include zaleplon, zolpidem, and eszopiclone. All of these agents have been shown to have positive effects on sleep latency, total sleep time (TST), and/or waking after sleep onset (WASO) in placebo-controlled trials. Factors including symptom pattern, past response, cost, and patient preference should be considered in selecting a specific hypnotic agent (Schutte-Rodin et al., 2008).

Medications with short half life (zaleplon) are likely to reduce sleep latency but have little effect on WASO, and are less likely to result in residual daytime sedation. Whereas eszopiclone has a relatively longer half life, it is more likely to improve sleep maintenance and also more likely to produce residual sedation. Benzodiazepines (BZDs) such as lorazepam and clonazepam are not specifically approved for insomnia, although they might be used if appropriate for the patient's symptoms and comorbid conditions.

Potential adverse effects of BzRAs include residual sedation, memory and performance impairment, falls, undesired behaviors during sleep (including sleepwalking, sleep eating, and sleep driving), somatic symptoms, and drug interactions (Schutte-Rodin et al., 2008). A few cases of serious amnesic behaviors, with suicidal and parasuicidal gestures in patients with access to firearms, have been reported in patients taking zolpidem with alcohol (Gibson & Caplan, 2011; Chopra et al., 2013). These cases highlight the importance of discussing undesired sleep-related behaviors associated with zolpidem use and advising patients to take precautions, such as firearm safety and not mixing alcohol with hypnotic medications, in order to prevent untoward events. There seems to be a consensus that triazolam carries the highest rates of reported amnesia, dissociative episodes, and rebound insomnia and anxiety. BZDs should be used with caution in patients with compromised respiratory function (COPD, sleep apnea).

Empirical data supports both daily and intermittent usage in terms of frequency of hypnotic medications. In clinical practice, hypnotics are often used over duration of 1–12 months. Randomized controlled studies of medications including zolpidem/eszopiclone have demonstrated continued efficacy without significant side effects. Patients should be followed up at 6-month intervals if hypnotic medications are used on long-term basis to monitor efficacy, side effects, tolerance, or abuse. Gradual tapering of both dosage and frequency of hypnotic medications is recommended to prevent rebound insomnia and withdrawal symptoms (Schutte-Rodin et al., 2008).

RAMELTEON

Ramelteon is a melatonin receptor agonist which is FDA approved for treatment of insomnia. It is a short-acting medication administered at bedtime, and it is primarily used for sleep onset insomnia.

ANTIDEPRESSANTS

Sedating low-dose antidepressants may be tried if insomnia is accompanied with comorbid depression or prior trial of BzRAs or ramelteon has been unsuccessful. Examples of these drugs include trazodone, mirtazapine, doxepin, and amitriptyline. Factors such as treatment history, coexisting psychiatric and medical conditions, specific side effect profile, cost, and pharmacokinetic profile may guide the selection of a specific agent. These medications are not FDA approved for insomnia, and their efficacy for this indication is not well established (Schutte-Rodin et al., 2008).

OTHER MEDICATIONS

Medications including gabapentin, quetiapine, and olanzapine may be used in clinical practice, although evidence of efficacy for these drugs for the treatment of chronic primary insomnia is insufficient (Schutte-Rodin et al., 2008).

SLEEP AND PSYCHIATRIC DISORDERS

SLEEP AND ANXIETY DISORDERS

Patients with anxiety disorders often complain of difficulty initiating and maintaining sleep. PSG findings in patients with anxiety disorders comprise longer sleep latency, increased wake time after sleep onset, increased arousals leading to sleep disruption, reduced SWS, reduced sleep efficiency, and reduced total sleep time.

Generalized anxiety disorder patients demonstrate impaired sleep initiation and maintenance as compared to healthy controls along with normal latency to REM sleep, unlike depressed patients. Patients with panic disorder experience at least one nocturnal sleep-related panic attack, and one-third of the patients experience nocturnal panic attacks that preferentially occur in NREM sleep during transition to slow-wave sleep. Symptoms of nocturnal panic attacks are similar to daytime panic attacks. There is usually no reported dreaming before the panic attack.

Patients with posttraumatic stress disorder (PTSD) experience insomnia and recurrent distressing dreams of the traumatic event. Excessive motor activity and awakenings with somatic anxiety symptoms are sleep manifestations of heightened arousal in PTSD.

SLEEP AND MOOD DISORDERS

Patients with clinical depression almost uniformly complain of sleep disturbances, with a majority (80%) of them having insomnia and the rest complaining of hypersomnia. PSG

abnormalities in major depression include prolonged sleep latency, sleep fragmentation, increased wake time, early morning awakenings, decreased SWS, shortened REM latency, increased REM density, and increased overall REM as well as reduced TST and SE.

Improvement in these sleep parameters has been observed after treatment with both cognitive behavioral therapy and pharmacological treatment with antidepressants. Most antidepressants suppress REM sleep; many affect SWS and sleep continuity measures. Residual sleep disturbances have been associated with increased relapse rates in depressed patients in remission.

Patients with mania invariably have decreased need for sleep, and severe insomnia may be an early symptom and trigger for a manic episode. PSG findings in mania are similar to those found in major depression, including poor sleep continuity, reduced SWS, short latency to REM sleep, and increased eye movements during REM sleep.

SLEEP AND SCHIZOPHRENIA

Schizophrenia is associated with sleep disturbances including insomnia, disturbed circadian rhythm, and daytime sleepiness. PSG findings in schizophrenic patients include increased sleep latency, decreased sleep efficiency, decreased SWS, and decreased REM latency. Strong correlation has been demonstrated between insomnia and positive symptoms of schizophrenia including delusions, hallucinations, and disorganization.

Disruption of circadian rhythm patterns has also been noted in schizophrenia, with predisposition to delayed sleep phase pattern and increased daytime sleep. Poor sleep hygiene and substance abuse may further contribute to worsening of sleep patterns in schizophrenic patients.

Use of low-potency sedating antipsychotics has been associated with improved sleep continuity in schizophrenic patients, but this may occur at the expense of daytime sedation. The role of antipsychotics leading to sleep disturbances including REM or slow-wave abnormalities in schizophrenic patients is unclear, as these agents have been associated with both improvement and worsening of REM and slow-wave sleep parameters.

The side effects of neuroleptics that may affect sleep quality include akathisia and worsening of restless legs syndrome or periodic limb movements of sleep. Metabolic side effects of neuroleptic medications such as weight gain may also place schizophrenic patients at increased risk of obstructive sleep apnea and resultant day time sleepiness.

SLEEP AND ATTENTION DEFICIT HYPERACTIVITY DISORDER

The estimated prevalence of sleep problems in children with attention deficit hyperactivity disorder (ADHD) is 5 times higher as compared to healthy controls. The sleep problems in ADHD children may be attributed to ADHD itself, or ADHD comorbidities such as mood disorders, anxiety disorders, and substance abuse. Stimulant medications frequently

used to treat ADHD have insomnia as a common side effect. Polysomnography findings in children with ADHD include increased rates of periodic limb movements of sleep and sleep-related breathing disorders. Inattention and hyperactivity may improve upon adequate treatment of sleep-related breathing disorders in children with ADHD.

SLEEP AND ALCOHOL DEPENDENCE

Alcohol dependence is associated with sleep disturbances including insomnia, obstructive sleep apnea, and circadian rhythm disturbances. Decreased sleep efficiency and total sleep time, decreased REM latency, and decreased SWS has been noted on PSG. The suppression of SWS has been linked to growth hormone suppression in alcoholic patients and linked to poor quality of sleep. Nonrestorative sleep in alcoholics has been associated with increased alcohol consumption. OSA patients with alcohol abuse pose a special challenge, because alcohol is believed to decrease the neuromuscular tone of the upper airway. These patients often require higher CPAP settings to prevent apneas, and, if the sleep study is done when the patient is sober, often the pressure setting is inadequate.

CLINICAL PEARLS

- Questionnaires such as the Stanford Sleepiness Scale and Epworth Sleepiness Scale can assess the severity of daytime somnolence.
- From bed partners, collateral information can offer what patients don't know about their nighttime breathing complaints, such as snoring, apneic spells, or behavioral events such as dream enactment behaviors.
- Polysomnographic study is not indicated for diagnosis of restless legs syndrome.
- The American Academy of Sleep Medicine recommends that portable monitoring may be acceptable for assessment of obstructive sleep apnea (OSA) in certain carefully defined conditions including patients with high pretest probability of moderate to severe OSA and absent medical comorbidities, nonambulatory, or medically unstable patients, or to assess response to therapy in previously diagnosed OSA (Collop et al., 2007).
- The Maintenance of Wakefulness Test can be helpful in assessing the response to stimulants or a patient's fitness to drive.
- Supplemental oxygen alone is inadequate for OSA, and patients with both OSA and intrinsic lung disease who have persisting hypoxia despite CPAP may benefit from supplemental oxygen delivered via their CPAP masks.
- Clinical follow-up of potential problems once CPAP is instituted—including leakage through the PAP interface, claustrophobia due to the PAP interface, and dry mouth or nasal congestion—heads off PAP noncompliance.

- For patients who develop apneas only when lying supine, positional therapy may be effective. This may include having them use a device such as a t-shirt with an attached cloth tube of tennis balls that keeps them off their backs.
- Patients with OSA may report improvement in their mood and energy within days, and this positive reinforcement leads to good CPAP compliance (Berthon-Jones et al., 1996).
- Central sleep apnea (CSA) has been found in 30% of the stable methadone maintenance treatment patients and in patients prescribed time-release opioid analgesic management (Wang et al., 2005). CSA symptoms tend to improve upon reduction of opiate dosage.
- While dopamine agonists can treat restless leg syndrome (RLS), augmentation of the syndrome and an increase in impulse control disorders like gambling can be side effects.
- Bupropion, due to its primarily dopaminergic action in contrast to SSRIs, appears to reduce the periodic leg movements of sleep and RLS symptoms.
- If poor sleep is a major factor in the depressive phenotype, then screening for RLS should be considered.
- Delayed sleep phase disorder has been associated with increased incidence of depressive symptoms, depressive disorders, and schizoid and avoidant personality disorders.
- In patients with panic disorder, nocturnal panic attacks preferentially occur in NREM sleep during transition to slow-wave sleep.
- Polysomnography abnormalities in major depression include prolonged sleep latency, sleep fragmentation, increased wake time, early morning awakenings, decreased SWS, shortened REM latency, increased REM density, and increased overall REM, as well as reduced TST and SE.
- There is a strong correlation between insomnia and positive symptoms of schizophrenia, including delusions, hallucinations, and disorganization.
- OSA patients with alcohol abuse pose a special challenge, because alcohol is believed to decrease the neuromuscular tone of the upper airway. These patients often require higher CPAP settings to prevent apneas, and, if the sleep study is done when the patient is sober, often the pressure setting is inadequate.

PART II

THERAPEUTIC MODALITIES

PSYCHOTHERAPEUTIC PRINCIPLES AND TECHNIQUES

PRINCIPLES OF MEDICAL PSYCHOTHERAPY

Stephen A. Green

INTRODUCTION

The interaction between many physicians and patients remains an impersonal, if not mechanistic, encounter. Symptomatic individuals present themselves for diagnosis and treatment with the expectation that they will be cured, or at least significantly relieved of their particular suffering. Because of this cause-and-effect mindset, the *intellectual* activity of problem solving has become the basis of medical practice for many practitioners. Obviously, considerable empathy and concern is involved in this process, as the particular problems under consideration affect the physical and mental health of individuals. However, treating illness is generally considered an exercise of determining etiology, prescribing the indicated therapeutic regimen, and meticulously monitoring the treatment response and course of the illness. This approach is based on the biomedical model, a parochial standard that compromises patient care by embracing the inaccurate notion of a mind-body dichotomy and perpetuating the reductionistic notion that complex phenomena are ultimately explained by a single principle (Engel, 1977).

Given the evolution of medicine into a highly specialized world that utilizes increasingly sophisticated—and impersonal—technology, a major impact of the biomedical model has been to dissect the patient into more and more composite parts. It isolates individuals from their daily environment of psychosocial supports and stressors, thereby promoting “the physician’s preoccupation with the body and disease and the corresponding neglect of the patient as a person.” It fails to consider “how the patient behaves and what he reports about himself and his life” because “it does not include the patient and his attributes as a person, a human being” (Engel, 1980). In sum, the biomedical model suggests that treating a patient’s specific physical pathology is synonymous with treating the patient, which ignores the fundamental truth that all illness simultaneously affects one’s mind and body. Rigid adherence to this model thereby compromises patient care in a significant way: it prevents requisite attention to abnormal emotional states of medical patients that may derive from a psychological reaction to the illness or reflect concurrent psychopathology that is often unrecognized. For example, approximately 50% of patients who present to primary care physicians with depressive disorders remain

undiagnosed (Regier et al., 1988), despite studies demonstrating that two-thirds of the top 10% utilizers of primary care physicians have diagnosed recurrent major depression (Katon et al., 1990) and the fact that depression is possibly the most common illness presenting to primary care physicians (Katon, 1987).

The biopsychosocial model highlights the inextricable link between mind-body interaction and, consequently, enhances understanding of the pathogenesis, clinical course, and treatment of diverse disease processes, as well as mechanisms of death (Engel, 1968; 1971; Greene, Goldstein, & Moss, 1972; Lown, Verrier, & Rabinowitz, 1977; Reich et al., 1981). While Engel, an internist with psychoanalytic training, is credited with coining the term *biopsychosocial*, the concept that multiple genetic, physiologic, psychodynamic, environmental, and social factors all interact in a systems model to influence the onset and outcome of medical illness had been stated early in the 20th century by psychiatrists Franz Alexander and Adolph Meyer. The theories of Meyer, Alexander, and Engel in this respect have received extensive validation (Stoudemire, 1995; Stoudemire & McDaniel, 1999). The biopsychosocial model is now an established paradigm that recognizes how disturbances in physiologic functioning influence, and are in turn affected by, one’s psychological functioning; it thereby emphasizes the clinical reality that optimal medical treatment requires a comprehensive appreciation of the interplay between patients’ organic pathology, their intrapsychic lives, and the positive and negative impact of their social environment.

This biopsychosocial treatment approach, as discussed by Engel (1980), is conceptualized by interposing the patient between two hierarchies that combine to form an overall hierarchy of natural systems. The person is at the same time at the highest level of an organismic hierarchy, which ranges from subatomic particles through the nervous system, and the lowest stratum of a social hierarchy, which ranges from a two-person system to the biosphere. These two hierarchies are in a dynamic equilibrium, since every system (e.g., cells or two-person) within each hierarchy is a distinctive whole that is simultaneously interrelated with every other system. Consequently, disturbances at any system level can alter any other system level; through feedback controls, they may modify or aggravate the system originally affected.

According to the biopsychosocial model, pathologic mood states that exist concurrently with medical illness may be predominantly biological or psychological in origin. For example, the biological model advocates that depression is the symptomatic and behavioral expression of abnormalities associated with central nervous system biogenic amines, and that appropriate treatment requires use of pharmacological agents that influence neurotransmission. The psychological paradigm suggests that dynamic interaction of unconscious, preconscious, and conscious thoughts and feelings produce psychic conflict that may result in depression, and that treatment rests heavily on a comprehensive study of the patient's *illness dynamics* (Green, 1985)—that is, the varied psychosocial factors affecting, and affected by, the patient's organic pathology—information which is then incorporated into an individualized psychotherapeutic approach.

As this chapter discusses, psychotherapy is generally classified as a *supportive* or *introspective* treatment. The former attempts to minimize emotional distress; one such treatment is a patient support group. Introspective therapy, on the other hand, seeks to compel patients to actively confront and grapple with disturbing feelings in an effort to gain better affective control; insight-oriented psychotherapy is the prototype intervention. There are many variants of these therapeutic approaches (American Psychiatric Association, 1996), each emphasizing different methods for resolving distressing psychological states. For example, cognitive therapy attempts to modify irrational beliefs and distorted perceptions toward the self and the environment, while interpersonal therapy seeks to define and explore specific stressors, such as social isolation, in order to minimize their regressive impact. However, *all* psychotherapies ultimately are based in a supportive or introspective orientation, which can be administered on an individual basis or in broader settings such as couples, family, or group therapy. How individuals react emotionally to their illness determines whether supportive or introspective psychotherapy is indicated for the treatment of pathologic mood states that exist concurrently with a medical illness.

RESPONSES TO ILLNESS

Impaired health, whether it takes the form of a mild upper respiratory infection or a life-threatening cerebrovascular accident, is a universal condition that precipitates a predictable emotional response: *illness is experienced as a loss—specifically, the loss of health—because it diminishes one's level of functioning*. This is most obvious when serious ailments permanently and profoundly change an individual's physical status, such as the severe restrictions caused by blindness. However, even a limited illness may precipitate considerable feelings of loss due to the symbolic significance to the patient. In addition to challenging omnipotent wishes—highlighting one's vulnerability to physical ailments whose onset, course, and response to treatment are often unexplainable and unpredictable—an episode of ill health conveys specific symbolic meaning that derives from the highly personalized interplay between patients' physical pathology, intrapsychic life, and

social environment. This determines how, and to what extent, they react affectively to a particular loss of health.

Whether illness is experienced in the literal sense, as a result of concrete physical restrictions, or more symbolically, due to implied or anticipated limitations, it promotes the same psychological response—a *grief reaction during which patients mourn the loss of their previous state of health*. The process is akin to bereavement. Illness obliges one to acknowledge and confront a diminished level of functioning, causing individuals to progress through a series of feeling states—denial, anxiety, anger, depression, helplessness—before resolving the various emotions precipitated by their loss.

This is most obvious during a medical emergency, such as an acute appendicitis. The gravity of the initial pain caused by an inflamed appendix, which may be quite severe, is often dismissed as indigestion or the effects of an enterovirus. Other feelings supplant the early denial as the significance of the symptoms becomes clearer. Anxiety emerges as patients ruminate about the morbidity (and possible mortality) of surgery, as well as their need to abdicate considerable responsibility for their well-being and comfort to anonymous caretakers. This anxiety can persist during the recuperative period, focused on such issues as the restrictions and length of convalescence; however, emerging resentments usually predominate during this stage, prompting patients to discharge their anger on family members, friends, and even medical personnel who provide succor and support. These feelings eventually give way to a period of helplessness and overt depression, characterized by mood, behavioral, and cognitive changes, when one is most aware of the losses brought on by a surgical emergency that has relegated all other activities (e.g., professional and social responsibilities) to positions of secondary importance. Most patients emerge from this phase, progressively reestablishing an emotional equilibrium by working through all of the feelings precipitated by illness. This requires their appropriate assessment of the specific limitations caused by their disease, as well as a general acknowledgment of their vulnerabilities and ultimate mortality.

An abnormal emotional response to illness occurs when one is unable to effectively grieve the losses caused by ill health. For a variety of reasons idiosyncratic to a particular individual during a particular period of life, the patient may be unable to recognize, experience, and put into proper perspective some or all of the feelings precipitated by illness. That individual may completely deny all emotions, or, more commonly, experience a specific mood to the relative exclusion of all others. In effect, the patient becomes mired in some phase of the grief process, preoccupied with the feelings characteristic of that stage. This forestalls attainment of an emotional resolution regarding the loss of health, a situation that can evolve into an emotional state similar to pathological grief whose symptomatic expression may take the form of a mood disturbance (e.g., excessive anxiety and/or depression), a behavioral disturbance (e.g., compulsive eating or substance abuse), or impaired object relationships (Brown & Stoudemire, 1983). Subsequent effects on somatic functioning—which may aggravate the initial organic pathology—derive from mind-body interactions. Because of this interdependence, *affective resolution of the loss of health is*

essential for physical, as well as psychological well-being. Absent this grief work, a pathologic illness response emerges, characterized by a psychobiological disequilibrium generally more disabling than that caused by the initial illness. The most frequent abnormal psychological reactions to illness include pathologic degrees of denial, anxiety, anger, depression, and dependency.

THE DENIAL RESPONSE

Denial, the refusal to perceive or accept external reality, is a common ego mechanism that enables a person to partially or completely ablate distressing cognitions and/or moods. If a patient's denial is absolute in the presence of a serious illness, that primitive behavior is classified as a *psychotic ego mechanism* (Vaillant 1977). Less pronounced denial, however, may have an adaptive purpose by enabling individuals to temporarily ignore the overwhelming impact of a stressor that might otherwise threaten psychological integrity. For example, it is often invoked when specific circumstances limit the effectiveness of higher level ego functioning in emotionally healthy individuals (e.g., the conviction that one will certainly survive in battle). Similarly, it is associated with better short-term psychological adjustment following a myocardial infarction (Hackett & Cassem, 1974), and diminished morbidity and mortality during hospitalization (Levenson et al., 1989).

Denial becomes maladaptive when it is so excessive that it prevents accurate assessment and acceptance of the realities of life. At this point it is exclusively defensive, providing illusory comfort by prompting actions that promote a false sense of well-being, or insure inactivity such that a patient's reaction to illness is actually a nonresponse. Denial may be present throughout the course of illness, from the moment of onset, during the period of initial treatment and convalescence, and extending into the rehabilitative phase. The long-standing cardiac patient who attributes cramping in his left arm to "overwork," or the woman who decides to have her breast mass evaluated "in a few months," exemplifies acute denial of illness. Noncompliance with one's therapeutic regimen often reflects continued denial. This can apply to the period of initial hospitalization, illustrated by the patient who refuses to remain at bedrest (Reichard, 1964) as well as chronic care, seen in the individual with diabetes mellitus who repeatedly ignores dietary restrictions. It may also be observed in the terminal patient who adamantly refuses to acknowledge impending death. An excessive unconscious rejection of illness may therefore ultimately complicate accurate diagnosis and interfere with definitive treatment.

THE ANXIETY RESPONSE

Signal anxiety alerts one to danger and subsequently prompts purposeful, self-protective behavior. The onset of illness is always accompanied by heightened anxiety, as patients question the extent and degree of their ailments. Common concerns, such as whether or not symptoms signal the beginning of a fatal illness, usually give way to speculation about the diagnostic work-up, course of treatment, and ultimate

prognosis. Patients may wonder how they will be perceived by others, and how they will regard themselves if they become disfigured or chronically debilitated. They ruminate about the toll of their illness on family relationships, professional responsibilities, friendships, and day-to-day functioning. In short, they attempt to assess the impact of illness on the overall quality of life in the near and distant future. Although a difficult and disconcerting exercise, this is usually an adaptive response to illness, spurring them to seek timely medical attention and adhere to prescribed treatments.

Illness can also precipitate pathologic levels of anxiety that cause patients undue concern about their physical status. As a consequence, patients become hypersensitive to all aspects of care from diagnostic procedures to therapeutic interventions, a preoccupation that has diverse detrimental effects. A new sign or symptom may take on considerable significance, interfere with the patient's ability to provide an accurate medical history, significantly augment the apprehension accompanying routine examination and treatment, and generally distract the individual from the pleasures and responsibilities of daily life. If this evolves into a chronic anxiety, patients become burdened with unpleasant moods in addition to the discomfort of their physical pathology. Moreover, continued demands for reassurance from family, friends, and health professionals may progressively alienate supportive persons, ultimately isolating the patient from fundamental sources of emotional support. In this fashion, pathologic anxiety can compromise every phase of medical treatment and decrease the patient's potential for returning to optimal functioning.

THE ANGER RESPONSE

Patients who demonstrate anger as the predominant response to loss of health express the affect in the same way one grieves the death of a loved one—focusing feelings of frustration, resentment, and overt hostility in several directions. They may rage at the gods with a diffuse, globally expressed anger, cursing their bad luck and wondering, "Why me?" Alternatively, they may direct that anger toward themselves; the individual who herniates a lumbar disc while moving furniture holds himself most responsible for the painful disruption of his life. Anger is also focused on family members and friends, whose various behaviors are often implicated as contributors to the development or exacerbation of an illness; a patient may view the demands of her spouse as the primary cause of her hypertension or migraine headaches. Patients may judge members of their social network as insensitive to their plight, or resent family members because of their greater dependence on them. Patients may even blame ancestors for a defective gene pool that predisposes them to a particular illness. Finally, health personnel frequently bear the brunt of a patient's hostility. In addition to providing succor and support, caretakers exert considerable control over the patient's life, which often takes the form of deprivation and discomfort. They subject patients to unpleasant diagnostic tests, restrict diets, limit activity levels, and prescribe medications that cause unpleasant, sometimes dangerous side effects. Moreover, practitioners may fail to cure disease, and often bear grim news about an

individual's welfare and mortality. For these reasons, physicians are prime targets for patients' angry feelings.

The hallmark of an anger response is *conflict*. Instead of working through feelings evoked by illness, patients engage in a variety of struggles with the people in their lives. These struggles may be obvious, such as debate surrounding the refusal to submit to a diagnostic procedure or refusal to agree to rehabilitative therapy. The impotent pleas of family members urging reconsideration, as well as the frustration of healthcare providers, mirror the patient's considerable hostility. Struggles may also be covert. They can take the form of passive-aggression, such as ignoring dietary restrictions or irresponsible adherence to a medication regimen, behaviors that afford patients the pleasure of secret control over their caretakers by undermining efforts to help them. Displacement is an additional mechanism with which to disguise true anger about the loss of health. For example, an individual angry about the need for orthopedic surgery that will significantly restrict his physical activity for weeks may start struggling with his wife over long-standing marital difficulties as a way of discharging his feelings about the upcoming surgery and subsequent convalescence.

In sum, the anger response promotes a generalized non-compliance with the treatment, progressively transforming the patients' supportive alliances—including those with their caretakers—into adversarial relationships. In addition to detracting from the level of medical care, this reaction often isolates patients from a support system that could help them negotiate the stressful life situation of ill health.

THE DEPRESSION RESPONSE

Individuals who react to physical illness in this fashion manifest affective, cognitive, and behavioral changes characteristic of a clinical depression (Klerman, 1981; Rodin & Voshart, 1986). These changes vary in degree, depending on factors particular to individuals and their disease process; as a consequence, the intensity of the depression response may range from a relatively mild adjustment disorder to a major depressive episode. The clinical presentation encompasses four general areas of objective and subjective signs and symptoms.

First, alterations of affect occur. This usually presents as a *sustained lowering of mood accompanied by pronounced sadness, tearfulness, and anhedonia*, though affective changes may also include irritability, agitation, and hypomania. Second, the physiological sequelae of depression are manifest in *wide-ranging somatic symptoms* that can affect any organ system (Lindemann, 1944). Third, depression causes changes in usual patterns of behavior beyond those resulting from restrictions imposed by the illness state. This behavior change often takes the form of a *generalized withdrawal*—physically and psychologically—from one's environment. Mounting preoccupation with the loss of health causes patients to invest less and less energy into family matters, social relationships, and professional responsibilities. As this isolation grows, the patient's world becomes increasingly joyless. Finally, as with all types of depression, a prominent aspect of this illness response is *diminished self-esteem*. The effects of physical

impairment, aggravated by the patient's subsequent mood disturbance, raise considerable fear and doubt about the prospect of regaining the premorbid state of health. This negativism fosters self-criticism characterized by feelings of weakness, self-reproach, and worthlessness.

This depressive response to illness affects medical treatment in a variety of ways. Psychophysiological symptoms of depression complicate the diagnosis of a physical illness (e.g., when attempting to differentiate between a dementia and cognitive dysfunction caused by depression), making ongoing evaluation and treatment a difficult task. Depression has the capacity to suppress the immunological response (Schindler, 1985; Schleifer, Keller, Meyerson, et al., 1984), with obvious adverse effects on the body's ability to battle an illness, and can become so severe that it poses a greater threat to the patient than the physical pathology. Neurovegetative symptoms, such as extreme anorexia, may progress to the point of *passive self-destructive behavior; purposeful suicidal actions* also occur (Slaby & Glicksman, 1985). Finally, the withdrawal that is characteristic of the depression response progressively isolates patients from the usual supports of their environment. This subverts the therapeutic alliance with various healthcare personnel, alienates family and friends, and may become so extreme that the individual may essentially abandon the will to live (Engel, 1968).

THE DEPENDENCY RESPONSE

Illness limits autonomy because of factors internal to individual patients (e.g., restrictions caused by specific symptoms, general preoccupation with the disease), as well as external issues (e.g., limitations imposed by the structured hospital routine or requirements of a therapeutic regimen). The adaptive aspect of this regression permits patients to revert to more passive behaviors characteristic of early childhood. *This allows caretakers to take a necessary degree of control of the treatment, and simultaneously provides patients with the comfort and familiarity of diminished responsibility*. The defensive aspect of regression helps patients contend with the distressing emotions precipitated by illness by assigning to others concern and accountability for their welfare.

Although regression helps maintain emotional equilibrium during periods of illness, it can interfere with medical treatment if the dependency becomes too great, too intense, or does not diminish as the physical disorder improves. This danger is addressed in Parsons's (1951) description of the "sick role," which emphasizes the collaborative aspect of medical treatment. During the early phase of illness, functional impairment is legitimized by healthcare personnel who identify affected persons as *patients* and, consequently, exempt them from various societal responsibilities. Patients' dependency on their caretakers is acknowledged and accepted as caretakers labor to make them well. With improvement, however, individuals are expected to assume increasing levels of independent functioning. Parsons envisions this collaborative process as a "common task" between patient and healthcare provider and underscores the fact that individuals bear definite responsibility for aspects of their care (e.g.,

active participation in long-term rehabilitation). This transition period of the sick role has particular relevance to the dependency response. Patients may find the ministrations of others so gratifying that they are disinclined to strive toward the autonomy of their premorbid life. They abdicate increasing responsibility to family, friends, and healthcare personnel, and savor the nurturing pleasures of dependency. Unfortunately, this decline to greater levels of helplessness compromises patients' physical and emotional well-being.

Excessive dependency is often manifested as noncompliance with medical treatment. This may cause an individual to continue harmful habits (e.g., smoking), to be irresponsible with medications, or to allow known symptoms to get worse before seeking medical attention. Whether these motivations are purposeful or unconscious, they yield the same results—prolonged dependency on health personnel who are obliged to provide the care necessitated by the patient's neglect. In addition to possibly aggravating the patient's physical status, pathologic dependency often subverts supportive relationships. The prevailing dynamics within a family may be considerably disrupted by a patient's continued regression, altering established roles in a manner that undermines the emotional welfare of all concerned. In a similar fashion, relationships with professional colleagues may suffer, and medical personnel may come to view the regressed individual as a "hateful patient" (Groves, 1978), a realistic and understandable countertransference response often triggered by increasingly annoying dependent demands. All these behaviors—which reflect evolution into the role of "professional patient," in which a person becomes more concerned with being cared for than with discharging the responsibilities of adult life—may be overt or covert. It is particularly important for health providers to appreciate a dependency response that might be disguised by seeming compliance. The longer the patient's wish to remain in the sick role goes unrecognized, the likelier it is that the collaborative doctor–patient relationship will degenerate into an adversarial conflict harmful to each member.

MEDICAL PSYCHOTHERAPY

Reasoned attention by medical personnel to the heightened emotions precipitated by an individual's ill health can help facilitate an adaptive adjustment to illness, and thereby prevent the onset of an abnormal illness response. However, all therapeutic measures must be carefully tailored to each patient based on a comprehensive understanding of the patient's illness. Interventions designed to facilitate the grief work accompanying the loss of health are required for some individuals, but contraindicated in patients so overwhelmed by their affective state that they require support of adaptive ego functioning (e.g., by supplying obsessional patients with considerable information about their day-to-day condition, or prescribing psychoactive medications). Unfortunately, many patients become increasingly encumbered by the distressing feelings and harmful behaviors that characterize a particular pathologic reaction to illness. Continued negative impact on their physical and emotional well-being signals the need for

medical psychotherapy, a specialized form of psychotherapeutic intervention. Medical psychotherapy is based on "the communicated understanding between physician and patient concerning the biologic, psychologic and social aspects" of an individual's illness, as discussed by Goldberg and Green (1985). The treatment, which can be utilized for crisis situations (e.g., acute onset of illness) or chronic conditions (e.g., persisting illness), can take either a supportive or introspective approach.

The correlation between grief work and the usual emotional reaction to illness suggests that patients should routinely be guided toward working through feelings about their loss of health. However, that course is sometimes contraindicated, as insight-oriented therapy rests on their ability to tolerate the heightened anxiety attending exploratory work, and certain patients have characteristic personality features that render anxiety-provoking psychotherapy ineffective and/or harmful. Clinicians' expert knowledge concerning the substantive and temporal course of grief work is counterproductive if it prompts them to doggedly confront the defensive structure and maladaptive behaviors in these individuals. For example, patients who exhibit alexithymia, a relative inability to express psychological distress by direct verbal means (Sifneos, 1972–73), are more likely to regress if the clinician attempts to pressure them to confront affects associated with the stages of grieving. Their diminished capacity for self-examination, due to a fundamentally concrete style of perceiving, evaluating, and discussing life events (Nemiah & Sifneos, 1970), often impedes the grief process associated with loss of health.

When treating medical and surgical patients unable to contend with the emotions precipitated by illness, the clinician's most important decision concerns a clear delineation of therapeutic goals. The physician must choose between commending and encouraging the patient's usual style of emotional functioning, or pursuing a more introspective analytic path. The former approach attempts to foster an atmosphere of support and reassurance that can then be exploited to enhance the clinician's positive influence; the latter course attempts to help the patient work through conflictual feelings precipitated by illness. Correct treatment of a patient's abnormal illness response requires the physician to choose between a supportive, anxiety-suppressing approach or an introspective, anxiety-provoking stance as the appropriate form of medical psychotherapy. That clinical decision is based on understanding patients' *illness dynamics*, as well as conjointly assessing their physical state and emotional needs at any given time during their illness.

ILLNESS DYNAMICS

Everyone lives within a distinctive context of supports and stressors that influence day-to-day functioning and interpersonal relationships. *Illness dynamics* refers to those diverse factors as they affect an individual's response to a specific disease at a particular time in life (Green, 1985). Supports and stressors derive from conscious and unconscious determinants that converge in one's mind, causing the patient to perceive, assess,

and defend against the loss of health in a highly subjective manner (Box 10.1). Illness dynamics cause patients to evaluate all illness-related information in a fashion that reflects particular values, needs, wishes, and fears, thereby shaping a distinctive perception of ill health. This idiosyncratic biopsychosocial profile may help them accommodate to the emotions precipitated by loss of health or, alternatively, impede that effort.

Illness fosters regression when it affects major sources of gratification for an individual (e.g., an injury that impedes the activity of a vigorous athlete). It may also cause regression by promoting the emergence of unconscious fears (e.g., requiring a Type A individuals to become considerably dependent on caretakers). These types of reactions have widespread impact on the total organism as a result of diffuse mind-body interactions. Reiser (1975) discusses how the brain translates idiosyncratic symbolic meanings of events into physiological changes that may promote the onset of illness and/or aggravate its clinical course, or help maintain a healthy homeostasis. As an illustrative example, he posits the reaction of two individuals with comparable coronary artery disease to the final desperation play of a football game that determines its outcome. The excitement of victory for one individual *or* the disappointment of defeat for the other might precipitate an adverse cardiac event in *either* fan—depending on how each transforms his psychological reaction into a physiological reaction. In the extreme, Reiser suggests that “major life experiences, such as bereavement, can influence even the capacity to sustain the life process itself.” This thesis is supported by

considerable laboratory and clinical data that include investigation of immunologic responses and cardiovascular functioning (Henry, 1975).

Illness dynamics also affect the doctor–patient relationship as well as sources of support in an individual’s social network. According to Lipowski (1975), the process of evaluating the state of ill health

... influences the patient’s perceptions and mood as well as the content and form of what he communicates concerning his illness, how, to whom, and when. It affects his decision to seek or delay medical consultation, his degree of compliance with medical advice and management, as well as his relationship with his family, employers, health professionals and other concerned people.

These interactions significantly influence an individual’s ability to contend with illness. Engel has discussed the day-to-day impact of these interacting factors on clinical care in both theoretical (1977) and practical (1980) terms. A classic case report of the clinical application of the biopsychosocial model demonstrated how treatment of a middle-aged man suffering an acute myocardial infarction was compromised by inattention to his characterologic structure and style of interpersonal relationships (Engel, 1971). Heightened anxiety, which precipitated neurogenic responses that augmented a potentially fatal arrhythmia, may have been averted had the patient’s caretakers been familiar with his illness dynamics—specifically, his need to be obsessively informed about medical procedures in order to satisfy a fundamental need for control.

In sum, *illness dynamics derive from the interplay between the components of one’s biological, psychological, and social existence, transforming an episode of ill health into a highly subjective experience. By shaping its meaning in this fashion, these interacting factors can convert the same disease into very different illness experiences in two individuals who require the identical diagnostic assessment, acute treatment, and ongoing care.* Illness dynamics span an enormous and complex range—given the breadth of psychosocial factors influencing and being influenced by a specific organic pathology—causing patients to define their particular ailments in highly idiosyncratic terms. If this results in an abnormal illness response, the clinician must then decide if supportive or introspective psychotherapy is indicated for its treatment.

DETERMINING THE INITIAL THERAPEUTIC APPROACH

The decision of whether patients suffering from an abnormal illness response require introspective (anxiety-provoking) investigation of their emotions, or are more in need of supportive (anxiety-suppressing) treatment—and whether either approach should be supplemented by pharmacotherapy—is founded on the systematic assessment of objective clinical findings. The most fundamental component is an

Box 10.1 ILLNESS DYNAMICS

Biological

- Nature, severity, and time course of disease
 - Affected organ system, body part, or body function
 - Baseline physiologic functioning and physical resilience

Psychological

- Maturity of ego functioning and object relationships
 - Personality type
 - Stage in the life cycle
 - Interpersonal aspects of the therapeutic relationship (e.g., counter transference of health care providers)
 - Past psychiatric history
 - Effect of medical history on attitudes toward treatment (e.g., history of postoperative complications)

Social

- Dynamics of family relationships
 - Family attitudes toward illness
 - Level of interpersonal functioning (e.g., educational and occupational achievements; ability to form and maintain friendships)
 - Cultural attitudes

accurate DSM multi-axial psychiatric diagnosis, particularly as it applies to major mental illness. Psychosis, for example, demands intensive support in the form of highly structured psychosocial and pharmacological interventions. This applies whether the cause is physical (e.g., due thyroid dysfunction) or secondary to acute regression in an individual with a chronic mental illness (e.g., schizophrenia).

When patients do not exhibit evidence of major Axis I pathology, their general level of *ego functioning* and maturity of *object relationships* are the most useful criteria for determining the appropriate type of medical psychotherapy. More specific parameters are the selection criteria for brief psychotherapy proposed by Sifneos (1972), such as the level of sexual development and adjustment, intellectual skills, educational and occupational achievements, and the degree of autonomy and ability to assume responsibility. These criteria broadly assess psychological strengths and weaknesses and measure a person's ability to pursue self-selected goals while simultaneously contending with exceptional stresses of life, such as ill health.

Vaillant (1977) provides a more detailed evaluation of *ego functioning* in his excellent study of basic adaptational styles as determined by *prevailing ego defense mechanisms*. Anxiety-provoking work is definitely contraindicated in an individual who relies heavily on psychotic defense mechanisms (e.g., denial, delusional projection, and distortion). A middle-aged diabetic woman who responds to the recent amputation of her lower leg by acting as if the limb were still intact is ill-suited for introspective work. That individual requires considerable ego support, provided in the form of psychopharmacologic treatment and consistent reality testing. Although immature mechanisms (e.g., schizoid withdrawal, projection, passive-dependent and passive-aggressive behavior, acting-out, and hypochondriasis) may not cause such severe regression, they typify a personality structure that is generally unresponsive to an anxiety-provoking approach because of limitations on the patient's capacity to modulate mood and control impulses. Conversely, the presence of neurotic mechanisms (e.g., intellectualization, repression, displacement, reaction formation, and dissociation) and the more sophisticated mechanisms (e.g., suppression, humor, anticipation, altruism, and sublimation) reflect flexibility and resilience of ego functioning sufficient to tolerate the heightened anxiety of intensive emotional self-scrutiny.

The quality of an individual's *object relationships* provides a general measure of interpersonal functioning, another important barometer of one's ability to tolerate anxiety. This information helps define the patient's motivation and ability to be involved in a productive and gratifying manner with others, important data when assessing capacity for the emotional intensity and mutuality of a therapeutic relationship. The pattern of interaction with family members, friends, and professional colleagues may yield a picture of marked passivity, characterized by a patient's dependency on most of the people in that individual's life. Other maladaptive modes of relating, such as fight-flight behavior or a series of short-lived superficial encounters involving fluctuating idealization and unreasonable denigration of partners, may reflect the extreme anxiety emanating from unresolved issues of separation and

individuation. These patterns of object relationships suggest the necessity of a supportive psychotherapeutic approach, one which would be supplemented by pharmacotherapy in more extreme instances such as the inability to differentiate self from nonself. Conversely, patients' object relationships may reveal important criteria for introspective therapy, such as the importance they ascribe to independent functioning, their ability to abdicate autonomy when they recognize the need to rely on the support of others, and a history of at least one meaningful relationship reflecting basic trust and a shared emotional involvement.

Determining the appropriateness of anxiety-suppressing or anxiety-provoking psychotherapy is also influenced by the *patient's willingness for self-scrutiny and desire for emotional change*. These are predicated on a requisite degree of intelligence and psychological-mindedness, often evidenced in people's insights into their reactions to their own illness. *Attention to the therapeutic relationship* can supply other indicators for introspective work, including the patient's realistic expectations concerning the expertise of the therapist and the anticipated goals of treatment, the patient's ability to be affectively and cognitively involved in psychotherapy, and the patient's ability to relate consistently to the therapist throughout encouraging and disheartening phases of both the medical illness and the psychiatric treatment. An individual's responsiveness to trial interpretations provides data concerning each of these indicators for introspective work. Malan (1976), Sifneos (1972), and Davanloo (1980) discuss the diagnostic value of these interventions, and Viederman (1984) describes how communicating to patients an empathic and accurate understanding of their plight enhances a sense of trust that facilitates the psychotherapy.

All factors noted in this section help establish what Karasu and Skodol (1980) call a "psychotherapy diagnosis," a judgment concerning "the psychotherapeutic approach by which the patient is likely to derive maximal benefit" not exclusively determined by diagnostic criteria.

ANXIETY-SUPPRESSING PSYCHOTHERAPY

Ever since Freud (1919) praised the "gold" of psychoanalytic interpretations, supportive psychotherapy has erroneously been considered an "inferior" form of treatment as compared to insight-oriented work. This negative, and unfair, reputation derives from a variety of factors, ranging from the long-standing belief that characterologic change is the primary goal of psychotherapy to the frustration of practitioners who struggle to successfully implement this treatment modality (Wallace, 1983). The relative inattention afforded anxiety-suppressing psychotherapy over the years reflects this bias and may explain why it remains a somewhat nebulous form of treatment. Divergent conceptualizations confuse basic therapeutic issues, such as the distinction between supportive therapy and supportive relationships; and consequently, anxiety-suppressing therapy has frequently been explicated via "negative definitions" that declare *what it is not* (Buckley, 1986).

Winston, Pinsker, and McCullough's (1986) review of the literature significantly clarified the fundamental goals and techniques of this treatment modality, which highlighted its relevance to medical psychotherapy. *Anxiety-suppressing psychotherapy requires the clinician to be active and supportive in ways that contain the patient's anxiety within limits that were acceptable premorbidly and allowed the patient to function.* The overall treatment is focused on symptomatic relief as opposed to structural intrapsychic change, an approach based on concrete, sometimes controlling, therapeutic directives. The major goal of treatment is to dissipate the powerful emotions that negatively affect the patient's psychological well-being. The patient is not guided toward discovery of unconscious motivations and conflicts that may have crystallized into an abnormal illness response. Rather, therapists offer consistent encouragement and support intended to maximize their influence by exploiting a working alliance solidified by trust and cooperation (Werman, 1984). The clinician attempts to curtail emotional dysfunction precipitated by illness by altering factors external to the individual, such as effecting changes in living arrangements or prescribing psychoactive medication. The therapeutic maneuvers most often used to achieve this end are *abreaction*, *suggestion*, and *manipulation*, as classically described by Bibring (1954).

Abreaction involves catharsis of intense, often unconscious, emotions. Acknowledging and expressing these warded-off feelings brings at least a temporary sense of relief to individuals who, for example, previously resorted to unhealthy behaviors (e.g., social isolation) in order to avoid the impact of unrecognized yet intense affects. Absent the opportunity for such expression these feelings can build up and eventually overwhelm an individual (e.g., with uncontrollable anxiety or morbid depression), akin to a flooded stream overflowing its banks. *Suggestion*, according to Bibring, involves "the induction of ideas, impulses, emotions, actions . . . by the therapist (an individual in authoritative position) in the patient (an individual in dependent position) independent of, or to the exclusion of, the latter's rational or critical (realistic) thinking." He is describing a process of change effected by direct inculcation of beliefs, attitudes, or behavior; for a patient in the throes of an abnormal illness response, this might include insisting on better communication with family members or urging participation in a rehabilitation regimen. *Manipulation* is defined as the therapist's use of words or attitudes to "neutralize certain emotional systems in the patient, mobilize others and utilize them for technical purposes or curative aims." For example, a therapist may attempt to mute the hypochondriasis exacerbating a patient's dependency response by mobilizing healthier obsessional behaviors, such as keeping him apprised of laboratory data that indicate clinical gains.

Because anxiety-suppressing psychotherapy rests on the clinician's ability to influence and guide the patient, *eliciting and maintaining a positive transference* are primary goals of treatment. Careful attention to unconscious issues embodied in an individual's psychodynamics and illness dynamics identifies doctor-patient interactions that may be used by the therapist whose inherent power (Frank, 1961) can be enhanced

in a manner that parallels Alexander's studied manipulation of the transference (1946). Techniques used to foster the positive transference, summarized by Winston, Pinsker, and McCullough (1986), emanate from clinicians' basic posture of presenting themselves as real, objective, and analytic. They offer advice and reassurance (e.g., opinions concerning the patient's response to a given therapeutic regimen), as well as praise when warranted (e.g., when individuals engage in meaningful discussions about their illness with family members or progress in a rehabilitative program). Therapists provide "an auxiliary ego" to their patients, which may take the form of educating them to the facts of their illness, identifying and justifying their affective and behavioral responses to the sick role, explaining changes in interactions with friends and family members, and problem-solving life issues caused by ill health. Therapists communicate all this in a style more personally conversational than clinical, which at times might reveal some of their own feelings and values. The negative transference is addressed only when it directly interferes with treatment, and is interpreted in a circumscribed manner so as to overcome the patient's resistance without mobilizing intense affects that could be potentially disorganizing.

Supporting and enhancing a patient's defensive structure is another major goal of anxiety-suppressing psychotherapy. The therapist must identify and maintain those mechanisms that provide the basis of an individual's ego functioning. This knowledge is useful in helping to reinforce the patient's reality testing, particularly if the patient is observed to utilize projection and distortion. It also highlights important defenses that should not be challenged by the clinician. For example, primitive ego defense mechanisms can be adaptive under some circumstances, such as the denial following a myocardial infarction (Hackett & Cassem, 1974), and prevent a patient from becoming overwhelmed by emotional distress and/or acting out in a self-destructive fashion. In addition to preserving a patient's fundamental defenses, the therapist should attempt to discover and mobilize healthier ego functioning. For example, the reality testing of an individual with diabetes mellitus preoccupied with "slipping into coma," despite excellent control of the illness, might be enhanced by working with the patient's obsessional defenses (e.g., regular, detailed discussion of insulin needs and blood sugars).

Attending to an individual's diminished self-esteem is the third goal of supportive psychotherapy. When stressed by life events that limit the ability to cope with a variety of intensely painful affects, patients often become demoralized and begin to doubt their self-worth. The medical patient needs protection from the isolation attending the sick role and, consequently, benefits significantly from interventions that bolster self-esteem. The therapist's active interest and attention, which communicates concern and respect, can offset feelings of helplessness and hopelessness. Specifically, the clinician is reassuring (e.g., *validating the normalcy of a patient's feeling state*), and offers advice, (e.g., *recommending actions that have helped others plagued by the same illness*). The interventions provide support and educate patients as to the legitimacy of their emotional distress.

Two related aspects of supportive psychotherapy that are particularly relevant to treatment of abnormal illness responses are attention to a specific focus and a defined structure of the therapeutic environment. The “*benign neglect*” afforded unconscious material (e.g., fantasies, dreams, and transference distortions) helps to contain the patient’s level of anxiety, which permits him or her to concentrate psychic energies on the “here-and-now.” Treatment of individuals in the throes of severe anxiety responses, for example, would address worries concerning the potentially debilitating effects of their illness and not explore possible dynamic roots of their considerable separation anxiety. This focus is mirrored in the structure of the therapeutic interaction, which is predominantly characterized by an active *give-and-take* between the two participants, as opposed to the open-ended communication of introspective work and its characteristic intervals of silence. This helps the patient concentrate fully on concrete treatment goals.

ANXIETY-PROVOKING PSYCHOTHERAPY

Insight-oriented psychotherapy seeks to *promote psychological maturation by therapeutically exploiting the turmoil of an emotional upheaval*. The fundamental task is to help patients acknowledge, bear, and *put into proper perspective painful feelings that adversely affect their lives* (Semrad, 1969). This conceptualization of the treatment highlights its relationship to the grief process. The patient is first made aware of previously unrecognized emotions that have been kept out of consciousness by various defensive maneuvers. Patients then experience those affects within the therapeutic environment, as well as in the context of important relationships. Finally, *by recognizing the intensity, diversity, and ambivalence of these feelings, patients come to achieve some resolution of the conflicts such feelings arouse*.

Several disciples of the analytic school have tailored the anxiety-provoking model into a variety of brief psychotherapies well suited for the treatment of an abnormal illness response (Alexander & French, 1946; Davanloo, 1980; Malan, 1976; Mann, 1973; and Sifneos, 1972). Despite conceptual and technical differences, all these approaches share several characteristics: (1) *persistent pursuit of unconscious material (instinctual drives, as well as ego defenses)*; (2) *active, confronting interventions by the therapist*; and (3) *attention to a central focus that helps limit the degree of clinical regression*. The goal of such treatment is *working through*, a therapeutic process that guides the patient toward insight and self-understanding so as to effect significant and lasting behavioral change (Greenson, 1967). Except for time limitations—and the fact that the focus of treatment is circumscribed (e.g., to the emotional reaction to physical illness)—the process of these therapies is identical to long-term insight-oriented psychodynamic work.

Anxiety-provoking therapy is studied attention to the interrelationship between two general areas of individuals’ lives: first, *their libidinal impulses, the anxiety they provoke, and the defenses utilized to contain them*; and second,

lifelong patterns of object relationships that characterize each person’s historical past, current existence, and the transference relationship. Elucidating the dynamic interaction between these two triads provides patients with meaningful insights that help liberate them from long-standing repetitive maladaptive patterns. Although introspective therapy continually challenges defenses that contain unacknowledged affects, it periodically employs supportive techniques when the level of therapeutic tension threatens the treatment. *Consequently, all the technical maneuvers discussed by Bibring (1954) come into play, though clarification and interpretation are most often used*.

Clarification is a technique in which the therapist restates the patient’s observations in a manner that helps define those issues more clearly. In Bibring’s words, it refers to aspects of the therapeutic process “. . . which assist the patient to reach a higher degree of self-awareness, clarity and differentiation of self-observation . . .” As an example he describes how a patient’s feelings are clarified when the therapist “shows him that what he describes as fatigue. . . is actually an expression of depression” or that certain patterns of conduct reflect typical responses to distinctive situations. *Interpretation*, on the other hand, attempts to bring to awareness one’s unrecognized thoughts and emotions. This usually requires prior therapeutic maneuvers, such as manipulation or clarification, in preparation for an appropriately timed interpretative observation that “makes conscious the unconscious meaning, source, history, mode or course of a given psychic event” (Greenson, 1967). That is, interpretations provide insight that helps patients understand unconscious forces that motivate a specific behavior, and thereby afford them an opportunity to modify it.

THE ART OF MEDICAL PSYCHOTHERAPY

As noted, medical psychotherapy generally conforms to an anxiety-suppressing or anxiety-provoking approach. However, focusing only on the theoretical underpinnings and techniques of these two treatments neglects some realities of the clinical environment. The actual implementation of supportive and introspective interventions, within the context of a comprehensive treatment plan, requires *flexibility and pragmatism* on the part of the clinician. The task, which is fundamentally guided by constant attention to the patient’s illness dynamics, may be facilitated by the following guidelines.

First, although a specific type of medical psychotherapy is *predominant* in the treatment of an abnormal illness response, *a specific therapy rarely occurs in an isolated form* because of the ever-present interrelationship between anxiety-suppressing and anxiety-provoking techniques. Psychoanalysis, for example, places a premium on therapeutic neutrality and abstinence. However, even Freud acknowledged the importance of supportive maneuvers, most notably as they pertain to maintaining the working therapeutic alliance (Freud, 1913; Greenson, 1967). Alternatively, Winston, Pinsker, and McCullough (1986) discuss “a continuum of supportive therapies” that incorporate expressive (anxiety-provoking) work

to a degree determined by the patient's level of ego strength. Pine (1986) emphasizes this point, describing techniques for achieving "interpretive content" in the context of supportive therapy. He outlined specific maneuvers that enable individuals "generally characterized by a fragility of defense" to tolerate this anxiety-provoking intervention. These observations do not blur the distinction between the supportive and introspective approaches as much as they indicate a positive interaction between aspects of each approach, such as the need to interpret negative transference feelings that arise during anxiety-suppressing therapy. In Pine's words, "supportive and insight therapies are not *counterposed*, in some *opposition* to one another, but are *counterpoised*, in some *balance* with one another." The degree to which this occurs in the treatment of an individual's abnormal illness response is guided by the particulars of the patient's illness dynamics.

Second, supportive and introspective treatment have been discussed within the context of a single episode of ill health. However, most illness is chronic, and its elongated time course has implications for the practice of medical psychotherapy, both for the patient and clinician. *The onset of a long-term illness may so overwhelm individuals that they initially can only tolerate an anxiety-suppressing approach; however, this does not suggest that patients will require support throughout the entire clinical course.* Slaby and Glicksman (1985) observe that coping mechanisms appropriate to one stage of life-threatening illness are not necessarily appropriate at later stages. While some patients repeatedly require anxiety-suppressing work during the prolonged course of a disease, others might regress with that approach, since supportive treatment can help reestablish one's emotional equilibrium in a way that eventually fosters a sense of mastery. In this way it can protect against the recurrence of an abnormal illness response during subsequent bouts of ill health, as well as generally enhance adaptive ego function via a positive ripple effect. In this sense, supportive care can parallel the work of crisis intervention as described by Caplan (1964), which promotes the acquisition of new coping mechanisms, increases self-esteem, and diminishes fear about the recurrence of a particular stressor. That same adaptation can derive from a patient's assessment of illness over time, and can replace feared fantasies with the reality of symptomatic relief, loving support from family and friends, and a level of functioning that affords some sense of control over the illness. Such responses can minimize the emotional turmoil accompanying future progression of disease and may even facilitate subsequent anxiety-provoking work designed to help grieve a further decline in health.

Third, consultation-liaison psychiatrists are concerned with the *diagnosis and treatment of psychiatric disorders in the medically ill*. As a result, the practitioner must constantly deal with the interaction between psychic and physical events, which may be overt (e.g., delirium) or subtle (e.g., a "masked" depression). These problems are mind-body in origin, and their treatment frequently utilizes biological interventions in conjunction with psychotherapy. The use of psychoactive medications is often an integral aspect of medical psychotherapy, supplying structure and support the patient lacks because of the physical and/or psychological impact of illness.

Pharmacotherapy provides acute relief of symptoms and, with certain individuals, facilitates continued remission via treatment with maintenance medication. When the treatment goals of an abnormal illness response are concerned with interpersonal relationships, family issues, or occupational and social adjustment, then treatment predominantly shifts to *psychotherapy focused on resolving traumatic and painful emotions associated with the loss of health*.

The interactive effects of psychotherapeutic and biological treatments have been intensively studied. Klerman (1975) demonstrated that the patient's level of affective distress influences their accessibility and response to psychosocial interventions, a powerful argument for the use of medications to facilitate and/or optimize psychotherapy. *Subsequent investigation disproved long-standing hypotheses concerning negative interactions between medications and psychotherapy* (Rounsaville, Klerman, & Weissman, 1981), and further suggested the benefits of combining these therapeutic approaches (Luborsky, Singer, & Luborsky, 1976; Muskin, 1990). As a result, practitioners more readily accept that psychosocial and biological therapeutic interventions are complementary, and that in major mental disorders combined therapy is almost always superior to the exclusive use of one or another treatment as a single modality (Cohen-Cole & Stoudemire, 1987).

The combined approach has been conceptualized as a means of tailoring treatment to the particular state and trait issues affecting an individual (Extein & Bowers, 1979). Van Praag (1979) describes the combination of "tablets and talking"—the former directed toward neurochemically mediated issues (e.g., vegetative symptoms of depression; mania), the latter targeting psychosocial issues (e.g., intrapsychic and interpersonal events). When personality traits form the basis of an individual's pathologic illness response, then medical psychotherapy alone, either as supportive or introspective work, is the indicated treatment. However, pronounced disease-related symptoms often dominate a patient's illness response. For example, up to 20% of general medical inpatients have an anxiety disorder (Strain, Leibowitz, & Klein, 1981); panic disorder is present up to seven times more often in patients in medical settings than in the general population (Rosenbaum & Pollack, 1989); and depression is present in up to 30% of medical inpatients (Rodin & Voshart, 1986). When a patient's symptoms are severe, practitioners must rely on somatic therapies to alleviate affective turmoil as well as to strengthen the therapeutic alliance (Klerman, 1976), as severe agitation or psychomotor retardation can impede collaborative work between patients and caretakers and thereby undermine the effectiveness of psychotherapy.

Some general points concerning combined therapy should be noted. *First, practitioners must be particularly wary of the side effects of psychoactive medications.* Some, which are little more than an annoyance in fundamentally healthy patients, can seriously complicate treatment of the medically ill and sometimes be life-threatening. Also, because many patients who require medical psychotherapy are already taking a variety of other medications, clinicians must be particularly *mindful of drug interactions* when prescribing psychoactive substances (Brown & Stoudemire, 1998). Finally, a particular

medication within a general class of psychoactive medications may be indicated for specific medical conditions; for example, because the 2-keto-benzodiazepines (e.g., diazepam,) are metabolized via oxidation in the liver, their clinical effects are subject to the status of hepatic enzymes that may be affected by liver disease or concurrent medications.

Relief from state-related symptoms permits subsequent psychotherapy, which may be predominantly anxiety-provoking or anxiety-suppressing. There are several schools of brief psychotherapy within each of these broad categories, and consequently there is debate as to the therapeutic efficacy of each particular approach. Burke, White, and Havens (1979), for example, argue for the utility of matching a particular patient with a specific form of brief therapy based on the individual's psychosexual development. Utilizing an Ericksonian framework Erickson (1963), they suggest that Mann's (1973) time-limited, existential technique, which focuses on mastery of separation, is most effective for passive-dependent individuals who have not resolved the adolescent conflict of "identity versus role confusion." In contrast, patients with an Oedipal orientation struggling with issues of "intimacy versus isolation" are better served by the more confronting analytic approach of Malan (1976) or Sifneos (1972) that seeks to promote insight. Ursano and Hales (1986), on the other hand, believe that the spectrum of psychotherapies substantially overlap in selection criteria, technique, duration, and goals of treatment, and differ more in types of interventions. This lends support to Benner's (1984) caution that the clinician refrain from seeking "perfectionism" in trying to fit a patient with a particular form of brief psychotherapy. Ursano and Hales (1986) also underscore how the distinction between brief psychodynamic psychotherapy, interpersonal psychotherapy, and cognitive techniques has more to do with perspective and emphasis of specific aspects of treatment than with fundamental differences in the treatment approach. For example, much of the cognitive therapist's work helping an individual identify faulty perceptions that evolve into maladaptive defenses is quite similar to the clarification and interpretation of defenses in brief psychodynamic psychotherapy.

Fourth, although anxiety-suppressing and anxiety-provoking therapy are founded on a psychodynamic understanding of the patient, each of these treatment modalities has distinctive cognitive and behavioral attributes. For example, clarification and interpretation of defenses and unconscious material remains the foundation of insight-oriented work; however, behavioral interventions (e.g., limit-setting maneuvers) complement the exploratory process. And supportive work can occur within a clinical framework completely apart from psychodynamic psychotherapy. Moos and Schaefer (1984), for example, utilize a cognitive approach based on crisis theory when treating patients unable to cope with the impact of physical illness. They outline two sets of treatment goals for these individuals—illness-related tasks (e.g., dealing with pain and incapacitation, dealing with the hospital environment, and developing adequate relationships with healthcare staff) and general tasks (e.g., preserving a reasonable emotional balance, preserving a satisfactory self-image and maintaining a sense of competence

and mastery, sustaining relationships with family and friends, and preparing for an uncertain future)—and describes the major types of coping skills employed to deal with these various tasks. The treatment includes fundamental interventions of supportive therapy such as education, reassurance, and abreaction, which are effected via cognitive problem-solving techniques. Anxiety-suppressing therapy can also take the form of behavioral interventions, such as relaxation protocols and desensitization (e.g., to treat excessive anxiety) or positive and negative reinforcement (e.g., to deal with excessive regression).

Fifth, although supportive and insight-oriented therapy have been discussed in terms of individual treatment, medical psychotherapy is effected in a variety of clinical formats. An individual's abnormal illness response can be treated in the context of family therapy, couples work, or group psychotherapy. Each approach may be anxiety-suppressing or anxiety-provoking depending on the prevailing illness dynamics. When the psychological well-being of a family is adversely affected by the illness of one of its members (Borden, 1962; Binger, Alblin, Feuerstein, et al., 1969; Livsey, 1972), supportive work can facilitate the family's accommodation to the illness and may actually be part of the individual's treatment (Rosman, Minuchin, & Leibman, 1975). Couples work is indicated when an individual's abnormal illness response causes increasing distance in the relationship and threatens its viability. The psychological health of each member, their dynamic interaction, and the particular losses incurred by the patient's ill health (e.g., decreased sexual function) determine if a supportive or introspective intervention is indicated. The same decision making applies to group therapy. Several attributes of the group process (e.g., diffusion of the transference and greater interpersonal contact) bolster impaired ego functioning and, consequently, favor group therapy as a supportive form of medical psychotherapy. Group therapy patients benefit from information sharing (Bilodeau & Hackett, 1971) and a generalized acceptance of emotional expression (Adsett & Bruhn, 1968; Stein, 1971), as well as the mutual support derived from discussing common medical experiences such as amputation, myocardial infarction, and the impact of a mastectomy or colostomy (Slaby & Glicksman, 1985). As for insight-oriented groups, they have traditionally been used in the treatment of the so-called *classic psychosomatic illnesses* (Stein, 1971) and have been effective in helping patients adjust to terminal illness (Yalom & Greaves, 1977; Spiegel, 1979).

Moos and Schaefer (1984) points out that "a patient may deny or minimize the seriousness of a crisis while talking to a family member, seek relevant information about prognosis from a physician, [and] request reassurance and emotional support from a friend." Because one's illness response can take on such a complexity, varied therapeutic modalities are often used in combination to effect a medical psychotherapy that targets the patient's distinctive needs.

Sixth, mention should be made of the implications for the clinician when a patient's long-term illness necessitates ongoing medical psychotherapy, *particularly when the patient fails to adapt to the loss of health.* That circumstance

can readily promote a negative countertransference, which is often related to patients' character pathology (Groves, 1978; Kahana & Bibring, 1964; Lipsitt, 1970) or to specific clinical issues, such as hypochondriasis (Adler, 1981; Brown & Vaillant, 1981). In these instances health providers may become increasingly frustrated and resentful, as they respond to patients' overt and covert negativism by experiencing a corresponding helplessness and hopelessness of their own. When this type of countertransference remains unrecognized, clinicians are more likely to act out their anger as opposed to using it constructively. Sternbach (1974) describes how this destructive cycle sadly produces a multitude of patients derogatorily labeled "crocks," and how antagonism toward them promotes a progressive dissolution of the therapeutic alliance.

SUMMARY

All medical illness produces emotional responses that form an integral part of the disease process. Although many patients successfully accommodate to their particular impairment, others suffer abnormal illness responses because they cannot negotiate the affective turmoil precipitated by ill health. Medical personnel who ignore these psychological reactions provide suboptimal, if not detrimental, treatment. Effective medical care is founded on *understanding what a particular disease means to a particular patient at a particular time in life*. This requires a full understanding of illness dynamics. The patient's illness dynamics define a distinctive biopsychosocial environment that guides clinicians to the specific psychological needs to be addressed during the course of treatment. If this approach fails to abort an abnormal illness response, intensive focused attention via medical psychotherapy should be offered to the patient. *The form of the treatment* is also based on patients' illness dynamics, which measure their ability to tolerate anxiety by providing information concerning the maturity of their ego functioning and object relationships. The psychotherapeutic approach may be supplemented with pharmacotherapy when the patient's affective distress is extreme. This comprehensive biopsychosocial approach is the only acceptable medical model if "one is to treat the whole patient and not merely characterize the nature of an illness and impede biological deterioration" (Slaby & Glicksman, 1985). *The biopsychosocial approach to patient assessment and treatment is the cornerstone philosophy of this entire textbook.*

CLINICAL PEARLS

- When patients do not exhibit evidence of major Axis I pathology, their general level of *ego functioning* and maturity of *object relationships* are the most useful criteria for determining the appropriate type of medical psychotherapy.
- The presence of neurotic ego mechanisms (e.g., intellectualization, repression, displacement, reaction formation, and dissociation) and the more sophisticated ego mechanisms (e.g., suppression, humor, anticipation, altruism, and sublimation) reflect flexibility and resilience of ego functioning sufficient to tolerate the heightened anxiety of intensive emotional self-scrutiny.
- The quality of an individual's *object relationships* provides a general measure of interpersonal functioning, another important barometer of one's ability to tolerate anxiety.
- Viederman (1984) describes how communicating to patients an empathic and accurate understanding of their plight enhances a sense of trust that facilitates the psychotherapy.
- The major goal of supportive treatment is to dissipate the powerful emotions that negatively affect the patient's psychological well-being. The patient is not guided toward discovery of unconscious motivations and conflicts that may have crystallized into an abnormal illness response.
- *Abreaction* involves catharsis of intense, often unconscious, emotions. Acknowledging and expressing these ward-off feelings brings at least a temporary sense of relief to individuals who, for example, previously resorted to unhealthy behaviors (e.g., social isolation) in order to avoid the impact of unrecognized, yet intense, affects.
- Therapists provide "an auxiliary ego" to their patients, which may take the form of educating them to the facts of their illness, identifying and justifying their affective and behavioral responses to the sick role, explaining changes in interactions with friends and family members, and problem-solving life issues caused by ill health.
- The negative transference is addressed only when it directly interferes with treatment, and is interpreted in a circumscribed manner so as to overcome the patient's resistance without mobilizing intense affects that potentially could be disorganizing. In insight-oriented psychotherapy, by recognizing the intensity, diversity, and ambivalence of these feelings, patients come to achieve some resolution of the conflicts such feelings arouse.
- The actual implementation of supportive and introspective interventions, within the context of a comprehensive treatment plan, requires flexibility and pragmatism on the part of the clinician.
- Much of the cognitive therapist's work, helping an individual identify faulty perceptions that evolve into maladaptive defenses, is similar to the clarification and interpretation of defenses in brief psychodynamic psychotherapy.

FAMILY THERAPY IN CHRONIC MEDICAL ILLNESS

Gabor I. Keitner

Advances in healthcare technology, more medical treatment options, and more choices for improved lifestyle have contributed to longevity and more patients living with chronic illness and disability. The extended period of time spent with disability or chronic illness has profound effects on the lives of loved ones caring for and living with such patients (Schulz & Beach, 1999). The ways in which a patient's family of caregivers, in turn, deal with illness has a significant impact on the course and outcome of that illness. It is important to understand this reciprocal relationship between illness and family coping in order to assess the patient and social situation and to provide appropriate family interventions.

The goals of this chapter are to provide an overview of the impact of illness on families, to provide evidence for the benefit of family intervention for medically ill patients and families, to describe a model of family assessment that can guide relevant treatment options, and to present a family intervention approach that is applicable in a wide range of clinical circumstances.

THE IMPACT OF ILLNESS ON THE FAMILY

Numerous studies have evaluated the impact of a wide range of illnesses on families and caregivers. These include cardiovascular disease (Coyne et al., 2001; Gallo et al., 2003; Rohrbaugh, Shoham, & Coyne, 2006), diabetes (Fisher, Chesla, Skaff, Mullen, & Kanter, 2002) cancer (Cliff & MacDonagh, 2000; Manne, Norton, Winkel, Ostroff, & Fox, 2007; Northouse, Mood, Templin, Mellon, & George, 2000; Rolland, 2003; KL Weihs, Enright, T., & Simmens, 2008), gastrointestinal disorders (Baanders & Heijmans, 2007), fibromyalgia (Bigatti & Cronan, 2002), neurological disorders (De Ridder, Schreurs, & Bensing, 1998; Helder et al., 2002), rheumatoid arthritis (Riemama, Taal, & Rasker, 1999), chronic pain (Margolis, Merkel, Tait, & Richardson, 1991), hemodialysis (Kimmel et al., 2000), and dementia (Vitaliano et al., 2001).

Instead of detailing the unique problems associated with each of such a wide range of disorders, it is more useful to find common factors that most families experience while dealing with illness. Understanding the nature of such general stresses should allow for thinking of commonalities in family treatment approaches.

Research on families and health has led to the following general conclusions: (1) family relationships have a powerful influence on health, as great as that of well-known biomedical risk factors; (2) marriage is the family relationship with the greatest impact on health for adults; (3) the most important type of support provided by families is emotional support; and (4) the adverse effects on health of critical or hostile family relationships are of greater magnitude than the beneficial effects of positive or supportive relationships (Campbell, 2003).

Families influence health by a variety of different pathways. In addition to sharing genes that are risk factors for diseases or influences on the effectiveness of treatment, families that live together share exposure to infectious agents, noxious environments, or toxic substances. Behavioral patterns relevant to health such as smoking, eating habits, exercise, and adherence to prescribed medical treatments tend to be shared within families. Finally, family relationships also can affect physical health via neuroendocrine and psychoimmunologic mechanisms (Campbell, 2003).

There are a wide variety of responses by family members to chronic illness in their loved ones, ranging from functional adaptation to significant dysfunction. More than one-half of families caring for the chronically ill manage the burden effectively (Rabins, Fitting, Eastham, & Fetting, 1990). Such families are able to adapt to changing circumstances and are able to balance the needs of individuals and the family system so as to ensure the family's well being. A family's response to the illness of a member depends more on that family's functioning than on the nature of the illness. In general, the perceived impact of the illness on significant others is not dependent on the type of chronic disease (Baanders & Heijmans, 2007). More important is the adequacy of the fit between the psychosocial demands of the illness, the family's coping style, and the availability of adequate resources.

A biopsychosocial perspective of the family's situation ensures that the biological, psychological, and social components impacting the family are sufficiently evaluated. Biological parameters include the nature of the illness, physical limitations, and current pharmacological treatments. Psychological parameters include the meaning of the illness and its specific symptoms to the patient and to the family, habitual ways of coping with difficulties, personality styles, frustration tolerance and impulse control, intellectual functioning, insight, and spirituality. Social parameters include

interpersonal and family relationships, social connections and support systems, work functioning, and other situational stresses. Such a comprehensive evaluation leads to a biopsychosocial formulation that is shared with the patient and family as a foundation for developing an appropriate treatment plan.

A basic task for families dealing with chronic disorders is to create ways of understanding the illness that allows the family to retain a sense of competence and mastery (Rolland, 2003). Rolland (2003) has described a family systems health model for the assessment of and intervention with families facing chronic and life-threatening disorders. This model identifies three dimensions: psychosocial types of disorders, major phases in the natural history of the illness, and key family system variables.

Psychosocial types of illness refer to the demands on the family made by the varying nature of disorders. Some illnesses have an acute or gradual onset. Illnesses can be progressive, constant, or relapsing -remitting. Outcomes can be hopeful or terminal. Different phases of illness (crisis, chronic, terminal) also impose their own demands on the family requiring different adaptations. Key family variables that impact on the family's capacity to cope effectively include the family and individual life cycle, multigenerational legacies related to illness and loss, and belief systems.

A family is best understood and helped by utilizing such a broad conceptual framework, which takes into consideration the demands of the illness and the coping capacities of the family.

A number of family characteristics have been demonstrated by multiple studies to influence illness outcomes. Protective factors include good communication, adaptability, clear roles, achieving family development tasks, support for individual members, expression of appreciation, commitment to the family, social connectedness, spending time together, and religious/spiritual orientation (Weihs et al., 2002). Conversely, many risk factors for detrimental illness outcome have also been identified. These include low cohesion/closeness, poor family organization, inconsistent structure, poor conflict resolution, lack of agreement about disease beliefs and expectations, low relationship satisfaction, high conflict, high criticalness, poor problem solving, and high hostility (Fisher, 2006).

It is helpful to understand such protective and risk factors in order to develop and implement family treatment approaches that modify the risk factors and enhance those that are effective.

EVIDENCE FOR BENEFIT OF FAMILY INTERVENTIONS IN MEDICAL ILLNESS

A wide variety of family interventions have been developed and tested for many medical illnesses, including dementia, cardiovascular diseases, cancer, diabetes, arthritis, stroke, chronic pain, traumatic brain injury, systemic lupus erythematosus, and AIDS (Chesla et al., 2004). In spite of differences, most family approaches can be divided into two broad

categories: psycho-educational and relationship-focused. The goals of psycho-educational interventions are to increase knowledge about the illness and to teach patients and family members more effective ways of managing it. Skills training includes lifestyle modifications relating to diet and exercise, learning skills to monitor the illness such as blood pressure monitoring, and supporting adherence to prescribed medical treatment (DiMatteo, 2004). Relationship-focused interventions attempt to directly improve family functioning by helping families to communicate more effectively, solve problems, resolve conflicts, and develop a greater sense of cohesiveness. These interventions also include some degree of education about the illness and discussion of more effective illness-related coping skills.

Two meta-analyses of family/psychosocial interventions for adult patients with chronic illnesses have been published (Hartmann, Bazner, Wild, Eisler, & Herzog, 2010; Martire, Lustig, Schultz, & Miller, 2004). Martire et al. (2004) used meta-analysis to focus on the benefits of interventions that involved a family member, for patients and for family members. Patient outcomes examined included depressive symptoms, anxiety, relationship satisfaction, physical disability, and mortality. Family member outcomes included depressive symptoms, anxiety, relationship satisfaction, and caregiving burden. Family psychosocial interventions were defined as nonmedical interventions that were psychologically, socially, or behaviorally oriented and that involved a member of an adult patient's family or both the patient and the family member. All studies had to be randomized controlled trials and all had to include a comparison of the family intervention with a usual medical treatment. Of 235 studies identified, 70 met criteria for inclusion in this analysis. The majority of the family interventions consisted of a combination of different types of psychosocial and behavioral approaches. Most commonly these included education with emotional support or emotional support with skills training. Family members included spouses, children, or siblings. The most common illness groups studied were individuals suffering from dementia, cardiovascular disease, osteoarthritis, pulmonary disease, Parkinson's, and cancer.

Overall results showed the strongest evidence of efficacy for benefits to family members, with lesser evidence for an effect on the outcome of the patient's disease. Family interventions led to family members feeling less depressed and less burdened. The interventions also led to reduced anxiety in family members when the therapeutic focus was on relationship issues between the patient and the family member. Interestingly, the interventions did not appear to enhance the family member's satisfaction in his or her relationship with the patient. The family interventions led to a reduction in depressive symptoms in the patient only when the interventions focused on spouses or couples. Family interventions also enhanced patients' survival, particularly for patients with cardiovascular disease. This was more likely to happen when the interventions did not address relationship issues. There was no evidence that the family interventions reduced anxiety or disability in patients or that they increased their relationship satisfaction. Changes in patients were not dependent on

whether the patient was or was not included in the intervention. Family interventions were not associated with negative outcomes for either the patient or his/her family members (Martire et al., 2004).

Hartmann et al. (2010) also conducted a meta-analysis of randomized clinical trials evaluating the effects of family-based interventions for adult patients compared to standard treatment. Family interventions were categorized as being psycho-educational or those that addressed relationships and attempted to improve family functioning directly. The family was defined as any significant person with a close relationship to the patient. This meta-analysis focused on three outcomes: the physical health of the patient, including level of functional dependency, clinical symptoms, self-rated physical health status, and disease management; the mental health of the patient, including degree of depression, degree of anxiety, quality of life, general mental health, and self efficacy; and the health of family members, including caregiver burden, depression, anxiety, general mental health, and self efficacy in the family member. Sub-analyses were conducted to identify possible moderators such as types of disease, types of interventions, and types of family members involved in the treatment. Fifty-two randomized clinical trials involving over 8,000 patients (52% women) were chosen from over 4,000 potentially eligible studies. The diseases studied included cardiovascular diseases and stroke, cancer, arthritis, diabetes, AIDS, and systemic lupus erythematosus. All family interventions led to significantly better physical health of patients compared to standard treatment. Both psycho-educational and relationship-focused interventions showed a significant positive effect. The overall effect was greater when the family member involved in the treatment was a spouse rather than another type of significant other.

Family interventions also led to improved mental health of the patient compared to standard treatment. In this case it did not matter whether the involved family member was a spouse or another type of family member. Again, both psycho-educational and relationship-focused interventions showed similarly significant positive effects. Family members' health, such as caregiver burden, depression, anxiety, quality of life, and self-efficacy, were all improved by family interventions. In this case, relationship-focused interventions were more effective than those focused on psycho-education.

The results of this meta-analysis showed that family-oriented interventions in chronic illnesses were more effective for improving health outcomes and reducing mental health problems in both patient and caregivers than were commonly used treatments (Hartmann et al., 2010). Although the results were small, if statistically significant, effects, they corresponded to an OR of 1.7 to 1.84, meaning the patients receiving the family intervention had a 72%–84% greater chance of improved health compared to those receiving usual care. Family interventions also produced a more sustained improvement than standard care alone. There was also a tendency toward greater benefits from a longer course of family treatment, and a greater patient benefit when the family treatment focused on spouses as opposed to other family members.

These reviews show that many different types of family interventions are effective in helping to deal with a wide range of medical illnesses. They do not provide information on what specific interventions may be the most helpful for a given illness at a particular point in time, nor what are the mechanisms that lead to change. It is impractical to try to learn many different types of family therapies for different disorders, particularly when there is not any evidence to suggest such a need. It makes more clinical sense to become familiar with a family approach that lends itself to application in a wide variety of situations. The key to effective family treatments is a comprehensive evaluation of the family's needs and functioning, so that the intervention can be adjusted to meet those needs.

The first essential step in family therapy is an assessment of the family.

FAMILY ASSESSMENT

The essential task in meeting with families for the first time is to evaluate and assess their functioning in the context of understanding their problem. The family assessment is the first step in determining both the need for further interventions and the specific areas of family life that might need to be addressed. The family assessment provides more information about the problem as well as the social system. The family social system is the substrate for the evolution of the problem and may be contributing to improving or maintaining it. Family assessment should focus on (a) adjustments related to the diagnosis of the medical illness, (b) clarification of treatment options, and (c) collaboration in carrying out a treatment plan. The assessment should also identify family strengths.

There are many different ways to assess a family and many different kinds of information that can be gathered. Some assessments begin with a long history of the family's life, past connections, and evolution as a family unit. This can include information on families of origin and the construction of a family genogram. Other assessments focus mainly on process issues in the family during the assessment. The focus is on observations of current family interactional patterns, with the assumption that these are representative of the way in which the family deals with issues outside of the assessment session. All of these approaches have merit, and they are not mutually exclusive. The challenge for a clinician is to integrate various aspects of these different approaches in such a way as to meet the goals of the evaluation without becoming sidetracked by peripheral issues or too much detail, and taking so long to complete the evaluation that the family loses interest.

The most important step in meeting with a family for the first time is to establish connection with the family. The family needs to feel understood, respected and validated. The clinician needs to put the family members at ease and make them feel comfortable enough to participate openly in the assessment process. Family members should not be blamed for their loved one's problems and should not be judged for perceived deficiencies in managing an illness. The assessment is used to gain a better understanding of how everybody sees the problems at hand, to gather information to allow for a more

comprehensive treatment plan, to provide an opportunity for all members involved in trying to cope with the illness to ask questions and to solicit the help of all involved in setting up a meaningful treatment plan. It is useful to have as many family members and significant others as possible attend an initial assessment. Significant others can include extended family members, good friends, coworkers, other healthcare providers, and spiritual counselors.

GOALS OF THE FAMILY ASSESSMENT

There are three overriding goals when conducting a family assessment. The first is to orient the family to the assessment process by establishing an open and collaborative relationship with those present. The second goal is to have all family members identify current problems and concerns. The third goal is for the clinician to identify the family’s transactional style, which may be relevant for understanding the way the family deals with illness in one of the family members. Dysfunctional transactional patterns are repetitive interactional processes that prevent effective resolution of ongoing interpersonal problems. The assessment can take from 1 to 2 hours depending on the nature of the family’s problems and the skill level of the clinician (see Box 11.1).

MODEL OF FAMILY ASSESSMENT

A comprehensive family assessment should be focused and systematic. The McMaster Model of Family Functioning (MMFF) is one of the more developed and validated family assessment and treatment models available (Ryan, Epstein, Keitner, Miller, & Bishop, 2005). It provides a framework for evaluating multiple dimensions of family functioning, leading to a structured treatment program as indicated. The assessment process consists of four identifiable components: orientation, data gathering, problem description, and problem clarification (see Box 11.2).

Box 11.1 GOALS OF THE FAMILY ASSESSMENT

- 1. Establish an open and collaborative relationship to orient family
- 2. Have all family members identify current problems and concerns
- 3. Opportunity for clinician to identify family’s transactional style

Box 11.2 COMPONENTS OF FAMILY ASSESSMENT

- A. Orientation
- B. Data Gathering
- C. Problem Description
- D. Problem Clarification

The *orientation* explains the purpose of the evaluation and establishes goals for the assessment process. It is helpful to normalize the assessment process by explaining that family meetings are a regular component of the assessment and treatment of most patients. The clinician explains that the goal of the meeting is to provide an opportunity for all family members to identify what they see as problems and to bring up any areas of concern. They should also be assured that they will have an opportunity to ask questions and that they will be included in the development of ongoing treatment plans.

During the *data gathering stage*, the clinician should clarify the family members’ names, ages, relationships within the family, and living arrangements. It is also helpful to find out what family members do for a living and the phase of the family’s life cycle. The clinician should then ask each family member what he or she perceives are the problems. Each family member should be given sufficient time to be able to *identify problems*, and all family members should be helped to express their concerns without being interrupted by others. The challenge for the clinician is to gather sufficient information so as to be able to understand the problems but not to get so bogged down in details that there is no time for the exploration of other problems and concerns. Once the presenting problems are clearly outlined and there is consensus between the clinician and the family that its problems are understood and agreed upon, the clinician then moves on to assess *broader dimensions of family functioning*. These include problem-solving, communications, roles, affective responsiveness, affective involvement, and behavior control (see Box 11.3).

Problem-solving refers to a family’s ability to resolve problems to a level that maintains effective family functioning. Family problems can be affective or instrumental. *Affective problems* refer to difficulties in dealing with emotions such as anger or sadness. *Instrumental problems* refers to problems of everyday life, such as managing resources and dealing with daily obstacles. Questions about family problem-solving skills can be general, or the family can be asked to think of recent problems that they have dealt with to use as an example. The following questions may be helpful in exploring problem-solving skills: **Who noticed the problem? What was done after the problem was noticed? Did you discuss the problem together? What did you decide to do about the problem? Did you follow through on the decision that**

Box 11.3 BROADER DIMENSIONS OF FAMILY FUNCTIONING

- a) Problem-solving
- b) Communications
- c) Roles
- d) Affective responsiveness
- e) Affective involvement
- f) Behavioral control

was made about the problem? Did you review whether the solution to the problem worked or not? Do you deal with emotional and practical problems in the same way?

Communication refers to verbal exchange of information within the family. Nonverbal communication is obviously also very important but much more difficult to assess reliably. Communications can also be affective or instrumental. Families can have marked difficulties in affective communications but can communicate very well about instrumental issues. Families with poor functioning tend to have unclear and indirect forms of communication. The following questions may be helpful in exploring how the family communicates: **How much time do you spend talking with each other? Can you talk about practical things with each other? Can you talk about your feelings with each other? Do you feel that you can say what you want to, or do you have to be guarded about what you say? Can you talk to each other directly, or do you have to go through someone else to let each other know how you think or feel?**

Roles are repetitive patterns of behavior by which family members fulfill family functions such as the provision of resources, nurturance and support, sexual gratification, personal development, and maintenance and management of the family system including decision making, boundaries, and household finances. The following questions may be helpful in exploring family roles: **How do you divide family responsibilities? Who does the cooking? Who does the shopping? Who cleans the house? Who handles the money? Who looks after the home and cars? Who gets involved with the children's education? Who is involved in major decisions? Are responsibilities fairly shared between family members?**

Affective responsiveness refers to whether family members are able to respond to the full spectrum of feelings experienced in emotional life, and whether the emotion experienced is appropriate for the situation. It refers to a person's capacity to experience particular types of emotions. It assesses whether family members tend to be overcome with feelings or are not sufficiently capable of experiencing them. Two types of feelings are assessed. *Welfare emotions* consist of affection, warmth, tenderness, support, and happiness. *Emergency emotions* include fear, anger, sadness, and disappointment. The following questions can be helpful in eliciting information regarding emotional responsiveness: **Does anyone in the family seem to be overly emotionally responsive? Are there some family members who do not seem to respond with enough feelings? Do some people feel too happy or sad or angry, or not enough?**

Affective involvement refers to the extent to which the family shows interest in and values the activities of individual family members. Do family members show an appropriate amount of interest and concern for each other? Are they involved with each other? Do they support each other, or are they disconnected? The following questions can help explore aspects of affective involvement: **Does anybody care about what is important to you? Do you feel that your family is there for you? Do you think that they are really concerned about you, or are they just going through the motions? Do you think that your family intrudes too much into your life?**

Behavior control refers to the ways in which a family establishes rules about acceptable behavior related to physically dangerous situations, situations involving meeting and expressing psychological needs and drives, and situations involving socializing behavior between family members and people outside the family. It concerns parental discipline toward children as well as standards and expectations of behavior that adults set for each other. The following questions can be used to explore behavior control in the family: **Do you have rules in the family about how to handle different situations? Do you allow hitting or yelling at each other? Do you have rules about drinking? About driving too fast? Do you have rules about letting each other know where you are when you are away from home? Are the rules clear? Are they consistent? Do you know what to expect if the rules are broken? How do you deal with a disagreement about rules?**

ADDITIONAL INVESTIGATIONS

A comprehensive family assessment should not preclude a diagnostic workup that also includes psychological and biological information. For adults this may include a psychosocial history, psychiatric examination, medical history, and physical examination. Laboratory and radiology tests as well as neurological and psychological assessments should be ordered as indicated. Information from any of these sources may add to the understanding of what the family is dealing with.

PROBLEM DESCRIPTION

After an assessment, the problems that a family faces and the family's ways of dealing with the problems should be clear to both the clinician and the family. It is helpful to try to group problems into related clusters to avoid getting bogged down with excessive detail or to have such a large problem list that it makes the family feel overwhelmed. What may seem to be many different problems often emanate from a few core problems.

PROBLEM CLARIFICATION

The final step in the assessment process is to obtain agreement between the clinician and family members on the problems identified. If the clinician has been careful to listen to each family member and has checked out the understanding of the problems with the family, there should be good agreement on the final problem list. If there are disagreements about the problem list, these should be resolved before proceeding to recommendations for treatment.

TOOLS FOR FAMILY ASSESSMENT

There are family assessment instruments that allow for a quantifiable evaluation of family functioning, to track change over time, make comparisons with other families, and to carry out quantitative research.

SUBJECTIVE FAMILY RATING SCALES

Subjective family rating scales are self-report paper-and-pencil or computer touchscreen instruments filled out by individual family members to reflect their views of their family's functioning. These scales are cost effective, as they can be filled out in less than 30 minutes and do not require trained interviewer time. The disadvantage to their use is that they are restricted to an internal perspective of family functioning and may not reflect ways that a family may appear to function to an outside observer. Different scales also emphasize different aspects of family functioning or measure the same concept differently. Family members can fill out these instruments in the waiting room or at home before the first session, as well as during the course of treatment as a way of monitoring progress. The following are examples of commonly used instruments.

Family Assessment Device (Epstein, Baldwin, & Bishop, 1983): Assesses the dimensions of the McMaster model of family functioning—problem-solving, communication, roles, affective responsiveness, affective involvement, behavior control, and general functioning.

Dyadic Adjustment Scale (Spanier, 1976): Measures satisfaction, cohesion, consensus, and affectional expression in couples.

Family Environment Scale (Moos & Moos, 1981): Assesses relationship (cohesion, expressiveness, conflict), personal growth (independence, achievement, mortality/religion), and system maintenance (organization, control).

Family Adaptability and Cohesion Evaluation Scale III (Olson et al., 1989): Measures of adaptability (rules, power structure, roles) and cohesion (emotional bonding, autonomy, boundaries).

Self-Report Family Inventory (Beavers & Hampson, 1990): Assesses conflict resolution, styles of relating, intergenerational boundaries, and family competence.

EXTERNALLY RATED INSTRUMENTS OF FAMILY FUNCTIONING

These instruments are administered by trained interviewers and provide a more “objective” view of a family's functioning. They modify the tendency on a family's part to want to see themselves in a particular way. A disadvantage of these instruments is that they are relatively expensive to use, as they take longer to administer and require trained interviewers to rate the family reliably. The following are some of the commonly used instruments.

The Global Assessment of Relational Functioning (GARF) scale is similar to the individual based Global Assessment of Functioning but focuses instead on relational adjustment and on the quality of the family environment (Rosen et al., 1997). The GARF measures relational functioning on a scale of 1–99. Scores of 1–28 apply to a family that is too dysfunctional to be able to function together; scores of 21–40 describe a family that is seriously dysfunctional; scores of 41–60 define a family that has occasional times of satisfactory functioning, but dysfunction predominates; scores of 61–80 define the family that is functioning with some dissatisfaction; and scores of

81–99 define a family where family functioning is satisfactory. Areas assessed include problem solving, organization, and emotional climate.

The McMaster Clinical Rating Scale is a semistructured interview that assesses family dimensions including communications, problem solving, affective involvement, affective responsiveness, roles, behavior control, and general functioning (Miller et al., 1994).

The Beavers Interactional Styles Scale evaluates a family's competence and style. It also assesses power, parental coalitions, clarity of expression, conflict, negotiation, responsibility, and empathy (Beavers & Hampson, 1990).

The Camberwell Family Interview measures expressed emotion, the amount of criticism expressed by family members about each other, emotional overinvolvement, and the extent to which family members are involved in each others lives (Brown & Rutter, 1966).

The Psychosocial Adaptation to Illness Scale is a semistructured interview that evaluates patient and family adjustment to illness (Derogatis, 1986).

There is no absolute advantage to either an external or internal perspective on family functioning. Both perspectives are important, and each may be relatively more useful to answer different kinds of questions. A discrepancy between an outside evaluator and family members' perception of their family's functioning, as well as differences between individual family member's views of their own family's functioning, may provide particularly useful clinical information about the family's problems. Information from both kinds of assessments can be complimentary. Which one is used will depend on the questions being asked and the time and resources available to undertake the evaluation.

A systematic assessment of the family is central to understanding the relevant issues in the family and their potential role in influencing the patient's presenting problems. A good family assessment can be therapeutic in and of itself, as it provides an opportunity for family members to express and listen to concerns in a safe, nonjudgmental environment. The assessment of the family is part of a comprehensive biopsychosocial formulation that should be the foundation for a treatment plan that deals with the medical illness.

FAMILY THERAPY

There are many different schools of family therapy. These include strategic family therapy, structural family therapy, experiential family therapy, narrative therapy, cognitive behavioral family therapy, solution-focused therapy, emotionally focused family therapy, integrative family therapy, and problem-centered family therapy (Gurman & Jacobson, 2002; Nichols, 2010; Pisani & McDaniel, 2005). There is reasonable empirical evidence at this time that family interventions, as adjuncts to medical treatment, provide benefits to patients and family members above and beyond what they receive from usual medical treatment. There have not been any studies to date that compare the relative effectiveness of different types of family therapy. One cannot say with any degree of

assurance that any particular type of family therapy is better than another for any particular type of disorder or any particular type of family problem. Therapists tend to practice the kind of family therapy that they are familiar with, regardless of the problems they are presented with. How can a clinician interested in learning family therapy techniques to help families deal with the impact of medical illness know what to do, given this undefined state of affairs?

The large numbers of family therapies can be broadly divided into two groupings, *psycho-educational interventions* and *relationship-focused interventions*. Psycho-educational interventions educate patients and family members about disease processes, what is required for the best care for these diseases, information about how individuals and families are affected by the disease, and ways in which family interactions and behaviors can influence the course and outcome of that disease. Psycho-educational interventions assume that increased knowledge by family members will lead to better disease management and treatment outcome. Psycho-educational interventions can be provided to individual families or in a multifamily group format (Gonzalez et al., 1989).

Relationship-focused family interventions focus on the quality of intrafamilial life, the nature of interpersonal relationships in the family, and processes that prevent family members from being able to work together in such a way as to feel connected with each other and effective in dealing with demands being placed on them. Relationship-focused interventions involve attempts to improve communications, ways of solving problems, managing conflicts, setting realistic expectations, and increasing mutual support. Relationship-focused family interventions may also involve educating the family about the illness.

It is very unlikely that any one therapist can become proficient in a number of different types of family therapy. It may be useful to integrate different elements from different schools of family therapy for a given family, but there is a risk of losing focus and confusing families when the therapist does not have an internally consistent therapeutic framework. It is probably less confusing for therapists and their patients if the therapist is proficient in and practices, at most, one or two types of family therapy. A therapist may best be served by learning a family therapy model that is not rigid, one that encourages a broad assessment of the family's needs, and one that enlists the open collaboration of the family in working toward mutually agreed goals in treatment.

The Problem Centered Systems Therapy of the Family (PCSTF) (Ryan et al., 2005) is one such model of family treatment. The PCSTF was developed to help families clearly identify their needs and concerns, to assess obstacles in the way of addressing their concerns, and to work with them to develop more effective ways of functioning as a family. It is a generic family treatment model that addresses a wide range of family problems.

Problems in the family as they deal with a medical illness may come to the attention of clinicians in a variety of ways. Patients may be continually noncompliant with treatment. There may be lack of improvement in spite of following treatment recommendations. Patients may show signs of anxiety

Box 11.4 WHAT CALLS ATTENTION TO PROBLEMS IN THE FAMILY

- a. Patients who continually do not adhere to treatment
- b. Patients who follow treatment recommendations but don't improve
- c. Patients anxious or sad, feeling alone, unsupported, or blamed
- d. Persistent misunderstandings between patient, family members, and treatment team.
- e. Patient report of concern about relationships at home

and sadness along with feelings of being left alone to deal with their illness, feeling that they are not receiving sufficient support, or feeling blamed. There may be persistent disagreements and misunderstandings between the patient, family members, and treatment providers. Patients may also directly express concern about relationship problems at home when asked (see Box 11.4).

Particularly problematic times for the family in the course of a patient's illness are at the time of acute symptoms and diagnosis, during the acute treatment period (particularly if symptom control takes time), and during the maintenance phase when patients and families need to adjust to the reality of persistent symptoms with a chronic illness. Although the kinds of problems presented by these different phases of the illness may vary, the family's ways of dealing with the problem are likely to be consistent over time. It is largely for that reason that it is most useful to focus on the family's usual coping skills, ways of functioning, and problem-solving processes rather than attempting to tailor a particular family approach to a particular illness at a particular period of time. The goal should be to help a family identify its strengths and weaknesses in order to be able to make decisions about what they want to do, and, if they are willing, to help them to learn to deal with problems more effectively. Learning more effective ways of dealing with problems will put a family in the best position to deal with a variety of unforeseen problems in the future.

PROBLEM CENTERED SYSTEMS THERAPY OF THE FAMILY

The PCSTF is a problem-focused, behaviorally directed family therapy model that empowers families to work effectively on resolving distressing situations (Keitner, Heru, & Glick, 2010). A unique feature of the PCSTF is that it focuses on stages of treatment rather than on specific intervention skills or particular personality characteristics of the therapist. These stages are referred to as *macro stages of treatment* and differ from *micro-family techniques*, which occur within the macro stages. The major value attached to this treatment model is that optimal family functioning is most likely to be achieved when there is open, direct, and clear communication among family members. Apart from this expectation, the model

leaves it up to the family to determine which aspects of their family's lives they are content with and which they wish to see change, regardless of how an external evaluator may see the family's problems. The only exception to this norm is when there is evidence of dangerous behavior in the family, such as physical and emotional abuse of any family members. The PCSTF has been empirically validated as a useful adjunct in the treatment of patients with mood disorders (Miller et al., 2005, 2008; Solomon, Keitner, Ryan, Kelley, & Miller, 2008).

The PCSTF emphasizes the need for a comprehensive understanding of the family system, including its problems and strengths. In addition to the presenting problems, the assessment includes understanding the structure, organization, and transactional patterns within the family. The assessment process includes reviewing multiple dimensions of family life as described above in the assessment section. The presenting problem may not necessarily be the most important one. Focusing prematurely on the presenting problem, without understanding the broader context in which it is embedded, may lead to a preoccupation with peripheral issues and to missing a problem that might be generating the most distress. A thorough assessment also reassures family members that they are being understood, and helps them take a step back to understand their problems from a broader perspective.

It is preferable to include as many family members as possible, at least for the initial assessment. Having all family members present gives a clear signal that everybody is involved in the process and that each person may have an impact on outcome. It can also encourage family members to participate actively in the treatment process. Subsequent meetings can be more limited in the number of participants, depending on the issues being discussed and logistics concerning the ability of different family members to participate in the available time.

The emphasis is on the macro or major stages of treatment. These stages are *assessment, contracting, treatment, and closure*. *Micro moves* refers to specific techniques such as labeling, clarifying communication patterns, or focusing the family on a particular problem. Macro and micro moves are different from a therapist's particular personality style, which may include qualities such as choice of wording, use of gestures, and ways of helping families to look at difficult situations. A number of schools of family therapy have become well known because of the particular personality style and skills of a charismatic family therapist. The PCSTF focuses on these stages and steps in therapy and depends less on the particular personality of the therapist. It accommodates therapists with a variety of clinical styles.

The therapist models open and direct communication with the family by explaining his or her formulations and actions with the family along each step of the therapy process, and makes sure that family members clearly understand and agree. The PCSTF assumes that family members understand their problems and are interested in changing them and that they have the capacity to do so with support and guidance.

Active collaboration with all family members reinforces the therapeutic alliance between the therapist and the family. The family needs to be an active and willing participant in each step of the treatment. There needs to be agreement between

the therapist and family members about the formulation of the presenting problem and about the steps that are likely to be helpful in resolving them. The family also has to be committed to following through on the steps agreed upon to bring about the desired change in the family. The therapeutic contract is based on this mutual commitment to work at therapy.

The family's strengths are recognized and fostered during treatment. It is much easier and more helpful to the family to reinforce its strengths rather than trying to eliminate its weaknesses. Too much focus on pathology may bring about more pathology. The therapist helps the family recognize its own capacities to address and deal with difficult situations.

Family members are directly involved in identifying, clarifying, and resolving their difficulties. The role of the therapist is that of a catalyst, clarifier, and facilitator. The therapist provides a safe environment in which family members can be more open with each other, communicate more clearly with each other, and be more active in their problem solving. The goal is to help families develop effective problem-solving methods that can be generalized to resolve future difficulties.

The PCSTF focuses mostly on the current problems. When appropriate, it may be necessary to review past issues to obtain a full understanding of how the current problems came about, what it means to the individual family members, and what attempts have been made at resolution; but once the meaning of the problem is understood, the focus is on what the family wants to do about it now.

Changing attitudes, beliefs, and opinions is important, but the PCSTF emphasizes change primarily in observable behaviors. Such changes in behavior are the defined goals of treatment. Cognitions and affect are important, but behavioral change is more measurable and manifest. It is much easier to change what one does than what one thinks and feels.

Treatment is generally time-limited, taking six or eight sessions spaced over a period of weeks or months. The length of each individual session or the time between them will vary depending on the issues involved, the stage of treatment, and the urgency of the situation. The assessment session(s) may take longer (up to an hour or an hour and a half) while a later task-setting treatment session may range from 15 minutes to 45 minutes. Imposing time limitations on therapy sessions tends to stimulate therapist and families to be more actively involved in the treatment process, thereby facilitating change.

STAGES OF TREATMENT

The stages of treatment are assessment, contracting, treatment, and closure. Each stage contains a sequence of sub-stages, the first of which is always orientation. Orientation at each stage of the process is a critical component. Family members need to be oriented as to what to expect. Their agreement and permission to proceed needs to be obtained before treatment can begin, and again during the treatment process. It models a way of approaching potentially difficult situations and can be useful in minimizing resistance that may emerge in later stages, reminding families of their agreement to collaborate in the treatment goals.

ASSESSMENT

The assessment stage is made up of orientation, data gathering, problem description, and problem clarification. The assessment stage is the most important of the macro stages. It is the stage during which information and observations are gathered so as to be able to develop a comprehensive and meaningful biopsychosocial formulation, which is the roadmap for effective treatment. The assessment stage has three main goals. First, the therapist orients the family to the treatment process and establishes an open collaborative relationship with family members. Second, the therapist, with the help of family members, identifies all current problems in the family including the presenting problem. Third, the therapist identifies to families dynamic interactional patterns that appear to be related to the family's problems. The therapist's formulation is presented to the family for acceptance as accurate or for revision as needed. The assessment stage should not be rushed. Extra time taken at this point may well reduce the number of task-oriented treatment sessions that will be required later in the treatment process. The process of identifying, clarifying, and understanding various family members' perspectives of the problems are often therapeutic in and of themselves.

The therapist should orient the family by letting them know the purpose of the meeting and by finding out what each expects will happen during the session and what they hope the outcome will be. The orientation should normalize the meeting by explaining that this is common practice with most patients, as a way of avoiding the implication that there is something wrong with this particular family. The therapist should also empower the family by letting them know that not only will they be asked questions but they will also have the opportunity to ask questions of the therapist and will be included in any decisions about treatment options. If the family has no questions and is in agreement, then the next step is to gather the necessary data.

During the data-gathering stage, information is collected about the presenting problems, overall family functioning, additional investigations that may be indicated, and other potential problems. The therapist asks each family member what he or she thinks are the problems in the family. During this process the family learns to focus on specific issues, to communicate concerns clearly, and to listen. It is important to give each family member time to articulate concerns. Once the presenting problems have been sufficiently and clearly delineated, the family's overall functioning needs to be assessed. At this point the therapist can assess the family along the dimensions of the McMaster Model of Family Functioning (communications, problem solving, affective involvement, affective responsiveness, roles, behavior control) as outlined earlier in this chapter. The assessment should focus on detailing strengths and difficulties in each of these areas of family life to determine their impact on the family's ability to cope with illness. The emphasis should be on strengths, because this will be central to the therapeutic planning that will follow.

Throughout the assessment stage the therapist needs to be aware of and recognize potentially dysfunctional transactional patterns. Dysfunctional patterns tend to occur in association with the presenting problems and can

be dealt with once the problem is more comprehensively understood.

Additional investigations may be helpful to be able to arrive at a comprehensive biopsychosocial assessment. The therapist should gather appropriate information concerning medical history, physical examination findings, and related laboratory and radiological tests. Much of this information may need to be gathered outside of the assessment session itself, but it is information that needs to be incorporated into a proper understanding of what the family is trying to deal with.

The purpose of the problem-description step is to summarize the identified difficulties and to develop a list of problems to be addressed. The family and the therapist need to come to mutual agreement about the problem list. Any disagreements need to be resolved before the treatment process can proceed. With clarification and agreement on the problems, the family can move on to the stage of contracting.

CONTRACTING

The goal of this stage is to prepare a contract between family members and the therapist that delineates the expectations, goals, and commitments regarding therapy. The steps in this stage include orientation, outlining options, negotiating expectations, and drawing up a contract. The therapist orients the family to the stage of deciding what they want to do about the problems and solicits their agreement to move forward.

Although there are many options for how to deal with a variety of different problems, in fact there are generally four broad options that family members can choose in dealing with any problem. The family can continue to function as before, without attempting to bring about any change. The family can attempt to work out their problems on their own, without the help of the therapist. The family can choose another type of treatment. The family can agree to engage with the therapist in the current treatment format.

The likelihood of a successful outcome for therapy will be greatly enhanced if family members proactively, out of their own free will, agree to engage in the treatment process and in defining their own goals. The therapist should not try to persuade or entice the family into treatment. The only exception to this general rule is when a dangerous situation exists such as physical abuse, suicidality, or a behavior pattern that can significantly worsen illness in a family member.

The goal of the contracting stage is to formulate a set of expectations that each family member wants to see occur in order for the problems to be resolved successfully. The expectations should be stated in concrete behavioral terms to allow for clearly identifying and assessing change. The behaviors should be observable to all family members. The therapist and family should take each of the problems outlined in the assessment and negotiate a set of behavioral goals related to those problems—which, in fact, if carried out, will give the family a sense that they are making changes. The main technique for establishing treatment goals is that family members negotiate what they would like from each other and how they want each other to change. The therapist's primary role during this

process is to facilitate the interaction between family members to ensure that clear, behaviorally defined expectations of change are established. The therapy should also make sure that expectations are realistic for the time frame the family has designated to make the changes. The therapist may also need to raise additional problems that are not addressed by the family during the negotiating process, particularly if the therapist feels those problems may be central to the ongoing difficulties the family is experiencing. It is useful to limit, to two or three at a time, the number of changes that any family member expects from others. It is helpful to write down the list of expectations from each family member in order to decrease the likelihood of misunderstandings in subsequent meetings.

TREATMENT

The goals of the treatment stage are to develop and employ problem-solving strategies to change the identified problems. Two therapeutic techniques are used to accomplish these goals. The first is focused on producing behavioral change in the family through task setting. The therapist helps the family to set tasks that they can work on between meetings. Evaluation of the success or failure of the family in accomplishing these tasks becomes the main focus of the work in subsequent family sessions. The second set of techniques promotes cognitive and behavioral changes that are likely to increase the family's ability to address their problems successfully. The treatment stage consists of orientation, clarifying priorities, setting tasks, and task evaluation.

The first step, as usual, is to orient the family to this new stage and to obtain their permission and collaboration to proceed. Clarifying priorities involves listing problems in order of importance. In general, priorities should be given to problems that involve communications and behavioral control because problems in these areas can lead to difficulties in solving other problems. If families cannot communicate about issues, it is going to be difficult for them to negotiate expectations. Similarly, if chaotic behavior is allowed to proceed, this is likely to disrupt treatment.

When setting tasks, the therapist asks the family to negotiate with each other what changes they would like from each other that, if carried out, would represent a move in the direction of meeting their expectations of change. The problem to be worked on is taken from the priority list. Such behavioral changes are the tasks the family will be working on during the course of treatment. If family members are unable to come up with reasonable tasks and expectations from each other, the therapist may have to make some suggestions, checking with the family to ensure that these are agreeable to everyone. When negotiating and assigning tasks, the therapist should consider the following general principles.

The therapist should be open and direct with the family about the purpose of the assigned tasks. Often it is not a specific task that is important, but the fact that family members are making an effort to meet each other's needs in a way that is different from their usual patterns. The task should be direct and purposeful and not paradoxical. The idea is not to back

the family into change, but to have them move toward it in a proactive and purposeful manner. Tasks should be directed toward bringing about change in those dimensions of family functioning that had been identified as problematic during the assessment process.

Tasks should be directed at changing dysfunctional family transactional patterns. The initial tasks should be simple and achievable to increase the potential for success. As the family gains confidence in themselves and are empowered by the process of change, more complicated tasks can be negotiated. Tasks should be reasonable with regard to age, gender, and sociocultural norms for that family. Tasks should be oriented toward increasing positive behaviors rather than decreasing negative ones. Tasks should be behavioral and concrete enough to be understood and evaluated by family members.

Tasks should be meaningful and important to the family. Family members should feel that they could accomplish the tasks assigned to them, making it likely that they will commit themselves to carrying them out. Emotionally oriented tasks should emphasize positive, not negative, feelings. Tasks should fit reasonably into the family's schedule of activities.

A maximum of two tasks per session is usually reasonable in order not to overload the family. Assignment of tasks to family members should be balanced so that major responsibility for completing tasks does not reside with one or two members. Vindictiveness and rehashing of the past should be avoided, and focus should be placed on constructive ways of dealing with the current situation. These principles of task setting are made explicit to the family when tasks are being negotiated (see Box 11.5).

Task evaluation is a critical process. This is the crux of the therapeutic work. It is in the review of the family's success or failure in carrying out the tasks that the real issues in the family become manifest. The tasks, apart from their intrinsic value, are a stimulus for core family issues to emerge and become more evident, not only to the therapist but also to the family members through the eyes of the therapist. Obstacles in carrying out agreed tasks become stimuli and catalysts for bringing about

Box 11.5 PRINCIPLES OF TASK SETTING

- 1. Reasonable in regard to age, gender, sociocultural norms
- 2. Oriented to increasing positive behaviors
- 3. Behavioral and concrete so everyone can assess outcome
- 4. Meaningful and important
- 5. Feasible
- 6. If emotional, focused on positive emotions not negative
- 7. Fit into family schedule
- 8. Maximum of 2 tasks per session
- 9. Balance assignment of tasks among family members
- 10. Focused on constructive solutions (avoid vindictive rehashing)

subsequent changes. The ways in which families have difficulty accomplishing tasks provide the best immediate evidence of what the family needs to work on. Failure to accomplish tasks should not be seen by the therapist or the family as an obstacle to change, but as an opportunity to gain a much clearer insight into the problems of the family in a more immediate, nonintellectual and affective manner. If the family is committed to the change process, awareness of the particular ways in which they run into obstacles in carrying out their tasks allows them to make more constructive and effective changes.

If the agreed upon tasks are accomplished, the therapist provides positive reinforcement, reviewing and highlighting the positive aspects of the family's performance to ensure that the family members understand what worked so they can continue to resolve problems in the future. If the tasks are not accomplished or only partially accomplished, the therapist needs to go through the particular steps in some detail to find out what went wrong. Failure to accomplish a task provides important information about difficulties that may not have been fully understood during the assessment process.

In addition to reviewing the specifics of the family's attempt to accomplish a failed task, it is also important to determine whether the task was too difficult for that particular family at that particular time. If the task was too difficult, a simpler task, broken down into smaller, more manageable pieces, may be needed. A task may have failed owing to difficulties that were not apparent during the previous assessment. In this case, knowledge of the new difficulties can be incorporated into the formulation of the family's problems and into the setting of new tasks.

A failed task may also mean that the family is not interested in working to bring about change. They may have changed their minds about their commitment to therapy, or they may decide that the amount of effort involved is too great. If noncompliance is a key reason for the failure of tasks, this needs to be addressed with the family directly to determine if they are invested enough in the treatment process to make treatment succeed. In general, unless there is a dangerous situation involved, it should be more important for the family to obtain good results in therapy than it is for the therapist. If they are not ready to commit to the treatment process, they should be offered the opportunity to return to the therapist at some future date if and when they decide they are ready to make the effort they will need to put into the treatment. This perspective can be offered in a supportive way, indicating that success comes with true commitment when the family has the time and energy to apply themselves to the process.

During the treatment stage, the major part of each session is devoted to reviewing previously assigned tasks and developing and negotiating new tasks. There are, however, other specific intervention tools that can help the therapist and family negotiate their way through the process of bringing about meaningful change. The therapist can be helpful by clarifying problems and can provide feedback on the perception of family functioning. Clarification of problems helps families become aware of processes in the family patterns of organization and problem solving of which they may not have been aware. It is assumed that with sufficient knowledge, changes

will more readily take place. The therapist can also label and interpret transactional processes and unacknowledged affect. Labeling and interpreting of process is based on observable behaviors that occur during the therapy sessions, therefore making them more immediate and real. By learning to understand the transactional patterns, families can modify them to be less destructive. The therapist can also provide education to modify incorrect assumptions, expectations, and information about the illness, its consequences, and treatment options. Providing the family with information about the illness, its etiology, course, and treatment may help to eliminate misunderstandings and empower the family to develop better coping skill for managing the illness.

CLOSURE

The final macro stage of closure consists of orientation, summary of treatment, long-term goals, and follow-up. During the orientation step, the therapist points out to the family that the goals of treatment have been met. If the family wants to continue with further therapy, this needs to be renegotiated. It is expected that families should be able to resolve new issues that come up using their newly learned coping skills. They should return for treatment only if they run into significant problems that they could not resolve on their own. It is important not to make professional patients out of families by keeping them too dependent on the therapist. Family members should be asked to summarize what they have learned during treatment. The therapist confirms or elaborates on their perceptions and adds any insights that may have been overlooked. The family is encouraged to discuss and set long term goals. They should identify issues they anticipate might come up or prove problematic in the future. The family is supported by recognizing that they have been able to make significant gains and that they have developed effective ways of identifying and dealing with family problems. The therapy ends at this point, although for some families an intermittent follow-up schedule may be appropriate. This could be at 3, 6, or 9 months. If needed, the follow-up session should support and monitor progress rather than rehash issues that have already been dealt with.

SUMMARY

There is increasing evidence that involving the families of patients with a wide range of medical illnesses improves the management of the illness as well as the functioning of the ill patients' family members. Recognition of this evidence should lead to greater attempts at routinely involving the families of medically ill patients in their care. In reality, this does not happen commonly. Involving families will only happen when clinicians not only recognize the importance of doing so, but also feel competent to engage, assess, and treat families. Training in family assessments and family interventions are not standard components of most healthcare training programs. The goal of this chapter is to present a model of assessment and treatment that can be readily implemented.

Most families cope very well with adversity and do not require family therapy. Even families that are coping well, however, can benefit from further support and education as a way of helping them to sustain their efforts. Other families have a more difficult time in adapting to and dealing with the onset and course of an illness in one of their family members. It is becoming increasingly clear that it is in the patient's and family's best interest to address difficulties with a knowledgeable healthcare provider. The clinician's job in helping to manage an illness can also be made easier if families are included as collaborators in the disease management process. Recognition of this reality will, it is hoped, encourage clinicians to become trained in how to provide family assessment and interventions.

CLINICAL PEARLS

- A basic task for families dealing with chronic disorders is to create ways of understanding the illness that allows the family to retain a sense of competence and mastery (Rolland, 2003).
- The key to effective family treatments is a comprehensive evaluation of families' needs and their functioning so that the intervention can be adjusted to meet those needs.
- What may seem to be many different problems often emanate from a few core problems.
- A good family assessment can be therapeutic in and of itself.
- Optimal family functioning is most likely to be achieved when there is open, direct, and clear communication among family members.
- The presenting problem may not necessarily be the most important one.
- This model assumes that family members understand their problems and are interested in changing them, and that they have the capacity to do so with support and guidance.
- It is much easier and more helpful to the family to reinforce its strengths rather than trying to eliminate its weaknesses.
- It is much easier to change what one does than what one thinks and feels.
- The process of identifying, clarifying, and understanding various family members' perspectives of the problems are often therapeutic in and of themselves.
- The therapist should not try to persuade or entice the family into treatment.
- It is useful to limit, to two or three at a time, the number of changes that any family member expects from others.

- Often it is not a specific task that is important but the fact that family members are making an effort to meet each other's needs in a way that is different from their usual patterns.
- Tasks should be oriented toward increasing positive behaviors rather than decreasing negative ones.
- It is in the review of the family's success or failure in carrying out the tasks that the real issues in the family become manifest.
- Unless there is a dangerous situation involved, it should be more important for the family to obtain good results in therapy than it is for the therapist.

PARENT GUIDANCE FOR MEDICALLY ILL PARENTS

Vaughn L. Mankey and Cynthia W. Moore

INTRODUCTION

The challenges experienced as a result of a serious illness are usually not isolated to the individual with the illness alone. Often the innermost sphere of relationships is very much affected in both emotional and practical ways, typically including the nuclear family. Mounting evidence documents the distress that both adult family members and dependent children experience when a loved one is sick and/or going through rigorous treatment (Armistead, Klein, & Forehand, 1995; Braun, Mikulincer, Rydall, Walsh, & Rodin, 2007; Northouse et al., 2007).

A number of serious, sometimes fatal, conditions can affect individuals in their childbearing and child-rearing years, and parents may actually experience greater distress than nonparents with the same conditions (Bloom & Kessler, 1994; Rauch & Moore, 2010). After all, parents must contend with the stress of the illness and treatment as well as the ongoing responsibilities of caring for dependent children. By considering the number of serious illnesses that afflict adult patients at child-rearing age, the scale of illness' impact on families is more clearly seen. Examining a few illnesses and some associated statistics helps bring the issue to life more concretely.

CANCER

At least 18% of recently diagnosed cancer patients, and 14% of all cancer survivors, are parenting minor children. This translates to more than 1.5 million cancer survivors having close to 3 million children at home (Weaver, Rowland, Alfano, & McNeel, 2010). Over half a million of these children are living with a parent in the early stages of cancer treatment and recovery. These data underestimate the numbers of affected children, most notably by omitting noncustodial parents and children who have already experienced a parent's death from cancer. Furthermore, the cutoff of 18 years that defines minors does not reflect the ongoing need for substantial parenting support for older adolescents and young adults (Rauch & Moore, 2010).

DIABETES

The Center for Disease Control and Prevention's most recent National Diabetes Fact Sheet (2007) reports that there are

23.5 million adults over 20 years of age that have diabetes in the United States alone. If we subtract the 12.2 million U.S. adults over 60 years old with diabetes we see that roughly 11.3 million U.S. adults between the ages of 20 and 60 have diabetes. This age group includes the most common ages for having and raising children. According to Halle (2002) and collaborators, data from the National Health Interview Survey of 2000 indicates that 84% of males and 86% of females over 45 years old have had at least one biological child. Although these numbers are not specific to males/females with diabetes, it is safe to assume that there are millions of parents with diabetes in the U.S.

HIV/AIDS

Schuster et al. (2000) also describe that an estimated 28% of US adults with HIV have dependent children. An even larger proportion of adults with HIV are parents generally speaking, as this estimate does not include parents who have young adult children.

Looking only at these three illness categories quickly demonstrates that a significant number of parents and their families are affected by serious illnesses. If all serious illnesses were to be considered, the number of parents whose families must contend with the challenges of illness is certainly in the millions—just in the United States alone. Clearly this is a large public health issue, as the effects on parents, children, and family units can be several and severe at times.

CLINICAL GUIDANCE FOR THE PARENT

Parents with serious illnesses often worry about how their children could be affected by their illness almost immediately after diagnosis. In fact, for some ill parents, worries about their children are pronounced, distressing, and may even affect treatment decisions (Duric & Stockler, 2001; Yellen & Cella, 1995; Muriel et al., 2010).

As healthcare providers, learning more about these parental concerns is the first step to caring for this aspect of a patient's psychosocial needs. Providers can begin by routinely asking all adult patients if they are parents and, if so, learning a bit about each of their children in terms of age, temperament, functioning, coping abilities, specific challenges, and so forth. Parents usually like discussing their children. A provider's

open-ended inquiry, such as, “Tell me about your children,” can often enhance the relationship between provider and patient while eliciting important information. Asking parents directly if they have any concerns about how their illness may affect their children can elicit the parents’ primary concerns and can potentially identify children at risk of needing additional support. Once the parent’s concerns are understood, customized interventions can be designed and implemented. Clinical experience suggests that there is no simple formula to predict the effects of an individual’s illness on loved ones; therefore, there is no one-size-fits-all intervention that can be broadly applied. However, some of the variables that influence and mitigate the effects of an illness within a family can be considered for each family, allowing for personally relevant assistance. Some of these variables relate to features of the illness itself, and others to the families and family members affected. Many of these variables are discussed in this chapter, as are ways in which the healthcare team can consider them when providing personalized assistance.

CASE EXAMPLES

Throughout this chapter, two case examples will be used to illustrate many of the illness and family variables, along with the guiding principles for clinicians. The basic histories of the two patients and their families are described below, and additional information will be provided throughout the chapter as relevant.

PANCREATIC CANCER

Kelly O’Brien is a 45-year-old female diagnosed 2 months ago with unresectable stage III pancreatic cancer after evaluation for back pain and a 15-pound unintended weight loss. She and her husband Jim have three children: an 8-year-old son, Connor; a 6-year-old daughter, Brianna; and a 3-year-old son, Michael. Kelly has received two rounds of chemotherapy with gemcitabine and experienced some nausea, fatigue, and thinning hair. She knows that her lowered white blood cell count leaves her particularly susceptible to infections.

Kelly works part-time as a bookkeeper for Jim’s business from home, but she sees caring for their children as her primary job. She notes that Connor has had “challenges” in school since kindergarten, and was recently diagnosed with ADHD and a reading disorder at the beginning of this school year, making him eligible to receive supportive services at school. Brianna is “like a little mother” sometimes, both bossing her brothers around and looking for ways to “make Mom feel better.” Michael is “all boy,” loud, active, exuberant, and increasingly difficult for Kelly to manage.

DIABETES

David is a 50-year-old male with a 15-year history of diabetes. He and his wife Irene have two children: a 17-year-old daughter, Monica, and a 13-year-old son, Jason. Monica is creative, expressive, and involved in drama club and advanced

art classes. Jason is the star soccer player of his team, generally active, athletic, and a “doer instead of a talker.” David’s diabetes was of insidious onset and was discovered by his primary care provider (PCP) after presenting with polyuria. David tried to check his blood sugars regularly from the beginning, and usually did so at least once a day. Despite some small improvements in diet and beginning intermittent exercise a few times a week, his sugars remained fairly high. He had frequent follow-up appointments with his PCP, and about 12 years ago he was placed on Metformin, which he took regularly twice a day. However, his blood glucose levels tended to remain high.

About 10 years ago he was referred to an endocrinologist who specializes in diabetes, and he was started on insulin injections 3 times a day. He has had a number of appointments with other specialists over the years for monitoring of other possible sequelae of diabetes. He sees an ophthalmologist regularly, and more recently he had several appointments with a podiatrist after a small foot ulcer was slow to heal. He often has low energy and feels sluggish. He recently had a seizure that was witnessed by both children after he took insulin before breakfast, which was then unexpectedly delayed.

It can be helpful to have an organizing framework when considering the impact of a parent’s serious illness on the family system and the children. The same framework can also guide interventions with parents to support family functioning and children’s normal development. Rolland’s Family Systems illness model (1999), which emphasizes the goodness of fit between the psychosocial demands of the disorder and the strengths and vulnerabilities of the family, provides such a framework and will guide the following discussion. Rolland describes three lenses through which families facing medical illness can be helpfully assessed: the developmental stage of the family, the developmental phase of the illness, and the psychosocial aspects of the illness. The developmental stage of the family refers to the relative age of the family—from pre-parenthood, through the ascending ages of children, into their young adulthood. The developmental phase of the illness is delineated into the crisis, chronic, terminal, and survivorship phases. Psychosocial aspects of the illness include acuity of onset; a progressive, constant, or relapsing course; the degree of incapacitation; the illness outcome; and the predictability of the illness. Each lens interacts with the others and, considered together, they create a nuanced description of the family’s challenges.

DEVELOPMENTAL STAGE OF THE FAMILY

Parent guidance is most helpful when the uniqueness of a family’s identity is considered. The family’s current stage along the life cycle affects the developmental tasks and important issues the family faces. For example, some stages require intense bonding and high cohesion, while others call for loosening the external family boundary as personal identity and autonomy become more important (McGoldrick & Carter, 2003). In all stages, family cohesion, open communication among all family members, and a clear family identity apart from the illness are markers of good functioning.

HOPEFUL OR EXPECTANT PARENTS

Young couples dealing with a chronic illness may find that decisions about starting a family are affected by the medical picture. For example, a young adult with cancer may have to decide whether to bank eggs or sperm prior to beginning treatment, whether to delay attempts to become pregnant, or whether to have any, or additional, children. Other chronic illnesses can complicate fertility or a couple's confidence that starting a family is a good idea. A medical illness overlaid on a pregnancy may heighten anxiety about a range of possibilities, such as the effects of the pregnancy on the mother's health and/or the effects of the parent's medical condition on the pregnancy and eventually the child. Most expectant parents plan for the new baby's physical needs and arrange the surrounding environment to accommodate the new family member. These arrangements may require more creativity if a parent's medical needs must also be considered, for example, to limit trips up and down stairs or to minimize lifting and carrying. In addition, parents may spend a lot of time fantasizing about what changes the new baby will bring. For example, parents may wonder how the baby will affect other relationships and how time and tasks will be divided.

Clinicians can support couples as they prepare for, and adjust to, parenthood in a number of ways:

1. Encourage couples to build or broaden support networks.
2. Help couples anticipate the likely changes and practical needs they will have.
3. Emphasize communicating about and preparing for the added workload of parenthood.

FAMILIES WITH YOUNG CHILDREN

New parents and families with young children are typically in a stage of higher cohesion and bonding, as adults learn to provide consistent and responsive care for their wholly dependent children. Parents must learn about their children's unique personalities and temperaments and begin to create consistent routines. Infants and toddlers are forming trusting attachments that provide them with the security to explore the world, and comfort when they experience distress. Young children must also learn to communicate their needs, while adults learn to perceive them before language is fully developed. Once verbal, preschool children require time and guidance to use language effectively to get what they need and want.

Introducing a parent's medical illness into young families in which children are so dependent on parents for all their needs poses some particular challenges. Parents may find that effects of the illness make the physical demands of their children hard to manage—the diaper changes in awkward positions, lifting and carrying a tired or tantruming toddler, diminished sleep due to a child's being unable to settle himself at night. A child's access to one or both parents may be intermittently disrupted with hospital stays, doctor's appointments, or symptoms causing a parent's inability to manage the physical challenges of childcare. Even such young children are

likely to be aware of a parent's absence, without understanding the reasons for the absence. Additionally, infants and toddlers may recognize parents' anxiety and distress and feel (and act) distressed as a result.

Clinicians should emphasize that very young children feel more secure and thrive when consistent routines and caregivers are maintained. Clinicians can think creatively with parents about how to engage supports and utilize resources to increase consistency for the children. For example, if parental illness necessitates having additional caregivers, parents may try to write down the child's routine and preferences so that others can recreate a consistent environment.

Kelly described her 3-year-old son, Michael, as becoming hard for her to manage, primarily because of his high activity level and her exhaustion. Her patience with his efforts to do things "by myself!" was much less than she remembered with her other two children. Until recently, she and Michael had stayed busy during the school day with a preschool gym program, swimming lessons, and a play group. We discussed the fact that her fatigue and concern about contagious illnesses were obstacles to her providing Michael with the physical and social stimulation on which he thrived. She and Jim decided that they would look into preschool programs for Michael and also try to have her treatments occur during preschool time. This was not an easy decision, given the value Kelly placed on caring for her children during their early years, but made sense in terms of providing a predictable schedule for Michael and some unscheduled time for her.

FAMILIES WITH SCHOOL-AGED CHILDREN

Although elementary school-aged children spend many hours a week in school and after-school activities, family cohesion remains critically important to their well-being. Between ages 6–12 years, children rely on parents to help them achieve in school, connect with friends, and master skills that allow them to be competent and confident. Parents must support children's increasingly complex routines, negotiate limits and discipline, and discern when a child is impeded in meeting developmental challenges and what the impediments are. Thus, while the physical demands of parenting may be somewhat less intense, the emotional demands can feel just as challenging when medical illness is part of the picture. Fatigue, anxiety and depression, and frequent medical appointments can interfere with all these aspects of parenting.

In addition, school-aged children are capable of making comparisons—among peers who are fast and slow runners, fluent and challenged readers, "popular" and socially invisible—and among parents who look or function differently than others. Clinicians can encourage parents to engage in open, honest, and ongoing communication about the parent's medical condition with their children so they can understand and adjust to the ways their family may differ from others. Honest conversations about the illness itself and the changes it may bring can also allow a family to retain a sense of itself apart from the impact of the illness, as the differing needs and wishes of all family members can be discussed and negotiated.

Once again, clinicians can help parents think through how to spend limited energy. Frequently, parents' focus is on maintaining the routine—providing rides, procuring supplies, getting groceries, and doing laundry. While completing these tasks helps keep a household running smoothly, parents may not have enough energy left over to spend time talking with children, enjoying time together, or noticing a child's altered behavior or mood. Clinicians may help parents determine what tasks can be delegated to friends, family, or paid helpers, and what functions only they themselves can fulfill in their children's lives.

Kelly and Jim described their relief at having 8-year-old Connor finally receiving services at school to address his reading disability and ADHD, but Kelly noted that homework could still take far longer than Connor could sustain focus. She was accustomed to coaching him through homework daily, but found it more difficult to do so for several days after chemotherapy treatments. Without her calming presence, Connor could erupt in frustration or simply give up after only a halfhearted attempt to finish. Kelly and Jim were able to talk with Connor about why Kelly was not helping him on some days but was on others, how much his efforts in school mattered to them, and what he thought would help with homework on the days Kelly was not available. Connor surprised them by asking if a high school boy who lived nearby could help when his mother could not, and then practice baseball with him. This would give him the opportunity to spend time with an older youth he admired, and allow him to finish homework early in the afternoon while his focus was best.

FAMILIES WITH ADOLESCENTS

Families with adolescents enter a phase in which family cohesion and individual autonomy must be rebalanced. Adolescents are developing a clearer sense of their own identities—strengths, challenges, beliefs, and values—and practicing skills that will allow them to function as independent adults. Parents sometimes struggle to decide how much freedom to allow adolescents, how much to trust their impulse control (especially when with peers), and how to maintain a feeling of connection with teens who increasingly want to spend time with friends.

Although the way parents monitor their adolescents' behavior looks different from the more hands-on approach used with younger children, the function and importance of parents' monitoring does not change. When medical illness intrudes on family life, parents may be tempted to respond in ways that may not be in their teenagers' best interest. Parents might reduce their monitoring of teens' activities due to fatigue or side effects, physical absence necessitated by treatment, and adolescents' own pushback against needing to be "babysat" by other adults. Additionally, teens may be asked to "step up to the plate" and take on a variety of new roles to help out at home such as caring for younger siblings, household tasks, even caring for the ill parent. While an increase in expectations is not always problematic, a balance must be maintained between adult needs and expectations and age-appropriate adolescent needs for socializing and down-time (Pedersen & Revenson, 2005).

In addition, as adolescents approach the end of high school they typically engage in conversations about their next step toward adulthood—whether college, trade school, or a job. Parents have an enormously important role in supporting this "launch," one that requires time, energy, and patience. All three of these qualities can be in short supply when illness is also part of the picture. In addition, worrying about a parent can make it more difficult for an adolescent to feel comfortable leaving home. He or she may feel guilty for pulling away at a difficult time, responsible for taking care of family members, or anxious about making the adjustment to life away from home.

Clinicians can help parents think about how much they are expecting of adolescents, how this has changed because of the medical illness, and what are the benefits and disadvantages to the teen, and the family, of this arrangement. Ongoing, open communication is particularly important so that adolescents do not feel overly burdened or excluded from decision making.

David's need for three-times-daily insulin and frequent blood sugar testing are embarrassing and irritating to his 13-year-old son Jason, who wishes his father could be physically active or eat out at restaurants "without all the drama." When David suffered from his foot ulcer, he stopped coaching Jason's soccer team. Both of them miss the "guy time" together and David describes feeling a little less connected to Jason. When asked why he thought this was the case, David replied that coaching allowed him one-on-one time with his son when they drove to practices and games together, as well as a window into his son's friendships. When he couldn't think of any other activities that would keep him as well connected to his adolescent son, he decided to see if he could continue as an assistant coach and minimize as best he could the time standing when his foot was bothering him.

FAMILIES WITH YOUNG ADULTS

Once children are functioning independently, the tasks for the family change yet again. Young adult children are proving themselves in new careers, often searching for or sustaining intimate relationships, and taking on adult tasks such as saving money, buying a car, signing a lease, perhaps even starting a family. Although families vary widely, many young adults continue to rely on their parents for support, advice, and encouragement as they negotiate these new challenges. Parents' titrated involvement can enhance confidence as well as promote better decision making. Medical illness in a parent can disrupt this process. Some young adult children may feel pulled to stay very involved in family life, such as when parents consistently rely on young adult offspring for care or support. In other families, parents may not remain involved enough in the young adult's life at critical times.

Young adults are often better able to communicate directly with their parents about the impact the illness is having on their lives. However, clinicians should still encourage parents to invite their adult children to engage in this communication and even to discuss how the communication is going. Is the family talking too much, too little, or just the right

amount about the illness? Are people discussing the various aspects of the illness and its consequences that are important to everyone?

PHASE OF ILLNESS

Along with the family developmental phase, considering the developmental phase of the illness itself can elucidate some of the specific effects the illness can have on a family.

CRISIS PHASE

The *crisis phase* often occurs in the initial stages of the illness—when symptoms are first noticed, a new diagnosis given, or when the initial treatment options are presented. However, there can be additional crisis moments at any point in a serious illness. Factors contributing to a sense of crisis may include shock about what the patient is experiencing, the threat of disability or death, a fear of lasting loss or drastic change, and worry that the patient or family cannot cope with the situation. Individuals may openly display their sense of fear, shock, or sadness, or use other coping strategies such as intellectualization, problem solving, or denial that make it more difficult for physicians to notice the underlying sense of crisis.

Even well-meaning parents may have difficulties explaining the crisis to children and commonly try to “protect” them by hiding the ill parent’s symptoms or limiting shared information. Some parents tell partial truths or even overt untruths, hoping to shelter the children from the tumult of emotions that the parents themselves may be experiencing. However, children are often keen observers, especially in regards to their parents on whom they depend for the provision of their needs and wants. Children may sense that there is a significant problem through even small cues, such as a change in the day’s schedule, a different tone of voice, or a decrease in the parent’s attention. When children notice changes, they often wonder why they have occurred. Without accurate information about what is actually occurring, children are left to worry alone. They attempt to piece together the bits of information they have gathered to arrive at an explanation that makes sense to them. Depending on the developmental stage and temperament of the children (among other variables), many of these assumptions can be inaccurate, and some are even self-blaming and illogical. Some explanations may cause significant guilt or anxiety in children. In fact, Rosenheim and Reicher (1985) have described that children who know about a parent’s cancer diagnosis are less anxious than those who were not told. The wish to protect children by withholding information is actually an error of kindness that has the potential to do harm instead of good.

Clinicians can encourage parents to provide open, honest, and age-appropriate information to all children in the family. Euphemisms, like “booboo” and “ouchy” should be avoided, and specific illness names should be used because this will decrease confusion and the possible concern that the children themselves may experience similar symptoms the next time

they have a booboo. Providing information about the illness and the preliminary plan to deal with the crisis is helpful. A clear, definitive plan is not always available, though, and is not necessary. Clinicians can suggest that parents inform their children that the ill parent is getting good care, getting the proper tests, and the immediately appropriate treatment (if applicable). This is often sufficient information to help children feel like things are under control.

During the crisis phase when emotions are running high, parents are encouraged to temper strong displays of emotion while discussing information with children. It is certainly acceptable for parents to show and discuss that they are upset, worried, or sad, but efforts should be made not to project a sense of being completely overwhelmed, helpless, or out of control. Children often take their cues from parents, and a parent’s strong distress may be unsettling and internalized by the children. Compas and colleagues (1996) found that perceived stress predicted an adolescent’s anxiety, depression, and stress response syndrome in families where a parent has cancer.

Prior to her formal diagnosis, Kelly and Jim had shared the news of her feeling ill with the children, as they needed an explanation for why she seemed tired and less able to do things she had always done for them and the household. They had told the children that “Mommy’s back has been hurting, and she has been pretty tired. We’re going to the doctor to find out what is wrong and to help her feel better.” Once Kelly and Jim received the specific diagnosis, they were understandably very upset, tearful, and nervous. When they were able to be calmer, they brought the kids together and told them, “We found out what is causing Mommy’s back to hurt. It’s called pancreatic cancer, and it is causing pain because it is growing in Mommy’s belly and pushing on things inside where it should not be. We are talking with the doctors now about how to help Mommy feel better and to see if we can make the cancer stop growing. We will let you know more as we learn more. Do you have any questions right now?”

In addition to sharing information, parents in the crisis phase of an illness are often required to disrupt normal family routines and reorganize in order to meet the immediate needs of the ill parent and ongoing needs of the family. Supports are often summoned, and a host of well-wishers may descend upon a family. This outside support is often necessary but may be experienced by children as a disruption. Clinicians can encourage parents to minimize this sense of disruption, as structure, routine, and predictability is often stabilizing and comforting for children. Parents may consider designating a “Captain of Kindness” outside the nuclear family who can organize the efforts of volunteers. This will allow the family to receive the needed support without being responsible for all the administrative work that can come with organizing it. In addition, an outside “Minister of Information” can be appointed to relay news updates to supports, without intrusion into family time (Rauch & Muriel, 2006).

Sometimes, even in the crisis phase, it is immediately clear that an illness will have lasting effects throughout the parent’s life. Parents may immediately realize that life has irrevocably changed, and they will be dealing with uncertainty in the

days and years ahead. It can be a challenge to integrate this information into expectations of the ill parent, the couple's relationship, and the family's future. At times this involves an immediate sense of grief, as the "new normal" is imagined and the pre-illness identities and expectations begin to feel lost. While preparing children for the immediate realities is important, sharing all of these types of concerns at an early stage of illness can be overwhelming for some children. Younger children will not think immediately about many of these longer-term changes, and time will allow for step-wise explanations and realizations. However, adolescents in particular may have some of the same worries as adults and should be encouraged to bring all of their questions and concerns to the parents for discussion. Parents need not have all the answers, but the power of a parent's listening to and thinking with a child is immense. It is perfectly acceptable for a parent to respond to a perplexing question with, "That is a great question, and I'm really glad you asked. I'm not sure of the answer right now, but I will think about it, talk to the doctor (nurse, social worker, etc.) and get back to you." This builds trust and mutual respect and facilitates communication. It also helps the child to not worry alone or go seeking answers elsewhere, which is important given the host of inaccurate and personally irrelevant information that is abundantly available to them from other sources.

CHRONIC PHASE ("THE LONG HAUL")

The *chronic phase* of an illness occurs in conditions that are more prolonged and chronic in nature, as the name suggests. In these illnesses, both the course of symptoms and treatment can be marked by a sense of ongoing constancy, steady or step-wise progression, or drastic episodic changes.

During the chronic phase, family roles and relationships may remain stuck in patterns developed in the crisis phase. However, solutions that worked in the short term may not be adequate for the long-term nature of a chronic illness. For example, an adolescent daughter may have prepared dinner every night, cared for siblings, and done all the laundry during the week her mother was hospitalized, but this level of effort will be difficult to sustain for months. Parents should be encouraged to be thoughtful about the role changes that occur, to openly acknowledge them, and to talk about them in an ongoing way. Some role changes may be welcomed by all parties, while others may be resisted or felt to be inappropriate or burdensome. Therefore, when possible, children should be included in conversations about role changes. Often adolescents are asked to take on more responsibilities for the family to help "pick up the slack," but they may be resistant to doing so based on the historical roles of family members as well as their own current needs. Socialization, identity exploration, school achievement, and extracurricular activities, among others, are all developmentally appropriate tasks for a teen. Clinicians can remind parents of these normal developmental tasks for teens, and how the appropriate navigation of these tasks is important for their teens' long-term healthy development. Parents should be encouraged to remain mindful of the multiple tasks teens are juggling as they seek to divide up

new roles and tasks within the family. Often a balance can be struck between helping the family, coping with the illness, and normal adolescent activities. Again, ongoing honest communication typically facilitates attaining and maintaining this balance.

For children, maintaining as much of a "normal" life as possible under the "abnormal" conditions of a serious illness in a parent can be a challenging yet important endeavor. Clinicians can think with parents about how they can facilitate this relative normalcy by maintaining structure and routines, protecting family time, designating illness-free time (when the illness is not a topic of discussion or focus of activity), and anticipating changes and preparing for them.

When David had his seizure, he was afraid to drive for a while because he worried he could have another seizure at any time. Although he knew this was unlikely if he took good care of his blood sugar, he was hesitant nonetheless. This meant that Irene had to juggle more than her usual heavy load and was now responsible for taking Monica to play practice and voice lessons, as well as Jason to soccer practice—not to mention driving for all other household errands and social events. This was a significant change in role for Irene, because she and David had always shared the transportation of children and running errands, and she struggled to manage the new demands. She was able to share with David that she understood his concerns and that she felt it was important that he also understand the additional time the increased driving was taking her, as well as the challenges she was having in keeping up with everything as a result. They were able to commit to working together to find a solution that was agreeable to both. They decided to talk with the doctor about David's fears and, if need be, to obtain help with driving from a close family friend. They decided they would only change the children's schedules as a last resort.

With open communication and thoughtful consideration of each family member's needs, along with the collective needs of the family unit, a balance can be struck to maximize autonomy while maintaining intimacy and appropriate family cohesion. The challenge of living with the illness can be seen as a family struggle that affects all members as well as the unit, and is best faced and managed collectively. Clinicians may share the image that family members stand together as a team with interlinked arms—facing the opponent of chronic illness. This image not only highlights the cohesion of the family, but also identifies the true cause of the challenges, which is the illness itself. It is normal that all family members have negative feelings about the difficult circumstances that an illness can bring. Some of these feelings may seem shameful or be a source of guilt for family members, including children. Sometimes members may wish another family was dealing with the illness instead of their own. They may wish the ill person would die quickly to end suffering or to end the burden of caregiving. They may wish to escape and wonder about leaving the family. Clinicians can facilitate the sensitive expression, normalization, and validation of these feelings, which can be important for family members. When these feelings are shared in a format with everyone being "on the same team," with the illness as the true adversary and the

focus of negative feelings, family members can come together in support of one another instead of directing the feelings toward one another.

That being said, all families have typical ups and downs, and when a parent is sick, a common interpretation of distress is that it is caused by the illness. When parents share that their children are changing, clinicians can suggest that parents:

1. Consider whether the change is due to normal development rather than the illness.
2. Ask healthy adults if they have noted similar changes in their children.
3. Speak to the child directly about the observed changes and exploring the child's own observations and explanations.

An open-ended, nonjudgmental approach is usually most appreciated by the children and can garner significant information.

TERMINAL PHASE

The *terminal phase* of the illness involves a family's recognizing the impending loss of a loved one and coming to terms with the loss of what is, and could be. Parents and children alike may consider the future milestones that will be celebrated without the dying parent. Grief can be profound for all involved, but thoughtful preparation can be helpful.

If the terminal phase provides enough time, many families take the opportunity to discuss unresolved issues in hopes that no one will be left holding regrets. In addition, parents can plan ahead for the ongoing care and support of children. If the dying parent has a custodial co-parent already, then the two may brainstorm about what sorts of resources (both human and otherwise) could be helpful as the remaining parent continues raising the children. Some parents may opt to designate a close family member or lifelong friend who knows the dying parent well to be a guiding mentor, support, and a living legacy who can share a life history of the dying parent with a child. Thoughtful choosing of a supportive adult that has a good rapport and "fit" with a child is important, and a different adult might be selected for each child in the family. Similar considerations may be relevant in choosing a custodial guardian if the dying parent is single, with the important additional component of legal arrangements being required. Obtaining legal counsel to help with these arrangements should be advised by clinicians to ensure a smooth transition in the custody and care of children losing their only parent. Parents might also consider making appropriate financial plans for their children.

Other types of legacies may also be considered and prepared by the dying parent, such as letters, scrapbooks, videos, or voice recordings. These can be tangible ways in which children feel connected to a parent as they continue to grow and develop even after the parent is gone. Through such legacies, parents can be encouraged to reflect on and share favorite memories and moments with the child, their love and pride

for the child, and their intimate knowledge of the child. However, it is best if parents do not include critical materials (even with the good intention to spur self-improvement) or specific expectations for the child. Children will likely revisit these legacies many times at different stages of their lives. Material that could be viewed as critical, or parental expectations that have gone unfulfilled, could be a source of significant shame or guilt for a child later in life. Legacy leaving is discussed more in depth by Rauch and Muriel (2006).

During the terminal phase of the illness, parents often reach a point where a decision has to be made regarding treatment goals. Individuals vary widely in what types of treatment they accept and for how long. Parents of children at home are often willing to trade quality of life to gain a survival advantage (Yellen & Cella, 1995). However, at some point in the terminal phase, a parent's healthcare team will likely advise the parent that pursuing active treatment will no longer provide an additional survival benefit. Recommendations may include transitioning the course of treatment towards palliative care. Clinicians can help parents to share the news of the transition to palliative care with children by thinking with them about age-appropriate explanations. For example, parents may say that even after receiving the best treatments available, the illness is not responding the way everyone hoped it would, and more medicine cannot make the illness go away. For some medications, there may even be negative side effects that could make the parent feel worse if continued. Parents can describe how the new treatment goals are to improve the quality of life for the parent, to decrease pain and suffering, and to sustain functionality as much as possible. Parents can also describe their goal as being to live as well as they can, for as long as they can.

Once a parent requires significant care from others, which can be both physically and emotionally challenging, a decision may need to be made about whether this care should occur at home or at a hospice facility. Clinicians can help parents to think about the many variables involved in making this decision. Sometimes the dying parent wishes to spend the last days in the comfort of home, and this can be accomplished for many, even with children there. When a dying parent is quite ill at home, the location and setup of the space should be considered. Children may want to frequently see the dying parent, but may be distressed by some aspects of the terminal illness such as moments of great pain, agitation, or confusion. It is helpful for children to have space at home that serves as a reprieve from exposure to emotionally difficult situations.

Hospice care in a setting outside the home can be an appropriate choice for other families, as the healthy parent may not be able to adequately care for the dying parent, or some children may feel extremely anxious knowing the parent is going to die soon in the room down the hall. A thoughtful approach to either scenario can help children be resilient even in the final stages of a parent's serious illness. Clinicians can guide parents to help children say goodbye in ways that foster a minimizing of regrets both in the present and in the future. For each child this may mean the goodbye is quite different, but addressing unfinished business, sharing important feelings and sentiments, and spending time together in meaningful ways can diminish future regrets.

SURVIVORSHIP PHASE

While survivorship can mean many things, including the time following diagnosis, it is used here to describe the phase of illness encompassing remission or cure from a serious illness that has the threat of future return in some form. Not all illnesses have this phase, as sometimes remission or cure is not possible. However, when remission has occurred the threat of recurrence is a unique challenge.

A parent who has survived a serious illness knows first-hand the toll such an illness can take on the body, mind, and family unit. Thus, the *survivorship phase* may be colored by a sense of anxiety—less intense than in the crisis phase, yet still significant in its effects. Many parents who have had cancer may worry about the cancer’s potential return and feel uncertain about the future (Lee-Jones et al., 1997). Anxiety may peak at various points of survivorship, such as before a check-up, while awaiting scan or other test results, or on the anniversary of the initial diagnosis. Some parents describe feeling like their emotions are “on a roller coaster” during this phase in the illness.

Children can be sensitive to these ups and downs and have their own interpretations and feelings about them. Some children may worry more, for example, when a parent ends treatment because they feel like less is being done for the parent proactively. Clinicians can recommend that parents reassure their children that the ill parent is still being actively monitored, and that the children will remain in the communication loop. If children know they will be informed about important news, it may allow them to resume daily living without feeling they have to monitor the parent for signs of relapse. Children may have input as to what type of news they would like to hear, as well as when, how, and by whom it is shared. Often a brief discussion of these variables when there is only good news to share can help parents properly set the stage should bad news arise.

For some parents who have experienced a serious illness, survivorship feels like a new lease on life, and significant life changes are made. Children may have various reactions to these changes, so preparation and explanations can be helpful. In addition, the skew in relationship roles that existed during the crisis and chronic phases may begin to rebalance. This transition can bring its own challenges as some family members resist relinquishing new roles, while others may want to hoist all prior responsibilities onto the now healthier parent who is not quite ready to return to the premorbid level of functioning. Honest yet gentle and respectful sharing of feelings can help families re-navigate roles.

After David’s seizure he grew more concerned than ever about his health. He decided to commit to a strict regimen of exercise, healthy eating, and adherence to his doctor’s recommendations about medication. He sought the help of his physician, a nutritionist, and a personal trainer, and lost over 100 pounds, getting close to his ideal body weight. His blood glucose stabilized significantly, and regular insulin injections were no longer necessary. He felt more energetic, engaged, and happier, and became more active in his children’s and family’s activities. He also took up some hobbies of his own, like long-distance running. While very glad about David’s new energy and optimism, his daughter Monica had some difficulties with his increased interest

in her personal life. She had come to value having more independence as a 17-year-old, and they began to have more heated discussions about his “intrusiveness.” After Irene noticed that Monica became upset when David asked more personal questions, they were able to sit down and discuss ways to balance David’s interest with Monica’s privacy, and what boundaries felt comfortable to both of them.

PSYCHOSOCIAL ASPECTS OF ILLNESS

The third lens through which an illness can be viewed, Rolland’s “psychosocial” aspects of the illness, can be thought of as its unique fingerprint. The acuteness of onset, typical course, likely outcomes, incapacitation, and overall predictability comprise this fingerprint and predict elements of the family’s experience.

ACUTENESS OF ONSET

Medical conditions with an acute onset, such as stroke, heart attack, or injuries from a motor vehicle accident often feel shocking and frightening at first. Their “out of the blue” nature means that family members are unprepared and often overwhelmed. Parents may want help in quickly finding age-appropriate language to describe what has occurred to their children, to reassure children that the immediate danger is over, and to explain what steps must now be taken to help the ill parent heal. A clinician knowledgeable about child development can be an invaluable resource to parents in these situations. Such a clinician can advise parents about age-appropriate language and concepts, which can be used when describing the acute medical circumstances to children.

Illnesses like cancer and diabetes often have a more gradual onset, where symptoms are noticed over time and diagnosis is not immediate. Parents may have some choice about how and when they will talk to children and thus can be better prepared. However, the ambiguity of the period leading up to a firm diagnosis often leaves parents feeling anxious and not ready to talk openly with their children about unconfirmed worries. Children are frequently aware that something is amiss but feel reluctant to ask questions, a combination that can lead to distress.

Clinicians can think with parents about what children are noticing about the ill parent at home, the changes the illness has caused in the family’s daily life, and how they can begin to talk about a still-uncertain diagnosis. Parents can continue to ask children what they are noticing so that parents can continue to explain any observed changes to their children.

Kelly and Jim describe telling their children about her diagnosis of pancreatic cancer as one of the hardest things they have ever done. They worried about how much each child would understand and how they would react, predicting that Brianna would “cry for days” and that Connor would not say much, but be “a bear to live with.” They were reluctant to use the word “cancer” for fear of scaring the children, but realized that they had probably already overheard it mentioned in phone conversations. After some thought, they were able to sit down with all three children and explain that Kelly’s string

of recent doctor's appointments had been to help figure out why her back was hurting so much, and that the doctors had just told them that Kelly has an illness called pancreatic cancer. They clarified that cancer is not the kind of illness that anyone else can catch just by being near her, and that nothing she or the children did or didn't do, gave her cancer. They also described how she would begin receiving a special, strong medicine to treat the cancer, called "chemotherapy."

Kelly and Jim went on to elicit the children's questions and reactions, to normalize their fear and sadness and acknowledge their own, and to talk concretely about how Kelly's diagnosis and treatment would affect each of the children's day-to-day lives. Michael, their 3-year-old, had a predictably shorter attention span than Connor or Brianna, but did hear explanations for a number of new words, and the message that some things would change but a lot would stay the same. Later that day, and regularly thereafter, both parents checked in with each child individually to help ensure that questions were clearly answered, and no child was worrying alone.

COURSE

Expectations about how a parent's illness will affect the family in the near and distant future are influenced by the typical course of the illness. Rolland suggests that it is useful to think about three types, including progressive, constant, or relapsing illness courses. A medical event such as a stroke or spinal cord injury may be thought of as having a fairly constant course. Major adjustments will likely need to be made almost immediately but, once accomplished, daily life may be fairly consistent and predictable over the longer term. A relapsing course, as with cancer, may feel more like a roller coaster with uncertainty about daily functioning, unpredictable changes that contribute to loss of control, and more frequent family reorganizing. A progressive illness is one that becomes gradually worse, necessitating incremental adjustments over time. Although changes may be fairly predictable and gradual, the fact that the future will certainly be more difficult makes a progressive course quite challenging.

Parents may benefit from having their experience described by such a framework, with an emphasis on identifying areas that continue to be controllable for them and their children. Clinicians can think with parents about how to make sure that the balance of responsibilities in the family is allowing each member's continued normal development; they can also discuss key points in the illness course where that balance should be reassessed. For example, changes in roles typically occur when the functional status of the ill parent changes due to new or worsening symptoms. Clinicians can help families anticipate and prepare for the changes at home that are likely to occur with a new limitation. Clinicians may ask about or suggest ways the parent's previous roles, which are now compromised, might be filled by other family members, friends, or community resources. Again, it is important for children's normal developmental needs and perspectives to be included in such planning.

Kelly's family had finally adjusted to the rigors of her chemotherapy schedule when she had to be admitted to the hospital on an emergency basis due to vomiting and abdominal bloating and pain. She underwent

stent placement to bypass a blockage in her small intestine. When she returned home, the routine had to change, again. Kelly was unable to manage the household tasks that she had fiercely insisted on doing, and was not supposed to drive right away. Their 6-year-old, Brianna, struggled a great deal with these new changes although her parents had described her as being so "flexible compared to her brothers" up until this point. When they talked with Brianna, she could only say that she wanted "the old Mommy" back. With a little more encouragement, she said that she missed her "Mommy-daughter" time. Initially confused, after some thought Kelly realized that Brianna had spent quite a bit of time with her as she completed household tasks—folding laundry, cooking dinner—and that Kelly's ability to allow her daughter to feel helpful was one of the things that gave Brianna a sense of control.

INCAPACITATION

Illness incapacitation includes the sorts of treatments required, and changes to the patient's and family's quality of life. For children, the impact of incapacitation is partly mediated by parents' coping styles as well as by their own developmental stage. For example, a parent's 5-day hospitalization may cause significant separation anxiety in a preschooler but be easily tolerated by an adolescent who is reassured that the parent will be better after the hospital stay. An elementary school-aged child who is told only that the parent is "having some tests" may have a harder time adjusting to a weak, postsurgery parent than a child who was told that "the doctors are going to remove the part of Mom's intestine that has cancer, and when she gets home she'll need a few weeks to really rest in bed."

Clinicians can guide parents to anticipate changes in the ill parent, so that parents can in turn prepare children. Parents can be encouraged to think about all the ways they can keep life as normal as possible for the family while dealing with a variety of symptoms. The medical team may need to remind parents of the importance of optimizing support networks and asking for help, redistributing roles in an equitable, flexible way, and checking in regularly with children about what are the best and worst parts of home life recently.

Certain changes are more salient to children than others, and should be explicitly discussed. These include side effects of many chemotherapy treatments like nausea, fatigue, and hair loss; gross physical changes following surgery, such as large scars, amputations, colostomy bags; mood changes and irritability common with steroid use; and changes in eating or feeding habits. Particularly confusing are some of the cognitive changes that occur as a result of brain injury or disease—word-finding difficulties, short-term memory deficit, lack of organization or focus in someone who previously "kept everyone on track."

David and his wife Irene noticed that 13-year-old Jason was more withdrawn and irritable than usual. Both asked him what was bothering him, but didn't get far. A light bulb went off for Irene when she was signing off on Jason's homework and noticed that his science class was doing a unit on hormonal systems, which included a discussion of diabetes. She asked him about what had been presented, and he shared that the teacher had mentioned that "frequently uncontrolled diabetes leads to foot or partial leg amputation." He was terrified that

his father's recent return to coaching would hasten such an outcome. Knowing this, David and Irene were able to describe for him all the ways that David was working to prevent such a serious problem, as well as to clarify the likelihood for most diabetics of needing an amputation.

When a parent has such significant changes in functioning that they seem “not themselves,” each family member will need to grapple with how to redefine his or her relationship to the parent. There may be aspects of the relationship that are unaffected by the illness and can still be enjoyed. For example, a father and 12-year-old son shared a love of astronomy—they frequently visited a local observatory, as well as programs at a science museum relating to space. After this father became bedridden, his son was crushed that their field trips were no longer possible. After talking together about how much they missed the trips, they hit on the idea of watching *Nova* episodes online and talking about them together. It wasn't as exciting as using the observatory telescope, but preserved their capacity to bond over a common interest.

OUTCOME

Illness outcome describes the likely effect of the illness on the patient's expected lifespan. Whether an illness is life-threatening or not usually has a substantial impact on how it is experienced by the family. However, sometimes the seriousness of this threat is not obvious to children. In our case study, David's adolescents had not realized prior to his seizure that uncontrolled blood sugar levels could be a medical emergency and even fatal. When an illness worsens quality of life but is not life-threatening, parents should make this point clearly to children. A younger child whose mother experienced severe fatigue from rheumatoid arthritis worried that she might come home and find her mother “asleep forever in bed.” What seems more difficult to many parents is how to talk about an illness that is life-threatening or likely to be fatal.

In regard to the possibility of a parent's dying, clinicians may remind parents that children are often focused much more on the here and now. A question like, “Is Mom going to die?” often reflects worry about losing a parent in the near future (weeks to months). Parents, however, tend to think many years ahead and thus struggle with how to answer honestly while not worrying children needlessly. When possible, parents can create a “safety zone” for their children, as Kelly tried to do shortly after her diagnosis when asked by 8-year-old Connor, “Can't you die from cancer?”

“I'm glad you asked that tough question. You're right, people can die from cancer. But, right now no one is worrying about my dying . . . my doctors are focused on treating this disease and helping me feel better. I'm hoping that the next 4 months of treatment will leave me feeling well enough to take our usual summer trip. If anything changes, I'll let you know, ok?”

PREDICTABILITY

The predictability of an illness guides the family's expectations for what the near future will look like. Predictability is

somewhat in the eye of the beholder, as patients and families vary in how much they want to know about what *could* happen, and the same event may surprise some families but not others. While some families feel as though the best they can do is “expect the unexpected,” frequently there are patterns in certain aspects of the illness that become familiar and thus can be discussed and experienced as more controllable. For example, it is not uncommon for a patient who is very anxious at the start of chemotherapy to complete the final round feeling as though it is almost routine. Children may never be happy about a parent's needing to stay in bed for 2 days after treatment, but knowing which 2 days the parent will be less available can help.

Some families are also experienced at preparing for the unexpected, and these skills can be useful in the context of an unpredictable medical illness. Clinicians can help parents to anticipate events that might affect the children, such as emergency hospitalization, an ambulance at the home, the possibility of a seizure, and the potential of abrupt schedule changes. Parents can then consider whether there are plans to make that would minimize disruptions for children. For example, the family might discuss who would be available to come over in the middle of the night to care for children if needed, or post a list of important phone numbers, or review how to call an ambulance and what to say to the operator. When a family does get taken by surprise by some new development, it can help to discuss their response and what worked well and less well. This may enhance their sense of control about the possibility of managing something similar in the future.

David's diabetes had seemed fairly stable to his children for quite a while when they witnessed his seizure. Both were frightened by what they saw, and his daughter Monica later told her parents that she couldn't stop worrying that it would happen again. In hindsight, David and his wife Irene wished they had mentioned to their children that a seizure was a possibility, and what to do in response. Monica had called 911 while Jason stayed with his father, but neither knew the signs of the oncoming seizure or were aware that a sugary snack was what he needed in time to prevent it. Once the family discussed this information, both Monica and Jason felt more confident that they could help their father in the future.

SUMMARY

There are millions of parents in the United States and around the world who are living with serious illnesses and caring for children at home. Given that a serious illness can affect the physical and psychological functioning of a parent, the effects on the family (and children within the family) can be significant. As outlined throughout this chapter, and summarized in Table 12.1, there are a number of variables related to both the family and the illness than can modify the family's response to the illness. With thoughtful consideration of these variables, clinicians can provide parents with guidance that enhances the resiliency of children as they anticipate and experience some of the challenges an illness can bring.

Table 12.1 SUGGESTIONS TO CLINICIANS

	CRISIS PHASE	CHRONIC AND SURVIVORSHIP PHASES	TERMINAL PHASE
Parent of:	<p>Focus on maintaining children's sense of safety and security.</p> <ul style="list-style-type: none"> • Consistent rules and routines when possible • Identify readily available supports 	<p>Promote a sense of the family as a team, with more in common than just the illness.</p> <p>Be mindful of how role changes impact each person's development.</p>	<p>Focus on making the most of the time together for as long as possible, and on leaving children tangible reminders of the parent's love.</p> <p>Consider setting of end-of-life care from both adult and child perspectives.</p>
Toddler (1–3)	<ul style="list-style-type: none"> • Familiar caregivers • Consistent routines and micro-environment (portable crib and blankets) • Transitional objects available (blankie, stuffed rabbit) 	<ul style="list-style-type: none"> • Honest assessment of what additional help with child may be required, how often, and who is available • Written routines for caregivers • Prepare for toddler distress with parental absence • Be patient with regression 	<ul style="list-style-type: none"> • Preverbal, will have few memories of the parent • Consider letters, videotaping, annotated photos from parent • Identify people who can tell stories about the parent as child gets older
Pre-schooler (3–5)	<ul style="list-style-type: none"> • Provide basic information (who and what) • Confirm the child's lack of responsibility for the illness • Specify immediate impact on child • Minimize displays of strong parental emotion to child • Name child's emotions • Familiar caregivers, the fewer the better 	<ul style="list-style-type: none"> • Be understanding about egocentric concerns and requests • Emerging anxieties about the world (e.g., fear of the dark, monsters) are developmentally normal but may be heightened; be prepared to seek help if they are very distressing or long-lived • Be patient with regression but keep expectations consistent (e.g., use your words, not your hands) • Encourage teachers to maintain preschool's normalcy • Correct misperceptions and self blame about parent's mood or functioning 	<ul style="list-style-type: none"> • Consider letters, videotaping, annotated photos from parent • Provide notice of an imminent death, when known, so child has the option of a last visit • Many strangers in the home may be upsetting • Be clear that adult distress is not the child's fault
Grade-schooler (6–12)	<ul style="list-style-type: none"> • Provide simple, age-appropriate information about diagnosis and treatment • Clarify risk of contagion • Specify short-term impact on child • Ask what has been noticed and explain child's observations • Minimize displays of strong parental emotion to child • Elicit, discuss, normalize child's emotions • Emphasize areas of control 	<ul style="list-style-type: none"> • Separate treatment side effects from illness progression • Clarify risk of contagion • Child's distress will often be unrelated to parental illness; remember to inquire about child's own individual challenges • Consider what the ill parent uniquely provides the child and save time and energy for those functions • Maintain consistent school routine and expectations • Protect family time not focused on the illness 	<ul style="list-style-type: none"> • Begin to discuss the idea that the parent will not get better • Plan how to answer, "Will you die?" • Help child express love, in ways that are comfortable to child • Consider impact of setting of parent's care on child's access to parent and exposure to suffering • As above, consider leaving a written legacy to child • If death is imminent, may discuss how child wants to be notified
Adolescent (13–18)	<ul style="list-style-type: none"> • Provide age-appropriate information about who, what, when, where and why • Specify impact on child • Ask what has been noticed and explain child's observations • Elicit, discuss, normalize child's emotions while respecting privacy • Emphasize areas of control • Encourage reliance on friends, trusted adults for additional support 	<ul style="list-style-type: none"> • Include adolescent in discussions about role changes and new responsibilities; find a fair balance • Monitor teens, watch for risk-taking behavior • Provide enough information about expected changes so teens can make informed decisions about the future • Protect family time not focused on the illness, while respecting the adolescent's need for time with peers 	<ul style="list-style-type: none"> • Suggestions for grade-schoolers apply • Acknowledge the love underlying conflictual relationships • Demonstrate that surviving parent has ample support from other adults • Help adolescent make choices that will minimize regrets, without suggesting that they will or should have regrets

CLINICAL PEARLS

- As couples prepare for parenthood:
 - Encourage couples to build or broaden support networks.
 - Help couples anticipate the likely changes and practical needs they will have.
 - Emphasize communicating about and preparing for the added workload of parenthood
- For patients with young children: Clinicians can think creatively with parents about how to engage supports and utilize resources to increase consistency of routines for the children.
- For school age children: Encourage ongoing communication about the parent's medical condition with the children so children can understand and adjust to the ways their family may differ from others. Clinicians may help parents determine what tasks can be delegated to friends, family, or paid helpers, and what functions only they themselves can fulfill in their children's lives.
- For adolescents: Clinicians can help parents support their adolescents' friendships and "launch" into the world, while maintaining reasonable expectations for teens providing help at home.
- For young adult children: Clinicians should encourage parents to invite their adult children to engage in this communication and even to discuss how the communication is going.
 - Is the family talking too much, too little, or just the right amount about the illness?
 - Are people discussing the various aspects of the illness and its consequences that are important to everyone?
- At points in illness: Clinicians can suggest that parents inform their children that the ill parent is getting good care, getting the proper tests, and the immediately appropriate treatment (if applicable).
- Parents need not have all the answers, but the power of a parent's listening to and thinking with a child is immense.
- In the time after acute treatment, when things are better: Clinicians can recommend that parents reassure their children that the ill parent is still being actively monitored and that the children will remain in the communication loop.
- Children may have input as to what type of news they would like to hear, as well as when, how, and by whom it is shared. Often a brief discussion when there is only good news to share can help parents properly set the stage should bad news arise.
- Clinicians can think with parents about how to make sure that the balance of responsibilities in the family is allowing each member's continued normal development; they can also discuss key points in the illness course where that balance should be reassessed.

GROUP PSYCHOTHERAPY FOR MEDICALLY ILL POPULATIONS

Cheryl Gore-Felton and David Spiegel

INTRODUCTION

Decades of research has resulted in compelling evidence for the efficacy of group psychotherapy in reducing psychiatric and physical symptoms, as well as increasing social support among medically ill patients (Blake-Mortimer et al., 1999; Reuter et al., 2010). The diagnosis of an acute, chronic, or life-threatening illness poses challenges to individuals and their families that have considerable impact on psychosocial functioning. Patients are confronted with the sense of their own mortality, which often causes acute stress and, in some cases, chronic stress with substantial disturbance in psychiatric functioning that can be quite disabling (Blake-Mortimer et al., 1999; Evans et al., 2005).

Using group psychotherapy to treat medically ill populations has its origins at the beginning of the 20th century when social workers and physicians began co-leading groups of tuberculosis patients (Fobair, 1997). The focus of these groups was on providing patients with information, education, and support to deal with their illness. Groups developed specifically for cancer patients were first reported in the 1970s (Franzino et al., 1976; Yalom & Greaves, 1977).

Although individual psychotherapy has demonstrated efficacy in reducing psychological distress, group psychotherapy has particular advantages over individual therapy, in that it provides validation for normative processes that would otherwise be seen as abnormal, emotional support, exposure to new interpersonal and coping skills, symptom relief, and enhanced competence (Yalom, 1995). Moreover, there is burgeoning evidence of biobehavioral mechanisms that help to explain why groups are effective in enhancing psychosocial functioning. For example, Taylor et al. (2000) put forth a theoretical model of stress response in females that relies heavily on the influence of the hormone oxytocin to explain affiliative responses under duress. She also noted that such groups provide opportunities for “downward comparisons,” finding ways to feel fortunate in relation to others with similar problems. In addition, groups offer an opportunity for people to consolidate their own sense of competence in coping with problems by helping others with similar problems (Yalom & Greaves, 1977; Ferlic et al., 1979; Cummings & VandenBos, 1981; Mumford et al., 1984; Fawzy et al., 1990; Greer, 1991; Strain et al., 1991; Spiegel, 1993; Mittelman et al., 1996; Edelman et al., 1999; Block, 2001).

Although few would disagree that there is a robust empirical literature indicating the positive effects of group therapy on psychological well-being, there remains disagreement about whether or not group therapy can enhance health by altering disease processes. Indeed, people often ask, “Do groups help cancer patients live longer?” In this chapter we describe the rationale for group therapy among medically ill populations; the effects of group therapy on psychosocial, biomedical, and survival outcomes; different methods of group therapy; and group leadership issues. We emphasize intervention with patients diagnosed with cancer, human immunodeficiency virus (HIV), and acquired immune deficiency syndrome (AIDS). In this chapter we quote statements made by participants in therapy groups for patients with chronic general medical conditions that we have led personally. All patient quotes not otherwise attributed are from participants in our own groups.

RATIONALE FOR GROUP THERAPY

As the treatments for life-threatening illnesses such as cancer and AIDS continue to improve, individuals are living longer and healthier lives. This has resulted in these illnesses being thought of as chronic instead of terminal. The management of chronic illnesses poses challenges for patients and physicians, often requiring approaches that enhance the quality of survivorship. Indeed, the impact of chronic, serious illness on social, psychological, and physical demands faced by patients and their families can be profound and may require assistance to make adaptive changes (see chapter 11 on family therapy).

Although the treatments for cancer and AIDS have resulted in more life years, these medical treatments often contribute to survival at considerable cost. For instance, the physiological long-term and late effects of therapies for adult cancer can cause a variety of problems. These problems can include energy loss, sexual dysfunction, cognitive impairment, (Kesler et al., 2009) lymphedema, physical disfigurement, and major physiological complications that impair organ systems and can cause death (Loescher et al., 1989). Similarly, among patients with AIDS, long-term use of highly active antiretroviral therapy (HAART) has resulted in a wide range of disorders that include metabolic (Moyle, 2007) and dermatological disorders (Luther & Glesby, 2007) and alterations in serum lipids (Riddler et al.,

2003). These physiological impairments can have significant adverse effects on psychological as well as social functioning.

EFFECTS OF CHRONIC ILLNESS ON MOOD

Mood disorders are prevalent among the medically ill and occur at much higher rates than the general population. The lifetime prevalence rate of major depression in the US general population is estimated at 16%, while the prevalence among medically ill patients ranges from 20%–50% (Kessler et al., 2003). Moreover, there is evidence suggesting that depression significantly contributes to the progression of medical illness, worsening prognosis (Evans et al., 2005).

CANCER PATIENTS

Depression among cancer patients is associated with poor prognosis (Giese-Davis et al., 2011) and increased morbidity (Evans et al., 2005). The exact mechanism of this relationship remains unclear, resulting in no empirically validated standardized approach to treat depression among such patients. In recent years, research to develop efficacious interventions that ameliorate depression has increased. Researchers have also begun to examine pathways other than neurotransmitters to explain symptoms of depression. Psychiatric illnesses like depression were once thought to be solely brain disorders, but there is a growing body of research which asserts that an activated immune system that secretes cytokines is responsible for depression and explains the association of depression with disease (Capuron & Dantzer, 2003). Cytokines can cross the blood–brain barrier, and once in the brain they can cause all of the symptoms found in depression (e.g., fatigue, depressed mood, lack of interest; see Capuron & Dantzer, 2003). Indeed, a complex relationship between psychosocial factors, endocrine activation, circadian rhythms, immune defenses, and tumor progression suggests that interventions that enhance psychological functioning may influence biological functioning, thereby bolstering survival (Sephton & Spiegel, 2003). For instance, it has been asserted that the disruption of sleep/wake rhythms and corresponding sleep debt may suppress the cancer fighting immune response (Vgontzas & Chrousos, 2002). If this is true, then psychotherapy that focuses on reducing stress and regulating sleep patterns using sleep hygiene protocols (for review, see Stepanski & Wyatt, 2003) may be a very effective, noninvasive treatment that improves cancer survival.

Psychotherapeutic intervention can be beneficial at any time during diagnosis and treatment; however, there are indications that treatment may be particularly beneficial immediately following diagnosis. For example, patients' patterns of coping with a cancer diagnosis (Dunkel-Schetter et al., 1992) and the types of psychosocial needs expressed (Liang et al., 1990) usually do not change significantly after the initial diagnosis. Moreover, newly diagnosed patients are particularly vulnerable to severe emotional distress. A study of newly diagnosed patients with breast, colorectal, head and neck, lung, and prostate carcinomas, as well as skin cancers other than malignant melanoma, found that almost all (96%)

reported current symptoms of fatigue (66%), worry (61%), difficulty sleeping (48%), and pain (42%) (Whelan et al., 1997). For women, breast cancer is the most prevalent type of cancer, accounting for almost one-quarter of all cancer cases (Parkin et al., 2005). Treatment advances have resulted in women surviving longer, and with that comes treatment-related problems that are often persistent (e.g., vasomotor symptoms, body image, & fatigue), resulting in decreased quality of life (Duijts et al., 2011).

HIV/AIDS PATIENTS

Similar to breast cancer patients, newly diagnosed HIV or AIDS patients often experience severe emotional distress. Notification of positive HIV serostatus can be accompanied by depression, fear, anxiety, anger (Naar-King et al., 2007), and feelings associated with stigma (Alonzo & Reynolds, 1995). There is a growing body of evidence that indicates that depression, stressful life events, and trauma influence the course of HIV disease (Leserman, 2008). While the causal pathways of this relationship continue to be explored, there is evidence suggesting that behavioral mechanisms may account for part of the relationship: namely, depression, mood disturbance, and poor coping strategies to deal with stress predict noncompliance with antiretroviral therapy in HIV-positive patients, which has deleterious effects on health outcomes (Gore-Felton & Koopman, 2008). Interestingly, there is evidence that suggests that a positive psychosocial factor such as optimism is associated with better health behaviors and slower HIV disease progression (Ironson & Hayward, 2008).

The emotions that accompany life-threatening diagnosis and treatment are necessary responses to multiple problems that accompany the diagnosis. Typical emotional responses include a radical alteration in one's sense of self, which is frequently followed by a decrease in self-esteem, fear of abandonment, uncertainty about disease progression, and fear of dying and death. The distress can be chronic for some patients. There is evidence that less social support is associated with disease progression in breast cancer and HIV-positive patients. In a prospective study of 2,835 women diagnosed with stages 1 to 4 breast cancer, social isolation was associated with a 66% increased risk of all-cause mortality and a twofold increased risk of breast cancer mortality (Kroenke et al., 2006). Similarly, in a sample of 96 men followed prospectively for up to 9 years, higher cumulative average stressful life events and lower cumulative average social support predicted faster progression to AIDS (Leserman et al., 2002).

IMPACT OF CHRONIC ILLNESS ON SOCIAL SUPPORT

Despite the positive influence of social support on health, individuals suffering from chronic medical problems often find themselves with diminished social resources (White et al., 1992). Part of the explanation for this may be the amount of pain and suffering that is associated with the illness. For

example, cancer-related pain is associated with decreased physical and social activity (Strang, 1992). Additionally, the psychosocial impact of the illness on family members can be so overwhelming that their ability to be a source of support to the patient is diminished.

When a spouse is diagnosed with cancer, the threat of possible death and disability coupled with the financial burden of surgery and treatment can cause long-term loss of stability in family roles (Northouse, 1988). Moreover, existing family problems are often intensified, which creates a fragile family structure in which members are less capable of providing much-needed support (Cohen & Wellisch, 1974).

Distress increases among family members as the dying process ensues (Gotay, 1984; Northouse, 1988). The ability of the family to openly communicate about the probability of dying has been linked to positive adjustment, cohesion, and decreased conflict during terminal illness (Spiegel et al., 1983; Northouse, 1988; Block, 2001), and it has also been linked to better adjustment for the bereaved following the patient's death (Cohen & Wellisch, 1974; Northouse, 1988). When communication is poor, family members may restrict their expression of feelings as they attempt to protect one another from awareness of death. Also, family members may experience a sense of social isolation as those closest to the family find it difficult to visit the patient because of confusion about how much to say (Cohen & Wellisch, 1974; Northouse, 1988). Furthermore, excessive focus on aggressive medical treatment with apparent curative intent rather than hospice care is associated with poor end-of-life care (Earle et al., 2003), more depression, and even shorter survival. (Temel et al., 2010).

Understandably, significant others have difficulty coping with the patient's illness. As a woman diagnosed with AIDS stated in group: "My husband is acting like he is the one who is sick. I feel like I have to take care of him, and it should be the other way around."

Family and friends generally share the patient's anxiety, fear, and feelings of powerlessness, but they also struggle with accepting the physiological as well as psychological changes that accompany their loved one's diagnosis. The patient is likely to experience a pervasive sense of loss of control, often accompanied by feelings of isolation, and is in need of support. However, because of the psychological distress that the support system experiences, the patient may find that the support system is inadequate. Moreover, any conflict or unresolved issues that were part of the family before the patient became ill will complicate the family's as well as the patient's ability to adapt to the impending physical and psychological changes. In addition, patients with young children often experience considerable anxiety about how their illness will affect their children's lives. This is particularly true for single mothers who do not have adequate support systems to take care of their children if they become incapacitated or die.

Furthermore, loved ones often experience helplessness, which may manifest itself as feelings of inadequacy. These emotions frequently translate into cognitions such as, "I can't fix it," as family members and friends withdraw into silence or actually physically distance themselves. The impact of this

withdrawal on patients can be devastating. For example, in one group an HIV-positive woman sobbed:

"We are having a family reunion next month, and I called my grandmother to tell her when I would arrive. She told me I would have to stay in a motel because she didn't want me using her bathroom. Part of me thinks she is scared of getting something, but most of me thinks she just doesn't want to be bothered."

The overwhelming sense of rejection catapulted this patient into depression and a marked awareness of abandonment and aloneness.

The negative psychosocial impact on individuals and family members provides a rationale for group intervention for the medically ill. Moreover, group psychotherapy is a highly effective and efficient treatment modality that provides immediate social support, a "social laboratory" for assessing problems and trying out solutions, and a means of finding commonalities and differences (Spiegel, 1993; Yalom, 1995).

INDIVIDUAL VERSUS GROUP THERAPY

There is evidence that individuals benefit from individual psychotherapy (Cain et al., 1986); however, group therapy has been shown to be at least as effective (Cain et al., 1986; Fawzy et al., 1996; Hosaka, 1996). Moreover, group therapy offers unique advantages as a psychotherapeutic intervention, and many studies have demonstrated positive effects of group therapy for cancer patients. These positive outcomes include beneficial effects on mood, adjustment, and pain (Gustafson & Whitman, 1978; Wood et al., 1978; Ferlic et al., 1979; Spiegel et al., 1981; Spiegel & Bloom, 1983; Fawzy et al., 1990; Butler et al., 2009).

Group psychotherapy offers four unique advantages over individual therapy:

1. *Universality.* Many patients are socially isolated from others who are suffering from the same illness. Thus, the power of a group allows patients the opportunity to experience others who are facing the same problems. This realization assists patients in disconfirming their feelings of uniqueness, which is often experienced as relief (Yalom, 1995). Individual therapy also assists patients in normalizing their feelings and behaviors, but there is no opportunity for patients to experience consensual validation and at the same time develop interpersonal intimacy with others who have suffered similar experiences. When patients come to realize that problems they thought were the result of their own poor coping also happen to others, it becomes clear that the problems are inherent to the disease process rather than to their particular personality and life situation. This realization helps patients accept their situation while at the same time assists them in overcoming feelings of stigmatization that occur with diseases such as cancer and HIV/AIDS. In learning to like and

respect others who are coping with similar problems, they come to like and respect themselves.

2. *Helper-therapy principle.* The helper-therapy principle is the process through which patients gain enhanced self-efficacy through their ability to help others (Riessman, 1965). Having cancer or AIDS is a meaningless tragedy to patients. But using that experience to be able to help others going through a similar situation enhances one's sense of competence and helps to develop a renewed sense of meaning in life; in other words, something genuinely good emerges from a bad situation. Helping others has been extremely beneficial to women attending a support group for women living with HIV/AIDS. For example, a woman in a HIV/AIDS support group stated:

"There are times when I'm so sick of being sick and tired, then I come to group and something I say is helpful to someone else. It makes me think that I'm good for something and my life is not so meaningless after all."

Group therapy increases the likelihood of constructive compassion with other patients (Yalom, 1995). The group format allows patients to give unique support to one another and provides an expanded social network, role models for coping with various aspects of the illness, and an opportunity to enhance self-esteem by giving concrete help to others in a similar situation.

3. *Social support.* An often-noted benefit of attendance at support groups is that members can relate to each other in special ways that counter the social isolation they often experience after a diagnosis (Tracy & Gussow, 1976; Toseland & Hacker, 1982). Being part of a group can afford patients a sense of community necessary for successful coping and provide opportunities to learn from one another (Spiegel, 1993). Members come to feel part of a new and accepting social group in which their common bond is the very thing that makes them feel excluded in the outside world (Spiegel, 1993). They can contact one another outside group meetings and thereby develop a new support network.
4. *Cost effectiveness.* Group therapy is clearly more cost effective than individual therapy, in that it makes limited professional resources available to many more people. Economically, group therapy may be up to four times more affordable for patients and for institutions (Hellman et al., 1990; Yalom & Yalom, 1990). Two well-conducted meta-analytic studies demonstrate that psychoeducational (Devine, 1992) and psychotherapeutic (Mumford et al., 1984) interventions produce cost savings in medical treatment. Mumford et al. (1984) examined 58 cost-offset studies and found that there was a significant reduction in inpatient costs (e.g., reduction in hospitalization) following outpatient psychotherapy. Devine (1992) analyzed 191 studies

that examined the effects of psychoeducational care on recovery, postoperative pain, and psychological distress in surgical patients. Across studies, psychoeducational care resulted in faster postoperative recovery, less postoperative pain, and less psychological distress. Moreover, there is evidence indicating that psychosocial intervention in medically ill patients results in shorter hospital stays (Mumford et al., 1984; Devine, 1992) and reduced distress-related outpatient visits to doctors (Cummings & VandenBos, 1981; Lorig et al., 1985; Browne et al., 1990). Thus, as a method of improving adaptive coping, improving adherence to complex and difficult medical treatments, preventing clinically significant anxiety and depression, and treating more serious psychiatric comorbidities, group psychotherapies are both effective and cost effective. Such interventions are far less expensive than other routine medical and surgical treatments for cancer and HIV, and the risk-benefit ratio is highly favorable. While growing healthcare costs are a problem, this is not a rational place to economize. Indeed, with the growing body of research suggesting that a viable pathway to tumor suppression is through psychosocial factors, it would seem prudent for medical health centers and hospitals to explore methods of delivering psychosocial interventions as adjuvant treatment to individuals with serious medical illnesses as the standard of care.

EFFECTIVENESS OF GROUP THERAPY AS ADJUNCTIVE TREATMENT

There have been a number of research studies that have assessed the effectiveness of group psychotherapy for cancer patients. There is also a growing body of literature examining the effects of group psychotherapy for people living with HIV/AIDS. The range of intervention types has increased over the past decade to include cognitive behavioral, psychoeducational, cognitive existential, and mindfulness approaches. The literature illuminates several psychosocial domains that have shown improvement with group psychotherapy: psychological distress, interpersonal functioning, quality of life, and survival.

PSYCHOLOGICAL DISTRESS

One of the first published studies examining the effects of group therapy was conducted by (Bloom et al., 1978). This important research revealed that patients who received group therapy had significantly higher levels of personal control compared to patients who received only standard medical care. The study was limited by small sample size and nonrandomization, making it difficult to generalize the results to the general population.

Building on several studies (Spiegel & Yalom, 1978; Bloom et al., 1978; Wood et al., 1978; Ferlic et al., 1979; Maisiak et al., 1981; Cain et al., 1986; Spiegel et al., 1981) Spiegel and colleagues conducted a one year prospective study

examining the effects of support groups for metastatic breast cancer patients. Oncologists referred 109 women to the study, and each participant was randomly assigned to either a weekly support group or a control group who received standard medical care. The group was facilitated by a psychiatrist and a social worker. Evaluations at 4 and 8 months showed no significant differences between the groups; however, at 12 months patients in the support group had significantly better coping styles, fewer phobias, and less confusion and fatigue compared to the control group. Furthermore, additional research has supported the finding that group psychotherapy is effective in improving overall mood, anxiety, and coping (Cunningham et al., 1993; Fawzy et al., 1990). This reduction in distress has been replicated in a new sample involving 125 women with metastatic breast cancer (Classen et al., 2001). In this study, the dependent variable was a reduction in scores on the Impact of Event Scale. The intervention group in this randomized trial also experienced a significant reduction in pain compared to the control group (Butler et al., 2009).

Various group interventions provide psychological benefits to cancer patients, independent of stage of diagnosis or type of treatment (Bottomley, 1997). Specifically, there is clear evidence that group psychotherapy for cancer patients is effective in reducing anxiety and depression (Gustafson & Whitman, 1978; Wood et al., 1978; Ferlic et al., 1979; Spiegel et al., 1981; Spiegel & Bloom, 1983; Mulder et al., 1992) and improving coping skills (Fawzy et al., 1990).

Group therapy has an opportunity to prevent full anxiety and depressive syndromes in cancer patients. The idea of preventing rather than treating anxiety and depression among cancer patients was tested in a large individual intervention trial (N = 465; see Pitceathly et al., 2009). The brief intervention, a cognitive behavioral format with two telephone sessions following the initial visit shortly after cancer diagnosis, was effective in reducing the incidence of anxiety and depression among high-risk but not low-risk patients. Clearly, there is a continuum from normal fear to anxiety and from sadness to depression. Some adverse affective response can be expected with the diagnosis and treatment of cancer. Interventions in the medical setting may help people manage their normal emotional responses to adverse medical conditions, and reduce or in some cases prevent the development of clinically significant symptoms of anxiety and depression. There is a continuum also between disease-related stress and clinical psychopathology. Often patients and their families are more receptive to receiving help with stress management than with psychiatric problems. Group interventions have the advantage of “normalizing” stress responses and potentially reducing the risk of developing more serious emotional problems. This intermediate zone of psychopathology is often diagnosed within the domain of “adjustment disorders” (American Psychiatric Association, 2000). While a substantial minority of cancer patients meet diagnostic criteria for clinical anxiety and depression (Derogatis et al., 1983; Breitbart et al., 1995; Grassi & Rosti, 1996), the majority have adjustment problems that may well benefit from group and individual psychotherapeutic intervention.

Meta-analyses of the psychosocial effects of group psychotherapies for cancer patients have generally concluded that there are robust treatment effects. One analyzing for three dependent outcomes among breast cancer patients— anxiety, depression, and quality of life, (Naaman et al., 2009)—concluded that there was a moderate effect for anxiety and a moderate to strong effect for depression. More severely affected patients showed a stronger improvement in quality of life with group intervention. The researchers also concluded that short-term interventions emphasizing coping skills seemed more effective for those with early-stage disease, while those with more advanced breast cancer benefitted more from longer interventions emphasizing support. A *Cochrane Database* meta-analysis of psychotherapy (most in group format) for patients with advanced cancer showed significant reductions in depression with a moderate effect size. The authors note that the moderate effect size found in their meta-analysis differed from the weak effect size found in the extant literature, and this difference was likely because most of the trials included in previous studies did not select patients with clinically diagnosed depression or advanced stages of cancer (Akechi et al., 2008).

However, some randomized trials have shown little or no psychological benefit. In one study involving 210 women recently diagnosed with breast cancer, the intervention consisted of an unusual combination of two weekly 6-hour sessions of psychoeducation and eight weekly 2-hour sessions of group psychotherapy. There were no significant effects of the intervention on psychological outcome, although patients in both treatment and control samples who were on antidepressants improved over time (Boesen et al., 2011). Another trial providing a 6-day cancer rehabilitation course shortly after diagnosis reported no significant differences between treatment and control groups at 6-month follow-up (Ibfelt et al., 2011).

Indeed, one meta-analysis that concluded there was little evidence for psychological benefit from psychosocial intervention for cancer patients (Newell et al., 2002) eliminated three-quarters of the published trials (from 327 to 82) based on criteria that included whether caregivers were blinded to the treatment condition, which is hard to imagine. Furthermore, they assessed a wide array of outcomes ranging from the psychosocial to treatment side effects to immune function. Thus, their surprising null conclusion seems to have more to do with the methods of the meta-analysis than the content of the studies reviewed. On balance, however, the bulk of studies and reviews conclude that group intervention improves quality of life and reduces distress for cancer patients.

Among HIV-positive homosexual/bisexual men, social support has been significantly and positively related to active behavioral coping (Wolf et al., 1991). Furthermore, brief group therapy for depressed persons with HIV infection effectively reduced symptoms of emotional distress (Cacioppo et al., 1992; Kelly et al., 1993), especially when it included a supportive/expressive approach which emphasized emotional expression and dealing with existential concerns.

INTERPERSONAL FUNCTIONING

The type of isolation experienced by patients with catastrophic illness reinforces death anxiety because death is often conceptualized as being alone, separated from family and friends (Spiegel, 1990). A support group has the beneficial effect of moderating the patient's sense of isolation by providing a new social network. The group becomes a powerful medium for restoring patients' homeostasis, in that the very experience that separates them from the rest of the world is what bonds them with others in the group (Spiegel, 1990). Being with others who have the same illness and who share similar experiences mitigates the anxiety of facing the illness on one's own and normalizes disease-related feelings and experiences. Involvement in a group also allows patients to better mobilize their existing resources, as well as to develop new coping strategies and sources of support.

QUALITY OF LIFE AND SURVIVAL

Support groups and other psychosocial interventions play an important role in enhancing the quality of life for HIV-positive persons (Beckett & Rutan, 1990; Markowitz et al., 1992) and cancer patients (Spiegel & Glafkides, 1983; Spiegel & Wissler, 1983; Forester et al., 1985). Moreover, there is surprising evidence that group psychotherapy may affect the quantity as well as the quality of life. A randomized clinical trial of palliative care for non-small cell lung cancer patients published in the *New England Journal of Medicine* (Temel et al., 2010) produced a clear but apparently paradoxical finding: "Despite receiving less aggressive end-of-life care, patients in the palliative care group had significantly longer survival than those in the standard care group (median survival 11.65 vs. 8.9 months; $P = 0.02$)." The palliative care condition reduced depression as well. The intervention involved an average of four visits that focused on choices about resuscitation preferences, pain control, and quality of life. The study demonstrates that at the end of life, the most aggressive treatments may not be the most effective—not only psychologically but also medically.

Eight of 15 published clinical trials demonstrate an effect of psychotherapeutic support on cancer survival time, and none show a worsening of outcome. Spiegel and colleagues (1989) first conducted a prospective randomized trial on the effect of group psychotherapy of patients with metastatic breast cancer in the 1970s and published the survival results in 1989. Fifty women with metastatic breast cancer were randomly assigned to a year of weekly support groups with training in self-hypnosis for pain control. Forty-eight months after the study had begun, all of the control patients had died but one-third of the treatment sample were still alive. Surprisingly, the treatment group survived an average of 18 months longer than 36 control patients who had been randomly assigned to routine care.

A decade later a replication study from the same investigators showed no overall effect of a similar group therapy intervention on breast cancer survival, but a significant interaction with tumor type such that those with estrogen receptor negative cancers who were randomized to group therapy lived significantly longer than did ER-negative patients receiving standard

care alone (Spiegel et al., 2007). While this failed to confirm the main hypothesis that facing death together could improve survival, major advances in hormonal and chemotherapies had improved overall survival for women with metastatic breast cancer in the interim (Peto et al., 2000); however, women with ER-negative tumors do not benefit from the major improvement in treatment outcome associated with anti-estrogen treatments (Peto et al., 2000). A randomized trial of psychoeducational groups for women with primary breast cancer found significantly reduced rates of relapse and longer survival (Andersen et al., 2008). In addition to this, our original study (Spiegel et al., 1989), our replication trial (Spiegel et al., 2007), the recent palliative care study (Temel et al., 2010), three other randomized trials (Richardson et al., 1990; Fawzy et al., 1993; Kuchler et al., 1999; Kuchler et al., 2007), and one matched cohort trial (McCorkle et al., 2000) have found that psychosocial treatment for patients with a variety of cancers results in both psychological and survival benefit. However, seven other published studies (Linn et al., 1982; Illyenkyj et al., 1994; Cunningham et al., 1998; Edelman et al., 1999; Goodwin et al., 2001; Kissane et al., 2007; Kissane et al., 2004), six involving breast cancer patients (Edelman et al., 1999; Illyenkyj et al., 1994; Goodwin et al., 2001; Kissane et al., 2007, 2004; Cunningham et al., 1998) found no survival benefit for those treated with psychotherapy. Three of these seven studies showed no emotional benefit of the intervention (Illyenkyj et al., 1994; Cunningham et al., 1998; Edelman et al., 1999), making any survival benefit unlikely. In a fourth study, the treatment group was more depressed than the control group at baseline (Goodwin et al., 2001), which gave them a poorer medical prognosis based on recent research (Giese-Davis et al., 2011). Furthermore, no studies show that such attention to emotion and mortality shortens survival (Spiegel, 2002).

Thus, there is growing evidence that group psychotherapy may influence survival time as well as adjustment to serious chronic medical illness. The mechanisms underlying such an effect are yet to be determined but may involve diet, exercise, sleep, adherence to medical treatment, or changes in endocrine and immune function (Spiegel, 1991; Sephton et al., 2000; Sephton & Spiegel, 2003; McDonald et al., 2005; Antoni et al., 2006; Innominato et al., 2010).

It should be mentioned that caregivers of patients with a chronic illness suffer a great deal of stress, which can impact the health of the patient. For example, Taerk (1983) found that groups for oncology nurses resulted in improvement in patient care and ward atmosphere. Moreover, among caregivers of Alzheimer's patients, support groups have been effective at delaying the onset of nursing home care for the patients (Mittelman et al., 1993).

DIFFERENT METHODS OF GROUP PSYCHOTHERAPY

Group interventions for chronically ill patients employ various strategies. Some of the groups are structured with more of an educational focus, while others are unstructured and more affectively oriented.

Educational groups have as a goal the dissemination of information. They can be very helpful to patients who have been newly diagnosed with a disease. Educational groups can also be effective in teaching prevention tools. For example, at-risk populations such as teenagers engaging in unprotected sexual behavior may modify risky sexual behavior after becoming informed through an educational group (Mansfield et al., 1993; Magura et al., 1994). Furthermore, educational groups can reduce feelings of helplessness and inadequacy by giving patients a sense of mastery and control (Fawzy et al., 1995).

Cognitive behavioral groups typically employ problem-focused skills-building and coping strategies. These groups have been successful at improving quality of life through better coping and increased medical compliance for chronically ill patients suffering from diabetes, asthma, HIV/AIDS, and cancer (Kelly et al., 1993). Many of the psychotherapies that have shown promise in improving emotional adjustment and influencing survival time involve encouraging open expression of emotion and assertiveness in assuming control over the course of treatment, life decisions, and relationships (Spiegel & Yalom, 1978; Spiegel et al., 1981, 1989; Fawzy et al., 1990).

Recently, as noted above, the range of interventions has grown. An existential group intervention known as *meaning-centered group psychotherapy* was designed to help cancer patients facing death to develop a sense of meaning, peace, and purpose in their lives (Breitbart et al., 2010). In a small randomized trial comparing this approach to supportive group psychotherapy, those in the meaning-centered intervention reported greater improvements in spiritual well-being and meaning and reductions in anxiety and desire for death. This finding is consistent with an important randomized trial of *dignity therapy*, an existentially oriented individual intervention designed for people with advanced disease. In that trial, 165 of 441 patients were assigned to dignity therapy, 140 to palliative care, and 136 to client-centered care. While improvements were noted in all conditions, dignity therapy proved superior in reducing depression and improving quality of life and spiritual well-being (Chochinov et al., 2011).

SUPPORTIVE-EXPRESSIVE THERAPY

Supportive-expressive therapy is group therapy option that deals with emotional, existential and practical issues of cancer patients. Its combination of components makes it relevant to cancer patients at different stages of illness, with different sources of psychosocial distress. Supportive-expressive therapy comprises:

1. *Social support.* Psychotherapy, especially in groups, can provide a new social network with the common bond of facing similar problems (Spiegel, 1993). There is strong evidence that social contact has positive emotional effects and reduces overall mortality risk (House et al., 1988). Social isolation has been shown to be as strongly related to age-adjusted mortality as serum cholesterol levels or smoking. Indeed, being married predicts better medical

outcome with cancer (Goodwin et al., 1987), while social stress such as divorce, loss of a job, or bereavement is associated in some studies with a greater likelihood of a relapse of cancer (Ramirez et al., 1989).

2. *Emotional expression.* The expression of emotion is important in reducing social isolation and improving coping. Moreover, emotional suppression and avoidance are associated with poorer coping (Greer et al., 1979; Greer, 1991). However, group and individual psychotherapies can facilitate the expression of emotion appropriate to the disease. Doing so seems to reduce the repressive coping strategy that reduces expression of positive as well as negative emotion. Emotional suppression also reduces intimacy in families, limiting opportunities for direct expression of affection and concern. Indeed, there is evidence that those who are able to ventilate strong feelings directly cope better with cancer (Derogatis et al., 1979; Greer et al., 1979; Pettingale, 1984; Temoshok et al., 1985; Greer, 1991).
3. *Detoxifying dying.* This component of the therapy involves examining the threat of death in a straightforward manner rather than avoiding it. The goal is to help those facing the threat of death by reducing their anxiety about it as well as exploring fears associated with the process of dying. This exploration enables patients to think about what they control. These discussions often lead patients into making positive life changes while reducing their overwhelming fears and anxieties. One woman with metastatic breast cancer described her experience in this way:

“What I found is that talking about death is like looking down into the Grand Canyon (I don’t like heights). You know that if you fell down, it would be a disaster, but you feel better about yourself because you’re able to look. I can’t say I feel serene, but I can look at it now” (Spiegel, 1993).
4. *Reordering life priorities.* When cure is not possible, a realistic evaluation of the future can help those with life-threatening illness make the best use of remaining time. One of the costs of unrealistic optimism is the loss of time for accomplishing life projects, communicating openly with family and friends, and setting affairs in order. Facing the threat of death can aid in making the most of life (Spiegel et al., 1981). Discussing these issues directly can help patients take control of those aspects of their lives they can influence while grieving and relinquishing those they cannot.
5. *Family support.* Psychotherapeutic interventions can also be quite helpful in improving communication, identifying needs, increasing role flexibility, and adjusting to new medical, social, vocational, and financial realities. There is evidence that an atmosphere of open and shared problem solving in families results in reduced anxiety and depression among cancer patients (Spiegel & Wissler, 1983).

Thus, facilitating the development of such open addressing of common problems is a useful therapeutic goal. Groups can also help family members to ventilate feelings that tend to be brushed aside in the face of those affecting the medically ill. As one husband of a metastatic breast cancer patient put it: *"This group is a place where I come to feel better about feeling bad."* Group members also learn role flexibility, rearranging family duties and decreasing the tendency to reassure rather than discuss serious problems. Group interventions may help to augment family support by helping to improve communication and to help patients practice ways of both giving to, and seeking help from, family members. At times, however, especially when there is resistance to facing and dealing with disease-related issues, family consultation or treatment may be important.

6. *Communication with physicians.* Support groups are useful tools for facilitating better communication with physicians and other healthcare providers. Groups provide mutual encouragement to get questions answered, to participate actively in treatment decisions, and to consider alternatives carefully. Groups must be careful not to interfere with medical treatment and decisions; rather, the goal is to encourage patients to be assertive in getting clear information that will assist in reaching informed decisions.
7. *Symptom control.* Many treatment approaches involve teaching cognitive techniques to manage anxiety, anticipatory nausea and vomiting, and pain. Cognitive techniques include learning to identify emotions as they develop, to analyze sources of emotional response, and to move from emotion-focused to problem-focused coping. Behavioral techniques include specific self-regulation skills such as self-hypnosis, meditation, biofeedback, and progressive muscle relaxation (Burish & Lyles, 1981; Morrow & Morrell, 1982; Zeltzer & LeBaron, 1982; Spiegel & Bloom, 1983; Spiegel, 1990).

ROLE OF SELF-HELP GROUPS

There is evidence suggesting that self-help groups are beneficial in assisting patients to modify behaviors, (e.g., Alcoholics Anonymous) and reduce psychological distress. In post-mastectomy patients, those who attended self-help groups experienced less psychological distress compared to patients who did not attend self-help groups (Silverman-Dresner, 1989–1990). Moreover, self-help members tend to utilize the services of professionals more than people who do not attend self-help groups and were more likely to use more than one source for support.

Self-help groups may be particularly helpful for newly diagnosed individuals who not only require social support but are in need of information. Self-help groups often have information on professional referrals in the community and surrounding areas. For a patient who is overwhelmed by a recent diagnosis of a severe illness, having a self-help group manage

the wealth of information and provide support during the process can be extremely beneficial. However, the complexity of medical problems and treatments facing patients with cancer and HIV infection, along with the array of frequently intense emotional responses, often requires the help of a well-trained therapist.

Simply "stirring the pot" by raising emotionally-laden issues without working them through to the point of active coping and mastery can proliferate problems, making group leadership by a professional therapist crucial. In one study comparing unstructured peer discussion groups to educational groups for women with early-stage breast cancer, those in the unstructured groups actually showed evidence of worsening self-esteem, body image, and intrusive thoughts about the illness (Helgeson et al., 1999). This study underscores the importance of well-trained group leaders and a clear and clinically tested theoretical orientation to treatment.

As people have growing access to the internet, online support groups will become more popular. This provides access to support for those too far from treatment centers or too physically impaired to attend groups regularly (Owen et al., 2004). There are few systematic studies, but there is evidence that such virtual interaction can be surprisingly effective in reducing distress (Lieberman et al., 2003; Lieberman & Goldstein, 2005).

GROUP MEMBERSHIP

The population of the group is an important question, because issues related to gender, sexuality, diagnosis, prognosis, age, culture, and so on, can be extremely important in terms of group cohesiveness. Heterogeneous groups are often educational. They meet for a brief period and do not require a great deal of group cohesiveness to function. As groups become more long term and require more group interaction to function properly, it is best to constitute the group to be as homogeneous as possible, especially in regard to prognosis. At the same time, if a woman in a group of primary breast cancer patients suffers a relapse, it is crucial for her and for the morale of all group members that she be made to feel welcome and supported in that group.

For HIV/AIDS populations, people will have very different issues to deal with in relation to their HIV infection. For example, issues arising for HIV-infected heterosexuals will not be identical with those arising for infected gay men. Moreover, individuals infected through intravenous substance use and struggling with recovery issues have unique needs. Additionally, people of color confront another set of issues stemming from their minority status within society and the specific cultural mores of their own ethnic communities. Furthermore, women, as a group, may be defined by their own set of issues including the gender-specific manifestations of HIV/AIDS infection. Age range within a specific group also needs to be considered. Young adults are typically grappling with adult developmental issues, which are significantly different from the issues faced by older adults.

The socioeconomic background of the population will vary. It is important to note that the majority of increase

of HIV infection is in low-income minority communities. Because of this, the efforts to reach out to these populations require special innovation. The social demands put upon this particular population affect their ability to adequately seek and maintain medical treatment for their illness. To address some of these issues and encourage treatment compliance, it may be necessary for treatment services to provide some of the group participants with assistance such as travel vouchers and childcare subsidies. Although treatment providers may feel this is expensive, it is considerably more costly to do nothing and to continue to allow this segment of the AIDS population to go untreated.

LEADERSHIP ISSUES

Groups are often led by two therapists. This is crucial for new therapists. Ideally, new therapists should be matched with a more experienced group facilitator (Yalom, 1995). Besides allowing the newer leader to learn from the veteran, the presence of co-leaders decreases anxiety and allows therapists to fully attend to the group process. Once the group is over, the co-leaders can debrief regarding the session. This provides valuable information about each therapist's behavior and deepens the understanding of the group process. Depending upon the specific group population and their collective issues and needs, each therapist should possess clinical expertise in that group's unique and defining issues. There are issues that define a group more specifically than simply sharing an HIV/AIDS diagnosis; for example, substance abuse, gay issues, heterosexual issues, issues regarding race or ethnicity, and issues specific to women infected with HIV/AIDS.

Therapists should have training and experience in psychotherapy or group therapy, as well as training and experience in psychosocial support for patients with life-threatening illness or medical management of HIV disease. In addition, they should also have at least minimal knowledge of the disease that is the focus of the group, such as HIV infection or cancer. This knowledge is crucial—not so much because the therapist can impart it to group members, but rather because it enhances the therapist's own understanding of living with this disease. Co-leaders should ideally complement one another's abilities. For example, a group may have one leader who is a psychiatrist and the other a social worker. This interdisciplinary approach allows for a broader context in which to place the group members' experience. This is particularly important when working with underserved populations who may need a great deal of support in accessing social services as well as medical services. For example, an African-American woman diagnosed with AIDS stated:

"I've got my two kids at home, but no one to watch them while I go to all my doctor appointments and I can't afford to pay anyone. So, when I run out of my meds I've been taking my friends' meds."

One of the co-facilitators of this group was a social worker who was able to refer this patient to a preschool program

in the community. This intervention not only allowed the woman to attend her medical appointments, but it also gave her a much needed reprieve from the stressful tasks and duties of being a single parent.

The training of group leaders is an important part of developing effective group interventions. For example, therapists who were trained in supportive/expressive group therapy improved in four areas: (1) facilitating the expression of affect; (2) facilitating exploration of personal and specific cancer-related issues in the here and now; (3) facilitating supportive group interaction; and (4) facilitating active coping strategies (Classen et al., 1997). Interestingly, these dimensions represent the areas that are thought to be associated with positive patient outcome.

It is not uncommon for therapists leading supportive/expressive therapy groups to feel uncomfortable with the emphasis on facilitating difficult and painful discussions about such topics as fears of disease progression, dying, and death. It may seem counterintuitive to encourage the discussion of "negative" topics, especially with most patients believing they should be thinking "positively." Indeed, one common concern about groups for the medically ill is that they will demoralize patients by exposing them to disease progression or death among other members. When a death of a group member occurs, the therapists are challenged with facilitating the grieving process among the group members.

In supportive/expressive therapy, the therapists facilitate the emotions of the group members, which are typically sadness, anger, and fear. While processing their emotions, many group members express a desire to attend memorial or funeral services. The therapists' role is to allow the group members to grieve in their own ways. Some group members may want to attend services, while others decide not to. Each group copes with the loss of a member in its own unique way. For example, in a women's HIV group one of the members died quite suddenly. This particular woman had a wonderful sense of humor and the uncanny ability to bring the group into full laughter effortlessly. The group members along with the therapists decided to attend the memorial service together. This shared experience of grief was processed in subsequent group meetings. One of the group members stated, "I know that if she could have seen us all there, she would have loved the attention and cracked a joke!"

This prompted the other group members to begin to share memories, funny anecdotes, and humorous moments related to the deceased group member. Amidst the laughter and the tears, the group members were able to accept the death and explore its effect on them in a therapeutic environment. This appeared to be extremely beneficial to the group members. There is evidence consistent with our clinical observation from a variety of studies indicating that patients feel better about themselves to the extent that they can face what may lie ahead (Fawzy et al., 1990). During the grieving process, group members are faced with the seriousness of their illness and often begin to explore spiritual issues related to faith and hope. Moreover, cultivating a fighting spirit (Greer et al., 1979), a kind of realistic optimism, seems to help those with serious illness accept the worst but hope for the best.

Training programs for therapists must be cognizant of an initial reaction to avoid the topic of death and dying. It is extremely important to assist therapists in tolerating their own emotional reactions to the worsening of illness and death of group members.

SUMMARY

Studies of psychotherapeutic treatments for cancer patients, both group and individual, have reported a variety of positive effects ranging from reduction in anxiety and depression to a number of recent studies suggesting increases in survival time.

There is substantial evidence of a need for psychotherapeutic intervention among cancer and HIV/AIDS patients, including those without a psychiatric diagnosis. Such interventions are effective in reducing distress, improving coping, improving adherence to treatment regimens, and enhancing interaction with healthcare professionals. In addition, groups provide social support, which has been shown to decrease disease progression among cancer and HIV patients. As health reform gets underway, psychotherapy may be seen as too costly. However, psychotherapy techniques have shown themselves in the medical arena to be needed, effective, and cost efficient. Psychosocial support for medically ill patients should be integrated into standard medical care and practice.

CLINICAL PEARLS

- Group therapy has a long track record of reducing psychiatric symptoms and increasing social support in the medically ill.
- Compared to individual psychotherapy, group therapy allows patients access to emotional support and to learn new interpersonal and coping skills without seeming to be abnormal.
- Patients get to help others and to see that others may have more troubles than they do.
- Group therapy has beneficial effects on mood, adjustment, and pain (Gustafson & Whitman, 1978; Wood et al., 1978; Ferlic et al., 1979; Spiegel et al., 1981; Spiegel & Bloom, 1983; Fawzy et al., 1990; Butler et al., 2009).
- Advantages of group therapy are as follows:
 - Patients discover that they are not unique in their predicament.
 - Patients can have intimate experiences and consensual validation with others suffering the burden of similar illness.
 - As they respect others coping with illness, they learn to respect themselves.
 - The opportunity to help others in a similar situation enhances the patient's sense of competence and ability to develop a renewed sense of meaning in life.

- Members come to feel part of a new and accepting social group in which their common bond is the very thing that makes them feel excluded in the outside world (Spiegel, 1993).
- Group therapy is cost effective.
- Breast cancer patients who received group therapy had significantly higher levels of personal control
- Eight of 15 published clinical trials demonstrate an effect of psychotherapeutic support on cancer survival time, and none show a worsening of outcome.
- Many of the psychotherapies that have shown promise in improving emotional adjustment and influencing survival time involve encouraging open expression of emotion and assertiveness in assuming control over the course of treatment, life decisions, and relationships (Spiegel & Yalom, 1978; Spiegel et al., 1981, 1989; Fawzy et al., 1990).
- Beneficial foci of supportive/expressive therapy are social support, detoxifying dying, emotional expression, reordering life priorities, family support, communication with physicians, and symptom control.

COGNITIVE BEHAVIORAL THERAPIES

Lara N. Traeger and Joseph A. Greer

INTRODUCTION

Cognitive behavioral therapy (CBT) refers to a diverse group of psychotherapies that share a set of fundamental assumptions: cognitions (e.g., interpretations and beliefs) affect behaviors, and cognitive activity can be monitored and altered to mediate behavior change. CBT interventions are applicable to medical patients, who may benefit from enhancing skills for health risk reduction or chronic disease management. Treatment models can be adapted to address associations of cognitions, health behaviors, emotions, and patient health outcomes, with an emphasis on the role of self-regulation. Common treatment goals include improving health behaviors such as medical adherence, reducing psychological symptoms that may exacerbate medical disability, and/or directly improving functional status.

CBT interventions have evolved over the past several decades through the convergence of behavioral and cognitive theories of change. Behavior therapy is considered a precursor to CBT; methods emerged as a response to psychodynamic therapies and through clinical applications of classical and operant conditioning theories (Eysenck, 1966; Wolpe, 1958). In comparison to psychodynamic treatment models, behavior therapy is time-limited and problem-oriented, with a focus on symptom reduction. Albert Ellis (1957) and Aaron T. Beck (1963, 1964) were among the first to formalize clinical models that emphasized the primacy of cognitions in therapeutic change. Ellis's rational emotive therapy introduced a directive therapeutic approach for changing irrational beliefs, whereas Beck elaborated specific cognitive patterns associated with depression (i.e., negative thinking about the self, world, and others) as targets for change. These approaches integrated cognitive mechanisms into existing behavioral models and, consequently, could be used to explain a broader range of psychopathology. Current models vary in the extent to which behaviors or cognitions are primary targets of change. However, since the early success of CBT to treat depression, support for CBT approaches has grown, and applications have expanded to diverse psychiatric and medical conditions. The CBT literature reflects a commitment to empirical validation of treatment methods (Dobson & Dozois, 2010).

COGNITIVE BEHAVIORAL MODEL

CBT emphasizes that a person's interpretations of a situation influence emotional reactions and behaviors used to cope

with or adapt to the situation. Cognitions, behaviors, and emotions continually reinforce each other via multidirectional paths. We highlight these associations and their implications in the following case study.

CASE STUDY 1

Patient K. B. is a 45-year-old woman who has recently returned to full-time employment despite residual fatigue following radiation therapy for an early-stage breast cancer. During K. B.'s first week, her supervisor noted a few errors in her work and asked her to correct them. Since then, K. B. has become increasingly worried that her work is noticeably suffering. Consequently, K. B.'s anxiety has escalated. She has started drinking more coffee, skipping exercise to reduce risk of worsening fatigue, and avoiding additional contact with her supervisor. K. B. is also frustrated that despite her daytime fatigue, she is having increasing problems with insomnia at night. K. B.'s sensitivity to fatigue appears to be increasing, triggering long-standing worries about incompetence, unemployment, and financial instability, and new ruminations about cancer recurrence.

This scenario demonstrates the cognitive, behavioral, and emotional cycle that can be triggered by a situational interpretation (i.e., the meaning of the supervisor's actions). Alternatively, K. B. could have interpreted the supervisor's actions as hostile, supportive, or of an unclear nature, leading to different outcomes. However, interpretations and coping often reflect existing patterns or styles of thinking and behaving—such as exaggerated fears of failure and behavioral avoidance in the case of K. B. When life stressors occur, these patterns can appear entrenched or rigid, leading to clinically significant distress. Identifying maladaptive cognitive and behavioral responses is a fundamental task in CBT that informs the therapeutic approach.

In medical populations, the confounding of psychological factors, disease symptoms, and treatment side effects highlights the importance of comprehensive assessment and consultation with patients' other providers. Several factors could be associated with K. B.'s fatigue and sleep concerns, including residual effects of radiotherapy, uncontrolled pain symptoms, misinformation about sleepiness versus fatigue, psychological distress, and compensatory behaviors that may further disrupt sleep/wake cycles (e.g., increasing caffeine intake or reducing daytime activity). In an ongoing downward spiral,

fatigue and insomnia may then interfere with the ability to appraise accurately and problem-solve current stressors. This case formulation highlights potential treatment targets for symptom reduction. The next section describes the basic characteristics of CBT and the key interventions that may be integrated into CBT treatment plans.

ELEMENTS OF COGNITIVE BEHAVIORAL INTERVENTIONS

CBT interventions reflect a problem-oriented, skills-based approach to therapeutic change. The first one to two sessions may be dedicated to collecting information about a patient's presenting problems, sharing and revising the CBT case formulation, and using this formulation to establish tailored treatment goals. At each subsequent therapy session, the therapist and patient review progress via informal feedback and relevant symptom inventories (e.g., Hospital Anxiety and Depression Scale [Zigmond & Snaith, 1983]), and set the current session agenda.

Throughout treatment, the therapist encourages active collaboration with the patient serving as cotherapist. Socratic questioning is used to guide patients in their own discovery of problematic patterns in thoughts and behaviors. Sessions typically focus on building skills that address these patterns. Patient self-efficacy is a critical concept in CBT, particularly for medical patients who may be facing some uncontrollable aspects of a disease or its treatment. Between-session assignments are used to practice and problem-solve the skills in real-life situations. Most interventions are time-limited, with the intention for patients to become increasingly independent in their use and application of CBT skills. Interventions typically conclude with a focus on relapse prevention by anticipating and problem-solving potential obstacles to the ongoing use of CBT skills.

In the following sections, we describe common CBT strategies and other methods that may be combined with CBT. Rather than simply strung together, strategies are selectively integrated into a cohesive treatment plan that is directly informed by the CBT case formulation. We also provide recommendations throughout this chapter for adapting treatment plans to incorporate factors associated with medical conditions.

PSYCHOEDUCATION

Psychoeducation is a core feature of CBT interventions. At the start of treatment, a critical aim for the therapist is to engage patients in understanding the CBT model and collaborating to identify how the model applies specifically to them. The model is an important road map to help patients discover and evaluate associations between their thoughts, feelings, and behaviors that may be impacting health and quality of life. Additionally, the model may be a tool for reinforcing areas in which patients may have personal responsibility or control over chronic disease management. For instance, a patient on long-acting pain medications may benefit from

reviewing the impact of missed or delayed doses on pain control. Among adults with asthma, a review of optimal inhaler use and education about associations of anxiety with asthma physiology may improve both disease knowledge and commitment to specific symptom management goals. Finally, given the goal-oriented and active nature of CBT, therapists must often employ treatment motivation strategies, which we further address in the next section.

MOTIVATIONAL ENHANCEMENT

Throughout treatment, CBT therapists commonly incorporate techniques for monitoring and enhancing motivation for therapeutic change. Motivation is a key element in complex health behavior change, such as cessation of tobacco use, changes in physical activity and dietary patterns, and improvements in medical treatment adherence. Ambivalence may be prominent in patients who are experiencing depression-related anhedonia or hopelessness, or anxiety-related avoidance. Patients also may be relying on health risk behaviors (e.g., smoking or overeating) to cope with negative affect. Examples of motivational techniques include collaborative treatment goal-setting, information provision, encouragement, feedback on goal progress, and treatment contracting.

In comparison to basic techniques, motivational interviewing (MI) is a brief (generally 1–2 sessions) evidence-based communication method that was developed to enhance personal commitment to behavior change (Miller & Rollnick, 2002). This method is based on assumptions of personal autonomy. A variety of strategies may be used to elicit a patient's own intrinsic arguments for change and to use these arguments as the source of motivation. MI is goal-oriented but does not involve teaching specific skills (Miller & Rollnick, 2009). In practice, MI is sometimes combined with CBT or used to enhance entry into an intensive behavior change program. For instance, Safren and colleagues include MI communication strategies as a prelude to their CBT intervention for improving depression and adherence to medical treatments in adults with a chronic illness (Safren, Gonzalez, & Soroudi, 2008).

BEHAVIORAL ACTIVATION

Behavioral activation (BA [Martell, Addis, & Jacobson, 2001]) is a straightforward, empirically supported intervention that was developed for depression treatment and relapse prevention, which is also a core component of CBT. BA does not simply encourage patients to become more active. Rather, the intervention represents a collaborative effort between the therapist and patient to identify specific activities that may be personally rewarding and that may interrupt current behavior/environment contingencies (e.g., impact of a patient's social avoidance on sadness and sense of isolation). The patient is encouraged to schedule meaningful and achievable activities and then monitor progress throughout each week. When working with medical patients, therapists must consider complicating factors such as medication regimens, functional status, symptoms (e.g., dyspnea, pain), and daily fatigue patterns in order to plan and adapt rewarding activities. Activity

pacing can help modulate daily activities according to current level of energy. Careful planning is necessary to maintain patient motivation and, in turn, promote patient confidence (Carney & Freedland, 2008).

GUIDED EXPOSURE

Exposure is a core component in many CBT interventions for anxiety (Craske, Antony, & Barlow, 2006; Craske & Barlow, 2006; Foa, Hembree, & Rothbaum, 2010). Patients learn to interrupt behavior/environment contingencies associated with anxiety through use of imaginal or in vivo (real life) exposures to feared situations. Interventions may also incorporate interoceptive exposure, the intentional induction of fear sensations such as hyperventilation. During treatment, the therapist and patient collaborate to plan systematic, graded exposure exercises that will provoke conditioned fear responses in the short term, so that patients accumulate evidence disconfirming their inaccurate appraisals and ultimately extinguish the conditioned responses in the long term.

In medical populations without clinically significant anxiety, exposure principles nevertheless may be relevant for cases in which subclinical anxiety is interfering with adherence to medical treatment or exacerbating disability (e.g., exaggerated fear-avoidance of physical activity in patients with fatigue or

pain). Duhamel and colleagues (2010) included an exposure component in their pilot trial of CBT for patients who underwent hematopoietic stem cell transplantation and were experiencing subsequent symptoms of posttraumatic stress. Guided exposure to stimuli that were associated with posttraumatic stress was combined with psychoeducation, cognitive restructuring, social support skills, and relaxation training. Patients who completed the treatment reported fewer posttraumatic stress symptoms related to their illness, including fewer intrusive thoughts and avoidance behaviors, relative to patients in a no-therapy control condition.

ADAPTIVE THINKING

Cognitive techniques represent a cornerstone of CBT interventions for reducing emotional distress and optimizing coping with current and future stressors. Patients are taught to identify inaccurate and unhelpful thoughts (e.g., “I bet my doctor has not returned my call yet because she has bad news to share”) that may be occurring automatically in stressful situations. Over time, patients may be able to identify cognitive distortions or problematic patterns of thinking (in this case, “fortune telling”) that frequently characterize their automatic thoughts. Several common cognitive distortions and example automatic thoughts are shown in Table 14.1.

Table 14.1 DEFINITIONS AND EXAMPLES OF 11 COMMON COGNITIVE ERRORS

COGNITIVE DISTORTIONS	DEFINITIONS	EXAMPLES
All-or-nothing thinking	Placing experiences in one of two opposite categories	“I missed my medication dose this morning. I simply can’t take care of myself.”
Discounting the positives	Deciding that if a good thing has happened, then it couldn’t have been very important	“I’ve been so fatigued since I started chemotherapy. Being able to play with my nieces today without feeling exhausted was just an aberration.”
Jumping to conclusions	Focusing on one aspect of a situation in deciding how to understand it	“The reason my doctor hasn’t yet returned my call is because she has bad news to tell me.”
Mind reading	Believing one knows what another person is thinking, with very little evidence	“That person is staring at me because they can tell that I’m sick.”
Fortune telling	Believing one knows what the future holds, while ignoring other possibilities	“I am never going to be able to change my eating habits.”
Magnifying/minimizing	Evaluating the importance of a negative event, or the lack of importance of a positive event, in a distorted manner	“Being diagnosed with diabetes has limited my whole life.”
Making “should” statements	Telling oneself that one should do—or should have done—something, when it is more accurate to say that one would like to do—or wishes one had done—the preferred thing	“My surgery was weeks ago. I should be back to work by now.”
Labeling	Using a label to describe a behavior, then imputing all the meanings the label carries	“I can’t seem to push myself to go to physical therapy. I must be lazy.”
Inappropriate blaming	Using hindsight to determine what one “should have done”	“I should have had my cough checked by a doctor a long time ago.”

Adapted from DeRubeis, R. J., Webb, C. A., Tang, T. Z., & Beck, A. T. (2010). Cognitive therapy. In K. S. Dobson (Ed.), *Handbook of cognitive-behavioral therapies*. New York, NY: The Guilford Press.

After learning to identify and label automatic thoughts, patients are then taught to challenge them (e.g., “What is the evidence that this thought is true?” or “What would I say to a good friend in the same situation?”) and replace them with new thoughts that are more rational and adaptive. The patient then tests the new thoughts to determine whether they help reduce distress and frame situations in a more helpful light. Skills are reinforced through the practice of monitoring and challenging automatic negative thoughts throughout the week.

A key challenge in applying adaptive thinking skills in medical populations is that patients with severe or advancing illness may indeed face realistic progression toward feared events. Greer and colleagues (2009) have adapted a decisional model to help patients evaluate the extent to which negative thoughts may contain both biased and realistic elements. Adaptive thinking skills may be supplemented with acceptance-oriented coping skills (e.g., mindfulness) when thoughts are deemed realistic, or with information seeking when more “data” are needed.

PROBLEM SOLVING

Problem-solving therapy (PST) is a CBT intervention that focuses on developing and strengthening attitudes and skills for resolving current problems (D’Zurilla & Nezu, 2007). In PST, attention is focused on evaluating and addressing each patient’s problem orientation (e.g., optimistic versus doubtful) and problem-solving style (e.g., constructive versus impulsive or avoidant). Patients learn to use a practical, systematic approach in which problems are viewed as solvable challenges. This approach emphasizes four main skills: articulating problems, generating potential solutions, evaluating each solution with regard to advantages and disadvantages, and executing and monitoring a plan of action. The primary aims of PST are to reduce psychological distress and improve quality of life among patients. Evidence supporting PST to improve symptom management and treatment adherence has been generated across a range of complex medical conditions, such as diabetes and cancer (Hill-Briggs & Gemmell, 2007; Lee, Chiou, Chang, & Hayter, 2010; Nezu, Nezu, Friedman, Faddis, & Houts, 1998).

RELAXATION

Relaxation training is frequently integrated into CBT for a wide range of psychiatric and medical conditions. A key aim of relaxation training is to promote resilience and optimal coping in the context of life stressors. Pioneering work by Herbert Benson and colleagues documented reductions in several physiologic stress indices following a brief meditation session among long-term practitioners (Wallace, Benson, & Wilson, 1971). Relaxation increasingly has been applied in therapeutic settings to elicit a state of downregulated sympathetic nervous system activity and upregulated parasympathetic activity, through attention to a variety of different stimuli (e.g., abdominal breathing, progressive muscle relaxation, yoga sequences, or imagery). Relaxation training typically

includes psychoeducation about stress symptoms and the purpose of relaxation practice, introduction to a relaxation exercise, monitoring of effects on current stress symptoms, and problem-solving regular relaxation practice. For patients with a medical comorbidity, stress symptoms should be discussed with the patient’s medical providers to rule out confounding conditions prior to initiation of relaxation training. Current symptom profiles should also be considered when selecting an appropriate relaxation exercise (e.g., imagery instead of muscle tensing/relaxing exercises in patients with chronic pain). The brief, portable nature of relaxation interventions supports delivery in medical treatment settings. For instance, relaxation training has shown anxiolytic benefits in adults undergoing intensive anticancer chemotherapy (Jacobsen et al., 2002) and radiotherapy (Decker, Cline-Elsen, & Gallagher, 1992) regimens.

BIOFEEDBACK

Biofeedback therapy refers to procedures that facilitate real-time observation and measurement of physiologic stress responses. A core assumption of biofeedback methods is that by increasing awareness of these responses, which are usually hidden, patients may be able to exercise more psychological or behavioral control over them. For instance, biofeedback can be combined with relaxation training so that patients may observe *in vivo* effects of relaxation on indices of peripheral autonomic activity. Demonstrations of mind–body connections may promote uptake of and adherence to CBT strategies for managing stress and stress-induced symptoms. Proposed outcomes of biofeedback will depend on the specific medical population and the type of physiological process that is monitored.

Diverse biofeedback protocols have been tested in a range of medical conditions, including epilepsy (Nagai, 2011), incontinence and constipation (Enck, Van der Voort, & Klosterhalfen, 2009), hypertension (Greenhalgh, Dickson, & Dundar, 2010), and Raynaud’s disease (Malenfant, Catton, & Pope, 2009), with mixed effects. Electromyographic and temperature feedback combined with relaxation have shown promise in reducing migraine headache frequency and severity (Nestoriuc & Martin, 2007). Biofeedback methods have also been integrated with other CBT strategies to treat conditions such as temporomandibular disorders (Crider, Glaros, & Gervitz, 2005).

SELECTIVE INTEGRATION OF COGNITIVE BEHAVIORAL TECHNIQUES

Many chronic medical conditions are associated with elevated risk for psychological problems such as depression. Depressed individuals, in turn, have difficulties with motivation, interest, and problem solving, and are therefore less likely to practice self-care behaviors such as physical activity, healthy eating, and adherence to medical regimens. The following case study illustrates some of these relationships and the selective integration of treatment methods to address them.

CASE STUDY 2

J. M. is a 32-year-old male who has been taking daily HIV medications for several years. He understands that the medications are needed to control his disease, but he sometimes skips doses to avoid this nagging reminder that all is not right in his life. He has not had a close, intimate relationship with anyone since he was diagnosed, and he can find few reasons to continue fighting for his health. J. M. volunteers at a local HIV center and is very good at mentoring others to take their medications on time and to seek social support from others. Other HIV-infected adults look to him for guidance. But when J. M. feels particularly down, his words seem hollow, and he avoids the HIV center in favor of staying at home in bed. On those days, even simple chores or a walk around the block feel overwhelming, so he reasons that he could not be of use to anyone else.

Despite J. M.'s careful efforts to hide his depressed moods, a case worker at the center takes note of his struggles and refers him for mental health services. By the time he meets with a CBT therapist for treatment evaluation, he has refused antidepressant medication and is maintaining an ambivalent stance toward "opening wounds" in talk therapy. The CBT therapist expresses her appreciation for his honesty. She provides some brief psychoeducation about the general purpose and rationale for CBT and also for antidepressant medications. They agree to have two trial CBT sessions and then revisit J. M.'s thoughts about continuing with the treatment.

The first session focuses on exploring J. M.'s current experiences. The therapist reviews the CBT model to help organize and illustrate associations between specific thoughts (perceived self-worth), feelings (despondence) and behaviors (social avoidance) that are elicited during the discussion. Socratic questioning is used to help J. M. critically examine his own cycles of depression and poor HIV self-care. Based on the model, the therapist and J. M. work together to identify realistic treatment goals. J. M.'s goals focus on improving depression and adherence, with a long-term aim of developing meaningful social relationships. The therapist shares her own diagnostic impressions and introduces CBT techniques that could help J. M. learn or enhance skills for meeting his goals. Given the initial ambivalence that J. M. expressed, the therapist also uses motivational interviewing to elicit J. M.'s motivation for engaging in therapy. Throughout treatment, this method is revisited as needed to reinforce J. M.'s personal autonomy and inherent desire to improve his quality of life. J. M. also regularly completes validated self-report inventories of depression symptoms and medication adherence, which provide continual feedback on goal progress.

Together, the therapist and J. M. generate a treatment plan based on the CBT model of J. M.'s depression. The therapist provides psychoeducation about depression and HIV. J. M. begins considering that medication adherence and self-care could be a step toward enjoying meaningful relationships with others (rather than a reminder of failure or loss). Behavioral activation is introduced to help J. M. increase engagement in activities that he considers personally rewarding, such as spending time with his uncle and helping the HIV center with creative projects. The therapist and J. M. also brainstorm a variety of activities for times when energy level or HIV medication side effects may fluctuate.

Weekly logs of activities and mood ratings allow the therapist and J. M. to pinpoint days in which enjoyable activities did not improve mood. This information facilitates a transition into

adaptive thinking skills. Through identification of automatic negative thoughts, J. M. begins to realize that he is engaging in a negative internal dialog with himself, focused on perceptions of low self-worth, especially when he is in group social situations. This pattern leads to sadness, shame, and the urge to isolate during social events. J. M. learns to monitor, challenge, and modify these thoughts through both in-session work and homework assignments. He continues to describe the exercises as awkward, but the therapist has noticed that J. M. has become increasingly able to recognize his own patterns of unhelpful cognitive and behavioral responses during setbacks—namely, angry self-talk and avoidance. The therapist and J. M. continue to problem-solve the use of adaptive thinking skills over the next few sessions. As J. M. engages in more helpful self-talk, his acceptance of living with HIV begins to increase. He has expressed more commitment to problem-solving the expansion of his social connections and to testing his old beliefs that he is not worthy of an intimate relationship.

CBT APPROACHES AND OUTCOMES IN MEDICAL POPULATIONS

CBT protocols that have been established in the general population commonly target specific psychiatric outcomes (e.g., worry in patients with generalized anxiety, or depression and anhedonia in patients with major depressive disorder). In comparison, research studies of CBT for medical patients are more likely to focus on individuals who are homogeneous with respect to medical illness. Interventions often comprise a combination of CBT strategies with multiple targets including psychological adjustment, health behaviors, disability, and/or disease-specific quality of life. Protocols that comprise this literature have varied in the extent to which they are based on theoretical principles for improving symptoms and/or facilitating complex health behavior changes (Eccleston, Williams, & Morley, 2009). The following section describes CBT approaches and supporting evidence for improving several common concerns in medical patients.

DEPRESSION

Across diverse medical populations, evidence supports the use of CBT to reduce depression symptoms, with larger effects in studies that limit participation to adults who meet criteria for clinical depression (Beltman, Oude Voshaar, & Speckens, 2010). Common treatment elements include psychoeducation, behavioral activation, adaptive thinking skills, and problem solving, with attention to associations between depression symptoms and aspects of disease-specific quality of life. A comparative review of nonpharmacological interventions for patients with chronic heart disease (education, relaxation, behavioral strategies, and cognitive strategies) demonstrated that both cognitive and behavioral strategies may reduce depression severity (Welton, Caldwell, Adamopoulos, & Vedhara, 2009). While older adults are typically underrepresented in CBT trials (Wilson, Mottram,

& Vassilas, 2008), reviews of CBT for depression in medical illnesses that are primarily diagnosed in older adulthood, such as chronic obstructive pulmonary disease (Fritzsche, Clamor, & von Leupoldt, 2011), suggest that CBT is feasible and potentially effective in this age group. Among patients, the long-term benefits of CBT have not yet been established.

ANXIETY

Common anxiety treatment strategies include psychoeducation, self-monitoring, exposure, adaptive thinking, and relaxation training. Specific protocols vary in the extent to which each strategy is emphasized. For instance, guided exposure to feared situations may be used to treat anxiety related to specific triggers (e.g., blood/injection/injury phobias), whereas this strategy is less relevant for nonspecific (generalized) anxiety. In the general population, CBT is efficacious for reducing anxiety severity within different anxiety disorders (Hofmann & Smits, 2008; Hunot, Churchill, de Lima, & Teixeira, 2007) and has also shown a potential advantage over pharmacological treatments for panic disorder in particular (Roshanaei-Moghaddam et al., 2011).

In medical populations, CBT interventions often address triggers for illness-related anxiety (such as fear of cancer recurrence) and typically adopt a generalist approach toward anxiety as a symptom. Anxiety is also often a secondary endpoint in treatments that target other problems such as depression or medical disability. Consequently, interventions vary in the extent to which they include theoretically based anxiety treatment strategies, and evidence for improvements in anxiety is mixed. CBT has shown promise in preventing or reducing anxiety in patients coping with a range of conditions such as cancer (Greer et al., 2012; Osborn, Demoncada, & Feuerstein, 2006), chronic obstructive pulmonary disease (Hynninen, Bjerke, Pallesen, Bakke, & Nordhus, 2010), and spinal cord injury (Mehta et al., 2011).

INSOMNIA

The objective of CBT for primary insomnia (Smith & Neubauer, 2003) is to improve sleep through changes in sleep hygiene practices and cognitions about sleep. Common strategies include psychoeducation, relaxation training, and cognitive restructuring (e.g., of catastrophic thinking related to sleep loss). Patients monitor sleep/wake patterns through daily sleep diaries, daytime activity records, and/or the use of an actigraph unit (a portable measure of gross motor activity) throughout the treatment period. These data provide feedback that can be reviewed at each treatment session. CBT approaches for optimizing sleep include stimulus control (facilitating sleep initiation) and sleep restriction (limiting actual time in bed to the amount of sleep time). In medical patients, primary insomnia versus insomnia secondary to a medical condition may be difficult to distinguish. CBT can be adapted to address unique sleep challenges among specific patient populations, such as disruptions in daytime activity and sunlight exposure, nocturnal dyspnea, or swallowing problems, and disease-related or treatment-related pain and fatigue.

CBT for insomnia has shown promise among medical patients, including those with HIV, cancer, and chronic pain (Smith, Huang, & Manber, 2005). Among older adults, limited data suggest that this treatment may lead to mild improvements in nighttime awakenings in particular (Montgomery & Dennis, 2003). CBT approaches to insomnia may also have a small to moderate effect on reducing comorbid anxiety, and very limited evidence supports that this effect may be comparable between patients with or without medical comorbidity (Belleville, Cousineau, Levrier, & St-Pierre-Delorme, 2011).

CHRONIC DISEASE MANAGEMENT

CBT protocols have been developed to treat or reduce disability associated with a range of medical concerns. These treatments emphasize that for patients with a chronic illness, disease self-management plays a critical role in effective patient care. CBT treatment targets and proposed outcomes may be multifold, including medical adherence, medical symptom reduction, optimal healthcare utilization, and disease-specific quality of life. Typically, treatments combine health education with CBT strategies to increase patient skills for engaging in self-care. For instance, CBT for adult asthma may integrate psychoeducation (e.g., about inhaler use and/or the link between anxiety and asthma physiology) with strategies for changing inaccurate thoughts (e.g., underemphasizing or overemphasizing respiratory symptoms) that provoke suboptimal inhaler use and/or worsen asthma attacks. CBT for chronic heart disease may combine education about cardiovascular function with strategies for promoting heart-healthy behaviors (e.g., physical activity, healthy eating behaviors) and adaptive thinking about the challenges of making such lifestyle changes.

Typically, CBT protocols for disease self-management have been tested in medical participants who do not necessarily meet criteria for clinical depression or anxiety. Rather, these studies reflect the assumption that all patients could benefit from additional skills for coping with the sequelae of their condition. Results of a small number of studies of CBT for adult asthma suggested that compared to control conditions, CBT may improve disease-specific quality of life but not depression symptoms or excess healthcare utilization (e.g., emergency room visits or hospitalizations [Yorke, Fleming, & Shuldham, 2006]). On the other hand, results from one of the largest psychological treatment trials in post-myocardial infarction (MI) adults suggests that CBT may improve both depression severity and quality of life among participants, in the absence of improving medical outcomes (Berkman et al., 2003). A comparative review of common psychological intervention elements for chronic heart disease identified that behavioral strategies in particular may improve depression and also reduce risk of both nonfatal cardiac events and mortality (Welton, Caldwell, Adamopoulos, & Vedhara, 2009). A small number of trials of CBT for adult epilepsy have examined diverse outcomes, with no reliable evidence to support benefits for seizure frequency, depression, or quality of life (Ramaratnam, Baker, & Goldstein, 2011).

PAIN

For patients experiencing chronic pain, CBT commonly targets the role of cognitions and behaviors that exacerbate pain intensity, distress, and disability. Strategies such as education, mental distraction from pain, relaxation training (e.g., muscle relaxation or deep breathing), and behavioral goal setting are used to improve pain management. Adaptive thinking skills may be used to modify unhelpful expectations about pain control (e.g., “my medications should completely cure my pain”) and beliefs about the meaning of pain symptoms. Through these methods, CBT participants learn to elucidate and interrupt cycles of behavioral inactivity (e.g., fearful avoidance of physical activity that could trigger pain) and physiological overactivity (e.g., anxious arousal and muscular tension) that lead to poorer pain outcomes.

Trials of CBT for patients with chronic pain commonly focus on altering pain severity, disability, and mood. It should be noted, however, that most trials have identified disability and mood as the primary outcomes. Findings suggest that CBT may be moderately effective in controlling low back pain intensity (Chou & Hoyt Huffman, 2007), with mixed evidence for improving disability (Hoffman, Papas, Chatkoff, & Kerns, 2007; Henschke et al., 2010). Results from a small number of studies also suggest that CBT alone or in combination with biofeedback has the potential to reduce orofacial pain intensity, as well as depression and interference of orofacial pain in usual activities (Aggarwal et al., 2011). Combined findings across different types of chronic pain (except headaches) have suggested small effects of CBT on pain severity and disability at 6-month follow-up (Eccleston, Williams, & Morley, 2009).

FATIGUE

As in the case of chronic pain, medical patients with fatigue symptoms may attempt to restrict physical activity, leading to unintended consequences such as increased sensitivity to transient fatigue symptoms and catastrophizing about the consequences of such symptoms. CBT interventions for fatigue commonly integrate basic CBT strategies (e.g., behavioral activation, adaptive thinking) with physical rehabilitation goals. Contingency planning (e.g., what to do on a day when fatigue is elevated versus relatively low) can facilitate the use of behavioral activation and promote patient confidence in engaging in meaningful activities (Carney & Freedland, 2008). Providers may also guide patients in planning “experiments” in which they incrementally increase exposure to physical activity while monitoring and challenging negative cognitions during each activity.

Fatigue is a common endpoint in trials of CBT for diverse medical populations. These interventions vary in the extent to which they include specific strategies to reduce fatigue. A randomized controlled trial of CBT for persistent fatigue in cancer survivors showed that CBT improved fatigue and functional status (Gielissen, Verhagen, Witjes, Bleijenberg, 2006), with sustained benefits at long-term follow-up (Gielissen, Verhagen, & Bleijenberg, 2007). Trials of CBT

specifically for patients with chronic fatigue syndrome suggest that CBT is moderately effective in reducing fatigue in this population (Malouff, Thorsteinsson, Rooke, Bhullar, & Schutte, 2008) and may be superior to other types of treatment (e.g., relaxation, counseling, activity pacing therapy [limiting stress and avoiding exacerbation of fatigue], and education [Price, Mitchell, Tidy, & Hunot, 2008; White et al., 2011]). Results from a parallel randomized trial of activity pacing, graded exercise (incremental increases in activity) and CBT showed that graded exercise and CBT interventions were both safe and moderately efficacious in improving fatigue and physical functioning relative to activity pacing or standard medical care alone (White et al., 2011). Incremental benefits of combining CBT with other types of treatment for fatigue have not been established.

PRACTICAL CONSIDERATIONS: ADAPTING CBT IN MEDICAL POPULATIONS

CBT interventions have been incorporated into clinical practice guidelines for a wide range of psychiatric disorders. Multicomponent approaches have been adapted to address how cognitions and behaviors can influence psychological adjustment, health behaviors, and functional status among medical patients. In practice, medical conditions introduce unique aspects to consider during CBT evaluation and delivery.

SYMPTOM OVERLAP

Psychiatric symptoms can overlap with or mask disease symptoms and treatment side effects (e.g., fatigue, dyspnea, appetite disturbances, and uncontrolled pain). Patient cognitions and emotional distress levels may also fluctuate over time in response to uncertain disease course or certain disease progression. Assessment and treatment planning should include collaboration with a patient’s other medical providers, and attention to complicating factors such as medication overuse, psychiatric comorbidity, stress and poor coping, and sleep disturbance (Lipchik, Smitherman, Penzien, & Holroyd, 2006). Contextual factors, including financial stressors and deficits in social support, may further reduce patient resources for accessing available resources and should be part of the initial assessment. In many cases, CBT approaches will be useful whether the symptoms are due to psychological factors, medical factors, or both.

PATIENT PREFERENCES, EXPECTATIONS, AND NEEDS

Patient histories play an important role in the acceptability of CBT for managing medical conditions. For individuals with idiopathic or poorly controlled symptoms, a long history of searching for proper diagnosis or symptom relief can lead to profound discouragement. On the other hand, patients who expect immediate symptom relief from CBT may

become disillusioned soon after therapy initiation (Lipchik, Smitherman, Penzien, & Holroyd, 2006). Motivations for talk therapy must be clarified at CBT entry; finding an appropriate balance between hope and realistic expectations is a critical step toward maintaining patient engagement in treatment.

Currently, the accessibility and acceptability of CBT and of talk therapies in general vary widely across geographic and clinic settings and individual patients. When available, CBT may be appealing to medical patients and healthcare providers for a number of reasons. For one, CBT interventions are unlikely to have side effects and contraindications relative to pharmacological agents. Patients may prefer talk therapy due to already complicated medication schedules or personal preferences. CBT interventions also largely rely on patients' personal efforts. Some conditions (e.g., chronic pain) may not be cured or completely controlled by medication or physical therapies, and CBT can help patients enhance their quality of life in the presence of residual symptoms. The CBT focus on learning and maintaining practical skills is also designed to reduce risk of relapse as stressors change over time.

CLINICAL PEARLS

- CBT strategies emphasize self-regulation (e.g., a patient with chronic fatigue may work on identifying and planning activities that correspond with daily level of fatigue)
- A situational interpretation (e.g., "My oncologist probably has not returned my call yet because she has bad news to tell me.") can trigger a cycle of negative cognitions, emotions and unhelpful behaviors.
- By developing a CBT model of the patient's symptoms, the therapist and patient may identify areas in which the patient can take personal responsibility or control over chronic disease management.
- Socratic questioning is an interview technique used to help a patient discover problematic patterns in thoughts or behaviors.
- Motivational interviewing is a method assuming patient autonomy, which elicits a patient's own intrinsic arguments for change and uses these arguments as the source of motivation.
- Behavioral activation represents a collaborative effort between the therapist and patient to identify specific activities that may be personally rewarding.
- Adaptive thinking skills may be supplemented with acceptance-oriented coping skills when thoughts are deemed realistic, or with information seeking when more "data" are needed.
- Problem-solving therapy emphasizes four main skills: articulating problems, generating potential

solutions, evaluating each solution with regard to advantages and disadvantages, and executing and monitoring a plan of action.

- Interventions typically conclude with a focus on relapse prevention by anticipating and problem-solving potential obstacles to the ongoing use of CBT skills.
- CBT in medical settings can help patients enhance quality of life in the presence of residual symptoms and related stressors that may change over time.

DISCLOSURE STATEMENTS

Dr. Traeger served as an independent consultant on a single advisory board meeting for Novartis Oncology. Her research has been funded through grants from the National Cancer Institute and the American Cancer Society.

Dr. Greer has no conflicts to disclose. His research is funded through grants from the National Cancer Institute and the American Cancer Society as well as institutional support from the Massachusetts General Hospital Cancer Center.

NONADHERENCE TO TREATMENT

Joseph A. Greer, Paul J. Helmuth, Jeffrey S. Gonzalez, and Steven A. Safren

INTRODUCTION

Prescribing physicians generally practice assuming a complex, though tacit, agreement with their patients under which they strive to listen carefully to the presenting symptoms, undertake appropriate testing and examination, provide a thoughtful diagnosis, and recommend a course of treatment. Patients, in turn, are expected to take medications as prescribed and return for follow-up care at some predetermined interval to report any progress or problems. Of course, this general approach to medical care, which derives from modern medical education and training, can break down for any number of reasons. For example, a patient may have insufficient trust in her doctor, may be unable to obtain the medication for financial or insurance reasons, may be frightened by potential dangers of taking the medication, may experience unacceptable side effects, or she may simply forget the doses. In any case, given the heavy reliance of physicians on regular dosing of prescription medications for the treatment of chronic illnesses, patient nonadherence represents a significant challenge because of the potential for poor medical outcomes. In this chapter we will focus on adherence to medications among patients with chronic medical conditions, with attention to the scope of the problem, causes and correlates of nonadherence, methods to assess adherence, and efficacious interventions to improve adherence.

When describing and discussing the extent to which patients take medications as prescribed, researchers and public health officials have employed a number of different terms. Starting in the 1950s, the term *compliance* has been used in the medical literature. However, the World Health Organization and National Institutes of Health now prefer the term *adherence*, given the pejorative implications of the word *noncompliance* with its connotation of a passive role for patients in receiving medical advice that seems to assign blame for patients' willful and deviant rejection of that advice. The term *adherence* is thought to imply a more active and collaborative role for patients in medical treatment decisions that includes an element of trust with the physician, and mutual agreement on the choice of medication and expectations for dosing (National Council on Patient Information and Education, 2007).

MEDICATION NONADHERENCE: PREVALENCE, COST, AND ADVERSE OUTCOMES

An extensive scholarly literature documents widespread problems with medication adherence across a number of disease states. According to a report by the World Health Organization, adherence to long-term therapies for chronic conditions averages 50% in developed countries, with even lower rates in developing nations (Sabaté & World Health Organization, 2003). However, deriving reliable estimates for adherence rates to medical recommendations is challenging given the variability of measurements, diseases, and thresholds for defining adherence. For example, DiMatteo conducted a meta-analysis of published studies over a 50-year period and observed much higher mean rates of treatment adherence among patients with HIV (88.3%) compared to those with pulmonary diseases (68.8%) or diabetes (67.5%). With respect to the type of medical recommendation, the mean rate for adherence to prescribed medications was 79.4% based on the average of 328 studies (DiMatteo, 2004).

While the prevalence rates vary widely in the literature, the problem of nonadherence is clearly costly to the healthcare system. Researchers estimated the total direct and indirect costs for failing to adhere to prescription drug therapy in the United States at approximately \$177 billion in 2000 (Ernst & Grizzle, 2001), while others have suggested that the figure may be much higher and closer to \$300 billion (DiMatteo, 2004). The costs incurred result from increased outpatient visits, emergency department visits, hospital admissions, and inpatient stays, as well as overall healthcare expenditures (Pittman, Chen, Bowlin, & Foody, 2011). For example, one study showed that patients who were less adherent to imatinib for chronic myeloid leukemia had more all-cause inpatient days (14.8 vs. 1.8 days, $p < .001$) and higher total healthcare spending (\$107,341 vs. \$58,278, $p < .05$) compared to those with better adherence to the oral chemotherapy (E. Q. Wu et al., 2010). Similar trends have also been observed for patients taking medications for HIV, hypertension, type-2 diabetes, and asthma (Bender & Rand, 2004; Dragomir et al., 2010; Nachega et al., 2010; Wu, Seiber, Lacombe, Nahata, & Balkrishnan, 2011). Efforts to improve patient adherence thus represent a useful investment for the US healthcare system,

as the increased pharmacy costs for treating chronic conditions are easily offset by savings related to decreased healthcare expenditures (Sokol, McGuigan, Verbrugge, & Epstein, 2005).

For most clinicians, the dramatic association between poor prescription medication adherence and adverse medical outcomes creates even greater concern than the substantial costs to the healthcare system. In general, patients who have low adherence to medical treatment recommendations (both prescription and nonprescription) experience 26% worse outcomes, according to a meta-analysis of the scholarly literature over the past three decades (DiMatteo, Giordani, Lepper, & Croghan, 2002). Patients with hypertension or coronary artery disease, for example, who are adherent to prescription medications experience decreased risk of stroke, heart failure, and cardiovascular events, as well as all-cause mortality (Bailey, Wan, Tang, Ghani, & Cushman, 2010; Dragomir, et al., 2010; Ho, Magid, Shetterly, Olson, Maddox, et al., 2008; Jackevicius, Li, & Tu, 2008). In fact, increasing adherence to a daily antihypertensive drug regimen by one pill per week appears to decrease stroke risk by 8%–9% and mortality by 7% over a 5-year period (Bailey, et al., 2010). Additionally, medication nonadherence helps to account for failures of patients to achieve lower blood pressures after physicians prescribe increased intensity of the antihypertensive regimens (Ho, Magid, Shetterly, Olson, Peterson, et al., 2008) and may in part explain the differential survival among African-American patients with heart failure as compared to Caucasians (J. R. Wu et al., 2010). Similarly, a number of adverse clinical outcomes are associated with nonadherence to antiviral medications among patients with HIV, such as disease progression, treatment resistance, and worse survival (Bangsberg et al., 2001; Harrigan et al., 2005; Hogg et al., 2002; Lima et al., 2007; Nachega et al., 2007). Taken together, these data underscore the importance of optimizing adherence to prescribed regimens as clinicians consider salient factors to reduce the risk of morbidity, and in some cases mortality, for patients with chronic conditions.

BARRIERS TO MEDICATION ADHERENCE

A variety of patient, provider, and system-level factors potentially compromise adherence to medications. Given the complex underlying causes of nonadherence, clinicians ideally would want to assess and consider the different types of barriers patients experience in order to tailor their interventions accordingly (Sabaté & World Health Organization, 2003). Using the case example below, we illustrate some of the various obstacles to medication adherence that patients experience and present strategies for identifying these barriers.

CASE STUDY

Ms. R is a 61-year-old, divorced woman of Puerto Rican descent who receives federal disability benefits for psychiatric reasons (depression and anxiety). She meets with her primary care physician quarterly to manage her chronic medical problems, including hypertension,

diabetes, and coronary artery disease. During a routine visit, Ms. R's blood pressure readings were higher than normal, and her blood sugar was also elevated. The patient became tearful during the clinical interview, noting that she had been feeling very stressed recently due to assuming the care of her grandchildren when her daughter had an accident. Initially, Ms. R attributed the elevated blood pressure readings to her increased psychosocial stress. However, upon further probing, the primary care physician learned that the patient was unable to provide the names and doses of her prescribed antihypertensive medications. Moreover, although Ms. R had been regularly refilling her insulin and diabetic supplies, her prescriptions for antihypertensive medications had lapsed for more than 2 months.

Patient Factors. To understand the reasons for nonadherence, a clinician working with a patient such as Ms. R may want to begin with an assessment of factors that are potentially within the patient's control. Indeed, researchers have observed that common barriers to adherence include issues ranging from simple forgetfulness and concerns about possible side effects to more subtle, underlying attitudes and beliefs regarding the severity of illness, effectiveness of the medication, need for ongoing therapy, and one's confidence in following through with complex regimens (Bartlett, 2002; National Council on Patient Information and Education, 2007; Osterberg & Blaschke, 2005). Moreover, Ms. R's comorbid psychiatric problems may be contributing to her difficulty in adhering to prescribed regimens. Several meta-analyses have documented the strong association between depression and poor treatment adherence in patients with various chronic conditions, including hypertension, diabetes, and HIV, both at clinical and subthreshold levels for mood symptoms (J. S. Gonzalez, Batchelder, Psaros, & Safren, 2011; J. S. Gonzalez et al., 2008; Grenard et al., 2011). Compounding these potential barriers are concerns about English language skills and health literacy. Many patients with chronic medical conditions may lack the ability to comprehend information and instructions regarding the frequency, dosing, side effects, and course of therapy (Kalichman, Pope, et al., 2008; Osborn et al., 2011).

Provider Factors. The provider–patient relationship has the potential to mitigate or exacerbate problems with medication nonadherence. A recent meta-analysis showed that patients whose physicians communicate poorly have a 19% higher risk of nonadherence than those whose physicians communicate well (Zolnieriek & Dimatteo, 2009). Time pressures during clinic encounters, lack of expressed empathy and inclusion of patients in the decision-making process, as well as overestimation of adherence are key issues that may impair communication about prescription medications. In particular, physicians often fail to consider the complexity and costs of regimens or sufficiently describe the benefits and risks of therapy, potential side effects, and relevant dosing information (Choudhry et al., 2011; Ingersoll & Heckman, 2005; Osterberg & Blaschke, 2005). Writing instructions down on paper, while helpful, is simply not enough to ensure proper adherence. In the case of Ms. R, had her physician accepted the patient's explanation for the elevated blood pressure reading without pursuing follow-up questions about the names and doses for the antihypertensive agents or calling the pharmacy, Ms. R's nonadherence would likely have been overlooked. Patient-centered approaches to care that solicit individual patients' reasons for missing doses, as well as motivations and supports for maximizing adherence, not only improve communication but also

build trust in the therapeutic relationship. Studies show that both quality of communication and level of trust in providers predict adherence to prescribed medications (Piette, Heisler, Krein, & Kerr, 2005; Schoenthaler et al., 2009).

Healthcare System Factors. Patient–provider interactions, of course, occur in the broader context of the healthcare system, which may serve as another salient barrier to accessing treatment and optimizing adherence. Specifically, in response to rising healthcare costs, third-party payers have sought to limit pharmacy expenditures by introducing restrictive formularies, increasing medication copayments, employing monthly prescription caps, and applying high deductibles to patient benefits. These efforts at cost reduction are especially problematic for individuals with chronic conditions, such as those with congestive heart failure, diabetes, or schizophrenia, who are more likely to utilize emergency department and inpatient medical services when faced with higher copayments, benefit caps, or other cost-sharing measures. In fact, for each 10% increase in cost-sharing overall, prescription drug spending on behalf of patients decreases by 2%–6% (Goldman, Joyce, & Zheng, 2007). In addition, older patients with chronic diseases and mood disorders are at increased risk of cost-related medication nonadherence (Briesacher, Gurwitz, & Soumerai, 2007).

Ms. R's Reasons for Nonadherence. As with many patients in clinical settings, Ms. R's reasons for medication nonadherence are complex and multifactorial. On further questioning, her physician discovered that she was experiencing a benefit cap in the form of the “donut hole” with respect to her Medicare prescription drug benefit. Ms. R then revealed that she felt that her diabetes was “the most important medical problem” she had. Given her limited resources, she had prioritized the purchase of insulin but felt she could forego her antihypertensive medications until after her prescription benefit resumed in the next calendar year. Although her language skills and known mood disorder may have contributed to her challenges with medication adherence at other times in the course of her illnesses, they were not relevant for the time period of the present vignette. She and her primary care provider then reviewed her medication regimen to incorporate some lower cost generic drugs that would most likely keep her yearly expenses below the benefit cap for the following year. Additionally, they reviewed the clinical importance of treating hypertension, as well as strategies for maintaining her drug therapy and improving communication about the costs and side effects of her medications.

METHODS FOR ASSESSING MEDICATION ADHERENCE

Accurate assessment of adherence to drug therapy is the first step in reducing the medical risks and associated costs resulting from prescription medication nonadherence. However, no single “gold standard” exists to evaluate this health behavior in either clinical or research contexts, with all forms of assessment possessing various biases or errors in measurement (J. S. Gonzalez & Schneider, 2011; Hansen et al., 2009). Even the most reliable and direct assessments, such as patient observation or laboratory measurements of drug metabolites in body fluids, are imperfect. In the case of directly observed therapy, patients may hold pills in their mouths without ingesting.

Although testing blood or urine samples may help overcome this concern, laboratory results only provide information about the use of the medication at one time point rather than over a sustained period (Farmer, 1999). In certain situations, direct assessment methods can be quite valuable, such as when a clinician tests for the presence of narcotics in urine to confirm that a patient is using the prescription opioids for a chronic medical condition rather than diverting doses. Nonetheless, these direct approaches are costly, time consuming, and generally impractical in clinical settings. Table 15.1 details common methods for assessing medication adherence and potential sources of measurement error (J. S. Gonzalez & Schneider, 2011).

Table 15.1 METHODS FOR ASSESSING MEDICATION ADHERENCE AND POTENTIAL THREATS TO VALIDITY

METHOD	POTENTIAL SOURCES OF MEASUREMENT ERROR
Direct patient observation	<ul style="list-style-type: none"> No significant source of error for observed doses
Medication level in biologic fluids	<ul style="list-style-type: none"> Metabolism and other ingested substances may affect accuracy Laboratory errors
Biologic markers	<ul style="list-style-type: none"> Metabolism and other ingested substances may affect accuracy Laboratory errors
Healthcare provider estimates	<ul style="list-style-type: none"> Healthcare provider has limited information on which to base estimate, and this may be biased by inaccurate patient reports and/or biologic markers as indicators of adherence
Pharmacy claims data	<ul style="list-style-type: none"> No information about ingestion of medication Patient may use more than one pharmacy or may share medications with family and friends Documentation errors
Electronic monitoring	<ul style="list-style-type: none"> No information about ingestion of medication Does not document pocketed doses or pills taken from other sources (e.g., pill box) Device errors/malfunctions
Pill count	<ul style="list-style-type: none"> Potential for medication dumping before assessment if not unannounced No information about ingestion of medication Human errors in counting
Self-reported adherence (patient interviews, diaries and self-report measures)	<ul style="list-style-type: none"> Inaccuracies relating to patient memory Report bias (patient may purposely overestimate adherence) Characteristics of the question and how they are administered (e.g., interview vs. questionnaire) may affect how patients respond Incomplete recording is common for diaries Numeracy and literacy issues could influence reporting

Adapted from Gonzalez & Schneider, 2011.

Due to ease of implementation, clinicians often prefer to use indirect methods for evaluating adherence to drug therapy. Such methods include estimates from the health-care provider, pharmacy claims data, electronic monitoring devices, pill counts, and self-report by patients. Multiple studies show that, across disease states, physicians overestimate their patients' adherence to prescribed medications, and their assessments often fail to correlate with other measures of adherence (Daniels et al., 2011; Trindade, Ehrlich, Kornbluth, & Ullman, 2011; Walshe et al., 2010). Therefore, clinicians would be better served by relying on alternative methods that provide a more valid and reliable estimate of patient adherence.

Pharmacy refill data may be used in a number of clinical and research scenarios. Traditionally, researchers have examined medical records and claims data from large databases to determine rates of prescription refills, noting that the proportion of days covered for filled prescriptions is strongly associated with medical outcomes and healthcare utilization patterns. Although the findings from investigations of large epidemiological studies that incorporate claims data are meaningful in demonstrating the potential clinical effects of non-adherence at the population level, such methods offer limited value in discerning an individual patient's use of a prescribed medication. Recently, in tandem with trends to provide incentives for improved disease management to providers and medical care organizations, both pharmacies and health insurers are using individual patient refill data to alert patients and clinicians directly about potential nonadherence to medications (Bambauer et al., 2006). While these initiatives may prove useful in improving patient adherence, some caution is warranted. Specifically, physicians do not routinely inform pharmacies and insurers when they advise patients to discontinue particular medication regimens. Such gaps in communication among medical providers, pharmacists, and insurers may lead to serious medication errors and adverse outcomes.

Electronic monitoring devices are an alternate, objective measure of medication adherence, most commonly used for research purposes. For example, the Medication Event Monitoring System (MEMSTM, Aardex; Zurich, Switzerland) consists of a standard pill bottle with a specialized cap containing an electronic microprocessor that records the exact date and time the bottle was opened, thus providing researchers with detailed information about medication-taking behaviors over time. Although this method of assessment has many strengths and correlates well with pharmacy refill data (Hansen, et al., 2009), opening of a MEMS pill bottle may underestimate the true rate of adherence because patients can remove pills for multiple doses at one time. For example, in a study of 128 HIV-infected individuals treated with at least three antiretroviral agents, 41% of the sample reported taking out more than one dose at a time (Bova et al., 2005). The converse is also a possibility, as patients perhaps may open the pill bottle without actually ingesting the medication. While MEMS devices have generally served more as a tool for assessment than for intervention, recent innovations have adapted electronic pill caps with a wireless technology that sends audiovisual signals to cue patients when to take their

medications. Still, these products are not only expensive but also may interfere with use of other strategies for improving adherence to prescribed medications, such as weekly pillbox organizers (Kalichman, Cain, Cherry, Kalichman, & Pope, 2005). For these reasons, their application in clinical settings is limited.

Another method of assessment for adherence commonly used in clinical trials involves counting pills and calculating the ratio of the number of pills remaining in the bottle compared to the total number of pills that should have been consumed during a specified time period. To use this approach, patients are generally asked to bring their medication bottles to the study assessment or medical visit, which has the potential to introduce significant error in measurement (Choo et al., 1999; Farmer, 1999). Since patients often transfer medications to other containers, such as pillboxes, they may unintentionally invalidate the pill count. Others may directly manipulate the number of pills in advance of an assessment in order to appear more adherent to the physician or researcher. To overcome these issues, investigators who study medication adherence in patients with HIV, for example, have begun to examine the feasibility, reliability, and validity of conducting unannounced pill counts over the telephone. This approach is unobtrusive and demonstrates very high concordance (>90%) with unannounced home-visit pill counts, even among patients of low socioeconomic status (Kalichman et al., 2010; Kalichman, Amaral, et al., 2008; Kalichman et al., 2007). Although pill counts have fallen out of favor somewhat with the advent of other objective measures, such as electronic monitoring devices, unannounced pill counts over the telephone may represent an acceptable, valid, and cost-effective measure of medication adherence that could be generalized to clinical settings.

Given their practical application, ease of administration, and low burden to patients, self-report assessments are the most popular tools for measuring medication adherence among individuals with chronic illnesses. Various interviews, diaries, questionnaires, scales, and single-item measures exist, some of which can be generally applied while others are disease-specific. More importantly, these measures tend to overestimate rates of adherence due to their susceptibility to response bias from poor memory or social desirability, and they may vary with respect to their validity and reliability in correlating with other, more objective measures of adherence (Shi, Liu, Fonseca, et al., 2010; Wagner & Miller, 2004). Nonetheless, in the case of HIV disease, for which adherence to antiretroviral therapy is especially important to clinical outcomes, investigators have found that responses on self-report questionnaires of medication adherence are significantly associated with virologic response to treatment (Nieuwkerk & Oort, 2005). Among the most common instruments is the Adult AIDS Clinical Trial Group (AACTG) adherence measure, which asks patients whether they have missed any prescribed doses within certain time frames (e.g., past 2 days, 7 days, 2 weeks, 1 month, etc.), along with reasons for non-adherence (Chesney et al., 2000). Otherwise, general medication adherence instruments that are widely used and possess adequate validity include the Morisky Medication Adherence

Scale, the Brief Medication Questionnaire, and the visual analogue scale (Morisky, Green, & Levine, 1986; Svarstad, Chewning, Sleath, & Claesson, 1999). While these measures appear to show moderate concordance with electronic monitoring devices, their correlation with pharmacy refill records is somewhat weaker (Cook, Wade, Martin, & Perri, 2005; Shi, Liu, Koleva, et al., 2010).

Despite the abundant literature on medication adherence for patients with chronic illnesses ranging from cancer and HIV to hypertension and diabetes, no single self-report measure has emerged as the optimal tool for predicting non-adherence or adverse clinical outcomes. Nonetheless, some general principles can be derived that may inform clinical practice. First, single-item global assessments of adherence, with which individuals rate their ability to take all medications as prescribed for the past month using either a visual analogue scale, percentage-base response, or qualitative assessment (i.e., very poor to excellent), perform very well when correlated with electronic medication monitoring methods (J. S. Gonzalez & Schneider, 2011; Lu et al., 2008; Schneider, Gonzalez, & Psaros, 2011). In addition, such global tools may be more accurate than asking patients to recall the number of missed doses and are especially useful for minority patients who are non-native English speakers or who may have limited health literacy and numeracy (i.e., the ability to process and respond to numerical and quantitative information) (Buscher, Hartman, Kallen, & Giordano, 2011; Giordano, Guzman, Clark, Charlebois, & Bangsberg, 2004; Golbeck, Ahlers-Schmidt, Paschal, & Dismuke, 2005). Finally, at least in the case of HIV medication adherence, studies suggest that both the reliability and predictive validity of measurements can be maximized by evaluating adherence across multiple time points and combining multiple methods of assessment (Liu et al., 2001; Llabre et al., 2006).

INTERVENTIONS TO IMPROVE MEDICATION ADHERENCE

Despite the accumulation of evidence underscoring the need to assess and address medication nonadherence in patients with chronic medical conditions, clinical and research efforts aimed at improving this health behavior have been disappointing to date. A meta-analysis of 78 intervention trials for enhancing medication adherence published by the Cochrane Collaboration reveals mixed results for both short-term and long-term adherence treatments (Haynes, Ackloo, Sahota, McDonald, & Yao, 2008). Specifically, less than half of the tested interventions led to significant improvement in medication adherence, and even fewer had effects on clinical outcomes. The target patient populations and diseases were diverse and included individuals with HIV, diabetes, asthma, chronic obstructive pulmonary disease, hypertension, rheumatoid arthritis, dyslipidemia, heart disease, and psychological disorders, among others. Moreover, treatment approaches varied considerably, ranging from simple educational and reminder systems to more complex combinations of psychotherapy, self-monitoring, reinforcement, telephone follow-up,

and supportive care. Unfortunately, the poor methodological rigor, small sample sizes, limited statistical power, imprecise measurement of adherence, diversity of interventions, and inconsistent clinical effects of the studies prohibit any conclusions about the overall utility and generalizability of any single approach. Two other recent meta-analyses highlight the potential promise of reinforcement and reminder systems (i.e., “reminder packaging”) for increasing adherence to medications (Mahtani, Heneghan, Glasziou, & Perera, 2011; Schedlbauer, Davies, & Fahey, 2010). Nonetheless, based on the studies to date, further high-quality research is undeniably needed to develop innovative, efficacious, and clinically relevant approaches for improving medication adherence over the long term, along with related medical outcomes.

In the following section, we describe two novel approaches for improving medication adherence among patients with various chronic medical conditions. Based on our federally funded research studies, the first depicts a cognitive behavioral therapy intervention tailored to patients with type 2 diabetes and depression (NIH 1R01 MH078571; Principal Investigators: Safren and Gonzalez); and the second details a Web-based disease management program for asthma in adult primary care patients (NIH 1R43 HL096244; Principal Investigators: Helmuth and Greer). We illustrate the principles of the different intervention strategies using clinical case examples.

COGNITIVE BEHAVIORAL THERAPY FOR ADHERENCE AND DEPRESSION (CBT-AD) IN TYPE 2 DIABETES

CASE STUDY

Mr. M is a 60-year-old, non-Hispanic White male who was diagnosed with type 2 diabetes 3 years ago. His other medical problems include hypertension, coronary artery disease, and obesity (BMI of 45). Additionally, he meets criteria for recurrent major depressive disorder and has been seeing a counselor for many years. Upon most recent testing, his diabetes was in poor control with a hemoglobin A1C of 10.2% (goal is less than 7.0%). Mr. M admits to poor adherence to his oral hypoglycemic medications, noting that his travel schedule for work interferes with his ability to take his daily doses on time. Similarly, he does not exercise and often eats out at restaurants due to his variable work schedule. Stating that he is “completely overwhelmed” by stressors in his job and marriage, the patient believes that he does not have the time or energy to focus on his diabetes care. Yet, he does report considerable shame and guilt about his health behavior patterns and his weight, noting that his wife continually pressures him to eat better, take his medications, and begin an exercise program.

Mr. M is a good candidate for CBT-AD given his presenting concerns, though his low motivation and negative thought processes about his self-efficacy may compromise his participation. CBT-AD is a 10–12 session treatment consisting of five core modules that focus on improving medication adherence and depression symptoms, given the strong comorbidity between the two in patients with type 2 diabetes (J. Gonzalez et al., 2010; J. S. Gonzalez et al.,

2007). To begin, Mr. M would meet with the CBT therapist to discuss and address his problems in managing his oral hypoglycemic medications. This first session is entitled *Life Steps* and comprises 11 informational, problem-solving, and cognitive-behavioral steps that target a range of self-care behaviors, namely medication adherence (Safren, Otto, & Worth, 1999; Safren et al., 2001). For example, these steps include educating the patient about adherence, scheduling doses, using stimulus control to cue taking medication such as alarms and visual reminder systems, reframing thoughts to be more adaptive regarding adherence, and improving communication with medical providers. The goal of the Life Steps session is to clarify and problem-solve obstacles to self-care by identifying barriers to optimal adherence, generating possible solutions, and developing targeted action plans. In the case of Mr. M, a key feature of Life Steps would be to address his concerns about missing doses because of his work schedule. Considering his frequent use of a calendar feature on his smart phone to manage his many work-related appointments, he could reasonably add medication dosage times to his electronic schedule. By doing so, he would not only increase the likelihood of remembering doses but also symbolically elevate the importance of medication adherence relative to his other daily priorities. In the subsequent sessions, Mr. M and his CBT therapist would spend the first few minutes reviewing these strategies to enhance medication adherence prior to learning and practicing new skills also aimed at treating comorbid depression symptoms.

After the first Life Steps session, the treatment turns to the first core module: *Education and Motivational Enhancement*. Spanning two sessions, in this module, Mr. M would learn about the principles of cognitive-behavioral therapy, including a discussion of the complex interactions among thoughts, behaviors, and physical symptoms in exacerbating depression. In addition, since Mr. M had spent many years in supportive, psychodynamic psychotherapy, he would benefit from an overview of the process of CBT including the goal-oriented nature of treatment, collaborative focus, and use of “homework assignments” to practice skills learned in session. Finally, the CBT therapist and Mr. M would work together to increase his motivation by clarifying his goals for treatment and examining the pros and cons of working on his mood symptoms and self-care behaviors versus maintaining the status quo. Mr. M might identify his desire to feel better about his body and improve his quality of life, or his wish to avoid having another heart attack, as salient factors motivating him to change.

The next module (approximately one session) focuses on behavioral activation and scheduling of pleasant events, while monitoring fluctuations in mood within and across days. Given the utility of identifying and engaging in meaningful and reinforcing activities to improve mood (Hopko, Lejuez, Ruggiero, & Eifert, 2003), Mr. M would want to examine the relationship between his stress level (i.e., “feeling overwhelmed”) and predominant focus on work-related activities at the exclusion of pleasurable events. In discussion with his CBT therapist, Mr. M might reveal that he had previously enjoyed taking ballroom dance lessons with his wife when they were younger. Capitalizing on this prior experience, he could perhaps reinstate this activity and schedule weekly dance classes, which would not only help his mood but also increase his physical activity level and potentially enhance his relationship with his wife. Other key components of this module pertain to tracking of blood glucose levels, exercise, and dietary behaviors.

Given the role that negative thoughts and self-talk play in perpetuating depression, the third module of CBT-AD involves training in cognitive restructuring the maladaptive thought processes that worsen mood and compromise self-care behaviors, including adherence to medications. Specifically, the aims of these sessions are to elicit patients’ negative automatic thoughts, examine potential distortions in perception, and reframe these thoughts to be more realistic and adaptive (A. Beck, 1987; J. Beck & Beck, 1995). For example, like many patients with type 2 diabetes, Mr. M may avoid checking his blood sugars because the readings remind him of how badly he is managing his disease, prompting negative thoughts such as, “This is useless; I’ll never be able to get my blood sugars down.” Recognizing that such extreme thoughts only make him feel ineffective and more depressed, Mr. M could work with his CBT therapist to challenge this distortion by identifying past exceptions to the perception or by taking a less judgmental approach, using the reading as one data point for understanding the factors associated with blood sugar control rather than as a measure of self-worth.

The problem-solving module covers the next two sessions and incorporates skills for overcoming behavioral avoidances and challenges to self-care. Drawing on the principles of problem-solving therapy (D’Zurilla, 1986; Nezu & Perri, 1989), patients work on deconstructing daunting tasks into a series of manageable steps by first brainstorming possible courses of action, evaluating those potential decisions, and executing a straightforward behavioral plan. For example, Mr. M might realize that successful weight loss will require reducing his work hours to allow for sufficient time to plan meals and participate in regular physical activity. To address this problem, he and his CBT therapist would explore possible solutions for modifying his schedule, rate each solution’s potential for resolving the problem, and then choose the optimal course of action that will help him move forward, recognizing that most solutions have salient advantages and disadvantages. In essence, these problem-solving skills aid patients like Mr. M to overcome ambivalence and avoidance in the face of challenging life decisions.

The final module consists of two sessions focused relaxation training, including diaphragmatic breathing and progressive muscle relaxation. Given Mr. M’s tendency to feel overwhelmed by multiple life stressors, such techniques may help him learn to identify the physiological triggers of his mood symptoms and to practice simple methods for calming his body. Also, as he builds mastery in these skills he may gain confidence in his ability to manage stress, which may improve his overall self-efficacy and generalize to other health behaviors.

CBT-AD is an evidenced-based treatment that was first tested in samples of patients with HIV disease and comorbid depression (Safren et al., 2009), now undergoing efficacy study for use in individuals with type 2 diabetes with medication adherence and depression symptoms as primary outcomes (J. Gonzalez, et al., 2010). The client treatment manual, along with therapist guide, has been published (Safren, Gonzalez, & Soroudi, 2007a; Safren, Gonzalez, & Soroudi, 2007b). Yet, we recognize that broad dissemination of CBT-AD may be challenging, particularly for clinicians practicing in resource-poor communities who don’t have access to psychotherapists possessing the necessary training and expertise in both CBT and management of

medication adherence. Therefore, in the following section, we present a novel approach to caring for patients with chronic medical conditions that utilizes automated Web-based tools to enhance medication adherence, self-management of disease, and patient-provider communication.

A WEB-BASED MODULE FOR ASTHMA MANAGEMENT IN PRIMARY CARE

CASE STUDY

Mrs. D is a 45-year-old African-American woman who has a lifelong history of asthma. She has had a recent increase in her symptoms of asthma with breathlessness, cough, and decreased exercise tolerance over the last 6 months. She attributes some of her symptoms to cigarette smoking. She had previously quit smoking at age 25 at the time of her first pregnancy and reports that she started smoking again in the past year because of stress related to her pending divorce. Furthermore, she has had problems with symptoms of increased worry regarding finances since her daughter is planning to go to college, and she recently lost her job as a rental property manager. Mrs. D uses her albuterol “rescue” inhaler two or three times per day and feels that it is “the only thing” that helps with her symptoms of breathlessness. Her primary care doctor has prescribed multiple controller medications in the past, but she doesn’t feel that they help sufficiently and has never continued taking them because “they don’t work well enough to be worth the copay amount.” She frequently uses all of her rescue inhaler doses before the prescription is due for renewal at the pharmacy.

At the time of enrolling in the Web-based asthma management program through her primary care physician’s office, Mrs. D was feeling especially frustrated with her symptoms of shortness of breath and insomnia. She attributed some of her sleep problems to anxiety, but admitted that she frequently wakes from sleep with coughing and needs to use her inhaler in the middle of the night. Mrs. D is a good candidate for use of the online disease management module because it would provide her with needed patient educational information as well as tools for self-management, among other resources.

When enrolling in the program, Mrs. D would be given a password and introduced to the online version of the Web-based asthma management module by a medical assistant in her primary care doctor’s office. She would learn about the two major functions of the program: (1) online questionnaires to assess her asthma control, medication adherence, and behavioral comorbidities; and (2) self-management tools to assist her in taking better care of herself with respect to her asthma. With her primary care doctor, she would review her symptoms and her office spirometry report and would be classified as having “moderate, persistent asthma.” Since patients with moderate asthma are noted to benefit from daily measurement of their peak flow rate using a simple handheld device, her doctor will give her a prescription to obtain her own peak flow meter. Also, at this enrollment visit Mrs. D and her doctor would work together to develop an online *Asthma Action Plan* (AAP), with instructions on what actions

to take should she have an asthma attack. For example, if her peak flow reading is low, it would place her in the “red zone” or the “yellow zone” as calculated as a percentage of her personal best peak flow reading. She would then follow the AAP instructions that she and her doctor decided upon regarding use of her inhalers, addition of prednisone, and instructions for when to go to the emergency department or call the medical office. Finally, at the initial visit, Mrs. D would complete baseline questionnaires in their online format. The self-report questionnaires in the asthma management program include the following:

- **Asthma Control Test:** A 5-item self-report questionnaire to determine asthma control over the past month (Nathan et al., 2004).
- **Morisky Medication Adherence Questionnaire:** A 4-item questionnaire to assess adherence to medications, in this case controller medications for treating asthma (Morisky et al., 1986).
- **Smoking Questionnaire:** Up to three items to clarify if the patient is a present smoker, former smoker, or never smoker (Centers for Disease Control and Prevention, 2008).
- **Hospital Anxiety and Depression Scale:** A 14-item tool for measuring symptoms of anxiety and depression during the past week in medical patient populations (Zigmond & Snaith, 1983).
- **Stage of Change Questionnaire:** Single-item instrument to assess patient readiness to make changes in taking medications as prescribed, with five possible stages including pre-contemplation, contemplation, preparation, action, and maintenance (Marcus, Selby, Niaura, & Rossi, 1992).

The self-report questionnaires are brief (26 items total), which Mrs. D would be able to complete in less than 10 minutes. The Web-based program immediately calculates the results of the questionnaires and provides a tailored response that is sent to the individual patient as well as to the medical provider. Thus, both Mrs. D and her doctor would receive concise messages similar to the one below. For Mrs. D’s physician, the results of the questionnaires would transfer into the electronic medical record in a similar manner as laboratory results. Her doctor would then be able to address the concerns raised by the results of the self-report questionnaires, although Mrs. D would have already received feedback herself in the following format:

Below are results from your asthma questionnaires. Please use the link to educational materials at the bottom of the screen to learn more about your asthma or other related conditions.

Asthma Control Score: Low

Your asthma control test results indicate that your asthma is not well controlled at this time. Please call your doctor’s office to arrange for a visit or to discuss your asthma medications.

Adherence to Asthma Medications: Low

You appear to be having difficulty using your asthma controller medications as prescribed. Please consider what may be interfering with your ability to use these medications on a daily basis. You and your doctor may discuss ways to improve your adherence at your next office visit.

Smoking Status: Current Smoker, daily. Has tried to quit.

Consider what might increase your chances of success when you try to quit smoking again. Please click on the educational links below to view information on resources to help you quit smoking.

Anxiety Symptoms: Mild

Your test for anxiety suggests that you have mild symptoms of anxiety. You may review links to information on anxiety below. Please also discuss your symptoms with your doctor.

Depression Symptoms: Mild

Your test for depression suggests that you have mild symptoms of depression. You may review links to information on depression below. Please also discuss your symptoms with your doctor.

Stage of Change (for improving use of controller medications): Contemplation

It seems that you are thinking about taking your asthma medications more regularly. Please consider the pros and cons of changing this behavior in order to help motivate you to take your medications on a daily basis. You may discuss this with your doctor at your next visit.

In addition to completing the Asthma Control Test, our comprehensive approach also assesses for the various behavioral and psychological correlates to asthma control such as medication adherence, psychological distress, and smoking status, using online self-report measures. The complex associations between asthma symptoms, psychological distress, and adherence to asthma medications remain incompletely elucidated, although symptoms of anxiety and depression are common among individuals with asthma (Goodwin, Jacobi, & Thefeld, 2003; Goodwin et al., 2003; Heaney, Conway, Kelly, & Gamble, 2005). Moreover, symptoms of depression have been associated with increased asthma severity, as well as functional impairment, increased

number of visits to physicians and emergency departments, and impairments in health-related quality of life (Dahlen & Janson, 2002; Mancuso et al., 2008; Strine, Mokdad, Balluz, Berry, & Gonzalez, 2008). Anxiety and depression are also associated with poor adherence to asthma treatment (Bosley, Fosbury, & Cochrane, 1995; Cluley & Cochrane, 2001; Smith et al., 2006).

Because the Asthma Control Test score for Mrs. D was low on the initial questionnaire, she will receive email requests to complete the questionnaires again in one month. The results of repeat testing will come to her and to her doctor, with concise interpretations and instructions for both. Ideally, because her asthma control was poor, she should receive information from her doctor and from the website about the importance of using controller medications even though they do not offer quick relief of symptoms. As she monitors her lung function at home by obtaining her daily peak flow rate and documenting it in the asthma management website, Mrs. D would see steady improvements in her lung function as she becomes more adherent to use of her controller medication. Moreover, the online patient educational materials about smoking cessation might help to improve her motivation for quitting cigarette smoking. After her asthma control improves, Mrs. D would receive less frequent email contact. The patient contact for the Web-based module is determined using an algorithm that prioritizes those patients with poor asthma control for more intensive intervention (see Figure 15.1 below).

At one of her subsequent follow-up visits, Mrs. D might discuss her symptoms of anxiety with her primary care doctor, noting that she has been feeling more stressed recently because of her divorce and her finances. She might have some questions about anxiety after being informed that her screening test was positive on the asthma control website. After discussing the overlap in symptoms of anxiety and asthma, especially breathlessness and chest tightness, she and her doctor could determine a plan of care for addressing her symptoms of worry and insomnia. Similarly, she might raise her concerns about cigarette smoking and ask for information about medications to help her quit, having read some online information about the options for prescription drugs that could improve her chances of quitting.

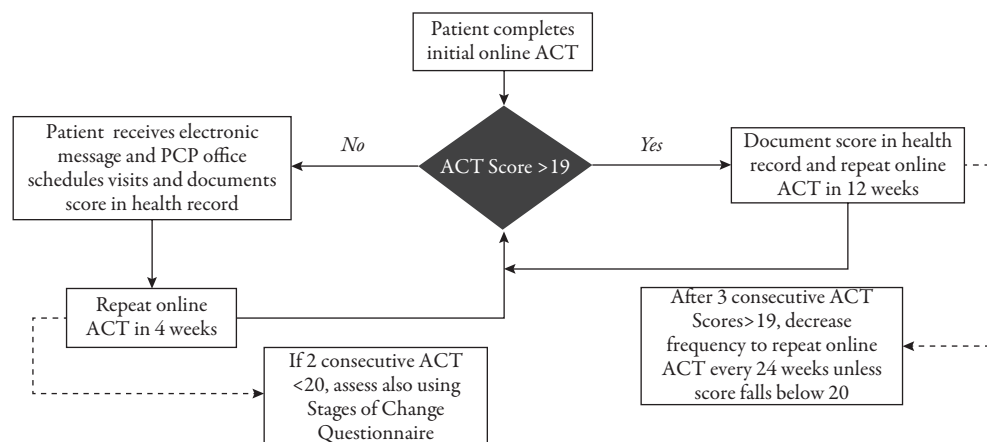

Figure 15.1 Web-based Asthma Management Algorithm.

If Mrs. D were to fail to complete a questionnaire, she would receive a second email message reminding her to do so. If she failed to respond to the second message, a notification would automatically go to her doctor indicating that Mrs. M is no longer adherent to the online program. The triage nurse from her primary care doctor's office would then try to contact her by phone to encourage her to continue using the online asthma management program.

Because medication adherence is the most proximal factor for asthma control, our tool applies Prochaska's transtheoretical behavior change methods to improve medication adherence (James O. Prochaska, 1979). Interventions derived from the transtheoretical model have also been used in diverse populations to improve health risk behaviors, including alcohol and substance abuse, smoking, poor medication adherence, and physical inactivity (Johnson et al., 2006; J. M. Prochaska et al., 2004; J. O. Prochaska, Velicer, Prochaska, & Johnson, 2004; Sarkin, Johnson, Prochaska, & Prochaska, 2001). We assess stage of behavioral change for improving adherence to asthma controller medications (e.g., pre-contemplation, contemplation, preparation, action, maintenance, or termination) in those patients who report poor adherence to medications. For example, patients who are in the contemplation stage are planning to change their health behaviors in the next 6 months, and although they are aware of both the pros and cons of changing they remain ambivalent. These patients are not yet ready for "action-oriented" programs, so clinicians should focus on enhancing motivation for change during office visits (J. O. Prochaska & DiClemente, 1983). Our tool provides such relevant data to clinicians, with suggestions for tailoring interventions to individual patients based on their current stage of change.

Our Web-based asthma management program is designed to help patients improve overall control of asthma, including medication adherence. The assessment of adherence is within the context of a comprehensive program to manage chronic diseases, consistent with recent trends in medical care that prioritize a patient-centered approach. Care management activities that provide services to patients with chronic illnesses are now required for physician practices to receive recognition in newer models of care such as the *Patient-Centered Medical Home* (NCQA, 2011). Moreover, through these programs and ongoing payment reform underway with public and private insurers, disease management activities, including assessment and support for medication adherence, will be increasingly tied to physician reimbursement (Rosenthal, 2008). Thus, physicians and their patients will benefit from greater access to cost-effective tools that provide patient-centered disease management programs that include patient educational materials, self-management tools, assessment and support for medication adherence, and resources for undertaking health behavior change.

SUMMARY

Nonadherence to self-administered medications remains a critical concern that compromises medical care and results in increased healthcare costs and utilization of services. Multiple

patient, provider, and system factors contribute to the problem of nonadherence, necessitating clear communication during clinical encounters as well as tailored interventions to maximize patient self-care behaviors and understanding of the importance of taking prescribed medications consistently. Although the scholarly literature on patient adherence to medications is vast and continually evolving, the following recommendations can be gleaned, which may offer some guidance to clinicians seeking to address this important problem with their patients:

1. When prescribing a new medication, communicate clearly the purpose of the drug, potential side effects, likely outcomes, and plan for follow-up care should questions or concerns arise.
2. Simplify complex medication regimens to utilize once-daily dosing with as few pills and dietary restrictions as possible.
3. Encourage patients to invite caregivers and family members to be present when giving instructions, in order to support and reinforce patients' efforts to take medications as prescribed.
4. Inquire about medication adherence at each medical visit in a patient-centered and nonjudgmental manner. (For example, "Many individuals have problems remembering to take their doses of medication exactly as prescribed. Has this been difficult for you over the past month?").
5. Probe about various factors related to the patient (i.e., forgetfulness, health beliefs, depression, motivation, side effects, etc.) and healthcare system (i.e., medical insurance problems, high copayments, inadequate access to follow-up care) that may be contributing to nonadherence.
6. To assess medication adherence, try to gather data from multiple sources when possible, such as patient self-report, pharmacy refill data, and/or unannounced telephone pill counts.
7. Consider using simple, global assessments or ratings of self-reported adherence, which may be most feasible, generalizable, and cost-effective in diverse clinical settings.
8. For patients not ready to make a positive change in their adherence behaviors, utilize motivational enhancement strategies to encourage progress from contemplation to action (i.e., defining patient goals, examining the pros and cons of improving adherence versus maintaining the status quo, exploring and problem-solving obstacles to self-efficacy and confidence, etc.).
9. When appropriate and available, make use of evidence-based interventions such as CBT-AD to provide support for patients seeking to improve medication adherence and comorbid depression.

10. Provide patient-centered resources for comprehensive disease management that integrate medication adherence, access to patient education materials, support for health behavior change (e.g., weekly pillbox organizers, diaries, reminder systems), and self-management tools (i.e., action plans for home-based monitoring of blood pressure, blood sugars, peak expiratory flow rate, etc.).

CLINICAL PEARLS

- Patients who have low adherence to medical treatment recommendations (both prescription and nonprescription) experience 26% worse outcomes.
- To understand the reasons for nonadherence by a patient, a clinician may want to begin with an assessment of factors that are potentially within the patient's control.
- Unannounced pill counts over the telephone may represent an acceptable, valid, and cost-effective measure of medication adherence that could be generalized to clinical settings.
- Among the most common instruments is the Adult AIDS Clinical Trial Group (AACTG) adherence measure, which asks patients whether they have missed any prescribed doses within certain time frames (e.g., past 2 days, 7 days, 2 weeks, 1 month, etc.), along with reasons for nonadherence (Chesney et al., 2000).
- A meta-analysis of 78 intervention trials for enhancing medication adherence published by the Cochrane Collaboration reveals mixed results for both short-term and long-term adherence treatments (Haynes, Ackloo, Sahota, McDonald, & Yao, 2008).
- Encourage patients to invite caregivers and family members to be present when giving instructions in order to support and reinforce patients' efforts to take medications as prescribed.
- Inquire about medication adherence at each medical visit in a patient-centered and nonjudgmental manner. (For example, "Many individuals have problems remembering to take their doses of medication exactly as prescribed. Has this been difficult for you over the past month?")

DISCLOSURE STATEMENTS

Dr. Safren is funded through various NIH grants, and no industry support. He, however, receives royalties from book publishers, including Oxford University Press and Guilford Press.

Dr. Greer has no conflicts to disclose. His research is funded through grants from the National Cancer Institute and the American Cancer Society, as well as institutional support from the Massachusetts General Hospital Cancer Center.

HYPNOSIS IN PSYCHOSOMATIC MEDICINE

José R. Maldonado

INTRODUCTION

Hypnosis is a psychophysiological state of attentive, receptive concentration, with a relative suspension of peripheral awareness. Hypnotic phenomena occur spontaneously, and the alteration of consciousness that hypnotized individuals experience has a variety of therapeutic applications.

Hypnosis is a natural state of attentive, focused concentration. As such, most individuals are able to experience variable trance-like states at different times in their daily lives. The hypnotic capacity or hypnotizability of a given subject (i.e., the degree of natural ability to enter a trance state) will determine the degree of assistance required to enter trance states. Highly hypnotizable individuals enter trance states with ease, on many occasions even without being fully aware of it. Individuals with moderate hypnotizability require more direction or help from a therapist who facilitates the trance experience, while those with low hypnotizability may not be able to benefit much from hypnosis as a treatment tool.

The ability to enter a trance state is widely and naturally distributed throughout the general population. Therefore, some patients may experience trance states or inadvertently take suggestions without planning. This may have potential positive or negative consequences depending on the patient and the circumstances of the interaction. For example, moderately to highly hypnotizable individuals may use hypnotic techniques to enhance pain management, stop the use of nicotine, diminish chemotherapy side effects, assist in managing the psychological and physical discomfort of intraoperative and postoperative procedures and childbirth, and assist in the management of various psychosomatic conditions (e.g., asthma, irritable bowel syndrome, warts). Similarly, high hypnotic capacity may actually become a liability to patients who are unaware of their hypnotic capacity or of their unconscious use of this mechanism, as in the case of individuals suffering from a dissociative and somatoform disorder or nocebo (i.e., negative placebo) effect.

BACKGROUND

The oldest written record of cures by hypnosis was obtained from the Ebers Papyrus, which gives us an idea about some of the theory and practice of Egyptian medicine before 1552 BC

(Joachim, 1890; Ebbell, 1937). In the Ebers Papyrus, a treatment was described in which the physician placed his hands on the head of the patient and, claiming superhuman therapeutic powers, gave forth with strange remedial utterances that were suggested to the patients and that resulted in cures.

The Egyptians are thought to have originated the "Sleep Temples," in which the priests gave similar treatment to their patients through the use of suggestion. These temples became very popular in Egypt and spread throughout Greece and Asia Minor (Okasha, 1993). Trance experiences were described by ancient Greeks, often as vehicles for treatment of mental or physical illness. Hippocrates is known to have discussed the phenomenon, saying, "the affliction suffered by the body, the soul sees quite well with the eyes shut" (Chadwick, 1950).

Hypnosis was identified as a formal phenomenon of psychotherapeutic usefulness in the 18th century. Franz Anton Mesmer (1734–1815) employed it as an alternative treatment for many ills that now would be labeled as stress-related or psychosomatic (Lopez, 1993). His work is credited with being the first Western conceptualization of a psychotherapy, a therapeutic talking interaction between doctor and patient (Ellenberger, 1970). Yet, the results of a Royal Commission in France concluded that the effects of hypnosis were the result of the "pure gold of imagination."

Jean-Martin Charcot (1825–1893), chief of neurology at the Salpêtrière Hospital in Paris, rehabilitated hypnosis as a subject for scientific study (Charcot, 1890). One of his disciples, Pierre Janet (1859–1947), a general practitioner and psychologist, laid the early foundation for dissociative reactions and ego states (Janet, 1887, 1889, 1904, 1907). In fact, the First International Congress for Experimental and Therapeutic Hypnotism was held in Paris, France, August 8–12, 1889.

More recently, interest in hypnosis seemed to wax and wane depending on the needs of the times. The extreme symptoms observed in patients with dissociative syndromes prompted the writings of William James (1902), Boris Sidis (Sidis & Goodhart, 1905), and Morton Prince (1906), who went on to found the *Journal of Abnormal Psychology*. The early use of hypnosis in the treatment of physical illness was championed by James Braid (1843) and James Esdaile (Esdaile, 1957; Ernst, 1995), including hypnoanalgnesia.

Interest in hypnosis revived during World War II, when army psychiatrists found the technique helpful in treating what was then called "traumatic neurosis" (Kardiner & Spiegel, 1947). This was followed by an era of serious

scientific exploration and the development of various hypnotizability scales (e.g., Stanford Hypnotic Susceptibility Scales (Hilgard, 1965; Weitzenhoffer & Hilgard, 1959; Weitzenhoffer, 1962) in an attempt to measure the presence and depth of the hypnotic experience. Later on, shorter hypnotizability scales were developed for use in clinical settings. Investigations included studies of the relationships among hypnotizability, placebo response, and acupuncture, studies of the differential hypnotizability of patients with psychosis and other psychiatric disorders, and investigations used in determining neurophysiological correlates of the hypnotic state and hypnotic capacity.

It was not until the second part of the 20th century, though, that the various professional associations in Europe and North America officially recognized hypnosis as a valuable therapeutic intervention (i.e., British Medical Association, 1955; American Medical Association, 1958; American Psychological Association, 1960; American Psychiatric Association, 1960). Since then, two professional hypnosis societies have emerged in North America: the Society for Clinical and Experimental Hypnosis (SECH, 1949), which emphasizes research in the field, and the American Society for Clinical Hypnosis (ASCH, 1957). A division of the American Psychological Association (Division 30, 1968; also known as the Society of Psychological Hypnosis) is devoted to the study of hypnosis in the field of psychology. In 1959 the International Society for Clinical and Experimental Hypnosis was founded. A more detailed account of the history of hypnosis is beyond the scope of this chapter and may be found elsewhere (Maldonado & Spiegel, 2008)

COMPONENTS OF THE HYPNOTIC PROCESS

The hypnotic experience may be understood as involving three interconnecting factors: absorption, dissociation, and suggestibility.

ABSORPTION

Absorption refers to the tendency to engage in self-altering and highly focused attention with complete immersion in a central experience at the expense of contextual orientation (Hilgard, 1970; Tellegen & Atkinson, 1974; Tellegen, 1981). Hypnotized individuals can become so intensely absorbed in their trance experience that they often choose to ignore the environmental context and other peripheral events. It facilitates complete immersion in a central experience at the expense of contextual orientation and peripheral awareness. As a person becomes absorbed in a central focus of attention, more peripheral perceptions, thoughts, and memories become less important. During the hypnotic process, individuals can become so intensely absorbed in their trance experience that they tend to, or are better able to, ignore many somatic (e.g., pain) and/or environmental stimuli (e.g., medical procedures).

DISSOCIATION

Dissociation refers to the ability to separate mental processes so they seem to occur independently from each other. The process of dissociation is complementary to absorption. During hypnosis, the intense absorption characteristic of the hypnotic state permits keeping out of conscious awareness many routine experiences that would ordinarily be conscious, by the process of nonpathological dissociation. When working properly in our daily lives, dissociation allows us to carry out several complex tasks simultaneously. There are a wide variety of dissociated states that range from the normal ability to carry out simultaneous tasks to a number of psychiatric disorders. An example of a rather common form of dissociation is the ability to perform a high-complexity task (i.e., a surgical procedure) while carrying out a conversation regarding one's political views or a recent sport event. In fact, not only motor activities can be dissociated but also rather complex emotional states and sensory experiences as well.

Dissociated affect and memories can elicit complex motor or pseudoneurologic dysfunction, as in the case of conversion disorder (Maldonado & Spiegel, 2000; Maldonado, 2007). Complex forms of dissociation can prevent access to memory, resulting in dissociative amnesia, dissociative fugue, or dissociative identity disorder (Maldonado, Butler, & Spiegel, 2000).

Another, more common, example of how dissociated memories affect patients is the hyperemesis experienced by some chemotherapy patients who experience nausea and vomiting just with the sight, or sometimes the thought, of the hospital (conditioned nausea and emesis). Memories that are dissociated at the time of the traumatic experience may reemerge when they are triggered by external cues, as in flashbacks associated with posttraumatic stress disorder that are often seen in cases of traumatic experiences such as motor vehicle accidents or traumatic surgical procedures or interventions.

SUGGESTIBILITY

Suggestibility implies the ability to influence someone's beliefs or behaviors by suggestion. Owing to the intense absorption experienced during trance, hypnotized individuals have a heightened responsiveness to social cues, including suggestions (formal or not) given by the therapist. This enhanced suggestibility allows hypnotized subjects to accept instructions more easily. Hypnotized individuals are not deprived of their will, but they do have a tendency to accept instructions in an uncritical way when under trance, a process that may be aided by the phenomenon of "source amnesia." Thus a hypnotized individual receives a suggestion, internalizes it, forgets the source of origin, then believes s/he generated the idea to which s/he now responds, thus lowering critical thinking about its validity.

This does not mean that the subject is deprived of will. Nevertheless, highly suggestible individuals do have a tendency to suspend the usual conscious curiosity that makes us question the reason for our actions and to respond to suggested ideas in a less critical fashion. Because of this, highly hypnotizable individuals are more prone to accept some

suggestions or ideas no matter how irrational or illogical they might appear to be. A conscientious physician may use this aspect of the hypnotic experience to bypass the patient's defenses and facilitate change or symptom relief. On the other hand, because of their decreased awareness, highly hypnotizable individuals are less likely to identify a physician's mistakes, and may be misguided and confused by comments or instructions (whether given under hypnosis or not) that are negative, vague, or misguided.

ASSESSMENT OF HYPNOTIZABILITY OR HYPNOTIC CAPACITY

There are definitive advantages associated with knowing a patient's level of hypnotic capacity. As previously mentioned, patients' hypnotizability levels vary considerably. The use of formal hypnotizability assessments allows physicians to objectively determine their patient's level of hypnotic capacity. Thus, while moderate and highly hypnotizable patients may be offered hypnosis as a treatment option, those with low capacity may be referred to more appropriate techniques (e.g., progressive relaxation, biofeedback). Data suggests that hypnotizability is a rather stable trait. The only long-term study published to date demonstrated that the initial hypnotizability assessment (i.e., SHSS) correlated highly with scores at a 10-year, 15-year, and 25-year retest, with obtained correlations of .64, .82, and .71, respectively (Piccione, Hilgard, et al., 1989). As stated by the study authors: "the flux in subjects' lives over a quarter of a century, through marriage and child-rearing, occupational shifts, traumas associated with illness, death of loved ones, and loss by divorce, cannot be assumed to be trivial" (Piccione, et al., 1989).

These findings compared favorably with other studies of similar sample size and duration, of measures of individual differences over time. These include the stability over time of IQ scores (i.e., test-retest correlations were 0.73 for the full scale IQ, 0.70 for Verbal IQ, and 0.57 for Performance IQ [Kangas & Bradway, 1971]), personality assessment (i.e., a retest correlation of 0.50 [Huntley & Davis, 1983]), and occupational interests (i.e., a 20-year test-retest correlation of 0.72 for men 22–25 years old at first testing and 0.64 for those 19–21 years old at first testing [Campbell & Hansen, 1981]). Standardized hypnotizability assessments can provide therapists with clinical data that allows for rational predictions about patients' expected responses. For instance, the relative ability, or lack thereof, to restructure one's inner experience aided by the use of hypnosis may provide information about a subject's interpersonal style.

From a therapeutic perspective, these data may help provide clues about likely response to intervention (i.e., hypnotic suggestibility predicted differences in responding to the hypnotic and imaginative analgesia suggestions, with higher hypnotizability associated with greater response to hypnoanalgesia suggestions). Hypnotizability levels may even facilitate the differential diagnosis. For example, we would expect patients suffering from dissociative disorders, PTSD, and conversion disorder to score high on hypnotizability measures while those experiencing psychosis and OCD would be

expected to score low; discrepancies from these predictions may make a practitioner rethink the diagnosis.

Brief scales have been designed for quick assessment in the clinical setting—for example, the Hypnotic Induction Profile (HIP [Spiegel & Spiegel, 1987, 2004], the Stanford Hypnotic Clinical Scale (SHCS [Hilgard & Hilgard, 1975])). They are brief—about 5 to 10 minutes are required for the HIP, and 20 minutes for the SHCS—and extremely accurate. An even briefer test is the use of the Eye Roll Sign (ERS) and its relation to innate trance capacity (Spiegel, 1972; Frischholz & Nichols, 2010). This is part of the more formal HIP assessment scale.

There are even group hypnotizability measures, which can be administered to larger groups of individuals at the same time and rated at the end of the experience to allow for assessments of larger groups. These scales are usually used in the screening of large groups for study rather than clinical purposes (Shor & Orne, 1962). All scales involve a structured hypnotic induction, followed by an assessment of the subject's response to a variety of suggestions.

The HIP is a brief (5–7 minutes) standardized assessment designed to measure the patients' natural ability to tap into and use their hypnotic capacity (Spiegel & Spiegel, 1987). It consists of a rapid hypnotic induction instruction for an upward gaze, quickly followed by lowering of the eyelids, and suggestions for physical relaxation and a floating sensation. The induction process is followed by a structured set of instructions. The individual's response to them, during and shortly after the test (posthypnotic suggestion), predicts hypnotic capacity and future response to treatment with hypnosis.

Subjects are rated on five important items that assess cognitive and behavioral aspects of the hypnotic experience: (1) hand dissociation; (2) hand levitation, after formal end of trance state; (3) unconscious compliance with posthypnotic suggestion; (4) response to the cutoff signal; and (5) sensory alteration (see Appendix A for a copy of the HIP and instructions for administration). At least one study suggests that the HIP compares favorably with longer (about 20–25 minutes) assessments such as the Stanford Hypnotic Clinical Scale for Adults (SHCS:A), with a 0.41 correlation ($p < .01$) (Gritzalis, Oster, et al., 2009).

NEUROBIOLOGY OF HYPNOSIS

There has always been some mystery regarding how hypnosis works. In ancient times it was blamed on spirits or gods. In medieval times it was believed to be caused by demonic possession. Mesmer believed it was elicited by manipulation of the body's energies or "magnetic fluid." The biggest dichotomy occurred early on between those like Charcot (1825–1893), who believed hypnosis to be the result of a diseased nervous system and argued that normal people could not be hypnotized (Charcot, 1890), and those like Bernheim (1840–1919) at the School of Nancy, who believed hypnosis to be a trait mediated by suggestion and exhibited to different degrees by normal individuals (Bernheim, 1889/1964; Widlocher & Dantchev, 1994).

Since those early days, various research efforts have attempted to correlate the hypnotic experience with actual physiological changes, which has prompted many theories. Rudolf Heidenhain (1880) explained it by the physiological mechanism of cortical inhibition (Windholz, 1996). Pavlov (1910) believed it was mediated via partial cortical inhibition (Windholz, 1996). Yet, to date, the “seat of hypnosis” has not been found in the brain, although recent research points toward involvement of the frontal and anterior cingulate cortex (Kropotov, Crawford, et al., 1997; Rainville, Hofbauer, et al., 2002; Spiegel, 2003). There is ample clinical and research experience indicating that the hypnotic process affects both electrical and metabolic processes in the brain. Similarly, as we have observed in clinical experience, hypnotic activity is capable of causing various physiological changes.

Hypnotizability has been found to be significantly correlated with cerebrospinal fluid levels of homovanillic acid, a metabolite of dopamine (Spiegel & King, 1992). This finding provides additional evidence suggesting the involvement of the frontal cortex in the hypnotic process. Further dispelling the myth of a link between hypnosis and sleep, studies have shown that the administration of psychostimulants (e.g., amphetamine) may enhance hypnotizability (Sjoberg & Hollister, 1965), while GABAergic agents and opioids may cause sedation, decrease absorption and attention, and thus interfere with the hypnotic process. Some have postulated that the automaticity observed in hypnotic motor behavior could represent an activation of the basal ganglia, which is involved in both implicit memory and routine motor activity (Graf & Schacter, 1985; Schacter, 1987, 1992; Mishkin & Murray, 1994).

Similarly, the brain electrical pattern of a hypnotized subject actually resembles that of a fully awake and attentive individual more than the pattern of a person who is asleep. In fact, power spectral analysis of brain electrical activity has found increased alpha activity among highly hypnotizable individuals, and an alpha laterality difference favoring the left hemisphere among highly hypnotizable individuals (Morgan, Macdonald, et al., 1974; Edmonston & Grotevant, 1975). Finally, some have demonstrated that highly susceptible subjects show more electric power in the right parietotemporal region than the left, while those with low susceptibility have left-side predominance or equilibrated power in all derivations (Meszaros & Szabo, 1999). Yet, not all studies support the right hemispheric dominance theory of the hypnotic process, suggesting that data analysis techniques led to misinterpretations of previously obtained data (Edmonston & Moscovitz, 1990).

Meanwhile, others have suggested that hemispheric activation on hypnotic challenge may depend in large part on the kind of task the challenge involves, and several general aspects of the hypnotic process may more appropriately be understood to be mediated by the left hemisphere, including concentrated attentional focus and the role of language in the establishment of hypnotic experience (Jasiukaitis, Nouriani, et al., 1997).

There may also be frontal versus posterior topographical differences among highly and poorly hypnotizable individuals.

In fact, more recent studies of power spectral analysis suggest that theta power, especially in the frontal region, best differentiates highly hypnotizable from poorly hypnotizable individuals. These studies found greater theta power in the more frontal areas of the cortex for highly hypnotizable subjects. During the actual hypnotic induction, theta power increased markedly for both groups in the more posterior areas of the cortex, whereas alpha activity increased across all sites. In the period just preceding and following the hypnotic induction, poorly hypnotizable subjects displayed an increase in theta activity, whereas highly hypnotizable subjects displayed a decrease. Finally, power spectral analysis studies found that theta power, especially in the frontal region, best differentiates highly hypnotizable from poorly hypnotizable individuals, suggesting that anterior/posterior cortical differences may be more important than hemispheric laterality for understanding the hypnotic processes (Sabourin, Cutcomb, et al., 1990; Graffin, Ray, et al., 1995).

Event-related potentials (ERPs) have been used to study the effects of hypnotic hallucination on brain electrical activity. These studies are based on the premise that hypnotically induced changes in perception should be reflected in alterations in ERP amplitude. Several studies have found that highly hypnotizable subjects who experience a visual hallucination obstructing visual contact with the target exhibited significant reductions in P_{300} amplitude throughout the scalp and in N_{200} in the occipital region (Spiegel, Cutcomb, et al., 1985; Jasiukaitis, Nouriani, et al., 1996).

Hypnotic auditory hallucination studies (using auditory evoked potentials, or AEPs) have yielded similar results, suggesting P_{300} differences among highly hypnotizable individuals hallucinating a reduction or increase in tones, while subjects with low hypnotizability did not show such a change (Sigalowitz, Dywan, et al., 1991). Others have confirmed these findings, backing the hypothesis that hypnotic susceptibility is associated with efficient attentional processing, such that highly hypnotizable subjects can more effectively partition attention toward relevant stimuli and away from irrelevant stimuli than can poorly hypnotizable subjects (Crawford, Corby, et al., 1996; Lamas & Valle-Inclan, 1998).

Postulating that somatic conversion disorders may represent a form of selective attention, we studied a group of patients presenting with lateralized (i.e., unilateral) motor deficits (i.e., motor conversion) using somatosensory event-related potentials (SERPs) (Maldonado, 1997, 2001). We found that subjects exhibited a “normal N_{140} ” on the unaffected side (as expected in all “normal controls”), but an *enhanced* N_{140} on the affected side (Maldonado, 2007). Even more remarkably, when we provided hypnotic suggestions for time regression (e.g., some time prior to the onset of symptoms), subjects experienced complete normalization of the SERP’s response. These findings suggest the possibility of an unconscious autohypnotic model used by patients suffering from conversion disorder in order to create their symptoms.

Similarly, others have examined the effects of positive obstructive and negative obliterating instructions on simultaneous visual and auditory ERPs— P_{300} signals. They found that highly hypnotizable subjects showed greater ERP

amplitudes while experiencing negative hallucinations and lower ERP amplitudes while experiencing positive obstructive hallucinations, suggesting a rather robust physiological marker of hypnosis—an alteration in consciousness that corresponds to participants' subjective experiences of perceptual alteration (Barabasz, Barabasz, et al., 1999)

Hypnoanalgesia may be similarly explained physiologically by a mechanism by which hypnotic suggestions facilitate the filtering of somatosensory (electrical) stimulation affecting ERP amplitude. Thus, suggestions of a tingling, cool, numbing sensation can be given with the idea that it would filter out any other sensations in the area by a process such as competitive inhibition. In fact, studies of moderately to highly hypnotizable adults with chronic low back pain have found that hypnotic analgesia led to significant mean reductions in perceived sensory pain and distress, suggesting that this was an active process that required inhibitory effort, dissociated from conscious awareness, where the anterior frontal cortex participates in a topographically specific inhibitory feedback circuit that cooperates in the allocation of thalamocortical activities (Crawford, Knebel, et al., 1998)

Finally, brain imaging studies (i.e., positron emission tomography [PET] scan studies) have demonstrated a global increase in cerebral perfusion during hypnosis (Ulrich, Meyer, et al., 1987). Further PET studies have suggested that during hypnosis there is specific activation of the anterior attentional systems involving focusing (anterior cingulate) and arousal (frontal, especially on the right) (Posner and Petersen, 1990). Similarly, PET scans were used to measure regional cerebral blood flow (rCBF) of highly hypnotizable subjects asked to produce vivid auditory hallucinations (Szechtman, Woody, et al., 1998). Studies found that subjects capable of producing the hallucinations had increased rCBF in the right anterior cingulate gyrus. Of interest, the “externality” and “clarity” of the hallucinations were highly correlated with blood flow in this region.

Subsequent PET studies found that among highly hypnotizable individuals, the hypnotic state was accompanied by significant increases in both occipital rCBF and delta EEG activity, which were highly correlated with each other ($r=0.70$, $P<0.0001$) (Rainville, Hofbauer, et al., 1999; Rainville, Hofbauer, et al., 2002). Peak increases in rCBF were also observed in the caudal part of the right anterior cingulate sulcus and bilaterally in the inferior frontal gyri. Hypnosis-related decreases in rCBF were found in the right inferior parietal lobule, the left precuneus, and the posterior cingulate gyrus. Hypnosis with suggestions produced additional widespread increases in rCBF in the frontal cortices, predominantly on the left side. Moreover, the medial and lateral posterior parietal cortices showed suggestion-related increases overlapping partly with regions of hypnosis-related decreases. Results support a state theory of hypnosis in which occipital increases in rCBF and delta activity reflect the alteration of consciousness associated with decreased arousal and possible facilitation of visual imagery. Frontal increases in rCBF that are associated with suggestions for altered perception might reflect the verbal mediation of the suggestions,

working memory, and top-down processes involved in the reinterpretation of the perceptual experience.

PET scans studies using $^{15}\text{O}\text{-CO}_2$ in highly hypnotizable subjects who were asked to “see changes in color patterns” in a number of visual stimuli found both the left and right hemisphere color areas were activated when they were asked to perceive color, whether they were actually shown the color or the gray-scale stimulus; moreover, these brain regions had decreased activation when subjects were told to see the gray scale, whether they were actually shown the color or gray scale stimulus (Kosslyn, Thompson, et al., 2000). Thus, the observed changes in subjective experience achieved while in a hypnotic state are reflected by changes in brain function similar to those that occur in perception. These findings suggest that hypnotic alteration of perception is more than mere compliance with suggestion; rather, it involves alteration in sensory experience.

APPLICATION OF HYPNOSIS IN PSYCHOSOMATIC MEDICINE

The literature on the usefulness of hypnosis in the treatment of medical conditions is limited. Most papers are based on single case reports or small size samples, thus limiting the interpretation of the findings. Nevertheless, numerous studies are underway, and the number of rigorous scientific studies and publication is growing. We suggest that practitioners interested in the use of hypnosis for the treatment of medical conditions continue to monitor the literature for newer and more rigorous studies on the subject. Already published studies that merit discussion will be summarized in the sections to follow.

SUGGESTIONS WITHOUT TRANCE: A POTENTIAL TRAP FOR THE HIGHLY HYPNOTIZABLE

As mentioned before, hypnosis is a natural phenomenon that most patients can experience to a certain degree. For better or worse, highly hypnotizable individuals can enter trance states with ease and, on occasion, without even being fully aware of it. Thus, it is important for physicians to know that some patients may experience trance states even without formal induction. Highly hypnotizable individuals are extremely receptive to suggestions given by a person in a position of authority (i.e., nurse, physician), and thus their attitude and comments may have profound effects, both positive and negative, in these individuals. This “hypnotic phenomenon” may augment the placebo effect in either a positive or negative way, as demonstrated by the following case study.

CASE STUDY 1: UNREMITTING PAIN

A 75-year-old woman was referred to me for treatment of pain with hypnosis. The patient had been diagnosed with metastatic breast cancer that now was invading her hip bone, which was the source of her pain. When she came for her hypnotic sessions

it was evident that she was a highly hypnotizable individual. In fact, she scored highly in objective hypnotizability measure (9 out of 10).

During her first session she entered the trance state with ease, and during it she was able to experience complete pain relief. Even with such success during trance, we were disappointed at the fact that as soon as she exited the trance state, the pain immediately returned. The same occurred during the second session. Thus, during the third session instead of working on the issue of pain control we did some hypnotic exploratory work to address the "reasons why she couldn't let go of the pain."

Under a hypnotic regression the patient was asked to "return to the moment when 'this pain started.'" Immediately the patient recalled a meeting with her oncologist a few months back. At the time of that meeting, the patient had just begun to experience pain and brought it to her oncologist's attention. After discussing with her the "dangers of addiction if opioid medications were used," he inadvertently suggested that she will live the rest of her life with pain. His words were forever "imprinted" in her mind: "I'm sorry, but there is nothing I can do. You will be in pain until the day you die." To a highly hypnotizable patient this meant a lot. In her mind, she made "being in pain" equal to "being alive."

Once the "source" of her pain was clarified, the session focused on the meaning of her pain. To her, it served as a reminder that she was still alive; as long as she could feel the pain at its most severe, even at night, when it sometimes seemed endless, she knew she was alive. So, her discomfort was a "painful reminder that she was alive" and thus her need to hold on to the pain.

Her high level of suggestibility allowed her to "take" the initial suggestion. Thus our strategy then was to use this same hypnotic capacity to reverse the initial damage and help the patient conquer her pain. In her case, we used hypnosis to alter her perception of pain for a tingling sensation on the affected site. This tingling "continued to provide her reassurances about her life" without the need for her to experience the pain. The suggestion was to have a constant "tingling sensation which would filter the hurt out of the pain." She was able to master self-hypnotic techniques, which she continued to practice at home with great success. She later used her newly learned skills to help control symptoms of nausea and vomiting associated with chemotherapy.

ANXIETY RESPONSES TO MEDICAL PROCEDURES

The hypnotic experience can be used to produce a state of relaxation. Therefore, hypnotic techniques can be used to reduce the anxiety associated with a number of medical procedures (Deyoub, 1980; Covino & Frankel, 1993). Once patients have been trained in the use of self-hypnosis, they can use it in preparation for both a hospital visit and for medical tests or interventions, and while in the clinic or the hospital.

Hypnotic techniques have been successfully used to assist phobic patients to undergo a number of medical/surgical and diagnostic procedures, thus diminishing the need for excessive anesthesia or antianxiety medication, improving compliance, and eliminating trauma to patients (Covino & Frankel, 1993; Cadranell, Benhamou, et al., 1994; Ellis & Spanos, 1994;

Rape & Bush, 1994; Chandler, 1996; Kessler & Dane, 1996; Lambert, 1996; Lang, Joyce, et al., 1996; Mize, 1996).

Among patients undergoing colonoscopic examination, for whom other forms of anesthesia were not available, those able to benefit from hypnotic intervention reported less intense pain than patients in whom hypnosis was unsuccessful (Cadranell, Benhamou, et al., 1994). In addition, the hypnosis group reported a much better rate of successfully completed colonoscopies (100% versus 50%) and were more compliant with further testing later on (100% versus 2%, $p < 0.001$).

Phobic responses to modern imaging studies (i.e., magnetic resonance imaging [MRI], PET scans, and computerized tomography [CT] scans) are among the most common types of phobias we encounter. Hypnosis has been highly successful in facilitating the performance of imaging procedures such as MRI and CT scans (Friday & Kubal, 1990; Phelps, 1990; Chandler, 1996; Simon, 1999).

CASE STUDY 2: CLAUSTROPHOBIA

Take for example the case of a 43-year-old woman who suffered from convulsions that were resistant to treatment with conventional anticonvulsant therapy. Appropriately, her neurologist wanted to obtain a brain MRI to assess for the presence of a possible source of irritation that could explain the onset and maintenance of the seizures. Nevertheless, the patient repeatedly refused the MRI scan because of claustrophobia. On two occasions the patient presented to the MRI suite. The first time she took a look at the machine and walked away. The second time she was premedicated with diazepam (30 mg), but was unable to tolerate the procedure after just a few minutes and had to stop. Finally, she had a psychiatric evaluation.

In my office she proved to be highly hypnotizable (9 out of 10). Under hypnosis we explored the associations between the scanner and her anxiety. Images of a coffin came to mind. These were followed by memories of her father lying in the funeral home. He had died suddenly, without prior history or warning, of a massive hemorrhagic stroke associated with a congenital aneurysm. We then explored her anxiety as it related to fears of what the test might show. This included the possibility of a malformed blood vessel or other pathology that might affect her brain, as happened to her father. Once this was discussed she felt that it "was better to know than to avoid." She was trained in self-hypnosis. After inducing a relaxed state, she was instructed to "create in your mind's eye a place where you can feel safe and comfortable, knowing that sounds and people in the room will not disturb you." We also "practiced" going to the MRI scanner room by having her imagine that she was both the patient in the room and the technician operating the machine. In this fashion she felt more "in control" of the situation. The next day, we met her at the scanner room. Once she was on the imaging table she induced a self-hypnotic trance. When the test began I left the room with the agreement that the technician would let her know when the test was over. She imagined herself walking through a forest and crossing a river. As she walked to the riverbank, instead of floating she saw herself slowly sinking as she followed the contours of the river, walking down to the bottom of the river. Once on the bottom she held on to some algae. When she exhaled, her breath formed a gigantic bubble or "cocoon" that allowed her to breathe under water and be safe. As the magnets in the MRI shifted in position she imagined that the sound was the clanking

sound of motorboat engines on the surface. She remained in this state for approximately 2 hours, while both noncontrast and contrast tests were performed. She tolerated the procedure well and easily came out of the trance state once the signal was given.

Hypnosis has been successfully used to help anxious patients tolerate procedures that otherwise would not be performed, or the patient might need to be exposed to larger than normal doses of antianxiety medications due to needle phobia. These include needle injections and phlebotomy (Dash, 1981; Zeltzer & LeBaron, 1982; Bell, Christian, et al., 1983; Kellerman, Zeltzer, et al., 1983; Morse & Cohen, 1983; Nugent, Carden, et al., 1984; Cyna, Tomkins, et al., 2007; Robertson, 2007; Abramowitz & Lichtenberg, 2009), needle biopsy and aspiration (Usberti, Grutta d'Auria, et al., 1984; Adams & Stenn, 1992; Ellis & Spanos, 1994; Lang, Berbaum, et al., 2006), bone marrow aspiration (Hageman-Wenselaar, 1988; Ellis & Spanos, 1994; Liossi & Hatira, 1999), and lumbar punctures (Hageman-Wenselaar, 1988; Ellis & Spanos, 1994; Simon & Canonico, 2001; Kellerman, Zeltzer, Ellenberg, et al., 1983).

CASE STUDY 3: NEEDLE PHOBIA

One of our patients, a 47-year-old, married, successful businessman was referred for "inability to participate in medical treatment." The patient had recently been diagnosed with esophageal cancer, after presenting to the emergency room with a 3-month history of weight loss, chills, shortness of breath, chest pains, and difficulty swallowing. Imaging studies revealed a large mass. Because of the size and location of the mass, and the stage of the disease, he was turned down for treatment in his previous hospital. He was presented to the tumor board of our institution where the gastrointestinal surgeons decided to take his case.

There was only one problem. The patient had experienced "terror of needles" from the age of 7. At that time he was receiving immunizations at school when he panicked and moved abruptly, causing a needle to break off the syringe and remain deep in his arm. He required surgery to remove it. From that moment on he did everything possible to "stay far from them."

In fact, while at the previous hospital institution he experienced an event which reinforced his fears. He was asleep when a phlebotomist entered his room. She placed her tray filled with syringes, collection tubes, and (of course) needles on his bed. As she began to explore his arm veins, he suddenly woke up, saw the needles, and fled. That was the end of his admission.

He now faced two (and according to him equally difficult) problems: the tumor and his phobia to needles. The proposed cancer treatment involved an aggressive course of high-dose chemotherapy and radiation. If this approach was successful at reducing the tumor size, surgery would follow. He discussed his phobia with his surgeon, who assured the patient that "every possible precaution would be taken." Nevertheless, the patient refused to enter the hospital. Finally, a psychiatric consultation was requested.

I saw the patient in my office. After reviewing his medical and psychiatric history it was obvious that aggressive treatment (both physical and psychological) was required if he was

to survive. He already had delayed his chemotherapy and surgical intervention because of his phobia. His surgeon had placed him on benzodiazepine medications, but despite his level of sedation, the phobia was still preventing him from obtaining the urgently needed treatment. I suggested the addition of a selective serotonin reuptake-inhibitor (SSRI), but realized that we might not have the time to wait for the medication to take effect. Therefore we decided to supplement his treatment with hypnosis.

The patient underwent his first hypnotic trance during the first session. Like many phobic patients, he proved to be highly hypnotizable with an HIP of 8.5 out of 10. He was trained in self-hypnotic techniques. His medications were rearranged. He was started on an SSRI, his short-acting benzodiazepine was switched to a longer-acting drug, and he was ordered to practice his self-hypnotic exercise six times a day. On the third day after our first session, he called to say that he thought he was "ready." I met him in the surgical clinic. With the patient under hypnosis, a central line was placed to administer his chemotherapy. After 3 weeks of aggressive chemotherapy and local radiation treatment, the patient was admitted to the hospital for surgical excision of the mass.

He was able to tolerate every treatment aspect with only minimal discomfort. Unfortunately, his course was difficult and filled by numerous complications including infections, the creation of several fistulas, and the development of a pneumothorax requiring bilateral chest tube and drainage placements. Nevertheless, he continued to manage his phobia well. Certainly, given his complications he required multiple needle sticks and even blood transfusions, but tolerated them well. In fact, the nursing staff was amazed and fascinated by his "little ritual" prior to injections or blood draws while he "self-induced a hypnotic trance." Certainly, we believe that medications helped his overall anxiety and phobic condition. The patient said, "I could not have gone through this without hypnosis."

The concomitant use of hypnosis and medications is common practice in the psychosomatic medicine service. Certainly, as in many other aspects of psychiatry and medicine, the combined use of multiple complementary treatment modalities is the norm. Sometimes hypnosis is used alone because it is the patient's preference, the patient is an extremely good (highly hypnotizable) candidate, there are medical contraindications to the use of central nervous system depressant agents (i.e., respiratory depression, intraoperative EEG monitoring), or the clinician is dealing with a relatively simple procedure. Other times, as in case study 3, the complexity of the situation requires more aggressive and prompt intervention. In that case, we needed to move so quickly that we didn't have much time for medication (the SSRI) to work. Hypnosis played a key role in the patient's accepting and going through treatment. It became an invaluable adjunct to his overall treatment.

DERMATOLOGICAL CONDITIONS

Psychogenic factors have been implicated in essentially all skin disorders (Cheek, 1961; Kellner, 1975; Manfredi, 1975; Medansky & Handler, 1981; Tobia, 1982; Arone di Bertolino,

1983; Elitzur & Brenner, 1986; Tsushima, 1988; Haustein & Seikowski, 1990; Gherardi, Fabrizio, et al., 1993; Bellini, 1998; Shenefelt, 2000, 2002, 2003)

Hypnosis has been helpful for several specific skin disorders: pruritus (Arone di Bertolino, 1983; Ament & Milgrom, 1967; Shertzer & Lookingbill, 1987; Sampson, 1990; Mitchell, 1995; Rucklidge & Saunders, 1999, 2002; Tuerk & Koo, 2008; Tsiskarishvili, Eradze, et al., 2010), eczema (Faure & Burger, 1954; Vlarsky & Janousek, 1960; Goodman, 1962; Zheltakov, IuK, et al., 1963; Kierland, 1965; Mirvish, 1978; Hajek, Jakoubek, et al., 1989; Hajek, Jakoubek, et al., 1990; Hajek, Radil, et al., 1991; Mantle, 1999; Ersser, Latter, et al., 2007), scleroderma (Surwit, Allen, et al., 1982; Freedman, Ianni, et al., 1984; Haustein, Weber, et al., 1995; Seikowski, Weber, et al., 1995), atopic dermatitis (West, Kierland, et al., 1961; Stewart & Thomas, 1995), genital herpes simplex virus (Putlin, 1961; Arone di Bertolino, 1981; Gould & Tissler, 1984; Elitzur & Brenner, 1986; Surman & Crumpacker, 1987; Fox, Henderson, et al., 1999; Pfitzer, Clark, et al., 2005), psoriasis (Novotny, 1962; Secter & Barthelemy, 1964; Frankel & Misch, 1973; Waxman, 1973; Winchell & Watts, 1988; Kantor, 1990; Zachariae, Oster, et al., 1996; Tausk & Whitmore, 1999), chronic urticaria (Shertzer & Lookingbill, 1987), chronic plaque-type psoriasis (Tausk & Whitmore, 1999) and warts, even though they result from viral agents such as human papillomavirus (Vollmer, 1946; Mc, 1949; Sinclair-Gieben & Chalmers, 1959; Ullmann, 1959; Wendel, 1959; Seeman, 1960; Ullman & Dudek, 1960; Clarke, 1965; Lyell, 1966; Dudek, 1967; Stankler, 1967; Leidman Iu, 1968; Konig, 1969; Nasemann, 1969; Tenzel & Taylor, 1969; Surman, Gottlieb, et al., 1972; French, 1973; Leidman Iu, 1973; Surman, Gottlieb, et al., 1973; Fischer, 1974; Clawson & Swade, 1975; Skalicanova, Nagyova, et al., 1977; Tasini & Hackett, 1977; Cohen, 1978; Dreaper, 1978; Johnson & Barber, 1978; Sheehan, 1978; Wilkening, 1978; Johnson, 1980; Rowe, 1982; Straatmeyer & Rhodes, 1983; Morris, 1985; Noll, 1988; Spanos, Stenstrom, et al., 1988; Steele & Irwin, 1988; Spanos, Williams, et al., 1990; Bolton, 1991; Esman, 1992; Ewin, 1992; Ferreira & Duncan, 2002; Herold, 2002; Meineke, Reichrath, et al., 2002; Phoenix, 2007; Ewin, 2011; Kekecs & Varga, 2011).

In chronic urticaria and atopic dermatitis, hypnosis has led to long-term improvements.

In chronic urticaria, remissions of 7 years duration as measured by three self-report parameters were achieved by hypnosis (Shertzer & Lookingbill, 1987). Of interest, highly hypnotizable subjects had fewer hives and more frequently related stress as a causative factor of their outbreaks. Improvements were maintained during a 2-year follow-up in a group of patients suffering from atopic dermatitis resistant to conventional treatment, who experienced statistically significant subjective and objective benefit ($p < 0.01$) after treatment with hypnosis (Stewart & Thomas, 1995).

A 3-month randomized, single-blind, controlled trial used hypnosis in adults with stable, chronic, plaque-type psoriasis. Highly or moderately hypnotizable subjects were randomized to receive either hypnosis with active suggestions of improvement or neutral hypnosis with no mention of their disease

process. The results demonstrated that highly hypnotizable subjects showed significantly greater improvement than did moderately hypnotizable subjects, independent of treatment group assignment (Tausk & Whitmore, 1999).

Published controlled studies on the use of hypnosis to cure warts are confined to using direct suggestion in hypnosis (DSIH), with cure rates of 27% to 55% (Johnson, 1980). Prepubertal children respond to DSIH almost without exception, but adults often do not. Clinically, many adults (80%) who fail to respond to DSIH will heal with individual hypnoanalytic techniques that cannot be tested against controls (Ewin, 1992).

A study comparing the effects of hypnotic suggestions versus topical salicylic acid and placebo found that subjects in all groups developed equivalent expectations of treatment success, but only the hypnotic subjects had lost significantly more warts than the no-treatment controls at the 6-week follow-up (Spanos, Williams, et al., 1990).

At least one carefully controlled study demonstrated that simple hypnotic instructions to the effect that the warts would "tingle and disappear" resulted in a rate of improvement that was significantly better than the spontaneous rate of remission of warts (Surman, et al., 1973).

The ability of highly hypnotizable individuals to control peripheral skin temperature and blood flow has been replicated in several well-controlled experiments (Zimbardo, Maslach, et al., 1970; Grabowska, 1971; Kistler, Mariauzouls, et al., 1999). Some have demonstrated plethysmographic measure changes caused by hypnotically mediated rapid vasodilatation after direct suggestion in cases of Raynaud's disease treated with hypnosis (Conn & Mott, 1984).

GASTROINTESTINAL CONDITIONS

Gastrointestinal conditions helped by hypnosis include inflammatory bowel disease such as ulcerative colitis, Crohn's disease, and related conditions (Susmano, Feldfeber, et al., 1960; Grumiller & Strotzka, 1973; Freiwald, Liedtke, et al., 1975; Snape, 1994; Schafer, 1997; Mawdsley, Jenkins, et al., 2008), irritable bowel syndrome (Byrne, 1973; Whorwell, Prior, et al., 1984; Whorwell, Prior, et al., 1987; Whorwell, 1989, 1991; Snape, 1994; Francis & Houghton, 1996; Houghton, Heyman, et al., 1996; Galovski & Blanchard, 1998, 2002; Vidakovic-Vukic, 1999; Forbes, MacAuley, et al., 2000; Gonsalkorale, Houghton, et al., 2002; Palsson, Turner, et al., 2002; Gonsalkorale, Miller, et al., 2003; Gonsalkorale & Whorwell, 2005; Tan, Hammond, et al., 2005; Whorwell, 2005, 2008, 2009; Barabasz & Barabasz, 2006; Palsson, 2006; Palsson, Turner, et al., 2006; Roberts, Wilson, et al., 2006; Simren, 2006; Whitehead, 2006; Wilson, Maddison, et al., 2006; Al Sughayir, 2007; Vlieger, Menko-Frankenhuis, et al., 2007; Webb, Kukuruzovic, et al., 2007; Hefner, Rilk, et al., 2009; Miller & Whorwell, 2009; Carruthers, Morris, et al., 2010; Shinozaki, Kanazawa, et al., 2010), dysphagia (Magonet, 1961; Black, 1980; Gurian, 1981; Kopel & Quinn, 1996), vocal cord dysfunction (Anbar & Hehir, 2000), esophageal achalasia/cardiospasm (Schneck, 1958; Jones,

Cooper, et al., 2006), irritable bowel syndrome (Houghton, Heyman, et al., 1996), and peptic and duodenal ulcer disease (Bick, 1958; Zane, 1966; Montera, 1968; Kanishchev & Shutova, 1974; Bishay, Stevens, et al., 1984, 1988; Colgan, Faragher, et al., 1988; Whorwell, 1991; Francis & Houghton, 1996; Soo, Moayyedi, et al., 2005).

The clinical relevance of these studies was illustrated by a controlled trial of hypnosis in relapse prevention of duodenal ulcers (Colgan, Faragher, et al., 1988). In this study, 30 patients with rapidly relapsing ulcer disease were randomly assigned after ranitidine treatment to hypnosis or no further treatment. On follow-up, 100% of the control subjects but only 53% of the hypnosis patients experienced relapse.

A randomized controlled trial demonstrated that IBS-patients treated with hypnosis reported significant improvement in pain, abdominal distension, and diarrhea, as well as emotional well-being compared with a control group. Absenteeism from work was reduced. These improvements continued during the 18-month follow-up period (Houghton, Heyman, et al., 1996).

A randomized study comparing the use of "gut-directed hypnotherapy" versus a specially devised audiotape intervention demonstrated a reduction in median symptom score, from 14.0 to 8.5, in hypnotherapy patients compared with an unchanged score of 13 in audiotape patients ($P < 0.05$) (Forbes, MacAuley, et al., 2000).

Hypnosis has been repeatedly used with great success for symptomatic control in emesis, regardless of the cause, in both children (Keller, 1995) and adults (Covino & Frankel, 1993; Faymonville, 1995). In an excellent example of how hypnosis actually exerts direct physiologic changes, researchers monitored the gastric acid secretion among 28 highly hypnotizable subjects (Klein & Spiegel, 1989). When subjects were hypnotized and instructed to eat an imaginary meal, basal acid output rose 89%. Similarly, when instructed to use hypnosis to experience deep relaxation they exhibited a significant (39%) drop in basal acid output.

CARDIAC CONDITIONS

In the treatment of cardiovascular problems, applications of hypnosis have been discussed in angina pectoris (Kobayashi, Ishikawa, et al., 1970; Wilkinson, 1981; Zaitsev, Shafikova, et al., 1990), essential hypertension (Friedman & Taub, 1977, 1978; Gay, 2007), and recovery from myocardial infarction and cardiac surgery (Gruen, 1972; Kavanagh, Shephard, et al., 1974; Zaitsev, Shafikova, et al., 1990; Greenleaf, Fisher, et al., 1992; Kosov, Zamotaev Iu, et al., 1997; Baglini, Sesana, et al., 2004).

Hypnosis can affect the patient's perception of exertion and influence the relation between the sympathetic and vagal systems. Gemignani et al. (2000) studied the physiological and EEG responses of highly hypnotizable volunteers suffering from simple phobia. Under hypnotic suggestion, subjects exposed to aversive stimuli experienced significant increases in heart rate (HR) and respiratory rate (RR), with a shift of the sympathovagal indexes toward a sympathetic predominance.

These subjects also experienced a significant increase in the EEG gamma band with left frontocentral prevalence.

Finally, Williamson and colleagues (2001), using healthy, highly hypnotizable volunteers, demonstrated dramatic changes in ratings of perceived exertion (RPE) when asked to imagine themselves in an uphill bicycle grade. They found significant increases in RPE, HR, mean blood pressure (BP), rCBF in the right insular cortex, and right thalamic activation. Conversely, when subjects were asked to imagine themselves on a perceived downhill grade they observed decrements in both the ratings of perceived exertion RPE and rCBF in the left insular cortex and anterior cingulate cortex, but it did not alter exercise HR or BP responses.

PULMONARY CONDITIONS

Hypnosis has been useful for asthma (Herraiz Ballester, Rodriguez Fontela, et al., 1952; Magonet, 1952; White, 1961; Maher-Loughnan, Mason, et al., 1962; Fry, Mason, et al., 1964; Brown, 1965, 1968; Gilder, 1968; Luparello, Lyons, et al., 1968; Maher-Loughnan, 1970; Smith, Colebatch, et al., 1970; Moorefield, 1971; Aronoff, Aronoff, et al., 1975; Collison, 1975; Ben-Zvi, Spohn, et al., 1982; Neinstein & Dash, 1982; Lewis, Lewis, et al., 1983; Zamotaev, Sultanova, et al., 1983; Ewer & Stewart, 1986; Pastorello, Codocasa, et al., 1987; Morrison, 1988; Spector & Kinsman, 1988; Murphy, Lehrer, et al., 1989; Wilkinson, 1989; Isenberg, Lehrer, et al., 1992; Kohen & Wynne, 1997; Hackman, Stern, et al., 2000; Anbar, 2003; Brown, 2007), hay fever (Langewitz, Izakovic, et al., 2005), and hyperventilation (Clarke & Gibson, 1980).

Patients can learn to use self-hypnotic techniques rather than medication when they begin to feel an anxiety-precipitated asthmatic attack coming on. This may help interrupt the vicious cycle of anxiety and bronchoconstriction (Aronoff, Aronoff, et al., 1975; Collison, 1975; Gluzman & Ziselson, 1987; Kohen, 1987; Kohen & Wynne, 1997).

A common technique is to have asthmatic patients enter a state of self-hypnosis and imagine that they are somewhere they naturally breathe easily, such as breathing cool ocean spray (Spiegel & Spiegel, 1987). In asthmatic patients, hypnotizability is correlated with treatment response (Collison, 1975). A study of 120 adult asthma patients experienced significant benefit from the use of hypnosis (Collison, 1975). The authors described that 21% of subjects had an "excellent response" to treatment, becoming completely free from asthma and requiring no drug therapy. An additional 33% had a "good response" with "worthwhile decrease in frequency and severity of the attacks of asthma" or a decrease in drug requirements. Furthermore, about half of the 46% who did not respond had a marked subjective improvement in general well-being. Others have reported similar results in children (Aronoff, Aronoff, et al., 1975; Kohen, Olness, et al., 1984; Gluzman & Zisel'son, 1987; Kohen, 1987).

A randomized controlled trial including 39 adults with mild to moderate asthma demonstrated that after brief treatment with hypnosis, patients with a high susceptibility score showed marked improvement (74.9%) in the degree of

bronchial hyperresponsiveness to a standardized methacholine challenge test, and a reduction in the use of bronchodilators by 26.2% (Ewer & Stewart, 1986).

Another study found that after self-hypnotic treatment and training, patients with treatment-resistant asthma reported a two-thirds decline in the number of hospital admissions (due to complications of asthma), decreased need for the use of PRN-steroid medications, reduced length in hospital stay, and an overall improvement in their perception of illness (Morrison, 1988). A retrospective analysis of 121 asthmatic patients who were treated by hypnotherapy showed that 21% of the subjects had an excellent response to treatment, becoming completely free from asthma and requiring no drug therapy (Collison, 1975). And an additional 33% had a good response, with worthwhile decrease in frequency and severity of the attacks of asthma or a decrease in drug requirements.

ONCOLOGICAL CARE

Hypnosis improves the tolerance of treatments such as chemotherapy (Hilgard & LeBaron, 1982; Zeltzer, Kellerman, et al., 1983; Zeltzer, LeBaron, et al., 1984; Katz, Kellerman, et al., 1987; Syrjala, Cummings, et al., 1992; Jacknow, Tschann, et al., 1994; Genuis, 1995; Steggle, Damore-Petingola, et al., 1997; Renouf, 1998; Marchioro, Azzarello, et al., 2000; Richardson, Smith, et al., 2006; Figueroa-Moseley, Jean-Pierre, et al., 2007; Neron & Stephenson, 2007; Richardson, Smith, et al., 2007; Jakubovits, 2011), anticipatory anxiety and side effects (Hoffman, 1982; Redd, Andresen, et al., 1982; Axelrod, Vinciguerra, et al., 1988; Marchioro, Azzarello, et al., 2000), external beam radiation therapy (Bertoni, Bonardi, et al., 1999; Steggle, 1999), interventional radiology (Lang, Joyce, et al., 1996; Lang, Benotsch, et al., 2000; Spiegel, 2006), and surgery, its recovery, and painful procedures (Kessler & Dane, 1996; Lambert, 1996; Spiegel & Moore, 1997; Wild & Espie, 2004).

As discussed before, hypnosis may be of assistance in the management of the discomfort and anxiety associated with many of the procedures needed in the treatment of cancer, such as chemotherapy, radiation therapy, claustrophobia, and the need for repeated diagnostic tests.

OBSTETRICS AND GYNECOLOGY

Hypnosis has multiple applications in the field of obstetrics and gynecology (Mun, 1964; Ferraris, 1975; Goldman, 1992; Oster, 1994; Baram, 1995; Schauble, Werner, et al., 1998; Brown & Hammond, 2007; VandeVusse, Irland, et al., 2007). These include assistance in obstetrical delivery and pain management during labor (Winkelstein, 1958; Werner, 1959; Rodger, 1961; Gueguen, 1962; Gross & Posner, 1963; Roden, 1970; Johnson, 1980; Freeman, Macaulay, et al., 1986; Oster, 1994; Schauble, Werner, et al., 1998; Brown & Hammond, 2007; VandeVusse, Irland, et al., 2007; Landolt & Milling, 2011), management of premature contractions (Omer, Friedlander, et al., 1986), hypnotic breech to cephalic

conversion (Mehl, 1994; Boog, 2004; Tiran, 2004), hyperemesis gravidarum (Kroger & De, 1946; Giorlando & Mascola, 1957; Mun, 1964; Piscicelli, 1968; Muzelak, 1974; Savel'ev, 1974; Fuchs, Paldi, et al., 1980; Smith, 1982; Poliakov, 1989; Frankel, 1994; Iancu, Kotler, et al., 1994; Torem, 1994; Simon, 1999; Simon & Schwartz, 1999; Brent, 2002; Buckwalter & Simpson, 2002; McCormack, 2010), pregnancy-induced hypertension (Smith, 1989), sexual dysfunction (Baram, 1995), urinary incontinence (Baram, 1995), condylomata acuminata (Straatmeyer & Rhodes, 1983; Klapper, 1984), chronic pelvic pain (Baram, 1995), and functional infertility (Mun, 1964; Gravitz, 1995).

Authors have reported the use of hypnotic preparation for labor and delivery, suggesting various advantages over Lamaze techniques (Oster, 1994). Among the advantages of using hypnosis are an improvement in the mother's psychological comfort, a heightened sense of involvement in the birth process, a diminished level of anxiety, and improved pain management.

A study of the effect of hypnotic relaxation as an adjunct to pharmacological treatment of premature contractions demonstrated that the rate of pregnancy prolongation was significantly higher for the hypnotic-relaxation group than for the medication-alone group (Omer, Friedlander, et al., 1986).

Unfortunately, most of the writings in this area are in the form of case reports or small series.

A prospective case series comparing 100 pregnant women whose fetuses were in breech position at 37 to 40 weeks' gestation and a matched comparison group of women with similar obstetric and sociodemographic parameters derived from clinical databases showed that 81% of the fetuses in the hypnotic intervention group converted to vertex presentation compared with only 48% of those in the comparison (control) group (Mehl, 1994). Others have further commented on the topic, but no other studies have been published (Boog, 2004; Tiran, 2004).

PAIN MANAGEMENT

The experience of pain does not exist in isolation. It is usually interpreted within the context of the subjective distress associated with a major medical illness or somatic trauma and in the context of the patient's life experiences and temporal social circumstances. The "pain experience" represents a combination of both tissue damage and the emotional reaction to it. There is ample evidence suggesting that psychological factors greatly influence the pain experience in either positive or negative ways (Beecher, 1956). In fact, the intensity of pain is directly associated with its meaning. Hypnosis, by the mechanisms of dissociation and absorption, can mediate an alteration in the subjective experience of pain.

Various well designed studies have described the usefulness of hypnotic intervention as adjunct to analgesia (Moskowitz, 1996). The use of hypnosis has been shown to increase tolerance to the procedure among angioplasty patients (Weinstein & Au, 1991). Similarly, patients on the hypnosis group reported lower levels of intraoperative pain scores during surgery compared to patients receiving conscious intravenous sedation

(control group [Faymonville, Fissette, et al., 1995]). Both studies found that hypnotized patients required less narcotic pain medication during the procedure compared to controls.

A randomized clinical trial of metastatic breast cancer patients demonstrated that a combination of hypnosis and group psychotherapy resulted in a 50% reduction in pain, which was accompanied by similarly significant reduction in mood disturbance (Spiegel, Bloom, et al., 1981).

Among subjects undergoing interventional radiologic procedures, the use of hypnosis was associated with a significant reduction in the need of anesthesia in the form of intravenous conscious sedation or patient-controlled anesthesia (Lang, Joyce, et al., 1996). The hypnosis group used less drug (0.28 vs. 2.01 drug units; $p < .01$) and reported less pain (median pain rating 2 vs. 5 on a 0–10 scale; $p < .01$). In addition, significantly more control patients exhibited oxygen desaturation and/or needed interruptions of their procedures for hemodynamic instability, thus suggesting that self-hypnotic relaxation can reduce the need for sedative medications and improve the safety of the procedure.

A study of moderately to highly hypnotizable adults with chronic low back pain demonstrated that they were able to significantly reduce pain perception following hypnotic analgesia instructions during cold-pressor pain training (Crawford, Knebel, et al., 1998). During the hypnotic condition there was evidence of an enhanced N_{140} in the anterior frontal region, suggesting inhibitory processing; reduced amplitudes of P_{200} (bilateral midfrontal and central, and left parietal) and P_{300} (right midfrontal and central), suggesting decreased spatiotemporal perception. Meantime, subjects reported highly significant mean reductions in perceived sensory pain and distress, reduction in chronic pain, increased psychological well-being, and increased sleep quality.

Most hypnoanalgesia treatment techniques involve the creation of a state of physical relaxation coupled with visual or somatic imagery, which allows a substitute focus of attention away from the physical sensation of pain. The technique to be used depends on the patient's hypnotic capacity. Highly hypnotizable individuals are much better at dissociating body parts or moving the pain to another part of the body or even away from the body. They can use fairly simple and direct imagery such as "seeing the pain melting away" or "being washed away by the river's waters." Some highly hypnotizable individuals may create a sensation of numbing at the affected area just by suggesting it.

Meanwhile, poorly suggestible patients may need more assistance from the therapist—for instance, more direct or concrete suggestions such as imagining injection of a local anesthetic into the affected area accompanied by its associated tingling numbness. A useful suggestion is to have subjects remember what a Novocain shot felt like the last time they went to the dentist. Then remind them of how slowly the gum, then the cheeks and the tongue became numb and "went to sleep." Once they can hold the image on their mind, they can imagine "the same shot" being administered "wherever it is needed in your body. Then slowly imagine the progressive numbing that follows as the medication spreads through the . . . (skin, nerves, muscle, or whatever the patient needs)."

Other images, such as changes in temperature, either warmth or coolness, of the area may also be helpful. Like "imagine the feeling of immersing your hand in cold water or snow until it is numb."

The images or metaphors that are selected for pain control may be used to filter the hurt or to transform the painful experience. Most patients who use hypnoanalgesia can still feel the pain, but may be unable to distinguish between the signal of pain and the discomfort caused by the signal. Thus, patients are taught not to fight but to transform painful signals into less uncomfortable ones. Fighting pain may only enhance it by focusing attention on the pain and increasing physical tension, which can place traction on painful body parts thereby increasing the sense of discomfort in adjacent tissues.

Regardless of any specific induction or metaphor use, there are four specific steps in the use of hypnosis that can make psychotherapy for pain management briefer, more goal-oriented, and efficient: (1) the assessment of hypnotizability; (2) the induction of hypnoanalgesia and development of individualized pain coping strategies; (3) the use of direct suggestion, cognitive reframing, hypnotic metaphors, and pain relief imagery; and (4) brief psychodynamic reprocessing, during the trance state, of emotional factors in the patient's experience of chronic pain (Eimer, 2000).

The precise mechanisms that mediate hypnotic analgesia are not known. Some time ago it was believed that hypnoanalgesia somehow involved the release or production of endogenous opioids (Frid & Singer, 1979). By now, several studies have not only failed to prove this theory but have proven that hypnotic analgesia is completely unaffected by the administration of opioid antagonist agents such as naloxone (Goldstein & Hilgard, 1975; Spiegel & Albert, 1983; Moret, Forster, et al., 1991). Despite lack of definitive explanation regarding its mechanism of action, there is no doubt that hypnotic analgesia works (DeBenedittis, Panerai, et al., 1989).

Studies have shown the superiority of hypnotic analgesia over placebo (McGlashan, Evans, et al., 1969) and acupuncture (Knox & Shum, 1977). In fact, a study using hypnosis as a method of analgesia reported significant increases of tolerance of pain and distress during hypnosis as compared to the waking state, thus hypothesizing that highly hypnotizable subjects were able to experience a hypnotically induced dissociation between the sensory/discriminative and the affective/motivational dimensions of pain (DeBenedittis, Panerai, et al., 1989). After measuring plasma concentrations of beta-endorphin and adrenocorticotrophic hormone (ACTH), they concluded that hypnotic analgesia was not mediated either by endorphins or by ACTH.

A number of studies have proposed new potential biological mechanisms mediating hypnoanalgesia. One study examined the changes in motor neuron excitability to electrical stimulus during conditions of resting wakefulness (not hypnotic) and suggestions for hypnotic analgesia. Its findings suggest that hypnotic sensory analgesia was, at least in part, (Kiernan, Dane, et al., 1995) mediated by either descending spinal cord antinociceptive mechanisms or by diminished nociceptive awareness mediated by other brain mechanisms.

Other studies utilizing SERP measures to noxious stimuli seem to confirm the presence of active inhibitory processes during cognitive strategies in hypnotic analgesia, and to confirm that these inhibitory processes also regulate the autonomic activities in pain perception (De Pascalis, Magurano, et al., 2001). For example, 33 subjects' neural responses (EEG) were measured during the 40–540 ms period following phasic electrical stimulations to the right hand, under control and hypnosis conditions (Croft, Williams, et al., 2002). Resultant amplitudes were computed and grouped into seven scalp topographies, and for each frequency relations between these topographies and pain ratings, performance, and stimulus intensity measures were assessed. Gamma activity (32–100 Hz) over prefrontal scalp sites predicted subject pain ratings in the control condition ($r=0.50$, $P=0.004$), and no other frequency/topography combination did. This relation was unchanged by hypnosis in the poorly hypnotizable subjects but was not present in the highly hypnotizable subjects during hypnosis, suggesting that hypnosis interferes with this pain/gamma relation.

In a group of patients with fibromyalgia, hypnoanalgesia studied using PET scans found that patients experienced less pain during hypnosis than at rest. At the same time, the cerebral blood flow was bilaterally increased in the orbitofrontal and subcallosal cingulate cortices, the right thalamus, and the left inferior parietal cortex, and was decreased bilaterally in the cingulate cortex, supporting the notion of the multifactorial nature of hypnotic analgesia with contributions from cortical and subcortical brain regions (Wik, Fischer, et al., 1999).

Another PET study compared brain images of subjects in a hypnotic resting state with mental imagery and a hypnotic state with stimulation; namely, warm non-noxious versus hot noxious stimuli applied to right thenar eminence (Faymonville, Laureys, et al., 2000). Statistical parametric mapping demonstrated that noxious stimulation caused an increase in rCBF in the thalamic nuclei, anterior cingulate, and insular cortices, while the hypnotic state induced a significant activation of a right-sided extrastriate area and the anterior cingulate cortex. The interaction analysis showed that the activity in the anterior (mid-) cingulate cortex was related to pain perception and unpleasantness differently in the hypnotic state than in control situations. Hypnosis decreased both pain sensation and the unpleasantness of noxious stimuli, which suggests that hypnotic analgesia with an instruction that the pain will not be bothersome (rather than literally reduced in intensity) is mediated by reduced activity in the anterior cingulate cortex (Faymonville, Laureys, et al., 2000).

A follow-up study among highly hypnotizable right-handed volunteers using H₂(15)O-PET found that hypnosis, compared to the resting state, reduced pain perception by 50%, while the pain perception during rest and mental imagery was not significantly different (Faymonville, Roediger, et al., 2003). Analysis of PET data showed that the hypnotic state compared to normal alertness (i.e., rest and mental imagery) significantly enhanced the functional modulation between midcingulate cortex and a large neural network encompassing bilateral insula, pregenual anterior cingulate cortex, pre-supplementary motor area, right prefrontal cortex, and

striatum, thalamus, and brainstem. These findings point to a critical role for the midcingulate cortex in the modulation of a large cortical and subcortical network underlying its influence on sensory, affective, cognitive, and behavioral aspects of nociception in the specific context of hypnosis.

More recently, PET imaging studies have confirmed that hypnosis, when used to produce hypnotic analgesia, can modulate the cerebral network involved in noxious perception (Faymonville, Boly, et al., 2006). In fact, when compared to the resting state, hypnosis reduced pain perception in somatosensory cortex by approximately 50%. In these subjects, hypnoanalgesia-induced reduction of affective and sensory responses to noxious thermal stimulation was modulated by the activity in the midcingulate cortex (area 24a). Also, compared to normal alertness (i.e., rest and mental imagery) the hypnotic state significantly enhanced the functional modulation between midcingulate cortex and a large neural network involved in sensory, affective, cognitive, and behavioral aspects of nociception.

After determination of the heat pain threshold of 12 healthy volunteers, fMRI scans were performed during repeated painful heat stimuli (Schulz-Stubner, Krings, et al., 2004). Subjects under the hypnosis paradigm exhibited less activation in the primary sensory cortex, the middle cingulate gyrus, precuneus, and the visual cortex when compared with responses without hypnosis. An increased activation was seen in the anterior basal ganglia and the left anterior cingulate cortex. There was no difference in activation within the right anterior cingulate gyrus in our fMRI studies, and no activation was seen within the brainstem and thalamus under either condition. These findings suggest that clinical hypnosis may prevent nociceptive inputs from reaching the higher cortical structures responsible for pain perception.

The development of “neurosignatures of pain” can influence subsequent pain experiences (Melzack, 1991;Coderre, Katz, et al., 1993; Melzack, 1993) and may be expanded in size and easily reactivated (Melzack, 1991, 1993; Elbert, Flor, et al., 1994). Therefore, hypnosis and other psychological interventions need to be introduced early as adjuncts in medical treatments for onset pain before the development of chronic pain (Crawford, Knebel, et al., 1998).

APPLICATION OF HYPNOSIS IN PSYCHIATRIC DISORDERS PERTINENT TO PSYCHOSOMATIC MEDICINE

The use of hypnosis in the management of psychiatric disorders in general is beyond the scope of this chapter and has been discussed elsewhere. (Maldonado & Spiegel, 2002, 2008). Yet, there are some specific psychiatric disorders that are particularly pertinent for the psychosomatic medicine specialist, such as the management of traumatic events related to posttraumatic stress disorder (Maldonado & Spiegel, 1994, 1998, 2002, 2008; Cardeña, Maldonado, et al., 2008), acute phobic reactions interfering with medical care (e.g., claustrophobia or needle phobia), behavioral modification (e.g.,

smoking and weight management, sleep disturbances), and treatment of some somatoform disorders (i.e., conversion disorder [Maldonado & Spiegel, 2000; Maldonado, 2007]).

POSTTRAUMATIC STRESS DISORDER

Initially, the principal role for hypnosis in the psychotherapy of trauma was limited to abreaction, based on Freud's cathartic method. The idea was that some intense affect associated with the traumatic event needed to be released, and that simply repeating the event with its associated emotion in the trance state would suffice to resolve the symptoms. However, it became clear to Freud that conscious cognitive work must be done on the material for it to be successfully worked through (Freud, 1914/1958).

A number of studies among individuals suffering from posttraumatic stress disorder (PTSD) have demonstrated that these patients usually score in the high hypnotizability range (Stutman & Bliss, 1985; Spiegel, Hunt, et al., 1988; Cardeña, Maldonado, et al., 2008). Reports also suggest high hypnotizability scores among children who were victims of severe punishment during childhood (Nash, Lynn, et al., 1984; Spiegel & Cardeña, 1991). Some researchers in the field suggest a possible explanation, that the impact of the stress suffered during trauma encourages a more effective use of dissociative defenses and self-hypnotic abilities, thus enhancing or mediating symptomatology (Spiegel, Detrick, et al., 1982; Kluft, 1984, 1992). If this hypothesis is correct, then the controlled use of hypnosis in the clinical setting may assist in modulating and managing symptoms associated with PTSD and, over time, help to integrate memories of trauma (Maldonado & Spiegel, 1994).

In fact, the major categories of symptoms in PTSD are similar to the components of the hypnotic process (American Psychiatric Association, 1994; Maldonado & Spiegel, 1994, 2007; Maldonado, Page, et al., 2002). Hypnotic absorption is similar to the intrusive reliving of traumatic events. When in a flashback, trauma victims become so absorbed in reexperiencing the traumatic event that they lose touch with their present surroundings and even forget that the events took place in the past. Similarly, patients suffering from PTSD may dissociate feelings to the extent of experiencing the so-called "psychic numbing," which allows them to disconnect current affects from their everyday experience in an attempt to avoid emotions triggering memories associated with the trauma. Finally, suggestibility is comparable to hyperarousal. The heightened sensitivity to environmental cues observed in patients suffering from PTSD is similar to that experienced by a hypnotized individual who responds to suggestions of coldness by shivering.

For therapy to be effective in cases of traumatic stress, cognitive restructuring, emotional expression, and relationship management must accompany the patient's controlled reexperiencing of the traumatic events. To that effect, the therapeutic environment must provide the patient with an enhanced sense of control over the memories of the experience. One of the ways to accomplish that is through symbolic restructuring of the traumatic experiences during work

with hypnosis (Spiegel & Spiegel, 1987) and the use of a grief work model (Spiegel, 1981). Hypnosis can be used to provide controlled and safe access to the dissociated or repressed memories of the traumatic experience at a pace the patient can tolerate, and then can assist patients to restructure their memories of the events.

Given the growing evidence that many people enter a dissociated state during physical trauma (Spiegel & Cardeña, 1991; Cardeña & Spiegel, 1993; van der Kolk, Hostetler, et al., 1994; van der Kolk & Fisler, 1995; Butler, Duran, et al., 1996; Cardeña, Maldonado, et al., 2008) and the principle of state-dependent memory (Bower, 1981; Bremner, Krystal, et al., 1996; Butler, Duran, et al., 1996), it makes sense that enabling patients to enter a structured dissociative state in therapy would facilitate their access to memories of the traumatic experience—memories that can be worked through to resolve the posttraumatic symptomatology. In the more immediate context of the medical setting, the use of hypnosis can help to control the dissociative symptoms and traumatic flashbacks, help manage anxiety symptoms, and improve sleep. Over the long term, though, hypnosis can be helpful in allowing the victim to review aspects of the trauma in a controlled manner. Memories can be experienced or reviewed for a time with the assurance that they can be put aside afterward. In the context of hypnotic facilitated psychotherapy, patients can be quickly taught how to produce a state of physical relaxation despite whatever psychological stress they experience, thereby dissociating the somatic reaction from the psychological preoccupation and allowing for modulation of the traumatic memory and an enhanced sense of control over the experience. Patient and therapist can then find a condensation image that symbolizes some aspect of the trauma.

The Split Screen Technique

It is often helpful to have patients project the images of the traumatic event on an imaginary screen, which gives them some sense of distance from the event. It is also useful to divide the screen in half, having the patient picture on one side some aspect of the event (e.g., a trauma victim's image of the accident) and on the other side of the screen some positive aspect of the event (e.g., having survived and being able to be with the family; veering the car into a divider in order to prevent hurting someone else). This exercise enables the patient to restructure his or her view of the incident—facing it, but not simply in the familiar terms of the powerlessness, victimization, pain, and fear with which it was initially associated. Patients can then be taught a self-hypnosis exercise in which they grieve and work through traumatic memories while enhancing their sense of control over the process (Spiegel, 1981).

CASE STUDY 4: TREATMENT-RELATED POSTTRAUMATIC STRESS DISORDER

Hypnosis can also be very effective in the management of patients who may have phobia due to previous bad medical experiences or have PTSD secondary to previous past procedures or treatment.

One of our patients was a 75-year-old married woman who had been recently diagnosed with breast cancer. She had discovered a “lump” in her breast a few months earlier, which she brought to her primary care physician’s attention. He suspected breast cancer and immediately referred her to a surgeon in our institution. She was soon scheduled to undergo a needle biopsy. She informed him that she had suffered from claustrophobia all her life and didn’t know whether she could tolerate a surgical procedure. He reassured her that “You will be sound asleep and will notice nothing.”

She was admitted to the one-day surgical suite thinking, “Everything has been taken care of.” Soon after arriving, she received her first “shock” when a nurse came into her area to place an IV line. The patient thought that someone would “give me something to take care of my anxiety.” After the IV was in place, someone injected a “sedative” but she didn’t feel any anxiety relief. Soon afterward her stretcher was wheeled to the surgical suite and before she had time to protest, her arms and legs were placed in restraints, she was draped, her face was covered, and then “the mask was placed.” She recalls that as “the most traumatic experience in my life.” For whatever reason she did not respond to the anesthesia well and remembers being conscious “most of the time.”

After surgery she was shaken. In fact, she exhibited many symptoms of PTSD. One thing was clear in her mind: “I will never go through this again.” A few days later, when she went to the surgeon’s office to get the results of her biopsy, she was informed that she had cancer and would need further treatment. Her options were a lumpectomy followed by radiation therapy or a radical mastectomy. She knew two things: she didn’t want to have further surgery. But if she needed surgery, she wanted to “preserve the breast if she could,” so she decided to explore the first option.

She made an appointment with the radiation oncology clinic for an evaluation as part of the lumpectomy/XRT treatment plan. When she arrived at the hospital she found that the XRT Clinic was in the basement of the building. It took her over three hours of pain and agony in the lobby “trying to force myself to get down there.” Finally, the social worker for the oncology service found her and brought her down. As she walked through the unit the patient had a panic attack. Frightened and anxious, she ran out of the building and decided she could not go through the treatment. Her surgeon was notified of the events and he quickly called her. She informed him that she “couldn’t do it.”

After much talking over the phone, the patient agreed to “think about it for a while.” When 2 months had passed with no news from the patient, the surgeon called her again and stressed the need to do something quickly. The patient asked for some more time. The surgeon gave her one more week to think about it. A week later, the surgeon called her again to find out her decision. If she could not undergo radiation therapy (XRT), she needed to do the radical mastectomy as soon as possible. She dreaded this alternative as much as the XRT, so she agreed to try the presurgical meeting with the radiation therapy group again. During her second visit to the XRT suite, the patient was greeted and escorted by a social worker and a nurse, who stayed with her the entire time. Nevertheless, once again the patient had a panic attack and left the unit before she could complete the necessary

pretreatment measurements. Finally a psychiatric consult was requested. It took her about 4 weeks to find the courage to make an appointment with my office.

I received her in the waiting room of our office building. It took her about 10 minutes to walk from the receiving area to the end of the hallway leading to my office. This walk usually takes me one minute or less. During this walk her anxiety and discomfort were evident. Once in my office she insisted that the door and the window blinds remain open. Similarly, she requested that the blinds to my windows be wide open. During my initial interview with her she made clear that she had suffered from claustrophobia all her life, but had always managed it by altering her life in a way that she was always able to avoid claustrophobic situations. For example, she had never taken an elevator in her life, and her husband did all the shopping.

Nevertheless, she remained very functional, managing a small 3-storey apartment building. She reported a remarkably small number of panic attacks given her extreme agoraphobia and claustrophobia. She had managed to do so well because, “I knew what to do. I would never force myself into those situations.” This was the first time in her life when she found herself completely “out of control.” She also described classic PTSD symptoms following her painful experience during her last operation. She had experienced flashbacks, recurrent dreams, and autonomic reactivity by just thinking of a radiation machine or lying on a medical table.

We discussed her biopsy, the XRT suite, and the events leading to the referral. She made it clear that she would like to “preserve the breast,” but “I don’t think I could go through it again.” Worse yet, she not only would not go back to the XRT suite but she had up made her mind that she couldn’t go through surgery, either. We discussed her treatment options including the use of medication, psychotherapy, and/or hypnosis. Given the fact that it had taken so much time to get to me, we were running out of time. Her surgeon had made it clear during our conversation that she should have initiated treatment weeks ago. She expressed a terrifying fear of medication side effects, “especially those that control the mind.”

Finally, she agreed to try hypnosis as an alternative. We discussed how hypnosis might help control some of her anxiety and at the same time allow her to regain some of the control she felt she had lost over her mind, her body, and her life. Like many phobic patients she proved to be a highly hypnotizable subject. She scored a 10 on the 10-point HIP scale. Over the following 3 weeks I saw her four times. During those sessions she learned to use self-hypnosis and to dissociate from unpleasant environments. In fact, she used self-hypnotic exercises to “practice going through surgery and being in the XRT suite.”

During the third and fourth weeks we worked on the surgery phobia. She had multiple unpleasant memories of her first surgery. The idea of been placed on the operating room table was unbearable. She could not even conceive the idea of being tied to the table and placed under anesthesia. A new phobia, to be intubated, had been developed.

She practiced under hypnosis coming to the hospital, sitting in the waiting room, changing into the hospital gown, going into the surgical suite, and inducing a self-hypnotic trance before “being put to sleep.” Under hypnosis she put herself into a trance.

She also imagined that she played the role of the anesthetist. In her mind, she intubated herself and she operated the gas and drips. Thus she had complete control over what was going on. Finally, toward the end of the fourth week, she underwent a lumpectomy. We worked in concert with the anesthesiologist who was fully aware of what we were doing. He allowed her time to put herself under. After she gave him the signal that she was ready, as we had discussed, he walked her through the procedure. The patient did beautifully in surgery.

After surgery we were faced with the real test, a prolonged course of XRT. By now the patient had mastered the use of self-hypnosis, but now she had to deal with confined spaces, loud machines, and prolonged periods of isolation for the next 3 months. During weeks 5 to 7 while she was recovering from the surgery, we had time to prepare, and we worked intently on her claustrophobia and panic attacks. She was then able to use her self-hypnosis exercise to undergo the first treatment of the 3-month, five-times-a-week radiation therapy course.

Not only did she do well during this surgery and subsequent course of radiation treatment, but about a year later this patient was faced with an additional surgical procedure when a follow-up mammogram revealed another mass. Once again, after a single hypnosis session, the patient was able to undergo the biopsy procedure without any difficulty. Fortunately, the mass was benign and no further treatment was required.

CONVERSION DISORDERS

As first suggested by Janet (1907), it is our belief that the symptoms of conversion disorder can be understood in part as reflecting the presence of uncontrolled hypnotic states. Studies have already reported that conversion patients are very hypnotizable (an average 9.7 on the HIP 12-point scale [Bliss, 1984]) Others have corroborated that conversion patients are more highly hypnotizable than the population at large (Maldonado, 1996, 1997; Maldonado & Jasiukaitis, 2003). For example, studies suggest that the percentage of the general population that is highly hypnotizable is between 20%–30% compared to about 69% in patients suffering from psychogenic seizures (Peterson, Sumner, et al., 1950; Peterson, Sumner & Jones, 1950). Maldonado and colleagues have hypothesized that patients suffering from a conversion disorder may indeed be using their own capacity to dissociate in order to displace the uncomfortable feelings or affects into a chosen part of the body, which then becomes dysfunctional (Maldonado, 1996, 1997; Maldonado & Jasiukaitis, 2003).

Even though most patients are not aware of it, highly hypnotizable individuals have an unusual capacity to control (albeit unconsciously) somatic functions. This is evident by the high hypnotizability levels observed in subjects experiencing psychosomatic disorders and conversion reactions. Years ago, Charcot correctly reported an association between conversion disorder and high hypnotic capacity (1890). However, he incorrectly assumed that they both indicated similar central nervous system dysfunction. The symptoms of conversion disorder can be understood in part as reflecting the presence of uncontrolled hypnotic states. Indeed, hypnosis may be useful in both the diagnosis and treatment of many psychosomatic

illnesses and conversion symptoms (Maldonado, 1996, 2007; Maldonado & Spiegel, 2000; Maldonado & Jasiukaitis, 2003)

Hypnosis by itself is not treatment. It should always be used as an adjuvant to, rather than in lieu of, medical treatment. In cases of conversion symptoms and psychosomatic processes, hypnosis is used not to treat but to allow patients to control the effects on their bodies of their emotional stress and mind states. It is not advised to force a cure in a patient. Rather, patients are trained in the use of self-hypnotic techniques and then allowed to improve at a pace that feels comfortable, while the clinician provides suggestions for improved control and mastery and explores the unconscious psychological reasons behind the presence of symptoms, including the possibility of secondary gain.

When considering the treatment of conversion disorders, hypnosis may be useful in two ways. First, it may assist in confirming the diagnosis. Second, it may be therapeutic (i.e., part of a comprehensive treatment plan that includes therapy to help the patient develop more mature and adaptive defense mechanisms; see (Maldonado, 2007). Clinicians treating patients with conversion symptoms must pay attention to verbal and nonverbal cues given to the patient. It is also not unusual for patients with conversion to present wide variations of symptoms during the course of a session. In fact, during a hypnotic induction the clinician may bring on symptoms, worsen, or ameliorate them. Even though it may be tempting to “cure your patient,” you must be aware that premature “cures” (i.e., before the patient feels safe and has developed the necessary tools to deal with whatever emotional distress caused the conversion to begin with) usually are followed by the development of symptom substitution. Also, educate the professionals for whom you are consulting to make certain they do not give the patient the message that the problem is “all in your head.” There are several steps to be considered (Maldonado, 2007) in the comprehensive treatment of patients with conversion disorder (see Box 16.1). The first step is a thorough neurological and medical evaluation, given the high comorbidity between conversion diagnoses and organic conditions (Krumholz & Niedermeyer, 1983; Barsky, 1989). The second step is timely diagnosis. Studies show a 6-year to 8-year delay before the diagnosis of conversion disorder is made (Bowman, 1993), usually because of previous misdiagnosis of and treatment for medical, neurological, or other psychiatric conditions. The failure to make a timely diagnosis and the use of excessive diagnostic tests or inappropriate treatments may lead to iatrogenic problems or may “validate” the patient’s perceived deficits. Some treatments, particularly psychoactive medications (e.g., anticonvulsants, benzodiazepines, barbiturates, antipsychotics) may worsen conversion symptoms by causing neurological side effects (e.g., balance problems, memory deficits) and promote dissociative states (e.g., depersonalization, derealization, mental slowing).

The third step involves the therapeutic reassurance by both sets of doctors (i.e., internist or neurologist and therapist) that there is a good level of certainty that the symptoms are not due to a deadly medical or neurological condition (e.g., “you don’t have a brain tumor,” “you don’t have a seizure disorder”) but are secondary to underlying psychological

Box 16.1 MANAGEMENT OF CONVERSION
DISORDER REQUIRES

1. A thorough neurological and medical evaluation.
2. A timely diagnosis of conversion disorder.
3. Therapeutic reassurance by both sets of clinicians that there is a good level of certainty that the symptoms are not due to a deadly medical or neurological condition.
4. A coordinated effort by both sets of clinicians to not let the patient fall between the cracks, to not have unnecessary tests, to not prescribe medications that worsen the symptoms, and to reinforce the mind–body connection in the symptoms.
5. Continuous surveillance to accurately diagnose and aggressively treat any comorbid psychiatric disorder.
6. Help the patient to develop more mature and adaptive defense mechanisms to prevent the development of future conversion episodes. The ultimate goal is the development of an appropriate level of control and mastery.

factors. Usually, an explanation of the mind/body interaction and how unconscious and psychological processes may affect the body in more common medical conditions is of help. Patients often feel reassured when physicians explain that psychological factors, pressures, and stress can create havoc in the body and be as serious nevertheless, thus in need of prompt attention.

The fourth step involves the development of a coordinated effort by both sets of clinicians that ensures the patient does not fall through the cracks, that no unnecessary tests and procedures are performed, medications that may worsen symptoms are not prescribed, and the mind/body connection is continuously reinforced. The fifth step is continuous surveillance to accurately diagnose and aggressively treat any comorbid psychiatric disorder. This is particularly important given the high comorbidity between conversion disorder and other Axis-I disorders (especially mood, anxiety, dissociative, and other somatoform disorders). The most common psychiatric diagnoses are major depressive disorder and dissociative disorders, both of which have been found in about 85% of acute conversion cases (Ziegler, Imboden, et al., 1960; Roy, 1980; Bowman, 1993).

The sixth (and last step) involves working through the patients' defenses and helping them develop more mature and adaptive defense mechanisms to prevent the development of future conversion episodes. The ultimate goal is the development of an appropriate level of control and mastery. This can be achieved with any number of psychotherapeutic modalities, but hypnotically facilitated psychotherapy is particularly useful and effective (Maldonado, 2007).

The use of hypnosis in the treatment of conversion disorder itself involves several phases (Maldonado & Spiegel, 2002; Maldonado, 2007). The first phase involves exploring the meaning of the symptoms: it is important never to eliminate a symptom fully without understanding its purpose and replacing it with a more mature and adaptive defense. The

second phase involves symptom alteration—that is, taking the patient's mind away from the presenting symptoms while allowing him or her to find more appropriate ways to cope with anxiety. This may be accomplished by *prescribed symptom substitution*, in which a given symptom is exchanged for another that is less impairing or pathological until the patient is ready to give up the original symptom (e.g., changing the perception of intense cancer pain to a numbing, tingling sensation in the same area), or by *symptom extinction*, in which the patient agrees to “give up” the symptom after working through the problem in psychotherapy. The third phase involves maximizing the patient's level of functioning. Hypnosis may be used to increase the patient's motivation, enhance his or her sense of mastery, and strengthen his or her defenses.

BEHAVIOR MODIFICATION

PRIMARY INSOMNIA

Even though the word *hypnosis* literally means sleep, hypnosis is not a form of sleep and it is not related to sleep. In fact, if you fall asleep you come out of trance. Nevertheless, because hypnosis can be helpful in inducing a state of physical relaxation and because by focusing intently on a pleasant scene you can avoid your mind wandering about the many problems causing sleep disturbance, it may facilitate a state of physiological sleep. In fact, the hypnotic experience can create a state of physical relaxation which in turn may diminish sympathetic tone. The hypnotic trance may provide patients a structured way of managing preoccupation with anxiety-producing problems, thereby facilitating entrance into a restful sleep.

After inducing a state of self-hypnosis, patients are taught to create a sensation of buoyancy, floating, or any other sensation that they associate with physical relaxation. Images such as floating on an inflatable mattress in a pool, or floating down the river on an inner tube could be rather effective. After patients are successful at this exercise they may proceed to put their worries or thoughts on hold for tonight, knowing that they can always deal with them tomorrow. There are a number of imagery techniques that patients can use to put problems on hold. For example, patients can project these thoughts onto an imaginary screen, and then imagine either changing the content of the screen (as you would change television channels), putting the podcast on pause, or simply turning it off.

Subjects can also imagine themselves sitting by a riverbank observing leaves flowing down the stream. They can then imagine themselves placing their thoughts over the leaves and watching them floating away, not holding on to any particular thought, while allowing the body to feel progressively relaxed; or they may imagine themselves lying restfully in a comfortable and safe place while they see themselves placing the disturbing thoughts onto the clouds, watching the breeze slowly carrying them away.

It is important to point out that any hypnotic approach should be accompanied by sound sleep hygiene practices.

These include going to bed always at the same time, avoiding large meals or exercise just prior to bedtime, keeping the bedroom as a place to sleep, avoiding doing work or reading in bed, and avoiding looking at the clock when awakened. It is important to trace the source of the problem, differentiating primary insomnia from sleep disturbances that occur secondary to physiological disorders such as sleep apnea, or serious psychiatric conditions such as major depression or anxiety disorders.

There are very few research data available on the efficacy of hypnosis in the treatment of sleep disorders (Bauer & McCanne, 1980; Stanton, 1989; Nielsen, 1990; Becker, 1993). Most of the literature is limited to case reports, or studies with such a small sample that it is difficult to interpret the results. Yet, they have reported that 50% of patients suffering from chronic dyssomnia experienced improvement in their sleep patterns lasting over 16 months after a simple 2-session treatment course (Becker, 1993). The largest reported study included 45 patients treated with hypnosis, stimulus control, or placebo (Stanton, 1989). It demonstrated significant improvement in early insomnia in the hypnosis group compared to comparators. Few formal studies have been reported, but most case reports suggest that hypnosis is useful in the treatment not only of primary insomnia but other sleep disturbances as well (Bauer & McCanne, 1980; Schenck & Mahowald, 1995).

SMOKING CESSATION

Effective smoking cessation consists of pharmacotherapy and behavioral support. Counseling increases abstinence rates parallel to the intensity of support. Nearly 100 articles dealing with the topic can be found in the published literature, all suggesting that hypnosis is useful in assisting in nicotine abstinence. Nearly half have been published in the last decade.

A meta-analysis demonstrated that unassisted smoking cessation (i.e., "cold turkey") has been reported to have a low success rate of as little as 7.3% at 10-month follow-up (Baillie, Mattick, et al., 1995). A *Cochrane* review examined pooled data from 17 trials of brief advice versus no advice (or usual care) and found an unassisted quit rate of 2% to 3%, and that a brief advice intervention can increase quitting by a further 1% to 3% (Stead, Bergson, et al., 2008).

First-line pharmacological drugs for smoking cessation include nicotine replacement therapies (i.e., patch, gum, inhaler, nasal spray, lozenge/tablets), the nicotinic acetylcholine receptor partial agonist (i.e., varenicline) and antagonists (i.e., bupropion) with scientifically well documented efficacy when used for 2–3 months and mostly mild side effects. Nicotine replacement therapy has a 12%–25% efficacy after 16 weeks on active treatment, but the abstinence rate drops to 17% at 1-year follow-up off active treatment (Tonnesen, Norregaard, et al., 1991). The newer agents have results. For weeks 9 through 12, the 4-week continuous abstinence rates were 44.0% for varenicline versus 17.7% for placebo ($P<.001$) and versus 29.5% for bupropion SR ($P<.001$). But for weeks 9 through 52, the continuous abstinence rates were 21.9% for varenicline versus 8.4% for placebo ($P<.001$) and versus 16.1%

for bupropion SR (Gonzales, Rennard, et al., 2006). In summary, the data suggests that at present, with the most optimal drugs and counseling, a 1-year abstinence rate is approximately 25% (Tonnesen, 2009).

Studies show that the success rate in cigarette cessation after hypnotic treatment ranges from 20% to 64% (Crasilneck & Hall, 1968; Spiegel, 1970; Hyman, Stanley, et al., 1986; Schwartz, 1987; Williams & Hall, 1988). These abstinence rates are superior to the rates of unassisted quitting (Gritz & Bloom, 1987). The success rate depends on a number of factors, including the patient's motivation and hypnotizability as well as the therapist's expertise. A variation of the single-session treatment approach, consisting of one to five sessions with or without the use of audiotapes or self-hypnotic training, as needed, is widely used in medical settings (Dengrove, Nuland, et al., 1970; Spiegel, 1970; Pederson, Scrimgeour, et al., 1975; Watkins, 1976; Stanton, 1978, 1991; Berkowitz, Ross-Townsend, et al., 1979; Javel, 1980; Rabkin, Boyko, et al., 1984; Barabasz, Baer, et al., 1986; Frank, Umlauf, et al., 1986; Hyman, Stanley, et al., 1986; Neufeld & Lynn, 1988; Williams & Hall, 1988; Elkins & Rajab, 2004).

The single-session approach (Spiegel, 1970) emphasizes training a susceptible subject on the use of self-hypnosis rather than relying on endless hypnotic sessions induced by a physician. The goal is to teach individuals to tap into their ability to enter a self-hypnotic trance, then provide them with a strategy that is intrinsically self-reinforcing (Spiegel & Spiegel, 1987). This allows patients to practice the technique whenever the urge to smoke comes. It uses cognitive restructuring to emphasize how the act of smoking is destructive to the body and how the effects of smoking limit what one can do with one's life due to a shortened life span and deteriorating quality of life. Repetitive self-hypnotic experiences are used to emphasize patients' commitment to protect their bodies from the poison in cigarettes.

The approach is based on the cognitive restructuring model. It involves emphasizing that smoking is destructive specifically to the patient's body and thereby limits what he or she can do. The focus during hypnosis is then placed on protecting the patient's body from poison in the same way that the patient would protect an infant or a pet from ingesting noxious food. This approach enables the patient to balance the urge to smoke against the urge to protect the body from damage. In other words, the focus is on what the patient is *for* rather than what he or she is *against* (Spiegel, 1970).

This method also reinforces the idea of self-control. The patient is trained in self-hypnosis and on how to think, rather than to avoid thinking about smoking. Once the technique has been learned, it is up to the patient to use it or not. Initially patients are asked to practice the technique a few times a day at prescribed times, plus at any other time the patient experiences nicotine cravings. Later on, as patients become more proficient and have less craving they are instructed to use the technique whenever they feel the urge to smoke. This approach requires that patients examine their priorities and balance their urge to smoke against the need to protect the body from the damage caused by further smoking. Smokers are instructed to focus on what they are for (i.e., protecting

their bodies) rather than what they are against (i.e., smoking). Thus, while there is no evidence that treatments using hypnosis are more effective than other interventions for smoking, they may well be more efficient in that they enable patients to employ self-hypnosis to reinforce a cognitive restructuring strategy, while at the same time providing an episode of physical relaxation. Strategies for smoking cessation, including the use of medications, are discussed in chapter 53.

WEIGHT MANAGEMENT

Unlike the case of hypnosis intervention for smoking cessation, there are few data on the long-term effects of hypnosis for weight control. Clinical experience suggests that patients who are within 20% of their ideal body weight may obtain the most benefit from restructuring techniques that use self-hypnosis in combination with a medical regimen.

A meta-analysis performed on 18 studies in which a cognitive behavioral therapy (CBT) was compared with the same therapy supplemented by hypnosis indicated that the addition of hypnosis substantially enhanced CBT's outcome (Kirsch, Montgomery, et al., 1995). In fact, the analysis suggested that the average client receiving cognitive behavioral hypnotherapy showed greater improvement than at least 70% of clients receiving nonhypnotic treatment. Effects seemed particularly pronounced for treatments of obesity, especially at long-term follow-up, indicating that unlike those in nonhypnotic treatment, clients to whom hypnotic inductions had been administered continued to lose weight after treatment ended.

Similarly, various studies suggested a significant correlation between hypnotizability scores and weight reduction (Andersen, 1985; Kirsch, Montgomery, et al., 1995; Kirsch, 1996). A meta-analysis of the effects of CBTs and hypnosis for weight reduction found that the mean weight loss in the group using CBT plus hypnosis was twice that of the group treated with CBT alone—in other words, the mean weight loss was 6.03 lbs. (2.74 kg) in the CBT/nonhypnosis and 14.88 lbs. (6.75 kg) in the CBT plus hypnosis, with an effect size of 0.98 SD (Kirsch, 1996). Correlational analyses suggested that the benefits of hypnosis increased substantially over time ($r = .74$). For example, in a study of 109 subjects who completed a behavioral treatment with or without hypnosis, the hypnosis group experienced significant additional weight loss at the 8-month and 2-year follow-ups, while those in the behavioral treatment exhibited little further change. Moreover, the subjects who used hypnosis were better able to achieve and maintain their personal weight goals (Bolocofsky, Spinler, et al., 1985).

When hypnosis is used for weight management, it must be applied within the context of a comprehensive medical treatment plan that includes sensible eating habits and an exercise program tailored to the patient's needs and capabilities. Just as in the case of smoking cessation, the goal of hypnosis is to restructure the patient's experience around food and eating practices. The intent is that the patient will modify his or her perception of food and understand what new approaches are for (e.g., lower body weight, healthier lifestyle, better controlled blood sugars and blood pressure) and not what they

are against (e.g., food). In addition, hypnosis can be used to help patients provide positive self-reinforcement for compliance with a revised eating regimen (Crasilneck & Hall, 1985).

During the course of psychotherapy, in and out of hypnotic trance, patients are asked to examine their relationship with food and their food intake practices and to consider the damaging effects of overeating or starvation on their bodies. The ultimate purpose is to restructure the eating experience so that it becomes an exercise about learning to eat with respect for one's body. Once again, the emphasis is on what the patient is for rather than what he or she is against.

When used as part of a weight loss program, the most important component of this approach consists in teaching patients how to use self-hypnosis to control their eating patterns. Patients are asked to prepare a list of foods that are consistent with their goals and their commitment to eating with respect for their bodies. Patients are then asked to compare their craving to eat with their stated goals and the healthy items they placed in their list. If the desired food is on the list, the patient is encouraged to eat it like a gourmet, focusing intently on all aspects of the eating experience and enjoying it. If the food is not on the list, the patient is asked to recognize the desire for it rather than to fight it or ignore it. At that point, the patient uses self-hypnosis to examine this urge in light of the commitment to protect and treat the body with respect and, therefore, to eat with respect.

Using this method, patients see their desire to eat not as an occasion to feel deprived, but rather as an occasion to enhance their mastery over their urges by choosing to protect their bodies. The use of self-hypnosis also allows patients to learn to respond in a planned way rather than to react to somatic signals of hunger and satiety—to eat when they are hungry but stop eating as soon as they are satisfied. But hypnotic capacity may play an even deeper role.

The literature suggests that aspects of hypnotizability may be involved in the etiology and maintenance of self-defeating eating. There may be further relationships between weight, shape, dietary concerns, hypnotizability, dissociative capacity, and fantasy proneness that are not fully understood (Hutchinson-Phillips, Gow, et al., 2007). A study of 102 female college students (mean age 21) completed the Eating Attitudes Test and the Goldfarb Fear-of-Fat Scale and were assessed for hypnotizability on the Harvard Group Scale of Hypnotic Susceptibility (Groth-Marnat & Schumaker, 1990). The results indicated that level of hypnotizability was related to attitudes toward food intake and the fear of becoming overweight, and support the thesis that hypnotizability may be one of a variety of predisposing factors in the development and maintenance of extreme attitudes toward eating and weight regulation.

One thing to consider is that the approach to all forms of disordered eating should not be the same. For example, patients suffering from bulimia have been found to be significantly more hypnotizable than control subjects ($p < .003$; Covino, Jimerson, et al., 1994). Not surprisingly, they have also scored higher on self-report scales of dissociative experiences ($p < .02$). These results are consistent with previous reports on hospitalized patients and college students and suggest that

psychological factors associated with hypnotizability might play a role in the etiology and treatment of bulimia nervosa (Kranhold, Baumann, et al., 1992). In that regard, a psychotherapeutic regimen that includes hypnotic exploration and training in self-hypnosis to promote self-control would be recommended. Chapter 32 outlines a comprehensive approach to weight control and reduction.

DENTISTRY

Hypnosis has long been used to advantage in dentistry as (1) an adjunct to dental procedures and in the management of dental phobia (Lu, 1994; Rustvold, 1994; Wilks, 1994; Hammarstrand, Berggren, et al., 1995; Moore, Abrahamsen, et al., 1996; Peretz, 1996; Robb & Crothers, 1996; Shaw & Niven, 1996; Shaw & Welbury, 1996; Kroll, 1962; Seidner, 1967; Gall, 1969; Smith, 1969; McAmmond, Davidson, et al., 1971; Newman, 1973; 1974; Benson, 1974, 1975; Lucas, 1975; Schey, 1976; Weyandt, 1976; Kevesater, 1977; Kisby, 1977, 1978; Romanson & Clark, 1981; Fassbind, 1983; Reis e Almeida, 1983; Katcher, Segal, et al., 1984; Smith, 1986; Forgione, 1988; Schmierer & Schmierer, 1990; Moore, Brodsgaard, et al., 2002; Gaspar, Linninger, et al., 2003); (2) an analgesic (or adjuvant to analgesic) for minor dental procedures (Herod, 1995; Enqvist, Bjorklund, et al., 1997); (3) the sole method of analgesia for patients with a history of hypersensitivity to local anesthetic agents (Kleinhauz & Eli, 1993); and (4) for the treatment of associated painful conditions such as temporomandibular dysfunction (Golan, 1989; Oakley, McCreary, et al., 1994; Simon & Lewis, 2000) and bruxism (LaCrosse, 1994).

It has been helpful for periodontal disease (Wood & Zadeh, 1999), promotion of routine flossing (Kelly, McKinty, et al., 1988), excessive gagging (Morse, Hancock, et al., 1984), placement of dental implants (Gheorghiu & Orleanu, 1982), dental extractions (McCay, 1963; Lucas, 1965), and psychogenic oral pain (Golan, 1997).

HYPNOSIS IN PEDIATRIC CARE

All children are highly hypnotizable, and hypnotic interventions can be very useful in the care of the pediatric patient. Several authors have also reported on the usefulness of hypnotic interventions in a variety of pediatric problems (Dikel & Olness, 1980; Olness, 1981; Olness & MacDonald, 1981; Place, 1984; Lambert, 1996, 1999).

Various researchers have described their experiences treating a large number of adolescents and children ($n = 505$) with hypnosis (Kohen, Olness, et al., 1984; Kohen, 1986, 1987; Kohen & Wynne, 1997). The problems treated included enuresis, acute pain, chronic pain, asthma, habit disorders, obesity, encopresis, and anxiety. In this population, half of the sample (51%) achieved complete resolution of the presenting symptom after hypnotic intervention (Kohen, Olness, et al., 1984). In addition, another third (32%) achieved significant improvement. Hypnotic interventions were used with

children as young as 3 years old. Impressively, their results suggest that maximum benefit was achieved after only four visits.

Similarly, others have described the usefulness of hypnosis in the management of side effects associated with the treatment of cancer in pediatric patients such as nausea and vomiting, fear, and discomfort (Olness, 1981; Gardner & Lubman, 1982; Hall, 1982; Hilgard & LeBaron, 1982; Redd, Andresen, et al., 1982; Zeltzer & LeBaron, 1982; Kellerman, Zeltzer, et al., 1983; Zeltzer, Kellerman, et al., 1983; Kaye, 1984; Hockenberry & Cotanch, 1985; Katz, Kellerman, et al., 1987; Fortuin, 1988; Hageman-Wenselaar, 1988; Feldman & Salzberg, 1990; Zeltzer, Dolgin, et al., 1991; Morrow & Hickok, 1993; Ellen & Burrows, 1994; Ellis & Spanos, 1994; Jacknow, Tschann, et al., 1994; Genuis, 1995; Keller, 1995; Spiegel & Moore, 1997; Steggles, Damore-Petingola, et al., 1997; Bertoni, Bonardi, et al., 1999; Lioffi & Hatira, 1999; Lynch, 1999; Marchioro, Azzarello, et al., 2000; Wild & Espie, 2004; Richardson, Smith, et al., 2006). In pediatric cancer patients, hypnosis has been demonstrated to be useful as adjunct in invasive procedures, such as bone marrow aspirations and lumbar punctures (Hageman-Wenselaar, 1988; Ellis & Spanos, 1994; Rape & Bush, 1994; Lioffi & Hatira, 1999). The use of hypnosis in these cases lowered pediatric morbidity by removing exposure to sedative hypnotic and anxiolytic agents. It also diminished later anxiety to multiple invasive examinations common in patients suffering from hematologic and malignant diseases. The use of imagery and hypnotic techniques with suggestions for a favorable postoperative course has been associated with significantly lower postoperative pain ratings and shorter hospital stays (Lambert, 1996, 1999).

Several randomized controlled studies on behavioral intervention for chemotherapy in children with cancer have found that children in the hypnosis group had the greatest reduction of both anticipatory and post-chemotherapy symptoms compared to controls (Zeltzer & LeBaron, 1982; Zeltzer, Kellerman, et al., 1983; Zeltzer, LeBaron, et al., 1984; Zeltzer, Dolgin, et al., 1991; Steggles, Damore-Petingola, et al., 1997). The cognitive distraction/relaxation intervention appeared to have a maintenance effect in which symptoms did not get much worse or much better, while children in the control group had symptoms that consistently became worse over time.

A prospective randomized and controlled single-blind trial of pediatric patients among cancer patients receiving chemotherapy found that those randomized to the hypnosis group used less PRN antiemetic medication than control subjects ($p < .02$). In addition, the hypnosis group experienced less anticipatory nausea than the control group at 1 to 2 month after diagnosis ($p < .02$; Jacknow, Tschann, et al., 1994).

Hypnosis has been used successfully in children to significantly reduce the pain associated with invasive procedures (Hilgard & LeBaron, 1982; Rape & Bush, 1994). In fact, hypnosis was superior to an attentional control condition for analgesia among children undergoing painful procedures (Zeltzer & LeBaron, 1982). A prospective randomized study assigned 44 children scheduled for an upcoming voiding cystourethrography (VCUG) to receive hypnosis ($n = 21$) or

routine care ($n = 23$) while undergoing the procedure (Butler, Symons, et al., 2005). Eligible children and parents met with the research assistant (RA) before the day of the scheduled procedure for an initial assessment. Immediately after this assessment, those who were randomized to the hypnosis condition were given a 1-hour training session by a trained therapist in self-hypnotic visual imagery. Parents and children were instructed to practice using the imaginative self-hypnosis procedure several times a day in preparation for the upcoming procedure. The therapist was also present during the procedure to conduct similar exercises with the child. Results indicate significant benefits for the hypnosis group compared with the routine care group in the following 4 areas: (1) parents of children in the hypnosis group compared with those in the routine care group reported that the procedure was significantly less traumatic for their children compared with their previous VCUG procedure; (2) observational ratings of typical distress levels during the procedure were significantly lower for children in the hypnosis condition compared with those in the routine care condition; (3) medical staff reported a significant difference between groups in the overall difficulty of conducting the procedure, with less difficulty reported for the hypnosis group; and (4) total procedural time was significantly shorter—by almost 14 minutes—for the hypnosis group compared with the routine care group. Moderate to large effect sizes were obtained on each of these four outcomes.

Among 75 children with urological diseases (i.e., in patients with total epispadias, exstrophy, and trauma of the urinary bladder), postoperative hypnotherapy helped in training and restoration of micturition, as a result of which a second operative intervention was not needed (Shulman, 1995).

Because children are highly hypnotizable and are easily absorbed in images, the main focus for children undergoing painful procedures is on imagery rather than relaxation. Images can be as simple as suggesting that they are playing an imaginary baseball game, picturing themselves going to another room in the house, or imagining themselves watching a favorite cartoon or television show. This enables them to restructure their experience of what is going on and dissociate themselves psychologically from pain and fear of the procedure.

Hypnosis has been long reported as a useful tool in the management of asthma and dyspnea in children (Aronoff, Aronoff, et al., 1975; Kohen, Olness, et al., 1984; Kohen, 1987; Kohen and Wynne, 1997; Anbar, 2000, 2001, 2003). Like their adult counterparts, asthmatic children treated with hypnosis reported a significant (50%) improvement in their symptoms (Aronoff, Aronoff, et al., 1975). Others have described that 20% of asthma patients (children between the ages of 2 and 5 years) experienced “complete symptom resolution” and an additional 33% experienced a “considerable improvement in symptoms” after hypnotic treatment and training (Collison, 1975; Kohen, Olness, et al., 1984; Gluzman & Ziselson, 1987; Kohen, 1987; Kohen & Wynne, 1997). Yet others reported that hypnosis use ($n = 303$ children) was associated with improvement in 80% of patients with persistent asthma, chest pain/pressure, habit cough, hyperventilation, shortness of breath, sighing, and vocal

cord dysfunction (Anbar, 2002). No patients’ symptoms worsened, and no new symptoms emerged following hypnotherapy.

Several authors have described the utility of hypnosis training in the management of chronic dyspnea (Anbar, 2001). On a small retrospective study, 16 patients were taught to use self-hypnosis in one session. A second session was provided to three patients within 2 months. Thirteen of 16 subjects reported their dyspnea and any associated symptoms had resolved within one month of their final hypnosis instruction session. Eleven believed that resolution of their dyspnea was attributable to hypnosis, because their symptoms cleared immediately after they received hypnosis instruction or with its regular use. The remaining three reported that their dyspnea had improved. Patients were followed for a mean 9 months (range: 2–15 months) after their final hypnosis session. Ten of the 16 regularly used self-hypnosis at home for at least one month after the final hypnosis session. There was no recurrence of dyspnea, associated symptoms, or onset of new symptoms in patients in whom the dyspnea resolved. Under supervision of the pediatric pulmonologist, two of seven patients discontinued their chronic antiinflammatory therapy when they became asymptomatic after hypnosis.

Others have reported on the use of hypnosis in children with cystic fibrosis (Belsky & Khanna, 1994). The experimental group demonstrated significant changes in locus of control, health locus of control, self-concept, and trait anxiety, and significantly increased peak expiratory flow rates using an air flow meter immediately after self-hypnosis when compared to the control group.

Hypnosis has also been used for the treatment of nocturnal enuresis (Krupnova, 1985; Banerjee, Srivastav, et al., 1993). When compared with imipramine, hypnotic suggestions for the management of functional nocturnal enuresis had equally positive response (i.e., all dry beds, with 76% on imipramine vs. 72% in the hypnosis group). Nevertheless, during a 9-month follow-up, 68% of patients in the hypnosis group maintained a positive response whereas only 24% of the imipramine group did (Banerjee, Srivastav, et al., 1993).

Hypnosis has been reported to be successful with various childhood dermatological disorders such as eczema (Mantle, 1999) and psoriasis (Winchell & Watts, 1988). There have been reports of a 95% “immediate improvement” of severe resistant atopic dermatitis with the use of hypnosis, which was maintained for up to 18 months after treatment (Stewart & Thomas, 1995).

The use of hypnosis for the treatment of warts in children has long been established (Mc, 1949; Wendel, 1959; Seeman, 1960; Dudek, 1967; Leidman Iu, 1968, 1973; Tasini & Hackett, 1977; Wilkening, 1978; Noll, 1988). An intriguing case reported the use of hypnosis for the treatment a 7-year-old female with 82 common warts. The lesions had been present for 12–18 months and were refractory to routine dermatologic treatment. Hypnotic suggestions were given for the facial warts to disappear before warts from the rest of the body. After 2 weeks, eight of 16 facial warts were gone, with no other changes. After three additional biweekly sessions, all 82 warts were gone (Noll, 1988).

A prospective randomized controlled study found that children could be trained in self-hypnosis with specific suggestions for control of salivary IgA ($p < .01$), although there were no significant changes in salivary IgG (Olness, Culbert, et al., 1989). Several papers have reported on beneficial hypnosis treatment in the management of other medical disorders in pediatric patients including headaches management (Kuttner, 1993) and migraine (Olness & MacDonald, 1981), functional abdominal pain, and irritable bowel syndrome (Vlieger, Menko-Frankenhuis, et al., 2007).

FURTHER INFORMATION, TRAINING, CERTIFICATION, AND REFERRALS

The two factors to consider are (1) does your patient suffer from a condition amenable to hypnotic intervention, and (2) is your patient hypnotizable? If the answer to both questions is positive, the next question is, should you use hypnosis? If you are trained in the use of hypnosis within the context of psychotherapy or your psychosomatic training, you are on your way to assisting your patients to develop mastery over their symptoms by providing them with a valuable tool to explore and control what they experience.

If, on the other hand, you are not skilled in the use of hypnotic skills you may need to refer the patient to a practitioner or therapist who is. And you are not alone. Unfortunately, the number of clinicians and psychiatrists well trained in hypnosis is very small. In a study of 400 physicians in central Texas, the majority of physicians (79%) and residents (67%) had received no prior training, and even fewer had experienced hypnosis themselves (Elkins & Wall, 1996). This study highlighted the need for patient and physician education, given the high rate of endorsed misconceptions about hypnosis held by patients and medical practitioners alike. On the other hand, it was somewhat encouraging to find that 85% of medical practitioners expressed interest in learning more about hypnosis.

Unfortunately, hypnosis training is widely variable within psychiatric residency programs and is dependent on the faculty and training director interests within each individual training program (Walling & Baker, 1996; Walling, Baker, et al., 1996). In a nationwide survey of all psychiatric residency directors in the United States, 63% of responding program directors report offering either required or elective courses in hypnosis. Yet, of the programs offering hypnosis training, the mean number of hours provided was 8 over the course during the 4-year residency program. This would suggest that many psychiatrists have only rudimentary understanding and training, and a very limited exposure to hypnosis during their formative years. The limited training is not standardized and likely inadequate to allow psychiatric trainees to be proficient or comfortable in the use of hypnosis in their clinical practice.

Despite the limited availability during residency, psychiatric residents seem to be interested in the topic. Studies show that 50% of interviewed psychiatric residents have sought additional hypnotherapy training beyond the standard

lectures and seminars offered during by their residency programs, and almost 30% had attended external hypnosis workshops or presentations.

In the U.S. there are two reputable professional organizations providing training and fostering research in clinical hypnosis: the Society for Clinical and Experimental Hypnosis, which emphasizes research in the field, and the American Society for Clinical Hypnosis. Each of these organizations holds annual scientific meetings, publishes a journal, and offers well-organized regional and national workshops providing basic training seminars and advanced training courses. ASCH offers a board examination and certification in clinical hypnosis. Faculty members from Stanford University offer basic and advanced workshops in clinical hypnosis during the annual meeting of the American Psychiatric Association and the Academy of Psychosomatic Medicine. For more information, contact Jose Maldonado, MD, course director (650-725-5599), or call one of the professional organizations listed. There are many similar professional organizations in Europe and throughout the world, including the International Society for Hypnosis, the European Society of Hypnosis, the British Society of Clinical Hypnosis, and the Australian Society of Hypnosis.

There are many excellent books and chapters devoted to providing practitioners basic training in clinical hypnotic techniques, and specific instructions and hypnotic suggestions (Erickson, 1967; Crasilneck & Hall, 1985; Spiegel & Spiegel, 1987; Watkins, 1987; Hammond, 1990; Maldonado & Spiegel, 1996, 2002, 2008; Spiegel & Spiegel, 2004). Despite how comprehensive these may be, they are no substitute for hands-on training and professional supervision.

SUMMARY

Hypnosis is a natural human trait that can be measured, taught, and mastered. The ability to use this hypnotic capacity varies throughout the population. This natural capacity to enter hypnosis may be a liability in certain cases, such as phobic and conversion disorders, pain syndromes, and certain psychosomatic and medical conditions. Nevertheless, hypnosis may also be used during the medical therapeutic process to help patients deal with a number of psychological, psychosomatic, and medical conditions. Patients may learn this technique during brief sessions and continue to derive long-lasting benefits through the ongoing use of self-hypnosis exercises.

Hypnosis may enhance other therapeutic processes, such as physical therapy, that can speed recovery and response to treatment. Thus, aided by the use of hypnosis patients may gain a different perspective on the relationship between psychological and physical states. Physicians using hypnosis as adjuncts to their primary treatment modalities are encouraged to train their patients in the use of self-hypnosis. This facilitates an enhanced sense of mastery and independence in patients. It allows patients to use their hypnotic capacity, rather than be used by it.

CLINICAL PEARLS

- The hypnotic capacity or hypnotizability of a given subject (i.e., the degree of natural ability to enter a trance state) will determine the degree of assistance required to enter trance states.
- High hypnotic capacity may actually become a liability to patients who are unaware of their hypnotic capacity or of their unconscious use of this mechanism, as is the case of individuals suffering from a dissociative and somatoform disorder, or placebo (i.e., negative placebo) effect.
- The hypnotic experience may be understood as involving three interconnecting factors: absorption, dissociation, and suggestibility.
 - **Absorption** refers to the tendency to engage in self-altering and highly focused attention with complete immersion in a central experience at the expense of contextual orientation (Hilgard, 1970; Tellegen & Atkinson, 1974; Tellegen, 1981).
 - **Dissociation** refers to the ability to separate mental processes so they seem to occur independently from each other.
 - **Suggestibility** implies the ability to influence someone's beliefs or behaviors by suggestion.
- Formal assessments of hypnotizability allow physicians to objectively determine the patient's level of hypnotic capacity.
- Hypnotizability is a rather stable trait.
- The Hypnotic Induction Profile (HIP) is a brief (5–7 minutes), standardized assessment designed to measure patients' natural ability to tap into and use their hypnotic capacity (Spiegel & Spiegel, 1987).
- For better or worse, highly hypnotizable individuals can enter trance states with ease and, on occasion, without even being fully aware of it. Thus it is important for physicians to know that some patients may experience trance states even without formal induction.
- A common technique is to have asthmatic patients enter a state of self-hypnosis and imagine that they are somewhere where they naturally breathe easily, such as breathing cool ocean spray (Spiegel & Spiegel, 1987).
- Most patients who use hypnoanalgesia can still feel the pain but may be unable to distinguish between the signal of pain and the discomfort caused by the signal. Thus, patients are taught not to fight but to transform painful signals into less uncomfortable ones.
- Regardless of any specific induction or metaphor use, there are four specific steps in the use of hypnosis that can make psychotherapy for pain management briefer, more goal-oriented, and efficient:
 - the assessment of hypnotizability;
 - the induction of hypnoanalgesia and development of individualized pain coping strategies;
 - the use of direct suggestion, cognitive reframing, hypnotic metaphors, and pain relief imagery; and
 - brief psychodynamic reprocessing, during the trance state, of emotional factors in the patient's experience of chronic pain. (Eimer, 2000).
- In the specific context of hypnosis, the midcingulate cortex appears to have a critical role in the modulation of a large cortical and subcortical network underlying its influence on sensory, affective, cognitive, and behavioral aspects of nociception.
- It is unlikely that opioid neurotransmission underlies the midcingulate activation or the mechanism of hypnosis.
- The development of "neurosignatures of pain" can influence subsequent pain experiences (Melzack, 1991, 1993; Coderre, Katz, et al., 1993) and may be expanded in size and easily reactivated (Melzack, 1991, 1993; Elbert, Flor, et al., 1994). Therefore, hypnosis and other psychological interventions need to be introduced early, before the development of chronic pain, as adjuncts in medical treatments (Crawford, Knebel, et al., 1998).
- Individuals suffering from PTSD usually score in the high hypnotizability range (Stutman & Bliss, 1985; Spiegel, Hunt, et al., 1988; Cardena, Maldonado, et al., 2008).
- The major categories of symptoms in PTSD are similar to the components of the hypnotic process (American Psychiatric Association, 1994; Maldonado & Spiegel, 1994, 2007; Maldonado, Page, et al., 2002)
- For therapy to be effective in cases of traumatic stress, cognitive restructuring, emotional expression, and relationship management must accompany the patient's controlled reexperiencing of the traumatic events.
- Many people enter a dissociated state during physical trauma (Spiegel & Cardena, 1991; Cardena & Spiegel, 1993; van der Kolk, Hostetler, et al., 1994; van der Kolk & Fisler, 1995; Butler, Duran, et al., 1996; Cardena, Maldonado, et al., 2008).
- Clinicians treating patients with conversion symptoms must pay attention to verbal and nonverbal cues given to the patient.
- It is often helpful to have patients project the images of the traumatic event on an imaginary screen which gives them some sense of distance from the event.
- As first suggested by Janet (1907), the symptoms of conversion disorder can be understood in part as reflecting the presence of uncontrolled hypnotic states.
- Even though most patients are not aware of it, highly hypnotizable individuals have an unusual capacity to control (albeit unconsciously) somatic functions.

- In cases of conversion symptoms and psychosomatic processes, hypnosis is used not to treat but to allow patients to control the effects on the body of their emotional stress and mind states. It is not advised to force a cure on a patient.
- Hypnosis may first assist in confirming the diagnosis of conversion disorder. Second, it may be therapeutic—part of a comprehensive treatment plan that includes therapy to help the patient develop more mature and adaptive defense mechanisms (Maldonado, 2007).
- Educate professionals caring for the patient to make certain they do not give the patient the message that the problem is “all in their head.”
- Even though the word *hypnosis* literally means sleep, hypnosis is not a form of sleep and it is not related to sleep. In fact, if you fall asleep, you come out of trance.
- The ultimate purpose of hypnosis for weight management is to restructure the eating experience so that it becomes an exercise about learning to eat with respect for one’s body. The emphasis is on what the patient is *for*, rather than *against*.

DISCLOSURE STATEMENT

Dr. Maldonado has no actual or potential conflict of interest to disclose, including any financial, personal or other relationships with other people or organizations within twelve years of the submission of this work that could inappropriately influence, or be perceived to influence the concept discussed in this chapter.

HYPNOTIC INDUCTION PROFILE PROTOCOL

UP-GAZE Get as comfortable as possible with your arms resting on the arms of the chair and both feet up. Now look toward me. As you hold your head in that position, look up toward your eyebrows-now toward the top of your head.

UPGAZE: 0 - 1 - 2 - 3 - 4

EYEROLL As you continue to look upward, close your eyelids slowly. That's right close, close, close...

ROLL: 0 - 1 - 2 - 3 - 4 SOUINT: 0 - 1 - 2 - 3 - 4

LEFT ARM LEVITATION Keep your eyelids closed and continue to look upward. Take a deep breath, hold.... Now, exhale, let your eyes relax while keeping the lids closed, and let your body float. Imagine a feeling of floating, floating right down through the chair There will be something pleasant and welcome about this sensation of floating. As you concentrate on this floating, I am going to concentrate on your left arm and hand. Touch arm and hand. In a while I am going to stroke the middle finger of your left hand.

Lift hand slightly and put it down again. Leave your right hand resting lightly on person's left hand.

After I do, you will develop movement sensations in that finger. Then the movements will spread, causing your left hand to feel light and buoyant, and you will let it float upward. Ready? Stroke finger and arm.

First one finger, then another. As these restless movements develop, your hand becomes light and buoyant. your elbow bends, your forearm floats into an upright position. You may get a sensation of a magnetic pull on the back of your hand.

<i>If happens right away</i>	4
<i>If no response in 5 seconds. This is an exercise in your imagination.</i>	
Just imagine your hand to be a big, buoyant balloon and let it float upwards. <i>If hand goes up now score:</i>	3
<i>If no response in 5 seconds. I'll help you get it Started. Encircle wrist, boost.</i>	
Let your hand be a balloon. Just let it go. <i>If person takes over, score:</i>	2
<i>If person does not takes over, continue: You have the power to let it float upward.</i>	
<i>If person now takes over, let go and say: That's right. score:</i>	1
<i>If person does not take over, continue: Help it along. Just put it up there. score:</i>	0
<i>Let go. If arm comes down, this is the end of the test.</i>	
<i>This is rare. Can say: This is not for everyone. Skip to treatment session.</i>	

Now I'm going to position your arm in this manner so ... and let it remain in this upright position. (*arm is positioned with the elbow comfortably supported on the arm rest of the chair and the forearm is in an upright position.*) In fact, it will remain in that position even after I give you the signal for your eyes to open. When your eyes are open, even when I put your hand down, it will float right back up to where it is now. You will find something amusing about this sensation. Later, when I touch your left elbow, your usual sensation and control will return.

Now I am going to count backwards. At two, your eyes will again roll upward with your eyelids closed. At one, let them open very slowly.

Ready ... three...two, with your eyelids closed, now roll up your eyes, and one, let them open very slowly.

All right, stay in this position and describe what physical sensations you are aware of now in your left arm and hand. (*let them describe*)

Is it comfortable?	YES	NO
Are you aware of any tingling sensations?	YES	NO

DISSOCIATION Does your left hand feel as if it is not as much a part of your body as your right hand?

YES	2
YES, A LITTLE BIT	1
No. Does your left hand feel as connected to the wrist as your right hand feels connected to the wrist? Are they exactly the same or is there a difference?	
THERE IS A DIFFERENCE	1
NO DIFFERENCE	

0

LEVITATION - POST INDUCTION (each reinforcement is followed by 5 second pause).

Now note this. <i>Gently lower left hand & wait to see if hand floats upward. If so, score:</i>	4
Now turn your head, look at your left hand, and watch what is going to happen.	3
While concentrating on your left hand, imagine it to be a huge, buoyant balloon.	2
Now, while imagining it to be a balloon permit it to act out as if it were a balloon.	
That's right, be 'big' about it.	1
This is your chance to be a method actor or a ballet dancer. Think of your left hand as a balloon or as the arm of a ballet dancer and permit it to act as if it were a balloon. That's right, just put it up there, just the way a ballet dancer would.	
If necessary, fake it, pretend.	0

CONTROL DIFFERENTIAL While it remains in the upright position, by way of comparison, raise your right hand. Now put your right arm down. Are you aware of a difference in the sensation in your right arm going up, compared to your left? For example, does one arm feel heavier than the other? Are you aware of a relative difference in your sense of control in one arm compared to the other as it goes up?
On a more or less basis, are you aware of any relative difference in your sense of control in one arm compared to the other as it goes up?

YES. In which arm do you feel more. control? <i>If difference is reported</i>	2
<i>If spontaneously reports "a little bit"</i>	1
NO. Circle the '0' and then repeat. Let's try it again. <i>Put person's arm down</i>	0
Now again. Look at your left hand. Imagine it to be a huge, buoyant balloon. Just like an actor or an athlete. Now raise your right hand up and put your right arm down. Now this time are you aware of any relative difference in control in one arm compared to the other as it goes up?	
If YES, in which arm do you feel more control?	
<i>If difference is reported now, draw square around the '1'</i>	1
<i>If still NO, draw a square around '0'</i>	0

CUT-OFF Now note this.

Cup person's elbow with your right hand and lower person's arm. Touch person's left hand give direction to "make a fist. Move your hand up to touch elbow and finally bring your hand down. patient's arm, ending by firmly pressing patient's hand.)

Before there was a difference in control between the two forearms. Is that difference still there or is it going away?

YES	2
NO (or) <i>It's beginning to go away: 'I still have more control in the right arm,' repeat "cut off" described above.</i>	
Make a fist a few times. That's right. Open your fist and now put your hand down. Shake both hands a few times and tell me when you feel that your control is equal.	
<i>If control becomes equal</i>	1
<i>If control is still not equal, repeat until control is equal, and score:</i>	0

AMNESIA TO CUT OFF You see that relative difference in control that was in your arms is gone. Do you have any idea why? Is there anything I said or did that might account for it?

If patient says 'NO' or says 'YES' and gives wrong answer score:	2
If patient mentions 'elbow' say: What about it? If patient can't remember elbow being touched, score:	1
If patient specifies "elbow touch" and being touched, ask: Are you inferring that I touched your elbow or do you remember whether or not I did?	
If "infers", score:	1
If "remembers", ask: How many times? If remembers one elbow touch, score:	1
If patient remembers two elbow touches, score:	0

FLOATING SENSATION When your arm went up before, did you feel a physical sensation that you can describe as a lightness, floating, or buoyancy in your left arm or hand? Were you aware of similar sensations in any other part of your body-such as your head, neck, chest, abdomen, thighs, legs, or all over--or just in your left hand or arm?

If floating in other parts of body in addition to left hand or arm	2
If floating in left hand and/or arm only	1

MIND–BODY MEDICINE

Gregory L. Fricchione

INTRODUCTION

The National Center for Complementary and Alternative Medicine defines mind–body medicine as an approach that “focuses on the interactions among the brain, mind, body and behavior, and on the powerful ways in which emotional, mental, social, spiritual, and behavioral factors can directly affect health” (NCCAM, 2007). Mind–body medicine may also be conceptualized as the scientifically based dimension of what was once named *complementary and alternative medicine* (CAM). In 2007 close to 40% of Americans were using CAM therapies and spending close to 34 billion dollars in out-of-pocket expenses to pay for them (Barnes, Bloom, & Nahin, 2008; Nahin, Barnes, Stussman, & Bloom, 2009). Mind–body therapies accounted for 17% of this CAM usage (Bertisch, Wee, Phillips, & McCarthy, 2009). However, mind–body medicine was never really “alternative” in the sense of the unresearched use of herbs, folk remedies, and rituals. Mind–body medicine uses the evidence-based effects of thoughts, beliefs, emotions, and behaviors to positively influence physical health.

The field of medicine may be thought of as having three component areas—medications, procedures, and self-care (Benson, 1975). This has been called the *three-legged stool* model. In this schema mind–body medicine may be conceptualized as the self-care leg, comprising information derived from the subspecialty of psychosomatic medicine. To promote healing it employs an array of heterogeneous, researched techniques including relaxation exercises, meditation, biofeedback, guided imagery, hypnosis, yoga, tai chi, qi gong, and autogenic training. In this chapter we will point out the common elements of these techniques and the core elements of the mind–body approach, which can all elicit the relaxation response (RR). The focus on a repetitive activity—such as breathing, or a phrase, word, or prayer—and disruption of the train of everyday thoughts and concerns are the two main features of eliciting the RR: a physiological state of decreased stress characterized by diminished heart rate, blood pressure, respiratory rate, and oxygen consumption, along with peripheral vasodilatation (Benson, 1975).

Mind–body medicine is often seen as a philosophical conception of healing and health as well as a group of techniques. Many techniques originated in ancient Eastern cultural traditions and may have a religious foundation based on a particular conceptualization of human life. However, even though

some people will feel attracted by the religious aspects they are not essential for therapeutic effect. Throughout this chapter we will attempt to show how recent research is providing evidence for the effectiveness of these treatments, establishing their scientific value and facilitating their integration into mainstream medicine. There is already enough evidence of the clinical efficacy of the mind–body techniques to make them viable options for patients who want to improve their self-care.

The approaches of mind–body medicine will be mainly complementary to current allopathic therapies, but for some conditions they may also be efficacious when used alone. These approaches reflect a unitary concept of mind–body integration and the more modern terms *integrative medicine* and *whole person medicine* focus attention on caring for the person interpenetrating with the organism. Within this framework mind–body medicine takes center stage as it stresses a multi-system integrative model that best comports with the organic unity that is the human being.

Perhaps mind–body medicine is best described in what Francis Peabody said to graduating medical students some 75 years ago:

“The good physician knows his patients through and through, and his knowledge is bought dearly. Time, sympathy and understanding must be lavishly dispensed, but the reward is to be found in that personal bond, which forms the greatest satisfaction of the practice of medicine. One of the essential qualities of the clinician is interest in humanity, for the secret of the caring of the patient is in the caring for the patient.” (Peabody, 1927)

It is essential for the physician to be interested in and to form a bond with the whole person as patient if true caring is to take place.

STRESS PHYSIOLOGY

DEFINITION OF STRESS AND DISTRESS

Being alive involves *stress* as a stimulus; stress requires biological, psychological, and social adaptations. *Eustress* can be thought of as the normal physiological workings of the living organism. It consists of homeostatic mechanisms called

eustasis, which can be visualized as a U-shaped curve with suboptimal responsivity on each side of the curve leading to poor adaptation (Chrousos, 2009). *Pathogenic stress* or *distress* occurs when homeostasis is threatened, or perceived to be so, in the setting of overwhelming or sustained external and internal stressors.

Stress as *distress* can thus be defined as a state of disharmony or of threatened homeostasis (Chrousos & Gold, 1992). It refers to a disruption of the dynamic equilibrium among the person's physiological, psychological, and social dimensions as a result of the perceived presence of an external or internal threat. Alterations in the environment may provoke a physiological response mediated by several interconnected physiological networks constituting the so-called *stress response system*. The stress response system is composed of elements of the central nervous system (CNS), the hypothalamus-pituitary-adrenal (HPA) axis, and the immune system. Stressors, the stress system, and the stress response are the three key elements in this process.

Distress is accompanied by overactivity of the stress response system mediated primarily by hypothalamic corticotrophin-releasing hormone (CRH), originally known as *corticotrophin releasing factor* (CRF), and locus coeruleus A1-A2 derived norepinephrine (NE). Walter Cannon in the early 1900s did groundbreaking work on one axis of the stress response system, the autonomic nervous system (ANS; Cannon, 1929). He focused on the sympathetic nervous system (SNS) and its production of "the flight–fight response" and was first to use the term *homeostasis*. Hans Selye, another 20th century stress researcher, focused on the HPA axis (Selye, 1946).

AUTONOMIC NERVOUS SYSTEM

The CNS and the peripheral ANS have sympathetic and parasympathetic components. All these systems constitute a complex matrix with overlapping boundaries under the ultimate top-down control of the brain. This interconnected system maintains homeostasis by modulating different bodily functions and controlling the administration, distribution, and use of energy. In this way the brain adapts the level of functioning of different organs to global bodily demands under each specific circumstance. It is constantly functioning at varying levels of intensity, autoregulated by negative feedback and feed-forward mechanisms. It can also be overactivated by persistent or overwhelming stressors that make adaptation difficult. It is at this point that we talk about *distress*, which can be acute in the face of an enormous stressor or chronic in the setting of persistent unrelenting ones.

When the stress response is activated, some functions can be stimulated, such as metabolism, cardiac output, vascular tone, respiration, and muscle contraction. Other functions can be suppressed, such as the excretory system and gastrointestinal and reproductive activity (Tsigos & Chrousos, 2002). The acute stress response is characterized by an increased heart rate, increased breathing rate, increased metabolism, increased oxygen consumption, and increased beta and reduced alpha brain wave activity. Chronic stress may lead to hypertension, depression, and prolonged inflammatory response.

The efferent pathways from the central nucleus of the amygdala travel to a multiplicity of critical brain structures, including the parabrachial nucleus (resulting in dyspnea and hyperventilation), the dorsomedial nucleus of the vagus nerve and nucleus ambiguus (activating the parasympathetic nervous system/PNS), and the lateral hypothalamus (resulting in SNS activation). Through reciprocal neuronal pathways connecting the amygdala to the medial prefrontal cortex, the specific cognitive experience of the specific anxiety disorder will differ, although fear symptoms may overlap. During panic attacks the fear is of imminent death; in social phobia, the fear is of embarrassment; in posttraumatic stress disorder, the traumatic memory is remembered or reexperienced; in obsessive compulsive disorder, obsessional ideas recur and intrude; and in generalized anxiety disorder, anxiety is "free-floating" (i.e., not conditioned to specific situations or triggers).

The CNS as stated above plays an essential role in the regulation of the stress response. The ANS controls a wide array of functions—cardiovascular, respiratory, gastrointestinal, renal, endocrine, immune, and others—that are affected under conditions of stress (Chrousos, 2007). While the SNS activates the stress response, the PNS can dampen this effect and restore balance in the autonomic response.

The SNS efferent output flows down the intermediolateral cell column in preganglionic fibers to synapse in a bilateral chain of sympathetic ganglia from whence postganglionic mostly NE fibers proceed to enervate vascular smooth muscle, the heart, the gut, the kidney and other organs. The SNS through its enervation of the adrenal medulla has a humoral component resulting in the secretion of circulating epinephrine. The great vagus nerve is the major PNS cholinergic outflow tract. The ANS also contains SNS and PNS subdivisions with neuronal subpopulations that co-locate special peptide transmitters. CRH, Neuropeptide Y (NPY), somatostatin, and galanin are co-localized in NE neurons of this type. Vasoactive intestinal peptide, substance P, and calcitonin gene-related peptide co-localize within cholinergic neurons (Chrousos, 2007).

HYPOTHALAMIC- PITUITARY-ADRENAL AXIS

Activation of the HPA axis results in secretion of glucocorticoids, hormones that act at many levels to modulate the body's energy resources and restore the body to homeostasis after acute disruption (Herman et al., 2003). The medial parvocellular division of the paraventricular hypothalamic nucleus (PVN) houses CRH neurons that release the CRH required for adrenocorticotrophin (ACTH) secretion from the pituitary, along with arginine vasopressin (AVP). CRH is also expressed outside of the hypothalamus in the hippocampus, amygdala, nucleus accumbens, bed nucleus of the stria terminalis (BNST), thalamus, hypothalamus, cerebral cortex cerebellum, and hind-brain (Denver, 2009). There are at least two G-protein-coupled receptors (CRF 1 and CRF 2) that mediate CRH functioning. CRH binds to CRF 1 receptors in the pituitary, where signal transduction involving protein kinase A (PKA) and protein kinase C (PKC) leads to ACTH synthesis and secretion. ACTH moves through the systemic circulation, arriving at the adrenal cortex where it promotes synthesis and secretion of

corticosterones like cortisol in the human. The CRH neurons are regulated by direct somatic, visceral, and humoral sensory afferents relayed from nuclei, like the nucleus of the solitary tract (NTS), the raphe, the subfornical organ and lamina terminalis, other parts of the hypothalamus, the BNST, and the thalamus. These “reactive” stimuli are generally excitatory. At the same time, the paralimbic medial prefrontal cortex and limbic forebrain structures such as the hippocampus, amygdala, and lateral septum, along with parts of the hypothalamus and thalamus, are thought to provide indirect “anticipatory” signals through projected connections to select brainstem, hypothalamic, and BNST regions that in turn enervate the PVN. It is thought that paralimbic and limbic areas that service “anticipatory” voluntary stress responses, when integrated with “reactive” reflexive stress responses, can modulate the HPA axis through tuning of the PVN CRH output.

Glucocorticoids can stimulate energy mobilization (glycogenolysis) in the liver, SNS-mediated vasoconstriction, proteolysis, and lipolysis; suppress innate immunity, reproductive function, and bone and muscle growth; and inhibit mood, leading to behavioral depression. This profile can become pathogenic if prolonged. Thus a premium is placed on multiple feedback control mechanisms to shut this response down.

The interaction of the ANS and HPA is shown in Box 17.1 and the modulation of the HPA stress response is outlined in Box 17.2 (Ulrich-Lai & Herman, 2009).

APPRAISAL

Cognitive and emotional appraisal of a stressor is accomplished as an amalgam by the brain (Lewis, 2005). A stressor is most distressing when it is perceived as such. Certain events or experiences are universally threatening, but there is a lot of room

Box 17.1 CNS REGULATION OF THE AUTONOMIC STRESS RESPONSE

SNS Activation: infralimbic cortex (IL), the central amygdala (CeA), locus coeruleus (LC) and the ventrolateral medulla (VLM)

PNS Activation: anterior bed nucleus of stria terminalis (aBST), prelimbic cortex (PL), dorsal motor nucleus of the vagus nerve (DMX), nucleus ambiguus (NA)

SNS and PNS Interactivity: nucleus of the solitary tract (NTS), paraventricular nucleus of the hypothalamus (PVN), dorsomedial hypothalamus (DMH),

Mediation: Sympathetic outflow to preganglionic SNS in the intermediolateral cell column occurs via direct innervation from the rostral VLM, LC and PVN, which are thought to initiate sympathetic responses. The NTS in turn receives direct input from neurons in the IL, the CeA, and the PVN. Other hypothalamic regions, most notably the DMH, modulate ANS activation through connections with the PVN (and possibly other descending pathways).

Parasympathetic outflow to postganglionic PNS occurs via effector organs mediated largely by descending outputs from the DMX and the NA and is under the direct influence of the PL, the PVN, and possibly other descending relays.

(Adapted from Ulrich-Lai and Herman, 2009, p. 400)

Box 17.2 MODULATION OF THE HPA AXIS

Modulation of the dorsal part of the medial parvocellular paraventricular nucleus of the hypothalamus (PVNmpd) is key to the HPA stress response and originates in several brain regions:

Stimulation:

1. The PVN receives direct noradrenergic, adrenergic and peptidergic innervation from the nucleus of the solitary tract (NTS).
2. The dorsomedial hypothalamus (dmDMH) and the arcuate nucleus (Arc) provide intrahypothalamic stress excitation.
3. The anterior part of the bed nucleus of the stria terminalis (BST), particularly the anteroventral nucleus of the BST, activates HPA axis stress responses.
4. The PVN also receives a stress-excitatory drive from the dorsal raphe, the tuberomammillary nucleus, the supramammillary nucleus, and the spinal cord, among others.

Inhibition (most of these inputs are GABAergic):

1. Activation of the PVNmpd is inhibited by numerous hypothalamic circuits, including the medial preoptic area (mPOA), the ventrolateral component of the dorsomedial hypothalamus (vlDMH), and local neurons in the peri-PVN region (pPVN), encompassing the PVN surround and the subparaventricular zone.
2. The posterior subregions of the BST provide a prominent forebrain inhibition of HPA responses.

(Adapted from Ulrich-Lai and Herman, 2009, p. 401)

for personification of particular threats. Depending on our appraisal, the mediators of the stress response may or may not emerge (Lazarus & Folkman, 1984). In fact, it has recently been shown that anticipatory cognitive appraisal is an important determinant of the cortisol stress response (Gaab, Rohleder, Nater, & Ehler, 2005). On the other hand, the brain also determines the physiological and behavioral responses to stress. The limbic system is a set of structures related to the control of emotional responses, behavior, and long-term memory. Key structures involved include the hippocampus and the amygdala. The amygdala, which is responsible for fear conditioning, serves as a tripwire for the stress response. It has connections with the prefrontal cortex (PFC), which is related to attention and motivation and can inhibit amygdalar tone, and with the hypothalamus, which regulates endocrine and autonomic system functioning. The hippocampus is a target of stress hormones, and chronically increased levels of cortisol induce a structural remodeling associated with selective atrophy and altered behavioral and physiological responses (McEwen, 1999).

THE VICIOUS CYCLE

The PFC regions (dorsolateral/ DLPFC, dorsomedial/ DMPFC, ventromedial/ vmPFC, and inferior/ iPFC) cooperate to help us plan for the future and manage higher order decision

making in concert with the anterior cingulate cortex (ACC). When we are not stressed, the PFC and its extensive connections to cortices and subcortices orchestrate behavior, thought, and emotion in a reasonable, goal-directed, and regulated way. Direct and indirect connections to the aminergic cell bodies in the brainstem allow the PFC to modulate NE flow from the locus coeruleus, dopamine (DA) from the ventral tegmentum, and serotonin from the nucleus raphe. When unstressed, there is the potential for optimal levels of amine releases in the PFC creating what is called a “delicious cycle.” This situation potentiates a top-down guidance of attention and thought (DLPFC), error monitoring and reality testing (DMPFC), inhibition of inappropriate actions (iPFC), and regulation of emotions (vmPFC; Arnsten, 2009).

When we are distressed, on the other hand, the amygdala stimulates the stress response pathways in the HPA axis and the brainstem with outpourings of cortisol, NE, and DA. Interaction of the basolateral nucleus (BLA) and central nucleus (CeA) of the amygdala with modulatory regions such as the medial prefrontal cortex (mPFC) is of importance here (Jovanovic & Kessler, 2010; Lanius et al., 2010).

The BLA is thought to compare conditioned stimulus inputs and unconditioned stimulus inputs regulating CeA activation of the hardwired fear and stress circuitry, leading to inhibition or activation of the fear response. Recent research has begun to determine the role of inhibitory neural circuitry in modulating the fear response at the cellular level (Herry et al., 2008; Likhtik et al., 2008; LeDoux & Gorman, 2001). Sensory inputs, as well as associative inputs from the hippocampus and cortex, project directly and indirectly to the CeA. “On” and “off” inhibitory circuits within the CeA are thought to differentially modulate fear output and extinction of fear. Additionally, direct projections from the infralimbic region of the mPFC activate inhibitory neurons in the intercalated region between the BLA and CeA, serving to inhibit, in a top-down manner, the stress-enhancing fear output of the CeA.

The neurochemical environment of highly elevated cortisol and NE may impair PFC top-down regulation and strengthen amygdala-driven bottom-up dynamics. On the other hand, optimal levels of catecholamine release enhance PFC regulation (Arnsten, 2009). In some disorders such as ADHD, an increase in noradrenergic tone back to effective levels is conceptualized to increase selective attention and thus enhance cognition. Stress-induced catecholamine excess impairs PFC higher order functioning in the context of activated amygdalar fear conditioning accompanied by bottom-up sensory hypervigilance and habituated motor responses as opposed to thoughtful, pliant approaches characteristic of top-down PFC control. Stress can thus set up an amygdala-centered “vicious cycle” (see Table 17.1).

IMMUNE SYSTEM

The immune system also plays an important role in the stress response, and it is well integrated in the psychoneuroendocrinology system. A variety of physical as well as psychosocial stressors stimulate the stress response systems, resulting in

Table 17.1 “DELICIOUS” VS. “VICIOUS” CYCLES

	DELICIOUS CYCLE	VICIOUS CYCLE
Anatomy:	DLPFC; rPFC; VMPFC; DMPFC → + LC; SN; VTA → optimal PFC	CeA→ ++++LC; SN; VTA → DLPFC; rPFC; VMPFC; DMPFC→ impaired PFC
Neurochemistry:	NE, DA, GLU, GABA	NE, DA, GLU, GABA
Physiology:	PFC can regulate its own transmitter input → optimal amine levels enhance PFC functioning including VMPFC control of CeA and nucleus accumbens	Distress activates CeA, which overactivates SNS, HPA and brainstem NE and DA→ impairs PFC regulation and strengthens amygdala function
Neurobehavior:	Attention, thought and action regulation (DLPFC) Inhibition of inappropriate motor response (rPFC) Appropriate emotional responses and habits (VMPFC) Error monitoring and reality testing (DMPFC) Thoughtful top-down control and selective attention through PFC	Impaired higher order PFC functions Elevated fear conditioning Reflexive, hot responder to sensory stimuli “Bottom-up” regulation

(Adapted from Arnsten, 2009, p. 411)

the output of CRH and catecholamines. It is of interest that postganglionic SNS fibers secrete CRH and that norepinephrine and epinephrine stimulate IL-6 release by immune cells and other peripheral cells through effects on beta-adrenergic receptors (Chrousos, 2009). Stress activates transcription factor NF-kB, which then produces proinflammatory cytokines (Bierhaus, Humpert, & Nawroth, 2004) This signaling molecule is an essential mediator at the blood–brain barrier that translates peripheral immune signals to the CNS. Catecholamines from SNS fibers increase NF-kB DNA nuclear binding in immune cells, including the macrophage predisposing to the inflammatory response syndrome (Miller, Maletic, & Raison, 2008).

During the inflammatory response syndrome, cytokine-induced activation of the monocyte enzyme indoleamine 2, 3 dioxygenase (IDO) leads to catabolism of L-tryptophan into L-kynurenine, which is then metabolized to quinolinic acid and kynurenic acid (Miller, 2009). These latter two metabolites are neuroactive and lead to cellular oxidative stress in

the hippocampus and other areas of the brain. A reduction in CNS stores of L-tryptophan can lead to depressive symptoms, while elevations in kynurenine metabolites can produce delirium and cognitive dysfunction. Interferon-alpha as part of an inflammatory response syndrome stimulates IDO and is thought to reduce serotonin function, deplete dopamine, and activate the dorsal ACC, resulting in vulnerability to depression, fatigue, psychomotor slowing, and anxiety and alarm.

Proinflammatory cytokines gain access to the circumventricular region of the brain directly through fenestrated endothelium zones (area postrema, subfornical organ, median eminence, pineal gland) and indirectly through cellular active transport, endothelial cell and perivascular macrophage activation, and peripheral vagal paraganglia stimulation that gets transmitted through the NTS and hypothalamus into the brain and proceeds to interact with neurotransmitter metabolism, neuroendocrine action, and neuroplasticity (Saper & Breder, 1994). This interaction may result in excitotoxicity, oxidative stress, aminergic changes, and trophic factor reductions.

Microglial cells are the primary central targets of proinflammatory signals originating in the periphery. Once activated, they release cytokines, chemokines, and reactive oxygen species, which then initiate a sequence of effects including activation of astroglial cells. The CNS inflammatory response syndrome is amplified as a result. Eventually IL-1, IL-6, and TNF-alpha and interferons stimulate IDO, which, as mentioned, breaks down tryptophan into kynurenine, thus reducing brain serotonin stores and increasing quinolinic acid—a potent NMDA agonist that can produce excitotoxicity and severe oxidative stress (Miller, 2009).

At the same time, oligodendrocytes are also sensitive to this cascade and especially to TNF-alpha, which can have a toxic effect leading to apoptosis and demyelination. Cytokines also stimulate CRH and the HPA axis. In acute stress situations cortisol elevation will, along with PNS vagal stimulation, tend to reduce NF-kB activation. This can shut down the inflammatory response if all goes well.

These aspects of the immune response's physiology hypothetically have relevance in the genesis or progression of multiple diseases. Distress has been related to proneness to viral infections, progression from HIV to AIDS, flares of multiple sclerosis, lupus, and arthritis, and risk of developing coronary heart disease and Alzheimer's disease (Cohen, Tyrrell, & Smith, 1991; Dong et al., 2004; Matthews & Gump, 2002; Mohr, Hart, Julian, Cox, & Pelletier, 2004; Sandberg et al., 2000; Cole et al., 2001).

Catecholamines and glucocorticoids both control the amplitude of immune response through negative feedback mechanisms. In physically threatening situations, inflammatory cytokines, mainly IL-6, stimulate the HPA axis, and the subsequent elevation of cortisol levels will eventually induce the suppression of the immune/inflammatory reaction. Simultaneously, the SNS causes systemic secretion of cytokines, which will eventually suppress the immune system (Stratakis & Chrousos, 1995). Thus, activation of the HPA axis helps to regulate the activity of the immune response

and, in the case of psychological distress, the immune system can be suppressed. However, paradoxically, under conditions of chronic stress such as caregiver burden, marital strife, or even perceived stress, there are increases in acute phase proteins (C-reactive protein- CRP), IL-6, and other inflammatory mediators that can become persistent, leading to a chronic inflammatory response syndrome (G. E. Miller et al., 2009). Maltreatment in early childhood is associated with elevated CRP 20 years later (Danese, Pariante, Caspi, Taylor, & Poulton, 2007). How does one reconcile this longstanding paradox in mind-body research?

PARADOX OF THE STRESS IMMUNE RESPONSE

If chronic stress enhances secretion of immunosuppressive glucocorticoids, why then do chronic stressors accentuate the vulnerability to inflammatory diseases? There is a current hypothesis that reconciles this apparent conflict (G. E. Miller et al., 2008). Under conditions of chronic stress, such as the caregiving of family members with brain cancer, functional resistance of monocyte-macrophages to cortisol negative feedback permits continuation of NF-kB signaling, resulting in the immune response syndrome. Early life stress can leave this same signature of blunted cortisol feedback inhibition of cellular immunity and increased proinflammatory signaling (Miller et al., 2009). It appears that chronic stress such as unemployment or chronic caregiving may result in a biphasic immune response with some reduction of cellular and humoral immune activity coinciding with low-grade, nonspecific inflammation (Segerstrom & Miller, 2004).

SPECIFICITY OF THE STRESS RESPONSE

The modification of the global activity of the immune system also depends on the time and the type of stressor. Stressors differ one from another not only in intensity but also in temporal and qualitative properties. This has been referred to as the *specificity of the stress response* (Pacak & Palkovits, 2001). Different types of stressors will affect the immune response in diverse ways leading to different disorders. A recent meta-analysis suggests that acute stressors are associated with suppression of specific humoral immunity, while brief naturalistic stressors tend to suppress cellular immunity and, as noted above, chronic stressors are associated with both cellular and humoral immune suppression as well as nonspecific inflammation (Segerstrom & Miller, 2004).

This discussion on stressor types leads us to stop and briefly consider the meaning of the flight or fight response. To more fully understand it, we need to adopt an evolutionary developmental perspective. The stress response is an adaptive preservatory phenomenon. Biologically, the "flight or fight response" is a primitive response, a reflection of early stages in our species' development, and thus it is not well suited to deal with the type of stressors we face nowadays. To understand how the stress response, evolutionarily designed to help us survive, can also hurt us, we will employ two useful concepts: allostasis and allostatic load.

ALLOSTASIS AND ALLOSTATIC LOADING

Allostasis, a concept introduced in the field of stress medicine by Sterling and Eyer, is the ability to achieve stability through change (Sterling & Eyer, 1988). It refers to the biological mechanisms that protect the body from internal and external stress and maintain the internal balance of homeostasis. But sometimes the stress system cannot maintain the internal balance for various reasons. Selye (1946) had already described the so-called “general adaptation syndrome” by identifying three stages: the *alarm stage*, in which the acute stress response is activated; the *stage of resistance*, in which the body makes an effort to return to a state of homeostasis, but the perception of a threat is still present, resulting in a persistent stress response; and the *state of exhaustion* in which the stress continues for a long time, the body cannot function normally, and organ systems fail.

In the presence of chronic stress, the persistent overactivation of allostatic systems can lead to a variety of diseases. This long-term effect of the physiologic response to stress has been called *allostatic load*—the metabolic wear and tear on the organism at the cellular level that occurs as the price for maintaining allostasis of physiological systems (McEwen & Stellar, 1993). There are four proposed mechanisms associated with allostatic load (McEwen, 1998): (1) frequent stress or multiple stressors; (2) prolonged exposure to stress and the consequent lack of adaptation; (3) inability to shut off allostatic responses or delayed shutdown once a stressor is terminated; and (4) inadequate (insufficient) response. These burdens on allostatic load lead to an overactivation of other systems in order to compensate for the deficit.

It is now increasingly clear that psychosocial stress can get translated into metabolic activation and be processed at the cellular level as *oxidative stress*. Mental stress reflects a challenge to the organism’s allostatic state of “stability through change” (McEwen, 1998). It takes metabolic energy input for the brain to maintain physiological parameters within a normative range in response to external and internal environmental stressors, and this can lead to allostatic loading. It is the brain’s stress response systems, consisting of the amygdala/lateral hypothalamus-driven SNS and the HPA axis, that serve as conduits to the body’s end organs of what the brain mesocorticolimbic system processes as a challenge or a threat. This stress hormone and transmitter-induced state alerts these target tissues to the need to alter their metabolisms to meet this new state of affairs in order to maintain allostasis. This works well if the challenge or threat is acute and self-limited. However, if the psychosocial stress is chronic, this process can be pathogenic because of cellular oxidative stress (Epel et al., 2006).

Allostatic load can also be conceptualized as a cumulative measure of dysregulation across the regulatory systems. There have been different proposed physiological parameters that reflect levels of physiologic activity of these systems, and allostatic load would be the composite sum of the number of parameters for which the subject was rated in the highest risk quartile. Among these proposed measures are systolic and diastolic blood pressures, overnight urinary cortisol,

norepinephrine and epinephrine, ratio of the waist to hip measurement, glycosylated hemoglobin value, high-density lipoprotein cholesterol and ratio to the total serum cholesterol concentration, dihydroepiandrosterone, fibrinogen, C-reactive protein, and Interleukin-6 (Seeman, Singer, Rowe, Horwitz, & McEwen, 1997; Gruenewald, Seeman, Karlamangla, & Sarkisian, 2009).

In one study, frailty defined as weight loss, exhaustion, weak grip, slow gait, and low physical activity correlated with higher allostatic load scores (Gruenewald et al., 2009). In another study of allostatic loading, Epel and her colleagues (2004) were able to show that psychological perceived stress measured on the Perceived Stress Scale, or objective psychological stress measured in chronicity of caregiving in mothers taking care of their chronically ill children, were both associated with peripheral blood mononuclear cell (PBMC) telomere length shortening, low telomerase activity (telomerase maintains telomere length) and oxidative stress. Mindfulness meditation appears to reduce oxidative stress and buffer against the aging effects on telomeres (Epel, Daubenmier, Moskowitz, Folkman, & Blackburn, 2009).

Meditation may impact allostatic loading via epigenetic pathways of gene expression. The genes of interest are involved in oxidative metabolism, apoptosis, activation of NF-kB, and ribosomal functioning. In one study, the cross-sectional PBMC gene expression profile of experienced meditators (M group) was compared with the gene expression profile taken at two times in novices who had never learned the core meditative RR practice. Time 1 is pre-RR training (N1 group) and time 2 is at 8 weeks post-RR training (N2 group). Results showed that certain genes activated and deactivated in the M group and 8 weeks post-RR training (N2 group) were not changed accordingly in the N1 group, suggesting that the N2 group after RR training was moving closer to the gene expression profile of the experienced meditators, all of whom had at least 5 years of experience in a wide variety of RR-eliciting meditative practices including mindfulness-based stress reduction and various yoga techniques (Dusek et al., 2008). The transcriptome changes seen with RR practice relate to more efficient mitochondrial metabolism, with improvement in insulin function and cell aging and reduction in NF-kB immune activation. These effects may relate to the known physiological results of RR elicitation, which include reduction in blood pressure and oxygen consumption. These results receive support from a recent study that employed a similar research methodology (gene expression profiling and bioinformatics analysis of PBMCs) to investigate changes in the leukocyte transcriptomes of highly stressed women undergoing primary treatment for stage III and below breast cancer, who underwent a 10-week course of treatment with cognitive behavioral stress management (CBSM), which includes RR training (Antoni et al., 2012). The authors found that the treatment can reverse anxiety-related upregulation of NF-kB-associated proinflammatory gene regulation.

The metabolic wear and tear and oxidative stress that comes with allostatic loading may be related to the epidemic of metabolic syndrome. This syndrome, which now affects nearly 40% of the US population, is characterized by truncal obesity,

insulin receptor insensitivity leading to Type II diabetes, hyperlipidemia, and hypertension (Ford, Li, & Zhao, 2010). It is of interest in this regard that mind-body therapies have shown some effectiveness for the management of metabolic syndrome, perhaps related to the common RR elicited transcriptomic effects of these therapies (Anderson & Taylor, 2011).

OXIDATIVE STRESS AND THE PROINFLAMMATORY TRANSCRIPTION FACTOR NF-KB

Allostatic loading can lead to oxidative stress, with the resultant production of free radicals and stress-sensitive heat shock protein (HSP) gene expression/production (e.g., HSP 40/70/90) as a ligand for the toll-like 4 receptor. Activation of this receptor can stimulate macrophages to produce proinflammatory and cytotoxic mediators (inducible nitric oxide-iNO, TNF-alpha, IL-6, IL-12) through an iNOSynthase/NF-kB/cAMP reactive element binding (CREB) protein/COX-2 mechanism (Billack et al., 2002).

The proinflammatory transcription factor NF-kB is a bridge between stress and oxidative cellular activation (Bierhaus et al., 2004). Activation of NF-kB, evoked by psychosocial stress, may directly target endothelial functioning in the vasculature and thus represent an additional risk factor for cardiovascular, cerebrovascular, and renal disease. At the same time hypertension, obesity, insulin-resistant diabetes mellitus, and hyperlipidemia (metabolic syndrome) can activate NF-kB, as can psychologically produced oxidative stress, cytokines, growth factors, angiotensin II, and advanced glycation end-products (AGEs). Activation then leads to NF-kB nuclear translocation in endothelial, smooth muscle, monocyte/macrophage, and renal glomerular and epithelial cells.

NF-kB then binds to DNA and activates transcription of genes for cytokines, adhesion molecules, coagulation factors, and AGE receptors (RAGEs) setting the stage for endothelial dysfunction, atherosclerotic cardiac and cerebrovascular disease, renal disease, and so forth. In addition, NF-kB stimulates the proliferation of tumor cells and enhances their survival by upregulating anti-apoptotic genes (Schottelius & Dinter, 2006).

The extent of NF-kB activation in PBMCs correlates with oxidative stress (Hofmann et al., 1999). In addition, PBMC NF-kB is activated by psychosocial stress (15-minute Trier Social Stress Test; Bierhaus et al., 2004). For instance, maternal caregiving stress, resulting in oxidative stress-induced telomere shortening in PBMCs, may be related to NF-kB activation. Immobilization stress in rats increases NF-kB activation and dependent gene expression (Madrigal et al., 2002). Lymphocyte NF-kB increases in women who are stressed by breast biopsy (Nagabhushan, Mathews, & Witek-Janusek, 2001). This activation is correlated with a stress-dependent increase in catecholamines and cortisol. And therapeutic interventions that decrease oxidative stress can reduce NF-kB activation (Hofmann et al., 1999).

When stress is removed, NF-kB usually downregulates within 60 minutes. Some individuals are unable to

downregulate this quickly, suggesting a variability in stress perception that can be translated into prolonged NF-kB activation. This differential response to stress stimuli may be a product of genomic activation differences. The group of individuals who are unable to downregulate NF-kB quickly may theoretically benefit most from RR training, perhaps through activating effects on the stabilizing Ik-Ba inhibitor complex.

Chronic diseases (coronary artery disease, diabetes mellitus, end stage renal disease, etc.) are associated with elevated allostatic loading. They also have higher levels of depression and anxiety as allostatic load disorders, and may be more susceptible to psychosocial stress. Chronically activated NF-kB states may then be exacerbated by repeated or perpetuated stress states. The so-called RAGE ligands (AGEs, amyloid B-peptides, etc.), already upregulated by NF-kB in chronic diseases, may in turn mediate a perpetuated NF-kB activation by overriding autoregulatory Ik-Ba inhibition.

In this way NF-kB activation by psychosocial stress may be converted into a constant allostatic threat. Psychosocial stress-induced NF-kB activation can now be tracked in accessible PBMCs. Along with measurement of genomic alterations, changes in oxidative metabolites, and telomere dynamics, NF-kB activation measurement will help with research into this potential link between stress and pathology. It will also help with the study of whether stress reduction therapies can influence cellular activities (Bierhaus et al., 2004).

One way to impact the stress-related upregulation of NF-kB is to stabilize the association of Ik-Ba with NF-kB. This reduces the production of protein activators of oxidative stress (Stefano et al., 2001). Mental activities such as RR or belief may be able to effect such stabilization through enhancement of constitutive nitric oxide mechanisms. Perhaps that is why individuals taught the RR had decreased oxygen consumption, which correlated with exhaled nitric oxide (Dusek et al., 2006).

Mechanisms involving oxidative stress and its mediator, NF-kB, constitute a plausible explanation of how stress is implicated in the genesis and progression of multiple disorders. The statistical association between stress and these disorders is clear, and although more research is required to establish unequivocally a causal link, consistent evidence suggests that this causal relation exists (Cohen, Janicki-Deverts, & Miller, 2007). In addition to the importance of stress management for the health of individuals, there are extraordinary socioeconomic implications as reflected in a review of studies showing that at least 60% of medical visits are associated with stress-related conditions (Perkins, 1994).

What does mind-body medicine have to offer? Interventions to reduce stress and enhance resiliency are available to promote health and prevent illness.

RESILIENCY

Resiliency is a term that comes to us from structural engineering and refers to the ability to rebound or to bounce back from a stressor or adversity. Resiliency reflects good adjustment across different domains in the face of significant adversity. It consists of five major capacities: (1) the capacity to experience

reward and motivation nested in dispositional optimism and high positive emotionality; (2) the capacity to circumscribe fear responsiveness so that one can continue to be effective through active coping strategies despite fear; (3) the capacity to use adaptive social behaviors to secure support through bonding and teamwork and to provide support through altruism; (4) the ability to use cognitive skills to reinterpret the meaning of negative stimuli in a more positive light; and (5) the integration of a sense of purpose in life along with a moral compass, meaning, and spiritual connectedness (Feder, Nestler, & Charney, 2009) (See Box 17.3).

Over the past decade, more has been learned about the neurobiology of mechanisms of passive resilience (the absence of key molecular susceptibility characteristics) and active resilience (the presence of central molecular promoters of healthy adaptations). (Russo, Murrough, Han, Charney, & Nestler, 2012). Molecular adaptations within the DA reward and motivation circuitries are associated with vulnerability and resiliency (Krishnan et al., 2007). For example, a naturally occurring single nucleotide polymorphism (SNP), G196A Met/Met, promotes insusceptibility to stress by virtue of deficits in activity-dependent Brain Derived Neurotrophic Factor (BDNF) release in the nucleus accumbens. In another study, the ratio of CRH to NPY also seems to reflect a relationship between vulnerability and resiliency. High CRH increase (associated with increased acute stress response + negative affect) with low NPY (associated with decreased anxiety) correlates with high allostatic loading and low resilience, and increased propensity to alcohol abuse (Valdez & Koob, 2004). When there is lower haplotype-driven NPY expression (SNPrs 16147 in NPY promoter region) in limbic areas associated with amygdala arousal and emotional valencing, there is higher amygdala activation and diminished resiliency (Zhou et al., 2008). Dihydroepiandrosterone –S over cortisol and NPY over norepinephrine ratios reflect resiliency in Navy Seal commandos exposed to a stressful capture exercise (Southwick, Vythilingam, & Charney, 2005).

Box 17.3 THE FIVE COMPONENTS OF RESILIENCY

1. Capacity to experience reward and motivation nested in dispositional optimism and high positive emotionality;

2. Capacity to circumscribe fear responsiveness so that one can continue to be effective through active coping strategies despite fear;

3. Capacity to use adaptive social behaviors to secure support through bonding and teamwork and to provide support through altruism;

4. Capacity to use cognitive skills to reinterpret the meaning of negative stimuli in a more positive light;

5. Capacity to integrate a sense of purpose in life along with a moral compass, meaning, and spiritual connectedness.

(Adapted from Feder, Nestler, & Charney, 2009)

In a human depression study, the serotonin transporter allele 5-HTTLPR with 2 short arms SS, thought to be a risk for depression in and of itself, when combined with maltreatment in childhood plus low social support will be twice as likely to cause depression when compared to those with 5-HTT SS and no maltreatment and low social supports. However, this latter profile is more likely than the 5-HTT SS group with maltreatment and good social supports to cause depression, which in turn is more likely to cause depression than the group with 5-HTT SS plus no maltreatment and good social supports (Kaufman et al., 2004). It should be noted, however, that a recent meta-analysis found no evidence that the 5-HTTLPR conveyed extra risk for depression beyond the stressful life events (Risch et al., 2009).

There are HPA axis–related genes that may interact with resiliency to stress. For example, SNPs of the *CRH type 1* receptor gene may moderate the effects of child maltreatment on susceptibility to depression in adulthood (Bradley et al., 2008). And four SNPs of the gene (*FKBP5*) that codes for a protein chaperone that regulates glucocorticoid receptor (GR) sensitivity modulate the association of child abuse with the risk of PTSD in adulthood (Binder et al., 2008). In addition there is a catechol-O-methyltransferase polymorphism (Val158Met) that has relevance to resiliency. Those with low-activity Met158 develop higher levels of catecholamines in response to stress, resulting in lower resilience to anxiety and negative mood states (Heinz & Smolka, 2006).

There are also epigenetic mechanisms of resiliency in which the environment can change chromatin structure through methylation or acetylation of histones or direct methylation of DNA.

If evolution made us a species that relies on social support for our survival and health, then it had to create a species that had the capacity to give social support, to be prosocial, and to be altruistic. Indeed, altruistic behavior has been associated with good health outcomes as long as stress does not overwhelm the individual’s ability to cope (Post, 2009). In the rat model, maternal nurturance has been shown to increase levels of the transcription factor nerve growth factor-inducible protein A (NGFI-A), known as EGR1, in the hippocampus of the nurtured pup. This allows for hypomethylation and stimulation of the hippocampal GR gene. Higher levels of hippocampal GR translates into certain neurobehavioral outcomes in the adult, including lower baseline and post-stress glucocorticoid secretion levels, lower anxiety-like behaviors, and in females improved nurturance of their own offspring (Meaney & Szyf, 2005). In resilient mice, chronic stress activates several potassium channel subunits in VTA DA neurons, and this blocks a stress-induced increase in VTA excitability and downstream release of BDNF in the nucleus accumbens (Krishnan et al., 2007).

CONSCIOUS POSITIVE EXPECTATION AND THE PLACEBO RESPONSE

We have talked about optimism, or conscious positive expectation, as part of resiliency. This leads to a consideration of placebo. The *placebo effect* is not an epithet, even though in

medicine it has developed that connotation. It is instead an important part of human self-care, and it stems from the fact that belief in conscious positive expectation aids in the healing process. There is very interesting work in three important human brain disorders—pain, depression, and Parkinson's disease—that establishes the importance of placebo. A possible reason why the placebo is so active in these three very important public health problems is because placebo actually works directly on the brain mesolimbic/mesocortical reward and motivation circuitries (Fricchione & Stefano, 2005). There are neuroimaging studies that point this out. One experiment shows that if you apply a standard heat pain paradigm to subjects, you will see the ACC activate while the DLPFC is relatively deactivated. The ACC is the place that modulates all forms of human pain, so this may represent a pain signature. Then if you do the same experiment but apply a placebo cream prior to the heat stimulus, you will see the opposite pattern—ACC activation goes down, DLPFC activation goes up, and pain is reduced (Zubieta et al., 2005). The endogenous opioid mu receptor system is of importance in placebo pain response, which can be blocked by naloxone. In depression, which is notoriously placebo responsive, functional neuroimaging studies reveal metabolic increases in PFC, posterior insula, inferior parietal cortex, and dorsal ACC, and decreases in the pregenual ACC, thalamus, and hypothalamus with successful placebo treatment (Mayberg et al., 2002). Antidepressant responses occur in similar regions but are more robust, and also included brainstem activation.

In elegant studies with Parkinson's disease (PD) patients, researchers using positron emission tomography with the DA ligand raclopride have been able to show that a placebo of subcutaneous saline can improve PD symptoms coinciding with the displacement of the raclopride, presumably by DA, from the substantia nigra and the ventral tegmentum DA cell bodies (de la Fuente-Fernandez, Schulzer, & Stoessl, 2004).

THE MIND–BODY MEDICINE HYPOTHESES

Four hypotheses of mind–body medicine emerge based on the science summarized above (Fricchione, 2009). The **first hypothesis** is that the mind and body are a unity. Every external and internal experience produced is the result of and results in biological reactions in the brain. These biological reactions change the ecology of the brain, and this transduction of experience unifies what we consider to be mind activity and the body.

The **second hypothesis** is that psychosocial stress gets transduced into cellular stress. This cellular stress is mitochondrial oxidative stress, and every cell has to deal with psychosocial stress in this very physiological way because of the influence of the stress response systems.

The **third hypothesis** is that this cellular oxidative stress is what uncovers disease vulnerability. This is essentially a nonspecificity stress diathesis model. If both of my parents died of coronary artery disease, it is a good bet that I have vulnerability for coronary artery disease. I may not manifest that

vulnerability if I can build my resiliency and hold in check my psychosocial stress and, by extension, my cellular oxidative stress. In short, cellular oxidative stress is a key factor in the elaboration of mind–body effects.

Our genetic endowment is not completely writing the script for us, and this fact is revolutionizing the field of psychosomatic medicine. The environment is having its say in terms of which genes are activated and which genes are inactivated, and this epigenetic transcriptomic effect is essential for the field of medicine in general. Meaney and colleagues (Weaver et al., 2004; Champagne & Meaney, 2007), in a series of experiments mentioned above, have shown that rat pup recipients of high nurturance have an activation of an important promoter gene that leads downstream to the production of an elevation in GR receptors in the hippocampus. It is the process of hypomethylation at the 5-HT7 gene that leads to the increased production of the GR promoter gene. This epigenetic change produces, in those highly nurtured rat pups when they become adults, the resilience to better face a standard stress paradigm in the laboratory. The Meaney lab has extended this exciting work by showing that environmental enrichment can reverse some of the effects of being a rat pup who has had a poorly nurturant upbringing, by causing epigenetic changes at the estrogen receptor that in turn elevates oxytocin functioning, leading to increased attachment behavior in adulthood.

In the human model it is now known that if you perceive a task as stressful, such as taking care of a chronically ill child, telomeres in PBMCs will age 10 times faster than average as measured in number of base pairs lost per year (Epel et al., 2004). This effect is tied to oxidative stress in these PBMCs, as the production of oxidative metabolites is increased along with telomere shortening and the reduced activity of the telomere maintenance enzyme telomerase. Studies like these establish for us the potential for a new field of medicine, which is being called **enviromimetics** (McOmish & Hannan, 2007). Can salogenic environmental changes be reliably mimicked to effectively change gene activation and deactivation so that the changes will have health benefits? This is an area ripe for study.

THE FOURTH HYPOTHESIS

Most of the stress-related challenges we face as human beings are consequences of the fact that we are all mammals. We all are subject to separation stress because, as summarized by John Bowlby, the great English psychiatrist and father of attachment theory, our environments of evolutionary adaptiveness have to be that of secure base attachment (Bowlby, 1982). Stress itself can thus be reframed as a separation challenge (Fricchione, 2011). Illness in this regard can be surmised to be an enormous separation challenge and consequently an enormous source of stress. Distress associated with insecure attachment style will lead to a compounding of the separation challenge associated with illness culminating in poorer coping and worse outcomes (Ciechanowski et al., 2004). Conversely, a secure attachment style nurtured in childhood and persisting in

adulthood will make coping with illness more adaptable (Ciechanowski et al., 2002; Thompson & Ciechanowski, 2003; Ciechanowski et al., 2010).

This leads to the **fourth hypothesis**, which we might call the **mind–body medicine equation hypothesis** (Fricchione, 2011). Building on the earlier work of medical sociologist George Albee (1982), it is very simple and heuristic. If one thinks about the numerator as being stress or allostatic loading and about the denominator as being resiliency, a pretty good picture of one’s vulnerability to illness in the future will emerge. This might be called an *illness index* or the propensity to illness (see Figure 17.1). Flip the numerator to resiliency and the denominator to stress, and you get the quotient changed to propensity to health—a *health index*. For example, if one studies women with systemic lupus erythematosus, when you populate the variables in the equation and you stratify the groups into low social support leading to a decrease in the denominator, the propensity to a lupus flare will go up. There are many examples of this relationship in the literature (Ward et al., 1999; Sutcliffe et al., 1999; Sewitch et al., 2001; Seeman, 2000; Case, Moss, Case, McDermott, & Eberly, 1992; Horsten, Mittleman, Wamala, Schenck-Gustafsson, & Orth-Gomér, 2000; Ruberman, Weinblatt, Goldberg, & Chaudhary, 1984).

Because of this relationship, it is advisable that doctors and nurses take heed of this equation when they evaluate patients and create treatment plans. There should be some ability in the clinical encounter to get an objective feel for the level of patient stress and the level of patient resiliency. The problem is compounded once illness takes hold because, as mentioned above, illness itself is an enormous stress because it ignites the threat of separation (Fricchione, 2011).

In a classic study in the *New England Journal of Medicine*, over 2,000 men post–myocardial infarction were followed by Ruberman and his colleagues (1984) for a period of 36 months. They stratified the groups into a high numerator group with high life stress. Mortality was increased over those 36 months. Then they looked at the group with low social support or high social isolation, a low denominator, and these subjects also died at a high rate over 36 months. But then, when the researchers looked at a group with combined high numerator and low denominator, the 3-year mortality was enormously high.

So what are the attachment solutions available to relieve the separation stress of illness?

At the Benson-Henry Institute (BHI), we have the RR Resiliency Enhancement Program (3RP), which offers a composite attachment solution strategy (Fricchione, 2011). It begins with individual integrative medicine consultations and management of stress-related conditions performed by our internists. They can then refer patients to our 3RP group interventions, which all start with RR training.

We teach RR first with a component of mindfulness and yoga, because it seems to be an enhancer of the educational component of the REP. We then teach cognitive behavioral skills in the group setting. This is geared toward breaking the negative thinking traps and catastrophizing that can lead to pathogenic stress. Also in the group setting, social support is an important component, as is encouragement of prosocial behavior. Optimism and belief in conscious positive expectation are important parts of the positive psychology aspect of our approach, as is accenting meaning, purpose, gratitude, and life enjoyment. Spirituality, basically defined as a sense of connectedness to something greater than ourselves, is also addressed in the 3RP. In addition, exercise and nutrition education are of course important factors. The 3RP is designed to reduce stress and enhance resiliency, theoretically improving the health index. Results show that 12 out of 23 symptoms on the Medical Symptom Checklist were significantly decreased in frequency, along with improvement in psychological symptoms on the Symptom Checklist-90-Revised and health-promoting lifestyle behaviors on the Health Promoting Lifestyle Profile-II (Samuelson et al., 2010). The improved physical symptoms included headache, visual disturbance, dizziness, nausea, constipation, diarrhea, abdominal pain, back ache, chest pain, palpitations, insomnia, and fatigue.

An example of this heuristic equation effect can be found in the BHI Mind Body Cardiac Wellness programs. In a recently released US Center for Medicaid and Medicare Services report, the BHI cardiac rehabilitation program was found to produce a significant reduction in post–cardiac event mortality and a significantly increased time to rehospitalization over the 3-year study period when compared not only to a noncardiac rehabilitation sample but also to a traditional cardiac rehabilitation control group in a cohort of cardiac patients 65 years old and older (Shepard et al., 2009). We cautiously surmise that this positive outcome results from the ability of our mind–body cardiac rehabilitation program to reduce stress and to increase resiliency, not only through exercise prescription and nutritional guidance but also through RR training, social support and teamwork, cognitive skills training, positive psychology, and conscious positive expectation.

USE AND EFFICACY OF MIND–BODY TECHNIQUES

A significant interest in mind–body medicine among the general population has been documented in national surveys in the United States (Wolsko, Eisenberg, Davis, & Phillips, 2004). Around 20% of the population have used a mind–body intervention of some kind in the last year. Meditation

$$\frac{\text{Stress-induced allostatic loading (separation threats) + genetic vulnerabilities}}{\text{Resiliency components (attachment solutions) + genetic endowments}} = \frac{\text{Oxidative stress}}{\text{Anti-oxidation}} = \text{propensity to disease}$$

Figure 17.1 Mind–Body Medicine Equation. (Fricchione, 2011).

and relaxation techniques were the most highly endorsed. In another study, health professionals manifested higher interest in learning these approaches and lower interest in biofeedback and hypnosis (Sierpina, Kreitzer, Cunningham, Elder, & Bruckner, 2007). Mind-body therapies were most frequently used for different chronic conditions such as anxiety, depression, chronic pain, insomnia, gastrointestinal disorders, and fatigue, for which currently available therapies are not entirely satisfactory. In fact, anxiety and pain have been proposed as the symptoms that best predict the public's search for alternative therapies (Hassed, 2006). However, the main reason why people use these kinds of interventions is not dissatisfaction with conventional medicine but because they have found these interventions to be more congruent with their own values, beliefs, and philosophical orientations toward health and life (Astin, 1998).

The RR-based approaches have been shown to be beneficial in many disorders (Mandle, Jacobs, Arcari, & Domar, 1996). However, not all studies are reliable and caution must be used. Many studies have methodological problems, and statistical significance is not synonymous with efficacy. The use of unblinded "pragmatic trials," which compare a treatment with "usual care" or no additional care, can carry a risk of bias (Power & Hopayian, 2011). The components of an outcome measure must be carefully considered and include not only the specific effect of a mind-body intervention but also non-specific effects such as placebo, cognitive measurement biases, and the "frustrate effect," which is the adverse effect in the control group of not receiving the treatment the subject thinks is needed. These confounders may lead to a nonspecific benefit being touted as a specific benefit of the mind-body intervention. Despite the difficulties inherent in this clinical research area, evidence for the efficacy of mind-body interventions is slowly proceeding, although integration within mainstream medicine will likely be more of a marathon than a sprint (Ernst, Pittler, Wider, & Boddy, 2007; Nahin, Pontzer, & Chesney, 2005).

With these caveats in mind, Astin and colleagues (2003) believe there is strong to moderate evidence based on meta-analyses of mind-body intervention efficacy in the following medical conditions: cardiovascular disease (Dusseldorp, van Elderen, Maes, Meulman, & Kraaij, 1999; Linden, Stossel, & Maurice, 1996); cancer treatment tolerance (Meyer & Mark, 1995; Devine & Westlake, 1995); incontinence (Weatherall, 1999); surgical outcomes (Devine, 1992; Johnston & Vogeley, 1993); insomnia (NIH Consensus Panel, 1996; Morin, Culbert, & Schwartz, 1994); headache (Haddock et al., 1997; Holroyd & Penzien, 1994); chronic low back pain (van Tulder et al., 2000; NIH Consensus Panel, 1996); arthritis self-care (Astin, Beckner, Soeken, Hochberg, & Berman, 2002; Superio-Cabuslay, Ward, & Lorig, 1996; Lorig & Holman, 1993); and hypertension (Linden & Chambers, 1994; Jacob et al., 1991; Eisenberg et al., 1993; also).

Pelletier (2004) reports that for acute pain (Seers & Carroll, 2004) and fibromyalgia (Hadhazy, Ezzo Creamer, & Berman, 2000) there is also strong evidence, and adds a number of other conditions where research is less definitive but

current RCTs indicate positive efficacy: allergies (Watkins, 1994), asthma (Castes et al., 1999; McQuaid & Nassau, 1999; Smyth, Stone, Hurewitz, & Kaell, 1999), dermatological disorders (Kabat-Zinn et al., 1998), diabetes (Aikens, Kiolbasa, & Sobel, 1997; Jablon, Naliboff, Gilmore, & Rosenthal, 1997; Henry et al., 1997), HIV progression (Cruess et al., 1999; Robinson, Mathews, & Witek-Janusek, 1999), irritable bowel syndrome (Schwarz, Taylor, Scharff, & Blanchard, 1990; Blanchard & Malamood, 1996; Galovski & Blanchard, 1998; Vollmer & Blanchard, 1998), post-stroke rehabilitation (Moreland, Thomson, & Fuoco, 1998), peptic ulcer (Levenstein, Ackerman, & Kiecolt-Glaser, 1999), pregnancy outcomes (Scott, Berkowitz, & Klaus, 1999), chronic obstructive pulmonary disease (Devine & Percy, 1996), and tinnitus (Andersson & Lyttkens, 1999). Many other disorders are also likely to respond to mind-body interventions, but sufficient studies have not yet been done.

The role of stress in the presentation of anxiety and depressive symptoms has been widely discussed (Esch, Stefano, Fricchione, & Benson, 2002; Swaab, Bao, & Lucassen, 2005) and mind-body interventions have been shown to be effective (Benson et al., 1978; Kabat-Zinn et al., 1992) in reducing these stress-related symptoms, although there are methodological limitations (Pilkington, Kirkwood, Rampes, & Richardson, 2005; Toneatto & Nguyen, 2007).

In one Cochrane meta-analysis of 11 randomized or quasi-randomized controlled trials of relaxation techniques (progressive muscle relaxation, relaxation imagery, autogenic training) in participants diagnosed with depression or having a high level of depressive symptoms, self-rated and clinician-rated depression scores and response/remission were the primary outcomes (Jorm, Morgan and Hetrick, 2008). Relaxation techniques were more effective at reducing self-rated depressive symptoms than no or minimal treatment, but data on clinician-rated depressive symptoms were less conclusive; overall, they were not as effective as psychological treatments. Meeks et al. (2007) found that mind-body approaches were effective in treating anxiety, depression, and sleep dysfunction in an elderly cohort. And in a pilot study, a 24-week multimodal mind-body group intervention consisting of psychoeducation, lifestyle modification, meditation, and mind/body skills training was shown to be promising in reducing chronic depression and aiding overall health (Little, Kligler, Homel, Belisle, & Merrell, 2009).

Both anxiety and depression play important roles in the prognosis of somatic complaints. While the level of depression is related to the reporting of somatic symptoms (Nakao, Yamanaka, G., & Kuboki, 2001), anxiety improvement is a good indicator for somatic symptom reduction through mind-body interventions (Nakao, Fricchione, et al., 2001).

Some studies are based on multicomponent approaches that include combinations of different interventions, while others are based on one specific intervention. Other studies have focused their attention on specific indications for interventions (Barrows & Jacobs, 2002). Meditation techniques such as mindfulness-based stress reduction appear to be helpful for mental health problems, cardiovascular conditions, insomnia, premenstrual syndrome, psoriasis, and chronic

pain. Hypnosis has been used for the treatment of acute and chronic pain, including surgical interventions. Biofeedback can be useful for defecation disorders, enuresis, stroke rehabilitation, and many pediatric conditions; and relaxation therapies are indicated for the treatment of insomnia, hypertension, and headache. These indications do not necessarily indicate specificity for each approach. When one technique shows efficacy for one condition, it is likely that the other techniques will also display some efficacy because of similar underlying mechanisms.

Because they promote self-care, mind–body interventions also appear to be cost effective. It has been documented that these approaches reduce ambulatory visits, postsurgical days in the hospital, unnecessary procedures, and medical costs (Benson, Beary, & Carol, 1974; Sobel, 2000). As part of the cost-effectiveness analysis, mind–body interventions also improve patient satisfaction, sense of control, and quality of life (Sobel, 1995). It should also be stressed that mind–body interventions in most cases are to be used as complementary therapies in combination with conventional medical treatments and procedures (Jacobs, 2001). So, for example, tai chi has been shown to augment escitalopram treatment of geriatric depression in one randomized controlled trial (Lavretsky et al., 2011). Tai chi training also appears to reduce balance impairments in patients receiving usual treatments for mild to moderate Parkinson’s disease, with additional benefits of improved functional capacity and reduced falls (Li et al., 2012). And in a study of tai chi for fibromyalgia, of 66 randomly assigned patients receiving usual treatments, the 33 in the tai chi group had clinically important functional improvements in the Fibromyalgia Impact Questionnaire total score and in quality of life (Wang et al., 2010). Research will also be needed to define the role of mind–body medicine in primary prevention as well as in secondary and tertiary prevention, considering that stress plays a role in the onset of many diseases and in their exacerbations (Astin, 2004).

SUMMARY

The heuristic mind–body medicine equation can be derived from the research described above. In this equation the propensity to health and optimal performance is defined by a relationship between the stress burden (allostatic load) and genetic vulnerability as denominator, and the personal resources, which help us to cope with stressors (resiliency), and genetic endowment as numerator. Included in the numerator of the equation are all the mentioned self-management skills regarding the ability to elicit the relaxation response, cognitive skills, social support, prosocial behavior, positive psychology, and spiritual beliefs. Gene expression changes, induced epigenetically, may form the links within the numerator between genes and resiliency and within the denominator between genes and stress. Thus mind–body medicine interventions, by promoting a secure attachment style and enriched environment, are effective in buffering against stress and in building resiliency (Fricchione, 2011). They give the body a better chance to heal.

This kind of approach is important in clinical medicine and in public health. Consideration of mind–body approaches to promote health—not only mental health but physical health as well—and also to prevent illnesses is warranted. Mind–body medicine is an important bridge between clinical medicine and public health.

CLINICAL PEARLS

- Catecholamines and glucocorticoids both control the amplitude of immune response through negative feedback mechanisms. In physically threatening situations, inflammatory cytokines, mainly IL-6, stimulate the HPA axis, and the subsequent elevation of cortisol levels will eventually induce the suppression of the immune/inflammatory reaction. Simultaneously, the SNS causes systemic secretion of cytokines, which will eventually suppress the immune system (Stratakis & Chrousos, 1995).
- It appears that chronic stress such as unemployment or chronic caregiving may result in a biphasic immune response with some reduction of cellular and humoral immune activity coinciding with low-grade, nonspecific inflammation (Segerstrom & Miller, 2004).
- It is now increasingly clear that psychosocial stress can get translated into metabolic activation and processed at the cellular level as *oxidative stress*.
- This long-term effect of the physiologic response to stress has been called *allostatic load*—the metabolic wear and tear on the organism at the cellular level that occurs as the price for maintaining allostasis of physiological systems (McEwen & Stellar, 1993).
- Mindfulness meditation appears to reduce oxidative stress and buffer against the aging effects on telomeres (Epel et al., 2009).
- Meditation may impact allostatic loading via epigenetic pathways of gene expression.
- When stress is removed, NF-κB usually downregulates within 60 minutes. Some individuals are unable to downregulate this quickly, suggesting a variability in stress perception that can be translated into prolonged NF-κB activation.
- Altruistic behavior has been associated with good health outcomes as long as stress does not overwhelm the individual’s ability to cope (Post, 2009).
- Environmental enrichment can reverse some of the effects of being a rat pup who has had a poorly nurturant upbringing, by causing epigenetic changes at the estrogen receptor that in turn elevates oxytocin functioning, leading to increased attachment behavior in adulthood.
- Secure attachment style nurtured in childhood and persisting in adulthood will make coping with illness more adaptable (Ciechanowski et al., 2002; Thompson & Ciechanowski, 2003; Ciechanowski et al., 2010).

- There should be some ability in the clinical encounter to get an objective feel for the level of patient stress and the level of patient resiliency.
- We cautiously surmise that mind–body cardiac rehabilitation programs are able to reduce stress and to increase resiliency, not only through exercise prescription and nutritional guidance but also through RR training, social support and teamwork, cognitive skills training, positive psychology, and conscious positive expectation.
- Self-management skills include the ability to elicit the relaxation response, cognitive skills, social support, prosocial behavior, positive psychology, and spiritual beliefs.
- Gene expression changes, induced epigenetically, may form the links between genes and resiliency and between genes and stress.
- Mind–body medicine interventions, by promoting a secure attachment style and enriched environment, are effective in buffering against stress and in building resiliency (Fricchione, 2011). Thus they give the body a better chance to heal.

SPIRITUAL AND RELIGIOUS ISSUES IN MEDICAL ILLNESS

Gregory L. Fricchione and John R. Peteet

*Science without religion is lame,
Religion without science is blind.
—Albert Einstein*

INTRODUCTION

Consideration of healthy religious factors during psychiatric treatment has traditionally been taboo ever since Freud alienated most of psychiatry and psychoanalysis from salutogenic religious behaviors in part due to his adoption of Feuerbach's wish-fulfillment and projection views on the subject (Stepansky, 1986). Within psychiatry itself, those seeking a more religious or spiritually oriented approach initially gravitated toward the psychology of Carl Jung, who tended to turn psychology into a form of mysticism of the self, and religion into a form of mystical psychology. Over the past 30 years, however, some physicians and nurses, as well as pastoral counseling and chaplaincy movements, have attempted to integrate the religious/spiritual and the psychotherapeutic aspects of patient care. In the past 20 years, improved research has validated the association between religion and health, if not the causality, and the positive role that it can play in recovery from illness. One need not be a believer to employ an understanding of the power of spirituality and religion to promote healing in the care of patients with medical illness.

This chapter explores the appropriate role of psychiatrists in dealing with the religious and spiritual concerns of their patients, particularly in the context of medical illness. To begin, we focus on the role of the physician and/or psychiatrist in the emotional crisis of physically ill patients. Then we will focus on the downstream effects of spirituality and religion on physical and mental health (Fricchione, 2011a). We discuss how the neurobiology of religious experience is related to the mammalian anatomy of attachment in the limbic system, and then the clinical approach to understanding a patient's religious beliefs, how to use this knowledge to better treat the patient, when to make a chaplaincy referral, and issues related to the care of Jehovah's Witnesses patients.

Patients encountering severe physical illness face what philosophers call the "limit questions": Who am I? What is the meaning of my life? Where am I going? Will I be separated from my loved ones?—questions that express universal

existential concerns in the domains of identity, hope, meaning, purpose, morality, and relationship to ultimate authority. The spiritual answer to each of these existential questions depends on the connection that the individual feels in relation to a reality greater than himself or herself. As our colleagues in medicine and surgery have less and less time to spend with individual patients, psychiatrists and palliative care specialists working in general hospitals are called upon more often than in the past to engage with their patients in a dialogue that bridges life and death, stepping into the anxiety-provoking and often terrifying "intermediate area" between separation and attachment first described by D.W. Winnicott (1953). From an object-relations perspective (Horton, 1981), the physician acts as a transitional object, an object that can be held in the transition, offering solace that comes from "transitional relatedness." The physician becomes a parental figure of protection and guidance, with the capacity to accompany the vulnerable individual facing the threat of separation to a safe place. One such place may be a safer emotional-spiritual world for the patient who holds a belief in such a reality.

Indeed, the origin of caring for all physicians may be traced to the anxiety-ridden separation/attachment experience of the person who is ill and the willingness of the physician to enter into the patient's emotional world by being a consistent, knowledgeable, and caring fellow human being. In the process, medically ill persons derive the solace and confidence required to negotiate their illness-precipitated developmental challenges, including the challenge of facing death (Fricchione, 1993).

While transitional relatedness, or providing an empathic caring presence, can seem like extra duty for physicians already burdened by the technical pressures of providing medical expertise, it is often key to the role played by medical psychiatrists. Nevertheless, it must be stressed that this transitional role is and always will be at the heart of every clinical physician's calling.

As Peabody (1927) said to medical students 70 years ago: "One of the essential qualities of the clinician is interest

in humanity, for the secret of the care of the patient is in caring for the patient.” Visitors to the Massachusetts General Hospital see these famous words etched in the lobby’s marble wall. Alongside it is another famous quote of Dr. Edward Churchill, speaking over 50 years ago: “Charity in the broad spiritual sense, that is our desire to relieve suffering, is the most prized possession of medicine.” So a major contention of this chapter is this: that clinicians and patients meet in the most spiritual of all earthly places—the bedside.

Healing is a product not only of curing but of caring, a caring that is spiritually inspired. The word *heal* comes from the old English word *haelen*. It means not only to restore to health by way of a cure but also “to set right; to amend” (American Heritage Dictionary, 1978), as in the phrase “to heal a rift between us.” In addition, “to heal” can mean “to restore a person to spiritual wholeness” (American Heritage Dictionary, 1993). This form of healing is the major goal of religion. It is of interest that the root meaning of the word *religion* comes from the Latin word *religio*, which can be translated as “to bind back”; that is, to reattach or to restore.

This theme of restoration and reattachment is at the core of human spirituality—a uniquely human capacity for consolation in response to the awareness of separation and loss. Both religion and medicine are formal human structures within which human spirituality can be given expression by offering care and consolation.

Paul Tillich and T.S. Eliot characterized the 20th century as an “Age of Anxiety,” and so far there is little evidence that the 21st century will become anxiety free. Tillich believed modern humanity was marked by a sense of disconnection, of separation from a spiritual source of life’s meaning and purpose, from what he called our “Ground of Being,” a term he essentially used for God (Tillich, 1951). Nevertheless, most Americans believe in a “Ground of Being.” This percentage has remained steady in polls taken over many years at 92% to 96%. While the percentage of Americans who believe institutional religion is essential to their lives has dropped from 75% to 58%, the percentage reporting that spirituality is essential has risen from 58% to 76%. The clear message is that God, spirituality, and even religion remain important sources of understanding and solace for most patients in the United States.

DEFINITIONS OF SPIRITUALITY

One of the obstacles to bringing religious and medical healing together has been the challenge of defining spirituality. One consensus, from the Fetzer Foundation’s 2003 conference on Spirituality in Palliative Medicine, has focused on spirituality as a connection to something larger than oneself that gives meaning to one’s life (Fetzer Institute, 2003).

The word *spirituality* comes from the Latin word *spiritus*, meaning breath. The Benedictine monk and psychologist Steindl-Rast defined spirituality as “aliveness—super aliveness. . . . It’s the breath of all of creation. Whenever we are alive, on every level, we are spiritual, and we are fully spiritual when we come alive on the highest level of our caring for

one another and caring for this planet” (Olsen, 1996). For Steindl-Rast the act of the spirit is caring. Spirituality in this sense is the lifeblood at the heart of medicine as well as religion. It attaches physicians and all of us to that “spark of life that can be felt,” to that “Ground of Being,” to that breath of all life one might call “the Holy Spirit.”

Several years ago, the Swiss theologian Hans Kung gave the annual Oskar Pfister lecture at an American Psychiatric Association meeting. He implored the audience to attend to spiritual life and religious heritage in patient care. Several psychiatrists have since written on the subject. One such psychiatrist was the late Irving M. Rosen, working at the interface of medicine and psychiatry, who came to view spirituality as a “domain, a level of development of the mature and responsible person” (Rosen, 1993). He came to the conclusion that “religion is man acting as the inclusive scientist searching for what is most real and lastingly valuable” (Rosen, 1993). He went on to say:

The whole person is one . . . who can find meaning; come through suffering, commit to trust and love and deal effectively with stress and the stress emotions of anxiety, anger, guilt, shame, and grief. From this matrix there emerges the “Witnessing Self” able to apply the powers of meditation and finally to reach a sense of compassion and unity with the universe, the ultimate goal of meditation. We can help our patients by seeing and affirming these issues or helping the patients to grow in them. The cognitive aspect of spirituality is accessible to our understanding and use. There is also an energy aspect, the ‘Spirit’ or spark of life that can be felt, but I think we need to learn more about it if it is to be controlled and used in helping (Rosen, 1993 p. 77).

In an effort to integrate spirituality into medical care, a recent consensus conference, *Improving the Quality of Spiritual Care as a Dimension of Palliative Care*, recommended the following definition of spirituality:

Spirituality is the aspect of humanity that refers to the way individuals seek and express meaning and purpose and the way they experience their connectedness to the moment, to self, to others, to nature, and to the significant or sacred (Puchalski et al., 2009, p. 887).

This definition includes the critical elements of connectedness, meaning, and the search for the significant and the sacred in life. These elements have theological, philosophical, empirical, and clinical dimensions. From the clinical and public health points of view, it is important to realize that spirituality thus understood will intersect with modern concepts of health-promoting human resiliency, which emerges from neurobiological substrates in the brain, motivation and reward circuitries, and paralimbic cortices that have the capacity to inhibit amygdalar fear conditioning.

The Consensus Conference recommended implementation of an inpatient spiritual care model that would include

In the outpatient setting, a spiritual history might lead to a chaplaincy or spiritual care provider referral. Existential concerns, particularly at end of life, feelings of abandonment by God or others, anger at God or others, concerns about relationship with deity, conflicted or challenged belief systems, despair/hopelessness, grief/loss, guilt/shame, reconciliation, isolation, religious-specific issues (ritual needs or inability to perform usual practices), and religious/spiritual struggle issues (loss of faith or meaning; disappointment with community aide) are common spiritual *diagnoses* that can trigger a clergy, chaplain, or pastoral counselor consultation (Puchalski et al., 2009, p. 894). It is important to realize that spiritual challenges are really threatened loss of connectedness.

The emotional center of the brain—the limbic system—is essential to the experience of illness. The limbic system brings emotional valence to the patient's cognitive appraisal of the crisis of illness and its meaning. Genetic endowment

The limbic system mediates the basic drives to self and species preservation, attachment behavior, and territoriality (MacLean, 1990). Thus, while the cortex may cognitively appraise the illness and its threat, the limbic system is buffeted by turbulent undercurrents of fear of excessive dependency and the possibility of a final separation from life and loved ones through death. This threat will be appreciated in a fear-conditioned amygdalar response that can then precipitate a lateral hypothalamic stimulation of sympathetic nervous system drive and a paraventricular hypothalamic stimulation of the pituitary-adrenal outpouring of adrenocorticotrophin and cortisol. When persistent and/or overwhelming, this distress response will be pathogenic to end organs. Clinically, this existential condition may give way to symptoms of anxiety and depression, the end-state of which might be conservation-withdrawal with disengagement and inactivity signifying a given-up state (Ironsides, 1980). Territoriality is threatened by illness

Figure 18.1 Proposed Spiritual Care Implementation Model. (From Puchalski et al., 2009)

when patients are removed from their homes, have their clothes taken away, and are forced to yield an element of control to strangers. The need for basic trust is heightened, while attachments are strained as patients are separated from family members both literally and symbolically. The amygdala, hippocampus, and thalamocingulate areas, among other limbic regions, mediate these experiences (LeDoux, 1996). The emotionality of the illness affects perception of predicament and allocation of cognitive focus, whether as “threat-stress” or as “opportunity-challenge.” Spirituality and religion, to the extent that they promote conscious positive expectation and the resiliency of connectedness, may serve to promote healthy adaptation to illness. Human resiliency is a product of the maturity of certain brain regions that can serve as brakes on a runaway amygdala-driven fear conditioning pathway (Charney, 2004). A healthy brain reward and brain motivation pathway, with terminal zones in the hippocampus and nucleus accumbens in the former case and in the anterior cingulate cortex and the dorsolateral prefrontal cortex in the latter case, will afford the individual a better chance of living life with pleasure, happiness, optimism, purpose, meaning, and conscious positive expectation and belief in the future. A healthy anterior cingulate will also provide the necessary feedbacks that encourage social support and prosocial behavior, which are also essential components of human resiliency. And finally, when these prefrontal and paralimbic cortical regions are capable of doing their jobs well, they will be able to modulate amygdalar responses and thus help the individual avoid the metabolic wear and tear of the distress that has its common source in human separation fear. Spirituality is another term for how we can enhance our brain’s capacity to achieve resilience through the strengthening of our connectedness to a source(s) of solace and nurturance, resulting in social support and in belief in a more benign future (Fricchione, 2011a,b). Spiritual and religious exercises such as meditations that can provoke an oceanic feeling of loss of self consciousness, coincident with deep connection to something greater than oneself, can enlist other areas of the brain such as the right parietal lobe in addition to prefrontal and paralimbic regions (Newberg & D’Aquili, 2001).

When asked what the worst part of their illness experience is, most patients will give answers that reflect the fear of separation and loss of attachment (Fricchione, 2011a). What seems like anxiety and depression, as described above, is perhaps better understood as a threat to the attachment to loved ones and life itself that all humans share. Family members also share the challenge of this separation. Here is an exchange with the wife of a terminally ill man in the throes of his final struggle with glioblastoma multiforme:

All three doctors decided I should stop giving John the chemo, for it is not fair to put him through it. I was glad I did not have to make that decision, but all three agreed that was best. No one knows, but they think John has a few weeks. My prayer has always been if the Lord takes him, John will be confused and

never have to say goodbye to his girls. It looks as if that prayer will be answered, for he is not aware he is ill but he does feel love all around him. I pray John will go peacefully as if he was going to sleep. We are keeping him at home. The girls and I are heartbroken, but we would never wish for John to suffer, and he can not even hold his head upright. My head hurts from crying, so I will write more tomorrow, but I had to tell my

best friend.
Love, Mary

Berlin (1986) has written about the practical implications of this emotional reaction to separation, which links the intellectual and emotional missions of religion and medicine, holding out the hope for an integration of medicine with patients’ spiritual lives. He suggests that it is essential that during hospitalization, patients find an atmosphere conducive to the formation of supportive attachments and that with the resultant reduction of distress, the chances of recovery from illness may be enhanced (Querido, 1959). In the same vein, patients who enjoy a sense of spiritual connection may experience a reduction in distress. In the “intermediate area” between separation and attachment that illness creates, spirituality in medical care can thus be examined and nurtured. The power of positive religious belief can be real and indeed may promote healing in some patients. The proinflammatory cytokine interleukin-6 may mediate some of these effects. Its rise correlates with spiritual struggles, and its reduction has been associated with religious attendance (Lutgendorf et al., 2004; Koenig et al., 1997).

From the perspective of what might be called the psychosomatic or mind–body medicine hypothesis, distress in response to a crisis (becoming more pathogenetic when chronic) is processed in limbic and cortical brain areas, resulting in “stress response system” (hypothalamic-pituitary-adrenal axis; locus coeruleus-sympathetic nervous system; vagal complex-visceral nervous system) and immune system changes that may predispose to or exacerbate disease states (Chrousos & Gold, 1992; Reichlen, 1993). Human physiology will seek a state of stability as a result of change, called *allostasis* (McEwen, 1998). To the extent that spiritual and religious behavior on the part of the patient and spirituality in the patient–doctor relationship mollify distress, there may be “downstream” effects that promote health, above and beyond the epidemiologic effects of a healthier lifestyle, better diet, and improved compliance. The placid state achieved through spirituality in the patient, the family, the staff, and the doctor may rekindle the “remembered wellness” of “secure base attachment” in the midst of illness-induced separation anxiety and depression (Benson, 1996; Bowlby, 1969). A less stressed, neurobiologic equilibrium may then promote healing. Human health requires secure attachment because it is part of our mammalian evolutionary heritage. Our brain’s reward and motivation circuitries in the setting of secure attachment provide us with survival advantage,

which in part results from the more metabolically efficient allostatic mechanisms associated with modulation of the stress and immune response systems.

Freud, to his credit, attempted to address the innate human fear of separation head on, so to speak. He contended that there is a mature “reality principle” according to which one realizes that life has no purpose and that the pain of separation must simply be endured. This endurance can be aided through “powerful deflections” such as scientific endeavors; “substitutive satisfactions” such as the “illusions in contrast to reality” provided by art; and “intoxicating substances” such as narcotics, alcohol, and cocaine (Freud, 1961). Then there is religion, whose technique, to quote Freud, “consists in depressing the value of life and distorting the picture of the real world in a delusional manner—which presupposes an intimidation of intelligence” (Freud, 1961, p. 36).

All of these approaches allow humans to tap into an ability to deny (or at least to hold in abeyance) the idea of their own death with its specter of purposelessness and to limit reflection on the myriad contingencies that may hasten death. Some approaches are more adaptive than others; indeed, pathogenic stress can be reduced by adaptive denial with documented health benefits (Hackett & Cassem, 1968; Levenson et al., 1989). Of course, psychoactive drugs still provide a popular strategy. This is reflected in Sydenham’s famous remark: “Among the remedies which it has pleased Almighty God to give to man to relieve his suffering, none is so universal and so efficacious as opium.” But drugs have many side effects, not the least of which is the potential for hastening the patient’s demise.

Understood in this light, Marx’s intended epithet that religion is the “opium of the masses” becomes a compliment. Ultimately, not even science as a powerful deflection or, as Yeats called it, “the opium of the suburbs,” can soothe the individual with severe illness who is facing death. In the midst of such an illness-induced threat, the typical patient moves from the suburbs and takes his or her place in an existential ghetto of need and sorrow. This is a corollary to the anecdotal common wisdom, “There are few atheists in a foxhole.”

RESEARCH ON RELIGION AND SPIRITUALITY IN HEALTHCARE

We now consider some of the issues that pertain to religion and spirituality in the medical setting.

In the last quarter-century, researchers have focused more attention on the interface of spirituality, religious commitment, and medicine. Matthews (Matthews et al., 1993a, 1993b; Matthews and Larson, 1995; Matthews and Saunders, 1997), Koenig (Koenig et al., 2001), and others (Chatters, 2000) have reviewed what has become a large literature. While the American people are highly religious and even participate in religious healing activities, healthcare providers are frequently less religious, leading to the neglect of religious factors in medical practice and the neglect of religious variables in clinical research (King & Bushwick, 1994; Maugans & Wadland, 1991; Waldfogel, Wolpe, & Shmueli,

1998). Furthermore, research into the provision of spiritual care to patients with advanced illness indicates that a majority do not feel their spiritual needs are being supported by the medical system (Balboni et al., 2007). Balboni et al. (2007) found in a study of 230 advanced cancer patients that most (88%) considered religion to be at least somewhat important. Nearly half (47%) reported that their spiritual needs were minimally or not at all supported by a religious community, and 72% reported that their spiritual needs were supported minimally or not at all by the medical system.

The importance of religious and spiritual needs and resources of 51 psychiatric and 50 medical-surgical patients were described by Fitchett and colleagues in a 1997 study. Three or more specific religious needs (average five), were reported by 88% of the psychiatric and 76% of medical-surgical patients. The most frequently reported needs were (1) expression of caring and support from another person, (2) knowledge of God’s presence, (3) prayer, (4) purpose and meaning in life, and (5) a chaplain to visit and pray. This study validates two major themes: illness uncovers existential vulnerability and clarifies for medical and psychiatric patients alike what the real limit questions are, and these questions are considered by most patients to be broadly spiritual in nature. Thus, in the context of the patient’s need for purpose and meaning when ill, the solace of relationships with caring individuals (physicians, nurses, and chaplains, as well as family members) and the consoling sense of a divine presence become important attachment resources. A significant majority of both psychiatric (80%) and medical-surgical patients (86%) defined themselves as spiritual, and more than two-thirds of both groups noted that religion was a source of great comfort and support.

There has still been a relative dearth of validated religious variables in clinical research, as noted by Matthews (1997). Over a 5-year period up to 1986, in 2,348 psychiatric studies, only 3% used a religious measure; and this was most often simply denomination. Only one study had used a validated measure of religious commitment (Larson et al., 1986). Of 603 *Journal of Family Practice* articles over a 10-year span up to 1988, only 4% used a religious measure and, again, only one used a validated measure (Craigie et al., 1988). And in a survey of 1666 *Clinical Research* abstracts, only 1% used religious measures and none used a validated tool (Dowell et al., 1993).

SOME SELECTED VALIDATED SCALES OF RELIGIOUS VARIABLES

A number of scales now measure dimensions of religious commitment including worship attendance, prayer, reading of scripture or other religious material, importance and meaning of religion in one’s life, intrinsic orientation toward religion, and intimacy with the patient’s concept of God (Matthews, 1997). For example, Koenig and his colleagues at the Duke University Center for the Study of Religion/Spirituality and Health devised the Religious Coping Index (RCI; see Koenig et al., 1992, 1995). The RCI studies the extent to which patients use religion to help them cope with the stress induced by illness. The RCI is composed of three items: (1) an open-ended question on how the person copes

with stress (a religious response is given a score of 10); (2) a self-rated item where the person rates on a visual analog scale from 0 to 10 the extent to which religion helps adaptation; and (3) an observer-rated item where the interviewer rates the patient on a 0 to 10 scale based on how much the person uses religion to cope. The RCI has a score range of 0 to 30.

While the term *religion* has usually been reserved for the beliefs, practices, and experiences entailed in a person's relationship to a purposeful God, it has in more recent times expanded to include such aspects of spirituality as a search for life's meaning and for answers to questions about human limitations, whether or not one takes part in traditional religious behaviors (Apolito, 1970). Kass developed a questionnaire called the Index of Core Spiritual Experiences (INSPIRIT) that measures experiences of the spiritual core (Kass et al., 1991). Kass went on to develop the Inventory of Positive Psychological Attitudes (IPPA), which assesses life purpose and satisfaction along with self-confidence during perceived stress. Comparing INSPIRIT and IPPA scores allows one to surmise the relationship between spirituality and well-being.

The Systems of Belief Inventory (SBI), developed by Holland and her colleagues, is a validated 54-item scale (Holland et al., 1998). The SBI seeks to combine the strengths of scales such as the RCI in defining aspects of religious behavior with the strengths of the INSPIRIT in measuring spiritual experiences.

One of the few validated instruments to measure existential well-being is the McGill QOL scale (Cohen et al., 1996).

THE EFFECTS OF RELIGIOUS BELIEF AND RELIGIOUS EXPERIENCE ON MEDICAL AND PSYCHIATRIC ILLNESS

Koenig (2001) acknowledges that religion can have negative effects on mental and physical health and cites the Jonestown and Waco tragedies, as well as situations wherein religious beliefs forestalled needed psychiatric care. He comes to the conclusion, nonetheless, that the evidence for positive health effects far outweighs the evidence for negative health effects. See Table 18.1 for a review of selected studies.

Table 18.1 SELECTED STUDIES OF RELIGIOUS EFFECTS ON HEALTH

<i>A. Substance Abuse</i>		
<i>Authors</i>	<i>Cohort</i>	<i>Results</i>
Desmond, 1981	248 males with opiate religiously Dependence	Those enrolled in long-term based treatment-significantly more abstinence (45% vs. 5%) from addiction to opiates over a year of follow-up, religiosity predicted lower alcohol and tobacco use
Adlaf & Smart, 1985	2066 High school students	More religious, less alcohol use
Amoateng & Bahr, 1986	16,130 High school students	More religious, less alcohol use
Moore et al., 1990	1014 Male med students	Lack of religious affiliation-strongest predictor of subsequent alcoholism in subsequent 16 years
Koenig et al., 1994a	2969 ECA participants	Weekly church attendance led to 29% of the risk of alcoholism during 6 months compared with less frequent attenders
Kendler et al., 1997	1902 White female twins	Religiosity predicted lower alcohol and tobacco use
Craig et al., 1997	101 Male VA patients	85% of those with no religious preference or non-mainstream preference had poor outcomes in a 12-step alcohol rehab program at 1 year follow-up while 63.3% (Protestants) and 70.1% (Catholics) had good outcomes
<i>B. Illness Coping and Life Adjustment</i>		
<i>Authors</i>	<i>Cohort</i>	<i>Results</i>
Cook & Wimberley, 1983	145 Parents of child cancer victims	80% comforted by religion: 40% with ↑ Religious commitment. Better physiologic and emotional adjustment
Conway, 1985–1986	200 Elderly families	91% used prayer to cope with medical illness; 86% thought of God or religious beliefs to cope
Kaczorowski, 1989	114 Advanced cancer	↓ State and trait anxiety correlated with (c/w) patients' spiritual well being (sex, age, use of support groups controlled for)
Burgener, 1994	135 Dementia caregivers	(1) Religious attendance significantly c/w general well-being and social functioning; (2) When spiritual needs met, mental health improved and caregiver stress decreased

(continued)

Table 18.1 (CONTINUED)

<i>C. Psychiatric Illness</i>		
<i>Authors</i>	<i>Cohort</i>	<i>Results</i>
Williams et al., 1991	720 Adults	Psychological distress inversely c/w religious attendance (age, sex, education, marital status, gender, race controlled for)
Koenig et al., 1992	850 Hospitalized veterans	Religious coping inversely c/w both self reported and observer measured baseline depression ($p < .001$) and depression risk at future hospitalization
Koenig et al., 1994b	2679 ECA participants	Church attendance c/w ↓ rates of psycho-pathology
Kendler et al., 1997	1902 White female twins	Religiosity predicted a lower risk of current or lifetime depression
Koenig et al., 1998	94 Elderly medical ill	Intrinsic religiosity (religious belief or experience) but not church attendance or private religious activities significantly and independently predicted shorter time to remission of mild to moderate depressive disorder
<i>D. Medical Illness</i>		
<i>Authors</i>	<i>Cohort</i>	<i>Results</i>
Hannay, 1980	1344 Outpatients	Monthly religious activity significantly c/w reduced medical ($p < .001$) mental ($p < .001$) and social ($p < .001$) symptoms
Byrd, 1988	393 CCU Patients	192 patients received intercessory prayer from prayer groups; 201 patients were un-prayed-for controls, prayed-for patients had better outcomes with less <ol style="list-style-type: none"> (1) Cardiac arrest (3 vs. 14, $p < .02$) (2) CHF (8 vs. 20, $p < .03$) (3) Pneumonia (3 vs. 13, $p < .03$) (4) Antibiotics need (3 vs. 17, $p < .005$) (5) Intubation need (0 vs 12, $p < .002$)
Idler & Kasl, 1992	2812 Elderly	Religiosity was inversely c/W subsequent disability ($p < .0013$) and c/w improved function ($p < .0014$) in this prospective study
Harris et al., 1995	40 Cardiac transplant Recipients	At one year post-transplant, religious beliefs and practices preoperatively predicted at the $p > .05$ level <ol style="list-style-type: none"> (1) Better physical function (2) Reduced health anxiety (3) Better compliance (4) Less overall anxiety (5) Higher self-esteem
Contrada et al., 2004	142 (115 men, 27 women)	Pre op Subjective intrinsic religiosity in patients post cardiac surgery c/w fewer complications and shorter hospital stay, independent of biomedical and psychosocial variables
Benson et al., 2006	post- CABG: 604 (?intercessory prayer->yes) 597 (?intercessory prayer-> no) 601 (known intercessory prayer)	In? of prayer group, complications in 52% of prayed for vs 51% of non prayed for; in 59% of those certain about being prayed for vs 52% uncertain
<i>E. Mortality</i>		
<i>Authors</i>	<i>Cohort</i>	<i>Results</i>
Comstock & Partridge, 1972	91,909 Individuals	At least weekly church attendance c/w: <ol style="list-style-type: none"> (1) 50% fewer deaths from coronary artery disease (CAD) (2) 56% fewer deaths from emphysema (3) 75% fewer deaths from cirrhosis (4) 53% fewer suicides

(continued)

Table 18.1 (CONTINUED)

Enstrom, 1989	Mormon men	Mormons had half the cancer and heart disease rates of control populations
Gardner & Lyon, 1982	Mormon men	Highly observant Mormons had half the rates of cancer and heart disease as less observant Mormons
Berkel & de Waard, 1983	Seventh Day Adventists	Adventist men lived 9 years and women 4 years longer than general population. Adventists had 50% fewer neoplasms, 41% fewer episodes of cardiac disease
Zuckerman et al., 1984	225 Elderly, forced to move	In a 2-year prospective study religiously committed had twice the survival rate
Schoenbach et al., 1986	2059 In church	Participants c/w lower mortality risk from cardiac disease in persons ≥ 60 years of age
Goldbourt et al., 1993	Jews	In a 23-year study, Orthodox Jews had a 20% lower mortality from coronary artery disease than did other Jews
Oxman et al., 1995	232 Elderly patients	Those with strong religious coping leading to comfort more likely to survive 6 months post-operative. Mortality rate three times as high in those without religious strength. Mortality rate 12 times higher in those without religious strength who are also socially isolated
Strawbridge et al., 1997	5286 Individuals	Weekly church attendance over 28 years of study c/w improved survival (demographic, social, health factors controlled for)
Ironson et al., 2002	279 patients w/HIV/AIDS	High scores on a Spirituality/Religiousness Index c/w long-term survival, health behaviors, less distress and lowering urinary cortisol levels

Levin and Schiller (1987) also concluded from their review that religiosity does confer beneficial health effects. This benefit was seen across a wide range of disease and conditions. When comparing religious denominations, a relatively lower risk for cardiovascular disease, high blood pressure, stroke, certain cancers, inflammatory bowel disease, and for overall and specific cause mortality appears to occur in more behaviorally demanding groups such as Seventh Day Adventists, Mormons, Orthodox Jews, and the clergy of all faiths (Levin & Schiller, 1987). And, when individual characteristics of religious commitment such as religious service attendance are studied, there is a trend toward health benefit and reduced morbidity and mortality in those with greater religiosity. Studies of specific diseases support both of these observations. Levin guardedly concludes that there is an association between religion and health.

Some researchers, however, find no association. (Sloan, Bagiella, & Powell, 1999) Sloan and Bagiella (2002) feel many articles cited to support an association between religion and health are methodologically flawed or irrelevant to the association. For example, religiosity and spirituality are value-laden factors usually measured by self-report questionnaires, which are subject to a variety of subjective variables. In the 266 studies they reviewed, 83% included nonpertinent health benefits; for example, those related to lifestyle and not to anything specifically religious. Overlap with community activity and social engagement confounds the religious attendance literature (Sloan, 2005). What is meant by religious behavior and

spirituality in these studies is not specific. The lack of consistency in the findings suggests that there is no easy way to operationalize religiosity. Subjects who want to present themselves as religious may be prone to embellish their activity level in interviews. Sloan also takes exception to the host of outcome variables used in many studies because the number of variables makes the study vulnerable to the sharpshooter's fallacy—shoot your bullets into the side of a barn and then draw the bulls-eye. He concludes that there is no empirical basis for the assertions that religious involvement is associated with health benefits (Sloan & Bagiella, 2002; Sloan, 2005; Sloan, Bagiella & Powell, 1999). This is certainly most clear with intercessory prayer (prayers of others on behalf of the patient), which has not been shown effective in any well-designed study. For example, Benson et al. (2006) found no benefit of such prayers for cardiac surgery patients. In this study, some subjects were unaware they were being prayed for after bypass surgery. There was no significant difference between health outcomes in those who actually were being prayed for versus those who were not prayed for. Furthermore, those subjects who knew they were being prayed for showed a slight trend toward more complications.

Most recently, the epidemiologist Lynda H. Powell and her colleagues at Rush-Presbyterian-St. Luke's Medical Center reviewed 150 papers, eliminating those with methodological flaws (Powell et al., 2003). Sloan sees this paper as the most thorough review of the empirical evidence to date (Sloan, 2005). Powell and her colleagues conclude that there

is a strong, consistent, prospective and often graded reduction in risk of mortality in church/service attenders. After adjusting for confounding variables, this reduction in overall mortality risk reaches approximately 25%. However, the researchers found no link between religious depth and physical health, and in patients no evidence that religion or spirituality improves recovery; in fact, there is a suggestion that recovery is impeded, although religiosity may increase with severity of illness. More methodologically sound studies are clearly needed.

So, is the association between religion and health due to chance, bias, or confounding, or is it valid? It appears unlikely that the association is due to chance, given the variety and number of studies showing significant health benefits and the fact that large censuses and randomized samples were used in many of them (Levin, 1987, 1994). Levin points out that bias is also unlikely given the fact that prospective and retrospective and cohort and case-control studies with children and adults and a wide variety of denominations and demographics with acute and chronic conditions have been used.

The issue of confounding is another matter. It could be that psychosocial rather than religious factors are at work. Health-related behaviors attendant to religious belief, such as the eschewing of tobacco, alcohol, and drugs, and the adoption of a healthier diet and exercise may be operative in the benefits attributed to religious activity. Social supports must be considered, as they have been shown to buffer the effects of anger and stress (Henry, 1982; House et al., 1988). Belief, ritual, and faith may all produce a sense of calm and harmony and a sense of being loved that not only improve subjective health perceptions but also enhance health based on expectancies, providing a ripe field for placebo response effects.

Thoresen and Harris (2002) have concluded that religious and/or spiritual factors do appear to be associated with physical and overall health, but the relationship is most likely more complex and modest than some contend. Clearly, more research about specific factors at work will be needed. As Chatters (2000) puts it: "Such investigations must appreciate the multi-dimensional nature of religious involvement, reflect an awareness of inter- and intragroup variability that may alter the meaning and significance of religious factors, and use state-of-the-art methods, study designs and analytic procedures." Future research will require a component analysis that explores the features of religion and spirituality that intersect with health variables.

The question of whether religiosity facilitates health is complex and hinges on the potential association's strength (moderate to strong according to Levin (1994) but weak according to Sloan), consistency (repeatedly observed), specificity (a specific disease effect not found, rather general effects on morbidity and mortality), temporality (not conclusively demonstrated that cause [religion] precedes effect [health]), biologic gradient (dose-response relationship suggested but not directly inferable), coherence (difficult to assess how association coheres because of multiplicity of conditions and outcomes), experiment (little evidence available for religious behaviors, attitudes, and affiliations), analogy (exists in that other psychosocial constructs have exhibited causal disease

effects), and plausibility (an effect of religion on health is biologically plausible given what we know of behavioral medicine and neuroimmunology). Using these so-called Hill criteria, Levin concludes that the answer to the question of whether religion causes health is a promising "maybe" (Hill, 1965).

Perhaps the most provocative criterion for causality involves plausibility: is it plausible that religion contributes to health? As Koenig and Levin both argue, the health benefit of religion is not necessarily dependent on supernatural phenomena. What Levin (1994) prefers to call "superempirical discarnate force or power" leaves open the possibility that some currently immeasurable phenomenon (e.g., *prajna*, chi, life force, etc.) might someday become measurable. So while the causal element may be a superempirical natural energy, which is tapped into by religious or spiritual pursuits, we need not invoke this construct to explain a plausible biomedical connection between religion and health. Well-known physiologic pathways linked to psychosocial and behavioral mechanisms (healthier lifestyles, less substance abuse, greater social support) may offer health-enhancing salutary effects that buffer against the pathogenic changes of disease-related high-risk activity and stress. Nevertheless, even when the positive effects of social support are controlled, studies like that of Oxman and colleagues (1995) suggest that there is still a separate benefit attributable to a strong personal religious belief system.

A look at underlying brain mechanisms with special attention to how and why the brain evolved may help clarify these issues. Max Horkheimer (1970) proposed that, in the third millennium, if it is not plausible to have a relationship with "the totally other" then there is no meaning at all in life that transcends self-preservation. While the urge to be cured in medicine may flow from the desire for self-preservation, the urge to be cared for and to care in medicine must have as its wellspring a spiritual source of connectedness to something beyond ourselves.

THE BRAIN AND SPIRITUALITY

Over the last several years there has been interest in neuroimaging studies of spirituality, including both meditative techniques and religious belief. Based on cerebral blood flow studies using single photon positron emission tomography (SPECT), Newberg and his colleagues have assembled a schema to explain the neural circuitry responsible for spiritual and religious experiences reflected in meditation and prayer (Cohen et al., 2009; Newberg et al., 2003; 2001). To summarize, this circuitry is dominated by activation in the dorsolateral prefrontal cortex (DLPFC), anterior cingulate cortex (ACC), basal ganglia and thalamus. The assumption is that the prefrontal cortex (PFC) strengthens focus and attention; the ACC enhances empathy and social awareness; and the basal ganglia add better modulation of movement and emotional tone. The thalamus then can develop a heightened sensory perception of the world and our place in it.

The first functional magnetic resonance imaging (fMRI) study of meditation was undertaken in 2000 and found that this brain motivation circuitry was activated against the background

general inactivation of other brain areas (Lazar et al., 2000). Long-term practitioners of meditation compared to controls had significantly more consistent and sustained activation in the DLPFC and the ACC during meditation versus short-term practitioners compared to controls (Baron Short et al., 2010).

Recently, the neural activation patterns that correlated with religious belief and with nonreligious belief using fMRI were studied in 15 committed Christian believers and 15 nonbelievers (Harris et al., 2009). The subjects were asked to evaluate the truth or falsity of both religious and nonreligious propositions. In both groups, belief was associated with activation in the ventromedial PFC. It is of interest that this region is noted to be important for self-representation, emotional associations, reward, and motivational behaviors.

In an earlier fMRI study, researchers described three psychological dimensions of religious belief including perception of God's level of involvement, perception of God's emotion (love vs. anger), and doctrinal/experiential religious knowledge (Kapogiannis et al., 2009). Subjects rated 70 statements on a Likert scale providing conceptual dissimilarity ratings for pairs of statements regarding religious beliefs. Perception of God's involvement activated two right-sided anterior (lateral and medial frontal gyri) posterior networks. Love modulated the right middle frontal gyrus, while anger stimulated the left medial temporal gyrus. Religious knowledge, on the other hand, when doctrinal, modulated right inferior temporal and medial temporal gyri, as well as right inferior parietal, left middle cingulate, and left superior temporal gyri; and, when experiential, modulated bilateral occipital, left fusiform, left precuneus, and left frontal regions.

Thus, religious belief appears to engage neural networks involved with abstract semantic processing, imagery, intention, and emotional *theory of mind* processes, which mediate the cognitive ability to understand mental states in others. The process of adopting religious beliefs seems to somewhat depend on cognition/emotion amalgamation in the anterior insular cortices. Signal in the insula reflects rejection of religious statements deemed false (Harris et al., 2009).

It may help to see the relevance of this new data to our discussion if we briefly survey the neuroscience of this circuitry. Mega and his colleagues (1997) reviewed the anatomy and phylogeny of the limbic system, focusing on the paleocortical and archicortical trends as two "para-limbic belts," to use Mesulam's term (Mesulam, 1985) (see Figure 18.2, Ballantine et al., 1967). The paleocortical trend ending in orbitofrontal cortex is closely linked with development of the amygdala. The archicortical trend ending in the cingulate cortex is closely linked with the hippocampus and its development. While the paleocortical belt is best at analyzing object features, the archicortical belt is best at analyzing object locations. This coincides with the view of Pandya and Yeterian (1990) in their conceptualization of two primordial moieties in brain evolution specialized for "what" (piriform-insular) and "where" (hippocampus) questions.

The paleocortical progression ultimately involves hippocampus-cingulate connections. Area 24 of the anterior cingulate cortex (ACC), with many overlapping reciprocal connections with the medial orbitofrontal cortex (MOFC),

is the intersection or the "nexus in the distributed networks subserving internal motivating drives and externally directed attentional mechanisms" (Mega et al., 1997, p. 323). It is a candidate zone for where the divisions of the limbic system work in concert to unite perceptions, internal relevance, and meaning with external attention to facilitate response selection. Thus, in the ACC we find the integration of paleocortical data, concerned with answering the "what" questions of life, with archicortical data pertaining to the "where" questions. Given the MOFC's intimate overlapping relationship with the ACC, it may be that they work in tandem to synthesize object feature and object location importance.

The limbic basal ganglia-thalamocortical circuit's cortical terminal zones are the ACC and MOFC, from the point of view of the functional neuroanatomic circuits proposed by Alexander and his colleagues (1990). Saver and Rabin (1997) suggested a "limbic marker hypothesis for religious-mystical experience," in which the limbic system signifies certain exteroceptive or interoceptive stimuli as numinous and meaningful. Of course the medial temporal lobe limbic zones have long been cited as important in this regard, due to the deeply felt experiences of those with limbic region seizures. But it would seem that the ACC and MOFC "limbic" cortices would be essential for spirituality given that the integrative "what" and "where" function they subserve could be applied to the larger context of universal concern in order to achieve such sensitivity.

Whether one ascribes to MacLean's "triune brain" or to Butler's "four brains in the forebrain" view of brain evolution, the clearest finding of central importance to the development of spiritual experience is the fact that the mammalian attachment strategy is a product of the evolution of what is called the *lemniothalamic-medial division of the dorsal pallium* (MacLean, 1990; Butler, 1994a,b). This results in the uniqueness of such medial limbic divisions as the thalamocingulate, which, as MacLean points out, is responsible for the mammalian behavioral triad of maternal nurturance, the infant cry of separation, and play.

With this background in brain evolution, we can hypothesize that there was indeed an evolution of basal ganglia-thalamo-"cortical" loops (Fricchione, 2011a). Primitive periallocortical loops were followed by an overlaying of proisocortical loops, culminating in isocortical circuits as afferentation from the thalamus moved into expanding cortical zones with return connections to basal ganglia and thalamus. In this context of evolutionary loop design, one sees a progression in function from earlier, more primitive levels of attachment behavior in terms of attraction to sources of food and repulsion from predators and in terms of attraction to potential sexual mates, on upward to the ACC/MOFC and prefrontal cortical loops and their mediation of familial and social attachments (Schore, 1996). The thalamocingulate connection, based on lesion and morphine experiments, is thought by MacLean to be particularly important for the development of what he calls a "memory of the past," given the key role played by the mammalian behavioral triad in our evolutionary survival strategy.

Figure 18.2 A Candidate Neurocircuitry for Spiritual Connectedness. (Adapted from Ballantine HT, Cassidy WL, Flanagan NB, & Marino N. (1967). Stereotaxic anterior cingulotomy for neuropsychiatric illness and intractable pain. *Journal of Neurosurgery*, 26, 488–495, p. 491; see also Fricchione, 2011a, p. 123).

While the ACC/MOFC loop refines brain reward circuitry and its emotional valencing to form a “memory of the past” as it pertains to mammalian behavioral attachment, the dorsolateral prefrontal cortical (DLPFC) loop also makes a major contribution (Fricchione, 2011a). The DLPFC was an outcropping, to a large extent, from both the ACC, which itself developed from the hippocampal moiety, and the insular cortex from the piriform moiety. As such, the DLPFC provides increasingly complex versions of the “where” and “what” questions as they relate to the separation/attachment process. “Where am I?” the organism asks, in relation to an object of attraction/attachment or repulsion/separation. Am I close enough to receive the positive reinforcement of ACC pleasure, or am I too far away, and as a consequence do I feel the negative valence of the pain of separation? Furthermore, what is the object to which I am attracted or repulsed? Is it truly an object to be attached to, or should I separate from it? These essential separation/attachment questions, which even the simplest of organisms must address in terms of sensorimotor behavior, become enhanced and refined in the complexity of the newly evolved basal ganglia thalamocortical loops (Fricchione, 2011a).

The human PFC maintains the *future action programs* for cognition and behavior (Ingvar, 1985). Because these action programs can be stored and retrieved for future use, Ingvar terms them “memories of the future” (Ingvar, 1985, p. 127). In the extensive connections of the DLPFC to the ACC and the connection of them both to the medial temporal lobe memory system (hippocampus) and

association cortices, the network from “memory of the past” to the “now-situation” to “memory of the future” is set (Fricchione, 2011a). The memory of past attachment serves as an attractant in the formation of our memory of the future. Humans tend to long for relationships that are associated with attachment security and solace. Once mammals who have adopted an attachment strategy for survival become conscious of their memory of the past in relation to memory of their mortal future, “paradise” is lost. Conscious mammals will always be beset by the knowledge of the tree of good and evil, namely that what they face is separation from those they love.

Thus, humans with their PFC expansion, which remains intimately connected with the past evolutionary loops associated with amygdala food status (LeDoux, 1996) and sexual reproductive attachment, and moreover with cingulate maternal, familial, and social attachment, can think into the future and gain survival advantage. Humans can also anticipate their exquisitely painful future separations and, by extension, plan how to avoid them.

However, in this evolutionary development a bargain has been joined. The price paid for anticipatory abilities that promote attainment of high attachments is the knowledge that there exists a seemingly final separation: death.

The person suffering with illness feels this *archetypal separation anxiety* (Fricchione, 2011a,b). Ironically, the birth of our spiritual drives derives from our unique ability to contemplate and affectively experience the meaning of separation and attachment.

IMPLICATIONS FOR THE DOCTOR-PATIENT RELATIONSHIP (PRAGMATIC APPLICATIONS FOR MEDICAL PSYCHIATRIC PRACTICE)

A patient's communion with family, friends, doctors, nurses, and other staff, along with religious observances, sacraments and prayer, contemplation, and meditation, facilitate attachment solutions to the separation problem of illness (Fricchione, 2011b).

Understanding brain evolution and the design of increasingly advanced basal ganglia thalamocortical loops enhances the development of a model of how spirituality or "spirito-taxis" can work downstream to alter physiologic functioning at the level of organs and tissues (Fricchione, 2011a). In such a scenario the corticolimbic interrelatedness among the loops exerts an overall modulatory effect on the stress response systems. Stress-system changes will then have important stabilizing regulatory effects on organs like the heart, and tissues like the immune system. The purpose of this control is to ensure metabolic economy in the face of internal and external pressures. While it is healthy to exert energy in the course of an acute illness challenge, it is necessary to have control mechanisms to modulate these energy responses when the acute stressor abates. Perhaps spirituality works downstream to help us make the most of our metabolic flow, improving modulation and the pliancy of stress and immune response potential. For example, Koenig et al. (1997) found an association between higher levels of interleukin-6, a cytokine associated with inflammatory response syndrome, and low church attendance. Others have found a relationship between spiritual struggle and IL-6, with preoperative spiritual distress associated with elevated preoperative IL-6 and post-cardiac surgery depression (Ai et al., 2010). Perhaps enhanced and refined attachment experienced in the spiritual and caring relationship works its way down the evolutionary chain of complexity, establishing a consonance of purpose at each level, thereby reducing the stress associated with isolation and loss of control. This should eventually be testable.

PRACTICAL CLINICAL IMPLICATIONS

To facilitate access to the potential positive aspects of the spiritual experience of connectedness in the midst of illness, physicians, including consultant psychiatrists, need to become more comfortable with exploring this area with their patients. Patients' psychological struggles with their illnesses can be more fully understood only when spiritual aspects of their lives are discussed. For patients who are not "psychologically minded," often to the point of being embarrassed or offended by the prospect of a psychiatric visit, a spiritual discussion can often detoxify the experience and pave the way toward "transitional relatedness" and a healing interaction (Horton, 1981). *Transitional relatedness* refers to the capacity of a caregiver to remain supportively connected to another person who is feeling torn away from all attachments. It requires the commitment to provide loving care by accompanying the patient into

an "intermediate area" between threatened separation from and safe attachment to loved ones. This relatedness provides insight into a patient's spirituality and can be used by the physician and consultant psychiatrist to develop treatment approaches that will strengthen coping, enlist the benefit of belief, and improve compliance (Waldfoegel & Wolpe, 1993).

It is essential not to predispose patients to a sense of guilt over not "being good at" religious practices and spiritual belief. We must avoid at all costs imparting to them a sense of responsibility for any worsening of their illness process, as if a failure of their spirituality and belief could cause such a downside. Moreover, spirituality is not a substitute for adherence to mainstream medical and surgical management.

Religion can be maladaptive as well as adaptive in terms of its impact on health (Jarvis & Northcott, 1987). Repression and overcontrol, especially in certain religious cults, can be destructive. Instead of tranquility and peace, such religious narrow-mindedness can lead to fear, prejudice, obsessive-compulsiveness, and even paranoia (Koenig, 1997). Dire physical consequences may ensue when competent members of certain religious groups (e.g., Jehovah's Witnesses and Christian Scientists) decline medical treatment (Coakly & McKenna, 1986). A psychiatric consultant will sometimes be needed to render a medical-legal opinion regarding the capacity of an individual to refuse treatment (Appelbaum & Grisso, 1988). In the case of Jehovah's Witnesses, a common dilemma for physicians and surgeons involves their 1945 decision to refuse blood transfusions on the basis of their communally held beliefs that blood cannot be taken in as nourishment (Panico, Jeng & Brewster, 2011). This belief is based on their interpretation of two biblical passages, one from Genesis and one from Leviticus. They will, however, frequently accept various coagulation factors as well as fractions of plasma such as albumin, cryoprecipitate, or immunoglobulin. Ever since the decision in *Schloendorff v Society of New York Hospital* in 1914, adults who have the capacity to give informed consent have the right to refuse medical treatment, and this legally holds in the case of a Jehovah's Witness who refuses a blood transfusion. When dealing with a Jehovah's Witness patient it is advisable to have extensive conversations about procedures and their risks and benefits and to document them as soon as possible in the chart. Making contingency plans regarding potential acute blood loss situations that can minimize blood loss, increase blood production through the use of erythropoietin stimulating agents, and optimize hemodynamic parameters is essential. After helping to determine if the patient has capacity to refuse, consultation psychiatrists can work with the team to provide support to the patient, family, and staff, and can work together with the Jehovah's Witnesses' Hospital Liaison Committee and Visitation Groups to provide comfort even though the psychiatrist may strongly disagree with the decision that has been made. The team may also work with the church's Hospital Liaison Committee and the church elders when the psychiatrist has questions about whether a particular patient's refusal of treatment is based on religious delusional material that lies outside of the commonly held canon of beliefs.

In a nonemergency, a competent adult patient who refuses blood on religious grounds must sign a Release of Liability for Blood-Free Treatment. If he or she has a minor child or is pregnant, the patient must also complete a Statement Regarding Arrangements for Care of Minor Child, to be used in the event of the patient's death. If the patient does not do so, or if there are questions about the suitability of any person named as caretaker, the hospital counsel should be consulted before treatment proceeds. In an emergency, the physician should honor refusal of blood if an adult patient is able to understand the risks of that refusal.

The decision to let adults make medically harmful decisions does not extend to their making decisions on behalf of their children. Parents of minors are not permitted to refuse lifesaving treatments that their children need, and physicians must alert their legal departments and seek guardianship when this occurs. In emergencies involving minor children, the law has always protected physicians who act to save the child's life regardless of religious opposition of the parents. In nonemergencies, legal counsel should be obtained before ever overriding parental or guardian religious protests.

A pregnant woman presents a complicated legal situation because of the state's interest in the fetus's life. In the latter stages of pregnancy, the administration of blood may be justified to preserve the life of the viable fetus. Before proceeding with treatment, the hospital counsel should be consulted. After delivery, the mother has the right to refuse blood for herself unless any minor child would be abandoned if she died. The courts have stated that the state's interest in the welfare of children will override the parent's or guardian's right to refuse blood on behalf of a child who is under 18 years of age. In an emergency, the hospital will administer blood over parental objection if necessary to preserve the life or health of the child. In other situations, before proceeding with treatment the hospital counsel should be consulted to determine whether court intervention is necessary. The courts have consistently overridden parental refusal of lifesaving medical interventions for children when they are refused by parents on religious grounds. In the emergency treatment of children in urgent life-threatening situations, physicians are essentially immune from liability if they proceed without parental consent.

Parents or guardians, therefore, may not refuse lifesaving treatment on behalf of their minor children. This principle has been defined in cases involving parents who, on religious grounds, refused blood transfusions necessitated by chemotherapy for their child, and parents who treated their son's bowel obstruction with prayer, resulting in the child's death. If parents refuse lifesaving treatment, the physician should consult with the hospital attorney to discuss the advisability of court intervention if time permits. In a medical emergency where death or a serious worsening of the minor's condition will occur without immediate treatment, the physician should always render treatment despite the lack of parental consent.

While overriding the parental decision to refuse treatment of a child based on religiously derived wishes is more clear-cut in acute life-threatening situations, cases in which the child suffers from a chronic, more insidious disease are

more problematic. In these latter situations, the consultation psychiatrist might advocate for maintenance of a therapeutic alliance with the family despite this special form of noncompliance. This is in some ways akin to what many diabetologists must do with patients with type I diabetes and their families, forgoing in the early stages of treatment the temptation to demand tight control and high compliance in favor of maintaining a therapeutic alliance. This maintenance of contact may allow for the physician's message, threatening at the outset, to gradually gain some degree of acceptance. It also allows the team to better anticipate impending acute emergencies so that lifesaving medical treatment can be delivered whenever necessary.

Individual adults outside of an organized religious body who suffer from religious delusions—idiosyncratic, fixed, false beliefs, often with an unusual supernatural theme—may be found by the psychiatric consultant to have diminished capacity to refuse treatment (Stotland, 1999).

SPIRITUAL ASSESSMENT

As mentioned in the Consensus Conference on Spiritual Care, all patients can benefit from simple spiritual screening at the point of entry into healthcare systems (Puchalski et al., 2009). This should be followed when appropriate by spiritual history taking and by spiritual assessment, which might then evoke a multidisciplinary spiritual care plan. Spiritual screening can be achieved with simple questions such as, "Is spirituality or religion important in your life" and "how well are these resources working for you in these times?" Next there is spiritual history taking, and there are now several bedside approaches available to clinicians. One that has become popular is the *FICA* method (Puchalski & Romer, 2000). In this approach the patient is asked four questions: "What is your faith or belief?" "Is it important in your life and does it influence you?" "Are you part of a religious or spiritual community?" and "How would you like me, your healthcare provider, to address these issues in your healthcare?"

In order to examine a patient's inner spiritual life, one may ask questions like these that come from the suggestions of Ned Cassem, former Psychiatrist in Chief at the Massachusetts General Hospital (Cassem, 1997):

- Which books hold special meaning for you?
- How do you want to be remembered?
- How would you rank the common virtues?
- Are there things you are especially proud of?
- Who are your role models?
- Who are your friends . . . and enemies?
- Is there anyone whose interest you would put ahead of your own?
- What are your strongest and weakest qualities?
- What would you like to be free of?
- Who are the people who see you at your best?

- Do you have an ideal sense of who you would like to be?
- Do you have a code or a rule to live by?
- Have you ever had a sense of union or closeness with God?

The enrichment of the patient–doctor relationship that emerges in the dialogue around questions like these adds to the spiritual strength of the “vulnerable self,” as Avery Weisman called it, and aids in the search for meaning in the midst of illness.

When spiritual distress—such as existential concern, a sense of abandonment by God, anger at God, challenged belief systems, despair, grief at loss, guilt or shame, need for reconciliation, isolation, ritual needs, and struggle over loss of faith or meaning—is appreciated, a request for a formal spiritual assessment by a board certified chaplain or pastoral counselor may be made.

CHAPLAINCY REFERRAL

In most instances when patients are not critically ill, it will be enough to do a spiritual screening and to gather a religious history, gauging whether these assets and strengths are available to the patient and determining if a chaplaincy visit is required or desired. A hospital chaplain is a cleric or layperson commissioned to provide pastoral care at a healthcare institution. Chaplains at most medical institutions require ecclesiastic endorsement, ordination or commission, and theological training. Many are certified for competency by chaplaincy organizations. By contrast, a pastoral counselor is a minister, priest, or rabbi, presumably with some formal training in counseling. Ideally, pastoral counselors integrate their mission of pastoral care with the behavioral sciences in an outpatient setting. Certification by the American Association of Pastoral Counselors requires religious endorsement, training in theology and the behavioral sciences, and counseling skills. There are some helpful guidelines physicians can follow in making chaplaincy referrals, providing the patient is agreeable (M. Means, personal communication; W. Moczynski, personal communication). Appropriate for referral are requests for:

- Prayer, religious rites, sacraments, a memorial service, devotional literature, prayer books, rosaries, Bibles, and other religious materials, initiated by the patient or family
- Emotional support and comfort
- Notification of local clergy
- Support regarding imminent death of a patient
- Support regarding ethical dilemmas
- Support regarding death of a patient’s family member
- Aid in dealing with visiting clergy or a difficult religious group
- Aid when spiritual screening and history gathering reveal spiritual distress or religious issues, or concerns that create problems for patients

The spiritual care specialist can devise a spiritual health intervention that will contain therapeutic communication techniques (compassionate presence, reflective listening, life review, support enhancement, and nonabandonment), therapies (guided visualization, storytelling, dignity-conserving therapy, meaning-oriented therapy) and self-care (spiritual readings, reconciliation, journaling, art, music, relaxation response techniques such as yoga, tai chi, meditation) (Puchalski et al., 2009).

It is important to remember that consultant psychiatrists may sometimes find themselves in the role of gatekeeper, discouraging chaplaincy involvement because certain patients may have their conditions exacerbated in the face of religious hyperstimulation. Such patients may be in the midst of a psychotic episode, or they may be suffering from temporal lobe epilepsy or delirium.

Clearly, chaplains and clergy are often able to help patients deal with concerns about guilt, anger, faith, and family in powerful ways because of the important role well-trained chaplains serve. Given their specialized training, chaplains may see grief as multilayered, with the sense of loss not only emerging from the material life disengagement that serious disease engenders, but also from spiritual estrangement that serious illness may imply to patients with a religious background. But despite their lack of specialized knowledge, physicians should feel comfortable enough, when appropriate, to encourage religious behaviors such as prayer and spiritual exercises such as meditation to reduce stress and enhance resiliency if patients are receptive to these practices. Of course, it is obvious that spiritual and religious beliefs and practices are not for everyone and that the atheistic or agnostic approaches used by certain patients deserve the respect of the physicians and psychiatrists caring for them. Meissner (1984) described prayer as a creative cognitive pursuit that engages the prayor in a close personal relationship with the patient’s concept of God, “someone” who will not abandon them no matter how vast and threatening the universe feels. Meditation is a practice that can provide an affective experience of closeness with God and often merges with mystical religious experience. Both prayer and meditation may reinforce a personal attachment to the patient’s conception of Divine comfort and confidence.

When physicians ignore patients’ religious beliefs, their medical diagnostic assessment may be incomplete (Waldfogel & Wolpe, 1993). Conflicts may emerge in the clinical milieu unless the physician develops a sophisticated understanding of religion’s importance in the patient’s illness experience (Waldfogel & Wolpe, 1993, p. 474). Having a grasp of the patient’s underlying religious structure is therefore not only important to providing solace but also is needed for effective diagnosis and treatment. Toward that end, Waldfogel and Wolpe have adapted Glock’s typology of religious issues that includes the five dimensions of ideology, intellect, ritual, experience, and consequence, to which they have added a sixth dimension of support provided by attachment to a religious community (Glock, 1962). Incorporating knowledge of religious beliefs, participation in religious rituals, and affiliation with a religious community in a treatment plan can enhance the work of the consultation psychiatrist

and bolster a patient's coping ability. When we seek to understand patients along the spiritual dimensions mentioned, we see them within a larger context. This can facilitate patient movement "closer to a transpersonal source of meaning and to the human community that shares those meanings" (Waldfoegel & Wolpe, 1993, p. 476).

When patients are severely ill, the discussion of religious and spiritual issues will often engage doctor and patient in a spiritual exchange. Patients frequently seek information about the physician's religious attitudes. In medical settings, when not contraindicated by the patient's psychiatric diagnosis, rather than being a boundary violation some clinicians consider that providing personal spiritual information may solidify the patient-doctor bond at critical moments, offering the potential for a psychologically healing interaction. I (GF) recall an elderly Sikh man with colon cancer on whom I consulted for the question of depression. I had very little knowledge of the Sikh religion. Nevertheless, we had a dialogue about our spiritual lives and I came away admiring his particular religious commitment, his framework for understanding his predicament. As he came to know me as someone with a spiritual orientation, he seemed more at ease and relieved of the fear that his religious beliefs would be minimized or denigrated. This is a personal strategy, however, that some clinicians would not employ.

Psychiatrists who are not comfortable discussing their personal spiritual leanings, or lack thereof, may help their patients by acknowledging, when appropriate, the pertinence of spirituality in humanity's search for meaning while respectfully declining to discuss their own particular sentiments. Of course, seeing hospitalized patients on the consultation-liaison service is different from dealing with patients longitudinally in insight-oriented psychotherapy. Psychodynamic considerations usually preclude the disclosure of religious beliefs and spiritual orientation on the part of the psychiatrist. This is especially true when psychoanalytic techniques are being used or when working with personality-disordered patients where boundary issues are a particular concern. In our experience, issues of transference and countertransference are not usually significant limiting factors when patients with severe medical illness and their doctors in the hospital discuss spiritual interests. When people empathically face the seriousness of a separation threat, whether they are alike or different, they often come together to form an attachment solution and to discover common ground.

Medical and psychiatric trainees can benefit from education in how religion and spirituality affect the illness experience. To date, 49 medical schools and 32 psychiatric residency programs have received curriculum awards for courses in spirituality and medicine from the Templeton Foundation (GWISH.org).

SUMMARY

As noted earlier, Edward Churchill once said, "Charity in the broad spiritual sense, that is our desire to relieve suffering, is the most prized possession of medicine." Our relief of

suffering and thus the carrying out of the spiritual mission of medicine may be strengthened at the bedside by improving our understanding of the multisystem integration of the whole person in terms of the separation/attachment process (Fricchione, 2011b). Treatments can then be devised that enhance the patient's spiritual connectedness.

Regardless of the religious orientation of the consulting psychiatrist, mounting clinical data suggests that integration of religious and spiritual supports into the overall treatment planning of medically ill patients may relieve their suffering and is perhaps associated with improved coping and prognosis (Table 18.1). Religious counseling should be available to those patients who request or seem suitable for such interventions.

The human spiritual imperative or "spirito-taxis" is made possible by the evolutionary maturation of the brain motivation circuitry. Spirituality provides an important attachment solution to the anxiety and dysphoria associated with the separation challenge of illness and death. This is the place in medicine where science and religion have an opportunity to meet in conciliation and wonder.

CLINICAL PEARLS

- Patients encountering severe physical illness face what philosophers call the "limit questions": Who am I? What is the meaning of my life? Where am I going? Will I be separated from my loved ones?—questions that express universal existential concerns in the domains of identity, hope, meaning, purpose, morality, and relationship to ultimate authority.
- From an object-relations perspective (Horton, 1981), the physician acts as a transitional object, an object that can be held in the transition, offering solace that comes from "transitional relatedness."
- *Transitional relatedness* refers to the capacity of a caregiver to remain supportively connected to another person who is feeling torn away from all attachments. It requires the commitment to provide loving care by accompanying the patient into an "intermediate area" between threatened separation from and safe attachment to loved ones.
- Clinicians and patients meet in the most spiritual of all earthly places—the bedside.
- The placid state achieved through spirituality . . . may rekindle the "remembered wellness" of "secure base attachment" in the midst of illness-induced separation anxiety and depression (Benson, 1996; Bowlby, 1969).
- Mammalian attachment strategy is a product of the evolution of what is called the lemnothalamic-medial division of the dorsal pallium (MacLean, 1990; Butler, 1994a,b), resulting in the uniqueness of such medial limbic divisions as the thalamocingulate, which, as MacLean points out, is responsible for the mammalian behavioral triad of maternal nurturance, the infant cry of separation, and play.

- “Where am I?” the organism asks, in relation to an object of attraction/attachment or repulsion/separation. Am I close enough to receive the positive reinforcement of anterior cingulate pleasure, or am I too far away, and as a consequence do I feel the negative valence of the pain of separation? Furthermore, what is the object to which I am attracted or repulsed? Is it truly an object to be attached to, or should I separate from it? These essential separation/attachment questions, which even the simplest of organisms must address in terms of sensorimotor behavior, become enhanced and refined in the complexity of the newly evolved basal ganglia thalamocortical loops (Fricchione, 2011a).
- Ironically, the birth of our spiritual drives derives from our unique ability to contemplate and affectively experience the meaning of separation and attachment.
- Insight into a patient’s spirituality and can be used by the physician and consultant psychiatrist to develop treatment approaches that will strengthen coping, enlist the benefit of belief, and improve compliance (Waldfogel & Wolpe, 1993).
- In discussing religious issues, we must avoid at all costs imparting to patients a sense of responsibility for any worsening of their illness process as if a failure of their spirituality and belief could cause such a downslide.
- While overriding the parental decision to refuse treatment of a child based on religiously derived wishes (for instance, in Jehovah’s Witnesses) is more clear-cut in acute, life-threatening situations, cases in which the child suffers from a chronic, more insidious disease are more problematic. Here, the consultation psychiatrist might advocate for maintenance of a therapeutic alliance with the family despite this special form of noncompliance.

TECHNOLOGY IN TREATMENT AND PHYSICIAN-PATIENT COMMUNICATION

Steven E. Locke and Tristan Gorrindo

Patient: Well, my boyfriend made me come here.
Computer: YOUR BOYFRIEND MADE YOU COME HERE?
Patient: He says I'm depressed much of the time.
Computer: I AM SORRY TO HEAR YOU ARE DEPRESSED.
Patient: It's true. I am unhappy
Computer: DO YOU THINK COMING HERE WILL HELP YOU NOT TO BE UNHAPPY?
Patient: I need some help, that much seems certain.
Computer: WHAT WOULD IT MEAN TO YOU IF YOU GOT SOME HELP?
Patient: Perhaps I could learn to get along with my mother.
 –Excerpts from a patient–computer psychotherapy session conducted with ELIZA in 1966

INTRODUCTION

Psychiatry is no stranger to technology. When ELIZA, the computer-based therapist, was unveiled in 1966, many felt that this was the beginning of a new revolution in psychiatry (Weizenbaum, 1966). And while ELIZA's inventor, Joseph Weizenbaum, never meant for it to be a formal treatment tool, computer-assisted therapy would not become widely available for another four decades.

In a specialty devoted to interpersonal relationships, self-awareness, and the human condition, patients and providers have been skeptical about the role of technology in psychiatry. For many, technology doesn't seem a natural fit in psychiatry. And while many providers are now seeing the usefulness of electronic medical records and computer-assisted treatments, technology's greatest influence on psychiatry may actually be the way in which it has influenced the patient–physician relationship.

TECHNOLOGY AS TREATMENT

INTRODUCTION AND OVERVIEW

In 1965, a man walked into a laboratory at the University of Wisconsin and, without understanding the significance of his contribution, opened a new chapter in the history of medicine. Sitting in front of a 3" × 4" sapphire blue screen, he watched

the white letters as they spelled out questions: "Are you sitting down?" Using the keyboard of the PDP-9 computer, he typed, "No." The screen flashed, "Why don't you pull up a chair and make yourself comfortable." Using a script prepared by Dr. Slack, the computer inquired about symptoms and the patient responded, mimicking a clinician–patient interview. And so the field of patient–computer dialogue was born.

The introduction of technology into the doctor–patient relationship has always been ambivalently received as an intrusion. Although Laennec's invention of the stethoscope improved the physician's ability to make accurate cardiac diagnoses, this disruptive innovation introduced a lasting change in the doctor–patient relationship. Today a doctor no longer places his ear on the patient's chest to listen to the heart, but performs the auscultative exam in a brief, often perfunctory fashion in anticipation of detailed information captured by modern diagnostic technologies. How has psychiatric practice fared during the transformative onslaught of technology in the era of information-age medicine? Perhaps unsurprisingly, adoption of technology has occurred more slowly in psychiatry than in other specialties. In this chapter we will describe a variety of ways that technology has appeared in psychiatric care, both at the psychiatry/general medicine interface and in behavioral health in other settings.

COMPUTER-BASED PATIENT ASSESSMENT

Medical History Taking

Four years after the publication of Warner Slack's seminal paper on computer–patient dialogue, the computer-assisted medical history was first implemented in clinical care around 1970 by Morris Collen, director of research at Kaiser-Permanente (KP) in Oakland, California. Patients completed a paper history form that was designed to be machine-readable, producing an electronic record that became part of the patient's electronic medical record. The KP standardized history had the advantage of thoroughness and increased the likelihood that often overlooked psychosocial factors and habits would be investigated. Around the same time, Slack and Maultsby programmed a computer to take a psychiatric history from a patient (Maultsby & Slack, 1971). Soon after, John Greist and his colleagues developed a computer-administered psychiatric symptom checklist that measured change in clinical condition by tracking a patient's symptoms over time (Greist, Klein, & Van Cura, 1973). These

early pioneers and their collaborators spawned a generation of clinical researchers dedicated to studying the use of computers in psychiatry and mental health.

Mental Health Screening and Assessment of Behavior

The development of computer-based screening tools for behavioral symptoms and mental disorders in the 1970s was soon followed by the introduction of the personal computer (PC). The PC made it possible to not only automate the use of standardized measures of psychopathology for use in mental health screening, but also to efficiently disseminate these tools more widely. The exponential growth of Internet access and broadband availability in recent years has led to the migration of computer-assisted assessment of signs and symptoms of mental disorders, from the personal computer to the Internet. Currently, the widespread availability of Software-as-a-Service (SaaS) providers has made it possible for these assessment programs and their data to be stored in “the Cloud”—secure servers accessible from any Internet-connected device including tablet computers and smartphones. While such programs offer many advantages, including scalability, access, and the potential for linkage with institutional and personal electronic health records as well as use from the “medical home” of the future, remaining questions about privacy, confidentiality, and security must be resolved before adoption can be widespread.

Lee Baer, John Greist, and their collaborators conducted computer-assisted screening for mental disorders beginning in the 1980s using automated telephone interviews to query people about their experience of a standardized list of psychiatric symptoms, with the goal of identifying those individuals who might likely benefit from psychiatric evaluation and treatment (Baer et al., 1995). Since then, the use of automated methods for screening large populations for a variety of mental disorders including depression, alcohol abuse, and eating disorders has become widespread and is used in community, military, college health, and workplace settings (www.mentalhealthscreening.org). Increasingly, automated screening for depression, alcohol and substance abuse, and other behavioral conditions is being deployed by healthcare organizations, insurers, employers, and student health services (Farzanfar et al., 2011).

Computer-assisted assessment of patient behavior can supplement the evaluations done in primary care and specialty care settings, where clinicians are pressed for time and assessment of behavioral and psychosocial issues often is neglected in favor of other priorities. Mental health measures can be completed easily using tablet computers in waiting rooms, secure patient Internet portals, or commercially available automated telephone screening services. Unfortunately, these screening tools are underutilized relative to the scope of the problem of psychiatric comorbidity in general medical illness. Despite the well-established relationship between depression and poorer clinical outcomes in coronary artery disease (CAD), and the recommendation by the American College of Cardiology that CAD patients be screened for depression routinely (American College of Cardiology, 2010), many

CAD patients are not screened. Automated, computerized screening for depression could address this deficit. It is not known why this obvious solution isn't utilized; one possible explanation is that while the direct cost of automated screening is low, the indirect costs and systems problems related to following up the patients who screen in for depression discourage its adoption.

Obviously, interactions with machines are not, in general, substitutes for human contact and communication—but there are ways and contexts in which computer-based interviews have advantages over conventional clinical interviews. Computers are more reliable than human interviewers, they pursue questions inexorably without finding it tedious, and the extent of their queries is limited only by patient fatigue. They easily accommodate multiple languages and can be available 24 × 7 in diverse locations, and computerized services can quickly be scaled to serve large populations at a low incremental cost. Computerized systems can offer information and education using interactive multimedia in a way that continually checks patients' understanding of the material presented; human clinicians are encouraged to verify patients' understanding of their illnesses and treatment, but often do not have the time to do so. Finally, computer–patient dialogue may be of extraordinary value in contexts where patients are asked to disclose information of a sensitive, personal nature that might cause them shame or embarrassment if expressed to a human interviewer. Patients' preferences to make disclosures during a computerized interview have been shown regarding questions about substance abuse, sexual behavior, and sexually transmitted diseases such as HIV (Locke et al., 1992; Richens et al., 2010), suggesting that computers are experienced as less judgmental. For these reasons there is growing interest in systems that augment traditional clinical care by adding well-designed and clinically effective computer-based behavioral technologies, in the belief that such systems will increase access to behavioral healthcare in a variety of resource-poor settings, as well as improve quality and reduce health costs. One website, PsychCentral (www.psychcentral.com) is a frequently updated source of self-assessment tools that can be used with patients. Other websites are emerging, and a search at www.nimh.gov, nida.gov, or va.gov will lead to other useful validated tools that are available online and downloadable for use in clinical practice.

One approach to reach underserved populations without access to computers or the Internet is the use of interactive voice response telephony, or IVR. Robert Friedman and his colleagues at Boston Medical Center have been studying the use of IVR telephony at the intersection of primary care and psychiatry for two decades. Friedman and his team have based their work on the concept of a “virtual visit” in which a computer-based telehealth system (which they call “Technology Linked Care” or “TLC”) guides a patient through an interactive interview that (1) collects information via an automated interview, (2) uses algorithms and expert systems to make clinical inferences, and (3) provides automated psychoeducation, care management, and health coaching to guide patients to manage their symptoms or improve health behavior between office visits. This procedure takes place with no

human intervention at all—in contrast to applications that screen patients and quantify symptoms, or provide structured psychoeducation, but ultimately rely upon a human interviewer to confirm diagnoses and prescribe interventions. Their research has demonstrated the usefulness of the TLC model in the management of hypertension, promotion of dietary change, increased exercise, medication adherence, help with smoking cessation and abstinence from alcohol, and management of depression and other mental disorders (Friedman, Stollerman, Mahoney, & Rozenblyum, 1997). TLC has screened for depression, dysthymia, bipolar disorder, PTSD, acute stress disorder, generalized anxiety disorder, panic disorder, somatization, social phobia, alcohol and drug abuse, stress, and violence. Usually, after screening, the automated IVR system encourages the person to seek help, provides resources, and monitors adherence using follow-up calls to ensure help has been sought (Farzanfar, Stevens, Vachon, Friedman, & Locke, 2007). The widespread use of smartphones that offer significant computer power in handheld devices broadens the potential scope of phone-based interactive applications. For example, smartphone applications can collect and transmit physiological data as well as self-reports of symptoms. Mobile phone transmissions can offer a high level of security, and the incremental cost of using them is low because most patients already own smartphones and have phone accounts with data transmission capabilities. Low-income patients without computers or other Internet access often own smartphones or have family members who do. For these reasons mobile phones are likely in the near future to become the most widespread personal health appliances. Mobile platforms and smartphones can also be used in technology-supported self-care. A systematic review of five studies found that interventions that used text messaging to provide motivation, support, and tips for quitting smoking delivered by mobile phones can help people stop, though the results varied. Whittaker and colleagues reported that as of November 2012, there are no published studies on smartphone applications designed to help people stop smoking (Whittaker et al., 2012). Nevertheless, there are many new apps for various mobile platforms and smartphones that, despite being untested in clinical trials, claim to be useful adjuncts to a self-care program for reducing tobacco and alcohol use. A common theme in this book, detailed in almost all of the specialty-specific chapters, is that chronic medical conditions and mental disorders are frequently associated both in primary care and in specialty settings. When general medical illness is associated with a mental disorder—particularly with depression or clinical severity—outcomes are likely to be poorer and the cost of care is likely to be higher (Ciechanowski, Katon, & Russo, 2000; Katon, 1996; Katon & Ciechanowski, 2002; Roy-Byrne et al., 2008). The continually widening availability and decreasing cost of Internet-connected mobile devices argues for the routine integration of “behavioral informatics” into clinical practice, facilitating the identification and treatment of comorbid mental disorders in patients with chronic general medical illness. This is an emerging area in both research and development, and there are many product companies that are field testing their mobile devices in partnership with clinical providers and delivery systems.

Psychometrics

Beginning in 1962 the most widely used psychometric ever developed, the Minnesota Multiphasic Personality Inventory (MMPI), was offered in a machine-scorable format (Fowler & Miller, 1969; Pearson, Rome, Swenson, Mataya, & Brannick, 1965). At first, computers were simply used to scan, read, and score multiple-choice forms, but starting in 1986 programs were sold for installations on PCs that could administer the questions, one at a time, to patients sitting in front of a monitor and responding via a keyboard. A proprietary program generated a report that could be printed at the site of care or mailed to the supervising clinician (Biskin & Kolotkin, 1977; Johnson, Giannetti, & Williams, 1978; Russell, Peace, & Mellso, 1986).

Currently, hundreds of psychometrics can be administered over the Internet or via personal computers or Internet-connected mobile devices. Computers can also administer interactive tests, interviews, and questionnaires via the telephone using IVR (Rose et al., 2010; Turvey, Willyard, Hickman, Klein, & Kukoyi, 2007). Many of these tests, particularly those that have been validated and standardized using reference populations, are protected by copyright and available only through payment of a license or subscription fee. Best-known examples of these are the MMPI-2, the SCL-90R, the MINI, and the Beck Depression Inventory. In contrast, other psychometrics have been validated in clinical trials and are available as computer-administered tests in the public domain with no fee required. Examples of these are the SCL-90, the Hopkins Symptom Checklist, the CIDI, and the Alcohol Use Disorders Identification Test (AUDIT; see http://whqlibdoc.who.int/hq/2001/who_msd_msb_01.6a.pdf). Some widely used psychometrics are copyrighted but have been made available for widespread use without need for prior permission. The PHQ-9 (Kroenke, Spitzer, & Williams, 2001) is the best known example.

Computer-based tests and interviews can be administered for automated clinical assessment, including the use of standardized histories or symptom inventories. Such instruments or clinical assessment tools have the advantages of scalability, affordability, reliability and, ideally, validity. Properly developed, implemented, and deployed, they can be efficient ways to screen for behavioral symptoms or mental disorders in large or at-risk populations. The Patient Protection and Affordable Care Act (2010) mandates that screening for depression in primary care will be a public health requirement for public and private insurers, effective in 2014. This federal mandate presents both an opportunity and a challenge to improve the quality and integration of behavioral health into primary care during the next decade.

Physicians are increasingly interested in developing their own interactive interviews or questionnaires for use with patients over the Internet or collected by a tablet computer or kiosk. Most institutions have policies, procedures, and guidance that address the means for collecting patient-level data using tools such as Survey Monkey and REDCap in a secure and HIPAA-compliant fashion. Many professional societies have telemedicine committees and they may also be a source for guidance.

Psychophysiology

Applied psychophysiological research during the last century led to a variety of computer-based psychodiagnostic tools (EEG, fMRI, evoked potentials, PET scans, etc.) as well as somatic treatments (electroconvulsive therapy, transcranial magnetic stimulation, etc.) in use today. Beginning in the 1970s, however, a new field generally known as *biofeedback* emerged, following Neal Miller's seminal research on operant conditioning of the autonomic nervous system (Chen, Ju, Sun, & Lin, 2009). Biofeedback involved training patients to alter measurable physiological variables such as skin conductance, skin temperature, surface EMG activity, or EEG alpha power. Biofeedback was directed at psychosomatic conditions that seemed poorly responsive to the nonspecific psychodynamic treatments that were highly prevalent at the time. Microprocessor-based systems would amplify electrical signals from physiologic sensors, interpret them, and present the patient with simple graphical or auditory cues that would change in real time. Responding to these cues, patients could acquire control of bodily processes ordinarily outside of their awareness. Ideally this would lead to relief of symptoms associated with the physiological processes modified by the procedure, such as tension headaches or high blood pressure. Biofeedback, with its emphasis on self-regulation rather than the use of drugs, proved to be a practical route for the introduction of behavioral medicine into primary care practices during the 1980s and 1990s (Schwartz, 2005). However, it has not become a fixture in mainstream primary care medicine, probably because of its limited applicability and efficacy. Biofeedback, buoyed by the popularity of complementary and alternative medicine with its emphasis on self-regulation as an alternative to pills, became a beachhead for the introduction of technology into clinical behavioral health practice. Technology-enhanced self-regulation accompanied relaxation training and meditation and became a comfortable modality to facilitate the integration of behavioral medicine into primary care during the 1980s and 1990s.

Wellness and Health Risk Appraisals

Research in behavioral medicine, preventive medicine, and occupational health began to document the "toxic" effects of psychosocial stressors in ordinary life and in the workplace. Since the 1960s it has become more widely accepted that exposure to prolonged or severe acute stressors is often followed by the emergence of physical symptoms (e.g., headache, pain) or even frank medical disorders (e.g., hypertension, myocardial infarction, cardiac arrhythmias). This awareness provoked interest in the use of computer-assisted assessment methods for measuring stress and coping effectiveness, both in the workplace and in medical settings. Health risk appraisals (HRAs), first developed by the CDC in the 1980s to identify individuals with lifestyle factors associated with adverse health change (Centers for Disease Control, 1984), were adapted by employers and "wellness" program vendors for computer administration and later for delivery via the Internet. These self-administered HRA questionnaires took histories that identified modifiable risks that could be addressed through

behavior change programs that were designed to facilitate adoption of a healthier lifestyle and reduction of unhealthy habits (e.g., smoking, poor diet, sedentary behavior, misuse of alcohol; Huskamp & Rosenthal, 2009). As research indicated that such workplace stress management programs led to healthier employees and reduced health care costs (Baicker, Cutler, & Song, 2010), pharmaceutical companies began to take notice. Johnson & Johnson has offered its employees the *Live for Life* program (now *Health & Wellness*) since 1979 and has sold it to employers throughout the United States. Today there are scores of such programs: most Fortune 500 companies offer them, either on-site through their employee assistance programs, via contractors, or through community-based services covered by their employee health benefits. The widespread use of computer-assisted HRAs has made it possible to efficiently screen entire populations for symptoms and signs of stress and to refer them to programs that teach and improve coping strategies and techniques (Hyner, 1999). In addition, the use of HRAs with Medicare recipients has been associated with reductions in annual health costs even without subsequent participation in wellness programs (Loeppke, 2011).

Suicide Risk Assessment

A clinician's ability to assess the risk of patient self-injury or suicide is a critically important but often overlooked skill, although it is essential in most clinical settings. All physicians are taught to assess suicide risk during medical school or residency, yet it is a skill often lost as pressing clinical workflow impedes busy clinicians who too frequently wish to avoid probing patients for feelings of hopelessness or thoughts of suicide and risk, opening a Pandora's box. However, because roughly half of the patients who commit suicide are seen by a physician within the month preceding their deaths (Luoma, Martin, & Pearson, 2002; Vannoy et al., 2010) deployment of better methods for screening patients for suicide risk in general medical settings is crucial. As it has been established that patients are more likely to disclose certain types of sensitive information during a computer-administered interview, it warrants consideration that computer interviews have a potential role in suicide risk assessment. Automated assessment provides an opportunity to introduce the screening into a busy clinical setting while minimizing the disruption in workflow. Furthermore, detailed screening can be performed as a second-stage assessment, restricted to use in the minority of patients who have disclosed suicidal thoughts (e.g., thoughts of self-harm or feeling that they or others would be better off if they were dead) during a prior depression screening administered in the waiting room (e.g., following a positive response to item 9 on the PHQ-9). However, the US Preventive Services Task Force assessed the value of routine screening for suicide and concluded, "the evidence is insufficient to recommend for or against routine screening by primary care clinicians to detect suicide risk in the general population" (Gaynes et al., 2004). Despite the lack of a USPSTF recommendation, the report endorsed the assessment of suicidal ideation as the standard of care in the evaluation of depression, and recommended routine depression screening to identify patients with

thoughts of suicide. The Task Force further recommended that primary care clinicians will need evidence-based management strategies for the patients who are identified as at risk for suicide.
