Apathy is a condition of diminished motivation even in the presence of normal consciousness, attention, cognitive capacity and mood. Patients are able to initiate and sustain behavior, describe their plans, goals, and interests, and react emotionally to significant events and experiences; however, they do all of these things less often than normal patients. Goal-related aspects of overt behavior, thought content, and emotion are decreased. (Marin, 1990; Marin & Wilkosz, 2005).

When apathy worsens, the patient is seen as having abulia, poverty of behavior and speech output, lack of initiative, loss of emotional response, psychomotor slowing, and prolonged speech latency. Akinetic mutism is the total absence of these behaviors. In the differential diagnosis of these states is stupor with altered consciousness, catatonia with waxy flexibility, and clinical depression with depressed mood.

The core circuit for motivation is the anterior cingulum, nucleus accumbens, ventral pallidum, medial dorsal nucleus of the thalamus, and the ventral tegmental area. Frontal and diencephalic diseases are prominent in the etiology of these syndromes. Therefore, the exam should assess olfactory function, visual acuity, visual fields, frontal release signs, *gegenhalten*, and extrapyramidal motor signs.

Loss of incentive and a sense of overwhelming loss of control can lead to apathy as a psychological dimension. Demoralization and despair can be factors that diminish motivation. Major depressive disorder, delirium, and dementia may present with syndromes of apathy.

The severity of apathy may be measured with the Apathy Evaluation Scale, an 18-item list graded from 1–4 (Marin, Biedrzycki, & Firinciogullari, 1991). The items ask

whether the interview supports these characteristics of the patient: interested in things, gets things done during the day, whether getting things started on his own is important to him, whether she is interested in new experiences, interested in learning new things, whether she puts little effort into anything or approaches life with intensity, sees a job through to the end, or spends time doing things that interest her. Does someone have to tell him what to do each day? Is he less concerned about problems than he should be? Does she have friends and get together with them? When something good happens, does he get excited? Does she have an accurate understanding of her problems? Is it true that getting things done during the day is important to him, that he has initiative and motivation?

Strategies for treatment of apathy include optimizing medical status, diagnosing other conditions like Parkinson's disease or hyperthyroidism, sometimes eliminating doses of psychotropics like SSRIs or dopamine antagonists and at other times treating depression or psychosis effectively (Brodsky & Burns, 2012). Specific drugs to increase motivation include dopamine agonist stimulants, and cholinesterase inhibitors (donepezil, galantamine, and rivastigmine). Pramipexole, amantadine, bromocriptine, selegiline, pergolide, l-dopa/carbidopa, and modafinil, may have a role as well as methylphenidate, dextroamphetamine, bupropion, protriptyline, and venlafaxine (Bowman, et al., 1997; Berman, et al., 2012).

TREATMENT OF CHRONIC FATIGUE SYNDROME

STEP 1: INITIAL PATIENT VISIT

Establish an understanding of the problem.

Help me understand what you are hoping that I can help with.

It is essential to carefully observe and listen to patients with complaints of CFS to understand what they are experiencing (Conn et al., 1978). Acknowledge and respond to their non-verbal cues and strong emotions (Ekman & Friesen, 1975) in order to fully appreciate the impact of their illness. This allows the physician to respond appropriately to any preconceived notions or lingering ill feelings that patients may harbor regarding previous experiences with health care providers who did not seem supportive in treating their illness. Listen carefully (taking notes if necessary) to learn exactly what it feels like to be in their shoes and how the illness has affected their life. Reflect back to the patient what they have reported (preferably in their own words), clarifying as necessary. For example,

Let me see if I understand. You've been so exhausted physically and mentally over the past 8 months that you lost the job you loved and are now afraid that your husband is sorry he married you. This has you feeling sad,

Box 34.1 CONDITIONS ASSOCIATED WITH APATHY, ABULIA, AND AKINETIC MUTISM

Neurological Disorders

Frontal Lobe

Frontotemporal dementia
Anterior cerebral infarction
Tumor
Hydrocephalus
Trauma

Right Hemisphere

Right middle cerebral artery infarction
Cerebral white matter disease
Ischemic white matter disease
Multiple sclerosis
Binswanger's encephalopathy
HIV

Basal Ganglia

Parkinson's disease
Huntington's disease
Progressive supranuclear palsy
Carbon monoxide poisoning
Diencephalon
Degenerative or infarction of thalamus
Wernicke-Korsakoff disease

Amygdala

Klüver-Bucy syndrome

Multifocal Disease

Alzheimer's disease (prefrontal cortex, parietal cortex and amygdala)

Medical Disorders

Apathetic hyperthyroidism
Hypothyroidism
Pseudohypoparathyroidism
Lyme disease
Chronic fatigue syndrome
Testosterone deficiency
Debilitating medical conditions, e.g. cancer, heart or renal failure

Drug-Induced

Neuroleptics, esp. typical
Selective serotonin reuptake inhibitors
Marijuana dependence
Amphetamine or cocaine withdrawal

Loss of Incentive or Perceived Control

Role change
Institutionalization

(adapted from Marin & Wikosz, 2003, Table 1)

desperate, and alone. You are coming to me to find out what has you so exhausted, and you want to feel better! What am I missing?

Sometimes patients will breathe a sigh of relief, feeling understood. There remains a high risk of disappointing the patient who wants a firm diagnosis and who comes with a great deal of distrust (Ax, Gregg, & Jones, 1997).

Formulate a diagnostic plan acceptable to the patient. Explain that there are numerous causes for fatigue and exhaustion and that it will be important to go through a comprehensive (1) history, followed by (2) a complete physical examination (including a careful neurological examination and a mental status examination) and finally, (3) perform selected laboratory testing as medically indicated. If the patient agrees with this plan, proceed with the evaluation. Teach throughout this diagnostic process, so that the patient is an active participant and understands the necessity of searching each area. This is very reassuring for the patient to understand that a serious physical etiology will be found if it exists.

1. Obtain a comprehensive history (Sharpe et al., 1997), including medical, psychiatric, and psychosocial issues. See Box 34.2.
2. Perform thorough physical and psychiatric examinations to rule out common causes of chronic fatigue (Epstein, 1995). See Box 34.3.
3. Recommended minimal laboratory testing (Fukuda et al., 1994): See Box 34.4.

Additional selected tests (i.e., HIV, VDRL, EBV, Lyme titer, ANA) are guided by an excellent medical evaluation. A conservative approach is prudent, basing each patient's diagnostic workup on suggestive findings and risk factors.

STEP 2: SCHEDULE REGULAR FOLLOW-UP PATIENT VISITS

Review Findings

Review the positive and negative findings from the history, physical examination, and laboratory testing, teaching how each finding relates to fatigue. Treat any underlying medical and/or psychiatric conditions appropriately. If no explanation is identified for the fatigue, patients may be reassured and educated about CFS:

You have an illness called "chronic fatigue syndrome." It is not an illness that leads to death. Despite a great deal of research, there is no single cause; many factors may contribute. There are no scientifically proven cures, but there are many claims for cure. You must be extremely cautious not to fall prey to particularly expensive treatment programs promising spectacular results.

It will take a lot of work to fight this illness and I will continue to help you in this long uphill battle. What we do know is that strategies of strict inactivity make CFS

Box 34.2 COMPREHENSIVE MEDICAL AND PSYCHIATRIC HISTORY

Presenting complaints

Fatigue
Other somatic symptoms
Sleep
Cognitive problems
Disability and distress

History of the illness

Course
Patient's understanding of the illness (health/disease belief regarding etiology)
Coping strategies (such as inactivity, avoidance, etc.)
Treatment history

Current situation

Family members
Employment and financial situation

Background

Family and personal history
Past medical and psychiatric history
Premorbid personality and lifestyle

Psychiatric history

Depression
Anxiety (besides anxiety disorders, what is overwhelming or anxiety provoking)
Somatic symptom disorders [This diagnosis will depend on the acquisition of a fully detailed medical history including records of hospitalizations and medical interactions that predated chronic fatigue (Sharpe, 1996).]

(Sharpe et al, 1997)

much worse in the long run. The most useful treatments include maximizing your overall health (this allows your body to heal itself naturally), normalizing your sleep, and increasing your activity level extremely slowly within a structured cognitive behavioral therapy program for CFS.

It is important to observe the patient's reactions to this news (Salit, 1985), including nonverbal communications (Ekman & Friesen, 1975), and to inquire as to thoughts, feelings, questions, and concerns.

Plan Comprehensive Treatment Strategy

Design the treatment strategy tailored for each unique patient, maximizing overall positive health behaviors (Denz-Penhey & Murdoch, 1993).

**Box 34.3 COMMON MEDICAL & PSYCHIATRIC
CAUSES OF CHRONIC FATIGUE (EPSTEIN, 1995)**

Medical disorders

Infections
Localized/occult abscess (including chronic sinusitis)
Chronic bacterial (endocarditis, Lyme disease, tuberculosis)
Fungal (histoplasmosis, blastomycosis, coccidioidomycosis)
Parasitic (e.g., toxoplasmosis, amebiasis)
Viral (EBV, HIV, hepatitis)
Malignancies
Connective tissue diseases
Other chronic inflammatory diseases
Sarcoidosis (including CNS sarcoidosis)
Endocrine/reproductive
Hypothyroidism or hyperthyroidism
Diabetes mellitus
Cushing's syndrome
Adrenal insufficiency
Hormonal status (r/o menopausal)
Neuromuscular diseases
Primary sleep disorders (e.g. sleep apnea, restless-legs syndrome, narcolepsy)
Rule out postural, positional, and orthostatic hypotension (Streeten, 1998)
Medication (prescribed or over-the-counter) side effects

Psychiatric disorders

Drug/alcohol dependency or abuse
Mood disorder with psychotic or melancholic features
Bipolar mood disorder (depressed)
Schizophrenia or delusional disorders of any subtype
Dementia of any subtype
Eating disorder (anorexia, bulimia, or severe obesity)
Dysthymia
Somatoform disorder
Mood disorder secondary to a general medical condition

1. Normalize sleep patterns (Shapiro et al., 1993). Review the sleep hygiene of the patient. Even small changes in activity make a difference. Ensure that the patient does not take daytime naps or have any unnecessary nocturnal interruptions of sleep. Consolidate sleep and restrict bedtime to improve sleep efficiency. Paradoxically, hypnotic drugs which may improve sleep may heighten daytime fatigue and create dependency problems such as with the benzodiazepines. Consider the possibility of a primary sleep disorder and investigate accordingly. Avoid caffeine, nicotine, or any other stimulating substance. Limit activities in the bedroom to sleep and intimacy. A sleep diary may be helpful.

2. Initiate cognitive behavioral therapy (CBT). There are at least 6 published cognitive behavior therapy randomized controlled trials noted in a Cochrane review 2008 (Price et al., 2008) and then in the review of clinical evidence (Reid, 2010) (Deale et al., 1997; Lloyd et al., 1993; Sharpe, et al., 1996; Prins et al., 2001; O'Dowd et al., 2006; Jason, 2007).

**Box 34.4 RECOMMENDED MINIMAL LABORATORY
TESTING FOR FATIGUE (FUKUDA ET AL., 1994)**

Blood count with differential
Erythrocyte sedimentation rate (ESR)
Alanine aminotransferase (ALT)
Total protein
Albumin
Globulin
Alkaline phosphatase
Calcium
Phosphorus
Glucose
Blood urea nitrogen
Electrolytes
Creatinine
TSH (thyroid stimulating hormone)
Urinalysis
Reproductive hormones as indicated, including prolactin

Sessions 1 to 3 involved engaging the patient(s) in therapy and offering a detailed treatment rationale. Presenting problems were assessed, and patients kept diaries in which they recorded hourly details of activity, rest, and fatigue.

At session 4 a schedule of planned, consistent, graded activity and rest was agreed upon. The initial targets were modest and small enough to be sustained despite fluctuations in symptoms. Rather than being symptom-dependent, activity and rest were divided into small, manageable portions spread throughout the day (for example, three 5-minute walks daily rather than a 45-minute walk once a week). Patients were encouraged to persevere with their targets and not to reduce them on a bad day or exceed them on a good day.

Once a structured schedule was established, activity was gradually increased and rest was reduced, step by step as tolerance developed. Therapist and patient agreed on specific daily targets covering a range of activities—for example, walking, reading, visiting friends, or gardening. A sleep routine was established—stopping daytime sleep, rising at a specific time each morning, reducing time in bed, and using stimulus control techniques for insomnia (Lacks, 1987).

Cognitive strategies were introduced at session 8 (while the graded activity program continued). Patients recorded any unhelpful or distressing thoughts and, in discussion and as homework, practiced generating alternatives (Beck et al., 1979). The unhelpful or distressing thoughts included fears about symptoms and treatment, perfectionism, self-criticism, guilt, and performance expectations.

In the final sessions, strategies for dealing with setbacks were rehearsed and patients drew up action plans to guide them through the coming months. The importance of maintaining the principles of therapy after discharge was reinforced.

CBT techniques directly confront the maladaptive cognitive and behavioral changes often associated with CFS that have lead to symptom perpetuation. Other related illnesses (anxiety, depression, chronic low back pain, rheumatoid

arthritis, and atypical chest pain) have been successfully treated and managed with CBT (Wilson et al., 1994).

Successful CBT interventions for CFS involve several key elements including: goal setting (increased activity levels, increased social and pleasurable events); education about the illness; relaxation training; exposure to avoided activities; restructuring of potential cognitive errors involving misinterpretation of events or stimuli (i.e., fearing the worst, “I’m bound to relapse”); and the evaluation of possible social, family, or personal reinforcers of disability. Several attempts at utilizing CBT for CFS have not been effective; these attempts utilized a shorter duration of treatment with a different form of reintroduction of activity than described by Deale. Adolescents with chronic fatigue syndrome have been treated effectively with internet-based CBT (Nijhof et al., 2013).

3. Encourage physical rehabilitation and exercise (Wilson et al., 1994). Muscle performance (including endurance and recovery) is normal in patients with CFS. It is important to educate patients that exercise will not harm them, but will benefit their recovery when done very gradually. Initially, activity may exacerbate symptoms (initial worsening followed by improvement). In population studies, inactivity has been shown to be associated with more reports of fatigue and greater risk of depression. 4. Maximize balanced nutrition (Morris, 1993). Patients with CFS are advised to eat a varied (normal) diet selected from and within the basic food groups to ensure adequate nutrient intake to reach and maintain a healthy body weight.

4. Unproven diet therapies for patients with CFS include megavitamin/mineral supplements; royal jelly and other dietary supplements; and elimination, avoidance, and rotation diets. Claims that these therapies relieve CFS symptoms and promote recovery are anecdotal and have not been substantiated by clinical research. The yeast-avoidance and sugar-free diets, both promoted to combat *Candida albicans* overgrowth, are of no proven value in treating patients with CFS. Diet strategies that call for the avoidance of food additives, preservatives, sweeteners, and other ingredients are not supported by scientific evidence and are not practical for patients with CFS (Morris, 1993).

5. Maximize physical health through preventative medical and dental care. It is important that patients with CFS have annual medical examinations to rule out occult or new illnesses (Denz-Penhey & Murdoch, 1993) and abnormalities throughout the year are investigated and treated appropriately. It is also essential to maintain dentition in good repair.

6. Treat psychiatric illness and operantly decrease sick role behavior. Be vigilant for comorbid depression, anxiety, and somatoform disorders and treat them vigorously. Help patients to identify and appropriately express their emotions. Contained emotions such as anger are exhausting. Encourage patients to be direct about their needs and limitations rather than needing to maintain a “sick role” to avoid being overwhelmed by the expectations and requests of others. Accept and encourage patients to appropriately grieve for the losses they have experienced (both personal and professional) as a result of having CFS. Assist them to redefine meaningful,

realistic life/career goals and support their efforts to strive for them. Continue to elicit a detailed understanding of their lives, including overwhelming stressors, psychosocial and financial pressures, and lifelong patterns of behavior. Attempt to understand possible perpetuating factors (e.g., the role of the family in the patient’s functioning).

7. Overcome facilitating factors. Individuals with CFS develop avoidance behavior toward activities perceived to worsen their fatigue. For example, many individuals exercise in spurts, overdoing it and suffering grave consequences. They then carefully avoid all levels of exercise, fearing the worst (Nijs et al., 2013). Figure 31.3 illustrates a cognitive model of the perpetuation of CFS (Fry & Martin, 1996).

8. Control symptoms. No available *somatic treatment* has been found to be consistently effective for CFS in controlled trials (Vercoulen et al., 1996). This leaves patients who suffer with CFS open to purveyors of folk remedies, unorthodox treatments, and exploitive practitioners and charlatans from a variety of health-related professions. Therefore, when patients find treatment programs that are particularly expensive and unproven, they should be advised to be particularly cautious.

The use of antidepressant medications (Wilson et al., 1994; Jorge, 1997), predominantly tricyclic agents, in patients with CFS has achieved widespread theoretical and clinical support despite a lack of controlled studies. In uncontrolled samples 70% to 80% of patients are said to have benefited (Jones & Straus, 1987; Manu et al., 1989). The rationale for the use of these medications includes their utility in primary depression with associated fatigue, sleep disturbances, and related disorders such as fibromyalgia; their site of action within the central nervous system; and the high rates of depression reported in CFS subjects. Clinical experience suggests that tricyclic antidepressants are often poorly tolerated in patients with CFS, even in low doses, due to their sedative and anticholinergic effects. In patients with fibromyalgia, tricyclic antidepressant agents such as nortriptyline have been evaluated in randomized, placebo-controlled studies and found to be effective in comparison to placebo and nonsteroidal antiinflammatory drugs (see Chapter 61).

Fluoxetine 20 mg per day was found to be ineffective in a randomized, double blind placebo controlled 8-week trial for treating CFS irrespective of whether depressive symptoms were present (Vercoulen et al., 1996). It should be noted here that fluoxetine is a drug developed, proved effective, and FDA approved for depression.

Controlled studies utilizing newer psychopharmacologic agents for the treatment of CFS are lacking although one trial of for neurasthenia suggested the power of treatment with CBT and then mirtazapine produced additive benefits. The timing of therapy and/or antidepressants may be important (Stubhaug et al., 2008). When treating comorbid depressive or anxiety disorders, antidepressants should be titrated and tailored to each patient. If insomnia is prominent, then more-sedating medications may be better tolerated. Non-sedating medications like bupropion or adjunctive agents like methylphenidate may be useful, especially since the patient will not be alarmed by sedation.

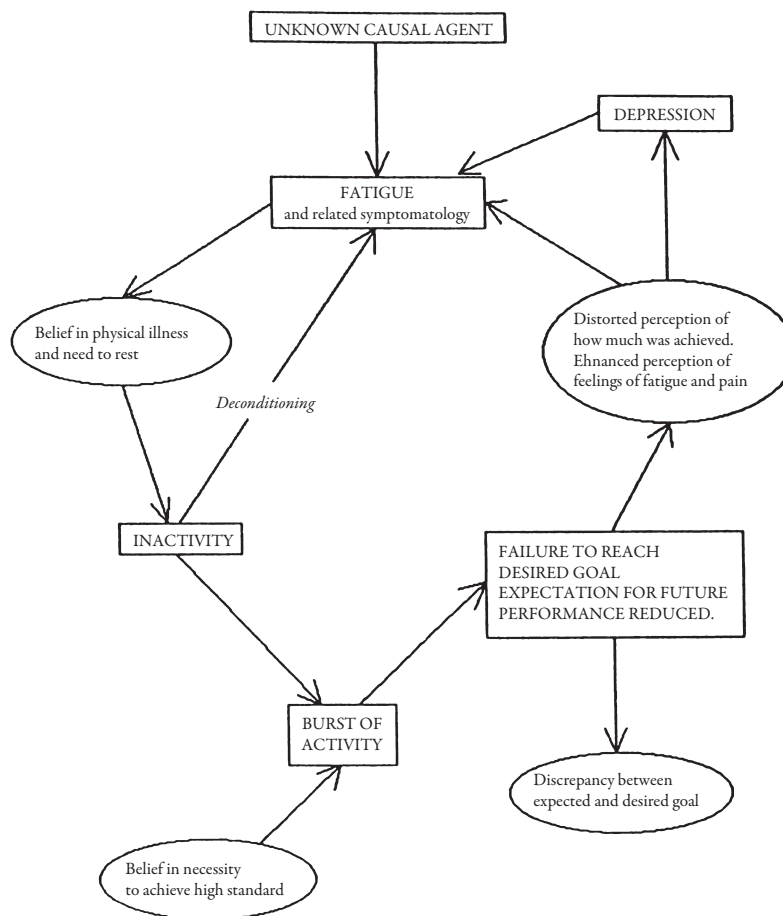

Figure 34.3 A cognitive model of chronic fatigue syndrome and the pathways that perpetuate it. From Fry & Martin, 1996.

Novel pharmacologic agents are available, but they are not yet proven to be clinically efficacious by reproducible double-blind randomized placebo-controlled trials. A recent review of the effect of treatments for CFS (Reid et al., 2011) concluded that the effectiveness of corticosteroids and intramuscular magnesium are unknown. Dietary supplements, evening primrose oil, oral nicotinamide adenine dinucleotide, homeopathy, and prolonged rest have not been studied in enough detail to draw conclusions. In one single randomized control study galantamine was no better than placebo. For gammaglobulin, two double blind placebo controlled trials were conducted utilizing intravenous gammaglobulin in adults with CFS. One study showed a significant improvement, but results were not replicated in the second study. A third study of 99 adults showed side effects but no benefit; therefore, gammaglobulin in the management of CFS cannot be recommended (Vollmer-Conna et al., 1997; Wilson et al., 1994).

Rintatolimod (trade name amplitgen), known as PolyI; poly C12U, is an experimental immunomodulatory double-stranded RNA preparation thought to have both antiviral and immunomodulatory properties. When administered to CFS patients in a randomized multicenter placebo controlled double blind study for 24 weeks it was found to significantly improve global performance and perceived cognition (Strayer et al., 1994). Unfortunately, the patient

group studied was atypical in that they were severely affected (many subjects were bedbound), and the magnitude of the therapeutic effect was small (Wilson et al., 1994). A double blind placebo controlled randomized clinical trial of this toll-like receptor 3 agonist and inducer of innate immune responses involved 234 subjects with long-standing debilitating CFS at 12 sites. The outcome of exercise tolerance was improved in the drug-treated group (Strayer et al., 2012); however, this orphan drug has not been approved.

9. Recognize countertransference. Recognize that it is normal to experience frustration and helplessness in treating patients with CFS. Be cautious not to base professional gratification on patient improvement. Patients often need unconditional empathy whether they are fatigued or energetic. Empathy, however, must be balanced with active efforts to mobilize these patients from sick and disability roles they may have adopted. In our present state of knowledge it is just as likely for clinicians to reinforce symptoms of CFS, including sick role behaviors, versus diminishing their severity.

CLINICAL PEARLS

- The risk of CFS is increased in patients with a history of depression. Rates of comorbid psychiatric syndromes

are high—higher than would be expected if the medical dimension of CFS led to psychological consequences (Holgate et al., 2011).

- Overall, the greater fatigue severity the more likely that the prognosis is worse (Vincent, 2012; Taylor, 2002; Jason, 2011). Consistent risk factors for poor prognosis include duration of disease, lifetime dysthymia (Clark et al., 1993), the strength of belief in a physical cause for symptoms, untreated psychological distress, and the use of avoidant coping strategies such as reducing activity and imposing dietary, social, and other restrictions (Wessely, 1996; Joyce et al., 1997).
- Diminished motivation or apathy without dysphoria may present as chronic fatigue without defined somatic symptoms and may be more effectively reexamined with a neuropsychiatric differential diagnosis.
- Apathy is seen in dementia and is a common symptom in first episode psychosis cohort 10 years after illness debut.
- Strategies for treatment of apathy include optimizing medical status, diagnosing other conditions like Parkinson's disease or hyperthyroidism, eliminating doses of psychotropics like SSRIs, dopamine antagonists, and treating depression effectively. Specific medications to increase motivation through stimulants include dopamine agonist stimulants, and cholinesterase inhibitors (donepezil, galantamine, and rivastigmine). Pramipexole, amantadine, bromocriptine, selegiline, pergolide, l-dopa/carbidopa, modafinil, may have a role as well as methylphenidate, dextroamphetamine, bupropion, protriptyline, and venlafaxine.
- For the patient with chronic fatigue:
 - (a) Acknowledge and respond to their nonverbal cues and strong emotions in order to appreciate fully the impact of their illness.
 - (b) Review the positive and negative findings from the history, physical examination, and laboratory testing, teaching how each finding relates to fatigue.
 - (c) Normalize sleep patterns.
 - (d) Use the techniques of cognitive behavioral treatment.
 - (e) Treat comorbid psychiatric disorders.
 - (f) Decrease sick role behavior.
 - (g) Add in physical therapy and graded exercise.
 - (h) Recognize countertransference.

SEXUAL DYSFUNCTION

Barry S. Fogel and Donna B. Greenberg

INTRODUCTION

Patients may bring to the medical psychiatrist their concerns about sexual function, their preoccupations about sex, or the quality of the sexual relationship with a partner. On occasion, sexual issues will be identified in the course of medical psychiatric assessment for a nonsexual presenting problem such as chronic pain or depression. In either case the medical psychiatrist often is the only medical professional who engages the patient in a detailed exploration of sexual issues. Patients for whom the presenting issue is not sexual sometimes are reticent to talk about their sexuality. Reluctance to talk openly about the subject does not signify that it is unimportant to the patient; epidemiologic studies suggest that the minority of individuals with common forms of sexual dysfunction, such as erectile dysfunction or postmenopausal dyspareunia, will bring their problems to a physician's attention. A satisfying sexual life contributes to a patient's happiness and overall life satisfaction, and, when it is a life goal, not having one can affect a patient's self-confidence and self-esteem. Thus, even when discussion of sexual issues is not timely at the initial encounter with the patient, the topic should remain as an open item in the psychiatrist's mind—one to be explored in the future with the patient if the professional relationship continues. The association of sexual dysfunction with internal disease, especially in men, is another reason to explore sexual issues that are not spontaneously raised. Erectile dysfunction before age 60 is associated with a significant increase in the risk of myocardial infarction, even after controlling for hypertension, hypercholesterolemia, and smoking. Mainstream cardiologists have recommended that the new onset of erectile dysfunction in a younger man warrants an cardiogram and a stress test, and some have gone so far as to recommend CT scan assessment of coronary calcification in this situation even when the stress test is negative (Nehra et al., 2013; Miner et al., 2014). In addition to cardiovascular disease, testosterone deficiency is another prevalent condition that can present with erectile dysfunction—with or without loss of sexual interest.

A trusted physician explaining the connection between health-related behaviors and sexual function can be useful in motivating a patient to make valuable changes in lifestyle. A man's belief that changes in his diet or exercise habits will improve his sexual performance can be more effective than general knowledge about lifestyle and longevity, and the

experience of improved sexual performance can be immediately reinforcing.

On a population level, better health is unequivocally correlated with more sexual activity and greater sexual satisfaction. For example, older heterosexual couples who engage in regular sexual intercourse have lower levels of depressive symptoms, better cardiovascular health, and a lower waist circumference than similarly aged couples that don't (Brody, 2010). More generally, individuals with good to excellent self-reported health are more likely to be sexually active than those with fair to poor self-reported health (Lindau & Gavrilova, 2010). Some patients will realize apparent physical and mental health benefits from an active sexual life while others enjoy good health without one. It is reasonable to assume that a younger patient who has never had a satisfying sexual life is likely to want one, and that an older patient who has previously had a satisfactory sexual life will feel a loss if sexual activity is no longer feasible, physically possible, or satisfying. Expectations of sexual behavior later in sexual life differ widely according to culture and according to age cohort. Regarding the latter effect, Beckman, Waern, Gustafson, and Skoog (2008) analyzed cross-sectional data from populations surveys in Gothenburg, Sweden, and found that between 1971 and 2000 the percentage of married men reporting sexual intercourse rose from 52% to 68%; for married women the percentage rose from 38% to 56%. The most dramatic increase was seen in rates of sexual intercourse among unmarried 70-year-old women, which rose to 12% in 2000 from less than 1% in 1971. Sexual life continues into very old age if health permits and a partner is available. An Australian study of men over 75 found that among men aged 75 to 79 years, 40% had been sexually active in the prior year; the percentage decreased with age to 11% for men aged 90–95 (Hyde et al., 2010). Longitudinal studies of aging suggest that some people remain sexually active past age 100 if a partner is available. However, many people regard it as normal to completely stop having sexual intercourse at some point in their later years, even if they live with a spouse or partner with whom they have been sexually active in the past (Lindau et al., 2007).

Interest in sex (a desire to be sexual) and sexual interest (a desire to have sex, whether in general or with a specific actual or fantasied partner) are not the same. A patient can wish to have sexual desire but not feel it. If the medical psychiatrist determines that a patient wishes to be sexual, this is sufficient reason to explore the issue further even if the

patient has not been sexually active recently or has not recently experienced sexual desire. The medical psychiatrist can determine what aspects of the sexual experience are most related to the patient's satisfaction; this will influence the focus of treatment. For some patients having an orgasm is less important than physical closeness to or the satisfaction of a spouse or partner. For others, arousal without orgasm is an intensely unpleasant experience. The mechanical aspects of sex—physical arousal, erection or lubrication, and orgasm—often are the easiest ones to address. For each there is a reasonable base of evidence for differential diagnosis and for treatment. In the 15 years since the last edition of this volume was written, accurate diagnosis and effective treatment for mechanical aspects of sex have become more widely available, and information about almost any sexual topic has become easy to find on the Internet (though not always accurate). Notwithstanding, even now patients with addressable physical impediments to sexual satisfaction do not necessarily seek treatment for them, and this is true even when the patient's sexual issues cause them emotional distress or adversely affect the quality of their marital relationship.

While there is much written about the workup of sexual dysfunction, the authors find it useful to think about the sexuality of medical-psychiatric patients in a broader context.

This chapter offers a framework for conceptualizing sexual issues in patients with general medical illness. Detailed discussion of physiological aspects of male sexual function and dysfunction can be found in this book's chapters on urology and on spinal cord injury.

ANALYZING SEXUALITY IN MEDICAL PSYCHIATRIC PATIENTS

The following sequence of questions describes the scope of an ideal inquiry into the sexual issues of a medical-psychiatric patient. The actual questions the clinician will ask will depend on the reason for the consultation, the amount of time available, the setting of the interview, the patient's current mental status, and, importantly, the scope of the clinician's "license". The latter will be quite different when the medical psychiatrist is intervening in a crisis where a patient is resistant to medically necessary care versus when he or she is responding to a patient's personal request for help in coping with the emotional impact of a serious illness.

1. *Set the context.* Is the patient sexually active in any way—with a partner or solo? If not, does the patient wish to be? If there is a wish but no activity, what is the reason? When was the patient last sexually active and what was the sexual experience like at that time? If there is no wish to be sexually active, when did they last have such a wish? If the patient has a regular sexual relationship how frequently do they have sex? Who usually initiates the sexual encounter?
2. *Assess sexual interest.* If the patient does not wish to be sexual at all, what is the reason? Is it related to a specific

traumatic event? Is the lack of an interest in sex due to a belief of some kind? For example, does the patient who has no sexual partner feel undesirable to a potential partner because of their age, appearance, or health status? Does the patient feel masturbation is wrong or harmful? Or, does the patient simply not care about sexuality at this particular point in their life? Is there any distress or perplexity associated with the loss of interest in sex? If the patient does not wish to be sexual because the spouse or partner is not interested, why does the spouse or partner lack interest? What is the recent history of the couple's sexual relationship? Does the spouse or partner find the lack of a sexual relationship to be acceptable?

3. *Assess desire.* If the patient wishes to be sexual but feels no desire, is that loss of interest generalized or specific to the current spouse or partner? Desire can be viewed as a balance of impulse and inhibition. It can be assessed over days or over hours. General medical illness, medications, and emotional reactions to illness can affect either impulse, inhibition, or both. Fatigue reduces the impulse, while the irritability that comes with fatigue increases the power of environmental effects to inhibit desire. How would the patient describe the interplay of impulse and inhibition in their own experience? Can they offer examples where they noticed a lack of response to circumstances that they would expect to find arousing? Can they recall specific reasons why sexual activity didn't take place because something interfered? Does the patient have a problem with sleep or with sleepiness? Sleep disorders are common. Lack of sleep is associated with reduced desire, greater vulnerability of desire to inhibition by distraction or discomfort, and decreased physical arousal. Snoring, restless legs or a disturbing parasomnia can inhibit the arousal of the partner.
4. *Assess arousal.* If the patient or partner is a woman, does she experience emotional arousal? If so, is there associated lubrication or does the vagina remain dry? If the patient or partner is a man, does he have an erection? Is the erection persistent? Is it firm enough for penetration?
5. *Assess sexually related pain.* Does the patient have, anticipate having, or fear having some form of physical discomfort during sexual activity? In the medical psychiatric contexts sexually related discomfort encompasses much more than dyspareunia. Sexually related discomforts range broadly from dyspnea on exertion to muscle pain to neuropathic dysesthesia of the pelvis or thighs to postcoital migraine. These symptoms or avoidance of them not only can cause conscious avoidance of sex but can also inhibit the patient's desire. Eventually "yes but" becomes "not tonight" and then just "no".
6. *Assess orgasm, including its qualitative aspects.* Does the patient have orgasms, and if so, is it qualitatively the same as in times past? If the patient is a woman, has she ever had an orgasm? If so has she had one with intercourse? If she does not have orgasms does she come close to having one? Is the experience of arousal without orgasm pleasant or unpleasant? If the patient is a man and he does not now

have orgasms does he get close to having one? Is the experience of arousal without orgasm pleasant or unpleasant? If he has an orgasm does he ejaculate normally? Does he ejaculate earlier than he desires? And with how much stimulation? Does he have a sense of control over his ejaculation?

7. *Assess the patient's view of the spouse or partner's sexual function.*
8. *Assess satisfaction and frustration of the patient and partner, qualitatively and quantitatively.* How does the patient's sexual dysfunction affect the quality of the sexual relationship? How distressing does the patient find the sexual dysfunction? Does the patient find intimacy with their spouse or partner to be satisfying despite the sexual dysfunction? What is the spouse or partner's point of view on these matters?
9. *Explore consideration of sexual alternatives:* Is the patient willing to consider alternatives to their customary sexual repertoire before illness? For example, willingness to consider alternatives to vaginal intercourse varies greatly with patients' cultural background and openness to new experiences. Even with the greater permissiveness of mainstream culture in Western countries, many patients come from a cultural or religious background that restricts the acceptable forms of sexual expression. Patients with such issues vary in their acceptance of permission to experiment when the permission is given by a physician. The patient's personality is relevant as well; those patients with personalities that are high on the openness factor are more likely to accept alternative forms of sexual expression.
10. *Consider specialist referral.* Is the patient open to referral to a specialist in sexual medicine? Such a referral would be a second or third referral, following the referral to the medical psychiatrist, which in itself might have come through another medical specialist or through a nonphysician mental health professional. Accepting this referral, which is based on an explicitly sex-related reason, requires that a patient believes that the sexual issue is important enough to deserve an investment of time and resources, that there is some hope of a good outcome, and that the specialist is competent, trustworthy, and will maintain confidentiality. Furthermore, it may require the approval—or at least the nonopposition—of a spouse or significant other. A referral to a specialist in sexual medicine may be more acceptable to a patient if the medical psychiatrist takes sufficient time to explore relationship issues, interest in sex, openness to alternatives, and the relationships of these sexual issues to the patient's personal history and current physical and mental health problems. Through the process of exploration, the explicitly sexual issue can become part of the patient's personal problem list. With this motivation a specialty referral usually will be appreciated; without it the patient may not follow through.

SCREENING PATIENTS FOR SEXUAL DYSFUNCTION

Studies of sexual dysfunction in medical patients have led to the development of efficient screening questions for detecting the most common sexual issues. Questions can be asked in writing via questionnaires to be completed by the patient or asked orally by the physician as part of the overall history and examination. Questionnaires and self-rated instruments sometimes will elicit information about sexual concerns that would not come out in a face-to-face interview. When they are available and applicable, sexuality related rating scales specific to the patient's medical illness or condition can be more informative than general scales of sexual function and dysfunction.

INTERVIEW QUESTIONS SCREENING FOR SEXUAL DYSFUNCTION

The following short list of sexuality related questions was recommended by Shafer (2008) for inclusion in a general diagnostic interview. Questions can be reworded if this would make the interview more comfortable for the patient.

1. Are you active sexually? With men, women, or both?
2. In your sex life:
 - a. is there anything you would like to change?
 - b. have there been any changes recently?
 - c. are you satisfied?

Additional screening questions have been suggested by Althof and colleagues (2013):

For both men and women:

1. Do you identify yourself as heterosexual, homosexual, or bisexual?
2. Are you satisfied with the level of your sexual desire or interest?
3. Are you satisfied with the frequency of lovemaking?
4. Do you experience pain during lovemaking?
5. Are you satisfied with the overall quality of your sexual life?

For men:

1. Are you satisfied with your ability to achieve and maintain an erection?
2. Do you frequently have difficulty ejaculating?
3. Do you frequently ejaculate too quickly without wanting to?
4. Have you noticed any changes to the shape of your penis?

For women:

1. During lovemaking do you have difficulty becoming mentally aroused?

2. During lovemaking do you have difficulty with genital lubrication (wetness)?
3. Do you have difficulty achieving orgasm when you want to?

QUESTIONNAIRES AND SELF-RATED INSTRUMENTS

Questionnaires for assessing sexual dysfunction can be either generic or problem-specific. Generic rating scales should be considered for use in medical-psychiatric settings where sexual dysfunction has a high prevalence and it is feasible to follow up any issues identified. Once a sexual issue has been identified, a problem-specific scale can be helpful in better characterizing it, gauging its severity, and assessing its response to treatment. Table 35.1 lists sexual dysfunction scales widely used in clinical research and increasingly in clinical practice.

An additional instrument, the Sexual Excitation/Sexual Inhibition Inventory for Women and Men (SESII-W/M; Milhausen, Graham, Sanders, Yarber, & Maitland, 2010), is a questionnaire comprising 30 four-point bidirectional ordinal items concerning what excites and what inhibits individuals' sexual desire. There are six domains: (1) inhibitory cognitions—for example, "Sometimes I have so many worries that I am unable to be aroused"; (2) relationship importance—for example, "I really need to trust a partner to be fully aroused"; (3) arousability—for example, "Just talking about sex is enough to put me in a sexual mood"; (4) partner characteristics and behaviors—for example, "If a partner surprises me by doing chores it sparks my sexual interest"; (5) setting—for example, "Having sex in a different setting than usual is a real turn on for me"; and (6) dyadic elements of the sexual interaction—for example, "It interferes with my arousal if there is not a balance of giving and receiving pleasure during sex". When counseling a patient with sexual dysfunction in the context of general medical illness, the clinician should help the patient and spouse or partner find practical strategies to increase excitement and decrease inhibition. Specific items on the SESII-W/M offer clues to these strategies, and the discussion of each other's answers to the questions on the instrument can help a couple communicate about issues related to sexual interest as opposed to performance.

INVOLVING THE SPOUSE OR PARTNER

When a patient is in an ongoing sexual relationship it is often—but not always—useful to involve the partner in addressing an issue of sexual dysfunction. The patient and the spouse or partner must agree to be seen together. If one and/or the other do not agree to this, the reason can be diagnostically informative. Whether the medical psychiatrist sees the couple or refers the couple to another professional for couples therapy or sex therapy will depend specifically on the medical psychiatrist's scope of expertise, expectations for the duration, and scope and focus for his/her future work with the patient. If the expectation is for time-limited or intermittent therapy with

a practical focus on coping with a general medical illness it is usually a positive for the medical psychiatrist to see the couple personally. If the expectation is for long-term psychodynamic psychotherapy, a referral for the couple probably will be more compatible with the patient's future treatment.

When a patient is not in a sexual relationship but wants to be in one, and is deterred by fear of a sexual dysfunction (such as erectile dysfunction, premature ejaculation, or vaginismus), referral to a sex therapy clinic is an attractive option when it is feasible. Such clinics offer sex education, evidence-based cognitive behavioral therapy, physical treatment for vaginismus, and in some cases treatment involving a surrogate partner. A referral for sex therapy offers the patient access to the most effective available treatments, while avoiding the ethical and transference-related risks of the psychiatrist's getting over-involved in a patient's sex life.

LOSS OF SEXUAL INTEREST (LOSS OF LIBIDO)

Patients of either sex can have the symptom of low libido, that is, the relative or complete absence of sexual fantasies or desire to engage in sexual activity. A patient may or may not be troubled by a loss of libido—in other words, patients without sexual interest may or may not retain an interest in sex. Loss of sexual interest is a common accompaniment of general medical illness and a side effect of numerous medications that affect the CNS, whether or not a CNS disease was their target. When evaluating a patient with this complaint, the medical psychiatrist should first determine if any of the following situations applies:

- The patient has some specific form of sexual dysfunction (e.g., ED or PE) and is not interested in sex because he or she does not wish to repeat an unhappy sexual experience.
- The patient's sexual function is intact, but the patient wishes to avoid physical symptoms, expecting or fearing that they will accompany or follow sexual activity.
- The patient has symptoms such as fatigue or pain that interfere with sexual arousal.
- The patient has a general loss of interest and pleasure in many activities, sex being one of them.

Each of these conditions implies a medical differential diagnosis, and in most cases there is some prospect for a return of sexual interest if the underlying medical condition is addressed or if an offending drug is discontinued. Most endocrine and neurological conditions that affect sexual interest also have other somatic and mental symptoms. Hypothyroidism, a relatively common endocrine disorder, causes a loss of libido that is reversed when the patient becomes euthyroid, though loss of libido would rarely be the *sole* symptom of the disorder at the time of presentation. A relatively specific loss of libido *can* be seen due to a deficiency of testosterone in men, or due to a deficiency of estrogen or testosterone in women (Yasui et al., 2012).

Table 35.1 SEXUAL DYSFUNCTION QUESTIONNAIRES

TEST	DESCRIPTION	REFERENCE
<i>For Either Gender</i>		
Arizona Sexual Experience Inventory (ASEX)	5-item questionnaire comprising six-point ordinal items; one week look-back period. Questions concern (1) sex drive; (2) ease of arousal; (3) erectile function for men, lubrication for women; (4) ease of reaching orgasm; (5) satisfaction with orgasms	McGahuey et al., 2000.
<i>For Men</i>		
Male Sexual Health Questionnaire (MSHQ)		Rosen et al., 2004
Sexual Health Inventory for Men (SHIM)	5-item screening form of IIEF. Also known as the IIEF-5.	Rosen et al., 1999; Vroeghe, 1999; Cappeliere & Rosen, 1999
International Index of Erectile Function (IIEF)	15-item questionnaire; 5- or 6-point ordinal items; five domains: erectile function, orgasmic function, sexual desire, intercourse satisfaction, overall satisfaction	Rosen et al., 1997; Rosen et al., 2002
Premature Ejaculation Diagnostic Tool (PEDT)	5-item questionnaire comprising 5-point ordinal items. Questions concern timing of ejaculation, sense of control, ejaculation with minimal stimulation, frustration with the problem, concern for partner's satisfaction	Symonds et al., 2007a; Symonds et al., 2007b; Abraham et al., 2008
Brief Sexual Function Inventory (BSFI)	11-item questionnaire; 5-point ordinal items. Five domains: sex drive, erection, ejaculation, perception of sexual problems, overall satisfaction	O'Leary et al., 1995
<i>For Women</i>		
Female Sexual Function Index (FSFI)	19-item questionnaire; 5-point ordinal items; 4-week look-back; six domains: desire, arousal, lubrication, orgasm, satisfaction, pain	Rosen et al., 2000
Female Sexual Distress Scale (FSDS)	12-item questionnaire; 5-point ordinal items rated on frequency; focus on distress, embarrassment, and other negative feelings related to sexual problems	Derogatis et al., 2002
Sexual Interest and Desire Inventory—Female (SIDI-F)	54-item interview based scale with 5-point ordinal items. Assesses four dimensions: evaluative, physiological, motivational, negative/aversive.	Clayton et al., 2006
Profile of Female Sexual Function (PFSF)	37-item questionnaire focused on HSDD, 6-point ordinal items measuring frequency. Seven domains: desire, arousal, orgasm, sexual pleasure, sexual concerns, sexual responsiveness, sexual self-image	Derogatis et al., 2004

MALE SEXUAL DYSFUNCTION

The most prevalent types of male sexual dysfunction in general medical settings are erectile dysfunction (ED), premature ejaculation (PE), loss of sexual interest, and ejaculatory dysfunction. All can usefully be viewed as conditions that are rarely purely “psychogenic” but almost always have emotional dimensions.

ERECTILE DYSFUNCTION

ED is defined as the inability of a man to maintain an erection sufficient to engage in intercourse. The prevalence of ED increases with age, mainly due to age-associated disease rather than to aging per se. ED in men under 60 especially raises the

suspicion of systemic disease, specifically cardiovascular or peripheral vascular disease, neuropathy, or endocrine disease. ED is seen in more than half of men with diabetes, and it can be the first symptom of the disease. A clearly new onset of ED in a man of any age should trigger a full medical reassessment, including an electrocardiogram and stress test, screening for glucose intolerance, and measurement of serum testosterone (Shamloul & Ghanem, 2013; Ghanem, Salonia, & Martin-Morales, 2013; Miner et al., 2014).

The medical causes of ED can be grouped into central (endocrine and neuropsychiatric), vascular and neurogenic. Under ordinary circumstances a man's erection begins with a central message of sexual arousal that is itself triggered by a sensory stimulus, a memory, or an association, sending a message through the autonomic nervous system to the penis. This

triggers engorgement of the corpora cavernosa, a process involving the inflow of arterial blood and the blockage of venous outflow. ED is explained by altered function at one or more points along this pathway. The various diagnostic tests that have been developed for diagnosing the cause of ED all aim to establish or rule out dysfunction at specific points in the pathway. For example, a Doppler ultrasound study of penile blood flow after intracavernous injection of prostaglandin specifically assesses whether arterial flow to the penis is adequate and whether the venous outflow is blocked without excessive leakage.

Historically physicians have been concerned with distinguishing “organic” from “psychogenic” ED. Practice has been moving away from this dualism because most patients with persistent ED have one or more general medical conditions that contribute to it, and ED in patients due to known general medical problems can be better or worse according to the patient’s mental state and situation. For this reason, the nocturnal penile tumescence (NPT) test is now seldom done, though medical psychiatrists will occasionally encounter the test. The NPT test uses an electrical strain gauge applied to the base and tip of the penis to determine the number of times and the degree to which the penis becomes rigid during sleep. The occurrence of multiple rigid erections during a night of sleep confirms that a complaint of ED is not due to peripheral neural or vascular factors. A lack of erections, or a lack of sufficient rigidity, suggests there are such neural or vascular factors contributing to the ED. The limitation of the NPT test is that a patient with normal erections during sleep can still have a nonpsychological reason for ED, for example, low testosterone. And a patient with impaired erections during sleep may have a significant emotional component to his ED in addition to the neural and/or vascular factors.

PDE5 Inhibitors

The advent of phosphodiesterase-5 (PDE5) inhibitors radically changed the diagnosis of ED as well as its treatment. At this time, most men without gross urological or neurological pathology who present to a physician with ED will have a general medical assessment followed by a trial of a PDE5 inhibitor,

unless they are taking nitrates for angina pectoris or the general medical workup reveals unstable cardiac disease. If the PDE5 inhibitor is effective the patient receives an ongoing prescription for one of them. If it is not, a further workup is done.

While this practice has made ED treatment much more widely available—and has thus encouraged men to recognize the problem and talk about it—it has two significant drawbacks. One is that important and treatable contributors to ED can be neglected if a PDE5 inhibitor works despite them. The second is that many men will try a PDE5 inhibitor as prescribed by their primary care physician or urologist, find that it doesn’t work or has intolerable side effects, and then give up on restoring their sexual potency—much as some patients who appropriately receive an SSRI for depression from their primary care physician may abandon efforts to treat their depression if that SSRI is not tolerated or is ineffective at the dose at which it was prescribed. In many of these cases either a different PDE5 or a different dose will be tolerated and effective; in others, another intervention in place of or in addition to a PDE5 inhibitor will work.

There are four PDE5 inhibitors approved in the US for treatment of ED: sildenafil (Viagra), tadalafil (Cialis), vardenafil (Levitra) and avanafil (Stendra). They are equally efficacious for treating ED but differ in their pharmacokinetics and in their specificity for inhibition of PDE5. The latter may account for some of the differences in side effect profiles. Sildenafil, the first PDE5 inhibitor to be approved, will be the first to be available in a lower cost generic version.

Table 35.2 summarizes the differences between the four PDE5 inhibitors available in the United States. Note that of the four, vardenafil is the only one associated with QT prolongation. Vardenafil is not recommended in patients taking type 1A or type 3 antiarrhythmics or those who have a prolonged QT interval (Corona, Razzoli, Forti, & Maggi, 2008). All of the PDE5 inhibitors can cause headache, flushing, nasal or sinus congestion, or dyspepsia. While about one-third of men will develop one or more side effects from use of a PDE5 inhibitor, fewer than 10% will discontinue the medication because of one of these side effects—and that percentage is even lower with tadalafil and avanafil. Considerations in the

Table 35.2 COMPARISON OF APPROVED PDE5 INHIBITORS

DRUG	ONSET OF ACTION	COMMENTS
Avanafil	Tmax 30–45 minutes; half-life 5 hours.	Most specific for PDE5; most rapid onset. No food effect. More flushing and headache than others. Lowest reported rate of discontinuation for side effects in clinical trials.
Sildenafil	Tmax 1 hour; half-life 4 hours	Absorption delayed by high-fat meal. Least specific for PDE5; most reports of vision or hearing loss; more benign visual symptoms than others. First to go off-patent.
Tadalafil	Tmax 2 hours; half-life 17.5 hours	Approved for daily use. More myalgias than others. No food effect. Preferred by most men who have tried several.
Vardenafil	T max 1 hour; half-life 4 hours	Associated with QT prolongation. Absorption delayed by high-fat meal. More back pain than others.

(Yuan et al., 2013; Raheem & Kell, 2009).

choice of a PDE5 inhibitor for a specific patient were comprehensively reviewed by Corona et al. (2011).

All of the PDE5 inhibitors will cause hypotensive reactions when combined with nitrates; because these reactions can be of life-threatening severity the combination is absolutely contraindicated. The combination of a PDE5 inhibitor with an alpha-adrenergic blocker can cause hypotension as well, although the degree is variable and the combination is not contraindicated; in fact, the combination can have additive benefits in patients with lower urinary tract symptoms (LUTS) due to benign prostate disease. When using the two drugs together, the risk of symptomatic hypotension is minimized by choosing an alpha blocker such as tamsulosin that is more specific for urinary tract alpha receptors, and by introducing the medicines one at a time with the second one started at a low dose and increased slowly.

Two very rare adverse effects of PDE5 inhibitors must be mentioned in the process of informed consent for their use (they are also likely to be mentioned by patients who are especially attuned to rare but serious potential side effects of medications). These are sudden loss of vision due to ischemic optic neuropathy and sudden loss of hearing due to ischemic cochlear damage. The risk of these adverse effects probably is less than one in 10,000 patients treated. The risk of either is greater at higher dosages; thus drug interactions due to CYP3A4 inhibition will increase the risk.

Nonarteritic anterior ischemic optic neuropathy (NAION) is a rare condition that can cause loss of visual acuity and even blindness. While numerous cases have been reported of NAION in men taking PDE5 inhibitors, the relationship of the drug to the eye disease is poorly understood. The overall incidence of NAION in adults over 50 is 2 to 10 per 100,000 per year. Thus, an extremely large sample would be needed to show the statistical significance of an increase in risk associated with a drug. Most patients who take PDE5 inhibitors have other risk factors of NAION, such as hypertension, nocturnal hypotension, smoking, sleep apnea, diabetes, hyperlipidemia, and/or prothrombotic factors. Notwithstanding, there are well-documented cases, most involving sildenafil, in which men developed sudden visual loss after taking a PDE5 inhibitor. The visual loss was resolved when the drug was stopped and recurred when the drug was restarted. There were other cases in which men lost vision in one eye coincident with taking a PDE5 inhibitor and lost vision in the other eye when rechallenged with the drug. The putative mechanism is hypotension in the branches of the posterior ciliary artery that supply the optic nerve head, possibly compounded by a loss of autoregulation of blood flow, endothelial dysfunction and choking off of the blood supply to the disc by ischemia-related edema. The last of these mechanisms can occur in men with small optic discs and a relatively small optic cup—so-called “discs at risk” (Danesh-Meyer & Levin, 2007). Patients should be warned about this potential issue and advised to stop their PDE5 inhibitor and consult an ophthalmologist immediately if they experience a sudden loss of visual acuity. Patients who have visible arterial disease in the optic fundi, small optic discs, and small optic cups should be warned that they are at particular risk for this side effect. If a patient with an elevated risk for

NAION wishes to try PDE5 therapy for ED and there are no other contraindications, low-dose daily tadalafil might be better than PRN sildenafil as it would avoid high peak levels of drug. However, there is no published evidence one way or the other.

Patients taking PDE5 inhibitors, especially sildenafil, can have benign visual symptoms such as altered color vision or increased glare sensitivity that do not alter or threaten to alter visual acuity and are completely unrelated to NAION. These are related to the effect of incidental PDE6 inhibition on retinal rods and cones. PDE6 is not found in the ophthalmic blood vessels (Laties & Sharlip, 2006). Among the four approved PDE5 inhibitors, avanafil is most specific for PDE5; a patient who develops troublesome though benign visual side effects on sildenafil might be switched to avanafil.

Sudden onset of sensorineural hearing impairment has been reported in association with PDE5 administration. Epidemiological evidence supports a potentially significant relationship to the use of sildenafil but not necessarily tadalafil or vardenafil. It is unclear if the mechanism of hearing loss is causally related: it could be due to local ischemia, to direct ototoxicity, or to eustachian tube obstruction with elevated middle ear pressure (McGwin, 2010). In a series of 18 men taking PDE5 inhibitors and monitored prospectively for hearing loss, four showed transient changes in auditory thresholds (Okuyucu, Guven, Akoglu, Uçar, & Dagli, 2009). However, the transient hearing loss observed by Okuyucu and colleagues is not necessarily due to the same mechanism as sudden and persistent hearing loss.

Among the PDE5 inhibitors, tadalafil is preferred by the majority of patients who have tried two or more. The preference has been attributed to the long half-life of the drug, which allows for greater spontaneity in the patient's sexual activity. Even so, some patients do not mind taking medication shortly before they anticipate having intercourse, and they may prefer avanafil or vardenafil because of their more rapid onset of action. In addition, a patient can have a side effect like headache, dyspepsia, or muscle pain with one PDE5 inhibitor and not with another.

All of the approved PDE5 inhibitors are metabolized by CYP3A4. Therefore, adjustment of the dosage of the PDE5 inhibitor often will be necessary if the patient is also taking another drug that induces or strongly inhibits CYP3A4. Patients suspected of having slow metabolism of CYP3A4 substrates because of their experience with other drugs should be started on lower than usual doses of PDE5 inhibitors.

In clinical use the PDE5 inhibitors raise issues homologous to those that arise with SSRI antidepressants: While the efficacy of the alternatives is the same in populations, individual patients can tolerate one better than another or can prefer one to another. Avanafil, the most PDE5-selective of the approved PDE5 inhibitors, may have the lowest incidence of adverse effects; in a recent Korean study fewer than 3% of men treated with avanafil over a 1-year period discontinued the drug because of side effects (Sanford, 2013). Dosage must be individualized and there are many potential drug interactions. A patient should be offered a trial of a different PDE5 inhibitor if they don't respond to the first one at the maximum tolerated

approved dosage or if they have unpleasant (though not medically serious) side effects at the minimum efficacious dosage. Four attempts at intercourse with a specific PDE5 inhibitor and dose are sufficient to make a judgment about its efficacy.

A patient with ED and a low testosterone level (total T level <300 ng/mL) who does not respond to PDE5 inhibitor therapy may become a responder when testosterone supplementation is added (Shamloul et al., 2005). A patient with ED and chronic lower urinary tract symptoms (e.g., from chronic prostatitis or BPH) who does not respond to PDE5 inhibitors may become a responder when an alpha-adrenergic blocker is added. However, the combination is associated with the potential for symptomatic hypotension. Some patients with a partial but not satisfactory response to intermittent PDE5 therapy will respond to daily tadalafil, though the dosage required may be higher than the approved dosage of 5 mg per day. Daily tadalafil therapy is of particular interest in men with both ED and LUTS. LUTS can improve significantly with daily tadalafil, though tadalafil is not approved for this indication the improvement is of similar magnitude to that seen with alpha-adrenergic blockers (Park, Won, Sorsaburu, Rivera, & Lee, 2013).

Several other options are available for treatment of ED not responsive to PDE5 therapy. PDE5 inhibitors require sufficiently intact parasympathetic innervation of the penis. In cases of neuropathic or surgically related denervation of the penis, an intra-urethral pellet of prostaglandin E1 (PGE1; alprostadil) administered via an applicator may be efficacious, as the effect of PGE1 effect on the blood supply to the corpora cavernosa is independent of neural inputs to the blood vessels. Intracavernosal injections of alprostadil are even more efficacious in the same situation, though less preferred by most patients than the urethral suppositories because of the inconvenience of injection; in addition they can cause—albeit rarely—priapism or penile fibrosis (Costa & Potempa, 2012).

When ED is based on leakage from the veins of the corpora cavernosa an erection can be maintained by placing an elastic band around the base of the penis to block the outflow of blood. When arterial inflow is insufficient none of the above treatments can work; in this situation a penile prosthesis is the remaining option. There are both semirigid and inflatable prostheses; the choice is a matter of patient preference (Porst et al., 2013).

Thus, most cases of ED based on neural factors, vascular disease, and/or testosterone deficiency can be treated effectively. Optimal results in terms of a satisfying sexual life often require nonpharmacologic therapy in addition. Patients with significant general medical illness can have issues of depression, anxiety, or specific fears that affect their sexuality. Couple issues may contribute. Men with limited and largely disappointing sexual experience associated with ED can be in a self-defeating cycle in which they lack confidence and approach potential sexual relationships with anxiety that adversely affects their erectile function as well as their communication with their potential sexual partner. Cognitive behavioral therapy and group therapy can be helpful to such patients. Patients with disabilities that they fear will put off a potential partner might be appropriate candidates for sex

therapy with a surrogate partner. In this case the patient would be referred to a well-reputed sex therapy clinic with an established surrogate program; less formal arrangements would be complicated by the potential for ethical and reputational issues.

PREMATURE EJACULATION

Premature ejaculation has been defined by the American Urological Association as ejaculation that occurs sooner than desired, either before or shortly after penetration, causing distress to one or both partners. A variety of alternative criteria have been proposed, some of which specify that ejaculation occurs within less than one minute or less than two minutes after penetration. However, the AUA definition is an inclusive one that is consistent with a patient-centered approach to the problem (Serefoglu & Saitz, 2012). The best established instrument for confirming a diagnosis of PE is the Premature Ejaculation Diagnostic Tool (PEDT; see Symonds et al., 2007; Althof & Symonds, 2007). The prevalence of PE in community studies has ranged widely, corresponding to the inclusiveness of the diagnostic criteria used. A recent study of almost 5,000 men using a criterion of PEDT ≥ 11 found a community prevalence of 16% (McMahon, Lee, Park, & Adaikan, 2012). Patients with PE usually do not seek treatment for it, and some younger men with the disorder will avoid sexual relationships or even intimacy with sexual potential because of embarrassment over the condition. Others present in infertility clinics, where a detailed history reveals that ejaculation prior to penetration has prevented fertilization.

PE can be either lifelong and consistent or acquired. Lifelong PE can persist for life if not treated; it represents a biological predisposition but is not due to medical disease. Acquired and subsequently persistent PE in a man with previously satisfactory ejaculatory function suggests either urological or endocrine disease, a drug side effect, or a psychological or relationship problem (Serefoglu & Saitz, 2012). Among psychological factors, anxiety related to the sexual relationship or the sexual act commonly contributes.

Treatment of lifelong PE should begin with sex education; treatment of acquired PE should begin with a medical-psychiatric evaluation. If the patient is in a marriage or other regular sexual relationship the spouse or partner usually should participate, although there are cases in which the patient wants to “own the problem” himself or in which working with the couple is otherwise complicated.

There are several efficacious pharmacological treatments, one of which is approved and available OTC. The approved treatment is a proprietary formulation of topical lidocaine—a eutectic lidocaine spray that the patient applies to the head and shaft of the penis about 10 minutes before intercourse. The lidocaine is formulated to penetrate the skin, providing sufficient reduction in sensation to increase the patient’s time to orgasm. Systemic absorption is negligible, and there is not enough lidocaine transferred to impair the partner’s sensation. The patient adjusts the number of sprays to the minimum necessary to attain a satisfactory post-penetration ejaculatory latency (McMahon, 2009; Promescent package insert).

Three off-label options are tramadol, SSRIs, and PDE5 inhibitors. Tramadol 25 mg taken shortly before intercourse can remarkably prolong intravaginal ejaculatory latency time (IELT); in one study IELT was extended by over 6 minutes (Salem et al., 2008). Tramadol has the potential to cause nausea, constipation, and sedation, as it does when used as an analgesic.

SSRIs taken daily at antidepressant doses will delay ejaculation, with a peak of effect after 1–2 weeks of treatment. A single dose of an SSRI taken 4–6 hours before intercourse can help, though less reliably than daily dosing. Loss of libido, ED, and orgasmic dysfunction are potential side effects in addition to the usual nonsexual side effects of SSRIs. Of greater concern to patients trying to conceive, SSRIs impair spermatogenesis and adversely affect semen quality (Safarinejad, 2008; Tanrikut, Feldman, Altemus, & Paduch, 2010; Koyuncu et al., 2011; Koyuncu, Serefoglu, Ozdemir, & Hellstrom, 2012; Alzahrani, 2012; Attia & Bakheet, 2013).

While PDE5 inhibitors don't prolong ejaculatory latency, they can help patients with PD in several ways. First, they address concomitant ED when it is present and, in any case, improve sexual confidence. Second, they reduce the refractory period following ejaculation, and patients who ejaculate prematurely with initial intercourse may have longer IELT on a second attempt a few minutes later. Third, they can mitigate ED that would otherwise be a side effect of topical lidocaine or SSRIs used to treat PE.

As with ED, combination of pharmacologic and nonpharmacologic therapy may be required for optimal outcome. However, it is worth noting that in men with lifelong PE pharmacologic therapies have larger effect sizes and more consistent results than psychotherapeutic and behavioral interventions. Psychotherapy and behavioral interventions have a more central role in acquired PE when the latter is not due to a new-onset endocrine or urological condition or a drug side effect.

ORGASMIC DYSFUNCTION

Orgasmic dysfunction can refer either to inhibited orgasm or to retrograde ejaculation; both conditions can be causes of male infertility. Retrograde ejaculation—semen discharge into the bladder rather than into the penile urethra, occurs when the internal urethral sphincter does not close during orgasm. Causes include prostate surgery and side effects of alpha-adrenergic blockers. Orgasm can be delayed by neuropathic sensory loss in the penis as well as by opiates; as noted above tramadol can profoundly affect time to ejaculation. Several classes of antidepressants can cause orgasmic dysfunction including SSRIs, SNRIs, MAOIs, and TCAs; among the latter clomipramine and amitriptyline are the worst as they have the greatest effects on serotonergic transmission. Anorgasmia due to these drugs sometimes can be reversed with PRN use of cyproheptadine, a serotonin antagonist. The dose is 4 mg 30–60 minutes before intercourse is planned; the main side effects are sedation and anticholinergic effects (which at worst can lead to ED). Yohimbine has also been used successfully to reverse anorgasmia induced by antidepressants (Keller, Hamer, & Rosen, 1997); in contrast to cyproheptadine, it sometimes can improve arousal and erectile function.

While drugs with potent effects on serotonergic transmission can affect libido, arousal, and erection as well as orgasm, they often cause orgasmic dysfunction disproportionate to changes in other aspects of sexual function. A wide range of other drugs that cause orgasmic dysfunction usually do so more in proportion to other sexual side effects.

When a patient in a long-term sexual relationship newly develops orgasmic dysfunction not explained by a drug side effect, it is likely that there is a relationship issue. An effort should be made to assess the couple, either directly by the medical psychiatrist or through a referral. When the patient is the only willing participant in the treatment, the spouse or partner's role in the couple's dysfunction must be inferred and addressed indirectly.

Drugs with effects on adrenergic and serotonergic function are most frequently associated with orgasmic dysfunction. However, any of a broad range of drugs that have been associated with sexual dysfunction in general can cause orgasmic dysfunction in some patients. A list of common offenders is provided later in this chapter. Typically orgasmic dysfunction due to medications develops within weeks of starting the drug. Suspicion of inducing orgasmic dysfunction should thus fall mainly on drugs recently introduced or increased in dosage and on medications with blood levels or effects that might have increased recently because of interaction with another medication recently introduced, discontinued, or changed in dosage.

The literature on drug-induced orgasmic dysfunction has focused more on ejaculatory dysfunction in men than on impaired orgasm in women. If a woman newly develops inhibited orgasm after a change in medication regimen, this possibility should be considered, especially if the drug is relatively new to the market, notwithstanding the absence of published reports concerning female orgasmic dysfunction with the new medication.

LOSS OF LIBIDO

Loss of libido—decreased sexual interest, desire, and ease of sexual arousal—is a common accompaniment of chronic medical diseases, a typical symptom of depression, and a side effect of several commonly prescribed classes of drugs including the beta blockers and thiazide diuretics, as well as SSRIs and other agents affecting serotonergic neurotransmission. Specific diseases and drugs will be discussed later in this chapter.

A common intermediate factor linking chronic diseases with loss of libido—or accentuating the effect of chronic diseases on sexual function—is androgen deficiency (Traish, Miner, Morgentaler, & Zitzmann, 2011). Low testosterone causes a characteristic combination of symptoms including muscle wasting, abdominal obesity (sometimes with the metabolic syndrome), diminished vigor, and loss of libido. The testosterone level required for normal sexual function differs significantly among men (Finkelstein et al., 2013). When a man has a serum testosterone of <200 ng/mL, accepted practice is to give testosterone supplementation. When the testosterone level is borderline low—between 200 ng/mL and 300 ng/mL—and

the patient has one or more characteristic symptoms of androgen deficiency, the patient should be given a trial of testosterone supplementation to bring the serum level to the middle of the normal range. If several weeks of supplementation to this level provides clear-cut symptomatic benefit, the treatment should be continued. Testosterone supplementation is given transdermally via a gel or a patch. A history of prostate cancer has until recently been regarded as a contraindication to testosterone therapy, and a survey of physicians suggested that fear of increasing prostate cancer risk was their greatest concern about testosterone replacement. However, no correlation has been demonstrated between testosterone levels and prostate cancer incidence in the general male population, and a multiple controlled trials of testosterone supplementation did not show a greater incidence of prostate cancer in men receiving testosterone than in those receiving placebo (Traish et al., 2011; Raynaud 2006; Shabsigh et al., 2004; Cui, Zong, Yan, & Zhang, 2014; Khera, Crawford, Morales, Salonia, & Morgentaler, 2014). Pastuszak et al. (2013) published a case series of men who had received radiation therapy for prostate cancer and subsequently received testosterone replacement therapy; none developed any recurrence of their cancer.

Morgentaler et al. (2011) have advanced the hypothesis that prostatic androgen receptors are saturated at a level of testosterone well below the threshold for symptomatic hypogonadism, so that men with prostate cancer and low testosterone levels who have not been castrated or treated with anti-androgens still have enough testosterone to saturate prostatic androgen receptors even though there are significant somatic symptoms of androgen deficiency. They infer that testosterone replacement to physiologic levels would not incrementally stimulate prostate growth, and thus that symptomatic testosterone deficiency could safely be treated in men with prostate cancer following cancer treatment that is appropriate for the size and stage of the cancer (Morgentaler et al., 2011). Notwithstanding, there remains some uncertainty on this point (Corona & Maggi, 2013). A conservative approach would be to monitor the patient for cancer recurrence for several months, then, if there were no evidence of recurrence and symptoms of hypogonadism were distressing, to replace testosterone to the physiological range. If the symptoms attributed to hypogonadism resolved and there were no increase in prostate-specific antigen or hemoglobin or change on the prostate examination, testosterone therapy would be continued. In most cases of sexual dysfunction encountered in medical psychiatric practice, testosterone deficiency is not the sole cause. However, correcting testosterone deficiency can be a necessary (though not usually sufficient) step to treat the dysfunction. For maximum diagnostic value, testosterone levels should be drawn in the morning. If results are borderline the test should be repeated, and free testosterone should be measured if the test is available.

FEMALE SEXUAL DYSFUNCTION

The most prevalent types of female sexual dysfunction are lack of sexual desire, impaired arousal, orgasmic dysfunction,

dyspareunia (painful intercourse), and vaginismus (involuntary spasm of the vagina that prevents insertion of the penis into the vagina). The point prevalence of any sexual dysfunction in American women was 43% in a recent survey; however, only 12% of the women reporting sexual dysfunction reported being distressed by it. Most women with sexual dysfunction do not seek help for it. However, many more women will report sexual dysfunction to a physician if they are asked specifically about it. For example, in one gynecology outpatient clinic the frequency of spontaneous complaints of sexual dysfunction was 3%, but 19% of patients acknowledged a complaint if directly asked (Buster, 2013). A focus on changes in sexual interest (desire) is a useful point of departure for eliciting, diagnosing, and treating female sexual dysfunction. Often diminished desire and another sexual dysfunction will have the same cause, for example, diminished desire and orgasmic dysfunction due to an SSRI. And, if desire is strong, a patient will be motivated to address other sexual dysfunctions and relevant relationship and communication issues.

SEXUALLY RELATED PAIN: VAGINISMUS

Vaginismus is pain and spasm of the distal third of the vagina when penetration is attempted or, in severe cases, even contemplated. The spasm physically prevents vaginal intercourse; the condition is the most common reason for unconsummated marriages. Some women with vaginismus have a lifetime history of the condition, for example, always having been unable to use tampons during their menstrual periods. Others develop the condition suddenly after a history of successful vaginal intercourse. Acquired vaginismus can occur after sexual or emotional trauma, but many cases are unexplained. In milder cases suggestions by the patient's gynecologist are sufficient to resolve the problem. These include the following: (1) do Kegel exercises to build control of the pubococcygeal muscle; (2) use a generous amount of lubricant when intercourse is attempted; (3) use the female-superior position, as this gives the woman control over the rate of insertion; (4) attempt intercourse in a generally relaxed state in a pleasant environment; (5) practice the insertion of objects of progressively larger diameter into the vagina. The gynecologist can use (or provide) a graduated set of vaginal dilators; a cooperative spouse or sexual partner can use fingers to accomplish the same purpose. The medical psychiatrist can address the patient's fear and anxiety associated with either pharmacologic or nonpharmacologic treatment. Here too a cooperative spouse or partner sometimes can help.

The situation may arise where a woman with vaginismus has no partner and avoids romantic relationships because of concern they will lead to sex—a prospect that raises fears not only of pain but also embarrassment and possibly romantic abandonment. Treatment of such a patient by a sex therapy clinic that provides a surrogate partner might be considered when the option is available.

More severe cases of vaginismus may yield to progressive dilation of the vagina under anesthesia. If a patient's vaginismus does not resolve with these maneuvers it may respond to injections of botulinum toxin into the levator ani muscle

(Ferreira & Souza, 2012). Uncontrolled case series suggest a high response rate (Pacik, 2011).

SEXUALLY RELATED PAIN: DYSPAREUNIA

Dyspareunia is pain with vaginal intercourse. It can be secondary to any of a number of gynecologic conditions including infections, tumors, and endometriosis. However, the most common cause of dyspareunia that medical psychiatrists will encounter is postmenopausal vaginal and vulvar atrophy, a condition that affects as many as 45% of women later in life (North American Menopause Society, 2013). During and after the menopause, the deficiency of estrogen leads to thinning of the vaginal mucosa and a loss of secretions. In this condition, called *atrophic vaginitis* or *vulvovaginal atrophy*, the vaginal wall can be tender or simply can be dry and subject to irritation by the friction of intercourse. In addition to pain there can be a blood-tinged discharge following intercourse that a woman may find frightening. Pain with vaginal intercourse can lead to reduced sexual desire that in turn reduces the woman's motivation to address and resolve the dyspareunia. The treatment of atrophic vaginitis has been comprehensively reviewed by Tan and colleagues (2012).

Physicians treating postmenopausal dyspareunia tend to avoid systemic hormone replacement therapy (HRT) because of concerns about cancer risk and thromboembolic risk; they consider use of systemic HRT when there are other problems such as vasomotor symptoms and insomnia in addition to the vaginitis. When dyspareunia is the sole or main problem, the usual treatment is topical estrogen delivered as a cream (e.g., Premarin or Estrace cream), a vaginal tablet (e.g., Vagifem), or a ring-shaped pessary (e.g., Estring) (Archer, 2010; Castelo-Branco, Cancelo, Villero, Nohales, & Juliá, 2005). Topical estrogens are intended to be safe for long-term use without a concomitant progestin; the amount of estrogen absorbed systemically should be low enough that there is no thickening of the endometrium, no increased risk of endometrial cancer. Patients taking vaginal estrogen therapy that does not significantly raise estrogen blood levels appear to have no increased risk of breast cancer. However, the safety of vaginal estrogens for patients with estrogen receptor–positive breast cancer, including those taking aromatase inhibitors, is unknown (Ponzone et al., 2005).

While serum levels of estrogens in patients taking one of the commonly used vaginal estrogen preparations *usually* are well within the usual postmenopausal range, the systemic absorption and subsequent metabolism of estrogens from topical preparations is in fact variable, with some postmenopausal women having serum estrogen levels outside the normal postmenopausal range (Bhamra et al., 2011)—or suppression of their FSH levels—when taking the labeled dosage of estrogen cream or the now discontinued 25 µg dosage of the Vagifem estradiol tablet. Absorption of estrogens will depend in part on the condition of the vaginal mucosa. Once absorbed, estradiol is metabolized by CYP3A4, so whatever estradiol is systemically absorbed from the vagina will accumulate more if CYP3A4 is inhibited or if the patient is, for genetic reasons, a slow metabolizer of CYP3A4

substrates. Medically significant elevation of serum estrogen would be unusual but not completely impossible with the 10 µg Vagifem tablet or with Estring, which delivers approximately 7.5 µg/day of topical estradiol. In a safety study of 336 women sponsored by its manufacturer, the 10 µg Vagifem tablet (estradiol), taken once daily for 2 weeks and twice weekly thereafter, did not increase estradiol levels beyond the postmenopausal range or suppress FSH. Patients who took it showed no thickening of the endometrium on ultrasound examination or endometrial biopsy after 1 year of use (Chollet, 2011; Simon & Maamari, 2013).

A more conservative option for treating dyspareunia due to atrophic vaginitis is using a vaginal moisturizer on a regular basis (e.g., three times weekly). Many women first deal with postmenopausal dyspareunia by using a lubricant to facilitate intercourse. However, thrice-weekly use of a vaginal moisturizer is fundamentally more helpful for symptoms of vaginal atrophy than occasional use of a lubricant. It makes the vaginal wall thicker and more flexible as well as wetter, reducing itching, lowering vaginal pH, and, over several weeks, eventually providing as much relief from painful intercourse as vaginal estrogens for most (though not all) patients who take them (Bygdeman & Swahn, 1996). Replens and similar vaginal moisturizers use ingredients similar to those used in sustained-release oral tablets; they might be thought of as “sustained release water” delivered to the dry vaginal surface.

A newly approved therapy for dyspareunia due to vulvar and vaginal atrophy is ospemifene, a selective estrogen receptor modulator (SERM). Given orally at a dose of 60 mg per day ospemifene restores the vaginal mucosa and relieves dyspareunia, without affecting the endometrium and thereby requiring concurrent progestin administration. It may have benefits for preventing osteoporosis like the SERM raloxifene, and preclinical studies suggest it might actually reduce breast cancer risk. As it was very recently approved, clinical experience and Phase 4 studies will be needed to delineate its place in the spectrum of treatment options (Soe, Wurz, Kao, & Degregorio, 2013).

There is some evidence that low doses of systemic testosterone (e.g., a 200 mg testosterone transdermal patch) can help atrophic vaginitis and restore sexual interest in postmenopausal women. Low-dose testosterone does not necessarily have unacceptable masculinizing effects (Davis et al., 2008; Braunstein et al., 2005), and it appears to be safe in this population (Shifren, Monz, Russo, Segreti, & Johannes, 2008). However, Endocrine Society guidelines do not at this time recommend androgens to menopausal symptoms (Wierman et al., 2006). Topical use of testosterone or DHEA may be an option for women who do not tolerate topical vaginal estrogens (Tan, Bradshaw, & Carr, 2012); research is ongoing.

Finally, some cases of discomfort with sexual intercourse are related to muscle pain that can be addressed by improving the tone of the pelvic muscles. This is done with the same Kegel exercises that are recommended for stress urinary incontinence, for vaginismus, and for preparation for pregnancy.

ORGASMIC DYSFUNCTION

In women orgasmic dysfunction refers to the lack of orgasm, delay of orgasm, or orgasms of markedly diminished intensity despite adequate stimulation and a high level of sexual arousal. Regarding the definition of “adequate stimulation,” note that most women require stimulation of the clitoris to reach an orgasm. The indirect stimulation of the clitoris during vaginal intercourse is sufficient for some women to reach orgasm, but most will usually require some degree of direct clitoral stimulation. Anorgasmia, the complete lack of orgasms, can be either primary or secondary. Women with primary anorgasmia have never experienced an orgasm; those with secondary anorgasmia have experienced orgasm and subsequently lost the capacity to do so. The International Society for Sexual Medicine has recently published practice guidelines for evaluating and treating female orgasmic disorders (Laan, Rellini, & Barnes, 2013).

The clitoral complex includes the glans clitoris and clitoral bodies and bulbs; it is larger than the glans only and extends to the perineal body (Foldes & Buisson, 2009). While many people think of the clitoris as just the glans clitoris, stimulation of any part of the clitoral complex can bring about an orgasm. Pressure on and movement of the clitoris’s root during vaginal penetration and subsequent perineal contraction may explain the sensitivity of the anterior vaginal wall. Systematic study has not confirmed the existence of “G Spot” in the vagina that has clitoris-like sensitivity to stimulation. When a woman reports inability to have an orgasm, the first step in evaluation is to confirm that direct and sustained stimulation of the clitoris has been tried either by the woman’s spouse or partner or by the woman herself while masturbating. Individual differences in the ability to have an orgasm without direct clitoral stimulation relate both to differences in genital anatomy and differences in the central processing of genital stimuli.

Women who have never experienced orgasm usually can do so with masturbation; some women require the permission implicit in getting medical treatment to feel comfortable with self-stimulation. Overall, an educational approach is often successful, with referral to a sex therapy clinic the second step.

When a female patient who has previously experienced orgasm loses the ability there are several initial considerations:

1. Does the patient experience the same degree of sexual arousal as she did when she was orgasmic? If not, is there a lack of desire or a lack of arousal despite adequate desire?
2. Does the patient suffer pain or discomfort—or the fear of pain or discomfort—during intercourse?
3. Has there been a change in the partner’s sexual technique, so that there has been a change in clitoral stimulation?
4. Does the patient almost but not quite reach orgasm? This is a common experience among patients who develop orgasmic dysfunction as a side effect of antidepressant medications that affect serotonergic transmission.

Sometimes changes in sexual technique can facilitate orgasm during intercourse. Alternatively, the patient’s spouse or

partner can bring her to orgasm with oral or manual stimulation and follow with vaginal intercourse. Good communication between the partners about sexual matters helps greatly; sometimes this can be facilitated by a single clinical visit by the couple in which the mechanics of intercourse are discussed in more detail than might be natural at home.

LOSS OF LIBIDO AND HYPOACTIVE SEXUAL DESIRE DISORDER

Women’s sexual desire is highest when estradiol levels peak, at the time of ovulation. Estrogenic action increases vaginal blood flow and the release of vasoactive substances such as nitric oxide by endothelial cells, leading to vasodilation and an increase of peripheral vibratory sensation. The postpartum period is a time of transition, and about half of women report less desire over 3 months after parturition. The majority of women (80%) resume sexual activity by 6 weeks after a baby is born. Another decline in desire occurs in the menopausal transition, the last phase before the final menses as estrogen is declining (Bitzer, Giraldis, & Pfaus, 2013). A persistent loss of sexual interest and desire that goes beyond normal changes with the menstrual cycle and life cycle, and that cause a woman significant distress and/or interpersonal difficulties may meet criteria for a diagnosis of Hypoactive Sexual Desire Disorder (HSDD). Given the wide variation in normal women’s sexuality, the element of distress is critical diagnostically. It can be measured quantitatively, for example, with the Female Sexual Distress Inventory (Derogatis, Clayton, Lewis-D’Agostino, Wunderlich, & Fu, 2008) or the Sexual Interest and Desire Inventory-Female (Clayton et al., 2006).

Clinical depression can cause low sexual desire in both sexes (40% for women and 30% for men). A study characterizing sexual dysfunction in a group of depressed premenopausal women as they were about to participate in an antidepressant study, found that 18% had hypoactive sexual desire disorder, 3% sexual aversion disorder, 6% arousal disorder, and 8% orgasmic disorder. The more severe the depression, the more severe the sexual dysfunction (Fabre & Smith, 2012). Aversion to sex, when not a consequence of sexual trauma, often is a reflection of anxiety and is viewed by some as a phobic disorder rather than a sexual dysfunction. Both behavioral treatments and antidepressant treatment can help relieve it, with the usual warning that the most commonly prescribed antidepressants frequently cause a loss of libido—thus, ironically, replacing an aversion to sex with simple lack of interest. Alternatively, the patient might be treated with an antidepressant less associated with sexual side effects, such as mirtazapine, or bupropion. Vilazodone, a new SSRI with 5-HT1A partial agonist effects, might have a lower incidence of sexual dysfunction and the other SSRIs (Clayton, Kennedy, Edwards, Gallipoli, & Reed, 2013). Each has its own unique side effects of potential medical-psychiatric relevance, such as lowering of the seizure threshold with bupropion or sedation and weight gain with mirtazapine. Vilazodone is relatively new to the market, and its place in the spectrum of antidepressants is not yet established.

The psychological contribution to diminished sexual desire is complex, particularly for women. To make this point, Basson and colleagues (2010) note that depression is the major factor determining whether women with multiple sclerosis, renal failure, or diabetes have sexual dysfunction. Automatic negative thoughts during sexual activity are the strongest predictors of decreased desire. Patients' general medical symptoms show indirect effects via distraction or anxious thoughts about sexual failure. Patients' negative past experiences or beliefs that sex is bad or sinful may color current attitudes. Concerns about body image or low self-esteem related to illness or disability can reduce desire.

Conflicts that reduce libido may be intrapsychic or may be between the patient and her spouse or partner. Besides the interpersonal relationship, personal psychological factors of importance include self-image, comfort with being vulnerable, and ability to allow intimacy with another despite the risk of suffering grief if that person is lost. In other words, the anxious and avoidant attachment styles are problematic for sexuality. Basson and colleagues (2010) also note that many women engage in routine intercourse-focused sexual activity that lacks eroticism, pleasure, and intimacy. Distinguishing these psychological factors in order to define a group of women with an isolated ego-dystonic reduction in desire for intercourse—in other words, hypoactive sexual desire disorder (HSDD)—is a challenging requirement for research.

Testosterone influences social behavior, and social behavior affects testosterone levels. The basal level of testosterone remains fairly constant in men and women and may define a trait. In women with ovariectomy, testosterone drops precipitously compared to natural menopause. 200 mg transdermal testosterone patches have been used off-label in ovariectomized women and those with natural menopause to increase sexual desire and frequency of sex. Potential side effects include hair growth and acne, though these would be expected to be rare at dosages that simply restored testosterone to the range ordinarily seen in premenopausal women. Data support the safety of testosterone for postmenopausal women; there are insufficient data to comment on safety for premenopausal women (Shifren et al., 2008).

As of this writing no medication is approved for the treatment of HSDD in women, and the evidence in support of specific medications is limited. Given the relative lack of an evidence base to guide treatment decisions, effective pharmacological treatment of HSDD is likely to involve both psychological and pharmacological exploration in a context of a trusting therapeutic relationship, informed consent, and careful analysis of the subjective and objective effects of each drug that is tried. Bloemers et al. (2013) have suggested that different women have different causal mechanisms for an intrinsic sexual desire disorder. Some women have a relative insensitivity for sexual cues, while others are inhibited during sexual stimulation. Sublingual testosterone 0.5 mg increases the sensitivity of the brain to sexual cues with a delay in effect of about 4 hours; this might be effective preparation for the arousal-enhancing benefit from a PDE5 inhibitor, the actions of which are contingent on the presence of sexual desire. In addition, a 5HT1A receptor agonist timed for maximal effect during a woman's window

of increased sensitivity to sexual cues might be helpful to reduce inhibition. Thus, the combination of testosterone and a PDE5 inhibitor may be effective for those with low sensitivity for sexual cues, while adding a 5HT1A receptor agonist medication to testosterone may work for women with sexual inhibitions (Poels et al., 2013; Van Rooij et al., 2013). The treatment of HSDD can be even more challenging in women with chronic general medical illness that are taking multiple medications for those conditions. A woman must really "want to want to" have sexual relations to succeed in the process. For this reason a more comprehensive medical-psychiatric assessment, including involvement of the patient's spouse or partner when feasible, should precede intervention more narrowly focused on the sexual issue. Conversely, it often makes sense to revisit issues of sexuality—including both the desire to be sexual and sexual desire—several visits into a course of treatment of a medical-psychiatric patient. If medical-psychiatric involvement continues over the long-term course of a chronic illness, issues of sexuality should be reopened from time to time. Such issues might only become relevant or only become addressable after more pressing issues like management of pain, treatment of depression, or coping with trauma or loss have been addressed.

Good communication between partners—whether explicit and verbal or implicit and nonverbal—is essential to a good long-term sexual relationship. Sex therapy and less specific communication skills training probably have equal efficacy for sexual dysfunction in couples with a stable relationship and previously satisfactory sex. Given that communication skills training has other benefits and may be less threatening to patients or their partners, it should be an early consideration. Most couples can understand that coping with general medical illness requires especially good communication, and that even a couple that has communicated adequately under normal circumstances might benefit from communication skills training to help them face the unusual challenges posed by illness.

Sexual behavior is inextricably intertwined with relationship issues, which is yet another reason to explore the sexual relationship when evaluating a patient with a chronic medical-psychiatric issue. In the acute medical situation, there are more pressing concerns, though occasionally a patient's concern about the impact of the general medical illness on future sexual life is a major contributor to depression or anxiety. Exploring a change in a couples' sexual relationship sometimes reveals information about the behavior or mood of the patient and the patient's spouse or partner. The discussion may be an opening to patients' misconceptions about general medical illness or to revelations about a dysfunctional caregiving relationship.

A history of sexual abuse does not always result in difficulty with orgasm nor can it be presumed to be the cause of dysfunction. Childhood experiences may, but do not necessarily, affect present attitudes. Among survivors of sexual abuse, low desire is the most common sexual symptom reported.

When the focus is sex with a spouse or partner, the spouse or partner should be involved in evaluation, and marital conflicts and/or communication difficulties should be addressed

first. Behavioral sex therapy overlaps with couple therapy. An approach of graded increases in treatment, the PLISSIT model (Annon, 1976) begins with a physician providing **P**ermission, **L**imited **I**nformation, **S**pecific **S**uggestions, and ultimately more **I**ntensive **T**herapy and referral.

For women with primary anorgasmia, the International Society for Sexual Medicine recommends cognitive behavioral psychotherapies with an initial focus on directed masturbation training. This training—which has been delivered successfully in group, individual, couples, and self-directed reading contexts—involves graded exposure to genital stimulation and may include role playing an orgasmic response and the use of sexual fantasy with or without a vibrator (Heiman, 2002).

Sensate focus can be added to this treatment. This strategy for couples includes graded exposure from nonsexual to sexual focusing, building trust and communication, and relieving anxiety first before focusing on a goal of intercourse or orgasm. It improves attention to pleasurable sensual and sexual feelings without demanding the outcome of intercourse.

SPECIFIC MEDICAL CAUSES OF SEXUAL DYSFUNCTION

DEPRESSION

Major depression, a common and remarkably morbid condition, most often occurs as a primary mental disorder and is more prevalent in women than in men. The syndrome of major depression frequently complicates general medical conditions that involve pain and/or loss of function. Some chronic diseases cause depression disproportionately, which implies that a specific endocrine, neurological, biochemical, or immunological process is mediating the connection of the general medical disease with the mood disorder. Major depression in turn causes sexual dysfunction that usually resolves when the depression remits. Low sexual desire is a symptom reported by approximately 40% of women and 30% of men with major depression. Greater severity of depression is associated with greater sexual dysfunction. Thus, when a patient with general medical illness has diminished sexual interest, depression should be identified and treated if it is present. The decision whether to treat the depression and the sexual dysfunction sequentially versus simultaneously should take into account the patient's presenting complaints and whether actual or feared loss of sexual function is an important contributor to the patient's emotional distress. In the latter case fully evaluating other potential causes of sexual dysfunction is essential.

SEXUAL DYSFUNCTION IN SPECIFIC MEDICAL CONDITIONS

ENDOCRINE DISORDERS

Sexual dysfunction can be caused or exacerbated by excess or deficiency of any of several hormones, and restoration of

normal hormone levels is a usually necessary and sometimes sufficient treatment for that dysfunction. There are nonetheless areas of ambiguity, particularly when hormonal abnormalities are “subclinical” apart from their hypothesized effects on sexual function.

Obviously, changes in the reproductive endocrine system can cause sexual dysfunction. Hyperprolactinemia reduces sexual interest and erectile function in men at levels greater than 35 ng/mL (735 IU/L), though many cases of hyperprolactinemia in men are caused by pituitary tumors that can have effects on other hormones, notably testosterone (Maggi, Buvat, Corona, Guay, & Torres, 2013). The endocrine environment of the immediate postpartum period (high prolactin and suddenly decreased estrogen and progesterone) is associated with low libido, as is the endocrine environment of the late perimenopause.

Thyroid disorders have remarkably specific patterns of associated sexual dysfunction. Carani et al. (2005) found that of 34 adult men with hyperthyroidism, 50% had premature ejaculation; other sexual dysfunctions were much less common. Of 14 men with hypothyroidism, 65% had orgasmic dysfunction (delayed ejaculation). The hypothyroid men had similarly high rates of loss of libido and ED, but only 7% had premature ejaculation.

The literature on male sexual dysfunction in acromegaly is mixed; it is unclear whether GH excess has a specific effect on sexual function. Low DHEA levels have been hypothesized to be related to various age-associated symptoms including sexual dysfunction. However, controlled trials have not shown improved male sexual function with DHEA supplementation (Maggi et al., 2013).

NEUROLOGICAL DISEASES

Neurological diseases can affect sexual function directly, via depression, via drug side effects, or via alterations in the couples' relationships due to caregiving burdens and changes in personality or behavior due to brain dysfunction. Three chronic neurological diseases have an especially high prevalence of sexual dysfunction: Multiple sclerosis, temporal lobe epilepsy, and Parkinson's disease.

In multiple sclerosis patients sexual dysfunction affects up to 50%–90% of men and 40%–85% of women. Both men and women with MS often have decreased libido. Men with MS may also have ED and/or ejaculatory dysfunction. Women may also have abnormal vaginal sensation, decreased vaginal lubrication, and orgasmic dysfunction. Sildenafil has been shown to alleviate MS-associated ED in a randomized controlled trial (Samkoff & Goodman, 2011).

Decreased libido is also seen in both men and women with temporal lobe epilepsy (TLE) (Sivaraaman & Mintzer, 2011). In men there may be hypogonadotropic hypogonadism, with a low testosterone level and an inappropriately low or low normal LH; these men also can have ED. In women there may be irregular menses and dysregulation of the cycle of LH and FSH. In both cases addressing the reproductive endocrine problem is necessary to normalize sexual function, but often it is not sufficient. For some patients with TLE hyposexuality is

lifelong. Several of the older antiepileptic drugs (e.g., phenytoin and carbamazepine) reduce bioactive testosterone by increasing sex hormone binding globulin. Those drugs that induce CYP3A4 will reduce the blood level of a PDE5 inhibitor for a given dose and thereby diminish the efficacy of that dose.

Neuropathies that affect pelvic sensory and/or autonomic function are associated with sexual dysfunction, as might be expected. Considering ED in a variety of neurological diseases, those with upper motor neuron lesions are more likely to respond to PDE5 inhibitors than those with lower motor neuron involvement. Men with the latter problem but without vascular disease might require a local treatment such as intraurethral alprostadil to attain a satisfactory erection. When neuropathic sensory loss is the issue, changes in sexual technique to increase stimulation sometimes can resolve issues both with ED and with orgasmic dysfunction.

Parkinson's disease (PD) is not only associated with a prevalence of sexual dysfunction as high as 80% in some studies, but also is remarkable for the very wide range of types of sexual dysfunction it can cause. Patients with PD can display any combination of decreased libido, problems with arousal, diminished lubrication in women, sexually associated pain in men and in women, impaired or premature ejaculation, orgasmic dysfunction, dissatisfaction with the quality of sexual experience, and problems with communication about sexual matters. Nonetheless most patients with PD, especially those with young-onset disease, are interested in maintaining a sexual life, and many men with PD regard sexual dysfunction as the single most troublesome nonmotor manifestation of their illness. In addition, men with PD can become hypersexual on dopamine-agonist treatment of PD, leading to conflicts with their spouse or partner over the frequency of sexual activity and to sexually inappropriate behavior in cases where cognitive changes of PD impair insight and impulse control. Sexual dysfunction, like other nonmotor symptoms of PD, can precede motor symptoms or can be disproportionate to them. Several points can be distilled from the extensive literature on the subject: (1) Patients with PD should be asked about sexual and marital issues both during their initial evaluation and periodically after that, as the disease progresses. (2) If the patient has impaired cognition and/or impaired insight, their spouse or partner should be asked about sexual issues. (3) Evaluation of sexual dysfunction should include measurement of testosterone levels, as many men with PD will develop androgen deficiency. (4) Both male and female patients should be asked about sexually related pain and discomfort, the latter including muscle pain related to the motor symptoms of PD. (5) Patients should be screened for anxiety and depression. (6) In patients with motor fluctuations the relationship between sexual dysfunction and motor status should be explored. (7) Interviews with couples should include exploration of incompatible levels of interest, quality of communication about sexual matters, and ways in which physical changes associated with PD might turn off the desire of the spouse or partner. (8) Autonomic symptoms should be considered in planning treatment, including both orthostatic hypotension that can increase the risk of PDE5 inhibitors

and incontinence associated with sexual activity. (9) Positive and negative effects of medications should be considered, with special attention to effects of antidepressants that are frequently prescribed to treat comorbid depression or anxiety.

Successful treatment of sexual dysfunction in PD usually requires the involvement of multiple specialties including neurology, psychiatry, and gynecology or urology. While the task is complex, it is worth pursuing both because sexuality matters greatly to many patients and because optimizing sexual function can aid in optimizing other aspects of the patient's treatment and in improving overall health-related quality of life.

END-STAGE RENAL DISEASE

Both men and women with end-stage renal disease (ESRD) suffer sexual dysfunction. The full spectrum of sexual function is affected from desire through orgasm; women with ESRD have lower desire, less arousal, worse lubrication, more orgasmic dysfunction, and a higher prevalence of dyspareunia (Kettas et al., 2008). The prevalence of sexual dysfunction is highest on patients receiving hemodialysis as compared with those treated with peritoneal dialysis or with renal transplantation. The underlying causes include anemia, endocrine disturbances, the disease(s) responsible for the renal failure (including diabetes and hypertension), side effects of medications, and depression (a condition highly prevalent in ESRD patients). Overall, approximately 50% of male pre-dialysis chronic kidney disease patients have ED, 80% of male patients on dialysis have ED, and 50% of women on dialysis have difficulties with arousal (Vecchio et al., 2010).

Sexual dysfunction in ESRD has been studied extensively, in part because there are many patients with ESRD of an age at which an active sexual life is a general expectation. Typically male sexual function is measured with the IIEF, and female sexual dysfunction is measured with the FSFI or the ASEX. Two consistent findings are that there is a strong correlation between depression and sexual dysfunction, and that sexual function is associated with a higher health-related quality of life and better self-rated physical health. Men on hemodialysis for ESRD have a higher divorce rate than those treated with transplantation or peritoneal dialysis. By contrast, most male transplant recipients who are in relationships are sexually active and satisfied with their relationship (Hegarty & Olsburgh, 2012).

While the relationships of sexual function, relationship satisfaction, self-rated health, and depression are all bidirectional, sexual dysfunction can be a productive focus for medical intervention when it is present and distressing to the patient. Efforts to resolve it can lead to more effective antidepressant treatment tailored to minimize sexual side effect, and can draw attention to suboptimally treated anemia or endocrine dysfunction. Meta-analysis of controlled clinical trials shows Class I evidence in support of the use of PDE5 for ED in men with ESRD. There also is evidence to support the benefit of oral zinc supplementation on testosterone levels, frequency of intercourse, and erectile function. In women with ESRD on hemodialysis sexual

dysfunction is the rule. A recent cross-sectional study of women on hemodialysis in Europe and South America who completed the Female Sexual Function Inventory showed that 84% of 659 women had sexual dysfunction of some kind. Disorders of arousal, orgasm, and desire were the prevalent, but all aspects of sexual function were affected. Factors with independent contributions to the risk of sexual dysfunction were age, lower educational level, menopause, diabetes, low serum albumin, and the use of diuretics (Strippoli et al., 2012).

CARDIOVASCULAR DISEASES

ED in men should lead to a full assessment for coronary artery disease and cardiac risk factors, and to a cardiac stress test in patients who have a profile implying increased risk of heart disease. ED is a risk factor for myocardial infarction beyond the risk associated with the disorders that are common risk factors for both, such as diabetes, hypertension, hyperlipidemia, and smoking (Morano, 2003).

Patients with congestive heart failure (CHF) have a prevalence of sexual dysfunction of approximately 80%, and 30% are not sexually active at all (Alberti et al., 2013). Sexual dysfunction in patients with CHF can affect any part of the process from desire through orgasm. Sexual activity usually is safe for CHF patients of NYHA Class I or II; patients with more severe heart failure can experience exacerbation of symptoms with the exertion of sexual intercourse. Chronic therapy with a PDE5 inhibitor for the ED associated with CHF may actually improve the symptoms of CHF by reducing pulmonary hypertension and improving endothelial function. While PDE5 inhibitors are not approved for treatment of pulmonary hypertension associated with CHF, it would be logical to use daily tadalafil rather than intermittent PDE5 therapy for a man with CHF who was in a stable sexual relationship. Recently attention has been drawn to the high frequency of testosterone deficiency in patients with heart failure: 26% to 37% of men with heart failure have been found to be testosterone deficient (Naghi, Philip, DiLibero, Willix & Schwarz, 2011). Testosterone supplementation potentially could improve their overall clinical status (e.g., by reversing anabolic deficiency and/or increasing exercise tolerance) and not only their sexual function (Alberti et al., 2013).

Many patients, both men and women, who have had a myocardial infarction (MI) are fearful about returning to sexual activity, especially if they have not received specific guidance on this subject from their cardiologist. The majority of both men and women who have had a myocardial infarction are less sexually active than in the year before their MI (Lindau et al., 2012). The standard guidelines for care after an MI suggest that stable patients without complications can resume sexual activity with their usual partners in a week to 10 days (Anderson et al., 2007). The implication is that sexual activity with a new partner involves greater arousal and in some cases involves anxiety, both of which entail sympathetic activation that could increase the risk myocardial ischemia. Overall, the risk of

myocardial infarction and sudden cardiac death associated with sexual intercourse is low, even in patients with coronary disease. The heart's ability to tolerate sexual activity is related to the functional reserve—how much the heart rate, blood pressure, and oxygen consumption approach the peak response to exercise. Cardiac symptoms during sex rarely occur in patients who have tolerated exercise testing at a level of 6 METs (i.e., exercise involving oxygen consumption six times the basal level of 3.5 mL O₂ /kg/min). Sexual activity pre-orgasm typically requires 2–3 METs and orgasm requires 3–4 METs. For comparison, 3 METs is the energy expenditure for walking on level ground at 5 km/hour (Alberti et al., 2013).

For men, there is less physical exertion if the woman is positioned on top. The risk of MI is not increased by the use of PDE5 inhibitors (DeBusk, 2000; Cheitlin, 2005). A recent review and meta-analysis found that both life style modification and medications to improve cardiovascular risk factors are associated with a statistically significant improvement in the severity of erectile dysfunction (Gupta et al., 2011).

Several of the drugs used to prevent or treat cardiovascular diseases cause sexual dysfunction, ED in particular. Thiazide diuretics, beta blockers (with the exception of nebivolol), clofibrate, digoxin, amiodarone, and disopyramide all can cause ED. Beta blockers and statin drugs have been implicated in orgasmic dysfunction. Nitrates used to treat angina pectoris are an absolute contraindication to the use of PDE5 inhibitors because of the potential for the combination to cause life-threatening hypotension.

CHRONIC OBSTRUCTIVE PULMONARY DISEASE

COPD is not a contraindication to sexual activity. In fact, oxygenation tends to improve during sexual intercourse, which increases the rate and depth of respiration and improves the balance of ventilation and perfusion. Patients with exercise-induced bronchospasm may require premedication with an inhaler prior to intercourse.

SEXUAL SIDE EFFECTS OF MEDICATIONS

A wide range of medications can cause sexual side effects; a complete survey is beyond the scope of this chapter. However, some drugs very commonly encountered—or prescribed—by medical psychiatrists cause sexual side effects frequently enough to be a major factor in treatment adherence. Several classes of such drugs will be discussed here.

Drug-induced sexual dysfunction should be suspected when a patient's sexual function changes soon after the introduction of a new drug, the discontinuation of a drug, or a change in the dose of a drug. In medical-psychiatric settings patients usually are taking multiple drugs, with the potential for pharmacokinetic or pharmacodynamic drug interactions. For example, a drug that is not itself suspected of causing

sexual dysfunction can precipitate it, if via a pharmacokinetic interaction it increases the blood level of a second drug that is associated with sexual side effects. Or, discontinuation of a drug that mitigates the sexual side effects of a second drug could cause sexual dysfunction: for example, the discontinuation of bupropion in a patient also on an SSRI could unmask sexual dysfunction caused by the latter drug.

ANTIHYPERTENSIVE DRUGS

Hypertension itself is associated with sexual dysfunctions including ED in men and loss of libido in both men and women. Effective treatment of hypertension improves sexual function as long as the treatment does not itself have sexual side effects. The sexual side effects of antihypertensive medications were comprehensively reviewed by Manolis and Doumas (2012). They concluded that thiazide diuretics and most beta blockers frequently have adverse effects on sexual function, whereas ARBs, ACE inhibitors, and calcium channel blockers were less likely to do so. In an earlier publications the same authors make the important point that when sexual dysfunction develops in a patient taking antihypertensive drugs it can be a warning sign of vascular disease needing a thorough investigation; sexual dysfunction developing on an antihypertensive medication is not necessarily due to that medication (Manolis & Doumas, 2008).

Pharmacological differences among the different beta blockers may explain their different propensity to cause sexual side effects. The lipophilic beta-blockers such as propranolol and metoprolol can cross the blood–brain barrier and affect libido by central mechanisms; hydrophilic drugs such as atenolol can cause ED but may be less likely to affect libido (Fogari et al., 1998, 2002). Drugs more selective for β_1 adrenergic receptors appear less likely to cause ED than nonselective beta blockers. Carvedilol (a nonselective beta blocker and an α_1 -adrenergic blocker that is moderately lipophilic) is a beta blocker that is especially likely to cause sexual dysfunction by multiple mechanisms (Cordero et al., 2010; Hackett, 2010; Baumhakel et al., 2011). Nebivolol, a lipophilic beta blocker that is β_1 -selective and also enhances the release of endothelial nitric oxide, essentially does not cause ED. Male patients who have ED while taking another beta blocker can regain erectile function if switched to nebivolol. For example, Doumas et al. (2006) reported on a series of 29 patients with hypertension and ED at baseline who were treated with atenolol, bisoprolol, or metoprolol for 6 months and continued to have ED despite control of their hypertension; after a switch of beta blocker to nebivolol, erectile function improved in 20 (69%) and normalized completely in 11 (38%).

In women, beta blockers can affect libido, arousal, and the capacity for orgasm. Switching a patient from another beta blocker to nebivolol or an ARB has the potential to improve sexual function, both in men and in women. Alpha adrenergic blockers have the potential to cause sexual dysfunction though they do so far less often than beta blockers. There is a potential for causing symptomatic hypotension when combining alpha blockers with PDE5 inhibitors; this risk can be

mitigated by low initial dosage and slow dosage change for the drug that is started second.

ANTIDEPRESSANT DRUGS

Sexual dysfunction can occur with SSRIs; many patients who initially have sexual side effects will improve after 2 weeks to 4 months on treatment. If a patient has persistent sexual side effects after 4 months—or if they cannot tolerate the sexual side effects at an earlier time—options are to change the dosage, change the drug, or add an adjunctive agent that may both improve sexual function and treat residual symptoms of depression. Dosage reduction alone should be considered only if the patient's depression is in remission; patients who are only partially improved are likely to get worse on a lower dose of the same drug. A switch to a different class of antidepressant would be preferred if the patient had an incomplete response to the SSRI (Baldwin, 2014). Options with a lower incidence of sexual side effects than SSRIs include mirtazapine and bupropion. Vilazodone *may* have a lower incidence of sexual side effects than the SSRIs, but the drug is relatively new, and clinical experience is still accumulating (Clayton et al., 2013; Wang, Han, & Lee, 2013). There have been no randomized studies comparing vilazodone with SSRIs; such studies would be needed to conclusively prove that vilazodone was superior with regard to sexual side effects. In the medical-psychiatric population, mirtazapine's frequent side effects of weight gain and sedation could be either a positive or a negative depending on the patient's nutritional status and sleep quality.

Augmentation of an SSRI with bupropion can potentially convert a partial remission of depression into a full remission. In addition, it can relieve sexual side effects of the SSRIs. PDE5 inhibitors may have the same effect. Used PRN they can be efficacious for antidepressant-associated ED (Fava & Rankin, 2002; Nurnberg et al., 2008). Shim and colleagues (2014) showed that daily use of the PDE5 inhibitor sildenafil improved measures of depression, cognition, and somatization in men with erectile dysfunction, lower urinary tract symptoms and no concurrent psychiatric diagnosis. Tadalafil, the only PDE5 inhibitor currently approved in the United States for daily use, may show benefits for mood as well as erectile function when used in a dose as small as 5 mg every other day (Choi et al., 2014). The effect of a daily PDE5 inhibitor on female patients, whether taking SSRIs or otherwise, has not been systematically studied. In a *Cochrane* review of strategies to manage sexual dysfunction induced by SSRI antidepressant medication that looked at 23 trials for antidepressant-induced erectile dysfunction, the addition of sildenafil or tadalafil appeared to be an effective strategy for men. For women with antidepressant induced sexual function, the addition of bupropion at higher doses appears to be the most promising approach studied so far (Taylor et al., 2013).

As noted above, both TCAs and MAOIs can cause sexual dysfunction of various types. MAOIs are particularly associated with orgasmic dysfunction. TCAs' anticholinergic effects can contribute to sexual dysfunction; these are less with nortriptyline and desipramine. Mitigation of

TCAs' anticholinergic effects with low dose donepezil or with Huperzine A with cholinergic agents is an off-label option when a TCA is an especially efficacious antidepressant for a particular patient and anticholinergic effects—not limited to sexual dysfunction—make the therapy intolerable. Trazodone is unique among the antidepressants in its potential for causing priapism as a side effect.

ANTIPSYCHOTIC DRUGS

In first-episode patients with schizophrenia (Baggaley, 2008) the disease itself influences sexual dysfunction. However, all of the antipsychotic drugs are associated with sexual side effects. Among the antipsychotic drugs olanzapine, risperidone, haloperidol, clozapine, and thioridazine have been associated with higher rates of sexual dysfunction than quetiapine, ziprasidone, aripiprazole, and perphenazine (Serretti & Chiesa, 2011). If the prolactin level is high with an antipsychotic drug such as risperidone or olanzapine, then the particular antipsychotic might be changed to one with lesser effect on prolactin, since hyperprolactinemia alone can cause erectile dysfunction, amenorrhea, and galactorrhea (Seeman, 2013). Peripheral anticholinergic and alpha-adrenergic blocking actions of antipsychotics can also contribute to the sexual dysfunction.

OPIATE ANALGESICS

Opiate analgesics are associated with ED in men and diminished libido in both men and women. The problem appears to be a class effect, but some opiates are worse than others. For example, men on methadone maintenance have been noted to have a higher rate of erectile dysfunction than men on buprenorphine maintenance treatment (Hallinan et al., 2008). Individual patients might have more sexual dysfunction on one opiate than another, so a change in drug might be considered for patients who require long-term opiate therapy for chronic pain. Tramadol has a remarkable propensity to delay orgasm. This can be used therapeutically in the treatment of men with premature ejaculation; for other patients it can be a problem.

H2 BLOCKERS

The H2 blockers cimetidine and ranitidine have anti-androgenic effects that can cause ED or loss of libido. An alternative H2 blocker or a proton pump inhibitor should be substituted if these side effects develop.

OTHER DRUGS WITH ANTI-ANDROGENIC EFFECTS

Any drug with anti-adrenergic effects—whether intentional or incidental—can affect libido or male erectile function. Common examples are leuprolide, goserelin, zoladex, finasteride, flutamide, ketoconazole, and spironolactone. In some cases alternate therapies may be available with lesser sexual side effects; when this is not feasible treatment of ED with a PDE5 inhibitor may be effective.

SEXUAL ISSUES IN CANCER SURVIVORS

Cancer and its treatment often have major effects on patients' sexuality, mediated by the patient's emotional reaction to a life-threatening illness, changes in body image, pain and other distressing symptoms, and changes in the couple's relationship, as well as the effects of cancer treatments on the endocrine and nervous systems. When the cancer involves the urogenital system issues such as erectile dysfunction or pain on intercourse may contribute (Bober & Varela, 2012). Yet, it often is worth the effort for a patient to overcome the barriers to a satisfying sexual life despite his or her cancer; healthy sexuality is a powerful affirmation of physical and emotional survival.

Anti-estrogen treatment for breast cancer precipitates an abrupt menopause, with symptoms of atrophic vaginitis, loss of lubrication, dyspareunia, and loss of libido. These local symptoms are common when aromatase inhibitors are part of the oncologic treatment regimen (Baumgart et al., 2013). Women taking aromatase inhibitors tend to report global sexual problems, including not only dyspareunia but also reduced sexual desire, difficulty becoming sexually aroused, and problems with orgasm (Bradford, 2013). For many patients the principal problem is vaginal pain related to lack of lubrication but not fully resolved by lubricants. Short-term studies of low-dose topical hormonal treatments with vaginal estradiol or testosterone have shown promise but long term data are not available. Because the elevation of systemic estrogen levels by topical hormone therapy is negligible at the doses needed to relieve vaginal atrophy, such treatment is unlikely to increase the risk of cancer recurrence (Witherby et al., 2011; Kendall, Dowsett, Folkard, & Smith, 2006).

With mastectomy and reconstruction, women who are satisfied with cosmetic results may still need to adjust to loss of breast and nipple sensation. Women who have had pelvic radiation may have complications of vaginal fibrosis, stenosis, and loss of lubrication. Colon cancer surgery can affect nerves important for erectile function in men and decrease vaginal function in women. Patients with ostomies must overcome social barriers to sexual contact, and patients who have had bone marrow transplants may have sexual dysfunction and fears about bacterial contagion in an immune deficiency state. Patients with head and neck surgery are sensitive about physical deformities that follow treatment; those who have tumors related to human papilloma virus may feel guilt about the effect of a sexually transmitted disease. Successful resolution of any of these cancer-related issues usually comes with some combination of individual and couples counseling, education, adjustment of sexual technique, and medical interventions. As an example of the latter, vaginal stenosis following radiation therapy can be addressed by the physical dilation of the vagina (Miles & Johnson, 2010).

Resolution of cancer-associated sexual dysfunction requires significant motivation on the part of the patient and his/her spouse or partner, and a commitment of time and energy. Thus illness-associated fatigue and apathy may be addressed, either sequentially or simultaneously, along with the more narrowly defined sexual issues; the expectations of the patient and the spouse or partner should be aligned.

Other things being equal, younger patients are more likely to regain sexual function after treatment for cancer. This may partly be due to differences in vigor, but differences in expectations also play a role. Young cancer patients usually expect to have an active sexual life. Older ones—with the age threshold differing by cultural background and family tradition—may see an episode of cancer as an indicator that their sexual life is over. This belief should be explored by the clinician; it is especially important to identify when the expectations of the patient and his/her spouse or partner are different in this regard.

SEXUAL DYSFUNCTION AFTER RADICAL PROSTATECTOMY

Sexual dysfunction affects the majority of men who have a radical prostatectomy (RP) for prostate cancer, although its incidence is lower with nerve-sparing procedures. It is noteworthy that medical centers differ significantly in their rates of sexual dysfunction following RP; a discussion of the risk of postoperative sexual dysfunction should be part of the informed consent discussion, and in the authors' opinion this should include comparison of local rates of postoperative sexual dysfunction with appropriate benchmarks. Depending on the extent of nerve damage during prostatectomy, postoperative erectile dysfunction might or might not respond to PDE5 inhibitors. If it does not, erectile function can be restored with one of the more invasive treatments described above. Identifying and intervening to restore sexual function relatively soon after surgery is associated with a better long-term outlook for recovery of sexual function. Moreover, early recovery of sexual function can help a man's emotional recovery from the trauma and loss associated with cancer and its treatment.

A specific problem common after RP is loss of urine during orgasm in an otherwise continent man. This problem improves with time in about half of those affected. The problem can be mitigated by emptying the bladder before intercourse, lying on the back or side during orgasm, and/or wearing a condom. Some men find Kegel exercises useful for this symptom. On occasion the symptom is so bothersome and persistent that surgical treatment is offered; it is usually successful. Other sexual complications seen after RP are shortening of the penis and orgasm without ejaculation.

Radiation therapy of prostate cancer reduces ejaculatory volume and can alter the experience of orgasm even when the capacity for orgasm is preserved. Anti-androgen treatment for prostate cancer can shorten the penis, cause testicular atrophy, and diminish desire, although these effects are variable (Higano, 2012). Most men on anti-androgen treatment continue to have sexual thoughts and erotic dreams, and many are able to continue sexual activity. When ED is present, PDE5 inhibitors may be effective despite the lack of androgens, although this too is variable.

Overall, the various and variable effects of prostate cancer treatment on sexual function call for especially good communication between a concerned physician, the patient, and the

patient's spouse or partner. Depending on the center where the patient is treated, discussion and intervention concerning sexual issues can involve the oncologist, an urologist, a medical psychiatrist, and/or a specialist in sexual medicine. When a medical psychiatrist is involved—often for a nonsexual presenting complaint such as depression, anxiety, or chronic pain—they should ensure that sexual concerns are elicited and discussed, and that someone takes responsibility for following them up.

CANCER AND COUPLE RELATIONSHIPS

Cancer and its treatment take an emotional toll on the spouse or partner of the patient, and the spouse or partner's emotional issues often are compounded by problems in the couple's communication. The emotional impact on the spouse or partner can affect *their* sexual function, and communication problems impede their resolution. For example, partners of patients who had hematopoietic stem cell transplantation reported a high burden of depression and sexual problems long after the transplant took place (Bishop et al., 2007). In the setting of metastatic breast cancer, sexual problems were associated with depressive symptoms for both women and their partners; however, depressive symptoms were reduced by mutual constructive communication. Successful communication included mutual discussion of cancer-related issues, expression of feelings, understanding of views, and a feeling that the issue was resolved. In contrast to this successful pattern of communication, one often encounters the pattern of demand-withdrawal communication in which one partner wants to talk about issues related to cancer and the other partner does not, responding by withdrawing emotionally (Milbury & Badr, 2013). This communication pattern is associated with a less satisfactory sexual relationship, whether or not the cancer-related issues concern sexual dysfunction. At best, the crisis of cancer—or any other major or life-threatening illness—can be an occasion for a couple to have increased intimacy and communication, one that draws out expressions of the partners' concern, love, and commitment. The medical psychiatrist should be alert to opportunities to facilitate this constructive outcome.

SUMMARY

Regular, satisfying sexual activity improves a patient's health-related quality of life. For couples in which one member suffers functional impairments due to chronic disease, a happy sexual relationship can mitigate some of the stress of caregiving. Moreover, uncovering and addressing the causes of sexual dysfunction can lead to new and important diagnoses and can contribute positively to the patients' overall care and its outcomes. In many chronic diseases sexual dysfunction affects more than half of patients at some point in their course. However, in any given clinical encounter with a general medical physician or even a medical psychiatrist, sexual concerns seldom are in the foreground. Active effort on a

clinician's part, at a propitious time in the patient's course of treatment, usually is needed to open the dialogue; screening tests and rating scales can help focus the conversation. The yield is high and the effort is worth making.

CLINICAL PEARLS

- Even when discussion of sexual issues is not timely at the initial encounter, the topic should remain an open item in the psychiatrist's mind—one to be explored in the future with the patient if the professional relationship continues.
- A desire to be sexual and desire to have sex, whether in general or with a specific actual or fantasied partner are not the same. If the medical psychiatrist determines that a patient wishes to be sexual this is a sufficient reason to explore the issue further, even if the patient has not been sexually active recently and has not recently experienced sexual desire.
- Clearly new onset erectile dysfunction in a man of any age should trigger a full medical reassessment, including an electrocardiogram and stress test, screening for glucose intolerance, and measurement of serum testosterone. (Shamloul & Ghanem, 2013; Miner et al., 2014)
- A patient can have a side effect like headache, dyspepsia or muscle pain with one PDE5 inhibitor and not with another.
- A newly approved therapy for dyspareunia due to vulvar and vaginal atrophy is ospemifene, a selective estrogen receptor modulator (SERM). Given orally at a dose of 60 mg per day ospemifene restores the vaginal mucosa and relieves dyspareunia, without affecting the endometrium and thereby requiring concurrent progestin administration
- Thiazide diuretics and most beta blockers frequently have adverse effects on sexual function, whereas ARBs, ACE inhibitors, and calcium channel blockers were less likely to do so. (Manolis & Doumas, 2012).
- Three common neurological diseases—multiple sclerosis, Parkinson's disease, and temporal lobe epilepsy—are associated with a disproportionately high rate of sexual dysfunction.

CHRONIC PAIN

David Borsook

INTRODUCTION

Chronic pain is defined as pain lasting for more than three months. It has reached pandemic proportions in Western countries, affecting over 100 million people in the United States alone. The evidence base for therapies is very small relative to the size of the *problem*. For the therapies that are considered effective—essentially, only pharmaceutical medication, based on randomized trials—the outcomes are relatively poor, with around a 30% efficacy rate, where “efficacy” is essentially a 2-point improvement on a 10-point scale. Increasing recognition of the chronic pain pandemic and the lack of well-established therapies has led to increased research on both the pathophysiology and the treatment of the condition. New research is leading to a new conceptualization of chronic pain that is likely to improve future treatment outcomes.

COMMON DISORDERS—IMPORTANT INSIGHTS

If one evaluates the conditions that are most prevalent in chronic pain, there are those that may be categorized along the lines of disease-based chronic pain problems. While mechanistic approaches in defining chronic pain are clearly the way forward, common pain clinical syndromes are provided as examples of disease states because of the special features that they provide for conceptualizing the problems that we face in treating chronic pain.

OSTEOARTHRITIS—NOT JUST A PERIPHERAL PAIN PROBLEM

Osteoarthritis is a disease of joints that affects millions of individuals. Osteoarthritis has been considered a chronic nociceptive pain disorder that is characterized by pain due to inflammation, local tissue damage, and attempts at tissue repair (Sofat et al., 2011). Although it is considered a predominantly peripheral pain disorder, more recent data have suggested central processes are at play, including central sensitization (Gwilym et al., 2009). While pain may be mostly exacerbated by activity, the activity produces increased pain processing in the brain, leading to changes such as thalamic atrophy (Gwilym et al., 2010). The ongoing pain may also

produce changes in brain systems (Parks et al., 2011). Thus targeted therapies and anti-inflammatory drugs, including non-steroidals (NSAIDs), have been a mainstay of symptomatic treatment (Hinz & Brune, 2004); however, patients often do not get complete relief. Given that osteoarthritis is a disease predominantly affecting the elderly, under-treatment may be a major issue (Marcum et al., 2011). Until better disease-modifying agents become routine, pain will continue to be a major problem in this group of patients.

CANCER PAIN—FROM DISEASE TO TREATMENT-INDUCED PAIN

Aside from the disease of cancer’s initiating pain through multiple mechanisms (inflammation, nerve entrapment, mass effect), treatment effects for cancer are the leading causes of chronic pain. All these, including radiotherapy, chemotherapy, and surgery, may result in a chronic neuropathic pain condition. Many of these treatment-induced syndromes, including chemotherapy-induced peripheral neuropathic pain, may be highly resistant to treatment. Of the chemotherapies that cause neuropathic pain, paclitaxel is perhaps the most noteworthy, but other chemotherapeutic drugs also produce the same problem (Loprinzi et al., 2011). Paclitaxel has been postulated to produce nerve damage through damage to mitochondria (Zheng et al., 2011). It should be noted that muscle pain is also a significant problem following chemotherapy—presumably because of similar damage to muscle fibers (Alvarez et al., 2011). Some agents have been thought useful in preventing pain related to chemotherapy-induced peripheral neuropathy (CIPN), including intravenous calcium and magnesium infusions and glutathione (Pachman et al., 2011); however, no benefit of intravenous calcium/magnesium to prevent oxaliplatin-induced sensory neurotoxicity was found in a recent placebo-controlled, double-blind study (Loprinzi et al., 2013). Unfortunately, there are few well-defined therapies for CIPN.

NEUROPATHIC PAIN—TRAUMATIC INDUCED NEUROPATHIES ARE EPIDEMIC

Neuropathic pain includes all pain—peripheral or central—that results from damage to pain pathways (Borsook, 2011). Many diseases produce neuropathic pain, such as diabetes, complex regional pain syndrome,

degenerative spine disease, trigeminal neuralgia, and spinal cord compression, to name a few. A review on neuropathic pain and its mechanisms has been provided elsewhere (Costigan et al., 2009; Baron et al., 2010). However, one neuropathic pain condition that follows surgery is the so-called surgically induced neuropathic pain (SNPP) that affects 15–50% of individuals undergoing surgery (Kehlet et al., 2006). Given that there are around 29 million surgeries in the United States each year, the prevalence is epidemic. Neuropathic pain results in spontaneous pain (burning, shooting) and evoked pain (allodynia, hyperalgesia, and hyperpathia). It is now clear that significant changes in brain function and structure occur as a result of ongoing neuropathic pain. Such changes affect not only sensory systems but also emotional and cognitive systems. As such, many comorbid features arise from the condition, including depression, anxiety, and addiction.

Pharmacological treatment with neuropathic pain is largely empirical, with a trial-and-error approach utilizing some drugs that have shown to be effective in clinical trials (e.g., gabapentinoids, duloxetine, and others). These drugs may be grouped into calcium channel modulators (e.g., gabapentin), membrane stabilizers (e.g., mexilitene, sodium channel-blocking activity of amitriptyline, lidocaine patch), gamma-amino-butyric acid (GABA) inhibitors (e.g., baclofen), n-methyl-D-Aspartate (NMDA) antagonists (e.g., ketamine), capsaicin, and opioids. Other treatment modalities including neuromodulatory (spinal cord stimulation) and behavioral (e.g., cognitive therapy, biofeedback), and unconventional approaches such as acupuncture have all been deployed in trying to treat chronic neuropathic pain. In controlled trials, efficacy of around 30% has usually been achieved. Evidence-based approaches have been issued by a number of groups (Dworkin et al., 2007).

VISCERAL PAIN—FROM IRRITABLE BOWEL SYNDROME TO PANCREATITIS

Visceral pain is among the most difficult to evaluate and control. Visceral pain syndromes include chronic pancreatitis, cystitis, testicular pain, and irritable bowel syndrome (IBS). Even phantom visceral pain conditions have been described (Puhse et al., 2010). IBS is considered a hypersensitivity disorder (Barbara et al., 2011). Visceral hypersensitivity is an increased perception of events occurring in the gastrointestinal tract. It is characterized by hyperalgesia, an enhanced response to painful stimuli, and allodynia, a painful response to an innocuous stimulus. Central brain changes (Price et al., 2009) and significant aberrant behavioral processes are associated with IBS (Elsenbruch, 2011). The condition is also associated with mucosal abnormalities (e.g., immune, neural, etc.). However, compared with somatic pain, the syndrome is far less well understood (Sengupta, 2009), and includes abnormal inhibitory modulation of pain. Significant changes are present in the central nervous system (CNS) in IBS patients (Seminowicz et al., 2010), and there is evidence of decreased brainstem inhibition of pain (Berman et al.,

2008). Other visceral pain conditions have no understood etiology or mechanism (e.g., functional bowel disorders and chronic pelvic pain). Chronic pancreatitis is among the most difficult pain conditions to manage (Drewes et al., 2008), and treatments have included radical surgical approaches (Schnelldorfer et al., 2007). Inflammation of the pancreas that may include alterations in cytokines, glial function, and immune changes may produce a chronic inflammation in the organ suggestive of an autoimmune etiology (Sanchez-Castanon et al., 2010). Like many chronic pain syndromes, it “reorganizes” the central nervous system (Dimcevski et al., 2007; Fregni et al., 2007). By whatever mechanism, visceral pain syndromes are made more complex and more resistant to treatments, perhaps in part by the frequently associated comorbid features of depression, anxiety, and cognitive alterations that are often observed to be present in these patients. Functional abdominal pain syndromes are even more complex (Sperber & Drossman, 2011).

Visceral analgesic therapies, including pharmacological ones, are suboptimal (Camilleri, 2010). The new 5-HT₄ agonists like prucalopride seem to have a safer cardiac profile, and other agents such as intestinal secretagogues (e.g., chloride channel activators and guanylate cyclase-C agonists) may provide useful approaches to the treatment of the disease (Camilleri, 2010). {table visceral analgesia}

MIGRAINE—COMMON AND FORGOTTEN

Migraine is considered by the World Health Organization (WHO) to be in the top 20 causes of disability worldwide (Buse et al., 2009) and affects patients during their formative and most productive periods of their lives, between age 25 and 55 (Lipton et al., 2001; Lipton et al., 2002). It frequently starts in childhood, particularly around puberty, and affects women more than men. It has significant effects on the brain (Antonaci et al., 2014). The major challenge in migraine is developing preventive treatments or disease-modifying treatments (Barbanti et al., 2011). Acute therapies for migraine work reasonably well (triptans, NSAIDs), and they work best if taken at the onset of the attack (Burstein et al., 2004). While some treatments for chronic migraine or chronic daily headache (more than 14 headache days per month) have shown efficacy in controlled trials (e.g., topiramate; Ferrari et al., 2011), and botulinum toxin (Diener et al., 2010), these effects are not very strong, and other medications continue to be used (valproate, β -blockers, and tricyclic antidepressants). The continued migraine attacks change the brain and may make the condition prone to transforming from acute episodic migraine to chronic daily headaches. Of note, medication overuse, particularly of triptans and opioids (Bigal & Lipton, 2009) may contribute to such transformation. Mechanisms for transformation by medication have been reviewed elsewhere and may include processes of amplification including central sensitization and descending facilitation (De Felice et al., 2011a). Reversal of this state may also be possible with opioid withdrawal.

BRAIN-DERIVED PAIN SYNDROMES

The following discussion reviews examples of two pain syndromes wherein pain becomes a manifestation of changes or drivers within the nervous system.

Depression and Pain

While depression may be a consequence of pain (Haley et al., 1985; Wilson et al., 2002), it is also true that depressed individuals with no history of pain or tissue damage are at increased risk for the development of neuropathic pain (Gureje et al., 2001; Breslau et al., 2003). As a reward-deficit state, chronic pain may reduce the capacity to suppress negative emotion and may contribute to the evolution of unipolar depression (Levesque et al., 2003). Numerous studies have indicated common changes in the prefrontal cortex (PFC) in depression and chronic pain, including a decrease in volume of gray matter (Drevets et al., 1998; Apkarian et al., 2004) and dysfunction in prefrontal cortical processing (Drevets, 2000; Apkarian et al., 2001). Structural changes in the cortex have been linked with functional changes in pain experience (Apkarian et al., 2004; Horton et al., 2004), and functional imaging of chronic pain patients indicates significant alterations of frontal lobe function (Casey et al., 2003). The role of brain-reward systems in depression, the idea that an altered brain-reward system may be the underlying brain mechanism of the loss of pleasure and interest experienced in major depressive disorder, has been reviewed elsewhere (Naranjo et al., 2001). Thus, the intriguing feature of pain evolving from depression is that it implies that depression causes an alteration in neural circuits that produces a generalized pain syndrome. This is not unique to depression, since patients who are opioid addicts may have similar changes in which their drug intake may alter their neural networks such that they are more sensitive to pain (experimentally and clinically).

Fibromyalgia

Fibromyalgia is a syndrome that has widespread pain, and it is now considered to have an origin in the brain (Clauw, 2009; Clauw et al., 2011). It is an under-diagnosed condition, principally because it does not have a precise definition or objective measure. Although criteria for definition of the disease have been defined, these are not specific. Aside from pain, other significant clinical manifestations are noted, including fatigue, non-restorative sleep, and cognitive dysfunction. Treatment of fibromyalgia is challenging. Pharmacological approaches include classical antidepressants, and serotonin and noradrenaline reuptake inhibitors, used in sub-antidepressant doses, seem to be the most effective.

PAIN MECHANISMS

Reviews for disease conditions and their mechanisms are noted elsewhere: neuropathic pain (Baron et al., 2010; Nickel et al., 2011); migraine (Goadsby et al., 2009; Akerman et al., 2011); osteoarthritis (Mease et al., 2011); complex regional

pain syndrome (Bruehl, 2010); irritable bowel syndrome (Barbara et al., 2011; Zhou & Verne, 2011); fibromyalgia (Staud & Rodriguez, 2006); trigeminal neuralgia (Iwata et al., 2011); chronic pancreatitis (Vardanyan & Rilo, 2010); diabetic neuropathic pain (Calcutt & Backonja, 2007; Fischer & Waxman, 2010b); post-herpetic neuralgia (Fields et al., 1998); and central pain syndromes such as thalamic pain (Boivie et al., 1989; Kumar et al., 2009; etc.). Mechanistic approaches are currently a major focus, since therapies can be more logically targeted and developed. A number of important advances have occurred in the pain field in the past ten years. In the sections that follow, a brief overview of some of these is discussed.

GENETIC

Numerous candidate pain genes have been discovered (see Pain Genes Data Base (<http://www.jbldesign.com/jmogil/enter.html>)). Genetic association studies have identified approximately 20 genes that contain single nucleotide polymorphisms (SNPs) that may confer differences in response to acute and chronic pain (Muralidharan & Smith, 2011). Some SNPs associated with pain genes include the potassium channel alpha subunit *KCNS1* that is a prognostic indicator of chronic pain (Costigan et al., 2010). Others seem to regulate pain sensitivity and persistence, such as GTP cyclohydrolase (*GCHI*) (Tegeder et al., 2006). A haplotype of the *GCHI* gene was significantly associated with less pain following discectomy for persistent radicular low-back pain (Tegeder et al., 2006). Such discoveries will contribute to significant changes in the way we evaluate and treat patients with chronic pain. Similarly, genetic variants in individual drug responses (pharmacogenomics) also have important contributions to make in the future evaluation and treatment of patients (Webster, 2008; Stamer et al., 2010).

MOLECULAR MECHANISMS

Perhaps the most interesting molecular candidate has been the discovery of the transient receptor potential (TRP) channel vanilloid receptor (TRPV1; Caterina et al., 1999). It is expressed predominantly in the peripheral nervous system and has been a target for drug development (Wong & Gavva, 2009). Mice lacking the receptor have impaired analgesia (Caterina et al., 2000). Six TRPs (TRPV1, TRPV2, TRPV3, TRPV4, TRPM8, and TRPA1) have subsequently been shown to express in primary afferent nociceptors (Levine & Alessandri-Haber, 2007). Loss-of-function mutations in another gene, the *Nav1.7* gene, underlie congenital indifference to pain (Goldberg et al., 2007), while a gain of function of the same gene is linked to erythromelalgia (Fischer & Waxman, 2010a). Such insights point to new opportunities to evolving new concepts in pain and its treatment. Other channelopathies (calcium) are associated with other painful diseases such as familial hemiplegic migraine (Barrett et al., 2008). Many other ion channels have been implicated in chronic pain (Raouf et al., 2010).

GENDER AND PAIN

Clear differences in pain are seen across gender. Women have lower thresholds to experimental pain and are more likely to seek treatment for their pain and have differences to analgesics (Fillingim & Ness, 2000; Craft et al., 2004). While the exact role of hormonal differences in altering acute and chronic pain responses between sexes is not completely understood, clearly, alterations in the hormonal milieu must change neurons and glia across central and peripheral nerve systems (Aloisi & Bonifazi, 2006). Gender differences in pain modulation have also been shown (Popescu et al., 2010).

PERIPHERAL AND CENTRAL SENSITIZATION

Sensitization refers to the process of increased responses to normal stimuli. It may involve the peripheral nerve (peripheral sensitization) or the central nervous system (central sensitization) (Woolf, 2007). In the latter, it has been defined as “prolonged but reversible increase in the excitability and synaptic efficacy of neurons” (Woolf, 2011). Centralization has been inferred across most chronic pain conditions. It is important that the concept be understood as alteration in responses to stimuli but it may also have innate effects on the spontaneous pain condition, including chronification of the disease. Examples of central sensitization include photophobia in migraine, and opioid-induced hyperalgesia (Bannister & Dickenson, 2010). Opioid-induced hyperalgesia has been validated in normal human volunteers receiving chronic morphine infusions; and improvements in paradoxical pain intensity upon discontinuation of opioid therapy have been noted in patients on longtime opioids imply the need for a multidisciplinary approach to chronic pain. Numerous processes may contribute to central sensitization, including genetic, catastrophizing, gender, etc.

ALTERATION IN ENDOGENOUS PAIN MODULATION IN CHRONIC PAIN

Pain modulatory systems include those well documented in the brainstem such as the periaqueductal gray, the cuneiform nucleus, and the raphe magnus (Gebhart, 2004; Mason, 2005; Ossipov et al., 2010). However, it is now well known that other, more rostral brain regions, including the frontal cortex, the cingulate and basal ganglia, may all be involved in the pain modulation. The understanding of pain modulation will have implications for which treatments may augment endogenous processes of pain modulation. The placebo response is one “output” through which these endogenous systems may participate in placebo-induced analgesia (placebo response) or increased pain (nocebo response) (Pollo & Benedetti, 2009). Different brain mechanisms such as expectation, anxiety, and reward are all involved, as well as a variety of learning phenomena (Benedetti et al., 2011). Neuroimaging studies in healthy subjects have contributed to our understanding of placebo responses (Bingel & Tracey, 2008; Bingel, 2010). In a variety of chronic pain conditions, these endogenous systems show diminished inhibition of pain (Staud, 2009) and indeed may show facilitation of pain as demonstrated in animal models

(Edelmayer et al., 2009), while enhanced descending modulation protects against chronic pain (Vera-Portocarrero et al., 2006; De Felice et al., 2011b). Thus, understanding abnormal processing of descending controls (which are affected by a variety of processes, including catastrophizing, medications, affect, and placebo response) and how we can best delay or enhance them would seem like an important addition to our clinical approach to patients (Vanegas & Schaible, 2004).

GLIA AND CHRONIC PAIN

Evidence for astrocytes and glia involvement in chronic pain has become a new force in understanding chronic pain and developing novel therapies for the condition (Austin & Moalem-Taylor, 2010; Gao & Ji, 2010; Gosselin et al., 2010). Perhaps one of the best insights into this issue is the presence of glial hyperactivity in a patient with chronic pain following amputation: positron-emission tomography (PET) imaging displayed increased binding of a specific ligand to glia in the contralateral thalamus (Banati et al., 2001).

EPIGENETIC MECHANISMS

Epigenetic changes affect processes that modify chromatin and subsequently change gene activity without altering the DNA sequence (Geranton, 2011). The importance of understanding epigenetic mechanisms is that they may be potential targets for disease modification.

CENTRALIZATION OF PAIN

The term *centralization of pain* refers to progressive changes in brain systems that result from peripheral nerve injury; for example, changes in brain systems that produce pain such as depression. Perhaps the best examples are the progressive changes seen in brain dysfunction in patients who have a trivial nerve injury and then have manifestations of spread of pain beyond the area (frequently involving the whole body), alterations in autonomic tone, alterations in parietal function (e.g., hemi-inattention), changes in cognition, and movement disorders. These occur in various combinations in complex regional pain syndrome (CRPS). Clearly, a simple injury has not only produced chronic pain, but has led to changes in neuronal circuitry that have now been shown in brain-imaging studies, and correlate with many of the behavior syndromes described above.

CHRONIC PAIN—A COMPLEX DISORDER

Clearly, chronic pain is a disease of the nervous system that encompasses sensory, emotional, cognitive, and other changes as a result of ongoing pain. In addition, comorbid features include a variety of defined conditions, including depression (Nicolson et al., 2009), anxiety (Gureje, 2008; Nicolson et al., 2009; Robinson et al., 2009), addiction (Bailey et al., 2010), or traumatic brain injury (Nampiaparampil, 2008; Robinson et al., 2009; Jain et al., 2011). Thus, treating a chronic pain patient is a complex problem demanding

complex interventions that are, or should be, primarily “brain targeted” therapies. In the elderly, a group with increasing pain issues, other processes make the therapeutic approach more difficult, including cognitive decline (e.g., Alzheimer’s disease) and decreased mobility. In a recent review of neurological conditions and chronic pain, significant numbers of patients across the spectrum of neurological disease had high rates of depression (Borsook, 2011). In addition, many primary psychiatric diseases have chronic pain as a manifestation of their disease (e.g., depression, addiction, post-traumatic stress disorder [PTSD] or altered pain processing [schizophrenia]). Thus multimodal approaches are required for complex disease interactions (Kirsh & Fishman, 2011).

Psychological Factors

Many psychological factors are processed in chronic pain and an individual’s adjustment to chronic pain (Jensen et al., 2011). Among these, “catastrophizing” ranks the highest. Catastrophizing is a concept or term that relates to having a more intense pain experience and increased emotional distress; it is thus a negative cognitive-affective response to anticipated or actual pain (Quartana et al., 2009). It is a predictor for post-surgical chronic pain (Khan et al., 2011). Other psychological factors are important; for example, anxiety sensitivity is reportedly strongly associated with fearful appraisals of pain (Ocañez et al., 2010).

Reward-Aversion

Pain and pleasure are at opposite ends of a behavioral spectrum (Becerra et al., 2001). Thus, aversion (pain) may be considered opposite to reward (pain relief/analgesia) and indeed these two are postulated to utilize similar “reward-based” brain networks (Leknes & Tracey, 2008). Chronic pain may be considered a “reward-deficit state” (Elman et al., 2011). Pain-relief is a rewarding process (Leknes et al., 2011). Pain relief is a concept that incorporates not only pain intensity reduction, but also other emotional and cognitive components related to the condition, including pleasantness. Patients are thus in a state where life is less eventful and satisfying, and this may lead to significant comorbid features such as depression and suicide.

TREATMENTS

Treatment of chronic pain is a real challenge because there are no good treatments. Current approaches are many (some are listed below), and the overall issue is to balance efficacy and adverse effects. In the pharmacological domain this is more easily done, because we have data on drug side effects and can change drugs. For interventional therapies, some are reversible (e.g., spinal cord stimulators) and others (e.g., lesions) are not. In the following sections, information on the possible impact of particular treatment domains is provided. This is not a “how to” approach (which can be found in many texts on pain treatment) but rather an attempt to provide an overall sense of

current therapeutic approaches. The number needed to treat (NNT) before a 50% benefit is observed in a single patient is observed has provided a sense of treatment efficacy; while the number needed to harm (NNH) is the same approach related to measures of side effects (Selph et al., 2011).

PHARMACOTHERAPY

Cochrane Database (and Other) Summaries of Drug Treatments

Anticonvulsants

The gabapentinoids are among the most commonly used drugs for neuropathic pain. Pregabalin at doses of 300 mg, 450 mg, and 600 mg daily was effective in patients with post-herpetic neuralgia, painful diabetic neuropathy, central neuropathic pain, and fibromyalgia (19 studies, 7,003 participants). Pregabalin at 150 mg/d was generally ineffective (Moore et al., 2009). However, as noted in this review, “A minority of patients will have substantial benefit with pregabalin, and more will have moderate benefit. Many will have no or trivial benefit, or will discontinue because of adverse events.” The NNH for minor harm for gabapentin accumulated in randomized clinical studies is reported to be 3.7, and the NNT is 2.9 for diabetic neuropathy and 3.9 for post-herpetic neuralgia (Wiffen et al., 2011). When NNTs were evaluated for other “anticonvulsants” and specific neuropathic pain conditions, the following was reported in the Cochrane Database: carbamazepine for trigeminal neuralgia is 2.5 vs. 3.2 for gabapentin; for diabetic neuropathy the NNTs are 2.3 for carbamazepine, 2.1 for phenytoin, and 3.8 for gabapentin. However, the NNH (minor harm) were 3.7, 3.5, and 3.2 for each of these drugs, respectively (Wiffen et al., 2010). As can be seen from these data sets, different drugs have different NNTs that relate to individual differences that determine response rates at a population level, but not for the individual being treated. Nevertheless, they provide one approach to a more rational choice of drug until better methods that are adaptable to the pressures of normal “clinic life” become available.

Antidepressants

Current evidence supports the use of tricyclic antidepressants (amitriptyline, nortriptyline, desipramine) in neuropathic pain, headaches, low back pain, fibromyalgia, and IBS. No evidence supports the use of SSRIs (fluoxetine, paroxetine, citalopram) in chronic pain (Verdu et al., 2008). More recent evidence has shown efficacy for the SNRIs (duloxetine, venlafaxine) across a spectrum of chronic pain (back pain, fibromyalgia, and osteoarthritis) (Dharmshaktu et al., 2011). NNTs for duloxetine (60mg/d but not 20mg/d) for diabetic neuropathy are 6 and for fibromyalgia are 8, but there were adverse effects.

Opioids

The evidence for chronic opioid use in chronic pain is controversial. A recent systematic review of randomized trials on the use of opioids for the treatment of chronic non-cancer

pain reported that only tramadol is useful (fair) in osteoarthritis, with poor evidence for all other opioids and chronic pain conditions. Therefore, the use of opioids is mostly based on non-randomized studies. None of the trials went beyond 12 weeks. Because of the relatively few studies, important additional insights into tolerance, addiction, and other aspects of chronic opioid use are not easily evaluated (Kalso et al., 2004). Evidence was insufficient to determine if long-acting opioids as a class are more effective or associated with fewer side effects (harms) than short-acting opioids (Carson et al., 2011).

Lidocaine

In a Cochrane-based review of 31 trials that met the inclusion criteria, lidocaine and oral analogues were safe drugs in controlled clinical trials for neuropathic pain and were better than placebo, and as effective as other analgesics (Challapalli et al., 2005). Currently, there is insufficient evidence to recommend the topical lidocaine patch as a first-line agent in the treatment of post-herpetic neuralgia (PHN) with allodynia (Khaliq et al., 2007). However, when considering side effects, newer studies have indicated that a lidocaine patch is associated with comparable levels of analgesia in patients with PHN or diabetic peripheral neuropathy (DPN) but substantially fewer frequent adverse events than pregabalin (Baron et al., 2009).

Ketamine

This antagonist of the N-methyl-D-Aspartic Acid (NMDA) receptor has been increasingly used in chronic pain. It has been administered intravenously and orally. Norketamine is the pharmacologically active metabolite believed to contribute to the analgesic effect of oral ketamine. It may be considered in resistant cases, and increasing dosing may have increased clinical efficacy (Borsook, 2009), although it is unclear how this is mediated, since the drug also has deleterious effects on neuronal populations.

High-dose Capsaicin

High dose (8%) capsaicin patches may be useful for neuropathic pain, although the evidence is not strongly supported.

Opioids

Initially used for cancer pain, opioids had been increasingly used for chronic pain (Przewlocki & Przewlocka, 2001), but their use still remains controversial (Katz & Benoit, 2005; Przewlocki & Przewlocka, 2001). Indeed, there is no evidence that they are effective for chronic pain conditions such as neuropathic pain (Carson et al., 2011). Their use seems justified under some circumstances, but risks of side effects like addiction and constipation need to be evaluated and managed. In recent years, there has been a move away from opioids, principally for three reasons—first, there is no good evidence for their efficacy in chronic pain; second, there are significant legal issues surrounding their use because of increased abuse of prescription opioids (Hernandez & Nelson, 2010), and third, because of increasing evidence that opioids alter brain systems (Upadhyay et al., 2010) in a way that may not be reversible. With respect to the latter, this may contribute

to either more pain or resistance to other pharmacological treatments, as is observed in migraine (Bigal & Lipton, 2009; De Felice & Porreca, 2009).

Combination Pharmacological Treatments

The notion of combination pharmacological treatments' improving pain gained notoriety following a publication in the *New England Journal of Medicine*, on gabapentin and opioids' significantly improving pain (Gilron et al., 2005). Importantly, the combination provided better analgesia at lower doses than did independent use of each drug. While long-term data are not available, such studies are suggesting the potential to enhance treatments with fewer side effects. For example, more recent data have indicated that combination therapy with duloxetine and pregabalin; lidocaine patch and pregabalin; or gabapentin with imipramine, nortriptyline, or venlafaxine, may have had a potential benefit compared with monotherapy, but there was an increased risk of adverse events (see Selph et al., 2011). Clearly, additional clinical studies are warranted (Vorobeychik et al., 2011).

Other Treatments

Botulinum Toxin

Evidence-based data indicate that administration of botulinum toxin in several human conditions (*viz.*, chronic migraine) can alleviate refractory pain (Jabbari & Machado, 2011). However, further studies are clearly indicated to evaluate the potential use of the drug in post-operative pain and chronic neuropathic pain (Jeynes & Gauci, 2008).

Expert Consensus Reviews on Pharmacotherapy for Pain

Because of the overriding lack of evidence for many pharmacological agents, particularly comparing one agent against another, guidelines from task forces have tried to provide a rational approach to treatment of chronic pain, including chronic neuropathic pain. For example, the European Federation of Neurological Societies Task Force (EFNS) (Attal et al., 2010) summarized their results in the PubMed abstract:

Drugs generally have similar efficacy in various conditions, except in trigeminal neuralgia, chronic radiculopathy and HIV neuropathy, with level A evidence in support of tricyclic antidepressants (TCA), pregabalin, gabapentin, tramadol and opioids (in various conditions), duloxetine, venlafaxine, topical lidocaine and capsaicin patches (in restricted conditions). Combination therapy appears useful for TCA-gabapentin and gabapentin-opioids (level A).

Another group, Special Interest Group on Neuropathic Pain (NEUPSIG), has evaluated drugs for chronic neuropathic pain and has put forward similar guidelines for pain management of this condition (Dworkin et al., 2010):

Tricyclic antidepressants, dual reuptake inhibitors of serotonin and norepinephrine, calcium channel $\alpha(2)$ -delta ligands (i.e., gabapentin and pregabalin), and topical lidocaine were recommended as first-line treatment options on the basis of the results of randomized clinical trials. Opioid analgesics and tramadol were recommended as second-line treatments.

Increasingly, it has become difficult to show efficacy of drugs vs. placebo in controlled trials for chronic pain as exemplified for lacosamide (Ziegler et al., 2010) or lamotrigine (Irizarry et al., 2009).

ACTIVITY-RELATED TREATMENTS

General fitness seems to confer benefits in chronic pain as well (Schaafsma et al., 2010). Similarly, appropriate physical therapy by individuals skilled in treating chronic pain (as opposed, for example, to treatment of acute orthopedic problems) can make a significant difference in chronic pain. The effects are not only related to muscle strengthening but seem to have changes on sensorimotor processing akin to the effects of prostheses in chronic pain that provide additional feedback in patients with amputations (Flor, 2003). The approach has to do with reorganizing the abnormalities producing chronic pain (Karl et al., 2001) by reconstituting cortical processes that these rehabilitation processes confer (see Giroux & Sirigu, 2003). Appropriate exercises specific to a pain problem (e.g., back pain, “frozen shoulder” pain) are easily implemented and may provide some of the best treatment outcomes. Proper clinical trials are needed to define this further (see Cherkin et al., 1998).

USE OF INTERVENTIONAL THERAPIES

Interventional therapies include injections of local anesthetics, steroids, intrathecal infusions of drugs, and neuroablation or stimulation (Shah et al., 2003; Markman & Philip, 2007; Bottger & Diehlmann, 2011). Repetitive nerve blocks as a monotherapeutic treatment are losing their importance in the therapy of chronic pain (Donner et al., 1998). Spinal cord stimulation is addressed above. There are no good outcome studies for any of these studies. However, in some cases, patients may receive benefit, and even if it is short-term, the provision of a respite may help them with accessing and getting involved in other therapies including increased activity (Abdelshafi et al., 2011). More aggressive approaches are used in cancer patients, including intrathecal administration of opioids, local anesthetics, or clonidine (Miguel, 2000). Obviously, invasive techniques may have some complications, but overall these seem to be relatively rare. What are clearly needed are outcome studies to define efficacy in a more rigorous manner.

PSYCHOLOGICAL/BEHAVIORAL THERAPIES

A recent Cochrane Database review reports on the efficacy of psychological therapies for chronic pain, based on a

systematic review of randomized controlled trials (Eccleston et al., 2009). Of the behavioral methods studied, only cognitive-behavioral therapy (CBT) showed even small positive effects for pain, disability, and mood. Thus, there are insufficient data on quality or content of behavioral therapies to evaluate their influence on outcome. In a similar Cochrane Database evaluation of psychological treatments in children and adolescents, such treatments were noted to be effective in pain control for children with headache (Eccleston et al., 2009). Psychological treatments may also improve pain control for children with musculoskeletal and recurrent abdominal pain.

NEUROMODULATION

Epidural motor cortex stimulation (MCS) was first reported to be useful for the treatment of refractory neuropathic pain, although its mechanism of action remains poorly understood (Lazorthes et al., 2007). Subsequent use of transcranial magnetic stimulation (TMS) has also provided seemingly beneficial results for a number of pain conditions, including neuropathic pain (Schwenkreis et al., 2010) and fibromyalgia (Mhalla et al., 2011), visceral pain (Villanueva, 2011), and migraine (Lipton et al., 2010). The attractive feature of TMS is that it is non-invasive and may augment other treatments like pharmacotherapy (Antal & Paulus, 2011).

The European Federation of Neurological Societies (EFNS) task force guidelines on the use of neurostimulation for neuropathic pain state:

Spinal cord stimulation (SCS) is efficacious in failed back surgery syndrome (FBSS) and complex regional pain syndrome (CRPS). Motor cortex stimulation (MCS) is efficacious in central post-stroke and facial pain at lower levels of efficacy. Deep brain stimulation (DBS) should only be performed in experienced centers. (Cruccu et al., 2007)

PAIN ETHICS

While the treatment of pain and access to treatment for pain should be considered a universal right (Lohman et al., 2010), the problem is that, by and large, treatments are relatively ineffective, and trial and error may help produce a best possible option. As noted by McGee and colleagues:

Raising awareness about chronic pain, improving access and outcomes to quality pain care, and resolving public policy debates about the use of opioids in chronic pain populations are the first steps to ensuring a morally justifiable approach to chronic pain management in the 21st century. (McGee et al., 2011)

In approaching this, there several issues that can be addressed, including disparities in treatment across age and gender, access to pain, standards of care, prevention of discrimination,

and the need to enhance studies that provide evidence-based outcomes to guide treatment. Doing better with the current armamentarium based on best practice seems like a reasonable measure to start with, while developments in these domains improve pain treatments. In a report from the Institute of Medicine (IOM), it is noted that:

Pain is a major driver for visits to physicians, a major reason for taking medications, a major cause of disability, and a key factor in quality of life and productivity. Given the burden of pain in human lives, dollars, and social consequences, relieving pain should be a national priority. (Relieving Pain in America: A Blueprint for Transforming Prevention, Care, Education, and Research; <http://www.iom.edu/Reports/2011/Relieving-Pain-in-America-A-Blueprint-for-Transforming-Prevention-Care-Education-Research.aspx>)

By getting rid of treatments that do not benefit patients, by education about what is possible based on scientific evidence, we can provide a more honest approach to patients who suffer from chronic pain.

MISSING ELEMENTS AND INTEGRATED TREATMENTS

Pain treatment is at a crossroads. There needs to be a modification of our approaches that incorporate integrated approaches. This is different from the so-called multidisciplinary approaches where the patient “hops from one discipline to another.” The approach needs to be patient-centric and treatments need to be measured according to the diagnosis. The best example is a recent paper on chronic back pain. It defines the contributions of additive therapies based on the level of the disease (Hill et al., 2011). By stratifying care into three therapeutic pathways according to the estimated risk of poor prognosis (defined in their study as persistent disability because of back pain), the authors improved clinical outcomes while remaining cost-effective.

For integrated treatments, there are numerous missing elements. While the mainstays of advanced pain treatments have been mostly procedural, there lately seems to be a major change in the way we approach pain treatment, based on the increasing demand for outcome studies on treatment efficacy. In order to improve our position, the following issues will need to be addressed:

1. Chronic pain needs to be understood as a disease of the CNS. Understanding reward-aversion processing and alterations in endogenous pain processing are critical.
2. Missing “elements” in pain treatment including neurology (Borsook, 2011) and psychiatry (Elman et al., 2011), which may provide additional approaches to patient evaluation and treatment. These two disciplines by and large do not involve themselves in pain.

3. Objective assays (biomarkers) for the diagnosis of pain and treatment (Borsook et al., 2011a, 2011b) or for segregating patient groups based on mechanism (Scholz et al., 2009) are needed.
4. Mechanism-based treatments should be the focus of therapy (Woolf, 2004).
5. Evidence-based management of chronic pain conditions is a critical need. Integrating science into the clinic will no doubt contribute to accelerating the development of improved treatment approaches.

CLINICAL PEARLS

- Chronic pain is defined as pain lasting for more than three months.
- Neuropathic pain includes all pain—peripheral or central—that results from damage to pain pathways (Borsook, 2011).
- Neuropathic pain results in spontaneous pain (burning, shooting) and evoked pain (allodynia, hyperalgesia, and hyperpathia).
- Changes in brain function and structure occur as a result of ongoing neuropathic pain.
- Irritable bowel syndrome (IBS) is a visceral hypersensitivity disorder (Barbara et al., 2011).
- Continued migraine attacks change the brain and may make the condition prone to transforming from acute episodic migraine to chronic daily headaches; medication overuse, particularly triptans and opioids, may contribute to such transformation.
- *Sensitization* refers to the process of increased responses to normal stimuli.
- Pain modulatory systems include those well documented in the brainstem and other more rostral brain regions, including the frontal cortex, the cingulate, and basal ganglia.
- Enhanced descending modulation protects against chronic pain; thus, understanding abnormal processing of descending controls is an important addition to the clinical approach.
- Centralization of pain implicates progressive changes in brain systems that occur as a result of peripheral nerve injury.
- Catastrophizing, the negative cognitive-affective response to anticipated or actual pain, is a prominent psychological factor contributing to the pain experience.
- In consideration of the reward-aversion pathways, pain relief incorporates not only pain reduction but improvements in emotional and cognitive components.

- No evidence supports the use of serotonin reuptake inhibitors in chronic pain (Verdu et al., 2008).
- Use of opioids in chronic pain is mostly based on non-randomized studies; none of the trials went beyond 12 weeks.
- Evidence was insufficient to determine if long-acting opioids as a class are more effective or associated with fewer side effects than short-acting opioids (Carson et al, 2011).
- There is increasing evidence that opioids alter brain systems that may not be reversible (Upadhyay et al., 2010).
- Combination therapy with duloxetine and pregabalin; lidocaine patch and pregabalin; or gabapentin with imipramine, nortriptyline, or venlafaxine may have a potential benefit compared to monotherapy (Selph et al., 2011).
- General fitness seems to confer benefits in chronic pain (Schaafsma et al., 2010).

EXCESSIVE ILLNESS BEHAVIOR

James C. Hamilton, Krystal A. Hedge, and Marc D. Feldman

INTRODUCTION

This chapter concerns the clinically important problem of patients whose reports of medical illness, physical discomfort, and disability are greater than one would expect on the basis of objective measures of disease or injury. These patients generally experience poor health outcomes and poor quality of life, despite minimal evidence of actual disease or injury. In addition, these patients can cause an admixture of anger and anxiety among their medical doctors, who may doubt the authenticity of the patient's complaints, but fear that the patient has a genuine problem that they have somehow failed to uncover. When a mental health referral is made in these cases, it often comes after the patient's relationship with medical caregivers has become strained by insinuations that the patient's complaints are not legitimate. This dynamic creates a guarded attitude in the patient that puts the consulting psychiatrist or psychologist at a disadvantage right from the start.

The goal of this chapter is to help the psychiatrist or psychologist and other medical physicians to better understand the problem of excessive illness behavior, and to provide them with the tools they need to manage patients who present in this way.

A BIOPSYCHOSOCIAL VIEW OF EXCESSIVE ILLNESS BEHAVIOR

The biopsychosocial approach to modern medicine (Engel, 1977) highlights a crucial distinction between disease and injury on one hand, and illness on the other. Whereas *disease* and *injury* can be defined in fairly narrow biological terms, the concept of *illness* expands from these biological realities to include the psychological, interpersonal, social, and even economic and political dimensions of having a disease or injury. An illness comprises the thoughts, feelings, and actions that a disease or injury provokes, as well as the changes in social and occupational functioning that occur in response to a disease or injury. It is these psychosocial aspects of the illness experience, not the biomedical ones, that cause people to seek medical care. A patient with a broken bone does not visit a doctor to get the bone fixed *per se*, but rather to be relieved of psychological distress (e.g., pain) and to return to normal functioning. Fixing the bone is the way to achieve those ends.

The term "illness behavior" can be used to encompass the intra- and interpersonal reactions of a patient to a disease or injury (Mechanic, 1966; Schwartz et al., 1994). Ideally, illness behaviors serve the purpose of protecting a person with a disease or injury (e.g., "guarding" behavior), and promoting physical recovery (e.g., increased sleep and rest for patients with a cold or flu). Illnesses are communicated to others who help the patient recover (e.g., allowing them to miss school or work). In some cases, illness behavior becomes dysfunctional, no longer serving the goals of prevention or recovery (Pilowsky, 1978). Excessive illness behavior can actually impede recovery, worsen the underlying disease or injury, or cause additional iatrogenic medical problems. For example, among persons with chronic back pain, guarding against re-injury and reduced activity level, which are adaptive short-term reactions to acute injury, can impede recovery over the long term: lack of exercise will reduce muscle support of the spinal architecture, predisposing the patient to more pain problems, and it may also increase broader health risks related to obesity and hypertension (Gatchel, Peng, Peters, Fuchs, & Turk, 2007). Patients who repeatedly seek out diagnostic testing to explain poorly defined physical complaints are at risk for false-positive results and the inevitable cascade of further tests and interventions that can lead to genuine, but iatrogenic, medical problems (Kouyanou, Pither, & Wessely, 1997).

The point of this discussion of the biopsychosocial model is to raise awareness of the fact that psychosocial variables that distinguish illness from disease or injury operate in every medical patient. In some cases, the clinical picture is complicated by too little illness behavior and a neglectful social milieu. In others, illness behavior may be excessive. The convenient dichotomy between patients who are genuinely ill and those whose problems are "all in their heads" is false and unhelpful. Instead, it may be best to regard every case as a complex interplay of biological and psychosocial factors that combine to produce the patient's unique experience and expression of his or her illness. Therefore, we believe there is value in attending to the psychosocial influences on the illness experience for all patients, not just the "difficult" ones.

The primary obstacle to the effective management of cases with excessive illness behavior is the stigma that attends psychological explanations of illness experiences. If the medical culture changed to more routinely consider the full spectrum

of factors that affect the illness experience, we could vastly decrease that stigma and clear the way for effective biopsychosocial case management.

DEFINING AND CHARACTERIZING EXCESSIVE ILLNESS BEHAVIOR

THE LANDSCAPE OF EXCESSIVE ILLNESS BEHAVIOR

Psychiatric training related to excessive illness behavior has traditionally been limited to discussions of disorders in the *Diagnostic and Statistical Manual of Mental Disorders* (DSM) for which excessive illness behavior is a central diagnostic criterion. These disorders include the somatoform disorders and factitious disorders. Beyond these official DSM diagnoses, there are a number of other clinical presentations in which excessive illness behavior is an important feature, and mental health consultants should be aware of them.

Somatoform Disorders

The somatoform disorders (SFD) in the DSM include six specific disorders: *Hypochondriasis*, *Conversion disorder*, *Somatization disorder*, *Pain disorder*, *Undifferentiated somatoform disorder*, and *Somatoform disorder not otherwise specified* (American Psychiatric Association, 2000). Each of these disorders is characterized by excessive illness behavior. For each disorder, the patient is presumed to believe that he or she has a medical problem and is unaware of psychosocial influences on their illness experiences or behaviors. That is to say, the illness behavior is regarded as an expression of unconscious or implicit psychological processes.

Generally speaking, this category of diagnoses has been a failure (Creed, 2006; Levenson, 2011). The disorders lack affirmative psychological signs or symptoms, and are instead fundamentally diagnoses of exclusion (i.e., excluding a physical explanation): they cannot be verified without considerable medical information (Voigt et al., 2010). These disorder categories have also been criticized as overly restrictive, excluding persons with clinically significant, persistent excessive illness behavior and attendant distress and disability (Escobar, Waitzkin, Silver, Gara, & Holman, 1998). Unlike most other DSM diagnoses that rely on self-reports, it is doubtful that patients are either able or willing to accurately describe their medical complaints as “excessive.” Consequently, the somatoform disorders have been omitted from most of the major self-report-based epidemiological studies of mental illness (Simon & VonKorff, 1991; Swartz, Landerman, Blazer, & George, 1989). Smaller-scale studies have addressed these disorders individually, but few have made comparisons among them.

The DSM-5 (DSM, 5th edition) includes major revisions to this category. The most sensible of these proposals are to: (a) distinguish health anxiety issues that are the hallmark of hypochondriasis, from disease conviction issues; and (b) combine the remaining somatoform disorders into

a single category (with the exception of *Conversion disorder*, which is renamed but otherwise unchanged). In addition, the new criteria include previously uncategorized cases of persistent and disabling excessive illness behavior for which an official diagnosis would be appropriate and helpful to the patient.

Factitious Disorder

Factitious disorder (FD) is characterized by conscious and intentional medical deception. Patients with FD may exaggerate, lie about, simulate, or actually induce disease or injury. They do so primarily for the purpose of enacting or occupying the sick role: to be regarded as sick by friends, family, and medical professionals; to receive medical assessment and treatment, often including hospitalization; and to receive the signs of love, concern, and nurturance that are typically afforded to the seriously ill (American Psychiatric Association Task Force on DSM-IV, 2000).

Since the inclusion of SFD and FD in the DSM-III (DSM, 3rd ed.), these two types of disorders have been segregated into completely different chapters, despite the fact that both types of disorders are fundamentally problems of excessive illness behavior. The distinction is based on the persistent belief that patients with SFD are not consciously and intentionally producing their excessive illness behavior, whereas patients with FD are believed to consciously and intentionally feign or induce illness. For reasons that are more historical than empirical, the DSM's authors chose to require affirmative evidence of intentional feigning or self-injury for the diagnosis of FD. In practice, such evidence is only available in the most audacious cases, in which patients enact medical deceptions, creating the possibility that the patient can be “caught in the act.” In the absence of tangible physical evidence of medical deception, the DSM presumes that excessive illness behavior is driven by unconscious processes, and therefore should be diagnosed as an SFD. This somewhat arbitrary nuance of the DSM criteria has cast FD as a rare, severe, and intractable disorder (Feldman, Hamilton, & Deemer, 2001). In doing this, it has also de-emphasized important motivational processes that may promote excessive illness behavior, in favor of cognitive explanations.

Malingering

Malingering is similar to FD in that its primary clinical feature is conscious and intentional medical deception. The key distinction is that, in malingering, the reason for the medical deception is to secure a tangible or instrumental benefit of some sort (e.g., a financial settlement, prescription drugs, disability income). Because these motivations do not distinguish malingers from common criminals who commit fraud to secure benefits they are not otherwise entitled to, the DSM does not classify malingering as a psychiatric disorder, though neuropsychological testing can be valuable in the detection of malingering in forensic cases (Hamilton, Feldman, & Cunnie, 2008).

Functional Somatic Syndromes (FSS)

The medical literature describes several medical syndromes—functional somatic syndromes (FSS)—that are characterized by subjective medical complaints and a moderate to high degree of personal distress, but not by any hallmark finding of disease or injury. The patient's distress may stem from the functional impairments associated with their symptoms, the uncertainty of not knowing exactly what is wrong with them, or the inability to obtain symptom relief. The FSS conditions include chronic fatigue syndrome, irritable bowel syndrome (IBS), fibromyalgia, and environmental intolerance (previously called “multiple chemical sensitivities”). These conditions have in common a clinical presentation that is predominated by subjective complaints (e.g., fatigue, gastrointestinal discomfort, pain) and a lack of reliable physical markers that distinguish them from the unaffected population.

Heated controversy surrounds these conditions, and the controversies exemplify the core issues addressed in the preceding section on the biopsychosocial model. Patient advocacy groups insist that these conditions are genuine physical diseases and vehemently oppose suggestions that psychological factors influence the sufferers' illness experiences or illness behavior. These reactions are perfectly predictable responses in the context of a society that views medical problems as more authentic, important, legitimate, and reimbursable than psychological problems. In this way, their reactions also show how far away society is from fully realizing a biopsychosocial view of health and illness.

Medically Unexplained Symptoms

The vast majority of empirical evidence about excessive illness behavior comes from studies of patients or community members whose illness behavior is excessive but may not meet the strict DSM criteria for an SFD or FD, or whose symptoms do not match one of the FSS. In addition to “medically unexplained symptoms” (MUS), these studies may refer to excessive illness behavior as “unexplained medical complaints” or “functional somatic symptoms,” or they may focus on patients who are frequent clinic visitors or “high utilizers” of health-care services. Also included in this category are studies that focus on subclinical levels of excessive illness behavior that do not meet DSM criteria for a somatoform disorder but meet various provisional or research criteria (Escobar et al., 1998; Kroenke et al., 1997). It is safe to say that the majority of our scientifically based knowledge of excessive illness behavior comes from studies falling into this category.

THE EPIDEMIOLOGY AND ETIOLOGY OF EXCESSIVE ILLNESS BEHAVIOR

PREVALENCE

Numerous studies suggest that roughly 20–30% of primary care *visits* are associated with patient complaints that are not clearly linked to an identifiable disease or injury.

In some sub-specialties, this figure may be as high as 50–80% (Nimnuan, Hotopf, & Wessely, 2001). These astronomical figures come mostly from chart review studies and may be inflated by reports of benign and self-limiting complaints with no particular psychological significance (Swanson, Hamilton, & Feldman, 2010). Physician surveys, which have both advantages and disadvantages, typically set the rate much lower, at around 10% (Swanson et al., 2010). More to the point is the prevalence of patients who present with persistent or multiple unexplained medical complaints. Studies of primary care patients set the prevalence rate between 0.3% (Smith, McGorm, Weller, Burton, & Sharpe, 2009) and 20% (Escobar et al., 1998; Steinbrecher, Koerber, Frieser, & Hiller, 2011), and the rate may be higher in specialty care. Rates for FSS are usually lower, around 7–10% (Aggarwal, McBeth, Zakrzewska, Lunt, & Macfarlane, 2006). Rates for the somatoform disorders are intermediate, at approximately 15–20% for any somatoform disorder (de Waal, Arnold, Eekhof, & van Hemert, 2004); however, the majority of these cases receive a diagnosis of “undifferentiated somatoform disorder” or “somatoform disorder NOS” (Faravelli et al., 1997; Fink, Hansen, & Oxhøj, 2004). In general, health-care contacts for unexplained medical problems appear to be clustered in patients who use a disproportionate amount of health services. In a startling study, Fink (1992) found that 56 “persistent somatizers” accounted for 3% of the annual non-psychiatric health care visits made in the entire nation of Denmark.

DEMOGRAPHICS

Given the wide landscape of excessive illness behavior, summarizing the demographics of patients with excessive illness behavior might seem like a daunting task. Actually, it is not. With only very minor exceptions, the demographic features of patients with SD, FD, FSS, and general MUS are highly similar. First, these cases are overwhelmingly female. Second, in all these settings, the prevalence is greatest among patients around 30 to 45 years of age. In studies of European populations, there is a consistent finding of high rates among the less well-educated, the unemployed, unmarried persons, and members of racial and ethnic minority groups. Similar findings are reported for American samples, but the results are less consistent.

PSYCHIATRIC COMORBIDITY AND FUNCTIONAL IMPAIRMENT

Patients with persistent excessive illness behavior lead difficult lives. There is a very high comorbidity between excessive illness behavior problems and anxiety and depression (Henningsen, Zimmermann, & Sattel, 2003; Schur et al., 2007; Steinbrecher et al., 2011). The functional status of patients with excessive illness behavior is also generally poor, with the worst functioning in those with comorbid anxiety and depression (de Waal et al., 2004; Dirkzwager & Verhaak, 2007). Interestingly, studies of specific FSS suggest that the distress and functional impairment associated

with unexplained symptoms are as bad as, or worse than, what is observed in patients with comparable confirmed disease; e.g., epilepsy and psychogenic non-epileptic seizures (Krumholz & Hopp, 2006) or irritable bowel syndrome and inflammatory bowel diseases (Pace et al., 2003; Reuber & Elger, 2003).

COURSE

Findings related to the persistence of excessive illness behavior are generally consistent in showing that 20–50% of patients continue to have difficulty a year or more after baseline assessment. A study of multi-somatoform disorder found that unexplained symptoms persisted for five years in 21% of patients (Jackson & Kroenke, 2008). Lieb and colleagues (2002) found that somatoform disorder persisted in 48% of patients after one year. Persistence of non-epileptic events was reported to be 71% after four years, with a poorer prognosis for cases with accompanying non-neurological unexplained symptoms (Reuber & Elger, 2003). It appears that the persistence of excessive illness behavior, and deterioration, are likeliest among patients with more physical complaints and greater psychiatric comorbidity at baseline (olde Hartman et al., 2009).

COSTS

In addition to the personal costs to patients of excessive illness behavior, this problem places an enormous financial burden on the healthcare system (Barsky, Ettner, Horsky, & Bates, 2001; Barsky, Orav, & Bates, 2005). A recent study by Barsky and colleagues suggests that in the United States alone, the annual costs of direct medical care related to somatization may exceed \$250 billion (Barsky et al., 2005).

CAUSES

Research has consistently found that excessive illness behavior is highly comorbid with anxiety and depression, particularly depression, and associated with high levels of negative affectivity and the basic personality trait of neuroticism (Watson & Pennebaker, 1989). From these findings, a group of theories has emerged that suggest that excessive illness behavior is a product of some combination of heightened autonomic arousal, hypervigilance toward bodily cues, and a tendency toward negative and exaggerated interpretation of these physical experiences (Barsky, Goodson, Lane, & Cleary, 1988; Brown, 2004; Deary, Chalder, & Sharpe, 2007; Looper & Kirmayer, 2002). More recent research suggests that the relationship between neuroticism and somatic complaints may be more due to a bias toward experiencing distress, rather than to heightened attention to bodily sensations (Marcus, Gurley, Marchi, & Bauer, 2007). This view is in harmony with the idea that excessive illness behavior is a dissociative phenomenon (Brown, Brunt, Poliakoff, & Lloyd, 2010). The majority of interventions for excessive illness behavior are based on these cognitive or information-processing models.

Emotion-regulation models view excessive illness behavior as an indirect expression of psychological distress that patients are not able to express directly (Gottlieb, 2003; Waller & Scheidt, 2006). The term “alexithymia” is used to describe a dispositional deficit in the processing of emotional experiences. Studies linking alexithymia to excessive illness behavior have produced mixed results. A review of the literature found that one aspect of alexithymia, difficulty identifying emotions, was consistently associated with symptom reporting—not necessarily unexplained symptoms (De Gucht & Heiser, 2003). However, subsequent studies suggest that alexithymia does not prospectively predict the emergence of new somatic symptoms (De Gucht, Fischler, & Heiser, 2004; Kooiman, Bolk, Rooijmans, & Trijsburg, 2004), and some studies that control for the effects of other variables, such as negative affect, anxiety, and depression, fail to show a unique relationship of alexithymia to symptom reporting (Bewley, Murphy, Mallows, & Baker, 2005; De Gucht et al., 2004). Using a language-analysis coding system to operationalize deficits in emotion processing, Lane and colleagues found evidence that low levels of emotional awareness predict the level and nature of physical symptom reporting, and that these effects are independent of negative affectivity, anxiety, and depression (Lane, Carmichael, & Reis, 2011; Subic-Wrana, Bruder, Thomas, Lane, & Kohle, 2005).

Motivational or functional explanations of excessive illness behavior suggest that illness behavior leads to psychosocial benefits that serve to perpetuate it (Hotopf, 2004). The benefits of the sick role were formally described by Parsons (1951), and referred to in psychoanalytic writing as “secondary gains” (Fishbain, Rosomoff, Cutler, & Rosomoff, 1995). They include tangible benefits such as legal settlements, worker’s compensation awards, Social Security Disability income, relief from military service or unpleasant jobs, and prescriptions for medications that can be used for recreational purposes or sold for profit. The benefits of illness behavior may also include predominantly psychological ones, such as avoidance of conflict, or securing care, nurturance, and forbearance from friends and loved ones. The existence of these psychological benefits is affirmed by the DSM-IV-TR (DSM-IV Text Revision), which lists them as the defining motivation of the illness behavior observed in FD.

Relatively little modern research has been done on the specific psychological benefits of illness behavior, or the individual characteristics that predispose some people to be so strongly drawn to them. Hamilton and Janata (1997) suggested that for persons with poor self-esteem or identity problems, the sick role may be a vehicle for securing a sense of uniqueness or importance, and it appears that certain features of the sick role may have desirable self-presentational effects (Hamilton, Deemer, & Janata, 2003). More recently, a well-replicated relation between MUS and *insecure attachment* (Taylor, Marshall, Mann, & Goldberg, 2011) has led to the development of an interpersonal theory of illness behavior (Noyes, Stuart, & Watson, 2008). According to this view, persons with attachment insecurity are reinforced by the care and nurturance that the sick role elicits in others, and are drawn into patterns of excessive illness behavior. This theory

is certainly consistent with the clinical evidence that links FD to borderline and narcissistic personality types (Ehlers & Plassmann, 1994).

SUMMARY

Excessive illness behavior is common in all medical settings, and exacts substantial personal costs from patients and their care providers, at a substantial cost to healthcare delivery systems. Despite a wide array of outward presentations and diagnostic labels, cases of excessive illness behavior share a core pattern of demographic features, psychiatric comorbidities, and psychosocial impairments. The psychosocial mechanisms that underlie excessive illness behavior are not well understood, and research in this area has reflected the aforementioned bias in the DSM that casts excessive illness behavior in terms of faulty information-processing rather than as functionally related to sick-role benefits or other reinforcers.

MANAGEMENT OF EXCESSIVE ILLNESS BEHAVIOR

There are two ways mental health professionals might contribute to the management of cases with excessive illness behavior. The first is by helping primary medical care providers and allied health professionals, who are usually the first to encounter these cases. The second is through direct care of patients with excessive illness behavior.

EDUCATION AND CONSULTATION

Providers who encounter a patient with excessive illness behavior may initially view the case as a challenge. When all efforts to diagnose and treat the patient's problems fail, the provider may passively dismiss the patient's concerns by providing reassurance and acquiescing to requests for assessments and treatments that the provider views as unnecessary but harmless. Alternatively, the provider may confront the patient by suggesting that his or her problems are "psychological" and suggest that the patient seek the help of a mental health professional. Still other providers may simply pass the patients along to other doctors, with whom the process will probably be repeated. None of these strategies advances the care of the patient. Medical providers should be encouraged to think about illness behavior from the biopsychosocial perspective outlined above. Specifically, they should be helped to view physical disease or injury and illness behavior as two interdependent influences on the patient's health-related quality of life, and taught the basic clinical skills necessary to assess and manage psychosocial influences on illness behavior.

Communication

It is frequently assumed that patients with excessive illness behavior insist on strictly physical interpretations of their problems. However, important research by Salmon and

colleagues contradicts the belief that patients demand somatic interpretations and interventions (Salmon, Humphris, Ring, Davies, & Dowrick, 2006, 2007). Instead, it appears that patients often broach psychosocial issues during medical visits, and that focus on somatic issues is reduced when physicians are responsive to those disclosures. Ironically, it appears that physician interactions with patients with medically unexplained complaints are especially lacking in the type of patient-centered communication that facilitates discussion of psychological issues (Epstein et al., 2006). Another study showed that patients with unexplained complaints were generally willing to accept a strategy of watchful waiting, but this acceptance was dependent on good communication between physicians and patients (van Bokhoven et al., 2009). Thus, the available research suggests unnecessary somatic interventions can be avoided if primary care physicians are able to effectively communicate with their patients about psychological distress and other psychosocial issues.

Identifying and Correcting Factual Errors

So what should physicians be encouraged to talk about? Important research by Leventhal and others on illness representations suggests that patients develop ideas about their diseases and injuries that include its name, symptoms, cause, course, and treatability/controllability (Leventhal, Leventhal, & Contrada, 1998). Frequently, patients' excessive illness behavior can be attributed to providers' failure to assess the accuracy of patients' information about these dimensions and to provide accurate corrective feedback. For example, in some cases, excessive health service use can occur because patients mistakenly believe that symptom flare-ups reflect a dangerous progression of their disease, when this is not necessarily the case. Physician colleagues should be advised to ask patients about these crucial dimensions of their illness representations, correct misconceptions, provide accurate information, and help patients cope with the fact that sometimes their questions do not have clear answers. Substantive conversations like these provide the foundation for meaningful reassurance about the patient's physical health.

Discussing the Role of Psychological Factors

Among the more important issues to openly discuss with a patient is the possible role of psychosocial factors that impact the illness experience. The key to an effective discussion of psychological factors is to clearly and directly reassure the patient that acknowledging the role of psychological factors is not tantamount to declaring that the patient does not have a legitimate medical problem. The focus should be on the role that stress and distress can play in the development of disease and in shaping reactions to disease. Physicians can be advised to call upon their knowledge of the effects of stress on the hypothalamic-pituitary-adrenal (HPA) axis to explain to patients, in biological terms, how stress and physical health can be intertwined. In addition, physicians can explain to patients how pain experiences are affected both by basic interpretation of pain sensations and by emotional centers of the

brain that are responsible for the experience of pain distress. In either model, a case can be made for why understanding and managing the patient's stress and distress are important in a comprehensive approach to maximizing the patient's health-related quality of life.

Maintaining Standards of Care

The care of patients with excessive illness behavior can be compromised by departures from standard clinical practice. In the early phases of care for these patients, the greatest risk is succumbing to patients' persistent complaints by over-treating them. When suspicions arise about the authenticity of the complaints, the opposite error can occur: doing less than is indicated. This pattern is most clearly apparent in cases of FD. As educators or consultants, mental health professionals can caution physicians about this pattern and urge them to make medical decisions based on medical data. Elsewhere we have likened this approach to a pilot flying in bad weather: pilots are encouraged to follow procedures and trust their instruments (Hamilton & Feldman, 2011). Physicians should be encouraged to do likewise: to do no more and no fewer tests and interventions than they would for patients with less dramatic illness behavior.

An interesting lesson from the literature on FD is that more medical errors are made *before* the possibility of FD is raised than after. This is because suspicions about excessive illness behavior and about a major influence of psychological factors in a case cause physicians to avoid departures from standard care. We believe heightened attention to psychological factors can have the same positive results in the management of all cases along the spectrum of excessive illness behavior.

Finding and Disrupting Adventitious Reinforcement

There are benefits that accompany the sick role; that is, illness behavior is often reinforced. This is true regardless of whether a patient intentionally seeks reinforcement or reinforcement occurs by accident. Unpleasant work is put off, demanding spouses and bosses temporarily relent, time is available for pleasure reading, and friends send fruit baskets. The kind attention of physicians and the palliative treatments they provide can also be reinforcing. These reinforcing consequences of illness behavior cannot be avoided entirely. However, excessive illness behavior can be reduced by paying attention to, and controlling, the contingent relationships between illness behaviors and reinforcers. For example, physicians sometimes react to patients with excessive illness behavior by putting them off, seeing them only when their complaints are urgent or alarming. This approach unintentionally reinforces the report of increasingly more urgent and alarming symptoms. Such cases might be better handled by scheduling regular appointments in order to break the contingent relationship between health crises and physician attention. This approach to managing pain-contingent care and attention is a standard part of cognitive-behavioral pain-management programs (Turk, 1999).

A Focus on Functioning

Another important theme in the care of patients with excessive illness behavior is an emphasis on the patients' social and occupational functioning over symptom reduction. Whereas patients believe that their medical problems cause or require limitations in their functioning, it is probably more often true that reduced activity and engagement exacerbate the patients' experience of their medical problems. Often patients hold beliefs that a decrease in normal daily activities is an important part of physical recuperation or preventing a worsening of their condition (Sullivan & Stanish, 2003). Physicians should take the time to explore these beliefs and provide accurate information about the relationship of activities to the medical condition, and when appropriate, to explain the physical and psychological benefits of gradually increasing their activity and engagement. The patient can be reminded that, ultimately, the problem is not their physical symptoms, but rather the effects the symptoms have on the quality of their lives. This perspective supports the usefulness of working directly on improved functioning and overall quality of life as a primary clinical goal.

Reattribution Therapy

There have been several attempts to create systematic physician-delivered interventions for excessive illness behavior. Reattribution therapy is among the better known and most systematically researched of these interventions. In reattribution therapy, physicians are taught to provide psycho-education and cognitive restructuring to their patients, with the goal of encouraging less alarming and disabling attributions for patients' physical experiences (Edwards, Stern, Clarke, Ivbijaro, & Kasney, 2010); or, in other words, to have patients "see their symptoms in a different way" (Goldberg, Gask, & O'Dowd, 1989, p. 690).

This model comprises three main stages. In the first stage, the physician aims to ensure that the patient feels understood, which is achieved through a thorough examination and history-taking, including social history. The second stage consists of "broadening the agenda beyond physical symptoms" (Edwards et al., 2010, p. 212). Goldberg, Gask, and O'Dowd (1989) suggest the physician achieve this goal by (a) summarizing the findings from the first stage; (b) empathically validating the patient's experience of symptoms and distress; and (c) suggesting other meanings or explanations of their distress and symptoms. The goal of the final stage is to address psychological factors that emerged in the first stage and normalize the relationship between psychosocial stressors and physical symptoms. This step involves drawing a direct connection between the patient's pain or physical complaints and potential psychological etiology. While Goldberg, Gask, and O'Dowd (1989) suggest a number of specific approaches to presenting this link, at the most fundamental level, each approach focuses on normalizing the connection between physical symptoms and psychosocial stressors. They describe the process as a negotiation in which the physician finds a model of the link that is acceptable to

the patient, but that allows him or her to move past an exclusive focus on physical causes and somatic interventions (see also Morriss et al., 2006).

Research on reattribution therapy has generally shown that physicians find the approach acceptable, and that they report feeling better able to manage patients presenting with unexplained medical complaints (Morriss et al., 2006). Also, there is evidence that the approach does increase communication about psychosocial issues between doctors and their patients (Morriss et al., 2010) and that it improves patient knowledge and satisfaction (Morriss et al., 2007). However, Morriss et al. (2010) report that 30% of their patients did not provide any psychosocial information, despite direct prompts from physicians. Qualitative analysis indicated patients failed to disclose emotional issues for fear their physician would not consider the possible physical underpinnings of their presenting problem.

There are mixed findings regarding the efficacy of this approach for reducing symptom reports and decreasing distress and disability (Morriss et al., 2006). A study conducted in Spain, with 39 physicians seeing 152 patients with unexplained medical symptoms, demonstrated significant improvement in general physical health, vitality, social functioning, and mental health (Aiarzaguena et al., 2007). There is little evidence that the approach reduces excessive illness behavior, and several studies show no effects, or even less improvement than treatment as usual, for more severe cases of excessive illness behavior (Morriss et al., 2007; Toft et al., 2010).

Consultation Letters

Another approach to the management of patients with excessive illness behavior is a one-time consultation between the patient and a mental health professional, followed by a consultation letter to the referring physician. The consultation ideally provides definitive information about the role of psychological factors in the patient's case, assures that medical risks in such cases are statistically low, and provides guidance on the management of the case (e.g., avoiding excessive assessments and treatments: scheduling frequent, regular appointments). Hoedeman and colleagues (2010) recently published a Cochrane review of the literature on consultation letters. Few studies met the rigorous inclusion criteria; however, the available evidence suggests that this simple intervention results in reduced medical expenditures and improved physical functioning in patients with medically unexplained symptoms.

DIRECT INTERVENTIONS

For cases in which the patient accepts a mental health referral, there are several effective approaches to therapy and case management. It should be noted that many of the same problems that arise in physician-delivered interventions also apply to the direct treatment of these patients by mental health professionals, particularly the issue of effective and empathic communication.

Cognitive-Behavioral Therapy

Cognitive-behavioral therapy (CBT) is perhaps the most well-researched treatment approach for patients with excessive illness behavior (Witthoft & Hiller, 2010). This approach includes "identifying and restricting automatic, dysfunctional thoughts that may compound, perpetuate, or worsen somatic symptoms" (Huang & McCarron, 2011, p. 30). There are several published models of excessive illness behavior that provide the conceptual basis for this application of CBT, and these models are generally consistent with one another (Brown, 2004; Deary et al., 2007; Looper & Kirmayer, 2002). Addressing the effectiveness of extant treatments for excessive illness behavior problems, Kroenke (2007) described CBT as "the one treatment for which there seems to be convincing evidence" (p. 885).

Kroenke and Swindle (2000) conducted a meta-analysis of 31 studies on the effects of CBT for somatization and functional syndromes. Twenty of 28 (71%) studies revealed significant improvement in physical symptoms, but fewer studies reported improved functional status (47%) or decreased psychological distress (38%). Results indicated that treatment outcome did not differ as a function of the frequency, duration, or mode (e.g., group versus individual therapy) of the CBT approach. However, as few as five sessions were found to be effective in treating somatization and functional syndromes, and outcomes were maintained for up to 12 months in nearly all studies. In a subsequent review of randomized controlled trials, Kroenke (2007) found that CBT produced better outcomes than treatment with antidepressants, psychiatric consultation letters, brief primary care interventions, and non-CBT psychotherapy. CBT was effective in treating somatoform disorder and subclinical levels of excessive illness behavior on at least one outcome variable in 11 of 13 studies. Results were inconclusive with regard to conversion disorder, and functional somatic syndromes and chronic symptoms (e.g., back pain) were not included in this meta-analysis.

Martin, Rauh, Fichter, and Rief (2007) conducted a study on the efficacy of a single three- to four-hour session of group CBT intervention with 104 primary care patients diagnosed with an SFD. They report a decrease in the number of medical visits in the CBT group compared to a control group. Medication usage and the number of sick days taken also decreased in the CBT group. However, the CBT group did not experience a significant decrease in the number of somatoform symptoms. Overall, it appears one session of CBT can have a beneficial effect on certain aspects of excessive illness behavior, especially the number of doctor visits and symptom severity. Escobar et al. (2007) found similar results regarding the effectiveness of brief CBT (ten sessions), with 60% of primary care patients who received CBT reporting relief from medically unexplained and depressive symptoms. However, benefit from the treatment was not sustained over time.

Heijmans et al. (2011) noted that studies examining CBT-based interventions have used varying and diverse combinations of basic CBT components. The lack of consistency across studies (which is expected at this stage of

development) raises questions about which components are most effective in reducing the various expressions of excessive illness behavior.

Psychodynamic Treatment Approaches

Psychodynamic psychotherapy has also been used to treat excessive illness behavior. This treatment approach targets unconscious processes, defense mechanisms, and attachment styles (Abbass, Campbell, Magee, & Tarzwell, 2009; Nickel, Ademmer, & Egle, 2010). At its core, “psychodynamically oriented theory holds that negative or dysfunctional attachment and experiences cause a high vulnerability toward stress as well as forming a basis for the therapists’ intervention” (Nickel et al., 2010, p. 225). Edwards, et al. (2010) noted this approach to have small to medium effects in empirical studies.

In a study using a pre-post design with a short-term dynamic psychotherapy approach, Abbass et al. (2009) compared rates of emergency room visits for patients with a provisional diagnosis of somatization, anxiety, or pain in the absence of a known acute cause. Results indicated emergency room visits decreased by 69% following the intervention. In addition, patients who were treated with short-term psychodynamic psychotherapy also had decreased scores on the Brief Symptom Inventory (BSI), indicating a decrease in somatic symptoms.

While some research may show improvement after treatment utilizing a psychodynamic approach, the accessibility of this approach serves as a major barrier in its implementation (Edwards et al., 2010). Psychodynamic interventions require significantly more training to be implemented than other approaches, such as CBT. Time-intensive training programs are required to fully understand and competently administer this intervention, which may not be practical for primary care physicians. Thus, the applicability of this approach will be limited if patients with excessive illness behavior refuse any treatment beyond standard medical care (e.g., psychotherapy).

Medication

The use of medication, especially antidepressants, was cited by 23 of 30 published papers as an important component in the management of excessive illness behavior (Heijmans et al., 2011). The effectiveness of this approach appears to be at least partially the result of a reduction of symptoms of depression or anxiety disorders that are frequently observed in patients with excessive illness behavior. One study found comorbid mood disorders in over 80% of a sample of outpatients with unexplained chronic pain (Aguera, Failde, Cervilla, Diaz-Fernandez, & Mico, 2010), which indicates that the use of antidepressant medications may be especially helpful in the management of excessive illness behavior in the large proportion of individuals with comorbid disorders. In a review of treatments for medically unexplained symptoms, Edwards et al. (2010) noted antidepressants might also reduce pain severity. A meta-analysis indicated improvement through the use of antidepressant medications in 69% of patients with unexplained symptoms or symptom syndromes on at least one

outcome measure (O’Malley et al., 1999). Han et al. (2008) conducted a study in which they compared the effects of fluoxetine and sertraline on 32 outpatients with undifferentiated somatoform disorder. The study design included a randomized, 12-week trial of the medication. A decrease in subjective ratings on the Patient Health Questionnaire (PHQ), indicating an improvement in somatic symptoms, was reported. In addition, patients reported improvement in depressive symptoms as measured on the Beck Depression Inventory (BDI). There was no statistically significant difference between the sertraline and fluoxetine groups on the outcome variables. While it may appear that the improvement in somatic symptoms was a byproduct of improvement in depression and/or anxiety symptoms, individuals with Axis I disorders that may explain somatic symptoms were excluded from the study. In general, medication used to address anxiety and/or depression appears to be effective in the management of these issues.

GENERAL TREATMENT GUIDELINES

In response to the disorganized nature of the literature on treatments for excessive illness behavior, Heijmans et al. (2011) performed a qualitative analysis of articles that contained clinical guidance on the treatment and management of these cases. Their review revealed four common themes: (a) creating a “safe therapeutic environment” (p. 3); (b) implementing generic interventions; (c) implementing specific interventions; and (d) taking a multicomponent approach. The authors suggest that empathy, demonstrating a willingness to help the patient, and clear, direct communication provide the basis of a safe doctor–patient relationship. Generic treatment interventions include motivational interviewing techniques, explanation of symptoms, reassurance, and regularly scheduled appointments. Specific interventions included cognitive approaches, pharmacotherapy (especially antidepressants), activating therapy (e.g., exercise, creative writing), and complementary and alternative medicine. Finally, effective treatment appears to require the strategic use of several of these treatment approaches. It is important to note that these recommendations derived from themes that emerged from the literature that was reviewed, but they have not been subjected to empirical tests. However, similar ideas emerged in a previous edition of this book (see Box 37.1).

A collaborative care model was also noted to be an effective approach in the management of excessive illness behavior (Edwards et al., 2010). This approach was typically described as collaboration among a number of healthcare professionals from a variety of fields (e.g., primary care physician, social worker, mental health practitioner). These teams work closely with patients, and often their families, to “define problems and jointly develop treatment goals and actions” (Edwards et al., 2010, p. 215). It is recommended that these collaborative efforts take place in a medical healthcare setting to maximize the patients’ response to mental health involvement, as many patients may reject freestanding mental health treatment. This approach, which is widely used and highly effective in the management of chronic pain, may be particularly useful

Box 37.1 EXCESSIVE ILLNESS BEHAVIOR: GENERAL PRINCIPLES OF CLINICAL MANAGEMENT

1. The presentation is considered within the context of psychosocial factors, both current and past.
2. Medical and surgical procedures and therapeutic interventions are based on objective findings.
3. The therapeutic alliance is fostered and maintained by the primary care physician and mental health professional.
4. A regular appointment schedule is maintained for outpatients, regardless of clinical symptoms.
5. The social support system and relevant life-quality domains are reviewed during each patient contact.
6. The need for psychiatric referral is recognized early, especially for cases involving chronic symptoms, severe psychosocial consequences, or morbid types of illness behavior.
7. Any associated, coexisting, or underlying psychiatric disturbance (e.g., mood or anxiety disorders) is assiduously evaluated and treated.
8. The significance of personality features, addictive potential, and self-destructive risk is determined and addressed.
9. The patient's case is redefined in such a way that management rather than cure is the goal of treatment.
10. The patient is not given speculative or spurious diagnoses or treatments intended to "pacify" him or her.
11. Consultations and referrals are arranged only when they are medically indicated.
12. Family members who may be oversolicitous and who reinforce illness behaviors should be included in the treatment plan.

Adapted from Folks, Feldman, & Ford (2000).

in the management of excessive illness behavior, as there is a high prevalence of comorbid mood disorders among these patients (Aguera et al., 2010).

PREVENTION AND EARLY INTERVENTION

In more severe or chronic cases of excessive illness behavior, the patient may become so entrenched in the sick role that it is difficult for him or her to relinquish it. Such patients may have encountered doubts and questions about the legitimacy of their health problems, or been told that their illnesses are "all in your head." Patients in this situation may be highly resistant to any psychological interpretation of, or interventions for, their suffering. The literature that we have reviewed on treatments for excessive illness behavior collectively suggests that many patients with mild excessive illness behavior problems are amenable to treatment. However, those with more severe or chronic problems (e.g., factitious disorder) often are not. Thus, prevention, or early intervention, may be

particularly important in addressing the problems of excessive illness behavior.

In recent years, there has been increased attention paid to excessive illness behavior in children (Campo & Fritz, 2001; Eminson, 2007; Kashikar-Zuck, 2006; Schulte & Petermann, 2011). The rates of excessive illness behavior problems in pediatric settings appear to be similar to those observed in adult primary care settings (Schulte & Petermann, 2011). Although there is a paucity of studies that directly address the question of whether patterns of excessive illness behavior that emerge in childhood continue on into adulthood, several lines of thinking support this possibility (Mulaney, Lambert, Garber, & Walker, 2006). If so, interventions for children and families in which excessive illness behavior is observed by pediatricians or educators may be a particularly important strategy for reducing the overall burden of excessive illness behavior.

SUMMARY

There are several conclusions that can safely be drawn from the literature on managing excessive illness behavior. The first is that patients prefer to be helped by their primary care physicians rather than mental health professionals, but primary care physicians do not seem to be particularly effective in managing these patients. The second is that interventions provided by trained mental health professionals appear to be effective, but patients are disinclined to avail themselves of this type of care. For both primary care interventions and mental health interventions, emphasis has been placed on effective doctor-patient communication, and on presenting patients with explanations for their illness experiences that integrate the role of psychosocial factors. However, it appears that this is precisely the point at which attempts to help patients with excessive illness behavior fail. That is, it appears that we have yet to develop an effective way of raising the issue of psychosocial influences that does not undermine patients' trust in their doctors or cause patients to fear that their medical care is being neglected. Within a culturally accepted belief system that portrays biological and psychological causes of human suffering as mutually exclusive explanations, such fears are inevitable.

Excessive illness behavior is a pervasive problem in nearly all medical settings. Left unaddressed, it erodes the quality of patients' lives, and places them at risk for iatrogenic disease or injury, which further degrades their quality of life. In a time when rising medical costs constitute a developing national crisis in the United States, we can ill afford to spend millions of dollars on unnecessary assessments and treatments for these patients.

The literature on the conceptualization and management of excessive illness behavior shows relatively close agreement on the role of faulty information-processing in the promotion and perpetuation of excessive illness behavior. Less attention has been paid to functional or motivational influences on excessive illness behavior, and, with the exception of comprehensive pain management programs, attention to these factors has been conspicuously poor in

discussions of intervention. Nevertheless, CBT interventions designed primarily to reshape the way patients think about their physical symptoms appear to have meaningful effects on healthcare use and health-related quality of life for the patients who are willing to accept a mental health referral. However, patient acceptance of such referrals, and of the possible role of psychosocial factors in their experience of their illness, appears to be the pivotal problem in the management of these cases.

We believe that more careful and specific attention must be paid to the details of how psychosocial conceptualizations can be presented to patients in ways they will accept. A good place to start would be to call on the growing body of research that links psychological stress and distress to metabolic and immune functions through the activation of the HPA axis. In addition, we can call upon emerging evidence that there is considerable overlap in neural systems that respond to physical threats and those that respond to social and emotional threats. Both of these lines of research provide a compelling way of connecting psychological factors to physical experiences in ways that do not undermine the authenticity or legitimacy of the patient's illness experience. Patients will not believe a "story" about the role of psychosocial influences on their illness experiences that care providers do not themselves believe. The available evidence does not simply support the believability of the story of how psychological processes may affect physical ones, and vice versa; it supports the basic truth of the story.

Ultimately, patients' acceptance of the role of psychosocial factors in physical illness and wellness will require a more widespread acceptance of the biopsychosocial model and its practical implementation in primary care. Until attention to patients' social and psychological functioning becomes a routine part of medical evaluations, the belief will persist, both among patients and doctors, that medical complaints derive either from genuine disease or illness or from psychological causes in a mutually exclusive manner. Patients will continue to view inquiry into their psychosocial functioning as a rare event, and as a frightening sign that their complaints are not regarded by their doctors as genuine.

The integration of the biopsychosocial model into primary care can be advanced through several means. These include greater emphasis on mental health training in general medical education and more training in the process of building and maintaining effective doctor-patient relationships. The cause can also be advanced by the promotion of collaborative and integrative care models in which mental health professionals become routinely involved in patient assessment and care (Gallo et al., 2004).

CLINICAL PEARLS

- Patients with excessive illness behavior are those whose reports of medical illness, physical discomfort, and disability are greater than one would expect on the basis of objective measures of disease or injury. These patients generally experience poor health outcomes and poor quality

of life and can cause an admixture of anger and anxiety among their medical doctors.

- The concept of illness expands from these biological realities to include psychological, interpersonal, social, and even economic and political dimensions of having a disease or injury.
- The demographic features of patients with SD, FD, FSS, and general MUS are highly similar. These cases are overwhelmingly female, with the prevalence greatest among patients around 30 to 45 years of age.
- Excessive illness behavior problems and anxiety and depression are highly comorbid (Henningsen, Zimmermann, & Sattel, 2003; Schur et al., 2007; Steinbrecher et al., 2011). The functional status of these patients is generally poor, with the worst functioning in those with comorbid anxiety and depression (de Waal et al., 2004; Dirkzwager & Verhaak, 2007).
- Illness behavior leads to psychosocial benefits that serve to perpetuate it (Hotopf, 2004).
- Persons with attachment insecurity are reinforced by the care and nurturance that the sick role elicits in others and are drawn into patterns of excessive illness behavior.

GUIDELINES OF MANAGEMENT

- Communication: Patients with unexplained complaints are generally willing to accept a strategy of watchful waiting, but this acceptance depends on good communication between physicians and patients (van Bokhoven et al., 2009).
- Ask patients about crucial dimensions of their patients' illness representations, correct their misconceptions, provide accurate information, and help them cope with the fact that sometimes the questions do not have clear answers.
- Educate patients about the role that stress and distress can play in the development of disease and in shaping their reactions to disease.
- The care of patients with excessive illness behavior can be compromised by departures from standard clinical practice.
- Excessive illness behavior can be reduced by paying attention to, and controlling, the contingent relationships between illness behaviors and reinforcers.
- Emphasize the patients' social and occupational functioning over symptom reduction.
- Focus on normalizing the connection between physical symptoms and psychosocial stressors: The physician negotiates with the patient a link that is acceptable to the patient, but allows the patient to move past an exclusive

focus on physical causes and somatic interventions (see Morriss et al., 2006).

- Goldberg, Gask, and O'Dowd (1989) suggest the physician (a) summarize the findings from the first stage; (b) empathically validate the patient's experience of symptoms and distress; and (c) suggest other meanings or explanations of distress and symptoms.
- A meta-analysis indicated improvement through the use of antidepressant medications in 69% of patients with unexplained symptoms or symptom syndromes on at least one outcome measure (O'Malley et al., 1999).
- Empathy demonstrates a willingness to help the patient, and clear, direct communication provides the basis of a safe doctor–patient relationship.
- Generic treatment interventions include motivational interviewing techniques, explanation of symptoms, reassurance, and regularly scheduled appointments. Specific interventions included cognitive approaches, pharmacotherapy (especially antidepressants), activating therapy (e.g., exercise, creative writing), and complementary and alternative medicine.
- Finally, effective treatment appears to require the strategic use of several of these treatment approaches.

TREATMENT OF ADDICTIONS AND RELATED DISORDERS

Robert Swift

INTRODUCTION

Patients with addictive disorders present a special challenge to clinicians who treat in medical settings. On average, addictive disorders, including smoking, are involved in the cases of more than one-third of patients presenting to general hospitals (Smothers & Yahr, 2005) and in similar numbers of patients in ambulatory settings. In public settings and Veterans Affairs (VA) medical centers, this figure is likely to be higher. Almost a third of all patients treated in emergency departments and about half of severely injured trauma patients screen positive for alcohol problems. The addictive disorder may be etiologically related to presenting medical or surgical problems, and it complicates the medical and surgical treatment of other illnesses.

THE NEUROBIOLOGY OF ADDICTIONS

Current thinking about addictive disorders posits that addiction is a chronic, relapsing condition with a multifactorial etiology that includes genetic, neurobiological, psychological, and environmental components (Koob & Volkow, 2010). In this regard, addictive disorders are similar to other medical illness (e.g., asthma, hyperlipidemia, and type 2 diabetes) and psychiatric illnesses (e.g., bipolar disorder, schizophrenia), for which there are complex genetic, biological, and psychosocial causes for the syndrome and for which the optimal treatment combines both biological and psychosocial treatments (McLellan, Lewis, O'Brien, & Kleber, 2000).

Drugs, alcohol, and compulsive behaviors such as gambling share common neurochemical substrates that produce acutely rewarding effects, relief of distress, and long-term neuroadaptations that can ultimately lead to addiction (Koob & Volkow, 2010). Although it is unclear precisely how these neural systems lead to dependence, it is thought that drugs of abuse and alcohol initially enhance reward mechanisms (Robinson & Berridge, 1993; Wise & Bozarth, 1987). Over time, continued use engenders a state of withdrawal, dysphoria, and distress, called *allostasis* (Koob & Le Moal, 2001) that is relieved only by continued drug and alcohol use. Individuals vary in their sensitivity to drug reward and susceptibility to allostasis; both environmental factors and genetic factors account for this variance, as well as gene by environment interactions.

Drug, alcohol, and behavioral rewards are, in part, mediated through activation of the mesolimbic dopamine pathway. The mesolimbic pathway and related limbic circuits, including the amygdala, hippocampus, and medial prefrontal cortex, are part of the motivational system that regulates responses to natural reinforcers, such as food and beverages, sex, and social interaction (Volkow et al., 2007). Activation of dopamine neurons in the ventral tegmental area of the midbrain increases dopamine release in the nucleus accumbens (also called the ventral striatum) and other areas of the limbic forebrain, such as the amygdala and prefrontal cortex. Dopamine is associated with reward and an increased salience for the stimulus. It is thought that repeated activation of this motivation-reward system sensitizes the system, resulting in increased craving in response to stimuli associated with substance use and compulsion with the development of craving (Nestler, 2001). Some drugs, like cocaine and stimulants, activate the mesolimbic pathway directly. Other drugs, like nicotine, cannabinoids, and alcohol, activate the pathway indirectly. Alcohol, morphine, and addictive behaviors like gambling also enhance endogenous opioid pathways that innervate the ventral tegmental area and the nucleus accumbens, producing a net effect of increasing dopamine release.

Most drug and alcohol dependence is associated with an unpleasant and distressing withdrawal syndrome that appears upon cessation of drug use; avoidance of withdrawal is an important factor in maintaining drug use. The withdrawal from most substances has two phases: an acute, intense withdrawal beginning within hours after the cessation of drug or alcohol use, lasting several days to a few weeks; and a chronic or protracted and more indolent withdrawal that can last from weeks to months. The duration and intensity of acute and chronic withdrawal symptoms depend on the pharmacokinetics and pharmacodynamics of the drug, the amount and duration of drug use, and individual differences in vulnerability to experiencing withdrawal. Withdrawal occurs because of adaptive changes in the nervous system in response to chronic drug or alcohol use. Typically, withdrawal symptoms are behaviorally opposite to the drug effects. Thus, sedative drugs like alcohol or benzodiazepines produce a withdrawal characterized by excitation; stimulant drugs like cocaine or amphetamines produce a withdrawal characterized by lethargy.

Chronic alcohol and drug use also activates the stress response system, resulting in abnormalities in corticotrophin

releasing factor (CRF), neuropeptide Y (NPY), and other neurotransmitters involved in stress response, and inducing a neural state of chronic stress (Koob, 2008). The inability to tolerate this internal stress and/or external stressors can precipitate drug use or compulsive behaviors (Elman et al., 2012). Long after acute withdrawal symptoms have abated, abstinent drug and alcohol dependent individuals continue to experience the protracted, distressing state of allostasis, characterized by increased anxiety, dysphoria, difficulty coping with stress, and just not feeling “right.” Because this allostasis can be relieved by the alcohol or drugs, it is a powerful inducer of relapse.

ADDICTION TREATMENTS ARE EFFECTIVE

A large body of research confirms that treatment for alcohol and drug addiction can be effective, both in reducing consumption of the substance and in reducing the medical, psychological, and social consequences of addiction (National Institute of Drug Abuse [NIDA], 2012). With proper diagnosis, intervention, and treatment, abstinence rates of 50–90% or significant reductions in substance use can be achieved on a long-term basis in recovery from drug and alcohol addiction. Although complete abstinence is the ideal for treatment, reduction in quantity and frequency of substance use can still result in *harm reduction*. Controlled research studies have demonstrated that treatment of addictive disorders is also cost-effective (Holder et al., 1991; Hoffmann et al., 1993; the Substance Abuse and Mental Health Service Administration [SAMHSA], 2009) in terms of reducing subsequent medical and psychiatric treatment utilization. The evidence for the effectiveness and cost effectiveness of addiction treatment has led to laws requiring parity for insurance coverage and equal access to treatment for addictive disorders.

Despite the high prevalence of psychoactive substance use among patients and its demonstrated morbidity and social costs, many clinicians are ill prepared to identify substance dependence and abuse and to treat these conditions. The sources of these deficiencies include poor training in the identification and treatment of substance use and dependence; a lack of knowledge of treatment resources; lack of confidence in treatment efficacy; and negative attitudes toward alcohol and substance abusers as patients (Geller et al., 1989; Holden, 1985; Samet et al., 1996). Effective treatment of substance abuse and dependence requires knowledge about therapies for the acute management of intoxicated patients or patients undergoing withdrawal, and knowledge about options for long-term treatment and rehabilitation. This chapter provides basic information on the etiology of addictive disorders, procedures for screening and diagnosis, and evidence-based treatment of these disorders in medical patients.

CRITERIA FOR THE DIAGNOSIS OF ADDICTION

The description of addictive disorders is complicated by ambiguity in the words used to describe psychoactive substance

use. Words such as *tolerance*, *dependence*, *withdrawal*, *abuse*, and *addiction* are often confused. *Tolerance* is a pharmacological concept describing the need for a larger dose of a drug to achieve the same effect after repeated drug use. *Withdrawal* describes a physiological state that follows cessation or reduction in amount of the drug used. *Dependence* refers to both a condition in which a drug-specific withdrawal state follows cessation or reduction in drug dose (pharmacological dependence) and also to continued drug use despite adverse consequences. *Addiction* describes a repertoire of pathological behaviors that serve to maintain drug use (e.g., compulsive use, loss of control over drug use). The concept of “addictive disorders” is also complicated by basic questions of whether use of psychoactive substances constitutes a medical or a “moral” condition. In addressing these issues, organizations such as the World Health Organization (WHO) and the American Psychiatric Association (APA) consider problem-causing use of psychoactive substances to be a “medical disorder” with defined diagnostic criteria. This definition does not rule out the role of personal responsibility for seeking and complying with treatment, and does not legally excuse patients for crime or damages to others that are a consequence of alcohol and substance use.

The latest published edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) of the American Psychiatric Association (APA, 2013) classifies the acute and chronic effects of psychoactive substances under two major categories: *Substance use disorders* (SUD) and *Substance-induced disorders*. There is now one substance use disorder, which combines the concepts of *Substance dependence and abuse* and describes behavioral symptoms and maladaptive behaviors resulting from the acute or chronic effects of the drug. These include repeated use with negative consequences, in hazardous situations, despite interpersonal issues, for longer or in larger quantities than intended, causing neglect of other important activities, and despite known continuing adverse consequences on health; tolerance, withdrawal syndromes, cravings, unsuccessful desire and/or attempts to cut down drug use; and long periods taken to obtain drugs or recover from the effect.

Fewer than two positive criteria are indicative of no SUD diagnosis. If two to three criteria are positive, this is indicative of a substance use disorder of mild severity. Four or five positive criteria are indicative of and SUD of moderate severity. Six or more positive criteria indicate a severe substance use disorder.

Substance-induced disorders describe the direct effects of the drug on the central nervous system (CNS). These include *Substance intoxication*, *Substance withdrawal*, *Substance-induced psychotic disorder*, *Substance-induced mood disorder*, *Substance-induced anxiety*, *Substance-induced sleep disorder*, *Substance-induced persisting dementia (and amnesic) disorders*, and *Substance-induced sexual dysfunction*.

There have been changes in the classification and criteria for diagnosis of addictive disorders. In DSM 5, the criteria are under the heading “Substance Use and Addictive Disorders.” The change in diagnostic classification to eliminate the “abuse” category and instead to redefine “dependence” as mild, moderate, or severe, brings the DSM-5 more into concordance with the International Classification of Diseases (ICD-10)

classification of the World Health Organization (WHO). The diagnostic criteria for the disorders remain identical, except that “craving” is added as a criterion, “committing illegal acts” is deleted as a criterion, and only two of 11 criteria are required for diagnosis instead of three of 11. Compulsive gambling is included as a non-pharmacological addiction.

Eleven distinct classes of psychoactive substances had been designated by the DSM-IV: alcohol; amphetamine or related substances; caffeine; cannabis; cocaine; hallucinogens; inhalants; opioids; nicotine; phencyclidine or related substances; sedatives, hypnotics, or anxiolytics. Each class is associated with both a primarily neurophysiological (organic) mental disorder and a substance use disorder. Under the category of *Substance use disorders*, ten of these classes (all but nicotine) are associated with abuse and dependence; dependence only is defined for nicotine. *Polysubstance dependence* is defined using three or more categories of substances. A category for *Other substance use disorders* includes use of anabolic steroids, nitrate inhalants, anticholinergic agents, and other psychoactive substances.

EVALUATING SUBSTANCE USE IN PATIENTS

Although some patients present with an addictive disorder or its sequelae as a chief complaint, many patients present with other medical or surgical problems and only later reveal an addictive disorder through physical or laboratory findings, or incidental discovery. Patients as well as their family members are reluctant to report the extent of their drug and alcohol use to physicians or other healthcare providers due to denial, guilt, and shame. Patients experiencing an altered mental status due to intoxication or withdrawal may be cognitively incapable of providing an accurate history. In situations where a patient is unable to give a history of substance use, it is important to obtain additional history from family or acquaintances of the patient. Such information should be obtained with the patient's knowledge and consent, if possible, but under emergency conditions this may not be possible. It is also important to examine pill bottles or other medications in the patient's possession.

The primary task of the physician or consulting psychiatrist evaluating a patient for problem substance use or addiction is to establish an effective therapeutic relationship with the patient. In the context of this relationship, the clinician should conduct a detailed alcohol and drug history, conduct a physical and mental status examination, order and interpret necessary laboratory tests, and call or meet with family or significant others to obtain additional information and promptly involve them in evaluation and treatment. While obtaining information about the patient's alcohol and drug use, most clinicians routinely ask “quantity” and “frequency” questions about psychoactive substances, such as “how much?” and “how often?” A more effective interview method focuses on whether the patient has experienced negative consequences from use of psychoactive substances, has poor control of use, or has received criticism from others

about the substance use. The description of personal, social, familial, occupational, and physical consequences of alcohol and substance use is usually more useful for diagnosis than reporting the actual amount consumed—which may be under-reported. Several practical, efficient, well-validated, formalized interviews have been developed that discriminate problem alcohol use using these criteria. Two of the most reliable and commonly used screens, with sensitivity of 90–98%, are the ten-question Alcohol Use Disorders Identification Test (AUDIT) (see Box 38.1) and the 25-item *Michigan Alcohol Screening Test* (MAST). Both of these scales identify abnormal drinking through the amount and frequency of alcohol use and its social and behavioral consequences (Selzer, 1971; Saunders et al., 1993). Shortened versions of these tests, the three-item AUDIT-C and the ten-item Brief MAST have similar efficacy. Because of its brevity and high sensitivity in identifying alcohol problems, the AUDIT-C is used by several large healthcare systems, including the Department of Veterans Affairs (VA) to screen all primary care patients. Another widely used, simple, and highly sensitive test is the CAGE questionnaire (Ewing, 1984). This four-item test uses the letters *C, A, G, E* as a mnemonic for the questions about alcohol use (Box 38.4). An affirmative answer on more than one question is considered suspicious for alcohol abuse. A discussion of several alcoholism screens and their use in specialized medical populations can be found at the following reference (National Institute Alcohol Abuse and Alcoholism [NIAAA], 2005).

Although less documentation exists regarding the optimal interview for the assessment of the drug-abusing patient, the same considerations apply: it is more effective to ask about the behavioral consequences of drug abuse from the patient, family, and significant others than to ask questions about quantity and frequency of use. Other red flags in the patient history that should increase suspicion about psychoactive substance use include divorce, problems at work (frequent job changes, chronic tardiness, absenteeism, work-related injuries), injuries (falls, auto accidents, fights), arrests, driving while intoxicated, leisure activities involving drugs or alcohol, financial problems, and the usual physical stigmata such as unusually ruddy face and nose, spider angioma, “beer gut,” estrogenic effects in men, hepatomegaly, evidence of head trauma, malnutrition, cerebellar signs, cognitive deficits, Wernicke's syndrome, and testicular atrophy. Having an alcohol- or drug-abusing biological parent or spouse or a concomitant psychiatric disorder increases the risk for problem substance use significantly.

THE PHYSICAL EXAMINATION

As noted above, the physical examination of the patient provides important information about the presence of substance abuse and its medical complications. Signs of repeated trauma, especially to the head, strongly suggest substance abuse (Skinner et al., 1984). Other physical stigmata of addictive disorders include track marks of intravenous drug abuse, a necrotic nasal septum from cocaine abuse, peripheral

The Alcohol Use Disorders Identification Test: Interview Version

Read questions as written. Record answers carefully. Begin the AUDIT by saying “Now I am going to ask you some questions about your use of alcoholic beverages during this past year.” Explain what is meant by “alcoholic beverages” by using local examples of beer, wine, vodka, etc. Code answers in terms of “standard drinks”. Place the correct answer number in the box at the right.

<p>1. How often do you have a drink containing alcohol?</p> <p>(0) Never [Skip to Qs 9-10] (1) Monthly or less (2) 2 to 4 times a month (3) 2 to 3 times a week (4) 4 or more times a week</p> <div style="text-align: right;"><input type="text"/></div>	<p>6. How often during the last year have you needed a first drink in the morning to get yourself going after a heavy drinking session?</p> <p>(0) Never (1) Less than monthly (2) Monthly (3) Weekly (4) Daily or almost daily</p> <div style="text-align: right;"><input type="text"/></div>
<p>2. How many drinks containing alcohol do you have on a typical day when you are drinking?</p> <p>(0) 1 or 2 (1) 3 or 4 (2) 5 or 6 (3) 7, 8, or 9 (4) 10 or more</p> <div style="text-align: right;"><input type="text"/></div>	<p>7. How often during the last year have you had a feeling of guilt or remorse after drinking?</p> <p>(0) Never (1) Less than monthly (2) Monthly (3) Weekly (4) Daily or almost daily</p> <div style="text-align: right;"><input type="text"/></div>
<p>3. How often do you have six or more drinks on one occasion?</p> <p>(0) Never (1) Less than monthly (2) Monthly (3) Weekly (4) Daily or almost daily</p> <p><i>Skip to Questions 9 and 10 if Total Score for Questions 2 and 3 = 0</i></p> <div style="text-align: right;"><input type="text"/></div>	<p>8. How often during the last year have you been unable to remember what happened the night before because you had been drinking?</p> <p>(0) Never (1) Less than monthly (2) Monthly (3) Weekly (4) Daily or almost daily</p> <div style="text-align: right;"><input type="text"/></div>
<p>4. How often during the last year have you found that you were not able to stop drinking once you had started?</p> <p>(0) Never (1) Less than monthly (2) Monthly (3) Weekly (4) Daily or almost daily</p> <div style="text-align: right;"><input type="text"/></div>	<p>9. Have you or someone else been injured as a result of your drinking?</p> <p>(0) No (2) Yes, but not in the last year (4) Yes, during the last year</p> <div style="text-align: right;"><input type="text"/></div>
<p>5. How often during the last year have you failed to do what was normally expected from you because of drinking?</p> <p>(0) Never (1) Less than monthly (2) Monthly (3) Weekly (4) Daily or almost daily</p> <div style="text-align: right;"><input type="text"/></div>	<p>10. Has a relative or friend or a doctor or another health worker been concerned about your drinking or suggested you cut down?</p> <p>(0) No (2) Yes, but not in the last year (4) Yes, during the last year</p> <div style="text-align: right;"><input type="text"/></div>
<p style="text-align: right;">Record total of specific items here <input type="text"/></p> <p><i>If total is greater than recommended cut-off, consult User's Manual.</i></p>	

The AUDIT can detect alcohol problems experienced in the last year. A total score of 8 or more on the AUDIT generally indicates harmful or hazardous drinking and requires further evaluation. Questions 1–8 = 0, 1, 2, 3, or 4 points. Questions 9 and 10 are scored 0, 2, or 4 only.

The AUDIT-C (Alcohol Use Disorders Identification Test—Consumption) consists of the first three questions of the audit only. The Audit-C is scored on a scale of 0 to 12 (a score of 0 reflects no alcohol use). A score of 3 or more in older adults is considered positive and suggests the need for further evaluation.

Box 38.2 THE C-A-G-E INTERVIEW

Have you ever felt the need to Cut down on drinking?
Have you ever felt Annoyed by criticisms of drinking?
Have you ever had Guilty feelings about drinking?
Have you ever taken a morning Eye opener?

neuropathy from solvent inhalation, signs of liver disease from alcoholism and needle-acquired hepatitis B or hepatitis C, and signs and symptoms of acquired immunodeficiency syndrome (AIDS) or HIV-related illnesses (Stein, 1990). Wernicke's syndrome, also known as Wernicke's encephalopathy, consists of evidence of sixth nerve palsy, ataxia, nystagmus, language dysfunction, and confusion. Wernicke's syndrome frequently coexists with Korsakoff syndrome, and is a substance-induced persisting amnestic disorder characterized by anterograde amnesia, confabulation, and other cognitive deficits.

MENTAL STATUS EXAMINATION

Each patient should receive a mental status examination to assess them for cognitive, neurological, or psychiatric impairments. Psychiatric disorders such as mood disorders, anxiety disorders, and personality disorders commonly coexist with alcohol and substance use (Grant et al., 2004; Regier et al., 1990). Cognitive mental status testing should be particularly detailed, because alcohol and drug abusers may have significant deficits in memory, concentration, and abstract reasoning, yet at the same time pass simple bedside tests of orientation, calculation, and immediate memory. The Mini-Mental Status Examination (MMSE) is useful for basic initial bedside testing (Crum et al., 1993). Formal neuropsychological testing is useful for detecting subtle deficits in attention, cognition, and performance and can better identify the type and localization of cerebral dysfunction (Berg, Franzen, & Wedding, 1987). Its expense limits its practical utility, and the expense involved must be justified by the value of the clinical information to be derived from the results.

LABORATORY SCREENING

Abnormal results on laboratory testing provide an important adjunct for confirming the diagnosis of substance abuse, but are not entirely reliable or specific. Few tests can

Each of the following ten items is evaluated, scored on a 0 to 7 scale, where 0 is normal and 7 is severe, and the item scores are totaled. A total score of 10 or greater is indicative of mild withdrawal, greater than 24 is indicative of a moderate to severe withdrawal state.

1. **Nausea and vomiting.** Ask “Do you feel sick to your stomach? Have you vomited?” Observation.
2. **Tremor,** arms extended and fingers spread apart. Observation.
3. **Paroxysmal sweats.** Observation.
4. **Anxiety.** Ask “Do you feel nervous?” Observation.
5. **Agitation.** Observation.
6. **Tactile disturbances.** Ask “Have you any itching, pins-and-needles sensations, burning, numbness, or do you feel ‘bugs’ crawling on or under your skin?” Observation.
7. **Auditory disturbances.** Ask “Are you more aware of sounds around you? Are they harsh? Do they frighten you? Are you hearing anything that is disturbing to you? Are you hearing things you know are not there?” Observation.
8. **Visual disturbances.** Ask “Does the light appear to be too bright? Is its color different? Does it hurt your eyes? Are you seeing anything that is disturbing to you? Are you seeing things you know are not there?” Observation.
9. **Headache,** fullness in head. Ask “Does your head feel different? Does it feel like there is a band around your head?” Do not rate for dizziness or lightheadedness. Otherwise, rate severity
10. **Orientation** and clouding of sensorium.

(Sullivan et al., 1989)

determine how much of a substance was used and exactly when the usage occurred (Miller et al., 1990). In heavy users of alcohol, laboratory tests such as mean corpuscular volume (MCV), and liver function tests such as aspartate aminotransferase (AST) and gamma glutamyl transferase (GGT) may be abnormal in a high percentage of patients. Elevated GGT levels are as sensitive as screening questionnaires, such as the CAGE, in detecting heavy alcohol use (Litten et al., 1995; Beresford et al., 1990). However, medical illnesses, such as liver disease and nutritional deficiencies, may produce similar abnormal results. Several other biochemical tests have been proposed to “detect” or at least raise suspicion for alcohol use, including carbohydrate-deficient glycoproteins (especially transferrin), high-density lipoprotein (HDL) cholesterol, fatty acid ethyl-esters, and ethyl glucuronide (Salaspuro, 1995; Takase et al., 1985). The carbohydrate-deficient transferrin (CDT) test is based on

the observation that alcohol inhibits the addition of sialic acid to glycoproteins, such as serum transferrin. Percent CDT has been found to be effective in discriminating heavy drinking (Litten et al., 1995). Ethylglucuronide, present in the urine, is formed by the condensation of glucuronic acid and ethanol. Because it persists in the body substantially longer than alcohol, it can detect even moderate drinking up to 72 hours after alcohol consumption. Fatty acid ethyl esters are condensations between fatty acids and ethanol. They are extremely long lasting and can be measured in hair samples, meconium, or other body tissues.

TOXICOLOGICAL SCREENING

Serum and urine toxicology screens have an important role in the assessment and treatment of patients with substance use disorders. Advances in testing technology have made drug testing widely available and reduced the per sample costs of testing. However, it is important that such testing be properly conducted and that the results be interpreted with great expertise. As with all laboratory tests, both false-positive and false-negative results may be obtained; and the test result may be affected by methods of sample collection and the accuracy of the laboratory (Hansen, Caudhill, & Boone, 1985). Most initial drug testing uses immunoassay methods to detect drugs or their metabolites in a body fluid, most commonly urine. Tests for five to ten different drugs are typically combined in a "panel." To minimize collection errors, samples should be obtained under direct but discreet observation. Optimally, informed consent should be obtained for all drug testing. Sometimes such screening is required by court order. Samples of both serum and urine should be obtained, as substances may be differentially distributed in body fluids. When drug testing is legally mandated, positive results must be confirmed by an alternate method, and for negative tests, validity verification testing must be conducted to identify possible tampering. For example, use of sympathomimetic agents to treat asthma may yield a positive urine test for amphetamines. A positive test suggests past use of a psychoactive substance but may not indicate the extent of the use, when it occurred, or whether there was behavioral impairment because of the use. The analysis of drugs in hair clippings can be used to detect substance use over long time periods, but this has little applicability to the immediate clinical situation. Details of laboratory testing in drug users and in psychiatric patients are discussed in several published reviews (Hawks & Chiang, 1986; Schwartz, 1988; Swift, Griffiths, & Camara, 1991).

THE TREATMENT OF ADDICTIVE DISORDERS

GENERAL CONSIDERATIONS

Addiction treatment may be defined as "medical, psychological, and social interventions to reduce or eliminate the harmful effects of psychoactive substances (drugs and alcohol) on

the individual, and on others in society." Treatment usually consists of several components:

Intervention: Initiation of treatment and/or referral

Detoxification: Removal of alcohol or drug from the body and the treatment of withdrawal

Rehabilitation: Medical, psychological, and social measures to help the person avoid the use of psychoactive substances in the future

Aftercare: Processes to assist them in maintaining a sober or drug-free state.

Treatment ranges from very low-cost, less intensive methods (e.g., brief advice to stop drinking or drug use and self-help programs such as Alcoholics Anonymous), to higher cost, more intensive methods (e.g., inpatient detoxification and residential rehabilitation programs) (Holder et al., 1991). Different treatment settings may have different philosophical orientations, ranging from the medical and biological to the spiritual and religious. Intervention includes the ability to identify patients with alcohol and drug disorders, to stratify patients diagnostically, and to triage patients to the most appropriate treatment level, such as brief initial interventions, counseling, and outpatient versus hospital detoxification. The treatment plan should be practical, economical, and based on well-established scientific principles. The American Society of Addiction Medicine (ASAM) has developed guidelines that match the severity of the addiction to the intensity of the treatment (ASAM, 2001). For patients with moderate to severe addictions, the goals of treatment usually include detoxification and the establishment of a drug- or alcohol-free state. If total abstinence is not realistically obtainable, a significant reduction in harmful drug or alcohol use may be of some benefit as a start toward achieving total abstinence. For patients with problem use without addiction, the goal should be a reduction in harmful drug or alcohol use and the associated pathological behaviors. The objectives of detoxification include: (1) establishment of a drug- or alcohol-free state, (2) relief of distress and discomfort due to intoxication or withdrawal, (3) stabilization of comorbid medical conditions, and (4) preparation and education for and referral to aftercare treatment or rehabilitation (Kosten & O'Connor, 2003). The objectives for longer-term treatment or rehabilitation are depicted in Box 38.5 and include: (1) maintenance of the alcohol- or drug-free state, and (2) psychological, family, and vocational interventions to ensure compliance. Dramatic changes in living situation, work situation, or friendships may be necessary to decrease drug availability and to reduce peer pressure to use drugs. Halfway houses, therapeutic communities, and other residential treatment situations are useful in this regard. Ongoing, sometimes lifelong, individual and group psychotherapy can be useful for understanding the role of the drug in the individual's life, to stabilize the family system, to improve their self-esteem, to provide alternative methods of relieving psychosocial distress, and

to reinforce the need for abstinence. Treatment of underlying psychiatric or medical illness may markedly reduce the psychiatric and physical morbidity and mortality associated with illicit drugs and abuse of alcohol (e.g., anxiety, depression, accidents, burns). Self-help groups, such as Alcoholics Anonymous (AA), Narcotics Anonymous (NA), Rational Recovery (RR), Secular Organization for Sobriety, and Al-Anon (for family members) provide treatment, education, emotional support, and hope to substance users and their families (Emrick, 1987).

Many patients presenting for treatment are part of a dysfunctional family. Sometimes the family dysfunction and substance or alcohol use are multigenerational and due to genetic and/or sociocultural factors. It is important for the clinician to be aware of dysfunctional family dynamics and any substance abuse, denial, defensiveness, and hostility present in family members. Family members need education, emotional and social support, and empathic confrontation of their possible role in maintaining denial and rescuing and facilitating the problem drinker or addict, a behavior pattern referred to as "co-dependency." Organizations such as Al-Anon and Alateen also may provide meaningful education and support for spouses and family members. It is important to involve the family in the patient's treatment as much as possible, and to recommend treatment for other family members, when appropriate.

Currently, the mainstay of addiction treatment in the United States has been psychosocial treatment. In spite of the evidence for a biological etiology of addictive disorders, clinicians and patients have been slow to adopt biologically based treatments. Some of the reasons for the reluctance to use evidence-based pharmacotherapies as adjunctive treatments include clinicians' lack of knowledge about the neurobiology of addiction, lack of knowledge about the effectiveness of medications, the increased cost of adding medications to treatment, and a paucity of prescribers (Thomas et al., 2003). Moreover, some clinicians and patients are uncomfortable in treating a drug problem with another drug. However, the evidence for the effectiveness of adjunctive pharmacotherapy in addiction treatment, along with the increased number of agents available, is gradually increasing the use of adjunctive medications by clinicians and their patients.

ALCOHOL

Alcohol dependence (AD) afflicts more than 12% of the U.S. population over the course of their lifetime, and causes serious morbidity and mortality, increased health-care costs, and lost productivity (Hasin et al., 2007). *Alcoholism* is defined as a "repetitive, but inconsistent and sometimes unpredictable loss of control of drinking which produces symptoms of serious dysfunction or disability" (Clark, 1981). Alcohol-related problems were found in approximately 40% of U.S. general hospital admissions; and of those positive for alcohol problems, only 24% were referred to treatment (Smothers et al., 2004). In an

American Medical Association (AMA)–sponsored poll of physicians, 71% felt they were either not competent enough or were too ambivalent to treat alcoholic patients correctly (Kennedy, 1985).

In the past decade, several methods have been developed to help general medical physicians and surgeons successfully identify and intervene with alcoholic patients (Samet et al., 1996). "The Physician's Guide to Helping Patients with Alcohol Problems," published by the National Institute on Alcohol Abuse and Alcoholism (NIAAA), presents several useful brief intervention methods (NIAAA, 1995). NIAAA defines "at risk" drinking (that is, at risk for adverse consequences) as more than 14 drinks per week or four drinks per occasion for men, and more than seven drinks per week or three drinks per occasion for women.

Brief interventions can consist of one or more sessions in the physician's office, during which education about substance use and dependence is provided and a plan for cutting down or eliminating substance use is negotiated. The patient and physician together should develop a contract, preferably written, defining the treatment and intervention plan. A formal means of assessment of effectiveness and follow-up should be part of the plan. Motivational interviewing, a technique that identifies and motivates patients to utilize their own treatment resources, is effective in engaging patients in treatment and reducing use of addictive substances (Miller & Rollnick, 1991; Miller, Benefield, & Tonigan, 1993). Meta-analyses of multiple studies of brief interventions in primary care settings found modest, but significant reductions in drinking (Bertholet et al., 2005; Moyer et al., 2002).

TREATMENT OF ALCOHOL INTOXICATION AND WITHDRAWAL

The treatment of alcohol intoxication consists of supporting vital physiological functions, maintaining metabolic homeostasis, and preventing behavioral problems. Patients using alcohol should *always* be medicated with thiamine and other B-vitamin supplements before being fed or receiving glucose to prevent the development of "Wernicke-Korsakoff syndrome," to use the classic terminology for the disorder. This frequently underdiagnosed condition is characterized by ocular disturbances (nystagmus and sixth nerve ophthalmoplegia), ataxia, and mental status changes, although many patients will not have the full triad of signs at any one time. The etiology is thiamine deficiency. Its presence should be considered a medical emergency, as delay in treatment diminishes chances of its reversibility. Because alcoholics may not absorb oral thiamine from the gastrointestinal (GI) tract, patients should receive high oral thiamine doses of 300–500 mg daily or receive 50–100 mg intramuscular thiamine daily for three days to ensure proper dosing (Thomson, 2000). In patients with florid neurological symptoms or signs, saving minutes may be critical, and thiamine should be administered intravenously at 100 mg three times per day. Magnesium and other electrolyte levels should be obtained and deficits corrected. Low magnesium

and abnormal electrolytes may intensify withdrawal and predispose to seizures (Mennecier et al., 2008).

Physical dependence on alcohol and the alcohol withdrawal syndrome are due to compensatory central nervous system (CNS) changes in response to a chronically administered depressant substance (ethanol). The withdrawal syndrome results from increased rebound neuronal activity in the central and peripheral nervous systems following the cessation of chronic alcohol intake. The acute actions of alcohol include facilitation of inhibitory GABAergic neurotransmission and inhibition of excitatory glutamate neurotransmission. (Hunt, 1983) With repeated and chronic alcohol administration, the brain adapts to downregulate the inhibitory gamma aminobutyric acid (GABA) receptors and upregulate the excitatory glutamate receptors, producing an excitatory state that balances the sedative effects of alcohol (Tsai, et al., 1995). When the alcohol-dependent person stops drinking abruptly, the sedative alcohol is no longer present and the person experiences a state of generalized CNS excitation, typically anxiety, tremors, insomnia, and in severe cases, seizures and hallucinations (*delirium tremens*, or DTs) (Swift, 1999). It has been suggested that withdrawal symptoms intensify and become more protracted as withdrawal episodes grow in number, a phenomenon called “kindling” (Heilig et al., 2010). Although most individuals experience mild anxiety, tremulousness, and insomnia, approximately 5–10% of alcohol-dependent individuals undergoing detoxification will develop complicated withdrawal characterized by alcohol withdrawal DTs or withdrawal seizures (Mennecier et al., 2008). Predictors of withdrawal delirium include structural brain lesions, hypokalemia, and thrombocytopenia; predictors of a withdrawal seizure are a previous seizure or structural brain lesion (Eyer et al., 2011). Alcohol-dependent patients are also at risk for other serious medical complications, including pneumonia and other infections, myocardial infarction, cardiac arrhythmias, electrolyte disturbances, and serious physiological derangements, including hypertension, tachycardia, tremors, agitation, and insomnia (McIntosh, 1982). The basic physiological mechanisms of delirium are discussed in Chapter 41.

The clinician should be aware that signs and symptoms of withdrawal can obscure an underlying illness. For example, fever and change in mental status associated with withdrawal may coexist with pneumonia, head injury, or an infection of the CNS, and require neuroimaging and/or lumbar puncture for diagnosis. Treatment of the alcohol withdrawal syndrome includes correction of physiological abnormalities, hydration, nutritional support, and pharmacological therapy for the increased activity of the nervous system (Sellers & Kalant, 1976). The American Society of Addiction Medicine has developed formal guidelines for management of alcohol withdrawal (Mayo-Smith, 1997; Mee-Lee, 2001).

PHARMACOLOGICAL TREATMENT OF ALCOHOL WITHDRAWAL

It has long been known that re-administration of CNS-depressant substances markedly attenuates the signs

and symptoms of withdrawal and greatly decreases medical morbidity and mortality. Historically, many pharmacological agents have been used to reduce the signs and symptoms of the withdrawal syndrome, including: chloral derivatives (e.g., chloral hydrate), paraldehyde, barbiturates, antihistamines, neuroleptics, antidepressants, beta-adrenergic blocking agents, and benzodiazepines (Golbert et al., 1967; Palestine & Alatorre, 1976; Sellers et al., 1980). Indeed, almost any CNS-depressant substance may be effective (Liskow & Goodwin, 1987; Litten & Allen, 1991).

Benzodiazepines

Benzodiazepine derivatives are the treatment of choice for alcohol withdrawal (Table 38.1), and their efficacy is well established by double-blind controlled studies (Ozdemir et al., 1994). Benzodiazepines bind to a distinct binding site on the GABA receptor-chloride ion channel complex and facilitate the inhibitory action of GABA on neurons (Johnston, 1996). Benzodiazepines are superior to other agents because of their low toxicity and anticonvulsant effects. Benzodiazepine use is optimal when the dose is titrated according to a withdrawal severity scale such as the Clinical Institute Withdrawal Assessment of Alcohol revised (CIWA-Ar) Scale (Sullivan et al., 1989; Saitz et al., 1994), reproduced in Box 38.4. Several methods have been described for titrating medication dosage to symptoms. The “symptom-triggered method” appears to have utility in many patients (Sellers et al., 1983). Its advantages include the avoidance of both under-medication and over-medication. Long half-life benzodiazepines (e.g., 10 mg diazepam intravenous [IV] or orally [PO], or 50–100 mg chlordiazepoxide PO) or short half-life benzodiazepines (e.g., lorazepam 1.0 mg PO, IV, or intramuscular [IM], or oxazepam 30 mg PO), are dosed every hour until the patient is sedated, develops nystagmus, or has a significant decrease in withdrawal signs and symptoms as shown by a withdrawal scale score, such as a CIWA-Ar score of less than 8. Those treated with long half-life medication may require no additional medication for their detoxification. Those receiving shorter half-life benzodiazepines will require continued dosing for three to five days. Withdrawal signs and symptoms of most patients treated with effective doses of sedatives are reduced within several hours. Occasionally, patients do require additional doses of medication after several days, to suppress re-emergent symptoms. During the period of benzodiazepine treatment, patients must be closely observed to avoid under-medication or over-medication. Patients with respiratory disease, cardiovascular disease, or hepatic disease must be monitored closely, and short half-life benzodiazepines that are glucuronidated (lorazepam or oxazepam) are preferred (D’Onofrio et al., 1999).

Two other medications used to treat alcohol withdrawal include barbiturates and clomethiazole. Barbiturates, like benzodiazepines, potentiate the action of GABA at the GABA-receptor chloride channel complex. However, barbiturates differ from benzodiazepines in binding to a different site and more strongly potentiating the effects of GABA. This

Table 38.1 PHARMACOLOGICAL THERAPIES FOR ALCOHOL WITHDRAWAL AND PREVENTION OF RELAPSE

TREATMENT PHASE AND DRUG CLASS	EXAMPLES	EFFECTS
ALCOHOL WITHDRAWAL:		
Benzodiazepines	Chlordiazepoxide* Diazepam* Oxazepam* Lorazepam and others†	Decreased severity of withdrawal; stabilization of vital signs; prevention of seizures and delirium tremens (alcohol withdrawal delirium)
Beta-blockers	Atenolol Propranolol	Improvement in vital signs; reduction in craving Propranolol has more CNS penetration due to lipophilicity
Alpha-agonists	Clonidine	Decreased withdrawal symptoms
Anti-epileptics	Carbamazepine	Decreased severity of withdrawal; prevention of seizures (may cause ataxia, hyponatremia, or elevate liver function tests [LFTs]).
PREVENTION OF RELAPSE:		
Alcohol sensitizers	Disulfiram*	Decreased alcohol use among those who relapse Associated with severe toxicity when alcohol ingested
Opioid antagonists	Naltrexone*	Increased abstinence, decreased no. of drinking days
Homotaurine derivatives	Acamprosate*	Increased abstinence
Anti-epileptics	Topiramate	Decreased drinking

*The drug has a Food and Drug Administration–approved indication for this use in the United States.

Adapted from O'Connor, P. G., & Shottenfeld, R. S. (1998). Patients with alcohol problems. *New England Journal of Medicine*, 338(9), 597.

increased potency of barbiturates increases their sedation and narrows the therapeutic window between effectiveness in suppressing alcohol withdrawal symptoms and toxicity. Nevertheless, long half-life barbiturates like phenobarbital are sometimes used to treat alcohol withdrawal and are preferred by some clinicians to treat more complicated, severe withdrawal (Mayo-Smith et al., 2004). Clomethiazole is a sedative and anticonvulsant medication used in Europe for the treatment of alcohol withdrawal. Clomethiazole potentiates GABA by acting as a positive allosteric modulator at the barbiturate-binding site at the GABA-receptor chloride channel complex.

Other Agents Used for Alcohol Withdrawal

Several other non-benzodiazepine GABA-ergic compounds have been used off-label and in research studies to treat alcohol withdrawal and have been found to be effective. These include: baclofen, a GABA-B receptor agonist; and the anti-epileptic medications carbamazepine, gabapentin, pregabalin, tiagabine, topiramate, and valproic acid (Leggio et al., 2008). Beta-adrenergic blocking drugs such as propranolol and atenolol have been exclusively used as primary agents in the treatment of alcohol withdrawal (Sellers & Kalant, 1976). However, beta-blockers are most effective in reduction of peripheral autonomic signs of

withdrawal, and less so for central nervous system signs such as withdrawal delirium or seizures. Beta-blockers are particularly useful for controlling tachycardia and hypertension for patients with coronary artery disease. These agents should be considered as adjuncts in withdrawal regimens and usually are not needed if benzodiazepines are used in adequate doses.

Since most medications used to treat alcohol withdrawal are anti-epileptic, single seizures may be managed with an increase in medication and do not require another anti-epileptic medication. For patients with multiple seizures during withdrawal, or with a chronic seizure disorder, the addition of an anti-epileptic medication such as phenytoin may be indicated. Given that many alcoholics are noncompliant with treatment, the erratic use of anti-epileptics on an outpatient basis may actually worsen a seizure problem (Hillbom & Hjelm-Jager, 1984). Neuroleptics, such as risperidone or quetiapine, are specifically indicated for the treatment of hallucinosis and paranoid symptoms, but are not primary agents for withdrawal.

NONPHARMACOLOGICAL TREATMENT METHODS

Recently, the widespread use of pharmacological agents in the detoxification from alcohol has been called into question.

Some alcohol-treatment facilities provide “social setting detoxification,” a non-drug method. This procedure relies on the extensive use of peer and group support and usually occurs in non-medical settings. This method seems effective in reducing withdrawal signs and symptoms, without an increased incidence of medical complications. Yet Shaw et al. (1981) claimed that even within a medical setting, most patients respond to “supportive care” and do not require pharmacological intervention. In a double-blind study comparing parenteral diazepam treatment with placebo, over half the patients receiving a placebo injection responded with a marked attenuation of withdrawal symptoms within five hours (Sellers et al., 1983).

In summary, although some alcohol-dependent individuals may be detoxified without the use of sedatives or other psychotropic drugs, medication-assisted detoxification smooths the withdrawal symptoms, causes less distress to patients, decreases the chances of seizures and hallucinations, and is a more humane approach.

OUTPATIENT VERSUS INPATIENT ALCOHOL DETOXIFICATION

Successful alcohol detoxification can be performed in day-treatment and outpatient settings at lower cost and with less disruption to the patient and family than hospital-based treatment (Abbott et al., 1995). Patients should be observed on a daily basis, and medications for withdrawal prescribed in small amounts, according to the severity of withdrawal signs and symptoms. Whitfield et al. (1978) reported large numbers of patients who were successfully detoxified from alcohol in an outpatient setting without the use of psychotropic drugs, although high-risk patients were excluded from this study.

Although few data exist for clinicians to predict which alcohol-dependent patients are candidates for outpatient detoxification, those with a stable living situation, history of mild withdrawal, and lack of medical and psychiatric problems are likely to be the best candidates. A history of DTs or seizures, the presence of medical disorders (such as diabetes, trauma, or pain), or surgical or psychiatric disorders increases the need for closer medical supervision and indicates that detoxification should be performed in an inpatient setting.

During and after detoxification, many alcoholic patients will appear to suffer from major depression and anxiety disorders. Some of these mood disorders are directly related to alcohol and will gradually resolve within two to four weeks after detoxification. Major depressive symptoms persisting beyond this time should be considered for treatment with antidepressants or electroconvulsive therapy (ECT). Patients previously known to have recurrent mood disorders should be treated immediately after detoxification if mood symptoms are severe. Non-dependence-producing anxiolytics such as buspirone or selective serotonin-reuptake inhibitor (SSRI) antidepressants may be excellent anxiolytics for patients with persistent anxiety disorders.

REHABILITATION AND AFTERCARE

The goals of rehabilitation and aftercare include maintaining a state of abstinence from alcohol and establishing psychological, family, and social interventions that serve to maintain this recovery. These goals may be best achieved through the patient’s participation in a comprehensive treatment program, beginning after discharge from the acute-care setting. Nevertheless, there are aspects of the long-term treatment that should be initiated during an acute hospital stay.

There are several effective, evidence-based behavioral treatments for alcohol dependence. These include motivational interviewing (MI), cognitive-behavioral therapy (CBT), Twelve Step (AA) facilitation, supportive counseling, marital/family therapy, community reinforcement, and case-management (Miller et al., 2003). Patients with a history of recurrent relapses or who are homeless may benefit from residential treatment in a sober setting. Self-help organizations such as Alcoholics Anonymous (AA) or Rational Recovery (RR) are independent groups composed of alcoholics at various stages of recovery that help individuals maintain total abstinence from alcohol and other addictive substances through group and individual interactions. Self-help programs benefit many patients, but there is a paucity of objective outcome data on the actual long-term efficacy of such groups (Emrick, 1974, 1987). Most detoxification and rehabilitation programs encourage liberal attendance at self-help meetings. General hospitals often are used as meeting sites by local AA groups, and medical and surgical inpatients may easily attend these meetings.

MEDICATIONS TO REDUCE ALCOHOL CONSUMPTION

Four medications are currently approved for the treatment of alcohol dependence in the United States: disulfiram, oral naltrexone, extended-release (injectable) naltrexone, and acamprosate. Several other medications, including topiramate, are used off-label, or are only approved abroad. Federal agencies, including the National Institute on Alcohol Abuse and Alcoholism (NIAAA) and the Center for Substance Abuse Treatment (CSAT), recommend consideration of the approved pharmacotherapies in the treatment of all patients (NIAAA, 2007; CSAT, 2009). Unfortunately, there have been few comparative effectiveness studies of the several approved medications to match patients with the optimal medication.

DISULFIRAM

Disulfiram (e.g., Antabuse) is an inhibitor of the enzyme acetaldehyde dehydrogenase, and is used as an adjunctive treatment in selected alcoholics. If alcohol is consumed in the presence of disulfiram, the toxic metabolite acetaldehyde accumulates, producing tachycardia, flushing of skin, dyspnea, nausea, and vomiting. This unpleasant reaction provides

a powerful deterrent to the consumption of alcohol (Chick et al., 1992, Brewer, 1993). Disulfiram is most effective when its administration is supervised by medical personnel or by a partner or significant other (Krampe & Ehrenreich, 2010). Patients started on disulfiram must be informed about the dangers of even small amounts of alcohol. Alcohol present in foods, cosmetics, mouthwashes, and over-the-counter medications may produce a disulfiram reaction. A usual dose of disulfiram is 250–500 mg, once daily. Disulfiram may interact with other medications, notably anticoagulants and phenytoin. It is contraindicated for patients with liver disease and psychosis.

ORAL NALTREXONE

Controlled clinical trials with the opioid-antagonist naltrexone show effects on reducing alcohol consumption in alcohol-dependent patients. Two different systemic reviews of literature and meta-analyses of published randomized, controlled clinical trials assessing oral naltrexone in alcohol dependence, found that naltrexone reduced the relapse rate to heavy drinking significantly, but with a small effect size. There was a non-significant trend in reduction of the abstinence rate (Bouza et al., 2004; Srisurapanont & Jarusuraisin, 2005). The large American multisite COMBINE Study, involving 1,380 alcohol-dependent patients, found naltrexone, compared to placebo, to produce small but significant reductions in relapses to heavy drinking in patients receiving a medically oriented behavioral intervention (Anton et al., 2006).

Naltrexone is believed to reduce alcohol consumption by reducing the pleasurable and positive reinforcing properties of alcohol. Both social drinkers and alcoholics receiving naltrexone and alcohol report less positive reinforcement and more intensely sedative effects of alcohol. Naltrexone also reduces craving for alcohol in response to alcohol cues. Predictors of a positive response to naltrexone include a high level of craving, a positive family history of alcoholism (Rubio et al., 2005), and possessing a specific genetic polymorphism (Asn40Asp) in the μ opioid receptor gene (Oslin et al., 2003).

The usual oral naltrexone dose is 50 mg per day, although doses of 25–100 mg per day have been reported to be effective. Naltrexone should be used only in the context of a comprehensive alcoholism-treatment program, which includes counseling and other psychosocial therapies (O'Malley, 1992). The most common side effects include anxiety, sedation, and nausea, in approximately 10% of patients. High doses of naltrexone (300 mg per day) have been associated with hepatotoxicity; however, hepatic toxicity is rarely observed at a 50 mg per day dose of naltrexone. It is recommended that liver function be monitored prior to naltrexone treatment and periodically thereafter. Patients with hepatitis or severe liver disease should receive naltrexone only with close monitoring.

Nalmefene is a μ -opioid antagonist that is similar to naltrexone. It currently is approved for the reversal of acute opioid intoxication and overdose in the United

States, but is approved for the treatment of alcoholism in Europe. Studies in alcohol-dependent patients using a targeted approach of taking nalmefene during periods of high risk for drinking find decreased drinking and increased abstinence in those receiving the medication (Soyka & Rosner, 2010).

EXTENDED-RELEASE NALTREXONE

Because the effectiveness of naltrexone depends upon medication adherence, a sustained release, once-monthly injectable formulation of naltrexone was developed. A sustained-released naltrexone preparation, marketed as Vivitrol[®], was Food and Drug Administration (FDA) approved for the treatment of alcohol dependence in 2004. A six-month, multicenter, randomized, controlled trial of placebo and two doses of sustained-release naltrexone in 627 actively drinking alcohol-dependent adults showed a significant dose-dependent decrease in the rate of heavy drinking (26% at the highest dose) compared with placebo (Garbutt et al., 2005). The most common adverse events associated with extended-release naltrexone are injection site tenderness, nausea (which affected 33%), headache, and fatigue. Occasionally abscesses occur at the injection site and have engendered an FDA warning letter. In addition to improved adherence, sustained-release naltrexone may produce less hepatotoxicity than oral naltrexone, as the injected, sustained-release drug does not undergo first-pass metabolism in the liver.

ACAMPROSATE

Acamprosate (calcium acetylhomotaurine) is a structural analogue of taurine, a brain amino acid with unknown function. Its mechanism of action is not completely understood but most likely involves modulation of the metabotropic glutamate receptor, which is upregulated in chronic alcoholism (Littleton, 1995). Acamprosate has been shown to reduce alcohol consumption in several animal models of alcoholism (Nalpas et al., 1990). In several European clinical trials involving alcoholic human subjects, acamprosate reduced craving for alcohol, reduced relapse drinking, and had minimal side effects (Lhuintre et al., 1990; Sass et al., 1996). Meta-analyses that compare acamprosate statistically across several studies have supported the efficacy of acamprosate in improving rates of abstinence and increasing time to first drink, although with small effect sizes (Bouza et al., 2004). Interestingly, the efficacy of acamprosate appears primarily in clinical trials conducted in Europe; two American trials, a six-month multi-site study (Mason et al., 2006) and the COMBINE Study (Anton et al., 2006) failed to find similar efficacy. The reasons for the differences in effectiveness of acamprosate between European and American studies are unclear. Researchers have suggested that differences in terms of severity of alcoholism, typologies of patients, and the use of inpatient detoxification in Europe account for the discrepant outcomes.

TOPIRAMATE

The anti-epileptic medication topiramate, although not approved by the FDA for the treatment of alcohol dependence, is endorsed as an effective alcoholism treatment medication by NIAAA in its "Clinicians Guide" (NIAAA, 1997). In a 12-week, randomized, controlled trial in 150 patients with alcohol dependence receiving medication-adherence therapy, topiramate treatment significantly decreased the numbers of drinks per day, drinks per drinking day, and drinking days, and increased the number of days of abstinence, compared to placebo (Johnson et al., 2003). A subsequent U.S. multi-site trial (Johnson et al., 2007) demonstrated the efficacy of a 300 mg daily dose of topiramate to reduce heavy drinking and to improve quality of life. An advantage of topiramate is that it does not require patients be detoxified prior to starting the medication. Topiramate causes a number of dose-dependent neurological and cognitive side-effects and must be titrated slowly over several weeks.

SEROTONERGIC MEDICATIONS

Studies show that almost 25% of alcoholics are treated with antidepressants, whether or not they are diagnosed with major depression. SSRIs, such as fluoxetine and sertraline, which augment serotonergic function, also appear to reduce alcohol consumption in animals and non-depressed humans (Naranjo et al., 1990). Several human studies on non-depressed heavy drinkers found SSRIs to reduce overall alcohol consumption by some 15–20%. Patients receiving SSRIs report decreased desire and liking for alcohol. Other studies of patients with greater alcohol-dependency, however, have yielded less impressive results. A double-blind study comparing fluoxetine and placebo treatment in non-depressed alcoholics receiving psychotherapy found no difference in drinking between groups (Kranzler et al., 1995). However, when alcoholics were subtyped into early onset, high-psychopathology (Type B) and late onset, less psychopathology (Type A), the Type B alcoholics drank more with sertraline. Similar results were found in a study of sertraline in non-depressed alcoholics, in which the Type A alcoholics drank less (Pettinati et al., 2000).

In alcoholics with comorbid major depressive disorders, antidepressants may improve both drinking and depression. In a double-blind, placebo-controlled antidepressant trial with imipramine in alcoholics with major depression or dysthymia, those treated with the antidepressant reported improved mood and decreased drinking (McGrath et al., 1996). A trial of fluoxetine in 12 depressed, suicidal alcoholics showed decreased depression and alcohol consumption, compared to pretreatment (Cornelius et al., 1997). A recent study of depressed alcoholics found that the combination of sertraline plus naltrexone reduced their drinking and improved depression (Pettinati et al., 2010). The results of these antidepressant studies indicated that depressed alcoholics may have improved mood and sometimes lessened drinking (Nunes

and Levin, 2004), but that antidepressants should not be used in non-depressed drinkers.

AMPHETAMINES AND SIMILARLY ACTING SYMPATHOMIMETIC AMINES

The amphetamines are a group of drugs structurally related to the catecholamine neurotransmitters norepinephrine, epinephrine, and dopamine. Amphetamines release catecholamines from nerve endings and act as catecholamine agonists at receptors in the peripheral autonomic and central nervous systems. Intoxication with stimulants such as amphetamines, methylphenidate, or other sympathomimetics produces a clinical picture of sympathetic and behavioral hyperactivity (Dietz, 1981). Chronic amphetamine users progressively increase drug doses for periods of several days to weeks, followed by a period of abstinence. An "amphetamine psychosis" with manifestations of agitation, paranoia, delusions, and hallucinosis, mimicking paranoid schizophrenia, may follow chronic high-dose use of these drugs (Ellinwood, 1969). Neuroimaging studies find that chronic users show dysregulation of corticolimbic connections. This results in chronic users' experiencing poor executive functioning, impulsivity, and deficits in information processing (Aron & Paulus, 2007).

Antipsychotic medication such as haloperidol, risperidone, or olanzapine can be used in the treatment of stimulant psychoses; however, such patients frequently require psychiatric hospitalization. Severe hypertension is seen in overdose and may be treated with alpha-adrenergic blockers such as phentolamine. The patient's cardiovascular status (EKG) also may need monitoring. A paranoid psychosis symptomatically similar to schizophrenia may occur with chronic use and persist following cessation of stimulant use. A withdrawal syndrome characterized by marked dysphoria, fatigue, and restlessness may occur. Stimulant users may suffer also from underlying psychiatric disorders such as mood disorders and attention deficit disorders (ADD). Thus, all patients should receive a comprehensive psychiatric evaluation both before and after the acute intoxication or psychosis.

The current treatment of stimulant dependence is predominantly psychosocially based (Lee and Rawson, 2008). No definitive pharmacologically based treatments that can address the underlying neurobiology of amphetamine dependence exist. There are ongoing clinical trials of modafinil, topiramate, and other medications that have been shown to be effective for other substances. One small, single-site trial using D-amphetamine as a substitution treatment for methamphetamine found reductions in methamphetamine use and better retention than placebo (Longo et al., 2010).

BARBITURATES AND OTHER SEDATIVE HYPNOTICS AND ANXIOLYTICS

Sedative medications are a major source of adverse drug interactions and drug emergencies, including overdose (Gottschalk

et al., 1979). Sedatives are used clinically for their anxiolytic and hypnotic effects and to induce anesthesia and conscious sedation for medical procedures. Medications in this group include barbiturates, benzodiazepines, chloral derivatives, ethchlorvynol, gamma hydroxybutyrate (GBH), glutethimide, meprobamate, and methaqualone. Patients may obtain these medications illicitly from the street or from physicians who, wittingly or unwittingly, may be contributing to abuse or dependence. Certain sedatives, such as methaqualone, GBH, and flunitrazepam, are not FDA approved and therefore are not marketed in the United States, yet they are widely available on the illicit market. Potent sedative agents like GBH are sometimes administered to unsuspecting individuals for nefarious purposes, such as date rape.

Medications in this group, like the benzodiazepines, derive their pharmacological activity by affecting the chloride channel-GABA receptor complex in the brain (Seeman, 1972). Specific binding sites exist for benzodiazepines, barbiturates, and other drugs, which, when occupied by such a drug, increase hyperpolarization (and inhibition) of neurons (Costa & Guidotti, 1979; Schulz & MacDonald, 1981; Skolnick et al., 1981). Since alcohol also has inhibitory effects at the GABA-A receptor, alcohol and sedatives can interact to significantly enhance sedation. Chronic use of sedative medications causes the brain receptors to adapt to the sedative medication by becoming less sensitive to inhibition and producing tolerance.

As with alcohol treatment, treatment of the sedative abuser occurs in four stages: intervention, detoxification, long-term rehabilitation, and aftercare. The withdrawal syndrome that follows cessation of sedative drug use may be severe, including seizures, cardiac arrhythmias, and death. The need for detoxification depends on the duration and amount of sedative drug abuse, which can be estimated by means of a pentobarbital challenge test (Wesson & Smith, 1977; Wikler, 1968). In this protocol, pentobarbital 200 mg is administered orally and the patient observed one hour later. The patient's condition after the test dose will range from no effect to sleep. If the patient develops drowsiness or nystagmus on a 200 mg dose, the patient is not barbiturate-dependent. If 200 mg lacks effect, the dose should be repeated hourly until nystagmus or drowsiness develops. The total dosage administered at this endpoint approximates the patient's daily barbiturate habit and may be used as a starting point for detoxification. The barbiturate dose should be tapered over ten days, with approximately a 10% reduction each day. Alternatively, the patient can be given a loading dose of a long-acting benzodiazepine such as diazepam or clonazepam, and this medication tapered over seven to ten days (Patterson, 1990).

An alternative treatment increasingly used for sedative detoxification is carbamazepine (Klein et al., 1986). The medication is administered until blood levels are in the range for effective anticonvulsant activity, maintained for up to two weeks, and then tapered and discontinued. Carbamazepine may affect a class of endogenous benzodiazepine receptors known as "peripheral" benzodiazepine receptors, although the brain is rich in these receptor sites.

Following detoxification, the patient should be engaged in long-term individualized treatment, which may include residential drug-free programs, outpatient counseling, or self-help groups such as AA or Narcotics Anonymous (NA).

CAFFEINE

Caffeine, and the related methylxanthines theophylline and theobromine, are ubiquitous drugs in modern society. These agents occur in coffee, tea, cola, and other carbonated drinks, and are consumed by more than 80% of the population (Dews, 1982). Caffeine is present in chocolate, and in many prescribed and over-the-counter medications, including stimulants (NoDoz), appetite suppressants (Dexatrim), analgesics (Anacin, Excedrin, APC tablets), and cold and sinus preparations (Dristan, Contac). CNS effects of caffeine include psychomotor stimulation, increased attention and concentration, suppression of the need for sleep, and unpleasant insomnia. Even at low or moderate doses, caffeine can exacerbate symptoms of anxiety disorders, precipitate panic attacks, and may increase requirements for neuroleptic or sedative medications (Charney et al., 1985). At high doses and in sensitive individuals, methylxanthines may produce tolerance and behavioral symptoms of tremor, insomnia, jitteriness, and agitation. Moderate to heavy users experience a withdrawal syndrome, characterized by lethargy, hypersomnia, irritability, and severe, continuous headache (which may persist for as long as a week), beginning within 24 hours of cessation of use. Clinically significant caffeine withdrawal symptoms are commonly observed in even low to moderate users of caffeine (Hughes et al., 1991) and may occur with reduced caffeine intake occurring during a medical or psychiatric hospitalization. The signs and symptoms of caffeine intoxication or caffeine withdrawal may complicate medical or psychiatric treatment by increasing patient distress and by leading to an unnecessary evaluation for other disorders.

Methylxanthines produce physiological effects through actions at the cellular level. They produce cardiac stimulation, diuresis, bronchodilation, and CNS stimulation through several mechanisms. They inhibit the enzyme cyclic adenosine monophosphate (AMP) phosphodiesterase and increase intracellular levels of this second messenger, thereby augmenting the action of many hormones and neurotransmitters, such as norepinephrine. They also have a directly inhibitory effect on adenosine receptors and may have other neurotransmitter effects as well.

Treatment of caffeine dependence relies on gradually decreasing consumption of caffeine-containing foods, medications, and beverages over a period of usually four to six weeks. Beverages such as coffee or cola may be substituted by their decaffeinated forms. Often, patients are unaware of the extent of their caffeine consumption and of the caffeine content of consumables. They require education about the caffeine content of these substances. Withdrawal symptoms such as headache and lethargy may be treated with caffeine

taper or symptomatically with analgesics, such as nonsteroidal anti-inflammatory drugs (NSAIDs) or acetaminophen, which are of variable help.

COCAINE

The use of cocaine in the United States has undergone a dramatic increase in the last three decades. The prevalence of cocaine use peaked in the mid-1980s and has slowly declined since. Based on the 1996 National Survey of Drug Abuse, over 20 million Americans tried cocaine at least once, and 2.6 million used it during the preceding year. During the mid-1970s, the pattern of cocaine use changed from intranasal “snorting” of cocaine powder to smoking or intravenous injection of the more potent cocaine “freebase.” Freebase cocaine is now widely available in a product called “crack,” which is extremely potent, very cheap, and easily distributed. Crack is self-administered by smoking, usually by adding a small piece to a burning cigarette and inhaling the vapor. Because crack is so inexpensive and freely available, it has greatly increased the pool of cocaine users, particularly among the poor. For example, the babies of “crack mothers” and the addiction of their mothers are major public health problems for almost all cities, and even in small towns. The tragic effects of crack on the fetus and newborns are similar to the effects of cocaine and are described below.

Cocaine has major physiological and behavioral effects (Gawin & Ellinwood, 1988):

1. It is a local anesthetic of high potency, the only naturally occurring local anesthetic. It blocks the initiation and propagation of nerve impulses by affecting the sodium conductance of nerve cell membranes (Seeman, 1972).
2. It is a potent sympathomimetic agent that potentiates the actions of catecholamines in the autonomic nervous system, producing tachycardia and hypertension. It is a potent vasoconstrictor.
3. Cocaine is a potent stimulant of the central nervous system, potentiating the action of central catecholamine neurotransmitters, norepinephrine and dopamine. Its effects include increased arousal, euphoria, a sense of creativity, expansiveness, excitement, and motor activation. At high doses, the effects may progress to agitation, irritability, apprehension, and paranoia. Cocaine easily mimics the symptoms of mania.

Cocaine intoxication produces elation, euphoria, excitement, pressured speech, restlessness, stereotyped movements, and bruxism. Physiological signs of sympathetic stimulation are present, including tachycardia, mydriasis, and sweating. With chronic use, paranoia, suspiciousness, and frank psychotic symptoms may occur over time, even after withdrawal. Overdose of cocaine produces cardiac arrhythmias, hyperpyrexia, hyperreflexia, and seizures, which may progress to coma, respiratory arrest, and death. Propranolol and

haloperidol administration have anecdotally been reported to be useful in overdose (Rappolt, Gay, & Inaba, 1977). Cocaine also has major deleterious effects on pregnancy, producing low-birth-weight infants, *abruptio placentae*, and behavioral abnormalities in the newborn (Chasnoff et al., 1985).

The plasma half-life of cocaine following oral, nasal, or intravenous administration is approximately one to two hours, which correlates with its behavioral effects (Van Dyke et al., 1978). With the decline in plasma levels, most users experience a period of dysphoria or “crash,” which often leads to additional cocaine use within a short period. The dysphoria of the “crash” is intensified and prolonged following repeated use.

COCAINE TREATMENT

The optimal treatment of the chronic cocaine user is still not established; perhaps no “optimal” treatment yet exists. While cessation of cocaine use is not followed by a physiological withdrawal syndrome of the magnitude of that seen with opioids or alcohol, the dysphoria, depression, and drug craving that follow chronic cocaine use are often intense and make abstinence difficult. Psychotherapies, group therapy, and behavior modification are all somewhat useful in maintaining abstinence (Rounsaville et al., 1985). An innovative, behaviorally oriented treatment program using payment vouchers to provide positive reinforcement for cocaine abstinence has shown considerable success in reducing cocaine use in research settings (Higgins et al., 1994; Higgins, 1996). Patients are essentially “paid” not to use cocaine.

Self-help groups such as Narcotics Anonymous (NA) may be useful both as a primary treatment modality for cocaine dependence and as an adjunct to other treatment. For recidivists, long-term residential drug-free programs, including therapeutic communities, may be efficacious for some patients, depending on their motivation and capability to change.

Various pharmacological agents have been proposed as adjunctive treatments. Several reports suggest antidepressant agents such as imipramine, desipramine, lithium, or trazodone can reduce cocaine craving and usage in some patients (Gawin & Kleber, 1984; Tennant & Rawson, 1983). The doses of medication used were similar to those used for antidepressant therapy. Carbamazepine was initially reported as a useful adjunct for treatment (Halikas et al., 1991) but was shown not to be effective in a placebo-controlled clinical trial. The dopamine-2 receptor agonists bromocriptine, methylphenidate, and amantadine have all been reported to be “somewhat useful” in cocaine treatment and may block cocaine craving (Dackis & Gold, 1985), but they are by no means universally effective, and what efficacy they possess is usually measured over relatively short periods of follow-up (6–12 months at most).

Dopamine-1 and dopamine-3 receptor agonists and antagonists reduce cocaine self-administration in animals and are being tested in human cocaine users. However, in spite of considerable research, no pharmacological agent has

been proven effective in cocaine treatment (Meyer, 1992). Cocaine use is a complex problem involving multiple social and cultural variables, and expecting an unlikely "biological" cure is naïve.

Certain psychiatric disorders such as depression and ADD may be common in cocaine users. Recognition and effective treatment of these underlying disorders might add to the likelihood that the patient will stop using cocaine. Many cocaine users also use alcohol or other drugs, particularly sedatives and heroin, and will require treatment for these substances as well. The use of naltrexone in opiate dependence is discussed later.

CANNABIS

Cannabis sativa, also called marijuana or hemp, is a plant indigenous to India but now grown worldwide. The leaves, flowers, and seeds of the plant contain many biologically active compounds, the most important of which are the lipophilic cannabinoids, especially delta 9-tetrahydrocannabinol (THC) and cannabidiol. The plant is also grown as a legal cash crop for hemp fiber. Cannabinoids have behavioral effects because they mimic the action of naturally occurring lipid-signaling molecules anandamide and 2-arachidonylglycerol (2-AG) at brain cannabinoid receptors, a G-protein linked receptor (Mackie, 2008). The biologically active substances are administered by smoking or ingesting dried plant parts (marijuana, bhang, ganja), the resin from the plant (hashish), or extracts of the resin (THC or hash oil). After inhalation or ingestion, THC rapidly enters the CNS. It has biphasic elimination with a short initial half-life (1–2 hours) reflecting redistribution, and a second half-life of days to weeks. THC is hydroxylated and excreted in bile and urine.

Cannabis intoxication is characterized by tachycardia, muscle relaxation, euphoria, and a sense of well-being. Time-sense is altered and emotional lability, particularly inappropriate laughter, may be seen. Performance on psychomotor tasks, including driving, is impaired (Klonoff, 1974; Fletcher et al., 1996). Occasionally, with high doses of the drug, depersonalization, paranoia, and anxiety reactions occur. Although tolerance to the effects of cannabis occurs with chronic use, cessation of use does not usually produce significant withdrawal phenomena; but some report anxiety, insomnia, appetite disturbance, and depression (Budney & Hughes, 2006). Chronic use of cannabis has been associated with an apathetic amotivational state, and even feminization effects in men, which usually improve upon discontinuation of the drug (Gersten, 1980). Marijuana has antiemetic and analgesic effects; it stimulates appetite in wasting illness, such as AIDS and cancer; and reduces intraocular pressure in glaucoma. Delta 9-THC is now available by prescription for the medical treatment of these conditions. As of the date of publication, marijuana use is legal in Colorado and Washington, and "medical marijuana" is available legally by physician prescription in

several states, although the federal government has challenged its distribution in this manner (Annas, 1997).

TREATMENT

Treatment of cannabis dependence is similar to treatment of other drug dependencies. As part of the initial assessment, all patients should undergo complete psychiatric and medical examinations. Short-term goals should focus on reducing or stopping cannabis use and interventions to ensure compliance. Inpatient treatment may be necessary to achieve an abstinent state. Since many patients with cannabis dependence are adolescents or young adults, involvement of the family in assessment and treatment is important.

Long-term treatment should involve addictive disorder specialists to implement behavioral and psychological interventions to maintain an abstinent state. Often, a change in social situation is necessary to decrease drug availability and reduce peer pressure. Individual and group psychotherapy may be useful for understanding the role of the drug in the individual's life, improving self-esteem, and providing alternate methods of relieving psychosocial distress. Self-help groups can provide group and individual support and are most effective when patients are matched with an appropriate peer group. There is interest in using dronabinol (pharmaceutical THC) as a potential substitution treatment in cannabis dependence. Dronabinol has been shown to block some of the intoxicating effects of marijuana and to reduce cannabis withdrawal symptoms. Other medications, including the alpha2 agonist lofexidine and lithium, are currently being studied as potential treatments.

INHALANTS

Inhalants are dangerous volatile organic compounds that are used for their psychotropic effects. Substances in this class include organic solvents, such as gasoline, toluene, ethyl ether, fluorocarbons, and volatile nitrates, including nitrous oxide and butyl nitrate. Inhalants are ubiquitous and readily available in most households and places of employment. At low doses, inhalants produce mood changes and ataxia; at high doses they may produce dissociative states and hallucinosis. Dangers of organic solvent use include suffocation and organ damage, especially hepatotoxicity and neurotoxicity in the central and peripheral nervous systems (Watson, 1982). Cardiac arrhythmias and sudden death may occur. Inhaled nitrates may produce hypotension and methemoglobinemia.

The typical user of inhalants is a male teenager. According to the National Household Survey on Drug Abuse, 9.1% of 12–17-year-olds and 12.8% of 18–25-year-olds have tried an inhalant at least once.

Optimal treatment of the inhalant user is not well established. Since most users are adolescents, treatment, as with other disorders in this category, must involve the family. Long-term residential treatment may be helpful for heavy users. Inhalants are perhaps the most lethal form of substance abuse, other than drunk driving.

NICOTINE

Nicotine is an alkaloid drug present in the leaves of the tobacco plant, *Nicotiana tabacum*. Native Americans have used the plant for centuries in ceremonies, rituals, and as a medicinal herb. Since its discovery by Europeans, tobacco use has spread worldwide, and today nicotine is the most prevalent psychoactive drug in use. Over 60 million persons in the United States (29% of the population) are daily users of cigarettes, with another 10 million using another form of tobacco. Since the publication of the U.S. Surgeon General's *Report on Smoking and Health* in 1964, there has been a gradual decline in the percentage of Americans who smoke. Most of this decline has occurred among men. The number of young women who smoke has increased, as has the prevalence of lung cancer among women. The use of other tobacco products such as smokeless tobacco has also increased. The morbidity and mortality resulting from use of nicotine are extensive and include an increase in cardiovascular and respiratory disease and in cancers, particularly of the lung and oropharynx. Many of the deleterious effects of tobacco are not due to nicotine, but to toxic and carcinogenic compounds present in tobacco extract or smoke. The morbidity and mortality associated with this legal drug of addiction dwarf the human misery caused by all other drugs combined. Society's tolerance of this lethal agent is one of the great paradoxes of history.

To maximize the absorption of nicotine, tobacco products are usually smoked as pipe tobacco, cigars, or cigarettes, or instilled intranasally or intraorally as snuff and chewing tobacco, or "smokeless tobacco." Following absorption from the lungs or buccal mucosa, nicotine levels peak rapidly and then decline, with a half-life of 30–60 minutes.

Nicotine has several effects on the peripheral autonomic and central nervous systems. It is an agonist at "nicotinic" cholinergic receptor sites and stimulates autonomic ganglia in the parasympathetic and sympathetic nervous systems, producing salivation, increased gastric motility and acid secretion, and increased catecholamine release. In the CNS, nicotine acts as a mild psychomotor stimulant, producing increased alertness, increased attention and concentration, and appetite suppression. The fact that tobacco use can prevent weight gain makes the drug attractive, particularly to young women who as adolescents are most susceptible to peer pressures associated with body weight and the "sophistication" attached to smoking and other tobacco use.

Repeated use of nicotine produces tolerance and dependence. The degree of dependence is considerable, as over 70% of dependent individuals relapse within one year of stopping use. Cessation of nicotine use in dependent individuals is followed by a withdrawal syndrome characterized by increased irritability, decreased attention and concentration, and an intense craving for and preoccupation with nicotine. Frequently, appetite and food consumption increase, and a significant weight gain occurs. Withdrawal symptoms may begin within several hours of cessation of use or reduction in dosage, and typically last about a week. Craving and weight gain may persist for weeks or even months, however.

The treatment of nicotine dependence should follow the principles of treatment common to all psychoactive substances. Short-term goals should consist of the reduction or cessation of tobacco use. Few patients are able to reduce tobacco use on their own, and a supportive, encouraging relationship with a physician and/or the use of a smoking-cessation group program are usually necessary to ensure success (Greene, Goldberg, & Ockene, 1988). The most successful treatment of nicotine dependence occurs with interventions that combine pharmacological (nicotine replacement or bupropion) and behavioral therapies (Hughes, Goldstein, & Hurt et al., 1999). According to the clinical practice guidelines review (U.S. Dept. of Health & Human Services [USDHHS], 2000), all nicotine-dependent patients should be offered some form of pharmacotherapy unless medical conditions contraindicate it. The treatment of nicotine dependence is discussed in great detail in Chapter 53.

OPIOIDS

Opioid addiction is a significant sociological and medical problem worldwide, with an estimated U.S. opioid addict population of greater than 700,000. These patients are frequent users of medical and surgical services because of the propensity for overdose and the multiple medical sequelae of intravenous drug use and its associated lifestyle. Over the past decade, there has been an increasing trend away from intravenous heroin to high-potency oral opioids (e.g., oxycodone), as users have become aware of the risks of HIV infection associated with intravenous injection.

Opiate drugs produce euphoria, decreases in stress and anxiety, and analgesia because they bind to neuronal opioid receptors and mimic the action of the endogenous opioid peptide neurotransmitters: enkephalin, endorphin, and dynorphin. Recent evidence suggests that there are at least three distinct types of opioid receptors, which are designated by the Greek letters *mu*, *delta*, and *kappa*. The closely related nociceptin/orphanin receptor is also stimulated by opioid peptides and certain opiate medications (New & Wong, 2003). Most of the opioid medications used clinically and most of those abused have their predominant effects on mu opioid receptors. With regular use of a mu opioid agonist, mu opioid receptors downregulate and other neuronal systems adapt, so that chronic opiate users develop tolerance and dependence. Then, cessation of opiate use results in an unpleasant withdrawal syndrome Jaffe & Martin (1985).

Opiate overdose is a life-threatening emergency that should be suspected in any patient presenting with coma and respiratory suppression. While miotic pupils are usually present, they are nondiagnostic and may not appear with ingestion of mixed agonist-antagonist opioids. Other effects of intoxication include hypotension, seizures, and pulmonary edema. Treatment of suspected overdose includes emergency support of respiration and cardiovascular functions. Parenteral administration of the opioid antagonist naloxone 0.4–0.8 mg or of nalmefene is of both diagnostic and therapeutic value (Martin, 1976). While opioid antagonists will rapidly reverse the effects of opioids, including coma and

respiratory suppression, they do not reverse CNS depression caused by other drugs, such as alcohol or sedative-hypnotics. Opioid antagonists will precipitate withdrawal in any patient who is dependent on opioids— sometimes causing a patient whose life was just saved to be “less than grateful.”

OPIOID WITHDRAWAL

The opioid withdrawal syndrome is characterized by sympathetic hyperactivity, anxiety, agitation, pain, and intense craving for opioids. Although not life-threatening, the symptoms are extremely distressing and often lead to reinstitution of opioid use. Reduction of withdrawal signs and symptoms is usually accomplished through slow taper of opiates (usually methadone) or the use of alpha-2 agonist agents, such as clonidine or lofexidine. Alpha-2 agonists act at presynaptic noradrenergic neurons in the locus coeruleus, block the activation of central norepinephrine systems in the brain that occurs during opioid withdrawal, and ameliorate the agitation and

anxiety of withdrawal (Aghajanian, 1976; Gold, Redmond, & Kleber, 1979). The time course of withdrawal depends on the pharmacokinetics of the opiate drug that causes the dependence. Withdrawal from short half-life drugs, such as heroin or oxycodone, begins within hours of stopping drug use and usually lasts for five to seven days. Withdrawal from long half-life opioids, such as methadone, begins 24–48 hours after stopping drug use and can last from 10–14 days. Two scales that are helpful for clinicians to assess the intensity of opioid withdrawal symptoms over time are the Subjective Opiate Withdrawal Scale (SOWS) and the Objective Opioid Withdrawal Scale (OOWS) (see Boxes 38.5 and 38.6).

TREATMENT OF OPIOID ADDICTION

Nonpharmacological and behavioral modalities are quite efficacious in the treatment of the opioid abuser. Programs may differ in their lengths of stay, their intensity, and their theoretical orientation. Long-term residential treatment may be most useful

Box 38.5 THE SUBJECTIVE OPIATE WITHDRAWAL SCALE (SOWS)

Time: _____

Date Time

PLEASE SCORE EACH OF THE 16 ITEMS BELOW ACCORDING TO HOW YOU FEEL NOW (CIRCLE ONE NUMBER)

	SYMPTOM	NOT AT ALL	A LITTLE	MODERATELY	QUITE A BIT	EXTREMELY
1	I feel anxious	0	1	2	3	4
2	I feel like yawning	0	1	2	3	4
3	I am perspiring	0	1	2	3	4
4	My eyes are teary	0	1	2	3	4
5	My nose is running	0	1	2	3	4
6	I have goosebumps	0	1	2	3	4
7	I am shaking	0	1	2	3	4
8	I have hot flushes	0	1	2	3	4
9	I have cold flushes	0	1	2	3	4
10	My bones and muscles ache	0	1	2	3	4
11	I feel restless	0	1	2	3	4
12	I feel nauseous	0	1	2	3	4
13	I feel like vomiting	0	1	2	3	4
14	My muscles twitch	0	1	2	3	4
15	I have stomach cramps	0	1	2	3	4
16	I feel like using now	0	1	2	3	4

Total score range, 0–64.

for the chronic opioid abuser who requires a change in lifestyle, with vocational and psychological rehabilitation. Attending Narcotics Anonymous is helpful for motivated patients.

Opioid Substitution

The concept of opioid substitution is to provide patients with a medically monitored opiate substitute to maintain opioid dependence, thereby preventing withdrawal and increasing tolerance to diminish the effects of illicit opiates. In this harm-reduction paradigm, patients remain opioid dependent, but typically stop the use of illicit opioids. Two medications are FDA approved for substitution: methadone and buprenorphine. All of these medications are best used in the setting of a structured, maintenance treatment program, which includes monitored medication-administration; periodic, random urine toxicological screening to assess compliance; and intensive psychological, medical and vocational services.

Methadone Maintenance

Methadone is a synthetic opiate, which is orally active, possesses a long duration of action, produces minimal sedation or “high,” and has few side effects at therapeutic doses.

Methadone was first shown to be an effective treatment in an open-label study of 22 patients in New York City (Dole & Nyswander, 1965) and is now used worldwide. Over the past 40 years, studies consistently have shown methadone maintenance to be effective in the treatment of addicts who are dependent on heroin and other opiates (Senay, 1985; O’Brien, 2008). A meta-analysis of studies comparing methadone maintenance to placebo or drug-free treatment found methadone maintenance to be significantly better than non-pharmacological therapy in reducing heroin use and improving program retention (Mattick et al., 2003). In addition, methadone maintenance has been shown to reduce opiate-related mortality and morbidity, reduce HIV transmission, decrease criminal activity, and increase employment (Vocci et al. 2005). A longitudinal study that compared more than 100 representative methadone maintenance programs found that the most effective programs provided intensive psychosocial and medical services and flexibility in methadone dosing, and allowed higher doses of methadone, in excess of 80 mg per day (D’Aunno & Pollack, 2002).

Methadone treatment is integrated with a comprehensive psychosocial treatment program. Methadone is dissolved in a flavored liquid and is administered to patients daily, under observation. Daily doses usually range from 20 mg per day to

over 100 mg per day. (Long-standing program participants are allowed to “take home” some doses of methadone under a contingency contract that permits take-home doses as long as treatment compliance is maintained.) Counseling sessions are held weekly with a counselor trained and certified in addiction treatment. Medical care, employment counseling, and other rehabilitative services are provided on a regular basis. Urine toxicological screening is performed randomly and periodically to assess compliance with treatment. Higher doses are shown to be generally associated with better treatment retention.

Buprenorphine

In 2002, the FDA approved sublingual buprenorphine tablets (Subutex[®]) and buprenorphine/naloxone tablets (Suboxone[®]) for the management of opiate dependence (Ling et al., 1994; Vocci et al., 2005). In 2012, the sublingual tablets were phased out in favor of dissolving strips, which are less subject to diversion for illicit sales. Buprenorphine is a partial mu- and kappa-agonist opiate that was used medically as an analgesic. Importantly, the drug’s agonist properties predominate at lower doses, and antagonist properties predominate at higher doses. These properties have led to its increasing use as an adjunctive substitution and maintenance treatment for opioid dependence. A randomized trial comparing buprenorphine maintenance to methadone maintenance for 16 weeks in 164 newly treated opiate users showed similar reductions in illicit drug use and similar retention in treatment (Strain et al., 1994). A six-month study comparing methadone maintenance with a approach to buprenorphine found identical rates of treatment retention (Kakko et al., 1997). Possible advantages of buprenorphine compared to methadone include a less intense withdrawal upon discontinuation and less potential for abuse, as agonist effects diminish at higher doses.

Federal law now permits individual physicians who are certified in buprenorphine and possess a special license from the Drug Enforcement Administration (DEA) to prescribe buprenorphine and buprenorphine/naloxone to up to 100 opioid-dependent patients who are also receiving psychosocial treatment. In the setting of a structured treatment program, daily buprenorphine dosing has been shown to be an effective maintenance treatment. Medication doses usually range from 4 mg per day to up to 16 mg per day, administered sublingually, since the medication is not effective orally.

In spite of the demonstrated evidence of effectiveness of maintenance treatment with methadone and buprenorphine, the concept of opioid substitution therapy remains extremely controversial. Indeed, opioid substitution therapies are among the most highly regulated treatments, and must follow strict guidelines described in the Code of Federal Regulations (CFR 42, section 8).

Naltrexone

Another pharmacological adjunctive treatment for the treatment of opioid dependence is antagonist therapy with naltrexone. Naltrexone is an opioid antagonist at mu-, kappa-, and delta-opioid receptors. When taken regularly, an oral daily dose of 50 mg naltrexone completely blocks the euphoric,

analgesic, and sedative properties of opiates (Resnick et al., 1980). Patients receiving naltrexone first must be completely detoxified from opiates, or risk experiencing opioid withdrawal. In spite of its potential, studies with oral naltrexone as an adjunctive treatment have shown high treatment dropout and poor medication compliance, particularly in poorly motivated individuals with poor social supports (Capone et al., 1986). Naltrexone was most effective in highly motivated individuals, such as impaired professionals and parolees (Kleber and Kosten, 1984).

To address poor medication adherence with oral naltrexone, several sustained-release, injectable forms of naltrexone have been developed. Sixty detoxified opioid-dependent patients receiving once-monthly injections of a sustained-release naltrexone preparation in conjunction with twice-weekly counseling, showed dose-dependent reductions in illicit drug use and improvements in treatment retention (Comer, et al., 2006). A 24-week double-blind placebo-controlled multi-site study of extended-release naltrexone in 250 opioid-dependent patients conducted in Russia found significantly reduced relapse, reduce opioid craving, and improved study retention in the naltrexone group (Krupitsky et al., 2011). Based on these findings, the extended-release naltrexone preparation (Vivitrol[®]) initially marketed for the treatment of alcohol dependence, was FDA approved for opioid dependence treatment in 2011. The preparation, containing 380 mg of naltrexone, is injected monthly and causes blockade of opioid receptors for approximately 30 days. A potential concern for opioid-addicted patients treated with sustained-release naltrexone is the possibility of an overdose if opioids are used after treatment with naltrexone stops, due to loss of opioid tolerance.

HALLUCINOGENS AND PHENCYCLIDINE

Drugs used for their hallucinogenic or psychotomimetic effects include psychedelics such as lysergic acid diethylamide (LSD), mescaline, psilocybin (“mushrooms”), and dimethyltryptamine; hallucinogenic amphetamines such as methylenedioxymphetamine (MDA) and methylenedioxymethamphetamine (MDMA, or Ecstasy [XTC]); phencyclidine (PCP, or “angel dust”), ketamine, and similarly acting arylcyclohexylamines; and anticholinergics, such as scopolamine. All cause a state of intoxication characterized by hallucinosis, mood lability, and delusional states. The mechanism of action of hallucinogens is not well understood and varies according to the drug. Hallucinogens of the LSD and amphetamine class are thought to act on dopaminergic and/or serotonergic brain systems (Abraham et al., 1996). Hallucinogens related to PCP and ketamine act at the n-methyl-d-aspartate (NMDA) glutamate receptor. Anticholinergics act at muscarinic cholinergic receptors. The rate of current use of hallucinogens in the American population has been stable at 0.6% in 1996. However, among youth ages 12–17, the rate nearly doubled in two years (1.1% in 1994 to 2.0% in 1996).

PCP intoxication has several definitive features (Young et al., 1987). Patients often present with impulsive violence, either directed at themselves or at others. Eye signs, including vertical and horizontal nystagmus, are often present. Myoclonus and ataxia are frequent. Autonomic instability, with hypertension and tachycardia, is common. Ketamine, used clinically as a dissociative anesthetic in pediatric surgery, has become increasingly popular as a party drug (“Special K”) to induce hallucinosis and euphoria, and to perpetrate date rape.

The differential diagnosis of hallucinogen- or PCP-induced psychosis includes schizophrenia, bipolar mood disorder, delusional disorder, neurophysiological mental disorders such as encephalitis and brain tumor, and other toxic ingestions. Psychoses, including those that are drug-induced, may produce an analgesic state, and the clinician needs to be aware of any coexisting medical problems, such as injuries, head trauma, or an acute abdomen that may be painless.

Treatment of the psychotic state includes supportive measures to prevent patients from harming themselves or others, maintaining their cardiovascular and respiratory functions, and urgent amelioration of agitation and psychotic symptoms. Often agitation and psychosis respond to decreased sensory stimulation and verbal reassurance; still, patients usually require sedation with benzodiazepines or high-potency neuroleptics. Lorazepam 1–2 mg PO or IV every 1–2 hours as needed, or diazepam 5–10 mg PO every 2–4 hours as needed, can be given to calm and sedate them. For PCP, the acute symptoms of intoxication and withdrawal are diminished or reversed by intramuscular haloperidol 5–10 mg or oral risperidone every 1–6 hours as needed for behavioral control. Lorazepam 1–2 mg IV or diazepam 5–10 mg PO every 1–6 hours can also be given as needed. Severe tachycardia and hypertension, if present, can be treated with antihypertensives.

Most cases of hallucinogen intoxication are short-lived (lasting several hours) and resolve without incident; however, occasionally, prolonged drug-induced psychoses may occur. This is particularly common with use of PCP, which may produce a prolonged psychosis lasting from two days to a week (Walker et al., 1981). In addition, it is believed that hallucinogenic drug use may precipitate psychotic illnesses in certain individuals predisposed to the development of such disorders (Bowers & Swigar, 1983). If psychosis persists beyond two weeks after hallucinogen ingestion, it should be regarded as another primary psychiatric illness and treated accordingly, with a concurrent addiction program. Following detoxification, the patient should be engaged in long-term treatment, which may include residential drug-free programs, outpatient counseling, and self-help groups.

ANABOLIC STEROIDS

The use of anabolic steroids and performance-enhancing drugs, once predominantly a problem in weightlifters and body builders, has become an increasingly prevalent problem

in professional and amateur athletes, and is common among adolescents and young adults. A recent study found 6.5% of adolescent boys and 1.9% of adolescent girls reported using anabolic steroids without a doctor’s prescription (DuRant et al., 1993). A survey of high school students found that 2.5% and 1.8% of twelfth-grade boys used anabolic steroids in 2005 and 2011, respectively (Johnston et al., 2012). The use of anabolic steroids is often associated with the use of other substances, including cocaine, alcohol, injectable drugs, marijuana, and cigarettes.

Medical complications of anabolic steroid use include liver disease and altered lipid metabolism, leading to myocardial infarction and stroke. There is a significant effect on endocrine hormones in both males and females, altering growth and sexual development (Daly et al., 2003). Women can develop masculinizing features, including baldness, and men can develop enlarged breasts and smaller testicles. Abscesses and HIV infection have been associated with shared needle use in steroid injectors. Psychiatric symptoms associated with anabolic steroid use include severe depression, psychotic (paranoid) symptoms, aggressive behavior, homicidal impulses, euphoria, irritability, anxiety, and hyperactivity (Pope & Katz, 1988). While most of these symptoms will gradually abate with drug discontinuation, depression, fatigue, decreased sex drive, insomnia, anorexia, and dissatisfaction with body image may continue. Users are usually completely naïve about or deny the medical hazards of anabolic steroid use.

The treatment of anabolic steroid dependence should be within the same general model of other addictions, with due consideration to the high likelihood of dependency on other drugs, particularly in adolescents. Psychiatric management of drug-induced mood and paranoid syndromes is necessary. Issues regarding dysmorphic body image are often present in certain athletes and body builders and should be considered in their psychotherapy.

CLINICAL PEARLS

- It is thought that drugs of abuse and alcohol initially enhance reward mechanisms (Robinson & Berridge, 1993; Wise & Bozarth, 1987). Over time, continued use engenders a state of withdrawal, dysphoria, and distress, called *allostasis* (Koob & Le Moal, 2001), that is relieved only by continued drug and alcohol use.
- Dopamine is associated with reward and an increased salience for the stimulus; it is thought that repeated activation of this motivation-reward system sensitizes the system, resulting in increased craving in response to stimuli associated with substance use and compulsion with the development of craving (Nestler, 2001).
- The withdrawal from most substances has two phases: an acute, intense withdrawal beginning within hours after the cessation of drug or alcohol use, lasting from several days to a few weeks; and a chronic or protracted and more indolent withdrawal that can last weeks or months.

- Although complete abstinence is the ideal for treatment, reduction in quantity and frequency of substance use can still result in *harm reduction*.
- Rather than asking how much or how often a person uses, a more effective interview method focuses on whether the patient has experienced negative consequences from use of psychoactive substances, has poor control of use, or has received criticism from others about the substance use.
- Cognitive mental status testing should be particularly detailed, because alcohol and drug abusers may have significant deficits in memory, concentration, and abstract reasoning, yet at the same time pass simple bedside tests of orientation, calculation, and immediate memory.
- Percent carbohydrate-deficient transferrin (CDT) has been found to be effective in discriminating heavy drinking (Litten et al., 1995).
- A false positive in drug testing: use of sympathomimetic agents to treat asthma may yield a positive urine test for amphetamines.
- NIAAA defines “at risk” drinking (that is, at risk for adverse consequences) as more than 14 drinks per week or four drinks per occasion for men, and more than seven drinks per week or three drinks per occasion for women.
- Predictors of withdrawal delirium include structural brain lesions, hypokalemia, and thrombocytopenia; predictors of a withdrawal seizure are a previous seizure or structural brain lesion (Eyer et al., 2011).
- During and after detoxification, many alcoholic patients will appear to suffer from major depression and anxiety disorders. Some of these mood disorders are directly related to alcohol and will gradually resolve within two to four weeks after detoxification.
- Predictors of a positive response to naltrexone include a high level of craving, a positive family history of alcoholism (Rubio et al., 2005), and possessing a specific genetic polymorphism (Asn40Asp) in the μ opioid receptor gene (Oslin et al., 2003).
- Antidepressants in depressed alcoholics may improve their mood and sometimes their drinking (Nunes and Levin, 2004), but antidepressants should not be used in non-depressed drinkers.
- Chronic amphetamine users progressively increase their drug doses for periods of several days to weeks, followed by a period of abstinence.
- Chronic use of cannabis has been associated with an apathetic amotivational state, and even feminization effects in men, which usually improve upon discontinuation of the drug (Gersten, 1980).
- In 2012, sublingual buprenorphine tablets (Subutex[®]) and buprenorphine/naloxone tablets (Suboxone[®]) for the management of opiate dependence were phased out in favor of dissolving strips, which are less subject to diversion.

DISCLOSURE STATEMENT

Dr. Swift has received research funding and consultation fees from Farmaceutico CT. He is an advisory board member for D&A Pharma and has received consultant fees from this company. He has been a speaker for Lundbeck and received travel reimbursement and fees.

EVALUATING AND MANAGING SUICIDE RISK AND VIOLENCE RISK IN THE MEDICAL SETTING

Phillip M. Kleespies, Douglas H. Hughes, Sarah R. Weintraub, and Ashley S. Hart

INTRODUCTION

In the medical setting, the management of the suicidal or aggressive patient differs in a number of ways from the management of such patients in a psychiatric unit or facility. In a psychiatric unit or hospital, suicidal and aggressive behavior is relatively commonplace, and there are clear levels of observation and guidelines for management. In the medical setting, however, the patients are physically ill, and the staff is focused on their acute medical problems as well as on any potential medical emergencies that might occur. The suicidal or aggressive patient is unusual or atypical, and the staff is not necessarily well trained to manage emotional and behavioral crises or emergencies. This problem is often exacerbated during nights and weekends when the staffing volume tends to be lower than on day shifts during the week.

On a psychiatric unit, there is great emphasis on sensitivity to the patient's emotional needs and reactions. The relationship or alliance with the patient is viewed as crucial. On the other hand, as Kelly, Mufson, and Rogers (1999) have noted, medical units currently use multidisciplinary treatment teams that are organized by specialty, and it is not uncommon to have two or three specialty teams consulting on the same patient. Contacts with the patient are often brief and concerned with specific medical issues, and, at times, it is hard to know who has the primary relationship with the patient and who is in charge. Especially with patients who have serious mental illness, such circumstances may not foster a strong working alliance.

Psychiatric units put a priority on providing a safe physical environment. They are scrutinized for objects or structural features that patients might use in attempts to harm themselves or others. On the other hand, medical wards often have many pieces of equipment in the patient's room that could be wielded as weapons. Some treatments can even offer the patient a means for self-harm, as, for example, with the dialysis patient who could remove an arteriovenous shunt and bleed to death.

Psychiatric units typically have graduated levels of observation and containment that can be tailored to the estimated risk level of the individual patient. As Kelly and colleagues

(Kelly et al., 1999) have pointed out, however, options are more limited in a medical setting where the approach to managing aggressive and suicidal behavior is done on an "all or nothing" basis; that is, either restraints and/or constant observation by a "sitter," or management that is no different from that for any other medical patient.

In a medical setting, it is critical that medical practitioners have a strong knowledge base about suicidal or aggressive behavior. More specifically, it is important for staff to recognize that behavioral risk can emerge from at least two sources: (1) from a patient who has a known mental illness but is being treated for a medical condition; and (2) from a patient who has no known mental illness but has a medical illness with an associated risk for suicide or violence.

In this chapter, we attempt to provide a knowledge base for the evaluation and management of suicidal and aggressive behavior, as well as a discussion of how to proceed with evaluating and managing such behavioral crises or emergencies in a medical setting. The chapter is divided into two major components: (1) the evaluation and management of suicide risk in a medical setting; and (2) the evaluation and management of violence risk in a medical setting. Under the first heading, we discuss:

- (a) medical illness as an independent risk factor for suicide;
- (b) specific medical illnesses with an associated risk of suicide;
- (c) a framework for evaluating the acute risk of suicide; and
- (d) the management of acute risk of suicide in a medical setting.

Under the second heading, we discuss:

- (a) medical illness and the risk of violence;
- (b) specific medical illnesses with an associated risk of violence;
- (c) a framework for evaluating the acute risk of violence; and
- (d) the management of acute risk of violence in a medical setting.

THE EVALUATION AND MANAGEMENT OF SUICIDE RISK IN A MEDICAL SETTING

MEDICAL ILLNESS AS AN INDEPENDENT RISK FACTOR FOR SUICIDE

As reported in detail by Clark and Horton-Deutsch (1992), community-based psychological autopsy studies have consistently found that over 90% of suicides (per official coroner reports) had a mental or emotional disorder. Less well known is the estimate that between 34% and 43% of those who ended their lives by suicide had a medical illness at the time of death (MacKenzie & Popkin, 1990; Whitlock, 1986), and that physical health problems were thought to contribute to suicide in 62% of a sample of elderly suicide victims (Harwood, Hawton, Hope, Harriss, & Jacoby, 2006).

Although mental illness seems more prevalent than physical illness among suicides, the findings above have led to further investigation of whether physical illness might have an independent association with suicide and suicidal behavior, an issue that is clearly significant for those who must assess suicide risk in a medical setting. Using data from a national comorbidity study of late adolescents and adults (ages 15–54), Goodwin, Marusic, and Hoven (2003) examined associations between a self-report checklist of medical illnesses and a question about lifetime suicide attempts. They found significantly increased odds of a suicide attempt with physical illness, even after controlling for demographic characteristics and mental disorders. They also found a linear, dose–response association between the total number of physical illnesses and the likelihood of a suicide attempt. In addition, Ruzicka, Choi, and Sadkowsky (2005), following the introduction of multiple-cause-of-death coding in Australia, reviewed all completed suicides over a five-year period (1997–2001) and compared them with deaths by accident. Their findings confirmed the significant relationship of suicide with mental health problems, but they also indicated that certain physical diseases (most notably HIV and cancer) were significantly associated with suicide. In general, mental disorders were more prevalent than physical illnesses among suicide victims under age 60, while physical illnesses were more prevalent than mental disorders among the suicide victims age 60 and over.

Finally, Waern et al. (2002) and Conwell et al. (2009) did case-control studies to examine the association of suicide with medical illness and psychiatric illness. In both studies, the authors examined samples of individuals who had committed suicide ($n = 85$ and $n = 86$, respectively) with matched living-community samples. In the study by Waern et al. (2002), the data for the suicide group were gathered from interviews with next-of-kin and by record review, while the data for the community sample were gathered directly by interview with control-group participants. In the study by Conwell et al. (2009), the data for both groups were gathered from interviews with next-of-kin and by record review.

The results in both studies supported previous findings of an association between psychiatric illness and suicide, and they also both found that physical illness was a significant, independent risk factor for suicide in the elderly. In the study by Conwell et al., it was also found that perception of deteriorating health status and functional impairment were significant risk factors, with functional impairment being the more robust predictor of suicide.

The findings above, of course, do not necessarily indicate a direct relationship between physical illness and suicidal behavior. As Ruzicka et al. (2005) have noted, the suicide risk associated with certain physical illnesses could be mediated by secondary mood or affective symptoms; or, as suggested by Conwell et al. (2009), perceived health status or functional impairment might also mediate risk. Nonetheless, the emerging data seem to suggest that certain physical illnesses (and particularly the burden of multiple concurrent physical illnesses in the elderly) warrant inclusion as risk factors for suicide.

Pertinent to this conclusion, it is noteworthy that in Oregon, assisted suicide for the terminally ill is legal under the Oregon Death with Dignity Act (ODDA). Of those people who have used the ODDA, 80.8% have had cancer. Under the ODDA, physicians are required to refer patients for psychiatric or psychological evaluation if their judgment is considered to be impaired by virtue of a mental disorder; yet, only 7.5% of patients using the Act have been referred (Oregon Public Health Services, 2011). These data suggest that most of these individuals with a terminal illness either did not have a mental disorder, or, if some proportion of them did, it did not seem to significantly impair their decision-making capacity for choosing an assisted death.

SPECIFIC MEDICAL ILLNESSES WITH AN ASSOCIATED RISK OF SUICIDE

There are a great many medical illnesses and conditions, and most of them, as single diseases or injuries, have no known associated risk of suicide (Harris & Barraclough, 1994). There is evidence, however, that a few specific illnesses or conditions are associated with an elevated risk (see Table 39.1 for a listing of illnesses or conditions and the factors that may lead to increased risk within each illness or condition). In terms of risk and specific illnesses, the evidence presented below is based, primarily, on large register linkage studies and meta-analytic reviews. If a particular illness or condition is not mentioned, it does not mean that there is no suicide risk associated with it, but only that we did not detect any large, trustworthy studies that would support its inclusion here.

HIV/AIDS

HIV/AIDS has long been associated with increased risk of suicide. In their frequently cited review of studies from 1966–1992, Harris and Barraclough (1994) found that the relative risk of suicide for men with HIV was seven times

Table 39.1 MEDICAL ILLNESSES/CONDITIONS AND INCREASED RISK OF SUICIDE

ILLNESS/CONDITION*	INCREASED RISK	SELECTED REFERENCES
HIV/AIDS	With progression of disease	Lu et al. (2006) Keiser et al. (2010)

*This listing of medical illnesses and conditions with associated suicide risk is not intended as an exhaustive list of medical illnesses and conditions with an associated suicide risk.

higher than the rate for men in the general population. With the introduction in 1996 of improved treatments such as highly active antiretroviral therapy (HAART), however, the level of risk may have been modified.

A review of the literature on the impact of HAART on suicide risk suggests that the evidence is mixed, with recent register linkage studies and meta-analytic reviews linking HAART to both an increase (Lu et al. 2006; Krentz, Kliever, & Gill, 2005) and a decrease (Keiser et al., 2010; Komiti et al., 2001; Rice, Smith, & Delpech, 2010) in the incidence of suicide. Researchers who found a decrease in incidence linked this reduced suicide risk to “HAART-related improvements in disease status” (Keiser et al., 2010, p. 4). Those who found an increase in incidence attributed it in part to the difficult side effects of life-long treatment with HAART, including mood disorders and other conditions, that impair quality of life (Carrico et al., 2007).

As Komiti et al. (2001) have noted, the psychological impact of improved medical treatments may be complex. For example, it is possible that cultural differences could account for the mixed findings. Indeed, the findings cited involve participants in Great Britain, Switzerland, Australia, Canada,

and Taiwan, where differences in availability of and approach to health care, as well as community attitudes about HIV/AIDS, might affect the impact of new medical treatments on suicide risk.

The heightened incidence of suicide among people living with HIV/AIDS, of course, has also been linked to stigma, discrimination, and social isolation, as well as to mental health problems, including anxiety, depression, and substance abuse (Komiti et al., 2001; Mahajan et al., 2008). In the study by Keiser et al. (2010), the results of a survey of the infectious-disease staff involved with the care of the study patients who committed suicide suggested that, in the staff's opinion, the most common reason for the patients' suicides was the progression of the HIV infection followed by psychosocial problems. This finding suggests that clinicians may need to exercise greater caution about suicide in the HIV/AIDS population as the disease progresses.

Although the causes may be multiple, it is clear that the evidence converges on the conclusion that HIV/AIDS continues to be a risk factor for suicide, although the risk may be diminished since the introduction of treatments such as HAART.

Cancer

Large cohort studies linking national cancer and death registries for the past several decades have revealed significantly higher suicide rates among cancer patients than in the general population (Ahn et al., 2010; Kleespies, Hough, & Romeo, 2009). In the United States, for example, the incidence of suicide among more than 3.5 million patients diagnosed with cancer between 1973 and 2002 was nearly twice the rate in the general U.S. population (Standardized Mortality Ratio [SMR] = 1.88; Misono, Weiss, Fann, Redman, & Yueh, 2008). Similar to gender differences in suicide in the general U.S. population, the frequency of completed suicides for female cancer patients has been found to be one-fifth that of males, with a hazard ratio of 6.2 for male suicide relative to female suicide (Kendal, 2007).

Research has also pointed to an association between cancer-related suicide and age at diagnosis. In a case-control study of suicide risk associated with medical illness among New Jersey residents age 65 and older, cancer was the only medical condition that remained associated with suicide in adjusted analyses that accounted for psychiatric illness and the risk of dying within a year (Miller, Mogun, Azrael, Hempstead, & Solomon, 2008). In addition, Misono and colleagues (2008) documented higher rates of suicide with increasing age at cancer diagnosis among men. An examination of suicide rates by age at cancer diagnosis revealed that the highest SMR of 2.51 occurred for male and female patients in the uppermost age bracket of 85 years and older.

Two periods of heightened risk of committing suicide have been identified for cancer patients—one being shortly after discharge from the hospital. Lin, Wu, and Lee (2009) examined suicides occurring within three months of hospital discharge among cancer patients in Taiwan during the period of 2002–2004. Almost half (46.3%) of the post-discharge suicides occurred within 14 days, and approximately 60% of suicides occurred within the first month after discharge. The mean interval from discharge to suicide was 39.7 days.

The second period of elevated cancer-related suicide risk was the year following diagnosis. Ahn et al. (2010) and Robinson, Renshaw, Okello, Moller, and Davies (2009) reported a downward trend in relative risk of suicide with increasing time since cancer diagnosis, with the greatest risk occurring in the first year after diagnosis for both men and women (SMRs = 2.42 and 1.44, respectively). An increased risk of suicide within one year post-diagnosis has been repeatedly documented for prostate cancer patients. Among men in the United States diagnosed with prostate cancer from 1979–2004, the risk of suicide was elevated during the first year (SMR = 1.4), and especially during the first three months after diagnosis (SMR = 1.9; Fang et al., 2010).

Evidence indicates that poor prognosis and cancer stage at diagnosis confer additional risk of suicide. In a study by Dormer and colleagues (2008), specific types of cancer were grouped according to prognosis (i.e., five-year relative survival

rates), and the very high SMR of 12.07 occurred for the poor-prognosis group in the first three months after diagnosis. Similarly, Robinson et al. (2009) found that cancers with high fatality carried a higher risk of suicide in both men (SMR = 2.67) and women (SMR = 2.17) compared to cancers with low fatality. Several studies have also found that suicide risk is related to cancer stage at diagnosis. Rates of suicide have been noted to be higher for patients in the United States with advanced disease at diagnosis (Misono et al., 2008). For example, data indicate that risk of suicide is elevated for metastatic disease at diagnosis (Kendal, 2007), particularly for prostate cancer (Fang et al., 2010). Kendal (2007) also found that cancer-directed surgery that could not be carried out (for head and neck cancers), high-grade tumors, and treatment contraindications all were associated with elevated suicide risk. Examining suicide rates across various types of cancer, Robinson and colleagues (2009) reported a strong effect of advanced stage of disease in women.

These findings suggest that varying rates of suicide across cancer sites may be explained at least in part by variations in associated survival rates. However, it is notable that even when the likelihood of survival is high, cancer is still associated with increased suicide risk relative to the general population (Christensen, Yousaf, Engholm, & Storm, 2006).

End-Stage Renal Disease

As Levy (2000) has pointed out, there are many stresses and losses associated with end-stage renal disease (ESRD) and with renal dialysis. Functional limitations typically lead to a loss of employment, a loss of income, and potentially a loss of one's role in the family. There can be a loss of sexual function and a fear of death, as the patient must rely on a life-sustaining treatment. With hemodialysis, patients become dependent on the dialysis machine and the dialysis staff. The routine of being dialyzed several times a week can become tedious. Continuous ambulatory peritoneal dialysis (CAPD), which can be performed at home, can reduce feelings of dependency, but the patient must observe the scrupulous antiseptic technique that is needed to avoid infections. Regardless of the dialysis technique, the individual needs to adhere to a low-phosphate, low-potassium, low-sodium, and restricted fluid intake diet. These stressors can make the patient more vulnerable to demoralization and possibly depression. Under such conditions, it is not surprising that suicide risk may be increased.

Bostwick and Cohen (2009), however, have contended that, by current standards, the suicide rate for ESRD patients may have been somewhat inflated in years past. They base their argument on the fact that ethical thought about the rights of patients to refuse life-sustaining medical treatment (LSMT) has markedly shifted over the past 30–35 years in the direction of respecting the autonomous choices of the patient. Thus, in the more paternalistic healthcare system of the past, an ESRD patient's refusal of, or request to discontinue, renal dialysis may have been

more likely to be viewed as a suicidal act; while in the current U.S. healthcare system, competent patients are seen as having the right to refuse any LSMT, renal dialysis included, that they find invasive and not in keeping with personal control of their body. Death under such circumstances is typically not considered a suicide.

Be that as it may, there nonetheless appears to be a moderately elevated rate of suicide among ESRD patients in the United States. In a large study, a total of 465,563 patients who initiated dialysis between 1995 and 2000 and were registered in the United States Renal Data System (USRDS) were linked to the ESRD Death Notification Form register (Kurella, Kimmel, Young, & Chertow, 2005). The ESRD Death Notification Form makes a distinction between those who decide to withdraw from dialysis before death, and those who commit suicide. Having made this distinction, the investigators nonetheless found a suicide incidence ratio of 1.84, indicating that the ESRD patients had a suicide rate that was 84% higher than the rate for the general population, even after accounting for demographic differences.

The rates of suicide among renal dialysis patients in the study by Kurella et al. (2005) tended to increase with age, with those 60 and over having the highest rates. There appears to be a somewhat different picture, however, with renal disease patients who have received a kidney transplant. Ojo et al. (2000) took a sample of 86,502 kidney transplant patients who were registered with the United Network for Organ Sharing or with USRDS between 1988 and 1997, and linked them with cause-of-death information from a transplant recipient follow-up form and with the ESRD Death Notification Form. They found an elevated rate of suicide for transplant patients (15.7 per 100,000 persons a year) relative to the general population rate (9 per 100,000 persons a year). Interestingly, 35% of the suicides occurred in the first 12 months after the transplant, and 16 months was the median time from transplantation to suicide. The mean age of the sample was 39 years, suggesting a higher risk of suicide at a younger age for transplant patients relative to the dialysis patients in the Kurella et al. study. The reason(s) for this apparent age difference are as yet undetermined.

Epilepsy

Increased rates of depression and suicidality among patients with epilepsy are well documented. In one study, a history of major depression was found to be almost two times as common in patients with seizures compared to those without seizures, and a history of a suicide attempt was five times as common (Hesdorffer, Hauser, Olafsson, Ludvigsson, & Kjartansson, 2006). In one meta-analysis, suicide was found to be the cause of death for up to 13.5% of all patients with epilepsy (Pompili, Girardi, & Tatarelli, 2006).

Recent population-based studies have explored the heightened risk of suicide among patients with epilepsy,

pointing out the role of comorbid psychiatric disease, seizure status and disease progression, and demographic variables in moderating suicide risk (e.g., Christensen, Vestergaard, Mortensen, Sidenius, & Agerbo, 2007; Mainio, Alamaki, Karvonen, Hakko, Sarkioja, & Rasanen, 2007). Christensen et al. (2007) found that patients with epilepsy had a risk of suicide that was three times higher than matched controls. They also found that the relationship among epilepsy, psychiatric diagnosis, and suicide was stronger in women compared to men.

Using another population-based sample, in northern Finland, Mainio et al. (2007) examined suicide among multiple populations ($n = 1877$) from 1988 to 2002. They found that the percentage of previous suicide attempts among suicide victims with epilepsy was double that of people without epilepsy. In general, suicide victims with epilepsy were older, were more likely to have suffered from depression, and were more often female. It should be noted that it is unusual to find a population in which women have more suicides than men. The factors that may contribute to such a finding with epilepsy patients have not yet been investigated. Disease status also influenced risk of suicide, with a heightened risk of suicide occurring among patients with chronic epilepsy.

Another line of research has explored the relationship between anti-epileptic drug use (AEDs) and the heightened risk of suicide among epilepsy patients (Bell & Sander, 2009). Research findings gathered by pharmaceutical companies, which used placebo-controlled trials of 11 different AEDs, determined that the odds ratio for suicidal ideation or behavior was significantly increased among patients taking AEDs for epilepsy, but not among patients taking AEDs for psychiatric or other medical problems. A recent, large, case control study in Great Britain, however, found a significant relationship between AEDs and suicide-related events when AEDs were used with patients with depression (Arana, Wentworth, Ayuso-Mateos, & Arellano, 2010). Which patients (i.e., those with epilepsy or those with psychiatric disorders) have an associated risk of suicidality when using AEDs has therefore not been settled. Nonetheless, the clinician should be aware that the U.S. Food and Drug Administration (FDA) issued a warning about AEDs and suicidality in 2008 (US FDA, 2008).

Stroke

Patients with stroke have also been shown to have an increased risk of suicide. Teasdale and Engberg (2001a) identified 114,098 stroke patients discharged alive from the hospital between 1979 and 1993 and screened this cohort in Denmark's national death register over the same time period. The suicide rate was nearly doubled for stroke patients, with SMRs of 1.88 and 1.78 for men and women, respectively. Suicide risk was greatest for patients under 50 years of age ($SMR = 2.85$) and was smallest for patients 80 years of age or older ($SMR = 1.3$). The rate of suicide was also greater for patients with a shorter duration of

hospitalization (i.e., less than two weeks versus more than three months; SMR = 2.32). Survival analysis indicated that the risk for suicide is greatest up to five years after a stroke.

Data indicate that depression and a history of prior stroke are risk factors for suicide following stroke. Pre-stroke depression more than doubled the risk of suicide relative to an absence of lifetime depression (Forsström, Hakko, Nordström, Räsänen, & Mainio, 2010).

Traumatic Brain Injury

Several studies have found a heightened risk of psychiatric disorders (notably major depression, panic disorder, obsessive-compulsive disorder, substance abuse) and an increased risk of suicidal ideation and suicide attempts in patients with traumatic brain injury (TBI) (e.g., Silver, Kramer, Greenwald, & Weissman, 2001; Simpson & Tate, 2002). Teasdale and Engberg (2001b) conducted a seminal study in Denmark focusing on TBI and risk of completed suicide. These investigators selected patients on a national register of hospital admissions from 1979 to 1993 for three types of traumatic brain injuries: concussion ($n = 126,114$), cranial fracture ($n = 7560$), and cerebral contusion or traumatic intracranial hemorrhage ($n = 11,766$). They then linked these lists of patients to a national register of deaths for the same period. Relative to the general population, the incidence of completed suicide was increased for all three groups with SMRs stratified by sex and age that equaled 3.0, 2.7, and 4.1, respectively. Using regression analyses for proportional hazards, patients with more serious brain injuries such as cerebral contusions or intracranial hemorrhages were found to have significantly greater risk of suicide than patients with concussions and cranial fractures. It is worthy of note, however, that even patients with no more than a concussion or a cranial fracture had an increased risk for suicide.

In a more recent U.S.-based study of mortality after traumatic brain injury, Harrison-Felix et al. (2009) have presented evidence supportive of an increased risk of suicide in TBI patients. These investigators linked all patients admitted to a rehabilitation hospital over a 40-year span ($n = 1,678$) to the Social Security Administration's Death Index. They found that TBI patients in their sample had an estimated average life expectancy reduction of four years overall and were three times more likely to commit suicide than people in the general population of similar age, sex, and race.

The causes of the increased risk of suicide in patients with TBI are likely to be complex and may include cognitive, psychosocial, emotional, and neurobiological changes. In the clinical setting, it is important to remain aware of the risk, particularly among those with a more serious TBI.

Multiple Sclerosis

Multiple sclerosis (MS) is a chronic disease of the central nervous system that involves cognitive, motor, and sensory

impairments. MS often leads to problems of living (e.g., financial difficulties, disruption in family life), in addition to significant emotional distress, including anxiety and depression (Gay et al., 2010). According to meta-analyses conducted in the 1990s (e.g., Harris & Barraclough, 1994, Stenager & Stenager, 1992), patients with MS appeared to have a suicide rate that was twice that of the general population. This finding has been confirmed in more recent record-linkage studies in Denmark and Sweden.

In Denmark, for example, Bronnum-Hansen, Stenager, Stenager, and Koch-Henriksen (2005) linked the Danish Multiple Sclerosis Registry, consisting of more than 10,000 patients, and Cause of Death Registry over the period from 1953 to 1996. They found that the SMR for suicide indicated that the risk for patients with MS was more than twice that for the general population (SMR = 2.12). The increased risk was particularly high in the first year after diagnosis (SMR = 3.15), but it also remained elevated for more than 20 years after diagnosis.

In Sweden, investigators linked all 12,284 cases of MS in the Swedish Hospital Inpatient Register during the period from 1969–1996 with the Swedish Cause of Death Register (Fredrikson, Cheng, Jiang, & Wasserman, 2003). Suicide risk of patients with MS was again found to be more than twice that of the general population (SMR = 2.3). As in the Danish study, suicide risk was particularly high in the first year after diagnosis. In this study, however, a gender difference was noted; the elevation in risk seemed to be greatest in young men (below age 40), while the risk for women was greatest for those between ages 30 and 59.

Studies have repeatedly found high rates of depression in patients with MS, with lifetime prevalence estimated in the range of 40–60% (e.g., Beiske, Svennson, Sandanger et al., 2008). Depression in MS patients often goes unrecognized and untreated (McGuigan & Hutchinson, 2006). Given that it is the mental disorder most frequently found among those who complete suicide, it seems critical that practitioners detect and treat symptoms of depression in these patients, particularly in the year following diagnosis. It should be noted, however, that not all suicides among individuals with MS occur in the context of a depressive episode. Other factors (e.g., decreased quality of life, decreased ability to participate in meaningful activity, loss of self-determination and control) may also be implicated (Williams et al., 2005).

Huntington's Disease

Research has revealed an elevated risk of suicide in relation to Huntington's disease (HD), a hereditary and progressive neurodegenerative disorder (see review in Kleespies, Hough, & Romeo, 2009). Additional studies have supported this linkage. Baliko, Csala, and Czopf (2004) found that, in the period from 1920–1997, suicide accounted for 10% of deaths among 96 Hungarian families with HD and occurred at a higher rate than in the general population of Hungary.

Studies have examined the psychosocial impact of gaining knowledge about one's genetic status as a result of predictive testing for HD. In a worldwide study of 4,527 HD test participants, Almqvist, Bloch, Brinkman, Craufurd, and Hayden (1999) found that the majority of individuals (84%) who experienced an adverse event—suicide, suicide attempt, or psychiatric hospitalization—had received a predictive testing result indicating increased risk of HD. Most individuals in the increased-risk group (62%) experienced an adverse event within the first year after receiving the result, and most (65%) were symptomatic at the time of the event.

Data also point to an elevated risk of suicide during the period leading up to predictive testing for HD among individuals at risk for the disease (Robins Wahlin et al., 2000; Larsson, Luszcz, Bui, and Robins Wahlin, 2006). The findings are consistent with previous work indicating that the two critical periods of elevated risk for suicide in HD are just before a formal diagnosis is received, and in Stage 2 of the disease, when independent functioning diminishes (see Kleespies et al., 2009).

A few studies have identified factors associated with increased risk of suicide in HD. A retrospective case-controlled study of instances of suicide in HD revealed that, among a variety of clinical and social variables, having no children was the most important risk factor and had an odds ratio of 13.6 (Lipe, Schultz, & Bird, 1993). In the study by Almqvist and colleagues (1999), both employment status and psychiatric history within the five years leading up to testing were significantly related to the frequency of an adverse event following predictive testing for HD; and age, gender, and marital status did not influence the likelihood of an event. Furthermore, in a recent prospective study of patients with prodromal HD, Fiedorowicz, Mills, Ruggle, Langbehn, and Paulsen (2011) found that a history of suicide attempts and the presence of depression were strongly predictive of suicidal behavior in these patients versus a control group.

Spinal Cord Injury or Disorder

Spinal cord injury or disorder (SCI/D) can cause complications and dysfunction in several organ systems leading to decreased survival or longevity. SCI/D patients often die from secondary illnesses such as pneumonia, septicemia, pulmonary emboli, or stroke. Over the past three or four decades, however, improvements in early care and in rehabilitation have led to an increased life expectancy that approaches 70% of normal for those with complete quadriplegia and 86% of normal for those with complete paraplegia. Yet, during this same time period, a study in Australia found that the death rate by suicide had reportedly trebled from an SMR of 2.5 before 1980 to an SMR of 8.7 since 1980 (Soden et al., 2000). The reasons for this increase are undetermined but may involve psychosocial issues that affect the quality of life and the mental health of SCI/D patients.

A recent register-linkage study in Norway that combined deaths by suicide and accidental poisoning (Hagen,

Lie, Reikand, Gilhus, & Gronning, 2010; SMR = 5.79) has confirmed findings in previous studies of an elevated rate of suicide for patients with traumatic spinal cord injury. Some have hypothesized that the elevated rate may, in part, be a function of heightened rates of mood disorder and substance abuse disorder in the SCI/D population. It is not uncommon for alcohol or drug intoxication to be involved in accidents that result in spinal cord injuries. Moreover, suicide attempts by individuals who are depressed and/or abusing alcohol or drugs can lead to spinal cord injuries. With regard to the latter, estimates of spinal cord injuries that result from suicide attempts have been modest; that is, in the range of 1.6–6.8% (see, e.g., Stanford, Soden, Bartrop, Mikk, & Taylor, 2007). Stanford et al. found that approximately 8% of the SCI/D patients in their study who had sustained their SCI/D in a prior suicide attempt eventually committed suicide. Relative to rates of suicide for the general population, this finding suggests that these patients constitute a high-risk group.

Suicide risk among patients with SCI/D tends to be greatest in the first two to five years after the injury (Soden et al., 2000). In a study of 5,200 individuals with SCI/D covering a 30-year period, Charlifue and Gerhart (1991) found that, of those who died by suicide, 50% did so within three years of SCI/D onset, and 76% did so within four years. Factors that distinguished suicides from matched non-suicidal people with SCI/D included (1) post-injury despondency, (2) experiences of helplessness and feelings of shame, and (3) pre-injury family fragmentation.

A FRAMEWORK FOR EVALUATING PATIENTS AT RISK FOR SUICIDE

A frequently used framework for evaluating patients at high risk for suicide has been described by Rudd, Joiner, and Rajab (2001). In this framework, the clinician examines the patient for predisposing or distal risk factors, acute or proximal risk factors, and protective factors. Distal risk factors form the background from which suicidal behavior can emerge. They contribute to what makes an individual vulnerable when proximal risk factors occur. Proximal risk factors, on the other hand, tend to be precipitating events that are closer in time to the occurrence of the behavior. In most circumstances, they are not sufficient to fully explain the occurrence, but, in combination with a significant set of distal risk factors, they can interact to create the conditions needed for these behaviors to occur. Protective factors are conditions or characteristics that, if present, may attenuate the risk of life-threatening behaviors, but, if absent or diminished, may make such behaviors more likely. Research on protective factors has unfortunately been under-developed.

The degree of risk for suicide can be estimated, ranging from minimal to severe, by weighing these three types of factors. An individual at minimal risk for life-threatening behavior might have no known distal risk factors or proximal risk factors and multiple protective factors. Someone at moderate risk, however, might have some distal and proximal risk factors, and some protective factors that are beginning to weaken. Those at serious or severe risk might have multiple

distal and proximal risk factors and essentially lack protective factors.

In the section that follows, we will use this framework in presenting factors to consider in a mental health or psychiatric evaluation of suicide risk. Those who work in a medical setting should, of course, also consider the risk factors related to medical illness (as presented above) in any effort to weigh the level of risk in the medically ill.

EVALUATING FOR THE ACUTE RISK OF SUICIDE

In this subsection, some of the major risk and protective factors for suicide that have empirical support in the research literature are presented. Given space limitations, it is not an exhaustive review.

Distal Risk Factors

Demographic Factors

By age group, the elderly (ages 75–84) have typically had the highest rate of suicide in America. Although the annual incidence of suicide for the elderly remains high, the suicide rate for the middle-aged (ages 45–54) has exceeded that of the elderly since 2006. The most recent national statistics indicate that, in 2010, the incidence of suicide for the middle aged (ages 45–54) was 19.6/100,000/year versus 15.7/100,000/year for the elderly (U.S.A. Suicide: 2010 Official Final Data, 2012). Youth suicide (ages 15–24 and 25–34) rose through the 1980s and early 1990s, then seemed to peak in the mid-90s, decline, and plateau. In terms of gender, men are approximately four times more likely than women to complete suicide, while women are approximately three times more likely than men to engage in non-fatal suicidal behavior. By race or ethnicity, whites typically have a suicide rate that is two to three times higher than that of African-Americans, and white males account for approximately 70% of all suicides in the United States. Socioeconomic status is not a strong predictor of suicide.

Serious Mental Illness

Literature reviews have summarized findings from a number of psychological autopsy studies indicating that over 90% of adults and adolescents who commit suicide have a history of a psychiatric disorder (Kleespies & Dettmer, 2000; Miller & Emanuele, 2009; Sullivan & Bongar, 2009). Mental illness is clearly a distal risk factor for suicide. Some mental illnesses can be both distal and proximal risk factors, such as when there is an acute exacerbation of depression in a patient with a history of chronic or recurrent depression. The literature reviews noted above have identified affective disorders, alcohol abuse, and schizophrenia as diagnoses most commonly found among those who commit suicide. It is estimated that 80–85% of adults who commit suicide have one of these diagnoses in their history, and many have comorbid conditions. Combat-related post-traumatic stress disorder (PTSD), bipolar II disorder, and borderline personality disorder have also been found to have an elevated risk

of suicide (Bullman & Kang, 1994; Rihmer & Kiss, 2002; Duberstein & Witte, 2009).

Family-Related Factors

There is considerable evidence of a familial and probably a genetic contribution to the risk of suicide (Brent, Bridge, Johnson, & Connolly, 1996; Mann & Arango, 1999; Moscicki, 1997; Roy, Nielsen, Rylander, & Sarchiapone, 2000). A genetic contribution may be indirect, in that some of the psychiatric disorders associated with a heightened risk of suicide (e.g., major depression and schizophrenia) have been found to have a genetic loading in their etiology. On the other hand, evidence in studies with monozygotic and dizygotic twin pairs and in adoption studies supports the hypothesis that, after controlling for psychopathology (including depression), there may be an independent genetic loading for suicidal behavior (Roy et al., 2000). Moreover, a now-classic study of the Old Order Amish of Lancaster County in Pennsylvania (Egeland & Sussex, 1985) found that certain family pedigrees had a heavy loading for affective disorders and suicide, while other family pedigrees had a heavy loading only for affective disorders but not for suicide. The investigators concluded that their findings indicated that there is an increased risk of suicide for patients with a diagnosis of major affective disorder and a strong family history of suicide.

Although there may be a genetic contribution to some suicides, most investigators continue to agree that suicide is typically a multi-determined act with psychological, social, and biological factors involved. Thus, families of suicidal individuals have been found to exhibit poor communication and problem-solving skills (McLean & Taylor, 1994). Moreover, it is possible that, in some cases, suicidal behavior may be a learned strategy for communicating with family members or coping with difficult situations. With adolescents, poor parent–child communication and negative family interactions have been identified as risk factors (King, Segal, Naylor, & Evans, 1993).

Proximal Risk Factors

Acute Risk Factors Within High-Risk Diagnoses

Most patients with high-risk diagnoses do not commit suicide. The question then becomes what acute risk factors within these diagnoses might differentiate those who are at high risk for suicide.

Fawcett et al. (1987), in a multi-site prospective study, identified several symptoms that heighten the risk of suicide for those with an affective disorder. They include severe anhedonia, global insomnia, severe anxiety (and/or panic), obsessive-compulsive features, and active alcohol abuse. Whether the patient is reporting suicidal ideation or not, the clinician would do well to exercise caution when the patient is depressed and presents with some or all of these symptoms. Among individuals with schizophrenia, prospective studies have found suicide risk is most associated with feelings of hopelessness, depression, obsessive-compulsive features, paranoid ideation, and subjective distress (Cohen, Test, & Brown, 1990; Peuskens et al., 1997). Risk is greatest for male

schizophrenic patients under age 40, particularly when these patients are not acutely psychotic, have a heightened awareness of the debilitating effects of their illness, and become depressed.

Among individuals with alcohol use disorder, retrospective studies examining risk factors for suicide have suggested that comorbid depression and the recent loss of a significant relationship are acute risk factors (Murphy, 1992). Suicide among patients with alcohol problems is generally more likely in mid-life and following a prolonged history of alcohol abuse and dependence. It is most likely to occur during an active phase of drinking. Increased risk of suicidal behavior and/or suicide has also been reported among inhalant users (Howard et al., 2010), heroin users (Darke & Ross, 2002), and cocaine users (Marzuk et al., 1992). Little is known about factors associated with the use of these substances that may increase risk. Borges, Walters, and Kessler (2000) found that the major risk of suicidal behavior was linked to the current use of these substances rather than to a history of use or abuse. They also found that polysubstance use was more important than a particular, single substance in predicting first suicide attempts.

Hopelessness

Hopelessness has been defined as a state of negative expectancies about the future (Weishaar & Beck, 1992). As a construct and a risk factor for suicide, it has been most intensively studied by Aaron Beck and his colleagues. In Beck's studies, hopelessness has been found to be more strongly related to suicidal intent than depression for both suicide ideators and suicide attempters. In a study of depressed and non-depressed schizophrenic patients, it was found that even non-depressed patients who had high levels of hopelessness had high levels of suicidal intent. In prospective studies, hopelessness has been strongly supported as a risk factor for completed suicide (see, e.g., Beck, Brown, Berchick, Stewart, & Steer, 1990; Fawcett et al., 1987). Hopelessness may be a factor to consider with patients who are suffering from serious medical illness or multiple medical illnesses or who have been given bad news about prognosis.

Protective Factors

As mentioned earlier, protective factors, when present, attenuate risk and increase resilience. When one is assessing risk, they are important parts of the equation used to determine the level or degree of risk. Although the research on protective factors is less developed than research on risk factors, several factors have received some empirical support.

Family Relationships

Positive family relationships appear to offer significant protection against suicidal ideation and behavior. Being married or in a committed relationship and having children under age 18 living in the home have been found to reduce suicide risk (Lester, 1987; Fawcett et al., 1987). With adolescents in particular, family connectedness and cohesion have been found to be strong protective factors that lower the risk of suicidal

ideation and behavior (Resnick et al., 1997; Rubenstein, Heeren, Housman, Rubin, & Stechler, 1989).

Social Support Outside of the Family

Friendships have been found to be protective for both adults and adolescents. Also, there is some evidence that religious commitment or membership in a church or temple reduces the risk of suicide (Stack, 1994). While having a few close friends is important for adults, acceptance and integration into a social group or a sense of connectedness to school have been found to be protective against suicide in adolescents (Resnick et al., 1997; Rubenstein et al., 1989).

Reasons for Living

It seems intuitive that having a sense of purpose and meaning in life would be protective against suicide. Linehan, Goodstein, Nielsen, and Chiles (1983) developed a scale to assess reasons for living (e.g., responsibility toward family and children, moral objections to suicide, fears of social disapproval, and pain involved in suicide). Subsequent studies have supported the assertion that such reasons for living or beliefs differentiate individuals with and without suicidal ideation and serve as protective factors against suicidal behavior in adolescents and adults (Gutierrez et al., 2002; Jobes & Mann, 1999). Other studies have identified additional protective factors such as hopefulness, spiritual well-being, and employment (Stack, 2000).

MANAGING THE ACUTE RISK OF SUICIDE

Both the inpatient medical setting and the outpatient medical setting present challenges for managing suicide risk. In this regard, it can be helpful for the clinician to think not only in terms of distal and proximal risk factors, but also in terms of static and dynamic risk factors. Often, proximal risk factors are dynamic and changeable. If the clinician can intervene to improve dynamic risk factors and/or strengthen protective factors, he or she may lessen the risk level.

In the Medical Inpatient Setting

Physicians generally under-treat emotional or mental conditions in the medically ill. Yet, there is evidence from a Swedish study (Rutz, von Knorring, & Walinder, 1989) that educating physicians about the diagnosis and treatment of affective disorders can lead to a significant improvement in the identification and treatment of depression and to an apparent reduction in the suicide rate. Having a staff that is informed and aware that certain medical conditions have an elevated risk for suicide and that psychiatric patients with particular diagnoses can be at heightened risk is an excellent starting point for managing suicide risk in the inpatient and outpatient medical setting. Awareness can be heightened by in-service presentations from the psychiatry or mental health service. Beyond awareness, however, it is important to ask patients how they are coping emotionally with their medical problems. If a patient has been given bad news, for example,

a subsequent inquiry might include asking whether he or she is feeling discouraged, depressed, hopeless, or like giving up. Questions about thoughts of ending his or her life might follow.

If these inquiries reveal that the patient is having difficulty coping or has thoughts of wanting to end his or her life, a consultation with the psychiatry consultation/liaison (c/l) team should be initiated. The psychiatry c/l team will assess the patient's emotional and mental condition, including his or her level of suicide risk. If the patient were to be considered at imminent risk (i.e., might harm him- or herself in next few minutes, hours, or days), a "sitter" might be assigned to be with the patient at all times until the crisis has passed. The sitter, of course, would notify staff if the patient were to make efforts to actively harm him- or herself or if he or she were to attempt to leave the hospital. If the patient made active efforts at self-harm or elopement, leather restraints might be necessary to prevent self-destructive efforts. Sedating medication to calm an agitated patient can also be helpful. Staff need to be aware, however, that antidepressant medication can take weeks to have an effect on mood and will not provide any rapid relief for a patient during a short hospital stay.

Unfortunately, as noted earlier in this chapter, the patient who is not considered at imminent or acute risk in a medical setting is typically treated like any other medical patient. The psychiatry c/l team may continue to follow the patient with daily contacts or contacts every several days, but there are rarely other levels of observation for moderate levels of risk. Management is therefore dependent on the staff's continuing to stay in contact with the patient about his or her emotional state and remaining aware of any signs of deterioration and increased risk.

In the Medical Outpatient Setting

Numerous studies have found that a high percentage of patients who committed suicide had not necessarily visited an outpatient mental health provider prior to their death, but had visited their physician. Conwell (1997), for example, found that an average of 62% of a sample of elderly people who committed suicide saw a primary care provider within 30 days of death, and an average of 35.5% had done so within a week of death. Studies such as these led Murphy (1986) to refer to the physician's office as "the primary suicide prevention center" (p. 171).

As in the inpatient medical setting, having physicians and a staff in the outpatient setting who are aware and informed that certain medical conditions have an elevated risk for suicide and that psychiatric patients with particular diagnoses can be at heightened risk is crucial in terms of managing suicide risk. Questions about how the patient is coping with his or her illness and about any wishes to "give up or die" should be part of routine questioning during an outpatient visit. If a patient reports significant emotional distress, a referral for psychiatric or mental health follow-up can be made. If suicidal thoughts or intentions are reported, the patient can be seen more immediately by psychiatry or

mental health in the emergency department. There, it will be the mental health clinician's responsibility to determine whether the patient's risk is at a level that can be managed on an outpatient basis or whether psychiatric hospitalization is necessary.

The current clinical standard of care for patients who are at mild or moderate suicide risk is mental health outpatient follow-up with a plan outlining what the patient can do to maintain safety in the event that his or her risk increases. So, as Stanley and Brown (2011) have suggested, the clinician and the patient can collaborate on identifying warning signs of increasing risk and then identify coping strategies that the patient might employ to take his or her mind off of troubling situations. The plan might next involve identifying people whom the patient might contact because they might provide distraction. If these efforts fail, the patient might identify people whom he or she might trust to tell about the risk, or professionals and agencies that could be contacted if the risk seems significant.

In terms of therapy, there is evidence from several randomized controlled trials that cognitive-behavioral approaches that make suicidality the central focus of the therapy sessions can be effective in reducing suicidal behavior (Rudd, Joiner, Trotter, Williams, & Cordero, 2009). Cognitive-behavioral approaches emphasize the identifying and correcting of cognitive distortions about self and others, learning emotion-regulation skills, learning problem-solving skills, and learning interpersonal relationship skills. If risk nonetheless begins to increase, the mental health clinician has options that include: (1) increasing the frequency of visits or having interim telephone contacts; (2) arranging for 24-hour availability or coverage; (3) reevaluating the treatment plan, including the medication regimen; and (4) evaluating the patient for hospitalization. Hospitalization is typically necessary when the risk has become severe, when it is not possible to establish or reestablish a firm treatment alliance, when crisis intervention techniques fail, and when the patient continues to have intent to commit suicide in the immediate future (Comstock, 1992). Although there is no evidence that hospitalization ultimately prevents suicide, it does provide a safer environment during a period of heightened risk. Typically, one or two hours with a patient who maintains imminent suicidal intent are sufficient to persuade clinicians to hospitalize them, either on a voluntary basis (if the patient is cooperative) or, if necessary, on an involuntary temporary commitment.

Clinical experience indicates there are times when involuntary hospitalization can damage the patient-clinician relationship. This damage can often be repaired once the patient has become more emotionally stable. It may also be possible to lessen the risk of such damage if the patient has been informed early in the treatment relationship that there are limits to confidentiality and that, if the patient is considered to be at imminent risk of seriously harming himself or herself or others, the clinician is ethically and legally obligated to break confidentiality to protect the patient or others who may be at risk from the patient.

THE EVALUATION AND MANAGEMENT OF VIOLENCE RISK IN A MEDICAL SETTING

MEDICAL ILLNESS AND RISK FOR VIOLENCE

There has been little systematic investigation of whether medical illness in general might be an independent risk factor for violence. There has been relatively strong interest, however, in the neurobiological bases of aggression and violence and in the associations of certain neurological conditions with risk for violence. Thus, considerable research has converged on the importance of brain circuitry involving activation of the limbic system (e.g., hippocampus and amygdala), and the regulating influence of the frontal lobes and particularly the prefrontal cortex (PFC) in aggressive behavior (Denson, 2011). This circuitry involves the interaction of the so-called phylogenetically older, reflexive parts of the brain that we share with other animals, and the newer parts of the brain that are unique to humans and that help them function more reflectively.

It should also be noted that the neurotransmitter serotonin has been found to facilitate the functioning of PFC regions, and depletion of serotonin has been associated with violent and impulsive acts. On the other hand, the selective serotonin-reuptake inhibitors (or SSRIs) that are typically prescribed for depression have been found to reduce impulsive aggression in personality-disordered subjects (Coccaro & Kavoussi, 1997). As a result, there has also been great interest in the role of serotonin in the functioning of the brain circuitry mentioned above.

In terms of neurological conditions associated with violence, a prospective study of patients with traumatic brain injury (TBI) found that aggressive or violent behavior was significantly more frequent among patients with TBI than among a comparable group of patients with traumatic injury that did not involve the brain (Tateno, Jorge, & Robinson, 2003). More specifically, and consistent with previously cited research, such behavior was associated with injuries to the frontal lobes and/or the prefrontal cortex as well as with depression, substance abuse, and impaired social functioning. The authors concluded that aggression following TBI was associated with multiple biological and psychosocial factors including the presence of frontal lobe impairment. Also, in a retrospective study known as the Vietnam Head Injury Study (VHIS) (Grafman et al., 1996), veterans with lesions limited to the frontal lobes were found to show more aggressive and violent behaviors than veterans with non-frontal head injuries and controls without head injury. Moreover, there have been multiple neuropsychological and neuroimaging studies (as reviewed by Bowser & Price, 2001) pointing to a strong association between increased aggression and impaired prefrontal cortical activity in TBI patients relative to control subjects.

Several primary progressive dementing disorders also affect the frontal lobes (White, Kregel, & Thompson, 2009). These disorders include Pick's disease and fronto-temporal dementia. The primary presentation of these diseases typically involves a loss of behavioral control. These patients

become irritable and unable to inhibit aggressive acts that they were able to inhibit premorbidly. In a study contrasting patients with fronto-temporal dementia with patients with Alzheimer's dementia, Miller, Darby, Benson, Cummings, and Miller (1997) found that patients with fronto-temporal dementia were significantly more likely to have exhibited antisocial behaviors such as assault, indecent exposure, and shoplifting than were Alzheimer's patients. In similar fashion, an increased risk of aggression or violence has been found with other neurological conditions such as cerebrovascular disease (multi-infarct dementia) and multiple sclerosis when there are lesions or demyelination involving the frontal lobes.

Findings such as those above comparing fronto-temporal dementia patients and Alzheimer's patients do not necessarily imply that those with Alzheimer's dementia are free of aggressive or violent behaviors. O'Leary, Jyringi, and Sedler (2005) evaluated 198 elderly patients with dementia related to Alzheimer's disease. They found that compared to elderly patients without dementia, those with dementia had displayed significantly higher levels of physical aggression against their partners. Twenty-five percent of Alzheimer's patients had engaged in physical aggression against their caregivers in the past year, and 33% had engaged in an act of physical aggression against any individual in the past two weeks. Dementia severity affected the frequency of aggressive acts, with acts of physical aggression more likely to occur in later than in earlier stages of the disease process. Physical aggression was related to agitation and most often included hitting, throwing, and grabbing.

Psychotic symptoms in Alzheimer's patients may also lead to aggression. In their review of research, Shub, Ball, Abbas, Gottumukkala, and Kunik (2010) found that eight out of nine studies (including both cross-sectional and longitudinal studies) showed a significant association between psychosis and aggression. For example, in a study of 771 patients with Alzheimer's disease, Mizrahi et al. (2006) found delusions to be significantly associated with overt aggression and agitation. Likewise, in their study of 194 dementia patients, Petrov et al. (2007) found that psychosis was significantly related to agitation, irritability, hallucinations, and anxiety. Treatment studies, however, have had more mixed results, and Shub et al. (2010) have noted that there is a need for prospective studies to confirm a stronger causal link between psychosis and aggression in dementia patients.

Huntington's chorea, the rare autosomal dominant genetic disease with increased suicide risk, is another neurological disorder that is associated with a heightened risk of violence. Huntington's patients seem to have difficulty inhibiting impulsive behavior. As noted by White et al. (2009), there is a great deal of evidence of antisocial behavior among Huntington's disease patients, including physical assaults and child abuse. There is controversy, however, about the degree to which these aggressive behaviors are a function of the neuropathology of the disease and/or the social effects of being in a family that must live with the specter of such a debilitating and incurable condition.

Of course, there are various metabolic disturbances that can cause delirium, the acute brain syndrome that can also

lead to agitation and violence. The delirious patient is typically disoriented and confused and may experience perceptual distortions or frank hallucinations. Delirium is typically reversible, so the initial efforts are focused on determining the cause and treating it before there is more serious damage. The immediate management of the delirious patient is behavioral and environmental and is aimed at keeping the patient and others safe, while not obscuring the clinical presentation.

EVALUATING FOR THE ACUTE RISK OF VIOLENCE

In this subsection, we propose that the clinician use the same process of weighing distal risk factors, proximal risk factors, and protective factors as proposed earlier for the evaluation of suicide risk, but apply it to the evaluation of violence risk (Kleespies & Hill, 2011). Of course, those who work in a medical setting should also consider the medical illnesses with associated risk of violence (as noted above) in any effort to weigh the level of risk. If time is available, there are several decision-support tools that can be utilized in assessing for risk of violence. These tools are not psychological tests, but were constructed in the framework known as “structured professional judgement.” The items included in these instruments were typically expert-generated. Several of them that have good reliability and predictive validity are the *Historical-Clinical-Risk Management–20* (HCR-20; Webster, Douglas, Eaves, & Hart, 1997), the *Structured Assessment of Violence Risk in Youth* (SAVRY; Borum, Bartel, & Forth, 2006), and the *Spousal Assault Risk Assessment Guide* (SARA; Kropp, Hart, Webster, & Eaves, 2008).

Distal Risk Factors

Demographic Factors

It is well known that adolescents and young adults have higher rates of violence, but, as noted in the section on specific medical illnesses and associated violence, elderly patients who suffer from dementia also have an increased rate of violence. It is also well known that, in the general population, men are far more likely to be violent than women (U.S. Bureau of Justice Statistics, 2010). Women with acute mental illness, however, have been found to be as likely as men with acute mental illness to become violent; but men with mental illness remain more likely to engage in more serious forms of violence (Monahan et al., 2001). Race or ethnicity has not been found to be a strong predictor of violence when socioeconomic level is controlled. Lower socioeconomic level itself, however, has been associated with increased risk (Swanson, Holzer, Ganju, & Jono, 1990).

Serious Mental Illness

Although having a major mental illness is a risk factor for violence, it is important to note that most violence in our society is not committed by the mentally ill (Fazel & Grann, 2006). We need to be careful not to “demonize” the mentally ill as extremely violent. As is the case with risk for suicide, however, certain mental illnesses are both distal and proximal risk

factors for violence. These include schizophrenia, schizoaffective disorder, bipolar disorder, and major depression (McNiel, Gregory, Lam, Binder, & Sullivan, 2003). In addition, military veterans with PTSD, and especially those with a history of war zone violence (Hiley-Young, Blake, Abueg, Rozyrko, & Gusman, 1995), have been found to be at increased risk.

Personality disorders that are marked by impulsivity and poor behavioral control (e.g., antisocial personality disorder and borderline personality disorder) have also been associated with violent behavior. In adolescents, conduct disorders as well as attention-deficit and hyperactivity disorders (ADHD) are at elevated risk of violence (Saterfield & Schell, 1997).

Historical and Dispositional Factors

It is widely known that the best predictor of future violence is a history of violent behavior. The risk level of future violence increases, however, when there has been an early onset of violent and aggressive behavior in the person's life. If children have engaged in violent acts or delinquent behavior before age 12, they are more likely to engage in violent and criminal activities over the course of their lifespan (Tolan & Thomas, 1995). In general, the greater the number of violent acts, the greater the likelihood of future violence (Borum, 2000).

Childhood maltreatment, physical abuse, and exposure to violence between parents increases the risk of perpetration of violence in adulthood (Ehrensaft et al., 2003). Such experiences are thought to model, reward, or reinforce the use and display of violence.

There is a constellation of affective, interpersonal, and behavioral characteristics, referred to as *psychopathy*, that has been found to be a clear risk factor for violence (see, e.g., Forth, Hart, & Hare, 1990). “Psychopathy” is said to refer to characteristics that include “egocentricity; impulsivity; irresponsibility; shallow emotions; lack of empathy, guilt, or remorse; [and] manipulateness” (Hare, 1998; p. 188). Hare (1991) developed a 20-item measure of the concept entitled the *Hare Psychopathy Checklist—Revised* (or *PCL-R*). The *PCL-R* has been found to be a good predictor of violence in diverse populations, including schizophrenic and personality disordered individuals (Harris, Rice, & Quinsey, 1993). Psychopathy is considered a static risk factor since treatment has not been effective in making substantial changes in psychopathic individuals.

Proximal Risk Factors

Acute Mental Illness and Substance Abuse

McNiel et al. (2003) have noted that schizophrenic patients are most at risk for violence when they are having a psychotic episode, and bipolar patients are most at risk when they are having a manic episode. In a hospital setting, manic patients often exhibit behavior that requires limit setting, but it is important to remember that manic patients often react with aggression to efforts at containment and limit-setting.

Active substance use significantly increases the risk of violence when it co-occurs in persons with serious mental illness. Swanson (1994), for example, studied mental illness, substance abuse, and community violence in a sample of

10,000 people. He found that mental disorder alone was twice as likely to be present in violent individuals as in those who were non-violent. He also found that substance abuse alone and in combination with comorbid mental illness was five times as likely to be present in the violent as opposed to the non-violent group.

Clinical Symptoms as Proximal Risk Factors

McNiel (1998, 2009) has noted that certain clinical symptoms can be used to estimate short-term risk for violence. McNiel and Binder (1994) studied a sample of decompensating patients at the time of admission to a psychiatric unit. They found that symptoms described as hostile-suspiciousness, agitation-excitement, and disturbed thinking (unusual thought content/hallucinations) were associated with aggressive behavior in the first hours or days after admission. In a similar vein, Link and Steuve (1994) identified a delusional state that they referred to as *threat/control override*. The term refers to a delusional state in which the person feels personally threatened to the point that he or she feels justified in overriding self-control to eliminate the threat. Beliefs such as these have been found to predict violent behavior by male patients (Teasdale, Silver, & Monahan, 2006). Finally, an acute risk of violence has been found with *command hallucinations*; that is, a *voice* telling the patient to harm or kill someone else. The risk is heightened further if the command is consistent with a delusional belief (e.g., a patient who hears a voice telling him to attack a supervisor whom he believes is a member of a devil-worshipping cult) (Monahan et al., 2001).

Situational or Contextual Factors

Family members of patients with major mental illness and violent behavior are at high risk. Straznickas, McNiel, and Binder (1993) evaluated 113 acute psychiatric patients admitted after a violent event. They found that 56% of the patients had assaulted a family member. Moreover, it has long been known that mothers who live with adult children who have schizophrenia have an increased risk of violent victimization (Estroff, Swanson, Lachiotte, Swartz, & Bolduc, 1998).

Despite the fact that we do not have good empirical evidence on female-to-male violence (Riggs, Caulfield, & Fair, 2009), Resnick, Acierno, Holmes, Dammeyer, & Kilpatrick (2000) have noted that female victims of rape, who fear being harmed again or who have feelings of anger and fear, have been known to express homicidal thoughts. These researchers recommend that their feelings of anger and fear be validated and that their risk of retaliating with violence be assessed.

Although there is little empirical evidence linking weapon availability and risk for violence in individual cases, it is clear that most homicides in the United States are by firearm (U.S. Department of Justice Statistics, 2010). Moreover, higher rates of gun-related violence have been reported in locales with greater access to guns (Kaplan & Gelig, 1998). It seems reasonable to assume that those who have ready access to weapons, if they become violent, are at greater risk of engaging in more serious forms of violence.

Protective Factors

Research on protective factors for risk of violence is even less developed than that for risk of suicide. There has been an effort to examine treatments that might reduce violence risk (Monahan & Applebaum, 1999), but there has been little emphasis on “personal strengths, resources, and protective or ‘buffer’ factors” (Hart, 2001, p. 21). Good personal and family support and involvement in a treatment or support program have been viewed as protective factors (Estroff & Zimmer, 1994). Some studies have noted factors that are, in essence, the reverse of known risk factors and therefore might reduce risk. For example, it has been reported that non-abusive men were less likely to have experienced violence during childhood, to have attitudes tolerant of spouse abuse, or to engage in impulsive behaviors (Hanson, Cadsey, Harris, & LaLonde, 1997). Clearly, however, further research on protective factors is needed and might improve the specificity of who is less likely to engage in violence.

MANAGING THE ACUTE RISK OF VIOLENCE

As with managing suicide risk, there are differences in how patients who are at risk for violence can be managed in the inpatient medical setting versus the outpatient medical setting.

In the Medical Inpatient Setting

In providing medical treatment for a patient who, by virtue of his or her medical condition or by virtue of a preexisting mental illness, poses a possible risk of violence, treatment providers would benefit from an awareness of certain verbal and behavioral signs of potential loss of control. Aggressive verbal statements or threats should be taken seriously. Clinical experience, however, has informed us that observing certain behavioral signs can also be important. These include: (1) psychomotor restlessness such as pacing, fidgeting, clenching fists, startle response, grinding teeth, or inability to sit or lie down; (2) affective and facial changes which may reflect either hostility, fear, or paranoia; and (3) the tone and loudness of the patient's speech.

If a patient seems hostile, agitated, or tense, initial empathic comments about his or her apparent distress should allow the staff member to observe how the patient responds. If he or she is able to verbalize what the issue(s) may be, it might be possible to de-escalate a potential crisis by discussing an immediate problem and finding an acceptable solution. It may also be the beginning of a working alliance. If the patient is not responsive to verbal efforts to reduce tension, however, a consultation with the psychiatry consult/liaison team should be initiated. As in cases of suicide risk, the psychiatry team will assess the patient's emotional and mental condition, including his or her level of risk for violence. If the level of immediate risk is considered mild or moderate, the psychiatry team might recommend the initiation of, or the addition of, a psychotropic medication to calm the patient. A sitter might be assigned if needed or helpful, and psychiatry could continue

to follow the patient on a daily basis, as needed, until the crisis is resolved and the patient is in better behavioral control.

If these efforts at intervention fail, however, and the patient continues to escalate or is at risk of losing behavioral control, there is typically a psychiatric emergency code team that can be called. At times, such a “show of force” (which includes members from the facility police or security service) helps the patient realize that, in the interests of the safety of others, there are limits to what behavior can be tolerated. If the patient continues to be agitated and is in marginal control, he or she can be offered medication. For short-term control of agitation and potentially violent behavior, benzodiazepines and anti-psychotics have been the medications of choice. Although benzodiazepines have sometimes been reported to increase aggressive behavior, it is a relatively rare phenomenon, and, far more typically, they have a sedating effect. If a patient is already prescribed an antipsychotic medication, more of the same can be offered. Otherwise, haloperidol (i.e., Haldol) 5 mg by mouth or intramuscularly, as well as a benzodiazepine such as lorazepam (i.e., Ativan) 1 to 2 mg by mouth or intramuscularly, is customary for an initial trial. Individually, these medications are both sedating within 30 minutes. When both of these medications are administered sequentially to a patient, the sedative effects are significantly augmented. So for female, young, and elderly patients, administering haloperidol or lorazepam as a single sedating agent may be sufficient. Alternatively, a clinician could also administer lower doses of each agent—for example, haloperidol 2 mg and lorazepam 0.5 to 1.0 mg—to achieve a comfortable sedative effect. For a robust adult male patient, doses may range from haloperidol 5 to 10 mg and lorazepam 1 to 2 mg to achieve a calming effect. Clinicians should be careful when administering sedating medication to patients who may have recently ingested or injected medications that have depressing central nervous system properties. The above dosages can be repeated in 30 to 60 minutes if the patient’s agitation persists. Bzotropine (i.e., Cogentin) is sometimes added as a prophylactic against dystonias and extrapyramidal side effects. Cardiac irregularities or changes in heart rhythm can also be a rare side effect of haloperidol.

Haloperidol and lorazepam are medications that have the advantage of being readily available and familiar to emergency psychiatry personnel. The risk of extrapyramidal side effects decreases dramatically after age 40, so the use of an atypical antipsychotic or of benzotropine prophylaxis is indicated only for younger patients. It is recommended that patients with liver disease be given lorazepam or oxazepam as the benzodiazepines of choice because they metabolize quickly and are eliminated by the kidneys (Saitz, Ciraulo, Shader, & Ciraulo, 2003). It is noteworthy that benzodiazepines such as lorazepam tend to be less effective for those who have developed a tolerance for them. Since both benzodiazepines and alcohol work on the same neural receptors, a tolerance can develop through excessive use of the medication or through excessive use of alcohol.

One of the most serious and life-threatening side effects of rapid administration of a neuroleptic medication is

neuroleptic malignant syndrome (NMS). It is an uncommon disorder, with an incidence of less than 1.0%, but it can be fatal. The signs of NMS include fever, muscle rigidity, autonomic instability, and an elevated white blood cell count and creatine kinase level. Treatment involves discontinuation of all neuroleptic medication. Acute admission to an intensive care unit (ICU) is recommended for full life-supportive measures. Should a patient have a history of NMS, employing lorazepam and the avoidance of acute administration of a neuroleptic may be wise.

Studies have found that beta-blockers help diminish aggressive behavior, particularly in patients with dementia, brain injuries, and mental retardation. The anti-aggressive effects of beta-blockers, however, usually occur four to eight weeks after the effective dose is reached, and they are not particularly helpful under emergency conditions. Lithium is the medication most likely to control aggression in the long run, but, again, it is not useful in circumstances that call for rapid action to reduce acute behavioral risk. Patients must be carefully educated about the potential side effects of any medication employed, and clinicians should try to select a medication with a side-effect profile compatible with a patient’s lifestyle to increase the likelihood of compliance.

If the patient will not voluntarily accept medication and/or continues to be agitated and threatening, or actually loses control, it may be necessary to consider more restrictive measures as a humane response to a situation that could otherwise lead to serious injury. Of course, patients have a legal and ethical right to refuse care. There are, however, exceptions to this rule, including patients who lack competency and/or patients who are at acute risk to harm themselves or others. The clinician in these life-threatening situations needs to employ and document the least restrictive but effective means available to help the patient regain composure. In the process, the clinician needs to be cognizant of state laws regarding the use of physical restraints and forced medication. Restraints, in most states but not all, are seen as less restrictive than forced medications. It is also difficult and potentially dangerous to administer intramuscular injections to an aggressive and unrestrained patient. A patient who has met criteria for physical restraints, however, does not necessarily or automatically meet criteria for forced medication. If the patient is still at demonstrable risk for harm to self or others while in restraints, the clinician may then force medication.

The physical restraint of an aggressive or agitated patient involves some risk to both patient and staff and should not be undertaken unless there is no good alternative. While some patients are cooperative with the restraint procedure, many are not. A sufficient number of staff is needed to manage a resistant patient; that is, one trained person to control each limb and one to protect and control the head. A sixth person should be available to coordinate the procedure and talk with the patient. Vital signs and agitation may increase for the first few minutes after a patient is placed in restraints. The positioning of the patient should be given some consideration, particularly for those who have been traumatized by violence or abuse in the past. Most patients are restrained in

the face-up position, but those who have experienced sexual trauma may become more agitated by being placed in such a vulnerable position. For these patients, restraint while lying on their side may be preferred.

After a patient is restrained, a staff member needs to sit with the patient to monitor his or her emotional and physical condition. Legal requirements and hospital policies can vary by state and by whether the patient is an adult or under 18 years of age; however, guidelines generally require that leather restraints be checked every 15 minutes to ensure that there is no interference with circulation. Unless it is unsafe to do so, each limb is to be removed from restraint for exercise once per hour. Restraint and the establishment of control have a calming effect on some patients. Others, however, may continue to be agitated or become more agitated. In such cases, and as noted above, it may be necessary to use medication to ease the patient's distress and help him or her to regain self-control. Restraints should be maintained for the minimum time necessary for this process to occur.

It is important for clinicians to be aware that coercing a patient to take medications ("If you don't take any medication, we will have to hospitalize you") is not ethical and could constitute an inappropriate use of involuntary medication. In an emergency situation, the clinician needs to apprise his or her patient of the consequences of their noncompliance, but the line between patient education and coercion can get blurred. If a physically restrained patient requires involuntary medication, it is important to continue to try to elicit his or her cooperation and select the least invasive and traumatic means to administer medication. Thus, the clinician should offer oral medications over injections. If the patient refuses oral medication, asking in which arm the patient would want the injection still provides him or her with some choice. Informing the patient that he or she will get an injection if they do not cooperate and take oral medication, depending on the tone of voice and manner of the clinician, could be perceived as crossing the line from patient education and voluntary medication into coercion and involuntary medication.

While oral and intramuscular medications are common in emergency situations, intravenous medications are not common. Intravenous administration of sedating medication has a rapid onset, which can approximate general anesthesia with all its inherent risks for respiratory and cardiac complications. There are exceptions, particularly in intensive care units when intravenous lines are already established and the patient's vital signs are already being electronically monitored by experienced critical care personnel who are equipped to deal with any adverse respiratory or cardiac sequelae.

Of course, in circumstances where physical restraints and forced medication are utilized, it is crucial for clinicians to document the facts in the chart, and his or her rationale in a risk-benefit note. This documentation should include clinical examples that clearly demonstrate how less-invasive techniques, including physical restraints, failed to contain the patient's behavior, and why involuntary medication was required.

In the Medical Outpatient Setting

If a medical outpatient makes threats or exhibits threatening behavior to staff, a psychiatric emergency code team can be called, as one might do in the inpatient setting. If the patient, however, makes comments or threats that indicate that he or she may be at serious risk to harm others in the community, the patient should be escorted to the hospital emergency department (ED) for evaluation by the mental health clinician on duty. If the patient were to refuse to go to the ED, the code team could be called to assess whether the patient should be escorted to the ED involuntarily for evaluation in a safer setting.

Depending on the estimated level of risk, Monahan (1993) has suggested three types of intervention for managing the patient at risk to others: (1) intensifying treatment; (2) hardening the target; and (3) incapacitation of the patient. If the patient is evaluated and does not appear to pose an imminent risk of violence, it may be possible to initiate follow-up mental health treatment, or intensify an ongoing treatment, as a way of managing risk in the community. Thus, the patient could be scheduled for therapy sessions that are more frequent than usual. He or she could have telephone safety checks, be asked to enter a more structured outpatient or partial hospitalization program, or be asked to enter a substance abuse treatment program (if needed). Medication that might reduce agitation or modulate mood could be considered or increased. A plan for 24-hour emergency coverage should also be developed, and there should be frequent reassessments of the level of risk. The focus of therapy sessions should be on developing strategies to reduce the likelihood of violence: for example, increasing insight, anger-management techniques, increasing frustration tolerance, improving affect regulation, and so forth.

If the patient were to elope from the medical setting without a plan for managing risk, it might be necessary to warn any intended victims and complete a temporary involuntary commitment form so that the local or state police might locate the patient and bring him or her to an emergency room for further evaluation. Warning the intended victim has become known as "hardening the target." In the case of the intended victim, this makes it possible for him or her to take protective measures. After the Tarasoff case in California, warning the intended victim became known to clinicians as the "duty to warn" (*Tarasoff v. Regents of University of California*, 1974). The California court, however, reviewed the case two years later and revised its opinion to what has now become known as the "duty to protect" (*Tarasoff v. Regents of University of California*, 1976). In effect, the Court's revised opinion was that therapists do have a duty to protect the intended victim or victims of their patients, and there are several ways to do so. Warning the individual in question may be one way, but it is not the only way or, depending on circumstances, necessarily the best way.

Borum (2009) has noted that warning the intended victim can be frightening to the individual and should be reserved for times when other interventions have been rejected by the patient or are not feasible. If a warning is given, his advice is that the clinician be careful in reviewing

the nature and seriousness of the threat, and then work with the individual to find sources of assistance and develop protective measures.

If a patient is evaluated and is considered to be a serious threat to others, it may be necessary to incapacitate the patient. Incapacitating the patient means utilizing measures that directly decrease the person's ability to act out in a violent manner. These measures can include involuntary hospitalization, the administration of sedating medication against the wishes of the patient, and physical restraints or seclusion. These are obviously very intrusive interventions and should be used only in situations where the danger of serious harm is great and less restrictive means have failed or are likely to be ineffective. As noted above in the discussion of restraints, the use of these means is typically regulated by law and institutional or agency policy. Their use is sometimes necessary to avoid a worse alternative (i.e., serious harm or death of an intended victim). They are not a solution to the longer-term risk of violence, but prevent immediate harm. They may also allow for a diagnostic evaluation and the initiation of treatment that may have longer lasting benefit.

SUMMARY

In the medical setting, the clinician must weigh the possible contributions of both mental illness and medical illness when assessing and managing the risk of suicide or the risk of violence. It is also important to note that the vulnerability to becoming suicidal and the vulnerability to becoming violent may not be entirely independent. Research has indicated that those who had a history of violence were at increased risk of suicidal behavior, and that rates of lifetime aggression and impulsivity were significantly greater in suicide attempters than in those who had never attempted suicide (Mann, Waternaux, Haas, & Malone, 1999). Thus, when evaluating a patient for risk of violence, the clinician may be well advised to also consider the possibility of risk of suicide, and vice versa.

Finally, in evaluating a patient for risk of suicide or risk of violence, the importance of practicing good risk-management practices should not go unnoted. First and foremost, good risk management includes documentation and consultation. Documentation should focus on statements that reflect that a risk-benefit analysis was done in arriving at a rationale for case decisions; while seeking the consultation of a colleague is one of the better ways to meet the community standard for working with a high-risk patient.

CLINICAL PEARLS

- Physical illness is a significant, independent risk factor for suicide in the elderly. In the study by Conwell et al. (2010) it was also found that perception of deteriorating health status and functional impairment were significant risk factors, with functional impairment being the more robust predictor of suicide.
- There is considerable evidence of a familial and a probable genetic contribution to the risk of suicide (Brent, Bridge, Johnson, & Connolly, 1996; Mann & Arango, 1999; Moscicki, 1997; Roy, Nielsen, Rylander, & Sarchiapone, 2000). Most investigators, however, continue to agree that suicide is a multi-determined act, with psychological, social, and biological factors involved.
- For male schizophrenic patients under age 40, the risk of suicide is higher when these patients are not acutely psychotic, have a heightened awareness of the debilitating effects of their illness, and become depressed.
- Suicide among patients with alcohol problems is generally more likely in mid-life and following a prolonged history of alcohol abuse and dependence. It is most likely to occur during an active phase of drinking.
- In prospective studies, hopelessness has been strongly supported as a risk factor for completed suicide (see, e.g., Beck, Brown, Berchick, Stewart, & Steer, 1990; Fawcett et al., 1987).
- The best predictor of future violence is a history of violent behavior. The risk level of future violence is increased, however, when there has been an early onset of violent and aggressive behavior in the person's life.
- Schizophrenic patients are most at risk for violence when they are having a psychotic episode, and bipolar patients are most at risk when they are having a manic episode.
- Certain behavioral signs can also be important signs of impending violent behavior: (1) psychomotor restlessness such as pacing, fidgeting, clenching fists, startle response, grinding teeth, or inability to sit or lie down; (2) affective and facial changes that may reflect either hostility, fear, or paranoia; and (3) the tone and loudness of the patient's speech.
- A patient who has met criteria for physical restraints does not necessarily or automatically meet criteria for forced medication.
- Coercing a patient to take medications ("If you don't take any medication, we will have to hospitalize you") is not ethical and could constitute an inappropriate use of involuntary medication.
- Depending on the estimated level of risk of violence, Monahan (1993) has suggested three types of intervention for managing the patient at risk to others: (1) intensifying treatment; (2) "hardening the target" (warning/protecting an identified victim); and (3) incapacitation of the patient.
- Those who had a history of violence were at increased risk of suicidal behavior, and rates of lifetime aggression and impulsivity were significantly greater in suicide attempters than in those who had never attempted suicide (Mann, Waternaux, Haas, & Malone, 1999).

DISCLOSURE STATEMENTS

Dr. Kleespies, Dr. Hughes, Dr. Weintraub, and Dr. Hart do not have any conflicts of interest to disclose.

PERSONALITY DISORDERS IN THE MEDICAL SETTING

Barry S. Fogel

INTRODUCTION

Medical psychiatrists have long been interested in the impact of personality disorders and personality traits on physician–patient relationships, patients’ behavior in general medical settings, and patients’ adherence to medical treatment recommendations. Fifty years ago, Ralph Kahana and Grete Bibring (1964), psychoanalysts who consulted in a general hospital, described prototypes of different personality styles (e.g., hysterical and compulsive) and suggested how treatment instructions could be adapted to the patient’s personality to promote treatment adherence. Their classic article illustrated the fundamental principle of customizing the details of treatment to respect individual differences in personality.

This chapter offers a contemporary perspective on the medical-psychiatric implications of personality issues. It takes account of the current context of medical-psychiatric practice. Specifically:

1. Accepted diagnostic practice combines categorical and dimensional views of personality pathology;
2. Questionnaire-based personality tests are ubiquitous;
3. Epidemiological studies have established the very high prevalence of personality disorders in several of the most common medical-psychiatric conditions;
4. Specific pharmacological and non-pharmacological therapies for borderline personality disorder are supported by high-level evidence;
5. Nonspecific effects of medical treatment—e.g., positive and negative placebo effects—are receiving renewed scientific interest;
6. Subjective and functional outcomes of medical care, including patient satisfaction, are regularly measured and utilized by healthcare systems; and
7. Boundary issues and obligations of physicians to their patients, always important ethical concerns, have become conspicuous legal issues as well.

ALTERNATE WAYS TO DESCRIBE PERSONALITY

Personality traits and personality disorders can be described in various ways that have different uses and different limitations. The clinical context suggests the perspectives on personality that are likely to be the most useful. The medical psychiatrist can make a valuable contribution to a case by choosing the best perspective to apply to the presenting problem. Diagnostic nomenclature will follow from the choice of perspective. Alternative perspectives comprise the following: *categorical, dimensional, mechanistic, typological, and based on analysis of defenses*.

CATEGORICAL PERSPECTIVE

In the categorical perspective, a patient is assigned or not assigned to a diagnostic category, such as *Borderline Personality Disorder*. This binary decision is based on whether the patient meets a sufficient number of criteria related to his or her history, behavior, and mental status. Maladaptive personality traits not meeting a sufficient number of criteria for a particular personality disorder can still be conceptualized categorically by describing them as “sub-syndromal” for the personality disorder(s) for which they almost meet criteria.

Advantages of the categorical perspective for medical-psychiatric usage include:

- Wide recognition of certain categorical diagnoses within the medical profession, even outside of psychiatry, including such diagnoses as borderline personality and antisocial personality (psychopathy). Using these diagnoses, a consulting psychiatrist can communicate a great deal in a few words.
- Extensive epidemiological literature on comorbidity of specific personality disorders with specific Axis I conditions and specific general medical disorders.
- Evidence that Axis II comorbidity—expressed in categorical terms—can help predict prognosis and treatment outcome of Axis I conditions, as well as the occurrence of

specific salient outcomes like suicide attempts or violence against others.

- Evidence for efficacy of specific pharmacological and non-pharmacological treatments for symptoms of borderline personality disorder, a condition relatively common in the general medical population, and one that is especially likely to disrupt medical treatment or worsen its outcome.

The primary drawback of a categorical diagnosis of personality disorders in the medical-psychiatric context is the lack of reliability and stability of categorical diagnoses made in the face of acute illness on Axis I and/or Axis III. Trauma, pain, loss, and emotional reactions to them, like depression and anxiety, can transiently worsen maladaptive personality traits and/or evoke conspicuous misbehavior, pushing a patient “over the line” to meet categorical diagnostic criteria. This problem can be mitigated by making categorical personality disorder diagnoses based on assessment when a patient is not acutely ill and by utilizing collateral data on the patient’s premorbid personality and behavior.

DIMENSIONAL PERSPECTIVE

In the dimensional perspective, a patient is described according to a set of personality dimensions that are applicable to normal people as well as to patients with personality pathology. A patient can be diagnosed as having a personality disorder or problematic personality traits when a statistically abnormal pattern of personality dimensions is combined with emotional distress and/or functional impairment. The five-factor dimensional description of personality promoted by Paul Costa and Robert McCrae (McCrae & Costa, 2010) is probably the most widely known dimensional scheme. The five factors are Extraversion-Introversion, Neuroticism, Openness, Conscientiousness, and Agreeableness. Advantages of the dimensional approach include:

- Stability of personality dimensions over decades of life, without flipping across binary categorical boundaries, even in the face of anxiety or depression and stressful life events. When a patient shows a major change in a personality dimension, the clinician should suspect brain disease, drug effects, or extraordinary circumstances.
- Applicability to improving physicians’ understanding of individual differences among their patients, including the majority who do not have any personality disorder diagnosis.
- Face validity of the personality factors, which can be easily understood by patients as well as healthcare professionals, and which are not in themselves associated with stigma.
- Free online resources for assessment and for patient education.

The five-factor characterization of personality can help the medical psychiatrist match patients with treatments and with

treatment providers. A patient with above-average scores on extraversion and openness is more likely to do well in a patient support group than one with below-average scores on those dimensions. Knowing a patient is low on the conscientiousness and agreeableness dimensions might guide a clinician to refer the patient to a competent medical specialist who is patient and tolerant, rather than another who is highly rated but arrogant and very busy. The best medical advice can be ineffective if it is not followed.

The principal drawback of the dimensional perspective is that it is not categorical, so it does not easily fit into clinical diagnostic practices and the conventions of coding and reimbursement. Furthermore, evidence on comorbidity, prognosis, and treatment outcomes is usually not organized dimensionally. Knowledge of a dimensional personality profile complements knowledge of a personality disorder diagnosis or its absence, but it does not substitute for it.

MECHANISTIC PERSPECTIVE

The mechanistic perspective on personality is a variant of the dimensional perspective that emphasizes underlying relationships of personality traits to neurochemical or neuroanatomical systems. A widely known mechanistic perspective on personality is the one expounded by Robert Cloninger and his colleagues (Cloninger et al., 1993). It identifies four temperamental dimensions: novelty seeking, harm avoidance, reward dependence, and persistence; and three characterological dimensions: self-directedness, cooperativeness, and self-transcendence. In Cloninger’s theory, the four fundamental dimensions of temperament are based on individual differences in neurotransmission and the function of brain circuits. Novelty seeking is associated with dopamine, harm avoidance with serotonin, and reward dependence with norepinephrine. Persistence is associated with the functioning of the frontal executive systems. The seven dimensions of personality described by Cloninger are measured by a 240-item self-rated questionnaire comprising true-false items, the Temperament and Character Inventory (TCI) (Cloninger, 1994).

A particular value of the mechanistic approach is that it enables the linkage of neuropsychiatric conditions with personality change. Three examples illustrate the point:

1. Novelty seeking is related to low dopamine. A patient with Parkinson’s disease (PD) progressively loses dopaminergic function, so might be expected to show an increase in impulsive behavior to the extent his or her motor function permitted it. In fact, patients with PD can develop sexual impulsivity, compulsive gambling, and other impulse-control disorders when treatment of the motor disorder enables them to act on their impulses. Another example is the association of major depression with harm avoidance.
2. Patients with major depression can show an increase in harm avoidance that reverts to normal when the patient’s depression is successfully treated. This makes sense if the patients’ major depression is linked to disruption of serotonergic transmission and is relieved by treatment with a selective serotonin reuptake inhibitor (SSRI).

3. Persistence (effective goal-directedness) is associated with good functioning of frontal executive systems. Patients with early frontotemporal dementia can display a personality change manifested by failing to follow through on plans, keep their word, and honor obligations.

The characterological dimensions of Cloninger's system have neuroanatomical correlates demonstrable on quantitative brain imaging, but there is a less developed understanding of their relationships to specific brain circuits and transmitters than there is for the temperamental dimensions. All three dimensions are positively correlated with better physical and mental health and with better ability to cope with adversity (resilience). Knowing these dimensions can help a clinician assess a patients' vulnerability to developing mental disorders in the face of illness or trauma, and the personal assets they might have to help cope with their current adversity.

TYPOLOGICAL PERSPECTIVE

Typological approaches are hybrids of the dimensional and categorical approaches to personality. They focus more on normal variations than on personality pathology, although extreme examples of personality types can qualify for personality disorder diagnoses. Two useful typological approaches are the Myers-Briggs Type Indicator (MBTI) and the typology of attachment styles.

The Myers-Briggs Type Indicator (MBTI) characterizes individuals into one of 16 types, based on four preferences in their cognitive and emotional processes: Extroversion (E)/Introversion (I), Sensation (S)/Intuition (N), Thinking (T)/Feeling (F), and Perceiving (P)/Judging (J) (Myers, 1998). Individuals' preferences on these four dichotomies can be more or less strong. For example, a person might be characterized as INTP if he or she were introverted, experienced the world more intuitively than through direct sensory experience, usually reached conclusions through reasoning rather than emotionally, and were relatively slow to make final judgments about experiences and issues. Scores on the MBTI are used to classify individuals into one of the 16 types. The MBTI comprises 93 binary items. There are also abbreviated and expanded versions, as well as options for confidential online administration. An extensive literature has related psychological type as measured by the MBTI to occupations, social roles, intimate relationships, and typical interpersonal conflicts. An example of how the MBTI relates to occupations is the correlation of psychological type and the choice of medical specialty by physicians: A physician of type INTP is 2.75 times more likely to become a neurologist and 0.44 times less likely to become an OB/GYN than would be expected from the distribution of medical specialists.

The typological view has been utilized extensively in organizational psychology and in marital therapy. It deserves consideration as an aid to understanding how physician-patient relationships can go wrong, and in judging whether a change in physician or some form of advice to the physician and/or patient is a practicable way to resolve a problem.

For example, consider the physician-patient relationship when the physician's type is INTP and the patient's type is ESFJ. The physician might quickly make a correct diagnosis and communicate it in a matter-of-fact way to the patient, while not taking the time to build rapport and warm feelings with the patient, and not doing a visibly meticulous examination. The patient, whose judgments are driven by feelings and immediate sensations, may reject or deny the diagnosis, not because it is incorrect, but because of the mismatch of the physician and the patient's personality style.

Another example is suggested by a recent report that the risk tolerance of surgeons is correlated with their personality type (Contessa et al., 2013). Greater risk tolerance is associated with higher scores on scales of extraversion, thinking, and perceiving. If there is a choice of similarly qualified surgeons, one might attempt to align the risk tolerance of the patient with that of the surgeon when making a referral.

Another typological perspective—limited in its scope but clinically useful—is expressed in the classification of attachment styles based on the attachment theory of the psychoanalyst John Bowlby (Bowlby, 1988), and further developed by numerous other psychodynamically-oriented psychologists and psychiatrists. Individuals are described with respect to dimensions of their close relationships: Are they avoided? Is their importance minimized? Are their attachments insecure? Both interview-based and questionnaire-based scales are available for assessing attachment styles (Ravitz et al., 2010). Moreover, detailed behavioral profiles of the four main attachment styles enable medical psychiatrists to characterize most patients from clinical information they would routinely collect (Maunder & Hunter, 2009). Because attachment styles are coherent (Hunter & Maunder, 2001) and strongly correlated with illness behavior, the characterization of a patient has predictive value. Some specific, simple and accessible self-report scales include the Relationship Scales Questionnaire (RSQ) (Bartholomew & Horowitz, 1991) and its four-item brief version, the Relationship Questionnaire (RQ); and the Experiences in Close Relationships Scale-Revised (ECR-R). The RSQ comprises 20 bidirectional (Likert) 7-point items; e.g., the patient is asked to rate how much the statement "I find it difficult to depend on other people" does or does not apply to him or her. Based on their responses to these questions, patients' attachment style can be characterized as *secure* (positive view of self and other), *anxious/preoccupied* (negative view of self, positive view of other), *avoidant/fearful* (negative view of self and other), or *dismissive* (positive view of self, negative view of other). The ECR focuses on romantic relationships and comprises 36 7-point Likert-type ordinal items (Fraley et al., 2000; Brennan et al., 1998).

Relationship style is remarkably stable over time. Relationship style predicts patients' relationships with their physicians, other professionals, their caregivers, and their intimates, thus affecting their ability to successfully navigate the health-care system, get the care they need, adhere to their treatment, modify health-related behaviors, and cope with their symptoms and impairments. Several examples from recent

research reports illustrate the value of the attachment style perspective:

1. Avoidant attachment style was linked to a higher incidence of post-traumatic stress disorder (PTSD) following operative birth (Ayers et al., 2014);
2. Avoidant attachment style was associated with a higher incidence of unsafe sexual encounters in gay men (Starks & Parsons, 2014);
3. Women in primary care with anxious attachment had more unsafe sexual encounters; women with avoidant attachment were more likely to be smokers (Ahrens et al., 2012);
4. In chronic pain patients, insecure attachment styles were associated with more pain intensity, pain-related behavior, pain-related disability, depressive symptoms, and a greater perception of a negative spousal responses (Forsythe et al., 2012);
5. In an oncology practice, insecurely attached patients were less likely to trust their oncologist or be satisfied with care one year after their cancer diagnosis (Hillen et al., 2014). More generally, avoidant and dismissive styles are associated with less trust in physicians and poorer adherence to treatment, while anxious/insecure attachment is associated with more psychosomatic complaints and greater utilization of healthcare resources.

Even without the results of questionnaires, medical psychiatrists can assess patients' attachment styles from their explicit responses and their behavior during the diagnostic interview. Patients' attachment styles can be kept in mind when planning treatment and aid in setting realistic expectations for patient behavior and treatment outcome with the patient, family caregivers, and medical colleagues.

PERSPECTIVE BASED ON ANALYSIS OF DEFENSES

One of the gifts of psychoanalysis to general psychiatry is the conceptualization and description of defense mechanisms—ways in which people cope with psychological stress using characteristic patterns of perceiving, thinking, and acting. These mechanisms also have been termed “involuntary coping mechanisms” by George Vaillant, who has done extensive longitudinal studies of defense mechanism and their lifetime implications (Vaillant, 2011). Defenses have six characteristics:

1. They mitigate the distressing effects of both emotion and cognitive dissonance;
2. They are unconscious (i.e., involuntary);
3. They are discrete from one another;
4. They are dynamic and reversible;
5. They can be adaptive and even creative as well as pathological; and

6. They are invisible to the user but not to observers (Vaillant, 1977).

Defenses have been organized into a hierarchy of four groups:

1. *Psychotic*, including delusional projection, psychotic denial, and psychotic distortion;
2. *Immature*, including acting out, dissociation, passive aggression, and non-psychotic projection;
3. *Intermediate (neurotic)*, including displacement, isolation, and repression; and
4. *Mature*, including humor, altruism, sublimation, and suppression.

Patients' defensive styles can be assessed using the Defense Styles Questionnaire (DSQ) (Bond, 1986). The questionnaire comes in various versions, with 88, 60, or 40 ordinal items. Scoring yields an overall assessment of defensive functioning. Defenses can be expressed in terms of three factors or placed into a seven-level hierarchy. The three factors are *image distorting*, *affect regulating*, and *adaptive*. The seven levels are *action*, *major image distortion*, *disavowal*, *minor image distortion*, *neurotic*, *obsessional*, and *adaptive*. Clinicians can appraise patients' defensive styles without questionnaires making use of their clinical observations and both the verbal and nonverbal responses of patients' to their questions during a diagnostic interview. The description and classification of the defensive styles utilized in the interpretation of questionnaires is applicable to interpretation of data from the medical record and clinical encounters.

Defense mechanisms have been associated with patients' symptoms and with medical outcomes across a broad range of medical conditions: patients with neurotic defenses have more symptoms, sick or well, than those with adaptive defenses (Hyphantis et al., 2013). Supportive psychotherapeutic interventions for medical-psychiatric patients—regardless of their severity of general medical illness—aim to identify, bolster, and mobilize patients' adaptive defenses and diminish the use of lower-level defenses by psychotherapeutic, behavioral, environmental, and/or pharmacological means.

Even patients with healthy personalities might utilize lower-level defense mechanisms when suffering from illness, trauma, loss, or other severe stress. The resulting adaptive failure can lead to a medical-psychiatric consultation. A perspective based on the analysis of defenses can be helpful to medical psychiatrists in conceiving their short-term psychotherapeutic work with such patients. The clinician aims to identify adaptive defenses that worked for the patient in the past, to discover why the patient is not using them or why they are not currently effective, and to get the patient to “move up” the hierarchy of defenses. This might involve pointing out alternatives and encouraging their use, or addressing impediments to the use of previously effective defenses. As an example of the latter tactic, note that many of the adaptive defenses have substantial cognitive demands. If a patient with cognitively intense adaptive defenses is given a benzodiazepine that

impairs his or her cognition, it can actually cause an increase in anxiety due to the loss of an effective defense mechanism. Stopping the anti-anxiety drug could actually reduce anxiety in this situation. Similarly, when a patient has adaptive defenses that require substantial mental energy and the latter has been reduced by general medical illness, giving a stimulant might reduce anxiety by helping the patient mobilize his or her adaptive defenses. In other patients with a different defensive style, benzodiazepines might relieve anxiety and stimulants might worsen it.

TIPS ON CATEGORICAL DIAGNOSIS

It is assumed that the reader is familiar with the *Diagnostic and Statistical Manual of Mental Disorders* (DSM) classification of personality disorders and with the ways in which patients with particular personality disorders are likely to show problematic behavior in medical settings. When the presence of a personality disorder or maladaptive personality trait impedes medical treatment, the specific personality diagnosis is relevant to the selection of a management strategy, but a current (re)assessment of the patient's defensive style and quality of interpersonal relationships is also necessary. This assessment is most important for individuals with narcissistic, histrionic, dependent, and passive-aggressive traits, who can have relatively more or less mature defenses and more or less unstable interpersonal relations. For example, histrionic or "hysterical" patients with relatively good impulse control and a more mature defensive structure require different management from less mature, impulsive histrionic patients with borderline features.

Antisocial personalities, diagnosed on the basis of history, always should be presumed to have "psychotic" or "immature" defenses, even if they appear to be functioning at a higher level on a single cross-sectional assessment.

The formal diagnosis of *Borderline Personality Disorder* (BPD) by DSM criteria is less important for medical-psychiatric management than identification of the patient as one with a poor quality of interpersonal relationships and a tendency to use the defenses of splitting and projective identification. Patients with a history of childhood sexual abuse, factitious illness, or multiple suicide attempts are highly likely to have a borderline personality organization.

Patients with *passive-aggressive* and *dependent* personalities can have either more mature or less mature defensive structures and object relations. More primitive passive-aggressive patients might passively attempt to sabotage medical treatment as an expression of rage against the physician, who serves as a transference figure. By contrast, the passive-aggressive patient with higher-level defenses primarily might have conflicts over control and autonomy, or might be identifying with a passive-aggressive parent. Management should be in accord with the patient's defensive style and specific emotional conflicts.

Schizoid and *avoidant personalities* may be difficult to distinguish on a single cross-sectional assessment. Both, however, fear closeness and may fear being controlled by others.

The enforced intimacy of medical settings and the attendant loss of control lead to anxiety, which is expressed according to the patient's defensive style.

Narcissistic personalities can have either a low or a high level of functioning. More severely impaired individuals might display demanding, manipulative, exploitative, entitled, and/or dishonest behavior that disrupts medical treatment and engenders angry reactions from their caregivers. Better-functioning narcissistic personalities might be less dramatically "entitled" but might reveal an excessive vulnerability to criticism, disappointment, and feelings of shame or embarrassment. They might overvalue particular physical or mental attributes and have an unusually difficult time adjusting to the limitations of a chronic illness. The physician, if not devalued, might be idealized to the point of discomfort. Physicians can find themselves rapidly idealized and then equally rapidly devalued.

SPECIAL ISSUES IN OLDER PATIENTS

As problematic as categorical personality disorder diagnosis can be in general medical patients, it can be even more difficult in older medical patients, because neither diagnostic criteria nor their application are age-neutral. The criminal behavior that is required for a diagnosis of antisocial personality is less prevalent during old age, as are the identity disturbances typical of borderline personality in young adults. Yet personality traits are relatively stable with age, suggesting that personality disorders do not disappear altogether but change their form according to the patient's life stage. Antisocial personalities might give up crime and turn to alcoholism and hypochondriasis, and borderline personalities can develop stable social and occupational functioning but fail to form close personal relationships. The focus of patients' concerns and conflicts shifts with life stage: narcissistic individuals might inflate their past accomplishments or the talent of their grandchildren; borderline personalities might apply splitting and projective identification to their caregivers and to their children instead of to their parents, spouses, or partners.

Age-specific events can evoke symptoms of personality disorder. Such situations include bereavement, institutionalization, forced intimacy with caretakers, and cognitive changes, particularly those of early dementia. Personality disorders thus can emerge during old age, especially in individuals who had sub-syndromal traits earlier in life.

Because categorical personality disorder diagnoses can help with prognosis, treatment planning and communicating with other clinicians it is worth the effort to attempt a categorical personality diagnosis in an older patient with evident maladaptive personality traits. This exercise can be aided by: (1) obtaining information on the patient's earlier adaptation, especially from reliable informants or old records; (2) considering traits and defensive style and de-emphasizing whether formal criteria are met; and (3) considering the possibility that disordered personality can emerge during old age as a function of changed life circumstances or alterations in brain function (Sadavoy & Fogel, 1992).

PRESENTATION OF PERSONALITY DISORDERS IN GENERAL MEDICAL SETTINGS

In general medical settings, patients with personality disorders are brought to the attention of the psychiatrist because:

1. They display angry, manipulative, self-destructive behavior, violent behavior, or make threats to harm themselves or others;
2. They adhere poorly to treatment recommendations or show unexpectedly poor treatment outcomes;
3. They develop somatic complaints in excess of diagnosable general medical conditions;
4. They develop severe anxiety or depression;
5. They show signs of an Axis I condition requiring treatment in its own right (e.g., substance abuse, PTSD, or psychosis);
6. Their treatment for an Axis I condition by their primary care physician or other principal physician is not successful;
7. They abuse or misuse prescribed medications;
8. They evoke frustration and anger in their family members or other informal caregivers;
9. They evoke negative or inappropriate emotional reactions in clinicians, or evoke conflict between clinicians caring for them;
10. They initiate or induce legal actions, either civil or criminal.

Most medical-psychiatric involvement with patients with personality disorders is reactive to one of the above situations. Prospective identification and preventive intervention with patients with personality disorders is an appealing alternative when a medical psychiatrist operates as a liaison to a service treating a clinical population with a high prevalence of Axis II comorbidity, such as patients with chronic pain, patients with addictions, or patients with somatoform disorders. The author's view is that when patients are diagnosed with a major chronic general medical disease, their personalities should be assessed, whether formally or informally, and the results of the assessment should be used to adapt the treatment to the patient. If the patient has borderline personality disorder (BPD), he or she should be offered evidence-based treatment to mitigate the symptoms of BPD, since improvement in the BPD will necessarily improve coping with the general medical illness; and the best time for therapeutic intervention is when the patient is both motivated by a momentous diagnosis and not so physically sick that psychiatric treatment is either irrelevant or intolerable.

Incorporating an understanding of *normal variations* of personality into treatment planning and patient management should be part of a medical psychiatrist's usual practice. When the medical psychiatrist will be involved in the long-term

management of a patient with a chronic or relapsing-remitting general medical condition, it is useful both to assess the patient for Axis II disorders and to characterize the patient's personality qualitatively from one or more of the different perspectives described above. Self-rated questionnaires are useful, but even without using specific questionnaires, the conceptual schemes that underlie them can be employed to organize the clinician's observations into descriptors that can be used to approach the literature and to communicate with colleagues.

AXIS I AND AXIS II COMORBIDITY

The large literature on the comorbidity of Axis I and Axis II will not be reviewed here. I will confine myself to several general observations that are well supported by empirical evidence and have special applicability in the medical-psychiatric setting.

1. *Avoidant personality* overlaps greatly with *social anxiety disorder* (social phobia). Both conditions can interfere with patients' relationships with healthcare providers and thus with medical treatment adherence. Social anxiety disorder, more than avoidant personality alone, has evidence-based and frequently effective pharmacological and cognitive-behavioral treatments. When a patient with social anxiety disorder is diagnosed with a chronic general medical illness, or is at high risk for developing one, intervention to treat the social anxiety prepares the patient to have a better course of treatment for his or her medical problem.
2. *Schizotypy* is a continuum from schizotypal traits to schizotypal personality to schizophrenia (Nelson et al., 2013). Schizotypal personality is a risk factor for developing schizophrenia, and patients with severe schizotypal personality have a very high risk of developing schizophrenia (Barrantes-Vidal et al., 2013). On brain imaging, patients with schizotypal personality and patients with schizophrenia share abnormalities in the temporal lobe, but schizotypal personality disorder patients without schizophrenia lack the relative atrophy of the frontal lobes seen in the latter disorder (Fervaha & Remington, 2013). With stronger frontal systems functioning, they are able to compensate better for their temporal dysfunction and thus prevent the emergence of full-blown psychosis. Schizotypal personality thus reflects a balance between a tendency toward psychosis and inhibitory mechanisms. Stress, general medical illness, traumatic brain injury, and/or the effects of alcohol or drugs can upset this balance, leading to the onset of overt psychosis. When providing comprehensive medical care to a patient with schizotypal personality disorder, great attention should be paid to brain health—discouraging alcohol and drug use, assessing potential central nervous system (CNS) side effects of drugs used for general medical conditions, etc.
3. *Obsessive-compulsive personality* overlaps with *obsessive-compulsive disorder* (OCD). The latter condition has evidence-based and often effective pharmacological and

cognitive-behavioral treatment. Some compulsive rituals cause medical harm; others interfere with patients' treatment for general medical conditions. These situations argue for the importance of treating OCD even when the patient's distress from his or her compulsions is not severe.

4. Patients who present with *major depression* often have a comorbid personality disorder. The effectiveness of treatment for major depression is lower when there is a comorbid personality disorder. Furthermore, depression can increase the severity of personality disorder symptoms or move a patient across the line into personality disorder from sub-syndromal status. Patients with major depression and comorbid personality disorder require especially conscientious treatment of the major depression that takes the distinctive interpersonal and defensive style of the patient into account.
5. Patients with *substance abuse* frequently have personality disorders—with antisocial and borderline personality disorder (BPD) especially common (Skodol et al., 1999). Patients with antisocial personality should be treated with appropriate mistrust and with precautions to avoid violent or criminal acting-out. Patients with borderline personality may benefit from non-pharmacological treatment of their BPD after they are abstinent from their substances of abuse.
6. Patients with BPD have a high rate of comorbid somatoform disorders, and the prevalence of BPD is high in patients with chronic pain and patients with medically unexplained symptoms or other forms of excessive illness behavior. When a patient presents with a new diagnosis of a somatoform disorder, the diagnosis of BPD should be considered.
7. In considering Axis I comorbidity in patients with BPD, the "80% rule" is useful: Over 80% of patients with BPD have a lifetime history of an anxiety disorder, over 80% have a lifetime history of a mood disorder, and slightly fewer than 80% have a lifetime history of a substance use disorder.
8. Adolescents and adults with *attention-deficit hyperactivity disorder* (ADHD) may display angry, impulsive, and uncooperative behavior in the hospital environment because of the combination of overstimulation and enforced passivity. Such patients' behavior can remove remarkably when they are given stimulants, and even some patients with comorbid BPD will show behavioral improvement. However, stimulants can precipitate psychotic symptoms in BPD patients, and it is difficult to predict which ones will have this reaction. A conservative approach would be to use stimulants in patients with comorbid ADHD and BPD in acute medical-psychiatric contexts only when prior treatment with stimulants has been an unequivocal success. Even greater caution applies to the use of stimulants in patients with comorbid ADHD and schizotypal personality. When ADHD occurs without either of these comorbidities, stimulants

usually help hospitalized patients' agitation and inattention. The author's impression from decades of consultations is that when patients hospitalized for acute medical illness become agitated, ADHD is relatively neglected in the differential diagnosis, and stimulants are neglected as a therapeutic option. A childhood history of ADHD or learning disability and the absence of delirium should prompt consideration of the diagnosis; if ADHD is present, the clinician should consider whether there is a psychiatric or general medical comorbidity that would contraindicate the use of stimulants.

AXIS II COMORBIDITY WITH GENERAL MEDICAL CONDITIONS

The study of the comorbidity of personality disorders with general medical illness is confounded by the relationship of personality with patterns of help-seeking and interaction with clinicians and institutions. For example, patients with BPD would be more likely to seek treatment for a general medical condition in an emergency room because of the intensity of the distress they might feel when ill and their inability to tolerate waiting for an outpatient appointment. A patient with avoidant personality might avoid seeking treatment for a medical condition until its symptoms became intolerable. Studying the comorbidity of general medical illness and personality disorder in population-based surveys has other shortcomings—an avoidant person with serious general medical illness might not respond to a telephone survey or home visit by a surveyor; neither might a person with significant paranoid traits. Hospitals, clinics, and physicians' offices are full of patients with personality disorders that rarely are diagnosed by non-psychiatric physicians. Specific medical populations with a high proportion of patients with personality disorders include: patients with chronic pain, patients with somatoform disorders, patients with sexually transmitted diseases, patients with self-inflicted injuries, patients injured in violent altercations, patients seeking disability status, and patients with eating disorders. Systematic screening for personality disorders and characterization of personality traits is clinically warranted in these populations, even if patients do not present in a way that demands immediate psychiatric attention.

Experienced primary care physicians with long-term patient relationships often have a good grasp of their patients' personality traits and characteristic responses to stressful life events. However, they are unlikely to make personality disorder diagnoses, even in situations in which a psychiatrist could make them. Missed diagnoses of personality disorders most often are missed opportunities to make a potentially helpful referral or modification of treatment strategy. However, in some cases, missed Axis II diagnoses are dangerous. Not recognizing that a patient has an antisocial personality, a physician might be manipulated into prescribing controlled substances that are then illegally diverted (e.g., resold). Or, not giving in to inappropriate demands for controlled substances, the physician might

be physically threatened or attacked. Not recognizing that a patient has a borderline personality, a physician might be seduced into a boundary violation, or give in to the patient's pressure to do unnecessary tests or procedures. In multi-specialty practices, non-psychiatric physicians should be encouraged to get psychiatric consultation routinely when an unfamiliar patient begins pushing for procedures or treatments despite the physician's reluctance—including prescription of controlled substances—or asks for a physician's help in documenting disability status that is not supported by objective signs.

PROBLEM-ORIENTED MEDICAL-PSYCHIATRIC CONSULTATION

Medical psychiatrists often are consulted by general medical physicians to assess patients with problematic behavior in a hospital or clinic or in the physician–patient relationship. Many of the patients involved in such difficult situations have personality disorders or personality trait disturbances. A practical approach to problem-focused consultations might consider these points in the initial assessment:

1. What is the patient's view of the problem? Is there a legitimate, practically resolvable issue? Is there a misunderstanding between the patient and the medical staff that needs clarification? The patient might have a valid concern, even if he or she expresses the concern in a way that is self-defeating or impinging on others.
2. Are there practical, negotiable issues compounded by emotional issues and interpersonal conflicts? If the practical concerns could be separated from the emotional and interpersonal ones, could they be resolved?
3. Is there evidence of an Axis I diagnosis? In particular, is there a treatable Axis I diagnosis that is more directly linked to the immediate problem than is the patient's personality? For example, non-adherence to general medical treatment by a patient with avoidant personality might be explained by social phobia or agoraphobia. Treating the phobia could improve their medical treatment adherence without requiring a change in the underlying personality.
4. Is the patient under the influence of prescribed medications, alcohol, or illicit drugs, or withdrawing from such substances? Patients with Cluster B personality disorders—antisocial, borderline, histrionic, or narcissistic—are more likely than patients in general to use and to abuse psychoactive substances. The proximate cause of a behavioral problem in a patient with a Cluster B personality disorder might be a manageable substance-related problem.
5. What is the patient's perception of the physician–patient relationship and of the patient's role in the treatment? Misalignment of expectations of the patient for the physician

and the physician for the patient can cause trouble in any circumstance, though the troubles are worse when one of the discordant parties has a personality disorder.

6. Is the immediate problem provoked by inappropriate or inflexible behavior by a physician, nurse, or other health-care provider? Tactless or inept limit-setting can bring out the worst in a patient with a borderline personality.
7. Has a medical disorder or medication side-effect been overlooked or misdiagnosed? Just because personality disorders can impair physician–patient communication, patients with personality disorders are more likely to get incorrect diagnoses, have under-treated or over-treated symptoms, or have unrecognized medication side effects. At the same time, patients with personality disorders can express emotional distress as physical symptoms disproportionate to the medical illness, and insist that a diagnosis has been missed or that medication side effects have been neglected. At best, a medical-psychiatric consultant can assess these issues with eyes unclouded by countertransference or the effects of an already-difficult physician–patient relationship.

When information from the interview, collateral sources, healthcare providers, and the medical record is synthesized, a tentative personality diagnosis might be possible, as well as a concise statement of the behavioral problem needing resolution. Specific strategies can be employed to address behavioral problems according to the patient's personality type, while concurrent Axis I and general medical problems receive appropriate pharmacological or psychotherapeutic attention, or both.

MANAGEMENT STRATEGY

Management strategy for patients with personality disorders in general medical settings comprises tactical responses to short-term problem situations; longer-term approaches to preventing crises, disruptions of medical treatment, and non-adherence to treatment for chronic conditions; and, where feasible, interventions to decrease the distress and impairments caused by the personality disorder itself in areas beyond their participation in general medical treatment. The strategy is based on a personality diagnosis that includes a categorical diagnosis of a specific personality disorder, if one is justified. Tactics for short-term problems with behavior, treatment adherence, or physician–patient relationships are selected with consideration of current defensive functioning. Longer-term considerations in treatment planning may include consideration of personality dimensions, attachment style, and psychological type.

When approaching acute behavioral problems in general medical settings that are potentially related to the patient's personality, the medical psychiatrist gathers data from the patient interview, medical records, and collateral sources and synthesizes them to make a tentative personality diagnosis that comprises an assignment of an Axis II diagnosis if appropriate, and an assessment of current defensive operations and the quality of the patient's interpersonal relations. Axis I and

Axis III disorders that contribute to the behavioral problem also are diagnosed, and their treatment is initiated or modified as appropriate. In this connection substance abuse, CNS side effects of prescribed medications, and brain diseases with frequent neuropsychiatric complications deserve special attention. The psychiatrist then develops a management strategy to reduce the interference of the patient's maladaptive personality traits and less mature defenses with his or her medical treatment.

Specific tactics for handling short-term problem situations are part of the tradition of consultation-liaison psychiatry. While evidence to support them is largely anecdotal, they are widely taught, and the author, among others, has found them useful. Several will be described here.

When the medical psychiatrist has an ongoing relationship with a subspecialty clinic, it may be feasible to prospectively identify patients with personality disorders or evident trait disturbances and act preemptively to prevent non-adherence or disruptive behavior. Identification of candidates for preventive action can be done informally, or a clinic can include some self-rated instruments in its intake process. While the latter step is unusual at this time, it would seem rational for a clinic that treats chronic diseases with a very high prevalence of psychiatric comorbidity.

However a patient with a personality disorder is identified, the Axis II condition should be dealt with like any other comorbid condition—psychiatric or medical—that can affect the outcome of the primary illness being treated. For example, a management strategy for a patient under the care of a rheumatologist with newly diagnosed systemic lupus erythematosus (SLE) and a BPD might include referral of the patient for a course of dialectical behavioral therapy or transference-focused therapy for BPD, and a trial of a mood-stabilizing antiepileptic drug if the patient has prominent affective instability. This might be combined with an informal conference with the members of the rheumatologist's practice team alerting them to the borderline patient's potential for splitting, and suggesting that they develop an explicit written plan of treatment that could be accessed by any physician who might be providing coverage for the patient after hours or on a weekend or holiday.

TACTICS FOR PATIENTS WITH IMMATURE DEFENSES

When managing a patient with less mature defenses, the physician must not assume *a priori* a trusting relationship or the patient's capacity to be consistent. Consistency and appropriateness must be provided by the physician, who must not be unduly moved by pleas, demands, manipulations, or threats, or be personally affronted by the patient's mistrust (Dawson, 1988).

Because patients with less mature defenses may react dramatically to disappointment, it is all-important to clarify treatment expectations. The patient's view of his or her implicit therapeutic contract with their physician(s) should be

explored and the goals and limits of the patient's medical treatment made clear at the outset. Conflicts can be minimized by frequently reorienting the patient, the significant others, and healthcare providers toward a basic and circumscribed treatment contract. Whenever possible, this implicit contract should be restated in the patient's own words. Management tactics useful for patients with immature defenses involve giving the patient a sense of control, simplifying the treatment plan, being consistent, taking the "one-down" position, limit-setting, avoiding or limiting hospitalization, and anti-splitting maneuvers.

GIVING THE PATIENT A SENSE OF CONTROL

Giving the patient a sense of control is maximizing the appropriate influence the patient has over the treatment situation. Maximizing patient autonomy while remaining consistent—or almost consistent—with evidence-based practice is a widely accepted principle in the United States, though perhaps patient autonomy receives less weight in some other countries with national health systems in which the patient is not viewed as a customer. Notwithstanding, given the time constraints and customary procedures of busy practices, physicians often tell patients what a plan of treatment will be, rather than ask them for their preferences. Patients with mature defenses usually will speak up and negotiate with a physician if the recommendation does not work for them; those with immature defenses are more likely to respond maladaptively, for example by getting angry, breaking off the treatment relationship, not showing up for appointments, or not taking medications as prescribed. These problems can be reduced by inviting patients to express their preferences before settling on the details of treatment; for example, a schedule of outpatient visits, a prescription of medication, or the hospital discharge date. Incorporating patient preferences sometimes requires deviation from usual procedures and sometimes requires the physician to advocate within a hospital, clinic, or health system on behalf of the patient. This can make sense when the alternative is worse; the physician should bear in mind that a treatment plan that perfectly follows evidence-based practice guidelines or the policies of the hospital or health plan is of little value if the patient does not accept it. For risk management purposes the reasoning for making an exception should be documented, and comment on the patient's personality or behavioral issues is sometimes necessary to support the physician's decision.

SIMPLIFYING THE TREATMENT PLAN

Following a medical treatment plan almost always involves behavior change on the patient's part. Intentional, consistent, and adaptive behavior can be difficult for any patient: consider the success rate with attempts at smoking cessation, weight loss, or increasing exercise! It is an even greater challenge for patients with immature defenses who are less able to manage anxiety and frustration and who might have deficits in executive control systems. The physician in charge of coordinating

a patient's care—and *there should be one*—should determine the top short-term priorities for behavior change (including treatment adherence) and limit what is asked of the patient at one time. This can mean delaying attention to a known medical problem until other problems are under control. Here, too, the reason for deviation from ideal practice should be documented.

BEING CONSISTENT

Being consistent means minimizing changes in the treatment plan, the healthcare providers involved, and the language in which information is conveyed, thereby reducing opportunities for confusion or misunderstanding. It is facilitated by giving the patient some control and simplifying the plan. Instructions should be written, and patients should be asked to restate them in their own words. When several healthcare providers are involved, one of them must “get the license” to coordinate the plans and recommendations of all. When patients have multiple comorbid conditions, it might be unrealistic for the primary care physician to be the team captain. In the author's experience, the best coordinator usually is the specialist treating the condition currently most critical to the patient's outcome: for example, the oncologist for a patient being treated for cancer, the cardiologist for a patient with a recent myocardial infarction, or the medical psychiatrist for a patient with melancholia and suicidal ideation.

Communication by email has can either be an aid or an impediment to being consistent. If patients email different physicians and other healthcare providers separately, they can accumulate inconsistent or even contradictory written advice. If all email communication goes through a common secure portal, designed so that all involved healthcare providers can see all of the messages, it can be a powerful tool for aligning everyone's advice and for identifying differences of opinion so they can be promptly resolved. Many health systems offer such patient portals. For a portal to work to promote consistency, everyone involved has to agree to use it and to not have side communications with the patient, and the patient has to agree that information will be shared among all of their providers.

TAKING THE “ONE-DOWN” POSITION

Taking the “one-down” position means realistically recognizing one's limitations in affecting another person's behavior, and approaching the patient with genuine and appropriate humility. It includes “allowing” some degree of pathological behavior to go unchallenged if it is not immediately or severely harmful to the patient. This approach—more an attitude than a tactic—forestalls many potential control struggles with personality-disordered patients. Taking the one-down position implies yielding control in some areas of contention between physician and patient; the empowerment of the patient helps alleviate any feelings of helplessness and vulnerability that can lead to rage reactions and defensive aggression. Distinguishing between appropriate humility and yielding to a patient's threats and manipulation is sometimes

difficult, however. Consultation with a colleague can help clinically and is also a useful risk management strategy in high-stakes situations.

Taking the one-down position also includes setting appropriately modest expectations regarding all treatments, both psychiatric and medical. Treatment with psychotropic drugs in particular should be preceded by a “universal disclaimer”—the physician's statement that, while any drug prescription will be supported by evidence, such evidence will only show that a given drug is better than a placebo or better than an alternative, and not that it will work for everyone. They should also note that individuals have different sensitivity to adverse effects and that dosage might need to be individualized. A careful personal and family history of relevant drug responses should be taken, and where applicable, pharmacogenomic testing, therapeutic drug monitoring, or scheduled email follow-up with questionnaires about symptoms and side effects should be considered.

LIMIT SETTING

Limit setting is the trump card—to be played if a patient is seriously impeding treatment or is endangering someone. For outpatients, typical circumstances for limit setting are diversion of prescription drugs, verbal abuse of the office staff, or threats of violence. For inpatients, limit setting is an appropriate response to such behavior as deliberately pulling out intravenous lines, smoking in a room with oxygen, or screaming all night in a room full of sick patients, when such behavior is not an expression of delirium or psychosis.

In the inpatient case, all involved healthcare providers are told of the problem and decide together what limits will be set. The patient is told without anger which behaviors are unacceptable “*in this hospital*” (or in this clinic or other setting of practice). If limits are set angrily, the patient responds more to the anger than to the limit. Reference to “in this [setting of practice]” restricts the control struggle to one setting rather than to the whole world. In the outpatient case, the patient is told that the physician will not continue to treat the patient (or prescribe medication, or continue certifying disability, or whatever) if the behavior continues. Appropriate alternative sources of care would be discussed with the patient to forestall accusations of abandonment.

In the variation called “sympathetic limit setting,” the physician acknowledges that there is something that could understandably provoke the patient's behavior, *but* that the behavior is nonetheless unacceptable in the current setting of care.

In the inpatient case, whether limits are set with or without an expression of sympathy, the patient is told that termination of the current treatment arrangement is inevitable if the unacceptable behavior continues. The patient will either be discharged from the hospital with a referral for some kind for follow-up, or, if involuntary psychiatric treatment is indicated because of a risk to self or others, a request for temporary certification is completed, and the patient is transferred an appropriate psychiatric facility. If the patient is too medically unstable for such a referral, control of violent or

potentially self-injurious behavior is maintained with antipsychotic drugs, special observation, and/or physical restraints until the patient's physical condition permits either transfer to a secure psychiatric facility or discharge to the community with a referral for follow-up. The referral usually will be to an organized care setting such as a community mental health center that has the staff and resources to provide continuous coverage and to respond to a psychiatric emergency.

The clinician's countertransference is a common—if not the most common—impediment to effective limit setting. Limit setting with obvious anger is one expression of countertransference; another is a failure to set limits either because of the clinician's fear of the patient's anger or the clinician's defense against his or her own unconscious anger.

Another reason why clinicians fail to set necessary limits is fear of litigation or a complaint to a professional licensing board; increasingly, the expression of "consumer dissatisfaction" or a complaint to a hospital or health plan is a concern. Complaints to licensing boards can be challenging for clinicians, because clinicians do not necessarily have the protection of legal due process, and an articulate but malignant individual can paint a convincing though distorted picture of the clinician's actions (Gutheil, 2005). Furthermore, applications for medical staff appointments frequently ask whether a physician has been the subject of patient complaints, even if those complaints have not been substantiated. Notwithstanding, the failure to set appropriate limits will inevitably make matters worse. Good clinical practice as well as risk management call for setting the necessary limits while thoroughly documenting the situation, consulting with colleagues to validate one's reasoning and assess one's countertransference, and providing a reasonable referral if the patient is to be dismissed from one's practice.

AVOIDING OR LIMITING HOSPITALIZATION

Hospitalization itself can aggravate regressive behavior in borderline patients. It may be difficult to get a borderline patient out of a helpless, dependent position once he or she is in it. The environment of the hospital can evoke immature defenses, either by increasing anxiety or by providing powerful transference figures (physicians and nurses) or situations that evoke imagery of past traumatic events. For this reason, both hospitalizations and their length should be limited, even when it means ignoring patients' threats or demands aimed at initiating or prolonging a stay in hospital. Strict criteria of medical necessity should be applied when making the decision to hospitalize a borderline patient. The goals of medical hospitalizations should be limited to carrying out the procedures and treatments that can be done only in hospital, and the goals of psychiatric hospitalizations usually should be limited to containing a patient when there is a high short-term risk of violent or self-injurious behavior, or making a diagnosis and initiating treatment of an Axis I disorder when this would not be feasible on an outpatient basis. To assess immediate suicide risk, the clinician can supplement clinical judgment with a widely recognized rating scale like the Columbia Suicide Severity Rating Scale (C-SSRS): If the scale score is low, it makes the

clinician's judgment more defensible if the patient acts out self-destructively; if the scale score is high, it helps support the legal or financial case for continued hospitalization. An exception to this general rule is the planned admission of a patient with BPD to a specialized medium-to-long-term inpatient treatment program. Such an admission might be part of a long-term strategy for managing a patient with BPD and a comorbid chronic medical illness, but it would not be a response to an acute behavioral crisis in a general medical setting.

ANTI-SPLITTING MANEUVERS

The "splitting defense," typically employed by borderline and lower-functioning narcissistic personalities, divides the important people in the patient's world into "good guys" and "bad guys"—the former loved and idealized, the latter hated and devalued. Patients' splitting behavior can induce among physicians and staff intense differences in attitude and feeling toward the patient, so that care providers split into two factions with strongly held and opposing views regarding the patient's diagnosis or treatment. Issues frequently disputed include pain management, the need for and choice of psychotropic or analgesic medication, the validity of the patient's physical complaints, and the limits that should be set on the patient's behavior.

Splitting of care providers can arise in three ways. First, the patient may manipulate some caretakers into a particular viewpoint, whereas others, unaffected by the manipulation, disagree and might view the patient negatively as "manipulative." Second, caretakers might have differing reactions to the patient's behavior. Some might respond with sympathy and protectiveness, whereas others respond with anger and annoyance. Third, the patient might have different transferences to different care providers, leading to quite different behavior with each of them in the absence of any conscious intent to manipulate or create chaos.

The consequences of splitting can include inconsistent care, inappropriate medication, and burdensome emotional demands on care providers. Clinical outcomes can be affected, not only for the patient doing the splitting, but also for others cared for by the same clinicians.

The basic "anti-splitting" maneuver is the network meeting. All physicians and staff involved in the patient's care are brought together, whether in person, by conference call, or via an online meeting. The medical psychiatrist identifies the problem of splitting and initially encourages ventilation of feelings and disagreements. The psychiatrist then points out that these feelings and disagreements are induced by the patient's behavior and that they provide valuable information about the patient. The psychiatrist then explains that the patient must be treated with the utmost consistency. A rational treatment plan must be agreed on and carried out, regardless of the patient's varying reactions to different care providers and despite any attempts made at manipulation. The psychiatrist works with the staff to develop a consensus on an appropriate care plan, and this plan is written down. The psychiatrist or other physician with a "license" to coordinate the patient's care then informs the patient of the meeting

and reviews the key points of the care plan with the patient. It is sometimes appropriate for patients with relatively higher functioning to be invited to join the meeting at the end and hear the consensus directly.

Meetings of involved physicians and staff might be required periodically if the patient's length of stay in the hospital is relatively long, or if the patient is receiving ongoing outpatient care from multiple specialties or disciplines.

The most common error during network meetings held to combat splitting is the failure to include an important stakeholder. When this error occurs, those who have attended the meeting and those who have not can wind up on opposite sides of a split. If several physicians are involved regularly in the patient's care, all must be present. In inpatient settings, if nurses on day and evening shifts are split, both shifts must be represented at the meeting.

Splitting in outpatient settings can occur when patients with borderline personality organization see multiple physicians for different medical problems. They seek opinions from each physician, often asking one to comment on the opinions or care given by another, and attending carefully to any differences or discrepancies among physicians' opinions. Perceptions of a lack of consensus can lead to noncompliance or to the patient's devaluing one physician while idealizing another.

Outpatient anti-splitting maneuvers are similar to inpatient ones, with three salient differences:

1. It is less clear than in the inpatient setting who has authority to call a meeting with a reasonable expectation that others will participate, since there is no one with the formal authority of an inpatient attending physician. The medical psychiatrist leading the meeting will need time and effort to line up the participants, often calling on either the primary care physician or a respected specialist for help.
2. Electronic communication by conference call or web conferencing usually will be necessary to include all relevant stakeholders.
3. If there is a friend or family member loved and trusted by the patient, who is higher functioning than the patient, it usually makes sense to include him or her, subject as always to the patient's consent.

When anti-splitting maneuvers are implemented, borderline patients can become anxious or enraged. Some will defect from treatment. Others remain in treatment but might require short-term antipsychotic drug therapy to contain the anxiety that emerges when the splitting defense is effectively confronted. Despite these problems, anti-splitting maneuvers probably are safer for the patient than ignoring the problem, because persistent splitting can induce errors in physicians' or other providers' judgments that lead to a poor clinical outcome.

COMBINING TACTICS FOR LESS MATURE DEFENSES

For patients with less mature defenses, begin by clarifying expectations, being consistent, giving them a sense of control,

and taking the "one-down" position. Even if there is a past history of inappropriate behavior in the medical setting, there usually is no need to set limits until the patient acts or threatens to act destructively. Then limit setting can be done—sympathetically in the case of borderline and antisocial patients, and matter-of-factly with paranoid and schizotypal patients. Sympathetic limit setting should not be used with paranoid, avoidant, and schizotypal patients because sympathy can arouse further anxiety by implying closeness. If sympathetic limit setting is ineffective with a borderline or antisocial patient, one should proceed with matter-of-fact limit setting. Limits framed so they save face for the patient often are embraced gratefully by patients with more primitive narcissistic personalities. When splitting of health-care providers occurs, anti-splitting maneuvers should be instituted.

TACTICS FOR PATIENTS WITH MORE MATURE DEFENSES

Tactics for patients with more mature defenses and better-quality interpersonal relationships presuppose a reasonable degree of trust and consistency; they attempt to use these patients' personality styles and personal issues as leverage to help them comply with prescribed therapeutic interventions. Tactics for these personalities include use of strategic reframing statements and personal leverage.

REFRAMING

"Reframing" is the tactic of presenting medical instructions in language that is most consistent with the patient's characteristic coping style. For example, after presenting a plan of treatment to a narcissistic patient, one might say, "Many patients would have difficulty with these instructions. Only a highly motivated and competent person could really follow this regimen as it was intended." The medical need for treatment adherence and its associated behavior change is expressed in language appealing to the patient's sense of specialness. A compulsive patient might be asked to carry out an instruction because "it will save you time and money." In this case, adherence to the treatment plan would be linked to the patient's concern with efficiency.

Reframing statements might emphasize illness as an occasion for personal growth, or the mastery of illness as a route to greater independence. These types of statements are particularly appealing to individuals with more mature defenses who have sympathy for the ideas of humanistic psychology and the concept of the physician and patient as peers. Reframing statements preferably use the patient's own language and focus on the patient's individual concerns. The process of creating reframing statements is similar to that used when developing hypnotic suggestions and self-hypnotic routines and can be combined with formal trance procedures by clinicians with sufficient expertise in hypnosis. Applications of self-induced trance in medical settings are described by Spiegel and Spiegel (1978).

PARADOXICAL INTENTION

“Paradoxical intention” includes tactics such as predicting a patient will fail at a proposed treatment or asking him or her to continue the problem behavior with even greater vigor. This somewhat controversial technique has worked with passive-aggressive patients who have an unconscious investment in proving the physician wrong or demonstrating their inability to comply with recommendations. It also can be applied with dependent personalities who fear they will lose their relationship with their physician if they improve, and because they fear the loss of the relationship more than they fear the continuation of their symptoms or disability.

For example, a passive-aggressive patient being treated as an outpatient for depression might be asked at each appointment “How badly did things go?” or the physician might conspicuously focus on questions concerning medication side effects. The patient could then prove the physician wrong by reporting only improvement or denying side effects. A patient disabled by a somatoform disorder who had a dependent personality might be given a detailed plan for a gradual return to normal activity and be told that it would be difficult to carry it out and that he or she probably could do it only by having weekly visits with the psychiatrist for support. Even then, if he or she did succeed, it would be largely due to perseverance in the face of a challenging situation. The medical psychiatrist would see him or her, however, only if he or she complied with the rehabilitative activities. A dependent patient lacking in self-confidence would thus be offered a situation in which he or she would get all the credit if they succeeded but no blame if treatment failed. The patient is also offered the opportunity to depend on the psychiatrist for support because of participation in rehabilitation rather than because of complaints or signs of psychopathology.

Paradoxical intention should be avoided with borderline personalities and other patients with immature defenses. Lacking a sense of humor and not crediting the physician’s goodwill, they can be offended by the psychiatrist’s well-intentioned manipulation and respond with self-destructive or hostile acting out.

PERSONAL LEVERAGE

Using personal leverage means motivating the patient with poor self-esteem by relating medically therapeutic behavior to an important personal relationship. The source of leverage can be a long-term primary care physician, a nurse, a consultant, a family member, or a member of the clergy. Personal leverage can involve suggestions, direct orders, recommendations, reassurance, or handwritten instructions. Typical statements are as follows: (1) “As your personal physician I recommend this treatment”; (2) “Dr. X, the top cardiologist in New York, thinks this is the best option”; (3) “For the sake of your children, now is the time to move to an assisted living facility.”

In some cases, having a personally influential person talk to the patient about the medical treatment or personal problems is most helpful. For instance, a spouse might be invited by the doctor to help explain a procedure to the patient,

assuming that the spouse has previously been shown to be positively influential toward the patient’s overall health.

Personal leverage is particularly relevant when there is a well-defined decision to be made or behavior to be changed, when the patient has a stable and positive relationship with someone who can be an ally in the treatment, and when a more rational, cognitive approach did not work or, based on the patient’s history, would be unlikely to work. The technique is not suitable for borderline patients with unstable relationships, and the clinician should take care to avoid the appearance of condescension. Personal leverage usually is not effective with compulsive patients, who tend to mistrust personal appeals and are much more comfortable with a rational, factually oriented approach.

Appeals to religious or philosophical beliefs, expectations of one’s family or one’s community, and other transpersonal concerns are variants of personal leverage that can be extraordinarily effective if the clinician has sufficient understanding of the patient’s cultural milieu and belief system. This topic is discussed further in this book’s chapter on spirituality.

COMBINING TACTICS FOR MORE MATURE DEFENSES

For patients with more mature defenses, the psychiatric interview determines the personal issue underlying the patient’s noncompliance or emotional difficulty. The physician then attempts to describe the proposed treatment in a way that addresses the personal issue. Typical concerns are associated with different personality disorders, traits, types, and attachment styles. Typical concerns can help guide an interview that aims to arrive at a specific, shared conception of the patient’s current personal issue.

For patients who avoid intimacy, whether they are avoidant, schizoid, schizotypal, paranoid, or simply have an avoidant or dismissive attachment style, it is useful for the physician to adopt a neutral, predictable, matter-of-fact manner with the patient. In inpatient settings, where other healthcare providers are involved with the patient, the medical psychiatrist might recommend that they do the same. In the author’s experience, nurses and house officers with less clinical experience are most likely to display unwanted warmth and sympathy to such patients. Adopting a cooler style with these patients helps avert the anxiety evoked when they experience intimacy. Reducing anxiety can diminish the expression of immature defenses against that anxiety.

TRAITS AND TREATMENT: TEACHABLE TIPS

Medical psychiatrists are consulted by their general medical colleagues to solve problems; less often a psychiatrist attached to a specialty service can help institute screening for mental disorders—including personality disorders—and actively intervene to prevent acute behavioral problems and to improve medical outcomes and health-related quality of life. A third contribution medical psychiatrists can make to

general medical care is raising their colleagues' awareness of mental and behavioral issues in their practices. This can take place in formal rounds and conferences, but informal interactions in hospitals and clinics probably have more impact.

Physicians of all specialties are interested in their patients' adherence to prescribed treatment, their satisfaction with care, and their clinical outcomes, and in not being the target of complaints and lawsuits. Medical psychiatrists can relate their informal advice to these shared objectives.

In this connection, personality traits and types, as captured by the five factors and by the classification of attachment styles, are teachable concepts with an obvious applicability to clinical practice. The idea of linking traits with treatment can be conveyed in brief bits of advice. For example:

1. "This patient really doesn't like intimacy. Don't be too warm with him—if he wants more information about his kind of cancer, refer him to the American Cancer Society website."
2. "This woman is very conventional and not very open to new ideas, but she'll trust you if there are no surprises. If you follow the practice guidelines, she'll follow your prescription, but don't give her anything off-label—it will make her nervous."
3. "This guy is very neurotic and complains all the time. But, if he comes in with a complaint you've never heard before, take it very seriously."
4. "This lady is very disagreeable, to be sure, and her son is even worse. Document everything you do; if anybody's going to see a lawyer if something goes wrong, she and her son are the ones."

USE OF PSYCHOTROPIC MEDICATIONS

Patients with personality disorders frequently are treated with psychotropic drugs. Even so, there is no medication approved for the treatment of any specific personality disorder. Moreover, a meta-analysis of adult patient preferences indicates that patients in general prefer psychological therapy over drug therapy by a wide margin (McHugh et al., 2013). To treat personality disorders with medications is an off-label adventure. Drugs are given to patients with personality disorders either: (1) to treat a concurrent Axis I disorder such as major depression or generalized anxiety; (2) to treat symptoms such as transient psychotic phenomena; or (3) to treat specific personality traits such as negative and unstable affect in BPD or cognitive and perceptual distortions in BPD or schizotypal personality disorder.

Regardless of the purpose for which psychotropic medication is given, some general principles are applicable:

1. The details of how a prescription is given to the patient will affect not only the likelihood the medication will be taken as prescribed, but also the how the patient will respond if there is an adverse reaction to it. The patient's

personality should be considered when deciding how to ask him or her to report any side effects. Compulsive patients might be asked to send a the physician a daily email reporting the side effects they experience, since some are expected in every case, and their pattern should be observed to determine whether they are a reason to modify the treatment. Schizoid and paranoid patients might simply be asked to read the package insert and let the physician know if they have any questions—the physician avoiding an interaction that might seem too warm or giving the impression that potential negatives are being glossed over.

2. Medications can have personal meanings to patients with personality disorders that go beyond their pharmacological effects. For some patients with primitive personalities, a familiar medication is an anchoring point in a chaotic world, and they will resist changing it even if there are problems with its efficacy or its side effects. For other patients, the use of an as-needed anxiolytic or analgesic is a psychological defense mechanism that they greatly fear losing, even though they are not physiologically dependent on the medication and do not necessarily misuse it.
3. Since patients with personality disorders have problems in living and associated emotional symptoms which will continue even when their Axis I condition is effectively treated, it is important to identify the specific symptoms that are the target of psychotropic drug therapy. The symptoms should be regularly measured with a rating scale. This approach helps align the expectations of the patient and the physician.
4. Patients with unstable lives due to low-level personality disorders and patients with the personality trait of carelessness (low conscientiousness) should be given prescriptions that are as simple as possible. If feasible, medication regimens should be tailored to reduce the requirement for the patient's effort and consistency. Specifically, the following should be considered: (a) choosing regimens for all of the patient's psychiatric and general medical conditions so that medication is taken just once a day, with some flexibility in the time at which it is taken; (b) reducing the number of discrete medications by using combination formulations; and (c) using long-acting formulations like depot antipsychotic drugs or transdermal patches.
5. When patients with borderline or antisocial personalities are given prescriptions for controlled substances, precautions should be taken reduce the risk of abuse or diversion—even if the patient does not have a history of drug abuse. Potential precautions include non-refillable prescriptions, random drug testing and written treatment contracts. The latter should make clear that medications must be filled at one specific pharmacy, that there will be no emergency refills or extra medication if doses are lost, that the patient will not get prescriptions for the same or similar medication from another physician, and that the penalty for violating the rules will be termination of the relationship and a referral for drug abuse treatment.

6. Benzodiazepines should not be prescribed to borderline personalities or other patients with poor behavioral inhibition. However, when a patient with BPD, or a history of dramatic acting out without the full syndrome of BPD, comes into treatment already on chronic benzodiazepine treatment, the psychiatrist should withdraw benzodiazepine treatment very slowly, alert to the potential for exacerbation of behavioral problems by drug withdrawal effects. If the patient has been taking short-acting benzodiazepines regularly, whether on a schedule or as needed, rebound anxiety can create a vicious cycle that mimics addictive behavior. Switching to a long-acting benzodiazepine and withdrawing the latter slowly may help.

TREATING AXIS I DISORDERS IN PATIENTS WITH PERSONALITY DISORDERS

While treatment outcomes for Axis I disorders can be worse when there is Axis II comorbidity, there is only one situation I am aware of in which a personality disorder is a potential contraindication to an otherwise efficacious treatment for an Axis I disorder: the treatment of ADHD with stimulants. Here there are concerns that stimulants will be abused or diverted by patients with comorbid antisocial personality disorder, and that they will precipitate psychosis in patients with borderline personality disorder. However, a large-population pharmaco-epidemiological study of ADHD treatment and criminality showed that treatment of ADHD, principally with methylphenidate, reduced criminal behavior by 32% in men and 41% in women, and that the effect was seen independently of whether there was a comorbid personality disorder diagnosis (Lichtenstein et al., 2012). A Medline search revealed no controlled study of stimulant treatment of ADHD with comorbid BPD, but it did turn up a report that open-label use of methylphenidate in adolescent girls with comorbid ADHD and BPD improved symptoms of both conditions without precipitating psychotic symptoms (Golubchik et al., 2008). A cautious conclusion is that ADHD comorbid with borderline or antisocial personality may be treated with stimulants *if* there are well-defined target symptoms and appropriate precautions are taken. In the case of patients with antisocial personality, atomoxetine or lisdexamfetamine would appear preferable to methylphenidate, dextroamphetamine, or Adderall, as the first two drugs are not suitable for abuse by the intravenous route. In the case of patients with BPD and ADHD, stimulants should be started gradually, with frequent visits during dosage titration and specific inquiry about any psychotic and pre-psychotic symptoms. Medical psychiatrists specifically may encounter patients with ADHD on Axis I, borderline or antisocial personality on Axis II, and a significant chronic medical condition on Axis III, in whom the inattention and disorganization due to ADHD prevent effective treatment of the general medical condition. In this situation, effective treatment of the ADHD can improve the outcome of the medical condition, supporting the idea of an ADHD treatment trial despite the complexity added by the comorbid personality disorder.

TREATING SHORT-TERM SYMPTOMS OF PERSONALITY DISORDERS

One of the main problem-focused interventions of medical psychiatrists is advising on pharmacological treatment of patients with personality disorders who display anger, hostility, agitation, and/or aggressive behavior that disrupts medical treatment. This can be accompanied by psychotic thinking or perceptions, particularly in the case of patients with borderline or schizotypal personalities. Evidence supports the use of antipsychotic drugs to manage these symptoms in the case of borderline and schizotypal personality; the doses required can be lower than typically used in treating schizophrenia, but this is not necessarily the case. Antipsychotic drug treatment for transient aggressive or psychotic symptoms in borderline or schizotypal patients should begin with testing the efficacy of a low dose before advancing to full antipsychotic dosage if necessary. With schizotypal and borderline personalities, antipsychotic drug treatment for these symptoms is therapeutic and supported by controlled studies of efficacy. In contrast, the use of antipsychotic drugs to manage angry and aggressive behavior in non-psychotic patients with decompensated narcissistic or antisocial personalities is better viewed as “chemical restraint.” It may be warranted when necessary to permit essential medical treatment. When it is used, the duration of treatment should be limited to that needed to permit necessary medical care, and the necessity for antipsychotic drugs should be well documented. Nonetheless, given the overlap between the various Axis II disorders and the high comorbidity of Axis II and Axis I, there will be patients with personality disorders other than borderline or schizotypal who develop brief psychotic episodes or mood disorders with psychotic features. In those cases, there is a sound, evidence-based justification for antipsychotic drug therapy that goes beyond symptom management.

TREATING COMPONENT TRAITS OF PERSONALITY DISORDERS

The concept of treating specific traits associated with a personality disorder is best developed for BPD, where negative and unstable affect, impulsiveness/disinhibition, and aggressive/antagonistic behavior are consistent behavioral dispositions that are potential, measurable targets for treatment. A recent review of controlled trials of drug treatment for these traits in BPD (Ripoll, 2012) reached the following conclusions:

1. Olanzapine and aripiprazole (but not ziprasidone), in dosages lower than typically used for treating schizophrenia, have a moderate effect on traits of antagonism, negative affectivity, disinhibition, psychotic symptoms, and interpersonal dysfunction;
2. Antiepileptic drugs (AEDs) have shown moderate-to-large effects on the traits of antagonism, disinhibition, and negative affectivity. Specifically, valproate has shown benefits for antagonism and disinhibition, lamotrigine for disinhibition and negative affectivity, and topiramate for all of the above-mentioned traits.

3. The omega-3 fatty acid eicosapentanoic acid (EPA) has shown moderate-to-large effects on the traits of antagonism and negative affectivity.

An open-label trial of quetiapine showed a highly significant reduction in impulsiveness in patients with BPD, most of whom did not have psychotic symptoms (Villeneuve & Lemelin, 2005). On the other hand, a review of antipsychotic drugs in BPD that included first-generation neuroleptics concluded that the overall effect of antipsychotic drugs on global functioning was small (Ingenhoven & Duivenvoorden, 2011).

The challenge with the medical-psychiatric population is that all of the medications proved to be useful in treating BPD can in various ways exacerbate medical problems known to have a higher prevalence in individuals with BPD. BPD is associated with an increased prevalence of obesity and type 2 diabetes; the metabolic side effects of olanzapine in particular make these conditions worse. Cognitive impairment often is the dose-limiting side effect of topiramate, and the attentional and executive functions made worse by topiramate are frequently impaired in BPD prior to any drug treatment. Lamotrigine requires a lengthy dosage titration to minimize the risk of severe dermatological reactions; patients with BPD may have a particularly hard time complying with a prescription while waiting many weeks to see its benefit.

The author's conclusion is that BPD patients, particularly those with cardiovascular risk factors, should be prescribed omega-3 fatty acid supplementation unless the compliance burden of taking the supplements would diminish a specific patient's adherence to other, more essential, treatment. Antipsychotic drugs should not be given chronically for treatment of BPD as such, but if the patient has a psychotic disorder on Axis I, or their psychotic symptoms were significant enough to impair function or to interfere with necessary general medical treatment, the antipsychotic of choice would be aripiprazole if the patient was overweight, had glucose intolerance, cardiovascular risk factors, or a family history of diabetes or coronary artery disease. Olanzapine could be a first-line treatment in a patient who was underweight or normal weight without increased risk of a metabolic syndrome. Antiepileptic drugs cannot yet be seen as first-line treatment for BPD, but there would be good support for giving lamotrigine or valproate if the patient had comorbid bipolar disorder, and for trying topiramate if the patient had migraines and did not have significant cognitive impairment.

Psychotropic drugs have also been studied in randomized controlled trials as a treatment for schizotypal personality disorder. In this population, antipsychotic drugs have a moderate-to-large effect on anger, a moderate effect on cognitive-perceptual symptoms, and a small effect on global functioning. Mood-stabilizing AEDs were more efficacious overall, except for cognitive-perceptual symptoms, than the antipsychotic drugs, and antidepressants were of little benefit, even for patients with depressed mood (Ingenhoven et al., 2010).

Omega-3 fatty acid supplementation, EPA in particular, might be helpful in preventing the development of frank psychosis in patients with schizotypal personality. The evidence

supporting this potential for EPA supplementation comes from a controlled study of omega-3 fatty acids at a dose of 1.2 g per day (700 mg EPA, 480 mg DHA) in preventing the development of a first episode of schizophreniform psychosis in patients aged 13–25 with sub-threshold psychotic symptoms (Amminger et al., 2010).

A conservative view would be that in patients with schizotypal personality, antipsychotic drugs should be reserved for those with cognitive-perceptual symptoms of near-psychotic proportions and those with intermittent psychotic symptoms or continuous low-level psychotic symptoms. As with BPD patients, schizotypal patients should be encouraged to take omega-3 fatty acid supplements, if adding the supplements will not unacceptably raise the burden of treatment compliance. If a schizotypal patient has cardiac risk factors, the case for doing this is even stronger.

Avoidant personality disorder overlaps significantly with the Axis I disorder of social anxiety disorder; treating the latter can alleviate symptoms of the former, including the avoidance of social situations and the morbid fear of rejection. The antidepressants sertraline, paroxetine, and venlafaxine are approved for social anxiety disorder; while not approved for this indication, monoamine oxidase inhibitors (MAOIs) have shown effectiveness in controlled trials (Dalrymple, 2012). MAOIs can help patients who do not respond adequately to SSRIs or serotonin-norepinephrine reuptake inhibitors (SNRIs) (Blanco et al., 2013). However, in the context of chronic medical disease, the use of MAOIs is fraught with risks of interactions with food and drugs. However, if patients are so avoidant that they do not show up for medical appointments, the option might be considered with appropriate risk management. While there is no controlled evidence to support its use for social avoidance *per se*, transdermal selegiline, an MAO-B selective MAO inhibitor—is an effective treatment of depression with particular efficacy for anxiety symptoms (Robinson et al., 2007). Unlike the approved oral formulations of MAOIs, transdermal selegiline does not require food restrictions, and it does not have pharmacokinetic interactions with drugs metabolized by the CYP450 system (Azzaro et al., 2007). It would be a rational choice for an avoidant, anxious, depressed patient for whom first-line therapies had failed and social anxiety was compromising medical treatment.

PSYCHIATRIC LIAISON VERSUS PSYCHIATRIC PRINCIPAL CARE

Patients with less mature defenses and poor interpersonal relations are particularly likely to produce anger in the people who care for them; the consequence of their splitting defenses is the polarization of the caregivers. For these patients, psychiatric consultation rarely helps unless the reactions of attending physicians and nursing staff are addressed explicitly. Attention to the requester of the consultation, liaison work with nursing staff, and ongoing availability of the consultant are needed to forestall crises. Weekend and holiday coverage for the consultant must be arranged to promote maximum consistency of advice given to all involved.

When dealing with other healthcare providers, the consultant should permit ventilation of anger and disagreement and then emphasize that these reactions provide diagnostic information about the patient. The consultant should help them “cool down,” so the basic principles of being consistent, giving a sense of control, and setting limits without anger can be emphasized. (Further details are offered in the earlier section in this chapter on preventing and managing staff splitting.)

Often, suggestion of a pharmacological intervention, such as recommending short-term antipsychotic drug treatment for the patient, permits a face-saving reappraisal of the patient by the staff. If the patient can be viewed as “stabilized” by an external agent, anger over the patient’s past behavior can be rationalized. These pharmacological interventions must not be carried out solely for their effect on staff, but should be indicated by the patient’s diagnosis and behavior.

Sometimes consultation, even with liaison and follow-up, is insufficient to contain the self-destructive, disruptive, or noncompliant behavior of the medically ill patient with a severe personality disorder. At other times, as with some pain patients, personality problems can prevent proper diagnosis and management in a purely medical setting. In these situations, principal care of the patient by the psychiatrist can facilitate resolution of the problem. When this arrangement is chosen, all orders are written by the psychiatrist, who sees the patient daily and uses medical specialists as consultants. At hospitals where there is a medical-psychiatric unit, an inpatient usually can be transferred there. Psychiatric primary care can greatly improve consistency of management because it puts the psychiatrist in the front-line position of deciding whether particular physical complaints need medical intervention or should be dealt with as somatic expression of a psychiatric disorder.

Psychiatric principal care is unsuitable if the medical problem is unstable; in such a case, concurrent care is better. Medical-psychiatric units may do better at containing the behavior of personality-disordered patients than they do at changing their maladaptive defenses; longer-stay, milieu-oriented units and outpatient therapy are more suited to promoting enduring behavioral change. Therefore, patients with severe personality disorders and active medical illness usually should be stabilized on a medical service or medical-psychiatric unit and then transferred to a conventional psychiatric unit if milieu-oriented inpatient treatment is still needed after medical stabilization.

Psychiatric principal care at times is suitable for long-term outpatient treatment. The patient’s coping with the chronic illness and health care system can be used as a focus for psychotherapeutic exploration and behavioral change.

HEALTHCARE PROVIDERS’ REACTIONS TO PATIENTS WITH PERSONALITY DISORDERS

Reactions to patients with personality disorders cover a wide range of possibilities, including hate, anger, desire to avoid or abandon the patient, personal attraction, overprotectiveness,

and taking sides with the patient against family members or other healthcare professionals. The detection of countertransference reactions can be more difficult when they are defended against with reaction formation. For example, compulsive over-concern or excessive inclusiveness during a medical workup can be a defense against an unacceptable desire to avoid the patient.

Gallop and Wynn (1987), observing the reactions of nurses and psychiatry residents to hospitalized patients with severe personality disorders, noted that nurses were likely to be explicitly angry, rejecting, and devaluing of the patients. The psychiatry residents were likely to feel incompetent and powerless, and to develop conflicts with their supervisors.

Even the *label* of personality disorder has effects on countertransference. Including the term “personality disorder” in a case vignette of a patient with a major depression led to a lower rate of psychiatrists’ recommendations for antidepressant drug treatment and to inferences that the patient was not motivated, or even seriously ill (Lewis & Appleby, 1988). (Patients with BPD don’t like being called “borderline,” either.)

In general psychiatric settings, a barrier to healthcare providers’ recognizing their countertransference is defensiveness, sometimes related to a feeling that that countertransference is undesirable, avoidable, or simply embarrassing. In medical-psychiatric settings, the greatest barrier to a clear awareness of countertransference is the distraction of the patient’s general medical care. On medical-psychiatric units, psychiatrists and nurses can lose sight of countertransference issues that would not escape their notice in a general psychiatric setting.

PERSONALITY DISORDERS IN LONG-TERM CARE

Elderly and/or disabled people living in nursing homes, assisted living facilities, or other long-term care facilities must contend with a loss of privacy and a loss of control, and unfortunately often with inappropriately familiar treatment by caregiving staff. Leaving the problematic situation is often difficult, because the facility is the person’s home and not merely a temporary locus of healthcare. Patients with mature defenses and an agreeable personality can tolerate these problems, and might even enjoy the social environment of a long-term care facility (if it is a good one). Patients with immature defenses can decompensate and, in addition to feeling distress, they might resist care, verbally abuse caregivers, become physically agitated, make threats, and show other forms of disturbing behavior.

In these situations, a consistent, regular, supportive psychotherapeutic relationship can have a remarkably stabilizing effect on the patient’s behavior. Indeed, many of these patients had supportive relationships with family members or primary care physicians prior to their move to a long-term care facility. The patient’s move to a facility might have been triggered by the loss of supportive relationship. Or, the move to the facility might lead to a loss of a supportive relationship, as when

the facility is inconvenient for a significant person to visit frequently.

Liaison interventions with the staff of long-term care facilities should focus on reducing the caregivers' level of affect and intimacy with the patient when it is clear that the patient is overwhelmed and the situation is becoming chaotic. Neuroleptic therapy, when considered because of acting-out behavior, should be kept to the low doses appropriate for treating personality disorders; full antipsychotic doses rarely are necessary and are associated with a high rate of disabling side effects. Second-generation antipsychotic drugs such as quetiapine or aripiprazole are preferable to first-generation agents or risperidone.

Age prejudice can lead to insensitivity to the distress of older patients with personality disorders; alternatively, oversolicitousness and excessive sympathy can lead to an underutilization of appropriate confrontation and limit-setting. Psychiatrists must carefully examine their own attitudes toward aging and aged people as well as the attitudes of the caregivers seeking consultation. Caregivers' beliefs about old age should be explored; even experienced caregivers can have misconceptions they have not questioned, despite contradictory experience. For example, many clinicians believe that older patients are more hypochondriacal than younger ones. Actually, they simply suffer from more diseases, and when this is controlled for, they do not display more illness behavior or worse self-rated health (Costa & McCrae, 1985).

BOUNDARY ISSUES

Psychiatrists' training sensitizes them to boundary issues with their psychotherapy patients; even a first-year psychiatry resident would not offer a patient a ride home from the clinic or purchase an investment on a patient's recommendation. The physical examination of a psychotherapy patient is constrained by concern about the implications of touching the patient's body and the potential for misunderstanding of the psychiatrist's intentions. On the other hand, a patient receiving electroconvulsive therapy (ECT) would necessarily require a physical examination by the psychiatrist, as would one suspected of having the neuroleptic malignant syndrome. In medical psychiatry, boundary issues are subtler. For example, when excessive illness behavior is suspected, the physical examination of the patient can give the psychiatrist a deeper understanding of the patient's actual physical condition and can occasionally provide new diagnostic information for the patient's non-psychiatric physicians. Or, in palliative care situations, the touch of the psychiatrist can be comforting and healing. How much the medical psychiatrist physically touches the patient ideally should be a flexible decision, responsive to the clinical issue and the context of care. However, when the patient has a personality disorder—particularly BPD or a personality disorder with paranoid features—the risk that the patient will perceive a boundary violation can be so high that it outweighs the benefit of physical examination by the psychiatrist. Of course, if there is a medical emergency, the

psychiatrist should do what is necessary, though even then a third party should be present if at all possible. In other situations where there is a strong case for a physical examination by the psychiatrist, consultation with a colleague—and documentation of the clinical reasoning—is recommended.

Similar issues arise when treating chronically disabled patients who cannot easily leave their homes but require psychiatric treatment. When the psychiatrist sees the patient in their home, there is a threshold that is literally crossed—but often quite appropriately. When the patient has—or is suspected of having—a severe personality disorder, the risk of a destructive interaction with the patient can be reduced by having a third party at hand when the psychiatrist visits the patient's home, whether a nurse, a paid caregiver, or a family member.

LEGAL CONCERNS

Patients with less mature defenses and personality disorders who have unstable interpersonal relations can rapidly turn against their physicians because of disappointment or disagreement. If there has been an error of judgment or an unexpectedly poor medical outcome, the patient might sue the physician or threaten litigation with manipulative intent. Lawyers, not understanding the dynamics of borderline personality, might with good intentions pursue patient claims that are based more on near-psychotic transference reactions than on reality (Gutheil, 1985).

In general medical settings, psychiatrists frequently are called to consult when a physician–patient relationship has begun to deteriorate and a threat of a malpractice suit has been made. While psychiatric interventions with the patient and involved clinicians are made to “cool down” the situation, the physician threatened with litigation should be asked to obtain a second opinion on their care of the patient to date and the current plan of treatment, and to document thoroughly the reasons for the medical decisions made to date if they are not completely clear from the medical record. With the medical records and the second opinion in hand, the medical psychiatrist discusses past medical treatment and future plans with the physician at risk. Then, with a good understanding of the medical issues, the psychiatrist interviews the patient, with the aim of separating problems in the physician–patient relationship from issues about the medical treatment as such. After the interview, the psychiatrist usually will know whether the patient and the physician at risk can work out their differences with the psychiatrist's help. If not, the psychiatrist's task is to prepare both the patient and the physician at risk for a transition of care that demonstrates compassion, empathy, and lack of defensiveness on the part of the physicians involved.

Occasionally, the psychiatrist has an opportunity for primary prevention of litigiousness against a general medical physician. The opportunity presents if the psychiatrist knows that patient with a chronic illness has a borderline or low-level narcissistic personality and becomes aware that the patient is idealizing their principal physician. In this situation, the psychiatrist can advise the physician to

gently disillusion the patient, repeatedly reminding him or her of the uncertainty of medical outcomes, the limitations of treatment, and the limitations of any physician facing chronic disease. The psychiatrist can prompt the physician to scrupulously document informed consent, to obtain second opinions whenever a suggested treatment has known adverse effects and there are reasonable alternatives, and in general to use the language of humble collaboration rather than of rescue. Specifically as regards consent, merely having the patient fill out a form that perfunctorily lists risks of a procedure or treatment is not sufficient. The physician should note specifically which risks were discussed orally, what other information was provided to the patient (e.g., video recordings or websites), and any specific questions the patient asked and how they were answered. It is admittedly burdensome to do all of this, and for most patients it is unnecessary. However, experience teaches us that the more extreme forms of idealization are no compliment to a physician—they are a warning that is best heeded.

CLINICAL PEARLS

- Different constructs of personality can be helpful to help the patient or caretakers to understand the patient. Besides DSM diagnoses, these constructs include attachment styles, Myers-Briggs types, Cloninger's dimensions of temperament and character, and analysis of defenses.
- Patients' different personality styles suggest that they will do better with physicians of certain personalities. The challenge is to make the best match.
- The medical psychiatrist's solution of a problem in a patient with personality disorder should consider:
 - the patient's view of the problem;
 - the practical, negotiable issues, which are compounded by emotional issues and interpersonal conflicts;
 - evidence of an Axis I diagnosis;
 - the influence of prescribed medications, alcohol, or illicit drugs, or withdrawal;
 - the patient's perception of the physician–patient relationship and of the patient's role in the treatment;
 - whether the immediate problem is provoked by inappropriate or inflexible behavior by a physician, nurse, or other healthcare provider;
 - whether a medical disorder or medication side-effect been overlooked or misdiagnosed.
- The physician in charge of coordinating a patient's care—and there should be one—should determine the top short-term priorities for behavior change (including treatment adherence) and limit what is asked of the patient at one time.
- In the setting of a patient with personality disorder, the need for consistency makes different email

communication systems a problem. If all email communication goes through a common secure portal, designed so that all involved healthcare providers can see all of the messages, it can be a powerful tool for aligning everyone's advice and for identifying differences of opinion so they can be promptly resolved.

- Taking the “one-down” position means realistically recognizing one's limitations in affecting another person's behavior and approaching the patient with genuine and appropriate humility.
- Limit setting is the trump card—to be played if a patient is seriously impeding treatment or is endangering someone.
- For outpatients, typical circumstances for limit setting are diversion of prescription drugs, verbal abuse of the office staff, and threats of violence.
- Sympathetic limit setting should not be used with paranoid, avoidant, and schizotypal patients because sympathy can arouse further anxiety by implying closeness.
- Limits framed so they save face for the patient often are embraced gratefully by patients with more primitive narcissistic personalities.
- Reframing aligns the physician's directive with the patient's style. In the case of narcissism, the medical need for treatment adherence is expressed in language appealing to the patient's sense of specialness.
- Experience teaches us that the more extreme forms of idealization are no compliment to a physician—they are a warning that is best heeded.

PART V

NEUROPSYCHIATRIC DISORDERS

DELIRIUM

NEUROBIOLOGY, CHARACTERISTICS, AND MANAGEMENT

José R. Maldonado

INTRODUCTION

Epidemiologically, delirium is likely the most common psychiatric syndrome found in the general hospital setting. Its occurrence parallels the severity of the underlying medical processes. Clinically, delirium presents as an acute or subacute organic mental syndrome characterized by disturbance of consciousness, global cognitive impairment, disorientation, perceptual disturbance, deficits in attention, changes in psychomotor activity, disordered sleep–wake cycles, and fluctuations in symptom severity, all representing a significant change over the patient’s baseline level of cognitive and behavioral functioning. Etiologically, delirium is a neurobehavioral syndrome caused by the transient disruption of normal neuronal activity secondary to disturbances of systemic physiology. The phenotypes of delirium (i.e., hyperactive, hypoactive, mixed) are likely a function of which of the various neurotransmitter systems predominates, which can change due to progression of illness or the influence of environmental and/or pharmacological agents.

Hippocrates provided a clear description of the syndrome, but called it *phrenitis*, meaning an “acute inflammation of mind and body” (Lipowski, 1991). In fact, *phrenitis* literally means “inflammation of the mind or diaphragm” (Greek *phren* = mind, diaphragm; *itis* = inflammation) (Sakai, 1991; Frederiks, 2000). It was an ancient disease concept or descriptive notion that denoted a disease consisting of a combination of a mental disorder and fever (the term *phrenes* had a double meaning, indicating both a mental and a somatic domain), distinguishing *phrenitis* from conventional madness (Sakai, 1991; Frederiks, 2000).

The term *delirium* is reported to have been first used by the lay Roman writer Celsus (A.D. 1) (Adamis et al., 2007) and described in his compendium *De Medicina* as “a madness which is both acute and happens in a fever; the Greeks call it *phrenitis*” (Celsus, 1814, Chapter XVIII, p. 115). According to Celsus, a fever becomes a *phrenitis* “when the delirium begins to continue without interruption; or when the patient, though he still have his reason, yet forms to himself some vain images: it is perfect, when the mind gives itself up to these images” (Celsus, 1814). It was also Celsus who was the first to declare that “not all deliria were reversible, but in some cases, although the causes disappeared, patients continued

to be demented.” *Delirium* is derived from the Latin roots *de* (meaning “away from”), *lira* (meaning “furrow in a field”), and *ium* (Latin for singular), and literally means “a going off the plowed track; a madness.” Celsus described the various forms of delirium: “Now there are several kinds of it: for among *phrenitic* people some are merry, others sad; other grow outrageous, and do acts of violence.... Those, who are more violent in their actions, it is proper to bind, lest they should hurt either themselves or any other person.” Despite Celsus’s introduction of the term *delirium*, the syndrome continued to be referred to as “*phrenitis*.”

In the second century A.D., Aretaeus classified diseases as “acute” or “chronic.” Among the known mental disorders of the time, *phrenitis* and *lethargy* (*lethargus*) were the chief acute diseases, and both were believed to be caused by fever or poisons and thus reflecting brain disease (Lipowski, 1991). The ancient description of *phrenitis* typically involved restlessness, insomnia, and hallucinations, and appears consistent with our current understanding of *hyperactive delirium*. Conversely, *lethargy*, involving undue quietness and sleepiness, is more akin to what we now call *hypoactive delirium*.

It was not until the sixteenth century that we find the first description of delirium in the English medical literature, in the textbook *The Method of Physick* (Barrough, 1583). Barrough called it “*frenesie*” and described it involved the derangement of three main functions: imagination, cogitation, and memory; also featuring disturbed sleep.

Thomas Willis (1621–1675) described delirium as resulting from “fever, poisoning, hemorrhage, lack of sleep, and drunkenness” (Willis, 1672). According to Willis, its core features included “incongruous conceptions and confused thoughts,” distorted visual perceptions, and disturbed behavior. Willis referred to *phrenitis* as “an inflammation of the whole sensitive soul and animal spirits” (Bynum, 2000).

It was not until the nineteenth century that the term *phrenitis* was replaced by the word “delirium,” in part due to the efforts of Gerard van Swieten (1700–1772), Giovanni Battista Morgagni (1682–1771), and Philippe Pinel (1745–1826) (Byl & Szafran, 1996; Frederiks, 2000). After the works of these luminaries of medicine, the word *phrenitis* fell into disuse, replaced by the term *febrile delirium* (Berrios, 1981). In 1813, the British physician Thomas Sutton introduced the term *delirium tremens* to designate delirium caused by

the withdrawal from “spirits, and in consequence of excess or habitual indulgence in them” (Sutton, 1813). In modern times, the term is exclusively applied to delirium resulting from alcohol withdrawal (2001). In the 1817 German treatise “The Dream and the Feverish Insanity” (*Der Traum und des fieberhafte Irreseyn*), Greiner first pioneered the term “clouding of consciousness” (*Verdunkelung des Bewusstseins*) to describe the pathophysiological abnormality responsible for delirium, and linking disordered consciousness to the phenomenon of delirium (Greiner, 1817). This relationship was further developed by Jackson, who viewed delirium as a clinical manifestation of disordered consciousness (Jackson, 1932). To Jackson, delirium represented a state of reduced consciousness that ranged from the “slightest confusion of thought to coma,” and was due to some degree of “dissolution” of the topmost layer of the nervous centers and consequent release from inhibition of the evolutionarily lower centers.

Some of the most significant contributions in the field of delirium include the works of:

Engel and Romano (1959), who demonstrated that the behavioral and cognitive manifestations of delirium were a reflection of an underlying metabolic derangement, and demonstrated the relationship between reduction of brain metabolic rate and electroencephalogram (EEG) slowing;

Blass et al. (1981), who first proposed that impaired cerebral oxidative metabolism resulted in reduced synthesis of various neurotransmitters, particularly acetylcholine, leading to some of the characteristic deficits; and

Lipowski (1967, 1980, 1987), considered by many the contemporary father of the study of delirium, who, in his early seminal work, summarized the history of the field, highlighted the problem with nomenclature, characterized its clinical features, summarized known etiological factors, suggested diagnostic criteria and management, and influenced the course of delirium research for years.

Unfortunately, one of the factors contributing to confusion about delirium is that there are many other terms used by various medical disciplines to describe the same phenomenon: for example, “ICU (intensive care unit) psychosis,” “sundowning,” “acute confusional state,” “toxic confusional state,” “post-anesthetic excitement,” “acute postoperative psychosis,” “post-cardiotomy delirium,” and “toxic-metabolic encephalopathy.” The author personally prefers the term *acute brain failure*, as this term is compatible with multiple etiologies and settings, describes the acuteness of the onset, implies that the most important organ in the body, the brain, is failing, and this may be associated with significant cognitive decline, morbidity, and mortality.

EPIDEMIOLOGY OF DELIRIUM

Delirium’s prevalence surpasses that of all other psychiatric syndromes in the general medical setting (Maldonado,

2008b; NICE, 2010). In fact, delirium has been reported to be one of the six most common preventable conditions in hospitalized elderly patients (Rothschild & Leape, 2000). Some specific medical conditions and surgical procedures are associated with a particularly high incidence of delirium during the postoperative period and among critical care unit patients (see Table 41.1). Terminally ill cancer patients, patients with moderate to severe traumatic brain injury, frail elders, and the critically ill are clinical populations generally recognized to have a high incidence of delirium over their course of illness, due to factors such as polypharmacy, comorbid medical conditions, and metabolic dysfunction.

A recent study at a large general hospital found that delirium had a point prevalence of one in every five inpatients, with some variation in certain medico-surgical units and populations (Ryan, et al. 2013). The frequency of delirium varies from 15% to 60% in hospitalized general medical and surgical patients (Smith & Dimsdale, 1989; Francis, Martin, & Kapoor, 1990; Levkoff et al., 1992; Schor et al., 1992; Williams-Russo, Urquhart, Sharrock, & Carlson, 1992; Pompei et al. 1994; Parikh & Chung, 1995; van der Mast & Roest, 1996; Elie, Cole, Primeau, & Bellavance, 1998; Bucht, Gustafson, & Sandburg, 1999; Fann Alfano, Roth-Roemer, Katon, & Syrjala, 2007; Aldemir Ozen, Kara, Sir, & Bac, 2001; Lepouse, Lautner, Liu, Gomis, & Leon, 2006; Siddiqi, House, & Holmes, 2006; Hala, 2007; Lundstrom et al., 2007; Maldonado, 2008b; Katznelson et al., 2009; Maldonado et al., 2009; Tognoni et al., 2011; Ryan et al., 2013). The rate of postoperative delirium has been reported to range from 10% to 74% (Dyer, Ashton, & Teasdale, 1995; Vaurio, Sands, Wang, Mullen, & Leung, 2006; Bruce, Ritchie, Blizzard, Lai, & Raven, 2007; Maldonado et al., 2009; Wiesel, Klausner, Soffer & Zold, 2011). Studies have demonstrated that up to 87% of critically ill patients develop delirium during their ICU stay (Ely, Margolin, et al., 2001). Delirium is common among cancer patients (Adams, 1988; Weinrich & Sarna, 1994; Morita, Tei, Tsunoda, Inoue, & Chihara, 2001; Breitbart, Gibson, & Tremblay, 2002; Centeno, Sanz, & Bruera, 2004; Gaudreau, Gagnon, Harel, Tremblay, & Roy, 2005; Gaudreau, Gagnon, Roy, Harel & Tremblay, 2007).

Among the elderly, studies have found that between 14% and 24% of elderly patients are admitted to the hospital with delirium (Inouye, 1998). It is estimated that new cases arise in 6%–46% of hospitalized elderly patients (Inouye, 1993). In the emergency department, the prevalence in elderly patients is 9.6% (Elie et al., 2000). This data is consistent with more recent studies demonstrating that among those aged 85+ years, the prevalence of delirium is about 10%, rising up to 22% in populations with higher percentages of demented elders and as high as 70% for those in long-term care facilities (de Lange, Verhaak, & van der Meer, 2013).

The occurrence of delirium seems to be highest among the very sick. Various studies have repeatedly demonstrated that up to 87% of those critically ill develop delirium during their stay in critical care units (Ely, Margolin, et al., 2001).

**Table 41.1 A COMPARISON OF THE INCIDENCE OF PSYCHIATRIC DISORDER
IN THE GENERAL POPULATION AND DELIRIUM AMONG MEDICALLY ILL PATIENTS**

MEDICAL POPULATIONS UNDER STUDY	PREVALENCE OF DELIRIUM (%)
General Medicine Wards	9–24% (Ritchie et al., 1996; Valdes et al., 2000; Maldonado, Dhami, & Wise, 2003; Gonzalez, de Pablo, et al., 2004; Speed et al., 2007)
HIV/AIDS	30%–40% (Fernandez, Levy, & Mansell, 1989; Uldall et al., 2000)
Medical-ICU	60%–80% (Ely et al., 2001)
Post-Stroke	13%–48% (McManus et al., 2007)
Surgery	
Postoperative Delirium	10%–74% (Vaurio et al., 2006; Wiesel, Klausner, et al., 2011)
General Surgical Wards	7%–52% (Dyer & Teasdale, 1995; Bucht, Gustafson, & Sandburgh, 1999)
Spine Surgery	12.5% (Kawaguchi et al., 2006)
Post-CABG	25%–32% (Nevin, Colchester, et al., 1989; Ebert & Herrmann 2001)
Post-Cardiotomy	50%–67% (Smith & Dimsdale, 1989; van der Mast & Roest, 1996; Maldonado et al., 2009)
Abdominal Aneurysm Repair	33% (Benoit et al., 2005)
Geriatrics	
Outpatient Minor (Cataract) Surgery	4.4% (Milstein et al., 2002)
At Time of Hospitalization	10%–15%
In Nursing Homes	15%–60%
Frail Elderly Patient	60% (Francis et al., 1990)
Elective Hip or Knee Replacement	25% (Gustafson, Berggren, et al., 1988; Marcantonio, Flacker, et al., 2000)
Bilateral Knee Replacement	41% (Williams-Russo et al., 1992)
Femoral Neck Fracture Repair	65% (Gustafson, Bucht, et al., 1988; Marcantonio et al., 2000)
Oncology	
General Prevalence	25%–40% (Weinrich & Sarna, 1994; Olofsson et al., 1996; Tuma & DeAngelis, 2000)
Palliative Care Units	26%–44% (Lawlor, Pereira, et al., 2000; Morita, Tei, et al., 2001; Lawlor, 2002; Centeno, Sanz, & Bruera, 2004)
Bone Marrow Transplantation	73% (Fann et al., 2007)
Advanced Cancer	Up to 85% (Lawlor et al., 2000)
Psychiatry	
Among Psychiatric Patients	14.6% (Ritchie et al., 1996)

In addition, delirium is common among cancer patients (Adams, 1988; Weinrich & Sarna, 1994; Morita et al., 2001; Breitbart et al., 2002; Centeno, Sanz, & Bruera, 2004; Gaudreau et al., 2005b). Among those with advanced cancer, delirium was diagnosed in 42% of patients on admission, while it developed in 45% of hospitalized cancer patients who were not delirious at the time of admission (Lawlor

et al., 2000). Similar to patients in critical care units, terminal delirium occurs in up to 88% of patients dying of cancer (Lawlor et al., 2000).

The large variation of incidence and prevalence data reported by the various studies reflects differences in patient populations studied, the severity of their medical conditions, and the diagnostic criteria used.

IMPACT OF DELIRIUM

MORBIDITY AND MORTALITY RELATED TO DELIRIUM

Across many hospital settings (e.g., emergency department, general medical ward, postoperative, critical care units) and after controlling for multiple variables (e.g., demographics, age, gender, illness severity, and comorbid medical conditions), patients who develop delirium fare much worse than comparable nondelirious cohorts (Vasilevskis, Han, Hughes, Ely, 2012). A recent meta-analysis, including 16 studies ($n = 6410$) among critically ill patients, demonstrated that, despite modern advances, when compared to their nondelirious counterparts, hospitalized patients with delirium had higher mortality rates (odds ratio [OR]: 3.22; 95% confidence interval [CI]: 2.30–4.52); had longer lengths of stay in both the ICU (weighted mean difference [WMD]: 7.32 days; 95% CI: 4.63–10.01) and in the general hospital (WMD: 6.53 days; 95% CI: 3.03–10.03); spent more time on mechanical ventilation (WMD: 7.22 days; 95% CI: 5.15–9.29); experienced a higher rate (6X) of complications (e.g., acute respiratory extubation, removal of catheter, cardiac arrhythmia; OR: 6.5; 95% CI: 2.7–15.6); and were more likely to be discharged to skilled placement (OR: 2.59; 95% CI: 1.59–4.21) (Zhang, Pan, & Ni, 2013).

Delirious patients, when compared with patients suffering from the same medical problem who do not develop delirium as a complication, experience prolonged hospital stays—five to ten days longer on average (Francis, Martin, & Kapoor, 1990; O’Keeffe & Lavan, 1997; Ely, Gautam, et al. 2001; Maldonado, Dhimi, & Wise, 2003; Ely, Shintani et al., 2004). Significantly more patients who develop delirium in the hospital ultimately require institutional post-acute care, such as placement in a skilled nursing facility (e.g., 16% for delirium patients versus 3% for those without delirium), even after controlling for illness severity, activities of daily living (ADL) status, prior cognitive impairment, and fever (Francis, Martin, & Kapoor, 1990; O’Keeffe & Lavan, 1997). Psychiatric hospital inpatients with delirium had hospital stays that were 62.1% longer than those of patients without delirium (Ritchie, Steiner, & Abrahamowicz, 1996).

Among critically ill patients there is an independent association between delirium present within 24 hours after admission to the critical care unit with an increased in-hospital mortality (i.e., 16.2% for delirious patients vs. 5.7% for nondelirious; van den Boogaard et al., 2010). Others have reported that patients who developed delirium in critical care units experience higher mortality, both at 90 days (11% vs. 3%; Pompei et al., 1994) and at 6 months (34% vs. 15%; Ely et al., 2004; (See <http://jama.jamanetwork.com/article.aspx?articleid=198503>)). A recent meta-analysis of clinical observational studies in critically ill patients revealed that, when compared with their nondelirious counterparts, delirious patients had higher mortality rate (OR: 3.22; 95% CI: 2.30–4.52); a higher rate of complications including removal of catheter, self-extubation, reintubation, acute respiratory distress syndrome, nosocomial pneumonia,

cardiopulmonary edema, and cardiac arrhythmia (OR: 6.5; 95% CI: 2.7–15.6); longer length of stay in both the critical care unit (weighted mean difference [WMD]: 7.32 days; 95% CI: 4.63–10.01) and hospital (WMD: 6.53 days; 95% CI: 3.03–10.03); spent more time on mechanical ventilation (WMD: 7.22 days; 95% CI: 5.15–9.29); and were more likely to be discharged to skilled placement (OR: 2.59; 95% CI: 1.59–4.21) (Zhang et al., 2013).

Delirium’s impact among the elderly is even greater. The mortality rate for elderly patients in acute care hospitals is much higher among those with delirium than those without delirium: 8% versus 1% in one study (Francis, Martin, & Kapoor, 1990). Among hospitalized, elderly, medically ill patients, incident delirium was associated with an excess stay after diagnosis of 7.78 days, even after controlling for covariates (McCusker, Cole, et al., 2003). Similarly, studies have demonstrated that delirium in the emergency department was an independent predictor of prolonged hospital length of stay (twice as long), compared to nondelirious patients, even after adjusting for confounding factors (Han et al., 2011). Furthermore, the number of days of delirium older patients experience while in the critical care unit is significantly associated with time to death within 1 year post-ICU admission, after controlling for age, severity of illness, comorbid conditions, psychoactive medication use, and baseline cognitive and functional status (hazard $p = 0.001$; hazard ratio, 1.10; 95% CI, 1.02–1.18); see Thoracic Society Journals, http://www.atsjournals.org/doi/abs/10.1164/rccm.200904-0537OC?url_ver=Z39.88-2003&rfr_id=ori:rid:crossref.org&rfr_dat=cr_pub%3dpubmed&#.VB9cea10wfg – Figure 2 Pisani, Kong, et al., 2009.

These bleak prognoses apply not only to severe cases; even patients with prevalent subsyndromal delirium (SSD) have been shown to experience longer acute-care hospital stay, increased post-discharge mortality, more symptoms of delirium, and a lower cognitive and functional level at follow-up than patients with no SSD (Cole, McCusker, Dendukuri, & Han, 2003). Among patients admitted to an intensive care unit, when comparing no delirium versus SSD, the mortality rate goes up from 2.4% to 10.6% ($p < 0.001$), ICU length of stay goes up from 2.5 to 5.2 days ($p < 0.001$), and the overall hospital length of stay goes up from 12.9 to 16.7 days ($p < 0.001$) (Ouimet, Kavanaugh, Gottfried, & Skrobik, 2007).

COGNITIVE AND BEHAVIORAL SEQUELAE

There appears to be a reciprocal relationship between delirium and cognitive decline, with evidence demonstrating that the presence of baseline cognitive deficits, including dementia, lowers the threshold to develop delirium (Inouye, 1998; Wahlund & Bjorlin, 1999; Litaker, Locala, Franco, Bronson, & Tannous, 2001; McNicoll et al., 2003; Benoit et al., 2005; Kalisvaart et al., 2006; Wacker, Nunes, Cabrita, & Forlenza, 2006; Smith, Attix, Weldon, Greene, & Monk, 2009; Franco, Valencia, et al., 2010; Tognoni et al., 2011). Data suggests that baseline dementia is the strongest risk factor for delirium among older patients (Elie et al., 1998; McCusker et al., 2003; McAvay et al., 2006; Inouye et al., 2007). On the other hand,

the development of delirium appears to increase the risk of cognitive decline, including long-term cognitive impairment (LTCl) and dementia (Rockwood et al., 1999; Morandi et al., 2012). A number of pathways and mechanisms have been proposed, yet, despite of some suggestive evidence, none has been conclusively proven as causative (see Box 41.1).

Both clinical experience and research data suggests that many patients do not fully recover (cognitively) from delirium, particularly the elderly. The proportion of patients with residual cognitive impairment reported in various studies depends on the clinical population under study, the cause of the delirium (when it is known), and the threshold and criteria used for diagnosing. In fact, a substantial number of patients who survive delirium are left with post-delirium cognitive impairment (Wacker et al., 2006; Griffiths & Jones, 2007; Bickel, Grading, Kochs, & Forstl, 2008; Kat et al., 2008; Maldonado, 2008b; Fong et al., 2009; MacLulich, Beaglehole, Hall, & Meagher, 2009; Girard et al., 2010). Data demonstrates that, when compared to controls, patients diagnosed with delirium are much more likely to experience LTCl (Macdonald, 1999; Rockwood et al., 1999; Jackson, Gordon, Hart, Hopkins, & Ely, 2004; Gunther, Jackson, & Ely, 2007). A study of mechanically ventilated patients who experienced in-hospital delirium found that at 3-month and 12-month

follow-ups, 79% and 71% of survivors had cognitive impairment, respectively, with 62% and 36% being severely impaired (Girard et al., 2010). These studies demonstrate that delirium duration was independently associated with long-term cognitive outcome (i.e., the longer the duration of delirium, the more significant the cognitive deficits). For example, an increase from 1 day of delirium to 5 days was independently associated with nearly a 5-point decline (i.e., a one-half standard deviation [SD] decline) in the cognitive battery mean score (95% CI, -9.2 to -0.1). In fact, more than 20 prospective studies (> 5,000 patients) during the last three decades demonstrate a significant association between delirium and long-term cognitive dysfunction (MacLulich et al., 2009; Witlox et al., 2010). The studies suggest that about 40% of patients with delirium develop some form of cognitive impairment when followed up from about 3 months to 5 years after an episode of delirium (Levkoff et al. 1992, McCusker, Cole, Dendukuri, Belzile, & Primeau, 2001; Jackson et al., 2004; Witlox et al., 2010). A comprehensive meta-analysis concluded that there is greater cognitive impairment among patients with delirium than matched controls; there is a higher incidence of dementia in patients with a history of delirium; and that one of three survivors of critical illness with delirium developed cognitive impairment (Jackson et al., 2004). A systematic search

Box 41.1 MECHANISMS MEDIATING DELIRIUM AND COGNITIVE IMPAIRMENT

1. A number of factors and mechanisms leading to delirium may also directly cause CNS damage and neuronal dysfunction, and thus mediate both the manifestations of delirium and long-term cognitive impairment, including:
 - a) cytokine release and other neuroinflammatory mediators;
 - b) decrease perfusion and oxygenation, leading to decreased cerebral oxidative metabolism;
 - c) changes in blood-brain barrier permeability;
 - d) hyper-catabolic states;
 - e) water and electrolyte imbalances;
 - f) excessive glucocorticoid levels and other HPA-axis dysfunctions;
 - g) melatonin and sleep-wake cycle abnormalities
 - h) genetic factors (e.g., some have described an association between APOE4 and prolonged delirium duration)
 - i) Amyloid- β deposition (e.g., increased amyloid- β levels have been associated with subjective cognitive dysfunction in critical illness survivors)
2. Pharmacological agents used to treat the underlying causes of the delirium (e.g., steroids, calcineurin inhibitors, other immunosuppressants, dopamine) or the agents used to treat delirium (e.g., dopamine-blocking agents, benzodiazepines) may themselves lead to neuronal damage in a fragile brain.
3. Any of the mechanisms listed above may themselves lead to alterations in neurotransmitter concentration or receptor sensitivity, which itself may underlie the different symptoms and clinical presentations of delirium and/or long-term cognitive dysfunction. Thus, the same mechanisms that cause the substrate for delirium may mediate the cognitive impairments observed after the acute presentation of delirium has resolved.
4. It is possible that instead of causing cognitive deficits or dementia, delirium (and its underlying causes) only serves as a catabolic agent leading to an acceleration of normal, physiological, cerebral aging mechanisms leading to dementia.
5. It is also possible that an episode of delirium simply unmasks subtle cognitive deficits already present, although not yet identified.

of studies published between January 1981 and April 2010 found that delirium is associated with an increased risk of death compared with controls (38.0% vs. 27.5%); that patients who experienced delirium were at increased risk of institutionalization (33.4% vs. 10.7%); and that patients who experienced delirium were at increased risk of dementia (62.5% vs. 8.1%) (Witlox et al., 2010).

Some have postulated four possible putative mechanisms or explanations for the relationship between delirium and long-term cognitive impairment: (1) that delirium is a marker of chronic progressive pathology but unrelated to any progression; (2) that delirium is a consequence of acute brain damage, which is also responsible for a “single hit” or triggering of active processes causing LTCI; (3) that delirium itself is the cause of the LTCI; and/or (4) that pharmacological agents used for the treatment of delirium or other conditions are the cause of the LTCI associated with delirium (MacLulich et al., 2009).

There appears to be a “dose effect” of delirium on cognition, with a longer duration of delirium found to be associated with worse average performance on neuropsychological testing at 3 and 12 months follow-up ($p = 0.02$ and $p = 0.03$, respectively) even after adjusting for age, education, preexisting cognitive function, severity of illness, severe sepsis, and exposure to sedative medications in the critical care unit (Girard et al., 2010). An increase from 1 to 5 days of delirium was independently associated with a 7-point decline in the cognitive battery mean score at 12 months follow-up ($p = 0.03$) (Girard et al., 2010). Various factors may be associated with this dose effect: neuroinflammatory changes; changes in brain–blood barrier permeability; the effect of psychoactive medications; anemia, hypoxia, anoxia, and other low-perfusion states; or systemic organ failure (Maldonado, 2008a, 2013).

Yet, whatever the cause, there appears to be an association between longer duration of delirium and greater brain atrophy as measured by a larger ventricle-to-brain ratio at hospital discharge ($p = 0.03$) and at 3-month follow-up ($p = 0.05$) (Gunther et al., 2012). As expected, greater brain atrophy (higher ventricle-to-brain ratio) at 3 months was associated with worse cognitive performance (executive functioning and visual attention) at 12 months ($p = 0.04$) (Gunther et al., 2012). Others have found that the longer the duration of delirium, the greater the degree of white matter disruption in the genu of the corpus callosum and anterior limb of the internal capsule ($p = .01$), up to 3 months after hospital discharge (Morandi, Rogers, et al., 2012).

A prospective study followed older hospitalized delirious patients who suffered from prevalent or incident delirium detected during the first week of hospitalization for up to a year and found that 39%, 38.5%, and 48.9% of patients with dementia met delirium criteria at discharge, 6-month, and 12-month follow-ups, respectively, compared to 11.1%, 8.8%, and 14.8% of patients without dementia (McCusker, Cole, et al., 2003). However, cognitive improvement during hospitalization and long-term changes in the number of symptoms were remarkably similar in the two groups, with inattention, disorientation, and impaired memory being the most common symptoms.

Another study found that only 4% of delirious patients experienced full resolution of all symptoms of delirium before discharge from the hospital (Levkoff et al., 1992). In this case, after following this sample longitudinally, an additional 20.8% experienced resolution of symptoms by the third month after hospital discharge, with an additional 17.7% by the sixth month after discharge from the hospital. Among elderly hip surgery patients, delirium was a strong independent predictor of cognitive impairment and the occurrence of severe dependency in ADL. In fact, 38 months after discharge from the hospital, 53.8% of the surviving patients with postoperative delirium continued to experience cognitive impairment, compared to only 4.4% of the nondelirious subjects (Bickel et al., 2008). Similarly, a prospective, matched, controlled cohort study of elderly hip surgery patients demonstrated that the risk of dementia or mild cognitive impairment (MCI) over a 30-month follow-up was almost twice as high in patients with postoperative delirium as in those without (Kat et al., 2008).

A large systematic evidence review demonstrated that the proportion of persistent delirium in older hospital patients at discharge, 1, 3, and 6 months was 44.7%, 32.8%, 25.6%, and 21% respectively; one study reported a proportion of 41% at 12 months after discharge (Cole, Ciampi, Belzile, & Zhong, 2009) (see Figure 41.1). The data suggest that many older hospital patients do not recover from delirium and that the persistence of delirium is associated with adverse outcomes. In some of the studies, the long-term outcomes (mortality, nursing home placement, cognition, function) of patients with persistent delirium were consistently worse than the outcomes of patients who had recovered from delirium.

Furthermore, the data shows that SSD (associated with critical illness), in the absence of full-blown delirium, has also been found to result in long-term cognitive dysfunction 2 months to 6 years following critical illness (e.g., 46%–70% of patients showed signs of cognitive dysfunction at 1 year and 25% at 6 years) (Cole et al., 2003; Morandi, McCurley, et al., 2012).

On the other hand, the data suggests that among elderly patients there is a significant acceleration in the slope of cognitive decline in those with Alzheimer’s disease (AD) following an episode of delirium (Fong et al., 2009). In fact, prospective data from hospitalized patients with AD ($n = 263$; median follow-up duration 3.2 years) found that after adjusting for dementia severity, comorbidity, and demographic characteristics, patients who had developed in-hospital delirium experienced greater cognitive deterioration in the year following hospitalization relative to patients who had not developed delirium (Gross et al., 2012). Cognitive deterioration following delirium in the year after hospitalization accelerated to twice the rate of patients who did not develop delirium. This rate of cognitive deterioration among delirious patients continued throughout a 5-year period following hospitalization (Gross et al., 2012). The Vantaa 85+ study (population-based cohort; $n = 553$ patients aged ≥ 85 years at baseline) followed examined individuals at 3, 5, 8, and 10 years after delirium and found that delirium increased the risk of incident dementia (OR 8.7, 95% CI, 2.1–3.5) and was associated with the loss of an additional 1 point per year in the Mini-Mental State

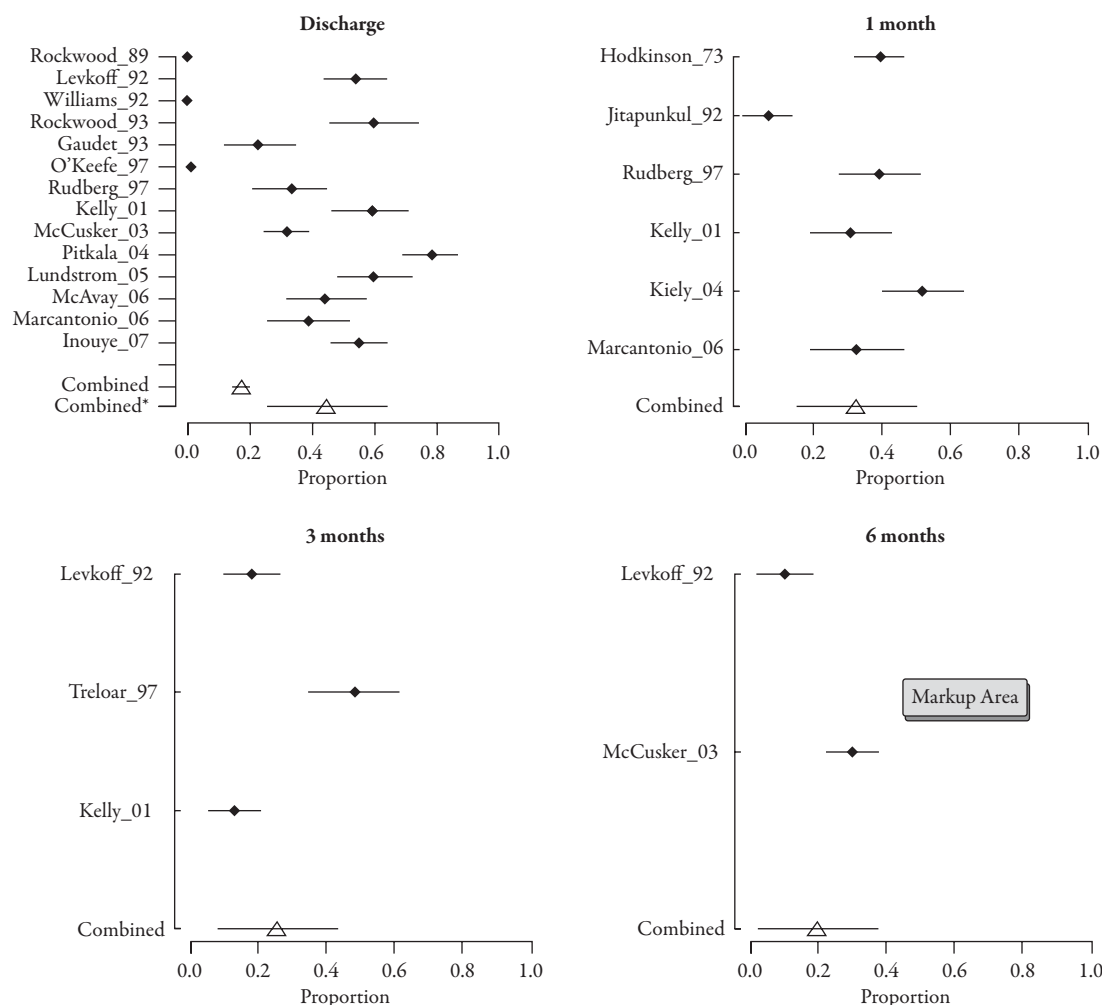

Figure 41.1 Individual and combined proportions (and 95% confidence intervals) for persistent delirium at discharge and one, three, and six months after enrollment. *Source:* (Cole, Ciampi et al., 2009)

Examination compared to those with no history of delirium (95% CI, 0.11–1.89) (Davis et al., 2012).

A prospective cohort study of 53 patients admitted for hip fracture surgery aged 75 years and older found that at the 3 months preoperative assessment, patients who had experienced postoperative delirium showed poorer performance on tests of global cognition and episodic memory, even after adjusting for age, gender, and baseline cognitive impairment (Basinski, Alfano, Katon, Syrjala, & Fann, 2010). No difference was found on tests of attention between patients with and without history of delirium after adjusting for relevant confounders. Another study of elderly patients (≥ 60) undergoing cardiac surgery (i.e., coronary-artery bypass grafting or valve replacement) found that at 6 months post-surgery, a higher percentage of patients with delirium than those without delirium had not returned to their preoperative baseline level of functioning (40% vs. 24%, $p = 0.01$), although that difference was not significant at 12 months (31% vs. 20%, $p = 0.055$) (Saczynski et al., 2012).

A different type of residual syndrome is post-traumatic stress disorder (PTSD) secondary to the dramatic and bizarre delusional and hallucinatory experiences that occur during

a delirious state. The incidence of PTSD related to postoperative delirium has been shown to be related to the nature and level of the sedation and analgesia, degree of factual memory recall, incidence of delirium, and underlying prevalence of preexisting psychiatric morbidity (Blank & Perry, 1984; Bourgon, 1985; Stukas et al., 1999; Dew et al., 2001; Jones, Griffiths, Humphris, Skirrow, 2001; Breitbart et al., 2002; DiMartini, Dew, Kormos, McCurry, & Fontes, 2007; Griffiths & Jones, 2007; Roberts, Rickard, Rajbhandari, & Reynolds, 2007; O'Malley, Leonard, Meagher, & O'Keefe, 2008; Basinski et al., 2010).

Finally, a number of factors associated with the medical setting may exacerbate the experience of hypnagogic hallucinations, such as medication use, physical restraints, and social isolation (Jones et al., 2001). Patients describe memories of these experiences as being very vivid, detailed, and frightening. A frightening “hallucinated” memory of a nurse trying to kill the patient or removing his organs, without a balancing memory of their medical condition and the care provided by the same nurse, is likely to contribute to the development of pseudo-memories with great emotional valence for that patient.

Studies have found that patients with delirium within the 4 weeks after myeloablative hematopoietic cell transplantation had significantly more distress and fatigue at 6 months ($P < .004$) and at 1 year ($P < .03$) and had worse symptoms of depression and post-traumatic stress at 1 year ($P < .03$), compared with patients without delirium (Basinski et al., 2010). Others have found that family members of delirious ICU patients can also develop PTSD. Both family caregivers (76%) and nurses (73%) have reported severe emotional distress related to a patient's delirium (Breitbart et al., 2002). In that study, family members were most distressed by patients' hyperactivity and functional impairment; nurses were most distressed by the severity of the patients' symptoms and by the presence of perceptual disturbances.

Data suggest that the impact of delirium on outcome may be changed by therapeutic interventions. (Please see the section on delirium management later in this chapter.)

THE COST OF DELIRIUM

The increased morbidity and extended hospital care associated with delirium have been associated with greater care costs (Inouye, 2000; Ely et al., 2004; Milbrandt et al., 2004). Delirious hospital inpatients require more nursing time per patient and have higher per-diem hospital costs, in addition to their increased lengths of stay (Siddiqi, Stockdale, Britton, & Holmes, 2007). The economic impact of delirium is substantial, rivaling the health care costs of falls and myocardial infarction (Hall et al., 1988; Rizzo, McAvay & Tinetti, 1996; Inouye, 2000).

A retrospective chart review of patients who received step-down critical care at a large university hospital showed that the 14% of the ICU population who developed delirium utilized 22% of total inpatient days (Maldonado, Dhimi, & Wise, 2003). The treated group consisted of the patients for whom a psychosomatic medicine consult was obtained and the team implemented at least 80% of the recommended regimen (as detailed in the treatment section at the end of this chapter). The average number of days from symptomatic onset to resolution was 10.8 days for untreated patients and 6.3 days for treated patients. As a group, delirious patients were older (71.3 vs. 63.6 years), remained hospitalized longer (16.4 vs. 6.6 days), and had greater total costs per case (\$63,900 vs. \$30,800). Another study of ICU delirium demonstrated that even after adjusting for age, comorbidity, severity of illness, degree of organ dysfunction, nosocomial infection, hospital mortality, and other potential confounders, delirium was associated with 39% higher ICU and 31% higher hospital costs (Milbrandt et al., 2004). They also found that the severity and duration of delirium were associated with incremental greater care cost. Similarly, a study of hospitalized medically ill elderly patients the average cost per day was 2.5-fold greater in those with delirium, and the total excess cost attributable to delirium ranged from \$16,303 to \$64,421 per patient (Leslie, Marcantonio, Zhang, & Leo-Summers, 2008).

The total annual direct healthcare costs attributable to delirium in the United States might be as high as \$152 billion (Leslie et al., 2008). These costs accrue after hospital discharge

due to the greater need for long-term care or additional home health care, rehabilitation services, and informal caregiving. A recent study looking at costs over one year following an episode of delirium estimated that delirium is responsible for an additional cost of \$60,000 to \$64,000 per patient for the year following the index hospitalization (Leslie et al., 2008).

ETIOLOGY OF DELIRIUM

Many factors potentially contribute to the development of delirium (see Table 41.2). I use the mnemonic "End Acute Brain Failure," to help recall the 20 of the most clinically relevant risk factors. The reason to use this term is to convey to all members of the medical team the seriousness of delirium—indeed, during delirium, the brain is experiencing acute failure, with potentially disastrous consequences. Only some of the risk factors are discussed here; readers are referred to my comprehensive review of delirium risk factors for further details (Maldonado, 2008b). In general, risk factors can be grouped as *non-modifiable* and *potentially modifiable*.

NON-MODIFIABLE RISK FACTORS

Recognition of the non-modifiable factors can help identify patients at high risk for delirium in order to provide enhanced surveillance and implement preventive measures. (Table 41.3). Four important non-modifiable factors are older age, baseline cognitive impairment, severity of underlying medical illness, and preexisting mental disorders.

Age

Old age is likely to be a contributor due to a greater number of medical comorbidities and overall frailty. The aging process itself is associated with some degree of cognitive deficits and increased risk of dementia. Finally, aging is associated with age-related cerebral changes in stress-regulating neurotransmitter and intracellular signal transduction systems. Chronic neurodegeneration is accompanied by an inflammatory response characterized by a chronic, but selective, activation of central nervous system (CNS) microglial cells that are "primed" to produce exaggerated inflammatory responses to immunological challenges. This inflammation is assumed to contribute to disease progression through the production of inflammatory mediators, including cytokines and acute phase proteins (Cunningham, Wilcockson, Campion, Lunnon, & Perry, 2005; Cunningham et al., 2009). Aging is also associated with decreased volume of acetylcholine (ACh)-producing cells and decreased cerebral oxidative metabolism. Thus, the decline in cognitive functioning associated with the normal aging process is aggravated by the presence of even mild hypoxia, which further inhibits ACh synthesis and its release.

Among elderly patients in the ICU, the probability of developing delirium increases by 2% per year of age for each year after age 65 (Figure 41.2) (Pandharipande et al., 2006). Many other studies confirm that older age is an independent

Table 41.2 DELIRIUM: PREDISPOSING AND PRECIPITATING RISK FACTORS—“END ACUTE BRAIN FAILURE”

RISK FACTOR	EXAMPLES
Electrolyte imbalance and dehydration	Electrolyte disturbances (e.g., hyperammonemia, hypercalcemia, hypo/hyperkalemia, hypomagnesemia, hypo/hyponatremia)
Neurological disorder and injury	<p>All neurological disorders: e.g., CNS malignancies, abscesses, cerebrovascular accident (CVA), vasculitis, multiple sclerosis (MS), epilepsy, Parkinson’s disease, normal pressure hydrocephalus (NPH), traumatic brain injury (TBI), diffuse axonal injury (DAI), limbic encephalitis (both non-paraneoplastic and paraneoplastic syndrome).</p> <p>Of the various forms of sensory impairment, only visual impairment has been shown to contribute to delirium. Visual impairment can increase the risk of delirium 3.5-fold.</p>
Deficiencies (nutritional)	Nutritional deficiencies (e.g., malnutrition, low serum protein/albumin, low caloric intake, “failure to thrive”), malabsorption disorders (e.g., celiac disease), and hypovitaminosis; specifically deficiencies in cobalamine (B ₁₂), folate (B ₉), niacin (B ₃ ; leading to pellagra), thiamine (B ₁ ; leading to beriberi and Wernicke’s disorder).
Age	Age [>65] and Gender [$m>f$]
Cognition	Baseline cognitive functioning, including dementia and other cognitive disorders and/or a past history of delirium have all been shown to increase the likelihood of delirium.
U-Tox (intoxication and withdrawal)	Substances of abuse—Acute illicit substance intoxication (e.g., cocaine, PCP, LSD, hallucinogens), as well as poisons, pesticides, solvents, and heavy metals (i.e., lead, manganese, mercury)—and substances withdrawal.
Trauma Toxins	<p>Physical trauma and injury; heat stroke, hyperthermia, hypothermia, severe burns, including trauma of surgical procedures.</p> <p>Various toxins, including bio-toxins (animal poison); heavy metals (lead, manganese, mercury); insecticides; poisons; carbon dioxide; toxic effect of pharmacological agents (i.e., serotonin syndrome, neuroleptic malignant syndrome, anticholinergic states); blood levels (toxic levels of various therapeutic substances; e.g., lithium, VPA, carbamazepine, immunosuppressant agents).</p>
Endocrine disturbance	Endocrinopathies such as hyper/hypo-adrenal corticoid; hyper/hypoglycemia; hyper/hypothyroidism.
Behavioral—psychiatric	Certain psychiatric diagnoses, including undue emotional distress; a history of alcohol and other substance abuse, as well as depression, schizophrenia, and bipolar disorder have been associated with a higher incidence of delirium.
Rx and other toxins	Several pharmacological agents have been identified, especially those with high anticholinergic activity, including prescribed agents (especially narcotics and GABA-ergic agents) and various OTC agents (especially anticholinergic substances; polypharmacy).
Anemia, anoxia, hypoxia, and low perfusion states	Any state that may contribute to decreased oxygenation (e.g., pulmonary or cardiac failure, hypotension, anemia, hypoperfusion, intraoperative complications, hypoxia, anoxia, carbon monoxide poisoning, shock).
Infectious	Pneumonia, urinary tract infections, sepsis, encephalitis, meningitis, HIV/AIDS.
Noxious stimuli (pain)	Data suggest that both pain and medications used for the treatment of pain have been associated with the development of delirium. Studies have demonstrated that the presence of postoperative pain is an independent predictor of delirium after surgery. On the other hand, the use of opioid agents has also been implicated in the development of delirium.
Failure (organ)	Organ and systemic failure; usually cardiac, hepatic, pulmonary, and renal failure.
APACHE score (severity of illness)	Evidence shows that the probability of transitioning to delirium increases dramatically for each additional point in the Acute Physiology and Chronic Health Evaluation (APACHE II) severity of illness score.
Intracranial processes	Stroke (especially non-dominant hemispheric); intracranial bleed; meningitis; encephalitis; neoplasms.
Light, sleep, and circadian rhythm	Sleep deprivation and insomnia, sleep disorders (e.g., obstructive sleep apnea) and disturbances/reversal in sleep-wake cycle.

(continued)

Table 41.2 (CONTINUED)

RISK FACTOR	EXAMPLES
Uremia and other metabolic disorders	Acidosis, alkalosis, hyperammonemia, hypersensitivity reactions; glucose, acid–base disturbances.
Restraints and any factors causing immobility	The use of restraints, including endotracheal tubes (ventilator), soft and leather restraints, intravenous lines, bladder catheters, and intermittent pneumatic leg-compression devices, casts, and traction devices all have been associated with an increased incidence of delirium.
Emergence delirium	Emergence from medication-induced sedation, coma, or paralysis; which may be associated with CNS depressant withdrawal, opioid withdrawal, REM-rebound, sleep deprivation.

risk factor among medically ill and surgical patients, with the increase in rate per year dependent on the specific context in which incidence is measured (Milstein, Pollack, Kleinman, & Barak, 2002; Khurana, Gambhir, & Kishore, 2011; Lee et al., 2011; Rudolph et al., 2011; Srinonprasert et al., 2011).

Baseline Cognitive Impairment

Baseline cognitive deficits, even those not rising to the level of dementia, significantly increase the risk of developing delirium. It is well established that individuals with compromised cognitive ability preoperatively (e.g., dementia) are at greater risk of delirium (Franco et al., 2010; Inouye, 1998; Litaker et al., 2001; McNicoll et al., 2003; Benoit et al., 2005). But recent evidence suggests that decrements in higher order cognitive functions, such as executive function (e.g., problem solving, processing speed, planning, complex sequencing, and reasoning), may also predict postoperative delirium in the absence of frank cognitive impairment (Rudolph et al.,

2006). A study of nondemented elderly patients undergoing elective orthopedic surgery demonstrated that subtle preoperative attention deficits, as tested by digit vigilance and reaction time testing, were closely associated with postoperative delirium (Lowery, & Ballard, 2007). In fact, these subtle changes predicted a 4-fold to 5-fold increased risk of postoperative delirium for subjects >1 SD above the sample means on these variables. Of note, in this study none of the previously identified risk factors for delirium was significantly associated with delirium (i.e., urea/creatinine ratio, visual impairment, blood pressure, sodium levels, hematocrit, bilirubin). Finally, a study of nearly 1,000 surgical patients found that preoperative executive dysfunction was associated with a greater incidence of postoperative delirium, independent of other risk factors (Smith et al., 2009). Furthermore, patients exhibiting both executive dysfunction and clinically significant levels of depression were at greatest risk for developing delirium postoperatively.

A study of elderly patients undergoing hip surgery found that preoperative Mini-Mental State Exam (MMSE) scores were an independent predictor of postoperative delirium (Kalisvaart et al., 2006). Similarly, a study of elderly subjects undergoing hip or knee replacement demonstrated that the presence of

Table 41.3 DELIRIUM RISK FACTORS

<ul style="list-style-type: none">• Various pharmacological agents, especially GABA-ergic and opioid agents, and medications with anticholinergic effects• Prolonged and/or uninterrupted sedation• Immobility• Acute substance intoxication• Substance withdrawal states• Use of physical restraints• Water and electrolyte imbalances• Nutritional deficiencies• Metabolic disturbances and endocrinopathies (primarily deficiency or excess of cortisol)• Poor oxygenation states (e.g., hypo-perfusion, hypoxemia, anemia)• Disruption of the sleep-wake cycle• Uncontrolled pain• Emergence delirium	<ul style="list-style-type: none">• Older age• Baseline cognitive impairment• Severity of underlying medical illness• Preexisting mental disorders

Figure 41.2 Age and the probability of transitioning to delirium. The most notable finding related to age was that probability of transitioning to delirium increased dramatically for each year of life after 65 years. Adjusted Odds Ratio –1.01 (1.00, 1.02) $p = 0.03$. Abbreviations: Y-axis = probability; X-axis = age in years. Source: (Pandharipande et al., 2006)

dementia increased the incidence of postoperative delirium from 32% to 100% (Wacker et al., 2006). Approximately 70% of elderly patients admitted to a specialized delirium ward had a preexisting cognitive disorder—either dementia or MCI (Wahlund & Bjorlin, 1999). A recent study of elderly patients undergoing urological surgery confirmed that age, baseline cognitive impairment, and previous history of delirium all were associated with a higher rate of postoperative delirium (Tognoni et al., 2011). The relationship between cognitive deficits and dementia seems to be reciprocal. So, while it is clear from the evidence presented above that the presence of baseline cognitive deficits, including dementia, lowers the threshold to develop delirium, data suggest that among elderly patients there is a significant acceleration in the slope of cognitive decline in patients with AD following an episode of delirium (Fong et al., 2009). This raises the question of whether prevention of delirium might ameliorate or delay cognitive decline in patients at risk, particularly those with AD.

Severity of Medical Illness

Studies have also shown that the severity of the patient's underlying medical problems has a significant effect on the development and progression of delirium (Ouimet et al., 2007; Girard et al., 2008; Maldonado, 2008b; Khan, Kahn, & Bourgeois, 2009; Pisani, Kong, et al., 2009; Maldonado, 2011; Srinonprasert et al., 2011; Ryan et al., 2013). A study of adult, mechanically ventilated ICU patients found that increased *severity of illness*, as measured by the modified Acute Physiology and Chronic Health Evaluation (APACHE II; a modified-APACHE II is reached by subtracting the Glasgow Coma Scale score from the usual calculation of the APACHE II total score) was associated with a greater probability of developing delirium (Pandharipande et al., 2006). The incremental risk increased with APACHE score until the latter reached 18 (see Figure 41.3), suggesting that for each additional point on the APACHE II scale, the probability of delirium increased by 6%. These findings were replicated in a

Figure 41.3 Severity of Illness and the Probability of Transitioning to Delirium. The probability of transitioning to delirium increased dramatically for each additional point in the Acute Physiology and Chronic Health Evaluation II (APACHE II) severity of illness score, until reaching a plateau APACHE score of 18. (Pandharipande et al., 2006)

study of elderly patients undergoing hip surgery (Kalisvaart et al., 2006) and another, of critically ill patients (Tsuruta et al., 2010), where APACHE II scores were identified as an independent predictor of delirium when controlling for the use of mechanical ventilation and length of ICU stay.

Preexisting Mental Disorders

A 1996 study retrospectively investigated incidence rates and risk factors for delirium among hospitalized psychiatric patients (Ritchie, Steiner, & Abrahamowicz, 1996). The overall incidence of delirium in the study sample was 15%. Patients with bipolar disorder had the highest incidence of delirium (36%). Only 48% of delirious patients were actually recognized as having delirium at the time it occurred. The hospital stays of patients with delirium were 62% longer than those without.

Delirious mania, also known as “Bell’s mania,” is defined as “a syndrome of acute onset of excitement, grandiosity, emotional lability, delusions and insomnia characteristic of mania, and the disorientation and altered consciousness characteristic of delirium. Almost all patients exhibit signs of catatonia” (Bell, 1849; Fink, 1999). The syndrome consists of a constellation of symptoms that can arise from both psychotic and affective psychiatric diseases, as well as from many medical diseases. It has been described as a subtype of the catatonia syndrome, having a rapid onset with signs of mania, delirium, and catatonia (Friedman, Mufson, Eisenberg, & Patel, 2003).

Among patients undergoing cardiac surgery—after adjustment for sex, older age, cross-clamp time, hemoglobin, and psychotropic drug use—major depression was significantly associated with delirium (OR = 3.86, 95% CI 1.42–10.52, $p = 0.001$) (Tully, Baker, Winefield, & Turnbull, 2010). A more recent study of cardiac surgery patients found that patients with a preoperative diagnosis of depression had an independently associated increased risk of developing postsurgical delirium (Kazmierski, Banys, Latek, Bourke, & Jaszewski, 2013). Thus, major depressive disorder has been associated with incident delirium after various types of surgical procedures, as well as among general hospital inpatients, independent of other risk factors (Schneider et al., 2002; Dasgupta & Dumbrell, 2006; Kazmierski et al., 2006; McAvay et al., 2007; Smith et al., 2009). A study of geriatric surgical subjects showed that patients with a greater number of preoperative depressive symptoms were more likely to develop postoperative delirium and experience a longer duration of postoperative delirium, even after adjusting for covariates (i.e., age, educational level, functional status, and preoperative alcohol use) (Leung, Sands, Mullen, Wang, & Vaurio, 2005).

Long-term benzodiazepine use is usually associated with the presence of an underlying psychiatric disorder (e.g., anxiety, depression, insomnia, alcohol abuse, benzodiazepine abuse), and thus it may be considered a marker of underlying psychiatric comorbidity. Studies have looked at the presence of postoperative delirium between long-term benzodiazepine users and nonusers and found that the incidence of delirium after orthopedic surgery in the elderly was significantly more frequent in long-term benzodiazepine users (26%) than in short-term users (13%)

(Kudoh, Takase, Takahira, & Takazawa, 2004). Benzodiazepines have been demonstrated to have a negative effect on memory (Lister, 1985; Ghoneim & Mewaldt, 1990; Ghoneim, Block, Ping, el-Zahaby, & Hinrichs, 1993), and it has been demonstrated that benzodiazepine use induces both nonamnesic and amnesic MCI (Tannenbaum, Paquette, Hilmer, Holroyd-Leduc, & Carnahan, 2012). Furthermore, chronic BZDP users had a significantly higher risk of cognitive decline in global cognitive and attention tests compared with non-BZDP users (Mura et al., 2013). It appears that even though there may be an improvement after BZDP discontinuation, there remains a significant impairment in most areas of cognition when compared to controls (Barker, Greenwood, Jackson, & Crowe, 2004, 2005).

As we discussed before, there is a relationship between dementia and development of delirium. New data suggest that the use of benzodiazepine is associated with an increased risk of Alzheimer's disease (adjusted OR 1.51, 95% CI, 1.36–1.69) (Billioti de Gage et al., 2014). Furthermore, the risk increases with cumulative exposure: 1.32 (1.01 to 1.74) for 3 to 6 months, and 1.84 (1.62 to 2.08) for more than 6 months (Billioti de Gage et al., 2014). Similarly, in a large nested-control study, after controlling for multiple variables (i.e., age, gender, education level, living alone, alcohol consumption, psychiatric history, and depressive symptomatology), the ongoing use of benzodiazepines was associated with a significantly increased risk of dementia (adjusted OR, 1.7; 95% CI, 1.2–2.4), while former use was associated with a significantly increased risk of dementia (adjusted OR, 2.3; 95% CI, 1.2–4.5) (Lagnaoui et al., 2002). Others have found similar results, with a marked increased incidence of dementia (OR = 3.50, 95% CI 1.57 to 7.79, $p = 0.002$) among those on long-term BZDP use (Gallacher et al., 2012). Finally, among subjects seeking acute treatment for alcohol withdrawal, 6.9% developed alcohol withdrawal delirium despite adequate treatment with benzodiazepine agents (Palmstierna, 2001). These findings raise the possibility that the use of benzodiazepines, when combined with other risk factors, may contribute or accelerate the rate of cognitive decline following delirium.

POTENTIALLY MODIFIABLE RISK FACTORS

Among the significant factors that are amenable to early intervention or prevention are electrolyte imbalances and nutritional deficiencies, metabolic disturbances and endocrinopathies, low oxygenation states, environmental factors disrupting the sleep-wake cycle and impeding adequate rest, pain and its treatment, the use of drugs with anticholinergic effects, substance intoxication and withdrawal states, the use of physical restraints, and the development of “emergence delirium” (i.e., an altered mental status occurring as a patient “emerges” from deep sedation or medication-induced coma).

Electrolyte Imbalances and Nutritional Deficiencies

Irrespective of the etiology, a water and electrolyte imbalance (primarily magnesium, phosphate, potassium, and chloride) provoking a hypo- or hyperosmolar state causes metabolic encephalopathy or delirium (Mattle, 1985; Schmickal et al.,

1989; Wetterling, Kanitz, Veltrup, & Driessen, 1994; Aldemir et al., 2001; Lawlor, 2002; Sagawa, Akechi, et al., 2009; Caplan & Chang, 2010). The correction of these electrolyte disturbances has been shown to significantly shorten the duration of delirium (Koizumi, Shiraishi, Ofuku, & Suzuki, 1988). The relationship between nutritional deficiencies and delirium has long been documented, and it is the clearest in patients suffering from Wernicke's encephalopathy (B_1 or thiamine deficiency) (Hoes, 1979; Newman, Grocott, et al., 2001; Onishi, Sugimasa, Kawanishi, & Onose, 2005). In addition, vitamin B_6 and B_{12} deficiency have all been associated with delirium (Peters & Neumann, 1960; Hoes, 1979; Buchman, Mendelsson, et al., 1999; Lerner & Kanevsky, 2002). Some data suggest that vitamin B_{12} supplementation (in patients with documented deficiencies) reduced the duration of delirium in elderly demented subjects. And, others have found a relationship between low albumin levels and the development of delirium among elderly demented patients (Culp & Cacchione, 2008).

Metabolic Disturbances and Endocrinopathies

Metabolic disturbances and various endocrinopathies have been associated with the development of delirium, primarily deficiency or excess of cortisol (Thiele & Hohmann, 1961; Millerowa, 1966; McIntosh et al., 1985; Basavaraju & Phillips, 1989; Olsson, Astrom, Eriksson, & Forssell, 1989; Fassbender, Schmidt, Mossner, Daffertshofer, & Hennerici, 1994; O'Keeffe & Devlin, 1994; Johansson, Olsson, Carlberg, Karlsson, & Fagerlund, 1997; Olsson, 1999; Robertsson et al., 2001; Abildstrom, Christiansen, Sirsma, & Rasmussen, 2004; Nemoto, Kawanishi, Suzuki, Mizukami, & Asada, 2007; Weng, Chang, & Weng, 2008) or thyroid hormone (Vidal & Vidal, 1961; Goldfarb, Varma, & Roginsky, 1980; Nibuya, Suda, Mori, & Ishiguro, 2000; El-Kaissi, Kotowicz, Berk, & Wall, 2005), and either high or low blood glucose levels (Fishbain & Rotundo, 1988; Aldemir, Ozen, et al., 2001; Miller, 2008). There have been case reports of Cushing's disease caused by adrenocorticotrophic hormone (ACTH)–producing pituitary adenomas, in patients who lacked the phenotypical signs of hypercortisolism (e.g., facial plethora, supraclavicular fat pads, buffalo hump, truncal obesity, and purple striae) and whose most prominent and distressing symptoms were severe myopathy and altered mental status (Tran & Elias, 2003). Similarly, there have been reports of hypoactive delirium as the primary presentation of a patient with tonsillar abscess and associated panhypopituitarism and secondary hyponatremia (Umekawa Yoshida, Sakane, & Kondo, 1996) and of a patient experiencing delirium secondary to serendipitously diagnosed hypocortisolemia, who presented none of the usual signs of adrenal insufficiency or endocrinopathy (Fang & Jaspán, 1989). Others have demonstrated that, among demented inpatients with no acute medical illness, there was a strong relationship between delirium and dexamethasone suppression test (DST) pathology, irrespective of age and the severity of dementia; suggesting the possibility that an impaired hypothalamus–pituitary–adrenal (HPA) system and a low delirium threshold may lead to delirium as a response to stress (Robertsson et al., 2001).

Low Oxygenation States

Poor oxygenation (i.e., hypoperfusion, hypoxemia, anemia) has long been associated with the development of delirium (Kinney, Duke, et al., 1970; Weissman et al., 1984; McGee, Veremakis, & Wilson, 1988; Fine, Anderson, Rothstein, Williams, & Gochuico, 1997; Maldonado, 2008a,b). Inadequate oxidative metabolism may be one of the underlying causes of the basic metabolic problems initiating the cascade that leads to the development of delirium; namely, inability to maintain ionic gradients, causing cortical spreading depression (i.e., spreading of a self-propagating wave of cellular depolarization in the cerebral cortex) (Moghaddam, Schenk, Stewart, & Hansen, 1987; Somjen et al., 1989, 1990; Iijima, Shimase, Iwao, & Sankawa, 1998; Shimizu-Sasamata, Bosque-Hamilton, Huang, Moskowitz, & Lo, 1998; Basarsky, Feighan, & MacVicar, 1999); abnormal neurotransmitter synthesis, metabolism, and release (Globus, Busto et al., 1988b, 1989, 1990; Busto et al., 1989, 1990; Globus, Wester, Busto, & Dietrich, 1992; Takagi, Ginsberg, et al., 1994; Busto, Dietrich, Globus, Alonso, & Dietrich, 1995; Busto, Dietrich, et al., 1997); and a failure to effectively eliminate neurotoxic byproducts (Busto, Globus, et al., 1989; Globus, Busto, et al., 1990; Globus, Alonso, et al., 1995).

Study findings correlate the development of delirium with findings suggestive of premorbid oxidative metabolism impairment. In a study of ICU patients, three measures of oxygenation (i.e., hemoglobin, hematocrit, and pulse oximetry) were worse in the patients who later developed delirium (Figure 41.4) (Seaman, Schillerstrom, Carroll, & Brown, 2006). Similarly, two measures of oxidative stress (sepsis, pneumonia) occurred more frequently among those diagnosed with delirium. Others have demonstrated that intraoperative cerebral oxygen desaturation (as measured by cerebral oximeter) is significantly associated with an increased risk of postoperative delirium and early cognitive decline and was associated with a nearly threefold increased risk of prolonged hospital stay after cardiac surgery (CABG) (Figure 41.5) (Slater et al., 2009). Finally, another large study of urgent cardiac surgery demonstrated that preoperative and intraoperative ScO₂ readings were lower in the group of patients who developed delirium. The binary logistic regression identified older age, lower MMSE, neurological or psychiatric disease, and lower preoperative ScO₂ as independent predictors of postoperative delirium (Figure 41.6) (Schoen et al., 2011).

Sleep Disturbances

Sleep is another factor that seems to play a significant role in developing delirium in the ICU. Sleep deprivation has long been linked to the development of delirium (Lipowski, 1987) and psychosis (Berger, Vollmann, et al., 1997). Patients in the ICU experience severe alterations of sleep, with sleep loss, sleep fragmentation, and sleep-wake cycle disorganization. Continuous polysomnographic recordings have demonstrated that despite sedative practices, the average amount of sleep in ICU patients is limited (e.g., as short as 1 hour and 51 minutes

Figure 41.4 Oxidative Stress Hypothesis. Three measures of oxygenation (Hg, Hct, pulse ox.) were worse in the patients who later developed delirium.

per 24-hour period) (Aurell & Elmquist, 1985). Sleep in ICU patients is characterized by prolonged sleep latencies, sleep fragmentation, decreased sleep efficiency, frequent arousals, a predominance of stage 1 and stage 2 non-rapid eye movement (REM) sleep, decreased or absent stage 3 and 4 non-REM sleep,

Figure 41.5 Cerebral Desaturation and Postoperative Delirium. Intraoperative cerebral O₂ desaturation was a significant risk factor for postoperative delirium in CABG patients. (Slater et al., 2009)

and decreased or absent REM sleep (Weinhouse & Schwab, 2006; Drouot, Cabello, d'Ortho, & Brochard, 2008; Friese, 2008b).

There are many factors that may contribute to sleep debt in the hospital, and particularly in the ICU. These include frequent diagnostic and therapeutic interventions and procedures; anxiety, fear, pain, and underlying illness and disease severity; and environmental factors, such as around-the-clock medical care (e.g., suctioning, ventilator settings, blood draws, line

changes/placement), noise, light, and discomfort (Weinhouse & Schwab 2006; Drouot et al., 2008; Friese, 2008b). Another large factor in sleep debt in ventilated patients is continuous sedation. In fact, studies have demonstrated that propofol and benzodiazepine agents (the primary agents used for continuous sedation) have a negative effect on sleep (e.g., severe alterations of sleep with sleep loss, ↓ REM sleep, loss of circadian rhythm, extreme sleep fragmentation, sleep–wake cycle disorganization) (Drouot et al., 2008; Matthews, 2011; Boyko, Ording, & Jennum, 2012; Hofhuis, Langevoort, Rommes, & Spronk, 2012; Kamdar, Needham, & Collop, 2012; McKinley et al., 2012; Nakos, 2012; Watson, Ceriana, & Fanfulla, 2012; Andersen, Boesen, & Olsen, 2013; Brummel & Girard, 2013; Gomez Sanz, 2013).

Pain Management

As in the case with sleep, both the experience of pain and some of the pharmacological agents used for the treatment of pain have been associated with the development of delirium. In fact, the presence of postoperative pain has been shown to be an independent predictor of postoperative delirium (Vaurio et al., 2006). There is also a direct relationship between levels of preoperative pain and the risk of developing postoperative delirium. Unfortunately, some opioid agents have also been implicated in the development of delirium (Fong, Sands, & Leung, 2006; Vella-Brincat & Macleod, 2007; Wang, Sands, Vaurio, Mullen, & Leung, 2007). In fact, opioid agents have been implicated in nearly 60% of the cases of delirium in patients with advanced cancer (Centeno, Sanz, & Bruera, 2004). Studies among cancer patients revealed significant associations between opioids and delirium (Gaudreau et al., 2007). The association remained significant after adjustment for corticosteroid, benzodiazepine, and antipsychotic exposure using generalized estimating equation regressions (OR of 1.37; $P = .0033$). Others have suggested that patients who used oral opioid analgesic agents as their sole means of postoperative pain control are at decreased risk of developing delirium compared to subjects using intravenous (IV) opioid-based, patient-controlled analgesia (PCA) (Vaurio et al., 2006; Wang et al., 2007).

Some opioid agents (e.g., meperidine) may have greater delirigenic potential than others (Marcantonio et al., 1994; Morrison et al., 2003; Fong et al., 2006). Studies suggest that an opioid rotation to less delirigenic agents like fentanyl or hydromorphone has been associated with improved pain management and lower delirium rating scores (Morita et al., 2005). The exact mechanism of delirium causation is unclear, but agent half-life, the presence of active metabolites, and anticholinergic potential have all been implicated in opioid-induced delirium (Slatkin & Rhiner, 2004). Some clinicians prefer the use of PCA, as the common wisdom is that patients usually “self-titrate” and end up receiving lower doses of medication, thus lowering delirium risk. This may be true in the cognitively intact individual; but in the cognitively impaired or already delirious patient, PCAs are contraindicated. The risk of a PCA apparatus for a patient who is already confused is that they may not know how to use it, what to do with the button. Essentially the question to answer is, is the patient cognitively intact and

Figure 41.6 Preoperative and Intraoperative Cerebral O₂ Saturation (ScO₂) Values Influenced the Risk of Post-op Delirium Intraoperative changes in ScO₂ in patients with or without delirium classified by normal or low preoperative ScO₂. Delta ScO₂base, difference between preoperative regional cerebral oxygen saturation with oxygen supplementation and minimal intraoperative regional cerebral oxygen saturation; ScO₂base, regional cerebral oxygen saturation with supplemental oxygen. (Schoen et al., 2011)

competent enough to use PCA appropriately? A simple rule: if the patient is experiencing any sign of confusion (e.g., disorientation, finger agnosia), do not use a PCA. This may be resumed when the patient's delirium resolves.

Medications

Besides opioid agents, a great number of *medications* have been associated with an increased risk of delirium (Table 41.4). Some have said that the highest incidence of medication-induced delirium has been observed in patients taking the greater number of agents (Inouye & Charpentier, 1996), agents with high *anticholinergic potential* (Tune, Carr, Cooper, Klug, & Golinger, 1993), and medications with significant psychoactive effects (Francis, Martin, & Kapoor, 1990; Olofsson, Weitzner, Valentine, Baile, & Meyers, 1996; Brauer, Morrison, Silberzweig, & Siu, 2000; Lawlor et al., 2000; Tuma & DeAngelis, 2000; Morita et al., 2001; Breitbart et al., 2002; Gaudreau & Gagnon, 2005). Among this latter group, opioids, corticosteroids, and benzodiazepines have been identified as major contributors to delirium in several studies (see Figure 41.7) (Gaudreau, Gagnon, et al., 2005b). In fact, narcotics, benzodiazepines, corticosteroids, and other psychoactive agents use have been associated with 3-fold to 11-fold increases in the prevalence of delirium (Morita et al., 2001; Morrison et al., 2003; Gaudreau & Gagnon, 2005; Gaudreau et al., 2005b, 2007; Fong et al., 2006; Pisani, Murphy, et al., 2009; van Munster et al., 2010).

There is significant evidence linking a medication's anticholinergic potential (as measured by serum anticholinergic activity) and their incidence of causing delirium (Tune, et al., 1981, 1993; Tune, Carr, Hoag, & Cooper, 1992; Golinger et al., 1987; Milusheva et al., 1990; Inouye & Charpentier, 1996; Flacker et al., 1998; Tune & Egeli, 1999; Tune, 2000; Kojima, Terao, & Yoshimura, 1993; Meyer, Meyer, & Kressig, 2010). Several studies have identified some of these substances, and we have become increasingly aware of the importance of understanding the cumulative serum anticholinergic activity (Tune et al., 1981; Tune & Folstein 1986; Tune et al., 1992, 1993; Tune & Egeli, 1999; Tune, 2000) (see Table 41.5). Others have demonstrated that, among medical inpatients, exposure to anticholinergic agents is an independent risk factor for the development of delirium and is specifically associated with a subsequent increase in delirium symptom severity (Han et al., 2001).

Despite its apparent usefulness, there are limitations to the use of the serum anticholinergic activity (SAA) assay in clinical practice: (1) assays of standard drug solutions do not account for pharmacokinetic differences among drugs, which limits the interpretation of such measurements; (2) emerging evidence has suggested that anticholinergic medications may not be the only cause of elevated SAA (Carnahan, Lund et al., 2002). For example, naturally occurring SAAs have been described in the absence of exposure to known anticholinergic pharmacological agents; their etiology, although they are postulated to be related to the primary illness state (or aging process), and their clinical significance remain unknown (Flacker & Wei, 2001). Despite these limitations, elevated SAA has been consistently associated with cognitive

correlation between the use of anticholinergic agents and incident dementia (Lopez-Alvarez, Zea Sevilla et al. 2014, Gray, Anderson et al. 2015, Mate, Kerr et al. 2015) and an increased risk of hospitalization for confusion (Kalisch Ellett, Pratt et al. 2014).

Among the main offenders, GABA-ergic medications have been increasingly implicated in the development of delirium (Marcantonio et al., 1994; Meuret et al., 2000; Pain, Jeltsch, et al., 2000; Wang et al., 2000; Ely, Gautam, et al., 2001). Several studies have demonstrated a relationship between benzodiazepine use and delirium (Tune & Bylsma, 1991; Marcantonio et al., 1994; Ely, Gautam, et al., 2001; Kudoh et al., 2004). In fact, the benzodiazepine agent lorazepam has been found to be an independent risk factor for daily transition to delirium (see Figure 41.8) (Pandharipande et al., 2006). A recent study found that among ventilated burn patients, exposure to benzodiazepines was an independent risk factor for the development of delirium ($P < .001$) (Agarwal, et al., 2010). Similarly, the use of various general anesthetics has been associated to structural changes leading to disruption of blood-brain barrier (BBB) integrity (Forsberg et al., 2014). This will be discussed in further detail under the inflammatory hypothesis of delirium.

There are many mechanisms by which sedative agents, particularly GABA-ergic agents, mediate delirium. These may include interruption of physiological melatonin and sleep patterns, interference with central cholinergic transmission, disruption of thalamic gating, and acute and long-term

Figure 41.8 Lorazepam and the Probability of Transitioning to Delirium
The probability of transitioning to delirium increased with the dose of lorazepam administered in the previous 24 hours. This incremental risk was large at low doses and plateaued at around 20 mg/day.

Abbreviations: Y-axis = delirium risk; X-axis = lorazepam dose (in mg) (Pandharipande et al., 2006)

cognitive disturbances. Please see Box 41.2 for a comprehensive list of the 12 mechanisms by which sedative and analgesic agents mediate their delirio-genic effects. Similar to more classic anticholinergic agents, acute benzodiazepine use has been linked to agitation, confusion and delirium (Daman Willems and Dillon 1986, Short, Forrest et al. 1987, Miller and Gold 1991, O'Reilly and Smith 1991, Trewin, Lawrence et al. 1992, Lechin, van der Dijs et al. 1996, Hofmann 2013); and chronic use is linked to Alzheimer's disease (Billioti de Gage, Moride et al. 2014, Kmietowicz 2014, Yaffe and Boustani 2014).

Box 41.2 SEDATIVE AND ANALGESIC AGENTS' DELIRIOGENIC MECHANISMS:

Sedative agents (mostly GABA-ergic) and opioids may contribute to the development of delirium by one of twelve possible mechanisms:

1. Acutely, benzodiazepines (BZDP) are associated with the development of psychomotor retardation, cognitive blunting, ataxia, poor balance, and decreased mobility, all known contributing factors for delirium (Sarasin, Ghoneim, & Block, 1996).
2. BZDP have been demonstrated to have a negative effect on memory (Lister, 1985; Ghoneim & Mewaldt, 1990; Ghoneim et al., 1993).
3. BZDP use induces both non-amnestic and amnestic mild cognitive impairment (Tannenbaum et al., 2012)
4. Chronic administration of BZDP induces a down-regulation of BZDP-receptors (Hutchinson, Smith, & Darlington, 1996), and a reduction in the number of these receptors seems to be correlated with cognitive decline (Shimohama, Taniguchi, Fujiwara, & Kameyama, 1988).

5. Long term BZDP use may induce a limitation in cognitive reserve capacity, which further reduces a person's ability to cope with early phase brain lesions by soliciting accessory neuronal networks (Stern, 2002).
6. New evidence suggests that BZDP use may be associated with an increased cumulative risk of dementia (Billioti de Gage et al., 2014).
7. BZDP use interferes with central cholinergic function muscarinic transmission at the level of the basal forebrain and hippocampus (i.e., causing a centrally mediated acetylcholine deficient state) (Schneck & Ruprecht, 1989; Meuret, Backman, et al., 2000; Pain et al., 2000; Wang et al., 2000); furthermore, BZDP activate GABAA receptors, which inhibit glutamate effect on NMDA receptors, thus limiting Ach release (Cervetto & Taccola, 2008).
8. BZDP use interferes with physiological sleep patterns (e.g., ↓ slow wave sleep → ↑REM latency → ↓REM periods duration → REM deprivation) (Borbely, Mattmann, et al., 1985; Achermann & Borbely, 1987; Bastien, LeBlanc, Carrier, & Morin, 2003, Qureshi & Lee-Chiong, 2004; Mazza et al., 2014).
9. BZDP use disrupts the circadian rhythm of melatonin release (Olofsson et al., 2004).
10. Long-term use of BZDP increases compensatory up-regulation of N-methyl D-aspartate (NMDA) and kainate receptors and Ca^{2+} channels (Chaudieu, St-Pierre, Quirion, & Boksa, 1994; Heikkinen, Moykkynen, & Korpi, 2009); enhancing NMDA-induced neuronal damage (Zhu, Cottrell, & Kass, 1997).
11. BZDP use disrupts thalamic gating function (Gaudreau & Gagnon, 2005).
12. Long-term BZDP use may lead to CNS-depressant withdrawal syndromes, upon abrupt discontinuation.

Immobility

Immobility—due to disease conditions, physical restraints, or medical apparatus that effectively limits the patient's mobility (e.g., ET tube [ventilator], IV lines, bladder catheters, intermittent pneumatic leg-compression devices, casts, traction devices)—has been shown to increase the incidence of delirium (McCusker, Verdon, Caplan, Meldon, & Jacobs, 2002; Inouye et al., 2007). Some may include chemical restraints in this group. Data show that patients who are mobilized early (i.e., alerted and provided physical and occupational therapy) during the course of illness demonstrate greater return to independent functional status at hospital discharge (59% vs. 35%), spend less time in the ICU (2 vs. 4 days), and experience less delirium (33% vs. 57%) compared to a control cohort (Schweickert et al., 2009).

Both psychoactive medications and immobility may contribute to emergence delirium (ED) or emergence agitation (EA), a postoperative behavior that may occur upon

awakening in patients exposed to general anesthesia (Bastron & Moyers, 1967; Gutstein, 1996; Haynes, 1999; Fong et al., 2006; Maldonado, 2008b) and that has been described in both children and adults (Albin, Bunegin, Massopust, & Jannetta, 1974; Lepouse, et al., 2006; Abu-Shahwan, 2008; Fronapfel, 2008; Hudek, 2009). Even though there is some suggestion that the incidence may be increased after the use of volatile (inhaled) anesthetic agents (Bajwa, Costi, & Cyna, 2010), many other agents commonly used for anesthesia and sedation in the ICU have been implicated (as already discussed above). All forms of conventional sedation may be associated with emergence delirium, although some are better than others. As a general rule, propofol is less delirio-genic than midazolam, but dexmedetomidine is less delirio-genic than both. The use of opioids as a sedative agent may be one of the main contributors of emergence delirium and should be avoided. The rule should be: Use sedative agents for sedation and narcotics for pain management, rather than the commonly practiced narcosedation. Another contribu-tor to emergence delirium may be CNS depressants (e.g., narcotics, benzodiazepines, other GABA-ergic agents) when a patient has been exposed to these agents for a long period of time, and the primary team feels “it is time to extubate” so the patient is quickly taken off these agents rather than being carefully weaned off them. Being more mindful of

this practice and its effects, and better planning, may signifi-cantly reduce delirium’s occurrence.

NEUROPATHOGENESIS OF DELIRIUM

Many theories have been proposed to explain the etiology of delirium, but Engel and Romano explained it best:

We thus arrive at the proposition that a derangement in functional metabolism underlies all instances of delirium and that this is reflected at the clinical level by the characteristic disturbance in cognitive functions.

(Engel & Romano, 1959)

Thus we will start with the premise that delirium is a neu-robehavioral syndrome caused by the transient disruption of normal neuronal activity secondary to systemic disturbances (Engel & Romano, 1959; Lipowski, 1992; Brown, 2000). Over the years, a number of theories have been proposed in an attempt to explain the processes leading to the development of delirium (Maldonado, 2008a). Most of these theories are complementary, rather than competing (see Figure 41.9). It is

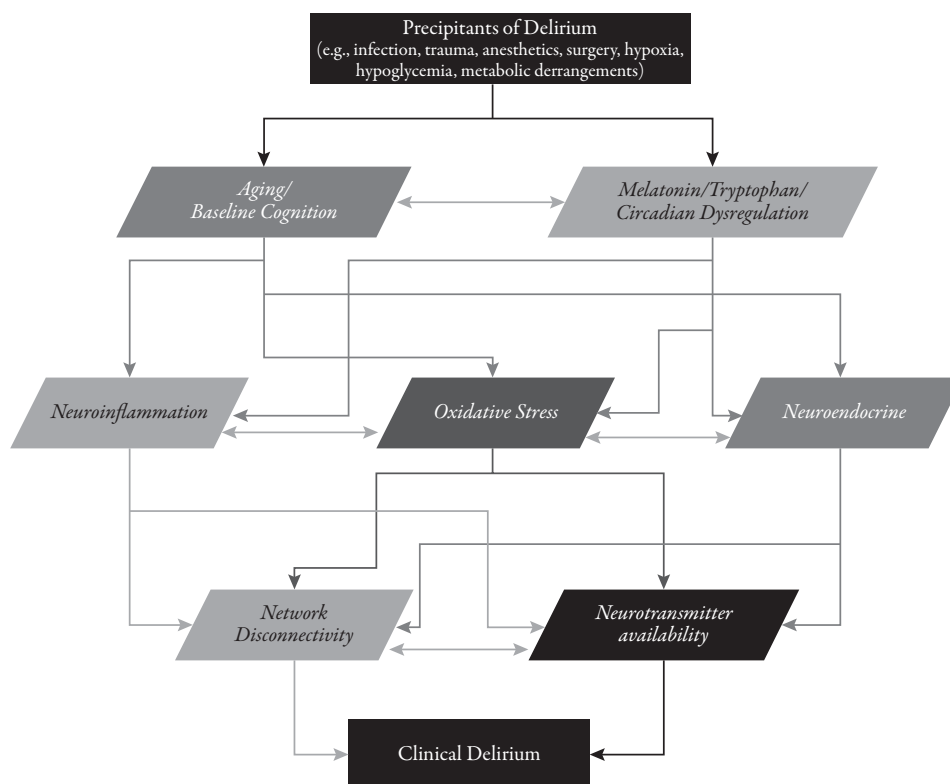

Figure 41.9 Neuropathogenesis of Delirium Schematics of the interrelationship of current theories on the pathophysiology of delirium and how they may relate to each other. Each proposed theory has focused on a specific mechanism or pathologic process (e.g., dopamine excess or acetylcholine deficiency theories), observational and experiential evidence (e.g., sleep deprivation, aging), or empirical data (e.g., specific pharmacological agents’ association with post-operative delirium; intra-operative hypoxia). Most of these theories are complementary rather than competing, with many areas of intersection and reciprocal influence. In the end, it is unlikely that any one of these theories is fully capable of explaining the etiology or phenomenological manifestations of delirium, but rather that their interaction leads to the biochemical derangement and, ultimately, to the complex cognitive and behavioral changes characteristic of delirium. (Adapted from Maldonado, 2013).

likely that none of these theories by itself explains the phenomena of delirium, but rather that two or more of these, if not all, act together to lead to the biochemical derangement we know as delirium. Here we will highlight four of them. A detailed review of all has been published elsewhere (Maldonado, 2008a, 2013).

NEUROINFLAMMATORY HYPOTHESIS

The neuroinflammatory hypothesis suggests that acute peripheral inflammatory processes (e.g., infections, surgery, trauma) induce activation of brain parenchymal cells and expression of proinflammatory cytokines and inflammatory mediators in the central nervous system, which in turn induces neuronal and synaptic dysfunction that may serve as the substrate for the neurobehavioral and cognitive symptoms characteristic of delirium (Godbout et al., 2005, Dantzer,

O'Connor, Freund, Johnson, & Kelley, 2008; Cunningham et al., 2009; Godbout & Johnson, 2009; Cerejeira, Firmino, Vaz-Serra, & Mukaetova-Ladinska, 2010; Cunningham, 2011) (Figure 41.10). Previous studies have already demonstrated the brain's ability to monitor the presence of systemic inflammatory processes (e.g., outside the BBB) and the development of nonspecific physiological (e.g., fever, pain, malaise, fatigue, and anorexia) and behavioral adaptations (e.g., anhedonia, lethargy, social withdrawal, depressed mood, cognitive impairment) upon exposure to infection or inflammation collectively known as "sickness behavior."

According to the neuroinflammatory hypothesis, delirium represents the CNS manifestation of a systemic disease state that has crossed the blood-brain barrier (Maldonado, 2008b). Indeed, many of the circumstances associated with a high occurrence of delirium (e.g., infections, postoperative states) can also be associated with compromise of BBB

Figure 41.10 Schematic Illustration of Neural-Immune Interactions Immune signaling of the CNS via systemic routes and the vagus nerve (Vagus n.) and CNS regulation of immunity via the HPA, hypothalamic-pituitary-thyroid, and hypothalamic-pituitary-gonadal axes and the sympathetic nervous system (SNS) and parasympathetic nervous system (PNS). Cytokine expression within the CNS is represented by asterisks within the brain. Dotted lines represent negative regulatory pathways, and solid lines represent positive regulatory pathways. CRH: corticotrophin-releasing hormone; AVP: arginine vasopressin; TRH: thyrotrophin-releasing hormone; GnRH: gonadotrophin-releasing hormone; ACTH: adrenocorticotrophin hormone; TSH: thyrotrophin-stimulating hormone; T₄: thyroxine; T₃: triiodo-L-thyronine; LH: luteinizing hormone; FSH: follicle-stimulating hormone; LC: locus coeruleus; A1, C1, A2, C2: brainstem adrenergic nuclei. (Marques-Deak, Cizza, & Sternberg, 2005)

integrity. It has been postulated that several illness processes (i.e., trauma, infections) and surgical procedures may introduce triggering factors leading to the activation of the inflammatory cascade: extensive tissue trauma, presence of foreign organisms or substances, elevated hormone levels, blood loss and anemia, blood transfusions, use of extracorporeal circulation, hypoxia, ischemia and reperfusion, formation of heparin-protamine complexes, and microemboli formation and migration (reviewed by Maldonado, 2008b, 2013). In addition, other factors associated with illness and surgery may directly lead to compromise of the BBB. For example, recent data suggests that the use of various general anesthetics (e.g., sevoflurane, isoflurane) can cause marked flattening of the surfaces of brain vascular endothelial cells along with disruption of BBB-associated tight junctions at cell margins, leading to holes in the vascular endothelial lining and increased BBB permeability, thus facilitating plasma influx into the brain interstitium (Forsberg et al., 2014). The frequency and magnitude of this effect increases with age, thus potentially serving as a mechanism to mediate postoperative delirium and its increased occurrence among elderly patients (Figure 41.11).

At least four pathways through which immune signals from the periphery are transduced to the brain have been proposed (Figure 41.12) (Dantzer et al., 2008). In the neural pathway, locally produced cytokines activate primary afferent nerves (e.g., vagus). In the humoral pathway, toll-like receptors on macrophage-like cells residing in the circumventricular organs and the choroid plexus respond to circulating pathogen-associated molecular patterns by producing proinflammatory cytokines, which enter the brain by diffusion. In the cytokine transporters pathway, proinflammatory cytokines overflowing in the systemic circulation can gain access to the brain through these saturable transport systems at the blood–brain barrier. The prostaglandin pathway involves

IL-1 receptors that are located on perivascular macrophages and endothelial cells of brain venules. Activation of these IL-1 receptors by circulating cytokines results in the local production of prostaglandin E2.

The neuroinflammatory hypothesis proposes that several conditions associated with delirium are characterized by activation of the inflammatory cascade with acute release of inflammatory mediators into the bloodstream (Cerejeira et al., 2010). CNS resident cells react to the presence of peripheral immune signals (cytokines and lipopolysaccharide [LPS]), leading to production of cytokines and other mediators in the brain, cell proliferation, and activation of the HPA axis (thus linking it with the neuroendocrine hypothesis, discussed next) through a complex system of interactions (Figure 41.13). These neuroinflammatory changes induce neuronal and synaptic dysfunction (i.e., affecting various neurotransmitter systems), leading to the neurobehavioral and cognitive symptoms characteristic of delirium.

Animal studies have shown that the administration of LPS induces sickness behavior, which requires activation of proinflammatory cytokine signaling in the brain (Dantzer et al. 1998; Dantzer, 2004). Microglia are the primary recipients of peripheral inflammatory signals that reach the brain (Figure 41.14) (Miller, Maletic, & Raison, 2009; Miller, Haroon, Raison, & Felger, 2013). Activated microglia, in turn, initiate an inflammatory cascade whereby release of relevant cytokines, chemokines, inflammatory mediators, reactive nitrogen species (RNS), and reactive oxygen species (ROS) induces mutual activation of astroglia, thereby amplifying inflammatory signals within the CNS. Cytokines, including IL-1, IL-6, and TNF- α , as well as IFN- α and IFN- γ (from T cells), induce the enzyme indoleamine 2,3 dioxygenase (IDO), which breaks down tryptophan (TRP), the primary precursor of 5-HT, into quinolinic acid (QUIN), a

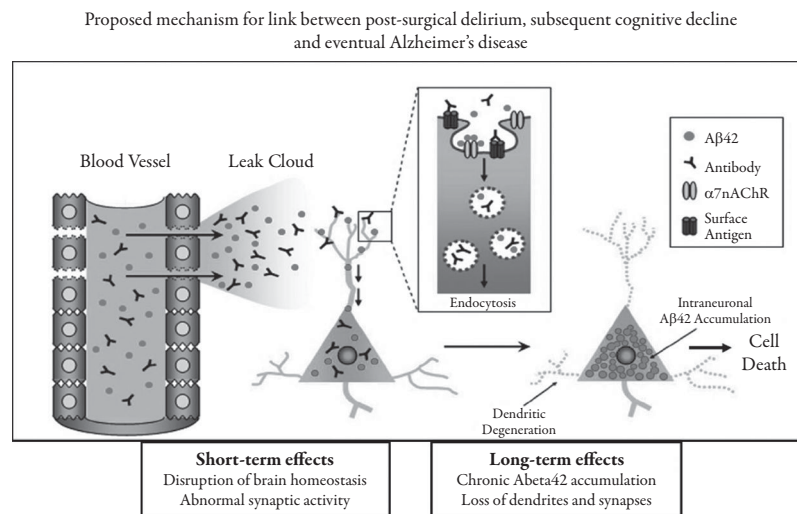

Figure 41.11 Exposure to anesthetics causes an immediate, short-term breakdown of BBB integrity. This leads to an influx of plasma components into the brain tissue that causes disruption of brain homeostasis and neuronal misfiring, all culminating into the array of symptoms that hallmark delirium. Failure to completely restore BBB integrity (most common in the elderly) may trigger long-term BBB breakdown, which can drive chronic plasma influx, more permanent disruption of brain homeostasis, and impairment of neuronal function. Chronic binding of bloodborne brain-reactive autoantibodies and soluble amyloid peptide (Aβ42) to neurons, and their internalization via endocytosis, are essential features of subsequent cognitive decline and early Alzheimer's disease pathology. (Forsberg et al., 2014)

Figure 41.12 Pathways that Transduce Immune Signals from the Periphery to the Brain The brain and the immune system communicate through different pathways. (a) In the neural pathway, peripherally produced pathogen-associated molecular patterns (PAMPs) and cytokines activate primary afferent nerves (e.g., vagal nerve, trigeminal nerves). (b) The humoral pathway involves circulating PAMPs that reach the brain at the level of the choroid plexus (CP) and the circumventricular organs, where PAMPs induce the production and release of proinflammatory cytokines, likely reaching the brain by diffusion. (Dantzer et al., 2008)

potent NMDA agonist and stimulator of glutamate (GLU) release. Multiple astrocytic functions are compromised due to excessive exposure to cytokines, QUIN, and RNS/ROS, ultimately leading to downregulation of glutamate transporters, impaired glutamate reuptake, and increased glutamate release, as well as decreased production of neurotrophic factors. Of note, oligodendroglia are especially sensitive to the CNS inflammatory cascade and suffer damage due to overexposure to cytokines such as TNF- α , which has a direct toxic effect on these cells, potentially contributing to apoptosis and demyelination. The confluence of excessive astrocytic glutamate release, its inadequate reuptake by astrocytes and oligodendroglia, activation of NMDA receptors by QUIN, increased glutamate binding and activation of extrasynaptic NMDA receptors (accessible to glutamate released from glial elements and associated with inhibition of brain-derived neurotrophic factor [BDNF] expression), decline in neurotrophic support, and oxidative stress ultimately disrupt neural plasticity through excitotoxicity and apoptosis (Figure 41.15)

(Behan & Stone, 2000; Stone, Behan, Jones, Darlington, & Smith, 2001; Darlington et al., 2007, 2010; Stone, Forrest, & Darlington, 2012).

Human studies have confirmed these findings. A study of adult patients admitted to inpatient medicine wards showed that those who developed delirium had significantly elevated levels (i.e., above the detection limit) of IL-6 (53% versus 31%) and IL-8 (45% versus 22%), compared with patients who did not develop delirium, even after adjusting for infection, age, and cognitive impairment (de Rooij, van Munster, Korevaar, & Levi, 2007). This was the first study to show a relationship between peripherally measured cytokine levels and delirium as a symptom of sickness behavior in acutely admitted elderly. It also showed that cognitive function can be impaired by a systemic infection in patients with a neurodegenerative disorder such as Alzheimer's disease, and that this cognitive decline is preceded by raised serum levels of IL-1h. Furthermore, aging and neurodegenerative disorders exaggerate microglial responses following stimulation by

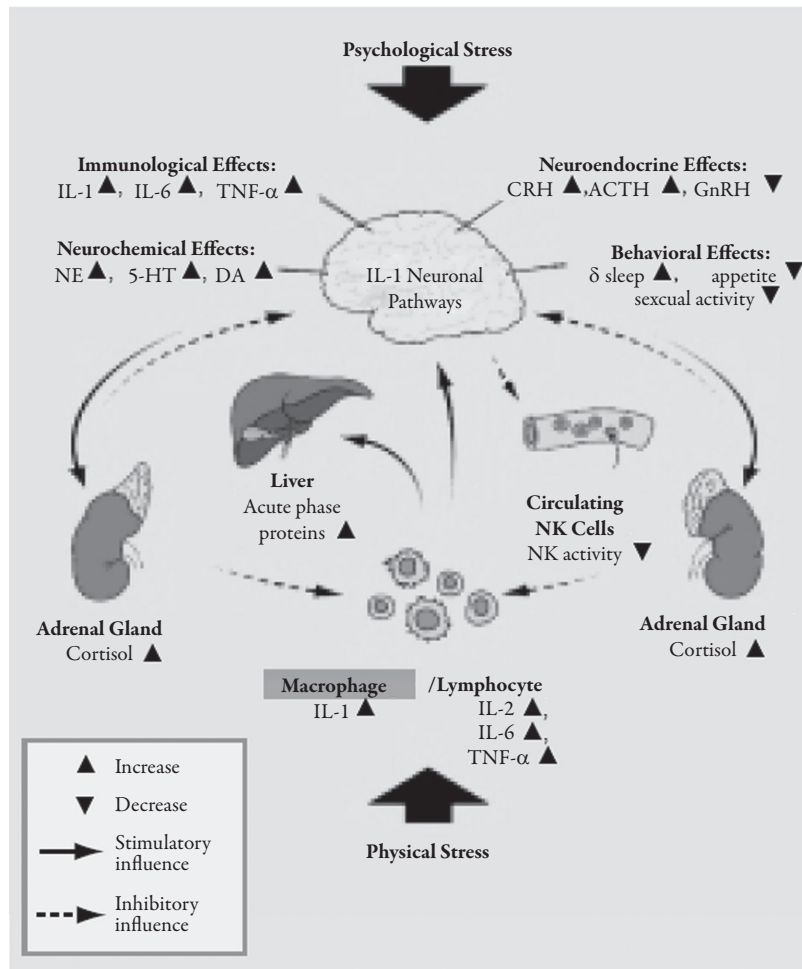

Figure 41.13 Interlukins and the Stress Response Both psychological stress (e.g., stress, depression) and physical stress (e.g., infection, trauma, surgery) can activate interleukin-1, which will trigger various phenomena both peripherally (e.g., cascade activation of other cytokines, induction of acute phase proteins) and centrally (e.g., various immunologic, neurochemical, neuroendocrine, and behavioral effects). Feedback mechanisms occur at several levels and include negative feedback exerted by cortisol. Abbreviations: IL = interleukin, TNF- α = tumor necrosis factor- α , CRH = corticotropin-releasing hormone, GnRH = gonadotropin-releasing hormone, NE = norepinephrine, 5-HT = serotonin, DA = dopamine, NK = natural killer. (Kronfol & Remick, 2000)

systemic immune stimuli such as peripheral inflammation and/or infection (as described in the neural aging hypothesis).

NEUROENDOCRINE HYPOTHESIS

The neuroendocrine hypothesis suggests excessive glucocorticoid (GC) levels may induce a vulnerable state in neurons. Glucocorticoids are hormones released during the stress response that are well known for their immunosuppressive and antiinflammatory properties; however, recent advances have uncovered situations wherein they have effects in the opposite direction (Sorrells, Caso, Munhoz, & Sapolsky, 2009). An extensive body of work has substantiated the idea that repeated or prolonged exposure to GCs has a deleterious impact on brain function, and has also provided evidence that GCs probably contribute to age-related decline in brain function (Goosens & Sapolsky, 2007). Others have

already demonstrated how stress (induced by illness processes, such as hypoxia/ischemia, hypoglycemia, or seizures) can lead to excess glucocorticoid release, which can exacerbate cell death by inhibiting glucose transport into cells (Figure 41.16 (Sapolsky & Pulsinelli, 1985; Sapolsky, 1990, 1996; Dinkel, Ogle, & Sapolsky, 2002)). But there is growing evidence showing that GCs may have proinflammatory effects in the brain and can even enhance neuroinflammation at multiple levels in the pathway linking LPS exposure to inflammation (Figure 41.17) (Munhoz, Sorrells, Caso, Scavone, & Sapolsky, 2010; Schiepers, Wichers, & Maes, 2005). In addition, glucocorticoids can increase proinflammatory cell migration, cytokine production, and even transcription factor activity in the brain (Sorrells & Sapolsky, 2007). This can lead to a number of deleterious effects, including inhibition of glutamate reuptake in the synaptic cleft, inhibition of Ca²⁺ efflux or sequestration, exacerbation of the breakdown of cytoskeletal proteins (i.e., tau), increase

Figure 41.15 Metabolic Pattern of Tryptophan, Serotonin, Melatonin, Kynurenine and Quinolinic Acid. Evidence suggest that some proinflammatory cytokines can not only induce sickness behavior, but also enhance activity of the ubiquitous indoleamine 2,3 dioxygenase (IDO), leading to deficient tryptophan (TRP) levels, thus a reduction in 5HT and melatonin production, and a shift to the production of kynurenine (KYN) and other neurotoxic tryptophan-derived metabolites. (Maldonado 2013; modified from Darlington et al., 2010, and Stone, Forrest, & Darlington, 2012)

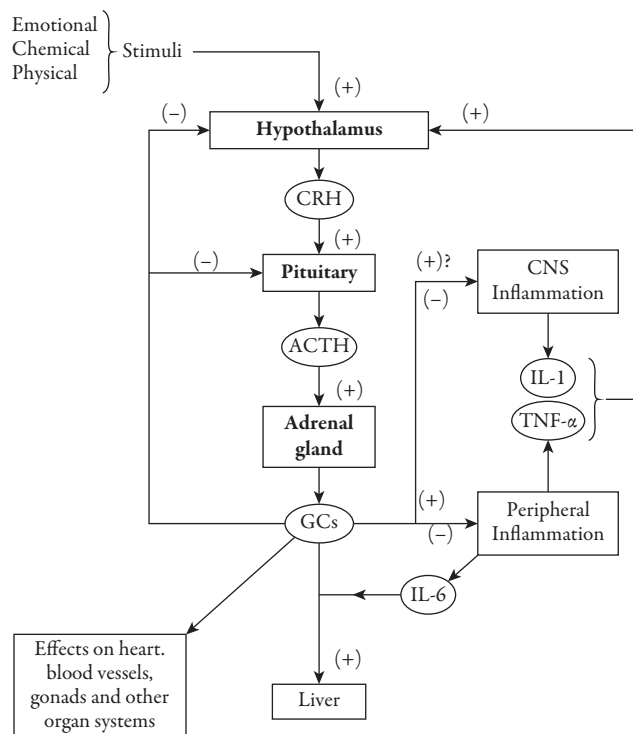

Figure 41.16 Neuroendocrine Circuits and the Effects of Inflammation. Various stressors can activate the HPA axis. The hypothalamus is stimulated to secrete CRH, which leads to ACTH secretion into the peripheral circulation. ACTH in turn triggers adrenal GC release and production. The CRH system is inhibited by GCs in a negative feedback loop. TNF- α and IL-1 are produced from inflammatory sites and are potent activators of the HPA axis. IL-6 acts synergistically with GCs to stimulate the hepatic secretion of acute phase proteins. Although GCs are widely known for their anti-inflammatory actions, “(-),” more recently also proinflammatory effects have repeatedly been reported, “(+)?” Abbreviations: HPA = hypothalamic-pituitary-adrenal; CRH = corticotrophin-releasing hormone; ACTH = adrenocorticotrophic hormone; GCs = glucocorticoids; IL = interleukin; TNF = tumor necrosis factor; (+) = enhancing; (-) = suppressing. (Dinkel, Ogle, & Sapolsky, 2002)

hippocampal–adrenal circuit may contribute to the amplification of delirious factors. There is evidence that, relatively early during the metabolic stress leading to delirium, the hippocampus begins to malfunction. This may explain some of the memory dysfunction and errors in information processing, leading to the confabulations that are commonly seen in delirious patients. The loss of normal inhibition of adrenal steroidogenesis results in the continuous secretion of peak amounts of corticosteroids, leading to further mitochondrial dysfunction and apoptosis and further exacerbation of the catecholamine disturbances. A key abnormality related to cortisol excess in delirium seems to be abnormal “shut-off” of the HPA axis tested by the DST. In experimental models, the hippocampal formation is of prime importance for normal HPA axis shut-off (Olsson, 1999). In this brain area, a close interaction between neurotransmitters—notably ACH, 5HT, and NE—and glucocorticoid receptors is relevant for the development of delirium in elderly patients with stroke and neurodegenerative brain diseases.

Figure 41.17 Inflammation, Neurotransmitters & the HPA Axis. The brain regulates the immune system, and the immune system modulates brain activity through various interactions. The hypothalamic–pituitary–adrenal (HPA) axis is the main route of immunoregulation, next to (para)sympathetic innervation of organs of the immune system. Immune cells secrete cytokines, which not only regulate the immune response but also act to block the actions of other humoral substances at different levels of the HPA axis (black bars). (Schiepers, Wichers, & Maes, 2005)

OXIDATIVE STRESS HYPOTHESIS

The oxidative stress hypothesis proposes that decreased brain oxidative metabolism leads to abnormalities of various neurotransmitter systems, causing cerebral dysfunction and the behavioral symptoms of delirium. Thus, severe illness processes, combined with both decreased oxygen supply and/or increased oxygen demand, may lead to the same common end problem; namely, decreased oxygen availability to cerebral tissue. This has been the subject of an extensive review described elsewhere Figure 41.18 (Maldonado, 2013). In summary, hypoxia triggers diverse reconfigurations of widespread neuronal network at all levels of the nervous system (i.e., molecular, cellular, synaptic, neuronal, network): synaptic transmission is depressed through pre-synaptic mechanisms and excitatory/inhibitory alterations involving K^+ , Na^+ , and Ca^{2+} channels. Cerebral ischemia leads to a rapid depletion of energy stores, triggering a complex cascade of cellular events, including cellular depolarization and Ca^{2+} influx, resulting in excitotoxic cell death (see Figure 41.19).

Inadequate oxidative metabolism may be one of the causes of the problems observed in delirium; namely, inability to maintain ionic gradients causing “spreading depression”; abnormal neurotransmitter synthesis, metabolism and release; and a failure to effectively eliminate neurotoxic byproducts. Decreased oxygenation causes a failure in oxidative

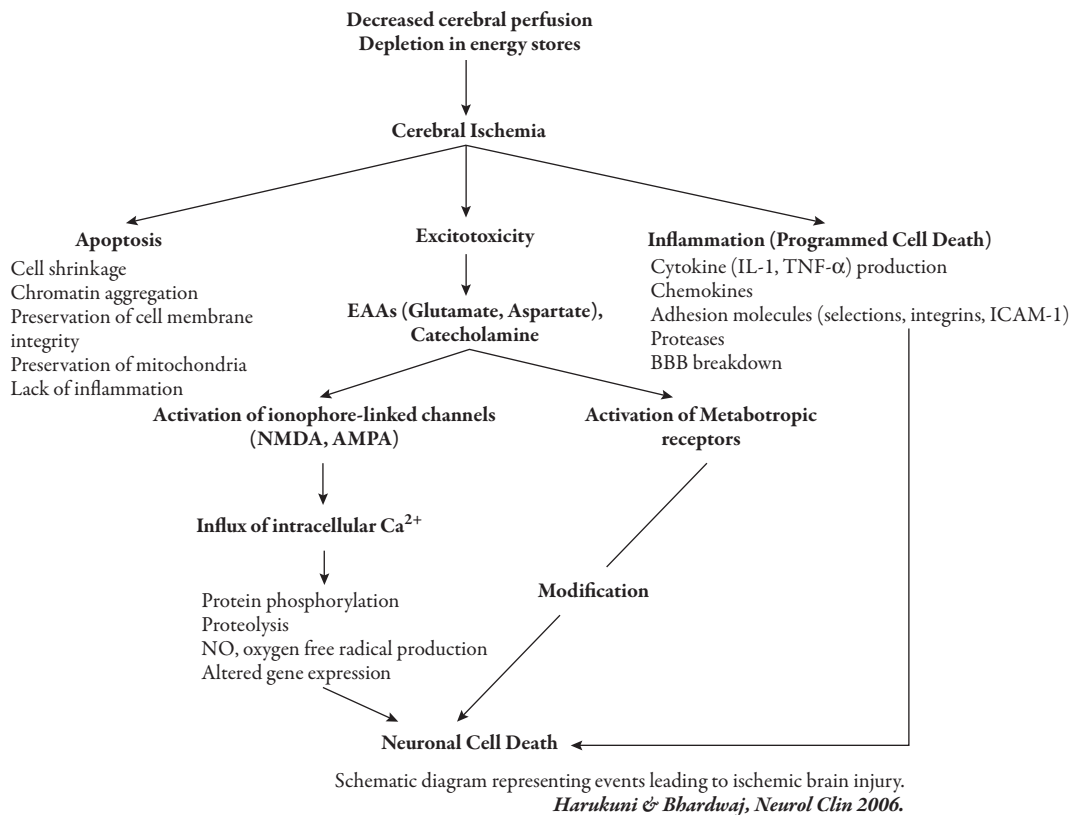

Figure 41.19 Mechanisms of Brain Injury after Global Cerebral Ischemia. During cerebral ischemia, excess glutamate exits into the extracellular compartment due to cellular depolarization, coupled with its impaired uptake, which results in increases in intracellular Ca^{2+} . The cascade of events responsible for glutamate excitotoxicity includes three distinct processes: (1) induction, whereby extracellular glutamate efflux is transduced by receptors on the neuronal membrane to cause intracellular Ca^{2+} overload, which leads to lethal intracellular derangements; (2) amplification of the derangement, with an increase in intensity and involvement of other neurons; and (3) expression of cell death triggered by cytotoxic cascades. Excess release of Ca^{2+} and its intracellular influx is thought to be the primary trigger for a variety of complex, deleterious intracellular processes that result from activation of catabolic enzymes such as phospholipases (which lead to cell membrane breakdown, arachidonic acid, and free radical formation) and endonucleases (which lead to fragmentation of genomic DNA and energy failure due to mitochondrial dysfunction). (Harukuni & Bhardwaj, 2006)

metabolism, which leads to a failure of the Adenosine triphosphate (ATP)-ase pump system. When the pump fails, the ionic gradients cannot be maintained, leading to significant influxes of sodium (Na^+) followed by calcium (Ca^{2+}), while potassium (K^+) moves out of the cell. Some have theorized that it is the excess inward flux of Ca^{2+} that precipitates the most significant neurobehavioral disturbances observed in delirious patients. The influx of Ca^{2+} during hypoxic conditions is associated with the dramatic release of several neurotransmitters, particularly glutamate (GLU) and dopamine (DA). Glutamate further potentiates its own release as GLU stimulates the influx of Ca^{2+} , and it accumulates in the extracellular space as its reuptake and metabolism in glial cells is impeded by the ATP-ase pump failure. In addition, at least two factors facilitate dramatic increases in DA: first, the conversion of DA to norepinephrine (NE), which is oxygen dependent, is significantly decreased; second, the catechol-o-methyl transferase (COMT) enzymes, required for degradation of DA, get inhibited by toxic metabolites under hypoxic conditions, leading to even greater accumulation of DA (Graham, 1984). At the same time, serotonin (5HT) levels fall moderately in the cortex, increase in the striatum, and remain stable in the brainstem (Broderick & Gibson, 1989).

Hypoxia also leads to a reduced synthesis and release of acetylcholine, especially in the basal forebrain cholinergic centers. Indeed, cholinergic neurotransmission is particularly sensitive to metabolic insults, such as diminished availability of glucose and oxygen. ACh synthesis requires acetyl coenzyme A, which is a key intermediate linking the glycolytic pathway and the citric acid cycle. Thus, reduction in cerebral oxygen and glucose supply and deficiencies in enzyme cofactors such as thiamine may induce delirium by impairing ACh production.

There are definite data correlating poor oxygenation and cerebral dysfunction. Studies have demonstrated a strong correlation between intraoperative oxygen saturation and postoperative mental function (Rosenberg & Kehlet, 1993). Studies have demonstrated that delirium can be induced in healthy control subjects by dropping PaO_2 to 35 mmHg (Gibson & Peterson, 1981). A study of ICU patients demonstrated that three measures of oxygenation (i.e., hemoglobin level, hematocrit, pulse oximetry; see Figure 41.4) were worse in the patients who later developed delirium, and that clinical factors associated with greater oxidative stress (e.g., sepsis, pneumonia) occurred more frequently among those diagnosed with delirium (Seaman et al., 2006).

A recent study demonstrated that intraoperative cerebral oxygen desaturation was a significant risk factor for postoperative delirium in CABG patients (Figure 41.5) (Slater et al., 2009).

DIURNAL DYSREGULATION OR MELATONIN DYSREGULATION HYPOTHESIS

The diurnal dysregulation or melatonin dysregulation hypothesis suggests that the 24-hour internal “clock” (circadian pattern) is maintained by environmental factors, primarily light exposure, which affect melatonin secretion (BaHammam, 2006). Sleep deprivation may lead to the development of memory deficits (Walker & Stickgold, 2004). In fact, “chronic partial sleep deprivation” (i.e., sleeping limited to 4 hours per night, for 5 consecutive nights) has been shown to lead into cumulative impairment in attention, critical thinking, reaction time, and recall (Dinges, 2006). In turn, sleep deprivation (even just 36 consecutive hours) may lead to symptoms of emotional imbalance (i.e., short temper, mood swings, and excessive emotional response). Cumulative sleep debt can cause delirium in itself, and can aggravate or perpetuate delirium (Ito, Harada, Hayashida, Ishino, & Nakayama, 2006; Pandharipande & Ely, 2006). Similarly, others have found sleep deprivation to consistently precede onset of delirium in cardiac surgical patients (Sveinsson, 1975), and that ICU patients with sleep deprivation were significantly more likely to develop delirium than patients without sleep deprivation (Helton, Gordon, & Nunnery, 1980).

Melatonin plays important roles in multiple bodily functions (Reiter, 1991; Brzezinski, 1997; Verster, 2009). It has a chronobiotic effect (affecting aspects of biological time structure), sleep–wake cycle regulatory effects, and helps reset circadian rhythm disturbances. It has extensive antioxidant activity (with a particular role in the protection of nuclear and mitochondrial DNA), extensive anti-inflammatory activity, and some anti-nociceptive and analgesic effects; and data suggest that melatonin receptors appear to be important in mechanisms of learning and memory. Melatonin also inhibits the aggregation of the amyloid beta protein into neurotoxic micro-aggregates responsible for the neurofibrillary tangles characteristic of Alzheimer’s disease, and it prevents the hyperphosphorylation of the tau protein. All of these factors may have potential implications regarding the development of delirium in the medically ill and postoperative patient.

In addition, current evidence suggests that acute and chronic sleep deprivation is associated with decreased proportions of natural killer cells, lower antibody titers following influenza-virus immunization, reduced lymphokine-activated killer activity, and reduced IL-2 production. Conversely, cytokines may play a role in normal sleep regulation by increasing non-REM sleep and decreasing REM sleep, and, during inflammatory events, an increase in cytokine levels may intensify their effects on sleep regulation. Moreover, sleep deprivation may alter endocrine and metabolic functions, altering the normal pattern of cortisol release and contributing to impairment of the regulation of glucocorticoid secretion via negative feedback mechanisms, insulin resistance, and glucose intolerance.

Several studies have demonstrated a relationship between melatonin secretion and delirium. A study of elderly patients after major abdominal surgery had their plasma melatonin levels measured preoperatively and every 2 hours during the postoperative period, and demonstrated that those who did not develop delirium did not have significant changes in plasma melatonin levels compared with preoperative values (Shigeta, Yasui, et al., 2001). Furthermore, patients who experienced postoperative delirium could be broken down into two groups: those who became delirious postoperatively, with an otherwise uncomplicated recovery; and those who developed postoperative complications such as pneumonia. Patients who went on to become delirious, but without other complications, demonstrated reduced plasma melatonin levels. Those delirious but with other complications had elevated plasma melatonin levels, similar to that seen in early sepsis (Mundigler et al., 2002). Similarly, a study of subjects undergoing thoracic esophagectomy demonstrated a significant correlation between ICU psychosis (i.e., delirium) and an irregular melatonin circadian rhythm (i.e., abnormally low serum levels of melatonin), measured every 6 hours during the first 4 postoperative days ($P = .0001$) (Miyazaki et al., 2003).

Of note, some have observed a relationship between the motoric delirium subtype and melatonin levels. A study of hospitalized elderly medical patients evaluated them daily using the Delirium Rating Scale (DRS) and conducted urinary measures of their 6-sulphatoxymelatonin (6-SMT), the chief metabolite of melatonin and a reliable proxy for serum melatonin (Matthews, Guerin, & Wang, 1991). The mean and standard deviation values of 6-SMT for each of the three motoric subtypes were calculated, and it was found that during periods of hyperactive delirium, subjects had decreased urinary 6-SMT levels compared with when they had recovered. Patients with hypoactive delirium had raised 6-SMT levels compared with when they had recovered, while those with the mixed form of delirium had no difference in urinary metabolite concentrations (Balan et al., 2003).

NEURONAL AGING HYPOTHESIS

Finally, the neuronal aging hypothesis suggests that elderly patients are at increased risk for developing delirium, based on the fact that aging is associated with age-related cerebral changes in stress-regulating neurotransmitter and intracellular signal transduction systems, and observations suggesting that chronic neurodegeneration is accompanied by an inflammatory response characterized by a chronic, but selective, activation of CNS microglial cells that are “primed” to produce exaggerated inflammatory responses to immunological challenges (Figure 41.20) (Cunningham et al., 2005, 2009). This inflammation is assumed to contribute to disease progression through the production of inflammatory mediators. Data suggest that the aging process is associated with a twofold to fourfold increase in baseline levels of circulating inflammatory mediators, including cytokines and acute phase proteins (Rosczyk, Sparkman, & Johnson, 2008). This may help explain why even minor surgical trauma was associated with increased IL-1b hippocampal expression in

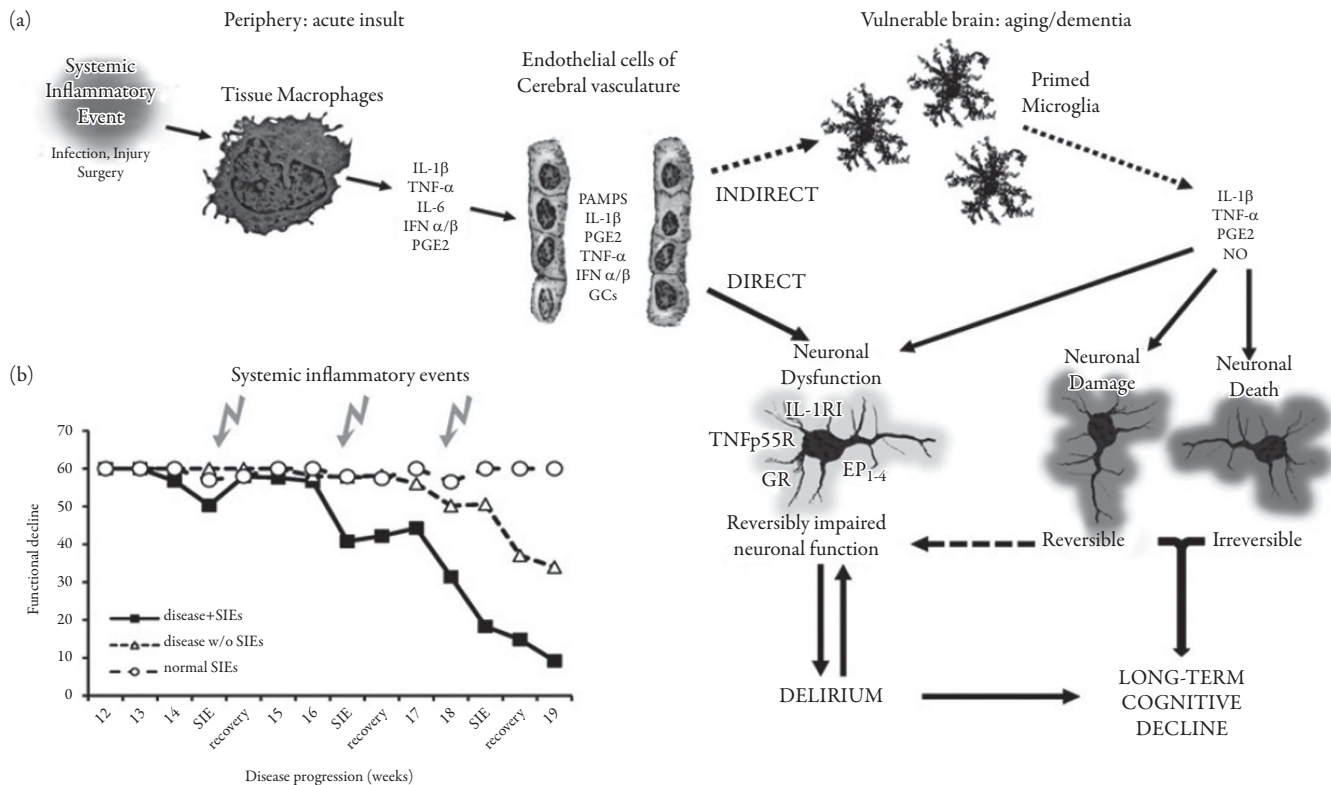

Figure 41.20 Effect of Inflammation on the Aging Brain. (a) Systemic inflammatory events trigger the release of inflammatory mediators by tissue macrophages and brain vascular endothelial cells. These mediators may affect neuronal function directly, or via the activation of microglial cells that have become primed by neurodegenerative disease or aging. Inflammatory mediators may cause reversible disruption of neuronal function, leading to various neurobehavioral syndromes including delirium. These mediators may also induce acute neuronal synaptic or dendritic damage that may be reversible and contribute to delirium, or may be irreversible and contribute to long-term cognitive decline. (b) Successive systemic inflammatory insults induce acute dysfunction, which is progressively less reversible each time, and also contribute to the progression of permanent disability. Abbreviations: IL-1RI, interleukin 1 receptor type I; TNFp55, TNFp55 receptor; GCs, glucocorticoids; GR, glucocorticoid receptor; NO, nitric oxide; EP₁₋₄, prostaglandin receptors 1–4; PAMPs: pathogen-associated molecular patterns; IFN α/β , interferon α/β ; SIEs, systemic inflammatory events.

animal studies. Aging is also associated with decreased volume of ACh-producing cells and decreased cerebral oxidative metabolism. Thus, the decline in cognitive functioning associated with the normal aging process is aggravated by the presence of even mild hypoxia, which further inhibits ACh synthesis and its release. As previously discussed, the probability of experiencing delirium rises with age. Of note, some have suggested that prostaglandins are responsible for the LPS-induced inhibition of sickness behaviors, either independent of cytokine activity or as complement (i.e., sensitizing certain targets to the effect of cytokines) (Teeling et al., 2007).

There has been some controversy about the contribution of apolipoprotein E and the development of postoperative cognitive dysfunction (POCD). To date, there have been nine published papers on the topic; four of them found that APOE-E4 genotype was not associated with POCD (Abildstrom et al., 2004; Tagarakis et al., 2007; van Munster, Korevaar, de Rooij, Levi, & Zwinderman, 2007; Bryson et al., 2011), while the other five suggested a positive relationship between POCD and APOE genotype (Adamis et al., 2007; Ely et al., 2007; Leung et al., 2007; Zhang et al., 2008; van Munster, Korevaar, Zwinderman, Leeﬂang, & de Rooij, 2009). (For a summary of all published studies see Table 41.6.) Of note, the only

published meta-analysis on the matter found a positive association between POCD and the APOE sigma4 allele.

In the end, any or all of the above theories lead to the same common result: changes in neurotransmitter concentration or receptor sensitivity (due to any of the mechanisms discussed by the previous hypotheses) mediate the different symptoms and clinical presentations of delirium. In general, the most commonly described neurotransmitter changes associated with delirium are excess release of norepinephrine (\uparrow NE), dopamine (\uparrow DA), and/or glutamate (\uparrow GLU), and increased Ca⁺ channel activity (\uparrow Ca⁺ Ch); reduced availability of acetylcholine (\downarrow ACh) and/or melatonin (\downarrow MEL); and either a decreased and increased activity in serotonin (\downarrow \uparrow 5HT), histamine (\downarrow \uparrow H1&2), and/or gamma-amino butyric acid (\downarrow \uparrow GABA), probably depending on the etiology or motoric presentation (see Table 41.7).

CLINICAL PRESENTATION OF DELIRIUM

Delirium is an acute or subacute organic mental syndrome characterized by disturbance in attention (often evidenced by a reduced ability to direct, focus, sustain, and shift attention) and awareness (with impaired orientation to the

Table 41.6 ASSOCIATION BETWEEN APOLIPOPROTEIN E GENOTYPE AND POSTOPERATIVE COGNITIVE DYSFUNCTION

STUDY(<i>N</i> = 10)	POPULATION	FINDINGS	<i>P</i> -VALUE
Abildstrom et al., 2004 Prospective, <i>n</i> = 967	Patients aged 40 yrs. and older undergoing non-cardiac surgery	<ul style="list-style-type: none"> One week after surgery, the incidence of POCD was 11.7% in patients with the epsilon 4 allele and 9.9% in patients without the epsilon4 allele. Conclusion: unable to show a significant association between apolipoprotein E genotype and POCD. 	<i>P</i> = 0.41
Adamis et al., 2007 Prospective, <i>n</i> = 164	≥70 y/o hospitalized medically ill patients	<ul style="list-style-type: none"> Recovery was significantly (<i>P</i> < .05) associated with lack of APOE 4 allele and higher initial interferon (IFN)-gamma. A model incorporating gender, APOE epsilon4 status and IGF-I levels predicted recovery or not from delirium in 76.5% of cases, with a sensitivity 0.77 and specificity 0.75. It further found a positive relationship between delirium with APOE genotype, IFN-gamma, and IGF-I, but not with IL-6, IL-1, TNF-alpha, and leukemia inhibitory factor. 	<i>p</i> < 0.05
Leung et al., 2007 Prospective, <i>n</i> = 190	nested cohort study; patients aged ≥ 65 yr, scheduled to undergo major noncardiac surgery requiring anesthesia.	<ul style="list-style-type: none"> The presence of one copy of the e4 allele was associated with an increased risk of early postoperative delirium (28.3% vs. 11.1%; <i>P</i> = 0.005). Even after adjusting for covariates, patients with one copy of the e4 allele were still more likely to have an increased risk of early postoperative delirium (OR, 3.64; 95% CI, 1.51–8.77) compared with those without the e4 allele. 	<i>P</i> = 0.005
Tagarakis et al., 2007, <i>n</i> = 137	Elderly adults undergoing cardiac bypass surgery; excluded dementia	<ul style="list-style-type: none"> Study confirmed the high incidence of cognitive decline and delirium after coronary surgery, but it does not support the role of the APOE-epsilon 4 allele in the occurrence of delirium. 	NS
Van Munster et al., 2007 <i>n</i> = 415	Acutely admitted patients to the Department of Medicine of 65 yrs and over	The OR for carriers of an APOE epsilon 4-allele compared with patients without an APOE epsilon 4-allele for developing delirium was 1.17 (95% CI: 0.49–2.78) in the cognitively intact patients and 0.42 (95% CI: 0.14–1.30) in the cognitively impaired patients. No relation existed between the total number of APOE epsilon 4-alleles and the different delirium subtypes (<i>P</i> = 0.12).	<i>P</i> = 0.12
Ely et al., 2007 <i>n</i> = 53	Mechanically ventilated ICU patients	Using multivariable regression analysis to adjust for age, admission diagnosis of sepsis or acute respiratory distress syndrome or pneumonia, severity of illness, and duration of coma, the presence of APOE4 allele was the strongest predictor of delirium duration (OR, 7.32; 95% CI, 1.82–29.51, <i>p</i> = .005).	<i>p</i> = .005
Zhang et al., 2008 <i>n</i> = 196	Elderly patients (>60 yo) scheduled for major abdominal surgery requiring general anesthesia	The presence of the e4 allele and low level of education were both associated with an increased risk of EA (36.9% vs. 15.8%, <i>P</i> = 0.005; 30% vs. 14.3%, <i>P</i> = 0.01). After adjustment for covariates, the patients with the copy of the e4 allele were shown to have a greater likeliness of an increased risk of EA (OR: 4.32; 95% CI: 1.75–10.05).	<i>P</i> = 0.01
Van Munster et al., 2009 <i>n</i> = 656 + Meta-analysis	Medical department and orthopedic/traumatology department of university hospital from 2003 to 2007.	The OR for delirium adjusted for age, cognitive, and functional impairment of sigma4 carriers compared with non-sigma4 carriers was 1.7 (95% CI: 1.1–2.6). Four studies were added to the meta-analysis, which included 1,099 patients in total. The OR for delirium in the meta-analysis was 1.6 (95% CI: 0.9–2.7) of sigma4 carriers compared with non-sigma4 carriers. This study and meta-analysis suggest an association between delirium and the APOE sigma4 allele.	<i>P</i> = 0.04
Bryson et al., 2011 <i>n</i> = 88	Patients ≥60 yrs. of age undergoing open aortic repair.	Delirium predicted POCD at discharge (OR 2.86; 95% CIs 0.99 to 8.27) but not at three months. Apolipoprotein E-ε4 genotype was not associated with either delirium or POCD following adjustment for covariates.	<i>p</i> = 0.625

environment; Criterion A; APA, 1994). An additional disturbance is present in cognition (e.g., memory deficit, disorientation), language, visuospatial ability, or perception (e.g., hallucinations or delusions; Criterion C; APA, 1994). Often, the syndrome is accompanied by a disordered sleep–wake cycle, (e.g., sleep–wake cycle reversal, sundowning) and alterations in psychomotor activity (e.g., decreased or increased depending on the type of delirium; APA, 1994). By definition, these changes develop over a relatively short period of time (i.e., hours to days) and represent a change from baseline attention and awareness, and have a tendency to fluctuate in severity during the course of a day (e.g., waxing and waning; Criterion B; APA, 1994). Similarly, the presentation cannot be better explained by a preexisting psychiatric disorder (e.g., schizophrenia or dementia) and are deemed to be caused as a result of a primary medical disorder and/or its treatment, or mediated by psychoactive substances (e.g., acute use or intoxication, or substance withdrawal, as in delirium tremens; Criteria D & E; APA, 1994).

Some have suggested there are three core domains of delirium: *cognitive deficits* (characterized by attention and vigilance disturbances); *circadian rhythm dysregulation* (characterized by fragmentation of the sleep–wake cycle); and *higher cortical dysfunction* (characterized by semantic and comprehension deficits, executive dysfunction, and thought process disturbances) (Meagher et al., 2007). In fact, sleep–wake cycle disturbance, inattention, and language/thought process/comprehension abnormalities were the most frequent, consistent, and differentiating symptoms of delirium in medical/surgical populations (Trzepacz et al., 2001; Meagher et al., 2007; Franco, Trzepacz, Mejia, & Ochoa, 2009).

The clinical features of delirium include a prodromal phase, usually marked by restlessness, anxiety, irritability; and the experiencing of nightmares, transient hallucinations (often hypnagogic), and sleep disturbances, which usually develop over a period of several hours to days before the patient exhibits the full-blown syndrome. Often patients recover from a comatose or medication-induced state (e.g., midazolam or propofol infusion) in a confused and agitated state (i.e., emergence delirium).

Even though delirium was originally defined as a transient syndrome, “chronic” forms may be seen in patients experiencing protracted medical problems (e.g., chronic infections), those with concomitant psychiatric disorders (e.g., bipolar disease, psychosis), those with baseline cognitive impairment (e.g., delirium superimposed on dementia, traumatic brain injury [TBI]), and patients with combined delirium and CNS-depressant withdrawal (e.g., delirium tremens, opioid or benzodiazepine withdrawal) (see “Impact of Delirium” section). More commonly, patients exhibit a rapid and fluctuating course with symptoms varying rapidly over time, giving rise to the classic waxing and waning picture. Patients often experience the appearance or exacerbation of behavioral disturbances in the evening and at night, leading to the classic “sundowning” syndrome (Cardinali, Brusco, Liberczuk, & Furio, 2002). Whether this represents a function of biological circadian rhythm or results from decreased sensory input is unclear. The appearance of lucid intervals in the clinical

course is an important observation and may even aid in the diagnosis of delirium.

As described above, global disturbance of cognition is a cardinal feature of delirium. All “main cognitive functions” (e.g., perception, thinking, memory) are impaired or abnormal to some extent. In addition, delirious patients have difficulty sustaining attention and responding to stimuli selectively. Usually, patients are easily distracted by their surrounding environment. Delirium may be better understood as a disorder of awareness, not arousal. Yet, arousal problems may be associated with the various presentations of delirium. For example, in the case of hypoactive delirium, the activating system may be hypoactive, in which case the patient would appear apathetic, somnolent, and quietly confused. In other patients, the brainstem’s activating system may be hyperactive, in which case the patient is agitated and hypervigilant, exhibiting psychomotor hyperactivity and agitation, leading to the hyperactive type of delirium.

Often, the sleep–wake cycle is disturbed. This is not only symptomatic of delirium, but in itself may either cause or exacerbate the condition due to sleep deprivation. More commonly, patients exhibit sleep–awake cycle reversal: night sleep is usually shortened and fragmented; while daytime wakefulness is often reduced, presenting in the form of drowsiness and the tendency to nap or being difficult to arouse during the day.

Problems with orientation are likely to be associated with the patients’ inability to adequately process incoming information and their impaired memory formation. In fact, delirious patients seem to experience a reduced ability to discriminate and integrate perceptions. This may include a reduced ability to relate incoming stimuli meaningfully to previously acquired knowledge. Thus, often patients have a difficult time telling apart perceptions, images, dreams, illusions, and hallucinations. This may be the reason why patients commonly report their experiences as happening “as if dreaming while still awake.” Often patients experience emotional dysregulation or lability.

Delirious patients’ memory is often impaired in most aspects (i.e., registration, retention, and recall). They may exhibit various degrees of both anterograde and retrograde amnesia, though their remote memory is often spared. Delirious patients often exhibit a disorganized and fragmented thinking pattern. The disturbances range from an inability to direct thoughts at will, to a complete inability to think coherently. This includes an inability to reason, solve problems, anticipate the consequences of actions, and grasp the meaning of abstract words. This disorganization of thinking, coupled with memory disturbance and misinterpretation of environmental stimuli, often leads to the development of delusional thinking (usually of paranoid nature) and confabulation.

DELIRIUM SUBTYPES

Historically, the first delirium subtypes have been based on behavioral and motoric characteristics (Liptzin & Levkoff, 1992). Factor analysis has confirmed the existence of at least

two different clusters of symptoms: hyperalert/hyperactive features (e.g., agitation, hyperactivity, aggressiveness, hallucinations, delusions); and the hypoalert/hypoactive features (e.g., decreased reactivity, motor and speech retardation, facial inexpressiveness) (Camus et al., 2000).

Subsequent studies have suggested that there are at least three types of delirium, based on their clinical (motoric) manifestations: hyperactive, hypoactive, and mixed (Meagher, O'Hanlon, O'Mahony, Casey, & Trzepacz, 2000; Meagher & Trzepacz, 2000). It is important to recognize that delirium seems to manifest differently in different populations under study (see Figure 41.21). For example, studies in the general adult medical population revealed that, among referrals to a consultation psychiatry service, the most common type appeared to be the mixed type (46%), followed by the hyperactive (30%) and the hypoactive (24%) among those meeting *International Classification of Diseases-10* (ICD-10) (Box 41.3) criteria for delirium (Meagher et al., 2000). Yet, the numbers seem quite different when we look at the critically ill populations. Among medical ICU (MICU) patients, the most common type continues to be the mixed type (54.9%), but there is a significant reversal on the remaining types, with a much larger percentage of hypoactive (43.5%) than hyperactive (1.6%) types (Peterson et al., 2006). Meanwhile, among surgical ICU (SICU) patients, there is a significant reversal on the types of delirium found, with the most common form of delirium being the hypoactive type (64%), followed by the mixed type (27%), and only a minority of subjects exhibiting the purely hyperactive (9%) type (Pandharipande, Cotton et al., 2007). Finally, a study of elderly patients in the medicine wards found that the significant majority of subjects experienced the hypoactive subtype (65%), compared to the hyperactive (25%) or mixed (10%) subtypes (Khurana et al., 2011).

What is most significant about these findings is not only that hypoactive delirium is often missed or misdiagnosed (Liptzin & Levkoff, 1992), but that these patients

experienced the worst prognosis (e.g., prolonged hospital stay, higher morbidity and mortality) (Kiely, Jones, Bergmann, & Marcantonio, 2007). Frequently these patients present with depressive-like symptoms (e.g., unawareness of the environment, lethargy, apathy, decreased level of alertness, psychomotor retardation, decreased speech production, and episodes of unresponsiveness or staring). Patients with hypoactive delirium often endorsed depressive symptoms, such as low mood (60%), worthlessness (68%), and frequent thoughts of death (52%) (Farrell & Ganzini, 1995). Studies have demonstrated that a large percentage of these patients are inappropriately diagnosed and treated as depressed. Hypoactive delirium is unrecognized (and therefore untreated or mismanaged) in 66%–84% of patients. In fact, studies have found that patients with hypoactive delirium demonstrated a seven-fold risk of under-recognition by nurses and that older, visually impaired, demented patients with hypoactive delirium were 20 times less likely to be recognized by nurses as having delirium (Inouye, Foreman, Mion, Katz, & Cooney, 2001). Our own experience at Stanford University Hospital, in parallel to that of others (Farrell & Ganzini, 1995; Kishi et al., 2007), found that 42% of the time when the psychiatry consultation service was called to treat a patient for “depression,” the patient’s correct diagnosis was hypoactive delirium (Maldonado, Dhimi, & Wise, 2003). The same study found that nearly 80% of these patients had been inappropriately prescribed antidepressant medications.

To most physicians, the clearest and most recognizable form is the hyperactive type. Most clinicians agree that a confused, disoriented patient who does not have a preexisting psychiatric diagnosis, who suddenly becomes agitated, combative, and/or assaultive, is probably suffering from the hyperactive or “agitated type” of delirium. We use the term “mixed type” to describe the classic “waxing and waning” pattern, commonly seen in medically ill patients who appear

Figure 41.21 Motoric subtype of delirium depending on population under study.

For a definite diagnosis, delirium symptoms, mild or severe, should be present in each one of the following areas:

1. Impairment of consciousness and attention, on a continuum from clouding to coma (e.g., reduced ability to direct, focus, sustain, and shift attention);
2. Global disturbance of cognition (e.g., perceptual distortions, illusions and hallucinations—most often visual; impairment of abstract thinking and comprehension, with or without transient delusions, but typically with some degree of incoherence; impairment of immediate recall and of recent memory but with relatively intact remote memory; disorientation for time as well as, in more severe cases, for place and person);
3. Psychomotor disturbances (e.g., hypo- or hyperactivity and unpredictable shifts from one to the other; increased reaction time; increased or decreased flow of speech; enhanced startle reaction);
4. Disturbance of the sleep-wake cycle (e.g., insomnia or, in severe cases, total sleep loss or reversal of the sleep-wake cycle; daytime drowsiness; nocturnal worsening of symptoms; disturbing dreams or nightmares, which may continue as hallucinations after awakening);
5. Emotional disturbance (e.g. depression, anxiety or fear, irritability, euphoria, apathy, or wondering perplexity).

The onset is usually rapid, the course diurnally fluctuating, and the total duration of the condition less than six months. The above clinical picture is so characteristic that a fairly confident diagnosis of delirium can be made even if the underlying cause is not clearly established. In addition to a history of an underlying physical or brain disease, evidence of cerebral dysfunction (e.g., an abnormal electroencephalogram, usually but not invariably showing a slowing of the background activity) may be required if the diagnosis is in doubt.

agitated and combative at times, with alternating episodes of somnolence and hypoactivity.

In addition to motoric subtypes, researchers have recently described a new delirium presentation form: subsyndromal delirium (SSD). Different from the other three described above, this is not differentiated by motor type but by an incomplete presentation of diagnostic criteria, along with cognitive impairment. In one study, patients with SSD (defined as meeting ≥ 2 DSM-delirium criteria, but did not meet Confusion Assessment Method [CAM] diagnostic criteria for delirium) had outcomes similar to or worse than those with mild CAM-defined delirium (e.g., nursing home placement or death at 6 months: 27% vs. 0%) (Marcantonio, Ta, Duthie, & Resnick, 2002). Others have demonstrated that when the appropriate screening or diagnostic test is used to allow differentiation between no delirium, subsyndromal delirium, and clinical delirium (e.g., severity scale), patients with SSD in the general medical wards experienced longer acute care hospital stays, increased post-discharge mortality, more symptoms of delirium, and a lower cognitive and functional level at follow-up than patients with no SSD, even after adjusting for illness severity, baseline cognitive status, and severity of baseline functional status (Cole et al., 2003). In addition, patients with SSD had the same set of risk factors that predict the likelihood of developing DSM-defined delirium (e.g., older age, baseline dementia, and greater physiological severity of illness). A recent ICU study similarly concluded that patients with SSD (which defined SSD as patients who have <4 points on the Intensive Care Delirium Screening Checklist [ICDSC]) (Bergeron, Dubois, Dumont, Dial, & Skrobik, 2001) experienced greater mortality (10.6% vs. 2.4%; $P < 0.001$), longer ICU length of stay (5.2 days vs. 2.5 days; $P < 0.001$), and longer overall hospital stay (40.9 days vs. 31.7 days;

$P = 0.002$); conversely, patients with no delirium were more likely to be discharged home and less likely to need convalescence or long-term care than those with SSD (see Table 41.8) (Ouimet et al., 2007).

DIAGNOSING DELIRIUM

Several studies have demonstrated that hospital staff in general, and physicians in particular, are not good at identifying delirium. In fact, studies have demonstrated that delirium is misdiagnosed, detected late, or missed in over 50% of cases across the various healthcare settings (Kean & Ryan, 2008). Despite its high prevalence in critically ill patients, delirium remains unrecognized in as many as 66%–84% of patients experiencing this complication (Francis et al., 1990; Inouye, 1994; Rolfson, McElhaney, et al., 1999; Ely, Margolin et al., 2001; Inouye et al., 2001; Pisani, Redlich et al., 2003; Pisani, Inouye et al., 2003; Pandharipande et al., 2007; Steis & Fick, 2008; Swigart, Kishi, Thurber, Kathol, & Meller, 2008; Steis, Shaughnessy, & Gordon, 2012). Unfortunately, the associated mental status changes are often misattributed to dementia, depression, or just an expected occurrence of medical illness. Several studies have demonstrated a high rate (45%–66%) of missed diagnosis (i.e., either missed completely or misattributed to another disorder) of delirium by general medicine and surgical services (Farrell & Ganzini, 1995; Armstrong, Cozza, & Watanabe, 1997; Kishi et al., 2007). A recent study of an adult, acute hospital population found that only 63.6% of patients with delirium were recognized by nursing staff to be confused or delirious, whereas 43.6% had confusion documented in the medical case notes (Ryan et al., 2013). The authors concluded that “even if some

Table 41.8 SUBSYNDROMAL DELIRIUM AND CLINICAL OUTCOMES

recognized, but undocumented, delirium cases occurred, these findings suggest that delirium is not a high diagnostic and therapeutic priority, despite its treatability and relevance to outcomes, especially for poorer prognosis in the elderly” (Ryan et al., 2013).

Factors contributing to the poor detection rate of delirium can be divided into three large components, which have significant interplay (Table 41.9):

1. *Patient factors* (e.g., older subjects, patients experiencing comorbid dementia, fluctuating course of presentation, presence of hypoactive features) (Liptzin & Levkoff, 1992; Inouye et al., 1993; Farrell & Ganzini, 1995; Inouye, 1999; Inouye et al., 2001; Pisani et al., 2003; Peterson et al., 2006; Kiely et al., 2007; Lowery et al., 2007; McAlpine et al., 2008; Meagher et al., 2008; Givens, Jones, & Inouye, 2009; Leonard et al., 2009; Collins, Blanchard, Tookman, & Sampson, 2010; Khurana et al., 2011; Srinonprasert et al., 2011; Morandi, McCurley, et al., 2012; Steis & Fick, 2012; Ryan et al., 2013);
2. *Clinician/practitioner factors* (e.g., lack of knowledge and training, lack of confidence, lack of suspicion, lack of time of the clinical staff, expectation that altered mental status
3. *Systems factors* (e.g., lack of consensus over the optimal assessment of delirium, location of care [worse in surgical than in medical settings], busy clinical settings [especially low nurse-to-patient ratio], inadequate application of “sedation holidays” in sedated-ventilated patients, and the rapid transfer of patients from one unit to another, which may decrease the proper documentation and diagnosis) (Inouye, 1991, 1998; Inouye, Schlesinger, & Lydon, 1999; Shinn & Maldonado, 2000; Inouye et al., 2001; Pisani, Redlich, McNicoll, Ely, & Inouye, 2003; (Pisani, Redlich et al. 2003) Siddiqi & House, 2006; Bickel et al., 2008; Davis & MacLulich, 2009; Collins et al., 2010; NICE, 2010; Wong et al., 2010; Boot, 2012; Brummel, Morandi, et al., 2012; Neto, Nassar, et al., 2012; Steis et al., 2012).

Table 41.9 FACTORS CONTRIBUTING TO THE POOR DETECTION RATE OF DELIRIUM

PATIENT FACTORS	CLINICIAN/PRACTITIONER FACTORS	SYSTEMS FACTORS
<ul style="list-style-type: none"> • Older subjects • Patients experiencing comorbid dementia • Fluctuating course of presentation • Presence of hypoactive features 	<ul style="list-style-type: none"> • Lack of knowledge and training • Lack of confidence • Lack of suspicion • Lack of time of the clinical staff • Expectation that altered mental status or delirium are a “normal occurrence” in certain medical settings, such as the ICU 	<ul style="list-style-type: none"> • Lack of consensus over the optimal assessment of delirium • Location of care (worse in surgical rather than medical settings) • Busy clinical settings (especially low nurse-to-patient ratio) • Inadequate application of sedation holidays in sedated-ventilated patients • The rapid transfer of patients from one unit to another, which may decrease the proper documentation and diagnosis

In order to accurately diagnose delirium, clinicians need to be vigilant and have a high level of suspicion, particularly in patient populations at higher risk, such as the elderly and those with the risk factors included in the mnemonic “end acute brain failure” (see Table 41.2).

To date, the diagnostic gold standard for delirium remains the *Diagnostic and Statistical Manual for Mental Disorders* (DSM). The previously published version was the Fourth Edition-Text Revised, published in 1994 (DSM-IV-TR; APA, 1994). A new DSM-5 (5th Edition) has changed the criteria slightly. The new DSM criteria change the diagnostic focus away from a “disturbance of consciousness” (DSM-IV) to a “disturbance in attention”—Criterion A. Criterion B relates to the acute or subacute onset of symptoms (to differentiate from more chronic cognitive deficits such as dementia; formerly Criterion C). New Criterion C refers to additional disturbances in cognition not better explained by another neurocognitive disorder (akin to former Criterion B in DSM-IV). New to DSM-5 is Criterion D, which stipulates that A and B “do not occur in the context of severely reduced level of arousal or coma.” And, finally, Criterion E is identical to Criterion D in DSM-IV, which stipulates that there is physical evidence that can give an organic etiology for the syndrome. Notice that DSM-5 seems to have got rid of the presence of psychotic symptomatology (formerly Criterion B in DSM-IV) as part of the diagnostic criteria.

The *International Statistical Classification of Diseases and Related Health Problems* (ICD-10; see Box 41.3) provides its own diagnostic criteria (WHO, 1992, 2010). Yet, both criteria have at their core the same three cardinal features: disturbance of consciousness (i.e., reduced clarity of awareness of the environment, with reduced ability to focus, sustain, or shift attention); global disturbance of cognition (e.g., problem-solving impairment or memory impairment) and/or perceptual disturbance (e.g., illusions or hallucinations); and an acute or subacute onset with a tendency to fluctuate (WHO, 2010; APA, 2013). These criteria are commonly used by medical personnel for the definite diagnosis of delirium. There are numerous clinically available instruments (see Box 41.4) developed to help medical providers screen for the presence of delirium. These instruments were designed to help nonpsychiatrists (e.g., nurses, internists, and research assistants) diagnose and follow the progression of delirium (Trzepacz, Baker, & Greenhouse, 1988; Marcantonio et al., 1994). All of these scales have been derived from, and validated against, expert psychiatric assessments using DSM or ICD diagnostic criteria. Some of these tools were designed and are better used for the purpose of screening for delirium (e.g., CAM, based on DSM-III-R, original sample size $n = 56$ [Inouye et al., 1990], CAM-ICU, based on CAM, original sample size $n = 38$ [Ely et al., 2001]). The CAM and CAM-ICU offer a binary result (i.e., delirium or no delirium), and there is no severity scale. Unfortunately, these tools have a high false-positive rate (as high as 10%); therefore, the team that developed the instrument recommends that all patients identified as delirious by screening instruments “have further evaluation to confirm the diagnosis” (Inouye et al., 1990; Liptzin & Levkoff, 1992). In fact, some have expressed

Box 41.4 OBJECTIVE MEASURES FOR THE DIAGNOSIS OF DELIRIUM

- DSM-IV-TR (“Gold Standard”; APA, 1994)
- Delirium Rating Scale (DRS) (Trzepacz, Baker, et al., 1988)
- Confusion Rating Scale (CRS) (Williams, Ward, et al., 1988)
- Confusion Assessment Method (CAM) (Inouye et al., 1990)
- Delirium Symptom Interview (DSI) (Albert et al., 1992)
- Delirium Assessment Scale (DAS) (O’Keeffe, 1994)
- Cognitive Test for Delirium (CTD) (Hart et al., 1996)
- NEECHAM Confusion Scale (Neelon & Champagne, 1996)
- Confusional State Evaluation (CSE) (Robertsson, Karlsson, et al., 1997)
- Memorial Delirium Assessment Scale (MDAS) (Breitbart et al., 1997)
- Delirium Severity Scale (DSS) (Bettin, Maletta, et al., 1998)
- Delirium Index (DI) (McCusker, Cole, et al., 1998)
- Delirium Rating Scale–Revised-98 (DRS-R-98) (Trzepacz et al., 2001)
- Intensive Care Delirium Screening Checklist (ICDSC) (Bergeron et al., 2001)
- Confusion Assessment Method for the Intensive Care unit (CAM-ICU) (Ely, Margolin, et al., 2001)
- Delirium Detection Score (DDS) (Otter, Martin, et al., 2005)
- Nursing Delirium Screening Scale (Nu-DESC) (Gaudreau et al., 2005a)
- Delirium Detection Tool–Provisional (DDT-pro) (Kean, Trzepacz, et al., 2010)
- *Diagnostic and Statistical Manual of Mental Disorders, 5th Edition* (DSM-5) (“New Gold Standard”) (APA, 2013)

concerns regarding the generalizability of the CAM-ICU findings (Young & Arseven, 2010; Boot, 2012):

On closer scrutiny of the methodology of CAM-ICU studies, it is important to highlight some considerations when interpreting the data: (1) three of the studies examined were conducted by the tool’s author who may have had a vested interest, and given that only 39% of the study population were intubated, it is difficult to conclude CAM-ICU’s validity in intubated patients (van Eijk, van Marum, et al., 2009); (2) the study population sizes were relatively small, thus CAM-ICU adaptability into different health-care organizations remains unclear (Page, Navarange, et al., 2009); (3) examination of the exclusion criteria (e.g., history of psychosis, learning disabilities,

depression, dementia) of these studies raises questions to CAM-ICU transferability to these populations, especially as these conditions can have similar characteristics but very different treatment pathways; (4) studies have demonstrated although CAM-ICU has high validity in the non-intubated ICU patients, it seems to fail to detect milder, subtler symptoms of hypoactive delirium; (5) individuals with a history

of mental illness (e.g., psychosis, learning disabilities, depression, dementia) were excluded, despite reports indicating delirium being of a medical cause (Boot, 2012, p.187))

In fact, a prospective study was used to assess the diagnostic validity of the CAM administered at the bedside by nurses in daily practice during a 5-month period to all patients ($n = 258$) consecutively admitted to an acute geriatric ward of a university hospital (Lemiengre, Nelis, et al., 2006). The CAM as administered by bedside nurses had a 66.7% sensitivity and a 90.7% specificity. The study suggested that bedside nurses had difficulties with the identification of elderly patients with delirium and that additional education about delirium is warranted, with special attention to guided training of bedside nurses in the use of an assessment strategy such as the CAM for the recognition of delirium symptoms.

A subsequent study compared the diagnostic accuracy of “delirium experts who diagnosed delirium in 75/181 subjects vs. the CAM-ICU as performed in ‘routine practice’” (i.e., nonresearch setting, conducted by a nonresearch nurse), where delirium was diagnosed in 35 out of 181 cases. This yielded a sensitivity of 47% (95% CI = 35%–58%), specificity of 98% (95% CI = 93%–100%), positive predictive value of 95% (95% CI = 80%–99%), and negative predictive value of 72% (95% CI = 64%–79%). This suggested that the “specificity of the CAM-ICU as performed in routine, daily practice appears to be high but sensitivity low. The low sensitivity hampers early detection of delirium by the CAM-ICU” (Van Eijk et al., 2011).

Moreover, a recent systematic review and meta-analysis of studies on delirium in critically ill patients (i.e., intensive care units, surgical wards, emergency rooms) published between 1966 and 2011 (including 16 studies, $n = 1,523$; and covering five delirium screening tools) demonstrated that the CAM-ICU was the most specific bedside tool for the assessment of delirium in critically ill patients (Neto et al., 2012). Considering only the two most commonly used tools, the pooled sensitivities and specificities of the CAM-ICU for detection of delirium were 75.5% and 95.8%, compared to the ICDSC at 80.1% and 74.6%, respectively. All but one study was performed in a research setting, and that study suggested that, with routine use of the CAM-ICU, half of the patients with delirium were not detected. The authors concluded that “the low sensitivity of the CAM-ICU in routine, daily practice may limit its use as a screening test” (Neto et al., 2012).

Other scales have been designed to diagnose and assess the severity of a delirium episode. These include the Delirium Rating Scale (DRS), based on DSM-III, original sample size $n = 20$ (Trzepacz et al., 1988); the DRS-98, based on DSM-IV, original sample size $n = 68$ (Trzepacz, Mittal, et al., 2001); the Memorial Delirium Assessment Scale (MDAS), based on DSM-IV, original sample size $n = 68$ (Breitbart et al., 1997); and the Intensive Care Delirium Screening Checklist (ICDSC), based on DSM-IV, original sample size $n = 93$ (Bergeron et al., 2001), among others. (Please see Box 41.4 for a comprehensive list of delirium diagnostic tools.) A significant advantage of diagnostic tools that measure delirium

Box 41.5 PRIMITIVE REFLEXES

Primitive reflexes are clinical features that indicate brain dysfunction but that cannot be precisely localized or lateralized. When present, these signs suggest cortical disease, especially frontal cortex, resulting in disinhibition of usually extinguished or suppressed primitive reflexes. Their clinical significance is uncertain and is difficult to correlate with psychiatric illnesses and other behavior disorders, including delirium.

- *Glabella Reflex*: With the examiner's fingers outside of patient's visual field, tap the glabella region at a rate of one tap per second. A pathological response is either absence of blink, no habituation, or a shower of blinks. Normal response = blinking to the first few taps with rapid habituation.
- *Rooting Reflex*: Tested by stroking the corner of the patient's lips and drawing away. Pursing of the lips and movement of the lips or head toward the stroking is a positive response.
- *Snout Reflex*: Elicited by tapping the patient's upper lip with finger or percussion hammer causing the lips to purse and the mouth to pout.
- *Suck Reflex*: Tested by placing your knuckles between the patient's lips. A positive response would be puckering of the lips.
- *Grasp Reflex*: Elicited by stroking the patient's palm toward fingers or crosswise while the patient is distracted, causing the patient's hand to grasp the examiner's fingers.
- *Palmomental Reflex*: Test by scratching the base of the patient's thumb (noxious stimulus of thenar eminence). A positive response occurs when the ipsilateral lower lip and jaw move slightly downward, and does not extinguish with repeated stimulation.
- *Babinski Sign*: Downward (flexor response) movement of the great toe in response to plantar stimulation.
- *Adventitious Motor Overflow*: Seen as the examiner tests one hand for sequential finger movements, and the fingers of the other hand wiggle or tap. Also if there are choreiform movements.
- *Double Simultaneous Stimulation Discrimination*: Tested with the patient's eyes closed. The examiner simultaneously brushes a finger against one of the patient's cheeks and another finger against one of the patient's hands, asking the patient where he has been touched.

severity is that they provide clinicians a means to measure the severity of the episode and determine whether the condition seems to be worsening or improving (i.e., consecutive measures). A severity score is also useful in research studies, as particular interventions may not be able to fully prevent delirium but may lessen the severity of the episode. Finally, severity scales may provide the ability to diagnose subsyndromal delirium (i.e., patients presenting with mental status changes that do not rise to the level of full DSM or ICD diagnostic criteria). Clinical experience and accumulating research data seem to indicate that the presence of subsyndromal symptoms may have similarly negative effects in the patients who are experiencing them. A study of ICU patients demonstrated that patients experiencing subsyndromal delirium experienced significantly greater ICU mortality (10.6% vs. 2.4%), longer ICU stays (5.2 days vs. 2.5 days), and longer total hospital stays (40.9 days vs. 31.7 days) compared to patients experiencing similar medical illness but without delirium (Ouimet et al., 2007). As expected, these subsyndromal patients experienced less ICU mortality (10.6% vs. 15.9%), shorter ICU stays (5.2 days vs. 10.8 days), but longer total hospital stays (40.9 days vs. 36.4 days) compared to patients experiencing similar medical illness but with full clinical delirium (see Table 41.8).

In general, no delirium screening or assessment tool is expected to be perfect. Some have criticized the fact that even the two psychometrically valid scales most commonly used in the ICU (i.e., CAM-ICU, ICDSC) have detection ranges of delirium from 10% to >80%, in similar populations. It may very well be that vigilance and close clinical monitoring are more useful than any commonly used tool. In fact, some authors have reported that the CAM-ICU scoring may be affected by sedation, thus limiting its diagnostic accuracy (Kress, 2010). A study of “real-life” conditions (as opposed to a research setting) suggested that “the CAM-ICU in daily practice showed not quite as good test characteristics as presented in the original validation studies” (van Eijk et al., 2011). In fact, these authors found that “after stratification according to type of delirium, sensitivity of the CAM-ICU was lowest in the hypoactive subgroup (31%; 95% CI, 17%–48%); highest in the hyperactive delirious patients (100%; 95% CI, 56%–100%); and intermediate in the mixed-type patients (53%; 95% CI, 35%–74%); exhibiting particularly poor test characteristics in neurocritical care patients (sensitivity 17%; 95% CI, 1%–64%) (van Eijk et al., 2011). A recent study suggested that clinical assessments by critical care physicians may identify delirium more rapidly and more accurately than screening tool assessments (Bigatello et al., 2013).

It is unclear what the new DSM-5 diagnostic criteria will mean to the diagnostic accuracy of existing tools. It is likely that some of them may require revisions, yet all will need to be validated taking the new criteria into consideration. Nonetheless, it may be important for the clinician to be aware that the 2013 American College of Critical Care Medicine (ACCM)/Society of Critical Care Medicine (SCCM) clinical practice guidelines for pain, agitation, and delirium (PAD), based on available evidence, strongly recommend that critically ill patients be routinely monitored for delirium in

the ICU using a validated tool. After their review of available delirium assessment tools, the 2013 PAD guideline group concluded that the Confusion Assessment Method for the ICU (CAM-ICU) and the Intensive Care Delirium Screening Checklist (ICDSC) are the ICU delirium screening tools with the strongest validity and reliability (Davidson, Harvey, Bemis-Dougherty, Smith, & Hopkins, 2013).

The most critical part of the assessment, given the characteristic waxing and waning of this syndrome, is to add to the clinical examination all available clinical information, including interview of the family members and caregivers, nursing and medical staff, and a thorough review of the chart for behaviors exhibited during the preceding 24 hours. Another potential clue of the presence of delirium may come from a thorough neurological examination. In our clinical experience, patients with delirium tend to exhibit a reemergence of primitive signs (see Box 41.5). This appears to be more consistent in cases of hypoactive delirium. The relationship between poor cognitive status and primitive reflexes has been described in patients suffering from HIV-related cognitive disorders (Tremont-Lukats, Teixeira, et al., 1999) and in cases of dementia (Paulson, 1977). One study described the presence of primitive reflexes in post-cardiotomy patients suffering from postoperative neuropsychiatric complications (Liu & Hsieh, 1993). A second study found that 55% of patients exhibiting at least two primitive reflexes and 80% of those exhibiting at least three primitive reflexes in the postoperative period developed delirium (Nicolson, Chabon, et al., 2011). Further studies are needed to determine whether an assessment for the presence of primitive reflexes may add to the diagnostic accuracy for delirium or at least assist in the characterization of delirium type, and whether such assessment has any prognostic value.

Some have advocated the use of the electroencephalogram (EEG) as a way to identify and diagnose delirium. Engel and Romano were the first to describe the relationship between delirium and the diffuse slowing and progressive disorganization of rhythm seen in the EEG (Engel, Webb, & Ferris, 1945) (Engel, Webb et al. 1945). The most common EEG findings in delirium include slowing of peak and average frequencies, and decreased alpha activity but increased theta and delta waves. Studies suggest that EEG changes correlate with the degree of cognitive deficit, but there does not appear to be a relationship between EEG patterns and delirium motoric type (Romano & Engel, 1944; Engel & Romano, 1959; Koponen, Partanen, et al., 1989; Koponen, Hurri, et al., 1989; Trzepacz, Scabassi, & Van Thiel, 1989; Trzepacz, Leavitt, et al., 1992; Engel & Romano, 2004; Plaschke, Hill, et al., 2007). The clinical usefulness of EEG in the diagnosis of delirium may be constrained by its limited specificity (given that there are many conditions and medications that may affect the EEG) and the practicality of conducting the test (particularly in the case of agitated and combative patients). Still, the EEG can be useful in differentiating delirium from other psychiatric and neurological conditions such as catatonic states, seizure activity (e.g., nonconvulsive status), medication side effects (e.g., posterior reversible encephalopathy syndrome due to the use of calcineurin inhibitors), or the manifestations of

the behavioral and psychological symptoms associated with dementia (BPSD). BPSD affects between 50% and 90% of patients suffering from dementia and is usually characterized by three main syndromes: agitation/aggression, psychosis, and an affective component. At times, apathy (as in the case of hypoactive delirium) or disinhibition (as in the case of hyperactive delirium) can be seen, particularly when there is frontal lobe involvement (Finkel, Costa e Silva, et al., 1996).

Finally, a 24-hour accelerometer-based activity monitor has been used to categorize the motoric behavior of patients with delirium. The continuous wavelet transform (CWT) provided by the instrument can then be used to characterize a delirium as hyperactive, hypoactive, or mixed (Godfrey, Conway, et al., 2009, 2010; Meagher, 2009). The technique has yet to find a clinical use, however.

MANAGEMENT OF DELIRIUM

ADEQUATE MEDICAL MANAGEMENT

The management of delirium has five main components (see Box 41.6):

1. Recognition of patients at risk (see Tables 41.1 and 41.2);
2. Implementation of prevention techniques (with pharmacological and nonpharmacological approaches), especially in populations identified to be at high risk;
3. Enhanced surveillance and screening;

Box 41.6 ALGORITHM FOR THE MANAGEMENT OF DELIRIUM

- I. Recognition of patients at risk
 - A. A particular patient's odds of developing delirium are associated with the interaction between the following conditions:
 - i. Knowledge of a patient's characteristics.
 - ii. Predisposing and precipitating medical risk factors (Table 41.4).
 - iii. Modifiable and non-modifiable risk factors for that particular patient or patient population (Table 41.5).
 - iv. Specific medical conditions and surgical procedures the patient is exposed to.
 - B. Obtaining the patient's baseline level of cognitive functioning using information from accessory sources (e.g., Informant Questionnaire on Cognitive Decline in the Elderly [IQCODE]).
- II. Implementation of prevention techniques
 - A. A key focus should be placed on prevention strategies, particularly in "at risk" populations.
 - i. Avoid all pharmacological agents with high deliriogenic potential or anticholinergic load, if possible.
 - ii. Promote a non-pharmacological sleep protocol.
 - iii. Early mobilization.
 - B. For patients in the ICU, especially those on ventilation or IV sedation, consider:
 - i. Sedating to a prescribed or target sedation level (e.g., RASS).
 - ii. Consider using the sedative agent with lowest deliriogenic potential:
 - Dexmedetomidine use is associated with the lowest incidence of delirium.
 - Propofol use is a good second choice; followed by midazolam.
 - iii. Reassess pain levels daily and titrate opioid agents to the lowest effective level required to maintain adequate analgesia.
 - Hydromorphone is preferred as baseline agent of choice for pain management.
 - Limit the use of fentanyl to rapid initiation of analgesia and as rescue agent.
 - Avoid the use of opioid agents for sedation or management of agitation or delirium.
 - iv. Provide daily sedation holidays:
 - Interrupt sedative infusions daily until the patient is awake
 - Restart sedation, if needed, at the lowest effective dose
 - Reassess target sedation level (e.g., RASS).
- III. Enhanced surveillance, screening and early detection
 - A. Most important aspects of surveillance:
 - i. Knowledge about the condition and presenting symptoms.
 - ii. A high level of suspicion.
 - B. Be vigilant for the development of delirium in high-risk groups:
 - i. Use a standardized surveillance tools (e.g., DRS-R-98; MDAS; CAM)
 - ii. Use psychiatric consultants (i.e., DSM-5/ICD-10 criteria)
 - iii. Be particularly aware of the presence of hypoactive delirium and its different manifestations.
 - C. Use psychiatric consultants to help with assessment and design of the treatment plan, if available.
 - D. Train medical personnel at all levels.
- IV. Treatment of all forms of delirium
 - A. Identify and treat underlying medical causes.

(continued)

- B. Treat or correct underlying medical problems and potential reversible factors.
- C. Conduct an inventory of all pharmacological agents that have been administered to the patient.
 - i. Discontinue any medication or agent known to cause delirium or to have high anticholinergic potential, if possible, or institute a suitable alternative.
- D. Implement early mobilization techniques, to include ALL of the following components:
 - i. Daily awakening protocols (sedation holiday), as described above.
 - ii. Remove IV lines, bladder catheters, physical restraints, and any other immobilizing apparatuses as early as possible.
 - iii. Initiate aggressive PT and OT as soon as it is medically safe to do.
 - a. In bedridden patients, therapy may be limited to daily passive range of motion.
 - b. Once medically stable, get the patient up and moving as early as possible.
 - iv. Provide patients with any required sensory aids (i.e., eyeglasses, hearing aids).
 - v. Promote as normal a circadian light rhythm as possible.
 - a. Better if this can be achieved by environmental manipulations, such as light control (i.e., lights on and curtains open during the day; lights off at night) and noise control (i.e., provide ear plugs, turn off TVs, minimize night staff chatter).
 - b. Provide as much natural light as possible during the daytime.
 - vi. Provide adequate intellectual and environmental stimulation as early as possible.
- E. Avoid using GABA-ergic agents to control agitation, if possible.
 - *Exception:* cases of CNS-depressant withdrawal (i.e., alcohol, benzodiazepines, barbiturates); or when more appropriate agents have failed and sedations are needed to prevent patient's harm.
- F. Adequately assess and treat pain.
 - i. Avoid the use of opioid agents for behavioral control of agitation.
 - ii. Rotate opioid agents from morphine to hydromorphone or fentanyl.
- G. For the treatment of delirium (all types), consider using:
 - i. Acetylcholinesterase inhibitor (e.g., rivastigmine) for patients with a history of recurrent delirium or delirium superimposed on known cognitive deficits. Physostigmine, for known causes of anticholinergic delirium.
 - ii. Melatonin (e.g., 3 mg q HS) or melatonin agonists (e.g., ramelteon 8 mg q HS) to promote a more natural sleep. If that is ineffective, consider trazodone (e.g., 25–100 mg q HS) or mirtazapine (e.g., 3.75–7.5 mg q HS).
 - iii. Serotonin antagonist (e.g., ondansetron).
- H. In case of *hyperactive delirium*, consider the use of the following agents:
 - i. Dopamine antagonist agents (to address DA excess) (e.g., haloperidol, risperidone, quetiapine, aripiprazole).
 - a. Moderate-dose haloperidol (e.g., <20 mg/24 hr in divided doses), is still considered the treatment of choice, if the patient's cardiac condition allows it.
 - b. Before using haloperidol:
 - Obtain 12-lead ECG; measure QTc.
 - Check electrolytes; correct K⁺ and Mg⁺, if needed.
 - Carefully review the patient's medication list and identify any other agents with the ability to prolong QTc.
 - If possible, avoid other medications known to increase QTc and/or inhibitors of CYP3A4.
 - c. When the use of haloperidol is contraindicated or not desirable, atypical antipsychotics should be considered:
 - There is better evidence for risperidone and quetiapine.
 - ii. Limited data for: olanzapine, aripiprazole, perospirone.
 - Avoid: clozapine, ziprasidone.
 - d. Discontinue dopamine antagonist agents' use if QTc increases to >25% of baseline or >500 msec.
 - ii. Alpha-2 agonist agents (to address the NE excess) (e.g., dexmedetomidine, clonidine, guanfacine)
 - a. Consider changing primary sedative agents from GABA-ergic agents (e.g., propofol or midazolam) to an alpha-2 agent (e.g., dexmedetomidine), starting at 0.4 mcg/kg/hr, then titrate dose every 20 minutes to targeted RASS goal.
 - iii. Anticonvulsant and other agents with glutamate antagonism or Ca⁺ Ch modulation (e.g., VPA, gabapentin, amantadine, memantine).
- I. Consider the use of NMDA-receptor blocking agents, to minimize glutamate-induced neuronal injury (e.g., amantadine, memantine), particularly in cases of TBI and CVA.
- J. G. In case of *hypoactive delirium*:
 - i. Evidence suggests that DA antagonists may still have a place, given the excess DA theory.
 - a. If haloperidol is used, recommended doses are in the very low range (i.e., 0.25–1.0 mg/24 hr). This is usually given as a single nighttime dose, just before sundown.
 - b. If an atypical is preferred, consider an agent with low sedation (i.e., risperidone, aripiprazole).
 - ii. In cases of extreme psychomotor retardation or catatonic features, in the absence of agitation or psychosis, consider the use of psychostimulant agents (e.g., methylphenidate, dextroamphetamine, modafinil) or conventional dopamine agonists (e.g., bromocriptine, amantadine, memantine).

4. Treatment or correction of underlying medical problems and potentially reversible factors (e.g., correction of electrolyte imbalances, infection, end organ failure, sleep deprivation, pain, metabolic and endocrinological disturbances, substance or medication intoxication or withdrawal); and
5. Treatment of all forms of delirium (with pharmacological and nonpharmacological approaches).

We advocate an integrative approach that incorporates input and collaboration among all pertinent medical teams, including psychosomatic medicine, critical care, internal medicine, surgery, neurology, nursing, respiratory therapy, physical therapy, and occupational therapy teams, which we like to call the “CNS pharmacotherapy algorithm” (see Figure 41.22) (Maldonado, 2008a, 2011, 2014). The idea is to optimize patient comfort (i.e., adequate sedation), minimize pain (i.e., adequate analgesia), prevent or treat delirium, restore an adequate sleep–wake pattern, begin physical mobilization as early as possible, improve cognitive recovery, and return to baseline functional level as soon as medically possible. Others

have found psychiatric consultations to be superior to a multidisciplinary geriatric team approach in treating individuals with depression and delirium (Cole, Fenton, et al., 1991).

The recognition of patients at risk begins with knowledge of your patient’s characteristics; an assessment of the predisposing and precipitating medical risk factors to which your patient is, or may be, exposed (Table 41.2); and being acquainted with the modifiable and nonmodifiable risk factors for that particular patient or patient population (Table 41.3). Finally, certain medical conditions and surgical procedures are more likely to be associated with the development of delirium than others. It is likely that a particular patient’s odds of developing delirium are associated with the interactions among these conditions. These have been discussed in detail elsewhere (Maldonado, 2008a, 2014).

Prevention techniques have been found to be rather effective, especially when targeted to patients at high risk for developing delirium. There is a whole host of pharmacological and nonpharmacological techniques available. It is important that providers carefully consider the potential side effects versus the benefits associated with effective delirium prevention.

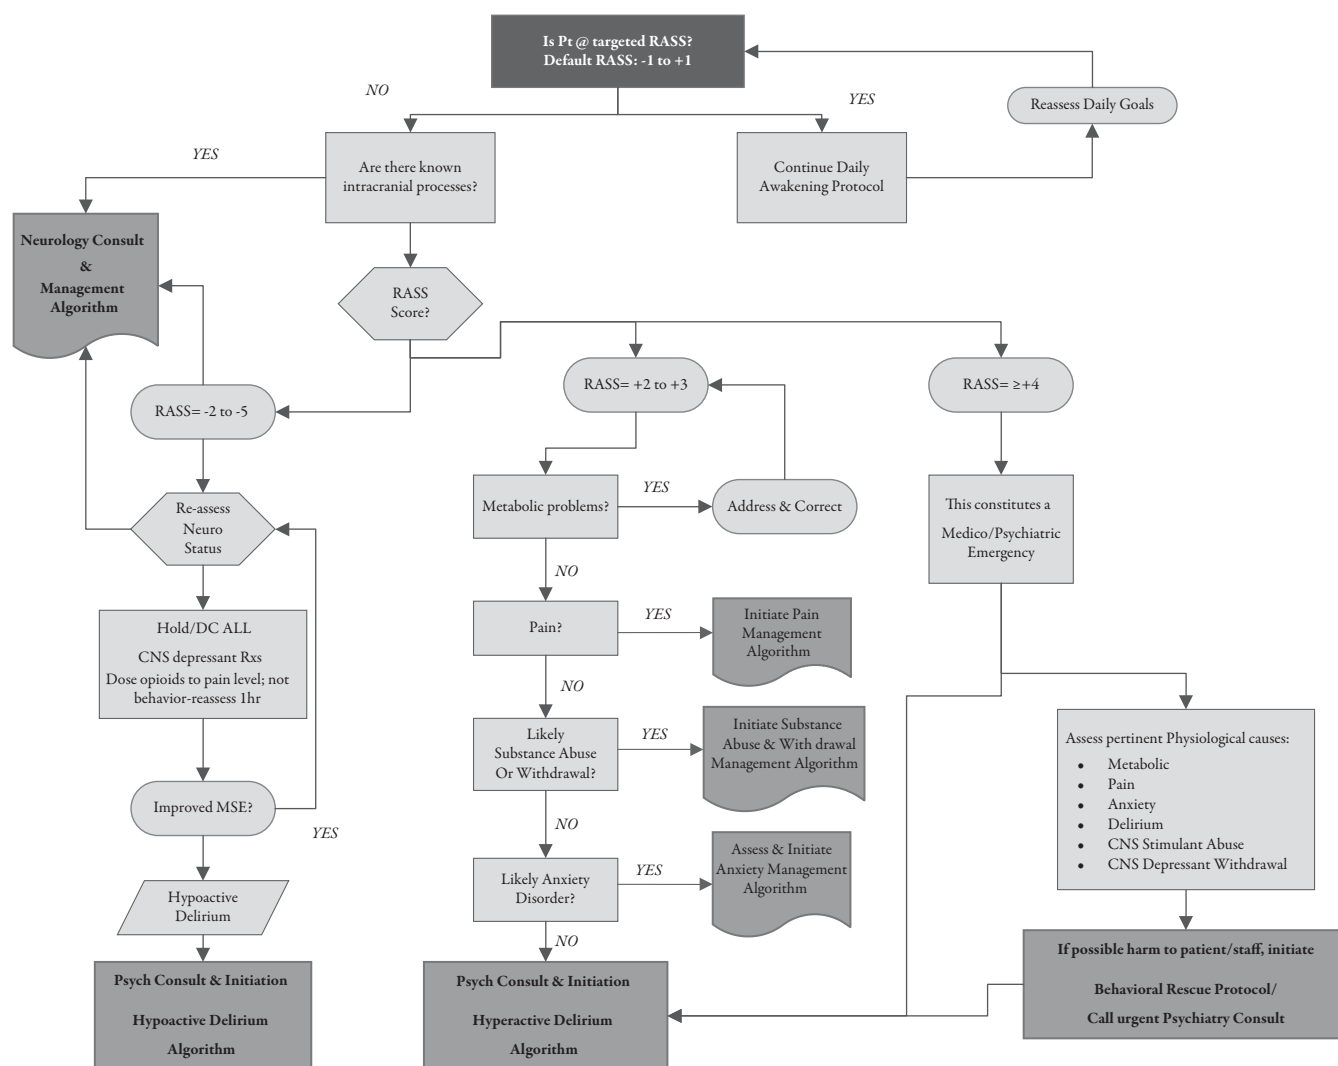

Figure 41.22 CNS Pharmacotherapy Model. (Adapted from Maldonado, 2008a, 2011, 2014)

The early recognition and prompt treatment of delirium is of utmost importance, not only because of issues of safety for patient and staff, but also because of the serious negative consequences of no treatment or delayed treatment. In fact, a recent study demonstrated that patients whose delirium treatment was delayed were more frequently mechanically ventilated (50.0% vs. 22.3%; $p = 0.012$), had more nosocomial infections (including pneumonia) ($p < 0.05$), and had a higher mortality rate ($p < 0.001$) (see Figure 41.23) than patients whose treatment was promptly started (Heymann et al., 2010). These data suggest that a delay in initiating delirium therapy may be associated with increased morbidity and mortality.

The most important aspects of adequate surveillance and early detection include knowledge about the condition and presenting symptoms (of all motor forms) and maintaining a high level of suspicion, especially in populations at risk. There are several surveillance tools and techniques (discussed earlier in this chapter) that can be used to efficiently screen subjects, especially those at greatest risk. Adequate training of medical personnel at all levels is paramount. Surveillance should be effectively implemented by all practitioners.

Once diagnosed, adequate management of delirium includes the following steps:

1. Management of the behavioral and psychiatric manifestations and symptoms to prevent the patient from self-harm or harming of others (e.g., use of tranquilizing agents to manage agitation);

Figure 41.23 Survival Estimates for Delirious ICU Patients with Immediate or Delayed Delirium Treatment. Kaplan-Meier survival estimates for 184 ICU patients with delirium treated within 24 hours of diagnosis (immediate therapy group) and 20 patients in whom delirium treatment started > 24 hours after diagnosis (delayed therapy group); the delayed therapy group showed a lower probability of surviving until ICU discharge than the immediate therapy group (vertical markers show censorship points). There was a significantly higher risk of death in the delayed therapy group versus the immediate therapy group (log rank test, $P < 0.001$; Breslow test, $P = 0.013$). (Heymann et al., 2010)

2. Treatment or correction of underlying medical problems and potentially reversible factors (e.g., correction of electrolyte imbalances, infection, end organ failure, sleep deprivation, pain, metabolic and endocrinological disturbances, substance or medication intoxication or withdrawal); and
3. Correction of the neurochemical derangement (triggered by the underlying cause) which leads to the behavioral manifestations of delirium (see Table 41.7).

NONPHARMACOLOGICAL MANAGEMENT STRATEGIES

Nineteen studies have been published on nonpharmacological prevention strategy in the non-ICU environment (see Table 41.10). The original study suggesting that nonpharmacological approaches may be of use was a nonrandomized clinical trial, where hospitalized elderly patients were assessed for manifestations of delirium in response to the correction of environmental factors commonly associated with increased risk for delirium (Inouye et al., 1999). The multicomponent protocol consisted of simple techniques applied by the hospital staff, including reorientation, appropriate cognitive stimulation three times a day, the implementation of a nonpharmacological sleep protocol to help normalize patient's sleep-wake cycle, early mobilization after surgery or extubation, timely removal of catheters and restraints, correction of sensory deficiencies (i.e., by eyeglasses and hearing aids), and early correction of dehydration and electrolyte abnormalities. As a result of these environmental manipulations, they observed an astonishing 40% reduction in the risk of delirium (see Figure 41.24). This landmark work was preceded by two negative studies and followed by seven positive and five negative ones. Among the positive studies, there were three positive randomized clinical trials, and these are condensed in Table 41.11. They were all conducted among elderly orthopedic patients, and all found that the implementation of nonpharmacological multicomponent interventions led to a reduction in the occurrence of delirium and fewer medical complications in the intervention groups (Marcantonio, Flacker, 2001; Vidan, Serra, Moreno, Riquelme, & Ortiz, 2005; Lundstrom et al., 2007). Given the findings reported by others, a multicomponent approach has been developed that targets identified, treatable contributing factors and addresses them early on: the Hospital Elder Life Program (Inouye & Charpentier, 1996; Inouye, Bogardus, et al., 1999). This program involves the implementation, by an interdisciplinary team, of targeted interventions for known risk factors (i.e., cognitive impairment, sleep deprivation, immobility, dehydration, vision or hearing impairment) for cognitive decline in the elderly.

More recently, a meta-analysis of published studies has found that, although the multicomponent interventions appeared to be effective in preventing delirium among post-operative hip replacement patients, the intervention made no difference in a number of important secondary measures, including discharge location or post-discharge dependency, length of hospital stay ($p = 0.12$), or mortality rate ($p = 0.77$) between intervention and control groups (Holroyd-Leduc,

Table 41.10 NONPHARMACOLOGICAL PREVENTION STRATEGY STUDIES IN THE NON-ICU ENVIRONMENT

Figure 41.24 A MultiComponent Intervention to Prevent Delirium in Hospitalized Older Patients. (Inouye et al., 1999)

Khandwala, & Sink, 2010). A separate study on the same population and by the same researcher, but this one conducted in a nonresearch environment, found that the intervention had no effect on the overall delirium rate ($p = 0.84$) and no significant difference on secondary measures (i.e., mean length of hospital stay), falls, or discharge to long-term care facilities (Holroyd-Leduc et al., 2010). Finally, a large study ($n = 1,516$) followed patients from admission to death at seven palliative care centers and compared usual care versus a nonpharmacological delirium-preventive intervention. The study found that the multicomponent preventive intervention

had no effect on the primary outcome, overall delirium incidence ($p = 0.66$); and, similarly, it had no effect on secondary outcomes of delirium severity, total delirious days, or duration of the first delirium episode (Gagnon, Allard, Gagnon, Merette, & Tardif, 2012).

Finally, a study examined the administration of nonprofessional, family-provided multicomponent intervention among high-risk elderly patients admitted to a medicine ward (Martinez, Tobar, Beddings, Vallejo, & Fuentes, 2012). The intervention consisted of educating family members about the clinical features and prognostic implications of delirium, plus the usual content of the traditional multicomponent intervention, but fully administered by family members. They found a significant reduction in the occurrence of delirium in the intervention group ($p = 0.027$). It is unclear why the multicomponent protocol yielded no results when implemented by the nursing staff in a “real world” scenario, but a possible explanation is that the average medicosurgical unit may not have the same nurse-to-patient ratio as research units, making the implementation of the protocol challenging. Therefore, an approach that combines the best of all available protocols and that takes into consideration available resources and limitations of each clinical setting may work best.

Of significance, a study of mechanically ventilated, critically ill patients used a combination of early physical and occupational therapy during periods of daily interruption of sedation to demonstrate a significantly greater return to independent functional status ($p = 0.02$), shorter duration of delirium ($p = 0.02$), and more ventilator-free days ($p = 0.05$) (Schweickert

Table 41.11 SELECTED NONPHARMACOLOGICAL RCT-PREVENTION INTERVENTION STUDIES

STUDY AUTHORS; TYPE; SIZE	STUDY DETAILS	FINDINGS
Marcantonio et al., 2001 RCT, $n = 126$	Studied the effectiveness of proactive geriatric consultation compared to usual care in reducing delirium in patients 65 and older admitted emergently for surgical repair of hip fracture.	While there were not statistical differences between intervention and control groups regarding baseline measures and characteristics, the study found a reduction in the occurrence of delirium in the intervention group (32%) compared to usual care (50%) ($P = 0.04$). There was an even greater reduction in cases of “severe delirium,” occurring in 12% of intervention patients and 29% of usual-care patients. Despite this reduction in delirium, length of stay did not significantly differ between intervention and usual care.
Vidan et al., 2005 RCT, $n = 319$	Studied patients were randomly assigned to daily multidisciplinary geriatric intervention or usual care during hospitalization in the acute phase of hip fracture.	The study showed that intervention subjects experienced shorter hospital stay (median length 16 vs. 18 days) ($P = 0.06$); lower in-hospital mortality (0.6% vs. 5.8%, $P = 0.03$) and lower rate of major medical complications (45.2% vs. 61.7%, $P = 0.003$). Overall, after adjustment for confounding variables, the geriatric intervention was associated with a 45% lower probability of death or major complications. More patients in the geriatric intervention group achieved a partial recovery at 3 months (57% vs. 44%, $P = 0.03$), but there were no difference between groups at 6 and 12 months assessments.
Lundström et al., 2007 RCT, $n = 199$	Studied randomly assigned elderly patients after femoral neck fracture repair to postoperative care in a specialized geriatric ward (i.e., staff education focusing on the assessment, prevention, and treatment of delirium and associated complications) or a conventional orthopedic ward.	Patients in the intervention group experience less postoperative delirium (54.9% vs. 75.3%, $p = 0.003$); those who did experience delirium did so for a shorter duration compared with controls (5.0 ± 7.1 days vs. 10.2 ± 13.3 days, $p = 0.009$). Patients in the intervention group suffered from fewer complications (e.g., decubitus ulcers, urinary tract infections, nutritional complications, sleeping problems, and falls) and shorter hospital stays (28.0 ± 17.9 days vs. 38.0 ± 40.6 days, $p = 0.028$).

et al., 2009). This is the first randomized, nonpharmacological intervention study shown to reduce ICU delirium. Others have found similar results (i.e., lower total amount benzodiazepine use, higher level of functional mobility, and reduction in delirium rates) by combining sedation reduction and early mobilization with physical rehabilitation (Needham & Korupolu, 2010). It is likely that the minimization of offending agents (e.g., sedatives), along with early mobility, may have something to do with the decreased rate of delirium among this cohort. Previously, I have suggested an approach that incorporates nonpharmacological and pharmacological approaches to the prevention and treatment of delirium, which is summarized in Box 41.6 but expanded elsewhere (Maldonado, 2008a, 2009, 2011). Given the significant adverse consequences of delirium, the primary goal should be prevention, particularly in populations at high risk. Key among them is minimizing the detrimental effects of prolonged and uninterrupted sedation. Therefore, we recommend that sedation be targeted to a predetermined goal using sedation scales such as the Richmond Agitation Sedation Scale (RASS; see Sessler, et al., 2002). As previously noted, daily awakening and sedation holidays are highly recommended. These will allow patients to awaken; then, if still needed, sedation should be restarted at the lowest needed level—again targeting a predetermined sedation level. Certain sedative agents are preferred to others, given pharmacological and pharmacodynamic qualities; and some appear to have less delirigenic potential than others (Maldonado, van der Starre, Wysong, & Block, 2004; Pandharipande, Pun et al., 2007; Maldonado, 2008a, 2009, 2011; Riker et al., 2009). Therefore, dexmedetomidine may be the preferred choice when clinically indicated and tolerated, followed by propofol, and last by midazolam. Similarly, some analgesic agents may be better at preventing or controlling delirium. For example, despite its faster onset of action, fentanyl's clearance is much slower than hydromorphone; thus it tends to accumulate, and this may be problematic (see Figure 41.25). Therefore, we prefer the use of hydromorphone as the baseline agent of choice for pain management and sedation supplementation and limit the use of fentanyl for rapid initiation of analgesia and as a rescue agent.

More recently, a randomized study suggested that not using sedation, compared to the standard treatment with sedation and a daily wake-up trial, may further reduce the

time patients require mechanical ventilation, shorten the length of the patient's stay in the intensive care unit, and decrease the overall hospital length of stay (Strom & Toft, 2011), thus providing further evidence that the use of sedative drugs should be reduced. Patients should be mobilized as early as possible, and individual patient sedative needs should be evaluated on a daily basis to minimize the untoward effects of these agents and optimize the care of each individual patient.

Given the high rate of underdiagnosed and missed cases, the routine use of assessment scales or diagnostic interviews by properly trained personnel will facilitate timely treatment and prevention of complications of delirium. Early involvement of a medical-psychiatric team is valuable for both prevention and early intervention. An active search for possible etiologies of delirium must first rule out the common causes of the syndrome (see Table 41.2). This must include a review of all medications and identification, and possible discontinuation of agents with high deliriogenic potential (see Table 41.4). Appropriate diagnostic tests and assays should be ordered and reviewed in a timely fashion and all abnormal findings addressed accordingly.

Conduct an inventory of all pharmacological agents that have been administered to the patient. Any medication or agent known to cause delirium (see Table 41.4) or to have high anticholinergic potential (see Table 41.5) should be discontinued if possible; if not, a suitable less anticholinergic alternative should be substituted.

Immobilizing lines and devices (e.g., chest tubes, IV lines, bladder catheters) should be removed as early as possible. Similarly, physical restraints should be avoided and eliminated as soon as it is safe to do. More importantly, early mobilization (e.g., daily interruption of sedation, minimization of restraint use, early physical and occupational therapy) has proven to be a key factor in minimizing delirium and improving the odds of returning to independent functioning upon discharge home (Schweickert et al., 2009).

Early correction of sensory deficits should be undertaken. That is, eyeglasses and hearing aids should be replaced or fitted (if the patient was not using them before the hospitalization) as soon as possible. This will allow patients to familiarize themselves with the environment and reorient themselves early on. It will also minimize the occurrence of misperceptions or misinterpretation of environmental cues and stimuli. Environmental isolation should be minimized if possible. Family members and loved ones should be encouraged to visit and provide a familiar and friendly environment, as well as provide appropriate orientation and stimulation to patients, especially those with baseline cognitive deficits. Dehydration and electrolyte abnormalities should be corrected as quickly and safely as possible. Malnutrition should be corrected, unless the patient is end-stage and their delirium is a pre-terminal phenomenon. In that situation, the decision to use a feeding tube, for example, would be a personal decision that different patients and families would make differently.

For intubated, sedated ICU patients, the approach must include judicious management of sedative and pain

Figure 41.25 Minutes to 50% decrement in plasma concentration of commonly used opioid agents.

management agents in order to allow for early extubation, minimize time in bed, and limit the amount of potentially deliriogenic agents a patient is exposed to. Daily cessation of sedative protocols combined with daily spontaneous breathing trials and early mobilization (through physical and occupational therapy) have resulted in a significant decrease in the duration of mechanical ventilation, the length of stay in intensive care, and the number of days patients experienced acute brain dysfunction, compared with control groups (Kress, Pohlman, O'Connor, & Hall, 2000; Kress et al., 2003; Girard et al., 2008; Schweickert et al., 2009; Needham, Korupolu, et al., 2010).

Finally, environmental manipulations to normalize the sleep–wake cycle may be considered, from reducing noise levels and decreasing nighttime tests and procedures to increasing the amount of natural light during daytime hours. Early correction of sleep disturbance, preferably by nonpharmacological means, should be attempted.

Some have advocated the use of bright light therapy (similar to that used for the treatment of seasonal affective disorder) as an alternative to medication agents but despite the logic behind this approach, very little evidence for it exists. A small pilot study demonstrated that bright light therapy (5000 lux applied for 2 hours in the morning) led to a significant difference ($P = 0.014$) in the incidence of delirium (Taguchi, Yano, & Kido, 2007). Yet there were serious methodological problems with this study, including a very small sample, lack of blinding, and late initiation of the intervention (after extubation rather than immediately after surgery). A second, larger study ($n = 228$) conducted in a geriatric monitoring unit compared bright light therapy (2000–3000 lux; 6–10 pm daily) against placebo. The study found that among those randomized to bright light therapy, there were significant improvements in modified Barthel Index (MBI) scores, especially for the hyperactive and mixed delirium subtypes ($P < 0.05$); significant improvements on the DRS sleep–wake disturbance subscore, for all delirium subtypes; and improvements in the mean total sleep time (from 6.4 hours to 7.7) ($P < 0.05$) and length of first sleep bout (SB; 6.0 compared with 5.3 hours) ($P < 0.05$), with decreased mean number of SBs and awakenings when compared to those in the placebo group (Chong, Tan, Tay, Wong, & Ancoli-Israel, 2013).

The National Institute for Health and Clinical Excellence (NICE) provided a set of guidelines containing 13 specific recommendations for the prevention of delirium in elderly at-risk patients (O'Mahony, Murthy et al., 2011). They are mostly based on the correction of modifiable factors that may precipitate delirium, and the implementation of the multi-component intervention package. The full version of these recommendations can be found at their website: <http://guidance.nice.org.uk/CG103/Guidance/pdf/English>. Similarly, the Society of Critical Care Medicine has developed pain, agitation, and delirium guidelines, promoted mobility to improve care of critically ill patients, and has developed tools to facilitate and rapidly implement the translation of guideline care recommendations into practice (Davidson et al., 2013).

PHARMACOLOGICAL MANAGEMENT STRATEGIES

It cannot be overstated that the “definitive treatment” of delirium is the accurate identification and treatment of its underlying cause(s). Nevertheless, pharmacological intervention with various psychoactive agents is often needed to help manage agitated patients and for the correction of the neurotransmitter derangements associated with delirium symptoms. Of note, no pharmacological agent has received Food and Drug Administration (FDA) approval for the treatment of delirium.

In an attempt to “first, do no harm,” we should first identify all agents that may contribute to, exacerbate, or perpetuate delirium. Chief among these are anticholinergic substances and GABA-ergic agents (Box 41.2). As described above, all such agents (e.g., benzodiazepines, propofol) may cause or aggravate delirium and its behavioral manifestations (Marcantonio et al., 1994; Ely et al., 2001; Pandharipande, Shintani, et al., 2006). The use of benzodiazepines in the management of delirium should be limited to (a) patients experiencing delirium related to the withdrawal from a CNS-depressant agent (e.g., alcohol, barbiturates, benzodiazepines), or (b) when other more appropriate agents have failed and the level of agitation and need for behavioral control outweighs the potentially detrimental effects of benzodiazepines. Following the same principle, we should avoid the use of opioid agents for behavioral control of agitated patients and use these agents only for pain management, as opioids have been implicated in the development of delirium in many patient populations (Morrison et al., 2003; Centeno, Sanz, & Bruera, 2004; Morita et al., 2005; Fong et al., 2006; Vaurio et al., 2006; Gaudreau et al., 2007; Vella-Brincat & Macleod, 2007; Wang et al., 2007). A summary of a comprehensive delirium management algorithm can be found in Figure 41.26.

Pharmacological management strategies have mostly been limited to the use of antipsychotic agents, acetyl cholinesterase inhibitors, and sedative-hypnotic agents. In this section, I will address possible pharmacological interventions based on the neurotransmitter being targeted. In general, delirious patients have an excess of dopamine, norepinephrine, glutamate, and hyperactivity of calcium channels (Ca^{+} Ch); reduced levels of acetylcholine and melatonin; and variable levels of serotonin, histamine, and gamma-aminobutyric acid, depending on the type and cause of delirium. We will tailor the discussion regarding pharmacological prophylaxis and treatment based on these assumptions. Studies will be discussed in order of publication. In the only published set of guidelines for sedation management of critically ill adults, the Society of Critical Care Medicine recommended haloperidol as “the preferred agent for the treatment of delirium in critically ill patients” (Jacobi, Fraser, et al., 2002). Accordingly, haloperidol is used by about 78%–80% of intensivists as the standard pharmacological agent to manage delirium in the ICU, while novel agents, the second-generation antipsychotics, are gaining popularity for delirium management, are now being used by 35%–40% of ICU physicians (Patel, Gambrell, et al., 2009; MacSweeney, Barber, et al., 2010). A more recent

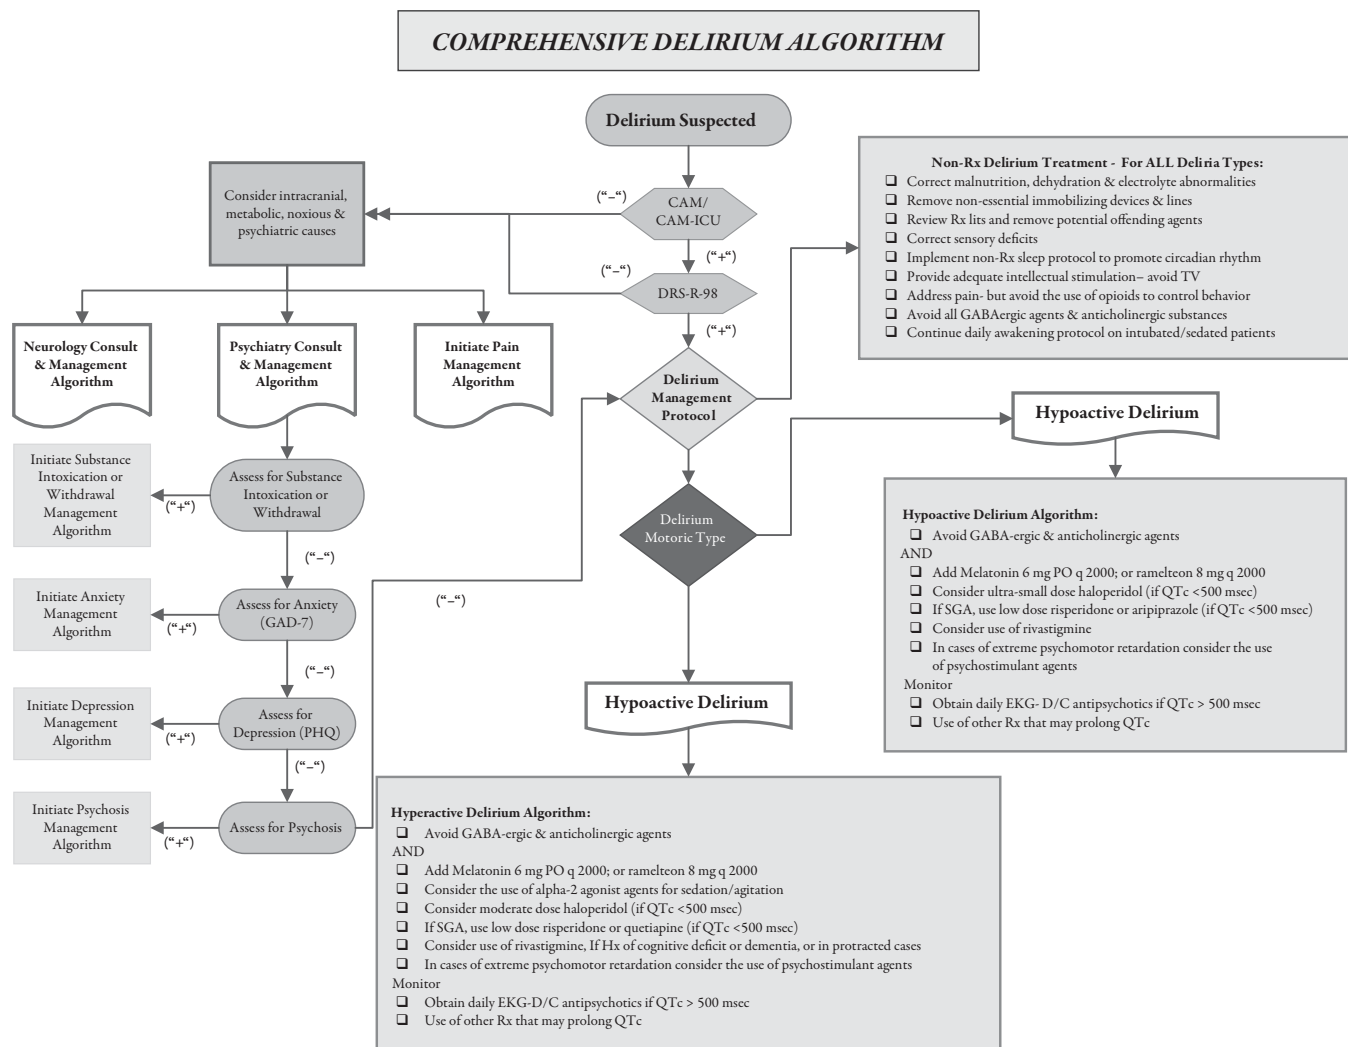

Figure 41.26 Comprehensive Delirium Algorithm. Source: (Maldonado, 2008a, 2011)

“post-publication perspective” of practice guidelines added no new information about pharmacological agents for the management of delirium in the ICU, but emphasized the benefits of early detection and patient mobilization. It is important to point out that soon after the publication of these perspectives a number of significant studies were published, all conclusively demonstrating the delirium-prophylactic benefits of antipsychotic agents in at-risk populations, which will be discussed in the next section.

Of note, no pharmacological agent has received FDA approval for the prevention of delirium.

Dopamine Excess

Dopamine Antagonists for Delirium Prevention

There are very few control studies on the efficacy of antipsychotic agents for the prevention of delirium, yet most studies suggest a positive effect (see Table 41.12). The first randomized controlled trial compared haloperidol to placebo in at-risk, elderly orthopedic patients (Kaneko, Jianhui, et al., 1999). The incidence of delirium was significantly lower in

the treatment group (10.5% vs. 32.5%; $p < .05$). Similarly, the intensity and duration of postoperative delirium were more severe and lasted longer in the control group.

The first double-blind, randomized, placebo control studies (DBRPCT) compared haloperidol to placebo, also in at-risk elderly orthopedic patients (Kalisvaart, de Jonghe, et al., 2005). Subjects received oral haloperidol 0.5 mg/d up to 72 hours preoperatively and then until the third postoperative day. The study found that prophylactic haloperidol use did not alter the incidence of postoperative delirium when compared with placebo (15.1 vs. 16.5%; $p = ns$). Nevertheless, it did have a positive effect on the severity (the mean highest DRS-R-98 score \pm SD was 14.4 ± 3.4 vs. 18.4 ± 4.3 ; $P < .001$) and duration (5.4 vs. 11.8 days; $P < .001$) of delirium and shortened the length of hospital stay (mean number of days in the hospital was 17.1 ± 11.1 vs. 22.6 ± 16.7 ; $P < .001$).

Many additional studies have followed, all with positive findings. A study of patients undergoing cardiac surgery with cardiopulmonary bypass (CPB), randomly assigned to receive either 1 mg of risperidone or placebo sublingually as soon as they regained consciousness postoperatively,

Abbreviations: RPCT=randomized placebo control trial; GI=gastrointestinal; PBO=placebo; DBRPCT=double blind randomized, placebo controlled trial; DSM=Diagnostic and Statistical Manual of Mental Disorders; CAM= Confusion Assessment Method; DRS=Delirium Rating Scale; Sx=surgery; CPB=cardio-pulmonary by-pass machine; ICU=intensive care unit. APA=antipsychotic agent; OLA=olanzapine; HAL=haloperidol; RIS=risperidone

demonstrated a significantly lower incidence of postoperative delirium in the risperidone group (11.1% vs. 31.7%; $P = 0.009$) (Prakanrattana & Prapaitrakool, 2007). A study examined the effects of olanzapine pretreatment (5 mg Zydis[®] formulation administered just preoperatively, and again 5 mg administered immediately after surgery upon awakening) to placebo in elderly subjects undergoing orthopedic joint-replacement surgery. The incidence of delirium in the intervention group was significantly lower in the study group compared to placebo (15% vs. 41%; $P < 0.0001$) (Larsen, 2007).

A large ($n = 457$; ages ≥ 65) postoperative delirium prevention study compared the efficacy and safety of low-dose IV-haloperidol (i.e., 0.5 mg intravenous bolus injection, followed by continuous infusion at a rate of 0.1 mg/hr for 12 hrs vs. placebo) vs. placebo in critically ill patients after noncardiac surgery. The study found the incidence of delirium during the first 7 days after surgery was 15.3% in the haloperidol group vs. 23.2% in the control group ($p = .031$). Other measures also appeared significantly improved: the mean time to onset of delirium and the mean number of delirium-free days were significantly longer (6.2 days [95% CI 5.9–6.4] vs. 5.7 days [95% CI 5.4–6.0]; $p = .021$; and 6.8 ± 0.5 days vs. 6.7 ± 0.8 days; $p = .027$, respectively); the median length of ICU stay was significantly shorter (21.3 hrs [95% CI, 20.3–22.2] vs. 23.0 hrs [95% CI, 20.9–25.1]; $p = .024$) in the haloperidol group than in the control group. There was no significant difference with regard to all-cause 28-day mortality between the two groups (0.9% [2/229] vs. 2.6% [6/228]; $p = .175$). No drug-related side effects were documented (Wang et al., 2012).

Finally, a study assessed the efficacy of haloperidol prophylaxis against delirium in “at risk” ICU patients ($n = 177$) (van den Boogaard, Schoonhoven, van Achterberg, van der Hoeven, & Pickkers, 2013). The results of the intervention were compared to a historical control group and a contemporary group that did not receive haloperidol prophylaxis, mainly due to noncompliance to the protocol, mostly during the implementation phase. The protocol consisted of low-dose haloperidol infusion (i.e., IV-haloperidol 1 mg/8 hr (or a lower dose, for patients ≥ 80 years), started as soon as patients were identified to be at increased risk, within the 24-hour period after ICU admission. All patients experiencing delirium received therapeutic doses of haloperidol according to the unit’s customary protocol. Patient characteristics were comparable between the prevention and the control groups; with the exception of prophylactic haloperidol, as per study protocol. The intervention resulted in a lower delirium incidence (65% vs. 75%, $p = .01$), more delirium-free days (median, 20 days [interquartile range 8 to 27] vs. median 13 days [3 to 27], $p = .003$), fewer ICU readmissions (11% vs. 18%, $p = .03$), and less frequent unplanned removal of tubes/lines (12% vs., 19%, $p = .02$) in the intervention group compared to the control group. Beneficial effects of haloperidol appeared most pronounced in the patients with the highest risk for delirium. Haloperidol was stopped in 12 patients because of QTc-time prolongation ($n = 9$), renal failure ($n = 1$) or suspected neurological side-effects ($n = 2$). No other side effects

were reported, including *torsades de point* (TdP) (van den Boogaard et al., 2013).

Two meta-analyses of studies using dopamine antagonist agents for delirium prophylaxis found that pooled relative risk of published studies suggested a 50% reduction in the relative risk of delirium among those receiving antipsychotic medication compared with placebo ($p < 0.01$). The studies suggest that perioperative use of prophylactic dopamine antagonist agents (both typical and second-generation antipsychotics), compared to placebo, may effectively reduce the overall risk of postoperative delirium, thereby potentially reducing mortality, disease burden, length of hospital stay, and associated healthcare costs (Hirota & Kishi, 2013; Teslyar, Stock, et al., 2013). A third meta-analysis, including all postoperative prevention strategies, found that both typical (3 RCTs; $n = 965$; RR = 0.71; 95% CI = 0.54–0.93) and atypical antipsychotics (3 RCTs; $n = 627$; RR = 0.36; 95% CI = 0.26–0.50) decreased delirium occurrence, compared to placebos (Zhang et al., 2013).

Dopamine Antagonists for Delirium Treatment

The literature has long recognized that intravenous neuroleptic agents are the recommended emergency treatment for agitated and mixed type delirium (Adams, Fernandez, & Andersson, 1986; Fernandez, Holmes, Adams, & Kavanaugh, 1988; Sanders, Murray, & Cassem, 1991; Ziehm, 1991; Riker, Fraser, & Cox, 1994; Inouye et al., 1999). Intravenous administration of haloperidol has always been thought superior to oral administration because the IV route has more reliable absorption, even in cases of systemic organ failure. Intravenous haloperidol use has the added advantage of requiring no patient cooperation, thus facilitating its use even in uncooperative and agitated patients. Studies suggest that the IV use of high-potency neuroleptic agents is associated with minimal effects on blood pressure, respiration, and heart rate (Ayd, 1978; Tesar, Murray, & Cassem, 1985; Adams, 1988; Sanders et al., 1991; Riker et al., 1994; Stern, 1994; Segatore & Adams, 2001). And, some have suggested that haloperidol has a lower incidence of extrapyramidal symptoms when administered IV versus orally (7.2% vs. 22.6%; $p < 0.01$) (see Figure 41.27) (Sanders, Minnema, & Murray, 1989; Maldonado & Kang, 2003).

Intravenous haloperidol has been identified as the agent of choice for the management of delirious critically ill patients by a

Figure 41.27 Haloperidol Route of Administration and Incidence of EPS. Rate of extrapyramidal symptoms and their association to mode of administration for haloperidol. (Maldonado, 2003)

number of national organizations, including Britain's National Institute for Health and Clinical Excellence (NICE, 2010) the American Psychiatric Association (APA, 1999, 2004) and the Society of Critical Care Medicine (Shapiro et al., 1995; Jacobi et al., 2002). Since then, a "best evidence topic in cardiac surgery" was written according to a structured protocol, addressing the issue of haloperidol safety for critically ill patients (Khasati, Thompson, & Dunning, 2004). Their search included 294 papers and concluded that haloperidol should be considered the first-line drug for agitated patients following cardiac surgery. Of note, in September of 2007, the FDA issued a "black-box" warning for the off-label clinical practice of using IV-haloperidol (FDA, 2007). It is important to remember that haloperidol has never been approved by the FDA for IV use.

Other antipsychotic agents have been studied for the treatment of delirium. Most of these include atypical or second-generation antipsychotic (SGA) agents. Because of the stigma and potential side effects associated with typical antipsychotics, SGAs have been used at increasing rates

over the last few years for the management of psychiatric and behavioral symptoms (e.g., agitation, psychosis, delirium) in medically ill patients. Large studies, particularly head-to-head comparisons between SGAs and more conventional agents (i.e., haloperidol), are lacking; therefore, most clinical practice is derived from case reports and open-label (OL) studies. Following are summaries of the only seven RCTs available; all others are summarized in Table 41.13.

The first study was a DBRCT that compared haloperidol (average dose 1.4 mg/d) vs. chlorpromazine (average dose 36.0 mg/d) versus lorazepam (avg. dose 4.6 mg/d) among HIV/AIDS patients (Breitbart et al., 1996). Results showed that treatment with either haloperidol or chlorpromazine in relatively low doses resulted in significant improvement in the symptoms of delirium, while no improvement was found in the lorazepam group. Treatment with either neuroleptic was associated with an extremely low prevalence of extrapyramidal side effects; all patients receiving lorazepam, however, developed treatment-limiting adverse effects.

Table 41.13 DOPAMINE ANTAGONIST—ANTIPSYCHOTIC AGENTS AS TREATMENT OF DELIRIUM

STUDY(N = 32)	POPULATION	INTERVENTION	DELIRIUM DEFINITION/ MEASURE OF RESPONSE	RESULTS
Breitbart et al., 1996; DBRCT, <i>n</i> = 30	AIDS, medical patients	Haloperidol vs. chlorpromazine vs. lorazepam	DSM-III-R/DRS	Tx either HAL or CPM resulted in significant improvement in the symptoms of delirium, while no improvement was found in the LOR group. Tx neuroleptic was associated with an extremely low prevalence of EPS, while all patients receiving LOR developed treatment-limiting adverse effects.
Sipahimalani & Masand, 1998; OL, <i>n</i> = 22	Med/Surg patients	Haloperidol vs. olanzapine	DRS	Improvement was similar in both groups (mean DRS +SD H = 11.1 ± 7.1; O = 10.3 ± 4.8; <i>P</i> = 0.760), with extrapyramidal symptoms found only in haloperidol patients. No side effects in olanzapine group.
Schwartz et al., 2000; Single-blind; <i>n</i> = 11	Med/Surg patients	Quetiapine vs. haloperidol— retrospective chart review	DRS	Effectiveness of 350% in reducing DRS scores. When compared with haloperidol, there was no difference in onset of symptom resolution, duration of treatment, and overall clinical improvement.
Kim et al., 2001; OL, <i>n</i> = 20	Med/Surg patients	Olanzapine PO, variable dose	DSM-IV/DRS	50% decrease in Delirium Rating Scale scores (from pre of 20.0 ± 3.6, to post of 9.3 ± 4.6; <i>P</i> < 0.01). No side effects, including EPS.
Breitbart et al., 2002; OL, <i>n</i> = 79	Hospitalized cancer patients	Olanzapine PO, variable dose	DSM-IV/MDAS	Olanzapine was effective in treating 76% of delirium patients as evidenced by the MDAS; caused excessive sedation in 30% of patients.
Horikawa et al., 2003; OL, <i>n</i> = 10	Med/Surg patients	Risperidone PO	DSM-IV/DRS	At a low dose of 1.7 mg/d, on average, risperidone was effective in 80% of patients, and the effect appeared within a few days. Most commonly cited adverse effects included sleepiness (30%) and mild drug-induced Parkinsonism (10%).

Table 41.13 (CONTINUED)

STUDY (N = 32)	POPULATION	INTERVENTION	DELIRIUM DEFINITION/ MEASURE OF RESPONSE	RESULTS
Sasaki et al., 2003; OL, <i>n</i> = 12	Med/Surg patients	Quetiapine PO, flexible doses	DSM-IV/DRS	100% of patients on quetiapine achieved resolution of delirium (mean on day 4.8 ± 3.5 days); no EPS reported.
Kim et al., 2003; OL, <i>n</i> = 12	Elderly medical inpatients	Quetiapine PO, flexible doses	DSM-IV/DRS	100% of patients on quetiapine achieved resolution of delirium by day 10 (mean on day 5.9 ± 2.2 days); no EPS reported. Delirium Rating Scale scores along with scores of the Mini-Mental State Examination and Clock Drawing Test continued to improve throughout the 3-month study period.
Liu et al., 2004; retrospective record review, <i>n</i> = 77	Med/Surg patients with hyperactive delirium	Risperidone (average dose 1.17 ± 0.76 mg/d) vs. haloperidol (avg. dose 4.25 ± 2.62 mg/d)	DSM-IV/various	Patients treated with haloperidol were younger than patients treated with risperidone ($P < 0.05$). The mean hyperactive syndrome scale score was higher in the haloperidol than that of the risperidone group. The authors found no significant difference in the efficacy or frequency of response rate between haloperidol and risperidone (100% vs. 95%; $p = ns$). Patients on risperidone experienced less EPS (7% vs. 69%).
Mittal et al., 2004; OL, <i>n</i> = 10	Patients admitted to Med-Surg unit	Risperidone, 0.5 mg PO BID, flexible PRNs	DSM-IV/DRS	Rapid resolution of delirium while receiving low dose risperidone (mean dose 0.75 mg/d); no EPS reported.
Parellada, Baeza, et al., 2004; OL	Prospective, multicenter, observational 7-day study	Risperidone PO	DSM-IV/ DRS PANSS-P MMSE	Risperidone was administered at the time of diagnosis, and treatment was maintained according to clinical response. Found a significant decrease in DRS scores in 90.6% of treated patients and significantly improved all symptoms measured by the scales from baseline to day 7 ($p < 0.0$); only 3% side effects.
Pae, Lee, et al., 2004 OL, <i>n</i> = 22	Med/Surg patients	Quetiapine PO	DRS-R9/ CGI8	DRS-R-98 and clinical global scores were significantly reduced by 57.3% and 55.1%, respectively. Quetiapine was effective and safe.
Han et al., 2004; DBRCT, <i>n</i> = 28	Med/Surg patients	Haloperidol vs. risperidone, 7 days medication trial	CAM/ DRS MDAS	Both groups showed significant improvement in baseline DRS and MDAS scores with either haloperidol (75%) or risperidone (42%) ($P < 0.05$). There was no significant difference in improvement of DRS ($p = 0.35$) or MDAS ($p = 0.51$) scores, comparing haloperidol with risperidone patients.
Hu et al., 2004; RPCT, <i>n</i> = 175	Med/Surg elderly patients	Haloperidol vs. olanzapine vs. placebo, 7 days medication trial	DRS/ CGI	All groups showed a decrease in DRS scores by 7th day, compared with baseline ($p < 0.01$). Decrease in DRS scores of treated patients at day 7 (OLA 72.2%; HAL 70.4%) differed significantly from DRS scores of PBO patients (29.7%; ($p < 0.01$), but not from each other ($p > 0.05$).

(continued)

Table 41.13 (CONTINUED)

STUDY(N = 32)	POPULATION	INTERVENTION	DELIRIUM DEFINITION/ MEASURE OF RESPONSE	RESULTS
Skrobik et al., 2004; OL-prospective RCT, <i>n</i> = 73	Critically ill Med/ Surg patients	Haloperidol (avg. 6.5 mg/d) vs. olanzapine (avg. 4.5 mg/d)	DIS	ICU Delirium Index Screening Checklist Scores were reduced in both groups, compared with baseline ($p < 0.05$), but there was no significant difference in DIS scores between active Tx groups ($p = 0.9$). EPS were found in 13% of haloperidol patients, but 0% in olanzapine group.
Toda et al., 2005; <i>n</i> = 10	Elderly inpatient general medicine	Risperidone, OL, 0.5 mg oral sol.; flexible titration, PRN	DSM-IV/ DRS	Resolution reported in 7 subjects (mean dose 0.92 ± 0.47 mg/d); 1 non-responder; side effects requiring Tx discontinuation reported in 2.
Lee et al., 2005; RCT, <i>n</i> = 40	Med/Surg patients	Amisulpride vs. quetiapine	DRS-R98/ CGI	After treatment, DRS-R-98 scores were significantly decreased from the baseline in both treatment groups ($P < 0.001$) without group difference. Both atypical antipsychotics were generally well tolerated.
Straker et al., 2006 OL, <i>n</i> = 14	Medically ill patients	Aripiprazole PO was used in a flexible dosing range, from 5 mg/day to 15 mg/ day, titrated as clinically indicated	DSM-IV/ DRS-R98 CGI	50% of patients had improved significantly by day 5, as indicated by a 50% reduction in DRS-R-98 scores. 86% of patients had a 50% reduction in their DRS-R-98 scores by end of treatment. Mean CGI Severity scores at the beginning of treatment were 5.2, with a mean CGI Improvement score after treatment of 2.1, indicating much improvement.
Takeuchi et al., 2007; OL, <i>n</i> = 38	Med/Surg patients	Perospirone, OL	DSM-IV/ DRS-R98	Perospirone was effective in 86.8% of patients, within several days ($5.1 \pm$ 4.9 days). The initial dose was 6.5 ± 3.7 mg/ day and maximum dose of perospirone was 10.0 ± 5.3 mg/day. There were no serious adverse effects.
Maneeton, Maneeton, & Srisurapanont, 2007; OL, <i>n</i> = 17	Medically ill patients	Quetiapine, flexible dosing	CAM/DRS, CGI	88% subjects responded. Means (SDs) dose and duration (SD) of quetiapine treatment were 45.7 (28.7) mg/day and 6.5 (2.0) days, respectively. The DRS and CGI-S scores of days 2–7 were significantly lower than those of day 0 ($p < 0.001$ for all comparisons). Only two subjects were shown to have mild tremor.
Reade et al., 2009; OL-RCT	Med/Surg ICU	Agitated delirium were randomized to receive an infusion of either haloperidol 0.5 to 2 mg/hour or dexmedetomidine 0.2 to 0.7 μ g/kg/hr	ICDSC Time	DEX significantly shortened median time to extubation from 42.5 to 19.9 hours ($P = 0.016$); it significantly decreased ICU length of stay, from 6.5 to 1.5 days ($P = 0.004$); and of patients requiring ongoing sedation, it reduced the time propofol was required in half (79.5% vs. 41.2% ; $P = 0.05$).
Devlin et al., 2010; DBRPCT, <i>n</i> = 36	MICU	PBO vs. quetiapine (50 mg BID) (multienter-3)	ICDSC	Tx w QUE was associated with: a shorter time to first resolution of delirium ($p = .001$), a reduced duration of delirium ($p = .006$), less agitation ($p = .02$), greater chance to be discharged home vs. long-term-care facility ($p = .06$), and lower requirement of as-needed haloperidol ($p = .05$).

(continued)

Table 41.13 (CONTINUED)

STUDY (<i>N</i> = 32)	POPULATION	INTERVENTION	DELIRIUM DEFINITION/ MEASURE OF RESPONSE	RESULTS
Girard et al., 2010; DBRPCT, <i>n</i> = 101	Mechanically ventilated Med/Surg ICU patients	PBO vs. HAL vs. Ziprasidone	CAM-ICU	Patients in the haloperidol group spent a similar number days alive without delirium or coma (14.0 [6.0–18.0] days) as did those on ziprasidone (15.0 [9.1–18.0] days) and PBO groups (12.5 [1.2–17.2] days; <i>p</i> = 0.66).
Kim et al., 2010; SB-RCT, <i>n</i> = 32	Elderly, Med/Surg patients	Risperidone vs. olanzapine	DSM-IV/DRS-r-98	Significant within-group improvements in the DRS-R-98 scores over time were observed at every time point in both treatment groups. The response rates did not differ significantly between the two groups (risperidone group: 64.7%, olanzapine group: 73.3%); and there were no difference in the safety profiles and side effects between groups.
Tahir et al., 2010; DBRCT, <i>n</i> = 42	Med/Surg patients	Quetiapine vs. placebo	DSM-IV/DRS-r-98, CGI	Quetiapine has the potential to more quickly reduce the severity of non-cognitive aspects of delirium. The study was underpowered for treatment comparisons.
Grover et al., 2011; Prospective, single blind, <i>n</i> = 64	Med/Surg patients	Haloperidol (0.25 to 10 mg) vs. olanzapine (1.25 to 20 mg) vs. risperidone (0.25 to 4), flexible dosing	DSM-IV/DRS-r-98	Patient in all three groups experience a significant reduction in DRS-R98 severity scores and a significant improvement in MMSE scores over the period of 6 days; with no difference between the treatment groups. Rate of side effects was also similar.
Boettger et al., 2011; OL, <i>n</i> = 21	Med/Surg patients at Cancer Center	Aripiprazole, flexible dosing	DSM-IV/MDAS	The mean dosage of aripiprazole required was 18.3 mg (range of 5–30) daily at T3. Patients treated for delirium with aripiprazole experienced significant improvement and resolution of delirium, with MDAS scores declining from a mean of 18.0 at baseline (T1) to mean of 10.8 at T2 and a mean of 8.3 at T3. There was a 100% resolution of hypoactive delirium, compared to patients with hyperactive delirium (58.3%).
Hakim et al., 2012; PCRCT	Patients aged 65 yrs. or older who experienced subsyndromal delirium after on-pump cardiac surgery	Randomized using a computer-generated list to receive placebo (<i>n</i> = 50) or 0.5 mg risperidone (<i>n</i> = 51) every 12 hrs by mouth	ICDSC	Seven (13.7%) patients in the risperidone group experienced delirium vs. 17 (34%) in the placebo group (<i>p</i> = 0.031). Competing-risks regression analysis showed that failure to treat subsyndromal delirium with risperidone was an independent risk factor for delirium (<i>p</i> = 0.002). Two (3.9%) patients in the risperidone group experienced extrapyramidal manifestations versus one (2%) in the placebo group (<i>p</i> = 1.0).
Kishi et al., 2012; OL, <i>n</i> = 29	Adult delirious cancer patients	Risperidone given orally once per day (mean dosage, 1.4 ± 1.3 mg/day)	DRS-R98	Entry DRS-R-98 score = 19.8 ± 6.8; 7-d follow-up score = 14.3 ± 7.8, results demonstrate DRS-R98 scores were improved in 79.3% of patients during the study period (<i>p</i> < 0.001); 38% achieved remission (i.e., DRS-R-98 ≤ 10).

(continued)

Table 41.13 (CONTINUED)

STUDY(N = 32)	POPULATION	INTERVENTION	DELIRIUM DEFINITION/ MEASURE OF RESPONSE	RESULTS
Tagarakis et al., 2012; <i>n</i> = 80	Consecutive patients who developed post-op delirium after on-pump heart surgery	Ondansetron IV (8 mg) vs. haloperidol IV (5 mg); patients were evaluated before and 10 min after the injection	Self-developed rating scale: 0–4	Noted a statistically significant improvement in the test score rating after the administration of both ondansetron (from 3.1 to 1.2, percentage improvement 61.29%, <i>p</i> < 0.01) and haloperidol (from 3.1 to 1.3, ± percentage improvement 58.064%, <i>p</i> < 0.01).
Yoon et al., 2013; Observational study; <i>n</i> = 80	Patients with delirium at a tertiary level hospital	Assigned to receive either haloperidol (<i>n</i> = 23), risperidone (<i>n</i> = 21), olanzapine (<i>n</i> = 18), or quetiapine (<i>n</i> = 18)	Korean version of the Delirium Rating Scale–Revised-98 (DRS-K)	Haloperidol, risperidone, olanzapine, and quetiapine were equally efficacious and safe in the treatment of delirium. The treatment response rate was lower in patients over 75 years old than in patients under 75 years old, especially for olanzapine.
Maneeton et al., 2013; DBRCT, <i>n</i> = 52	Medically ill patients with delirium	25–100 mg/day of quetiapine (<i>n</i> = 24) or 0.5–2.0 mg/day of haloperidol (<i>n</i> = 28)	DRS-R-98 and total sleep time	Over the trial period, means (standard deviation) of the DRS-R-98 severity scores were not significantly different between the quetiapine and haloperidol groups (–22.9 [6.9] versus –21.7 [6.7]; <i>P</i> = 0.59). Concluding that low-dose quetiapine and haloperidol may be equally effective and safe for controlling delirium symptoms.

Abbreviations: RPCT=randomized placebo control trial; DBRPCT=double blind randomized, placebo controlled trial; OL=open label; trial; DSM=Diagnostic and Statistical Manual of Mental Disorders; CAM= Confusion Assessment Method; DRS=Delirium Rating Scale; MDAS=Memorial Delirium Assessment Scale; GI=gastrointestinal; PBO=placebo; Sx=surgery; CPB=cardio-pulmonary by-pass machine; ICU=intensive care unit. APA=antipsychotic agent; OLA=olanzapine; HAL=haloperidol; RIS=risperidone; AIDS=autoimmune deficiency syndrome; CPM=chlorpromazine; EPS= extra-pyramidal syndrome; LOR=lorazepam; PO=by mouth.

The second included a head-to-head comparison between haloperidol and an SGA (risperidone), demonstrating that delirium scores decreased significantly over the study period with no significant differences between groups (Han & Kim, 2004). An RPCT 7-day treatment trial compared haloperidol to olanzapine versus placebo among hospitalized elderly subjects, again showing no difference in the rate of improvement of delirium with either active agent, but significantly greater for each than placebo (olanzapine 72.2%; haloperidol 70.4%; placebo 29.7%; *p* < 0.01, against PBO) (Hu, Deng, & Yang, 2004). Another study compared enteral haloperidol (avg. dose 6.5 mg/d) versus olanzapine (avg. dose 4.5 mg/d) in the critical care setting (Skrobik, Bergeron, Dumont, & Gottfried, 2004). Results show that measures of delirium decreased over time in both groups, as did the administered dose of as-needed (PRN) benzodiazepines, with the degree of clinical improvement being similar in both treatment arms.

An RCT comparing the antipsychotics amisulpride versus quetiapine showed that after intervention, DRS-R-98 scores were significantly decreased from the baseline in both treatment groups (*P* < 0.001) without group difference, and that both SGAs were generally well tolerated (Lee, Won, et al., 2005). A study on the use of SGA involved the comparison of quetiapine (50 mg twice daily [BID]) versus placebo in medical ICU patients in three academic centers (Devlin, Roberts, et al., 2010). The study found that treatment with

quetiapine was associated with a shorter time to first resolution of delirium (1.0 vs. 4.5 days; *p* = .001), a reduced duration of delirium (36 vs. 120 hrs.; *p* = .006), less agitation based on the Sedation-Agitation Scale score (6 vs. 36 hrs.; *p* = .02), greater chance to be discharged home versus long-term-care facility (89% vs. 56%; *p* = .06), and lower requirement of PRN haloperidol (3 vs. 4 days; *p* = .05).

The most recent published blinded RCT compared quetiapine (flexible dosing regimen of 25 to 175 mg per day, in divided doses) versus placebo among medico-surgical patients (Tahir et al., 2010). Results indicated the quetiapine group improved more rapidly, 82.7% faster (standard error [S.E.] 37.1%, *P* = .026) than the placebo group, in terms of the DRS-R-98 severity score; and 57.7% faster (S.E. 29.2%, *P* = .048) than the placebo group, in terms of the noncognitive subscale.

A Cochrane Database review compared haloperidol with risperidone, olanzapine, and placebo in the management of delirium and concluded that there was no significant difference between low-dose haloperidol (<3.0 mg per day) and the atypical antipsychotics olanzapine and risperidone (OR 0.63, *p* = 0.25); that low-dose haloperidol did not have a higher incidence of adverse effects than the atypical antipsychotics; and that low-dose haloperidol was effective in decreasing the intensity and duration of delirium in postoperative patients, compared with placebo (Lonergan, Britton, Luxenberg, & Wyller, 2007).

A subsequent meta-analysis on atypical antipsychotic agents for the treatment of delirium found that risperidone was the most thoroughly studied SGA for the management of delirium (Ozbolt, Paniagua, & Kaiser, 2008). Most studies found that risperidone was approximately 80%–85% effective in treating the behavioral disturbances of delirium at doses of 0.5–4.0 mg per day. On the other hand, olanzapine was approximately 70%–76% effective in treating the behavioral manifestations of delirium at doses of 2.5–11.6 mg per day. There were very few studies conducted using quetiapine; although available data suggest that it also appears to be a safe and effective alternative to high-potency antipsychotics. In the limited number of trials comparing SGAs to haloperidol, haloperidol consistently produced a higher rate (an additional 10%–13%) of extrapyramidal side effects.

Finally, there have been two case reports on the use of aripiprazole as an effective treatment of delirium (Alao & Moskowitz, 2006; Straker, Shapiro, & Muskin, 2006); and a retrospective case-matched study of aripiprazole vs. haloperidol that found an identical delirium resolution rate (76.2%) for both agents (Boettger, Friedlander, Breitbart, & Passik, 2011). In addition, there are two single case reports on the use of ziprasidone for the management of delirium (Leso & Schwartz, 2002; Young & Lujan, 2004) and one OL study ($n = 38$) on the use of perospirone, a recently developed atypical antipsychotic with potent serotonin 5-HT₂ and dopamine D₂ antagonist activity (Takeuchi et al., 2007).

A systematic literature review of 28 delirium treatment studies with antipsychotic agents concluded that:

1. Around 75% of delirious patients who receive short-term treatment with low-dose antipsychotics experience clinical response;
2. This response rate appears quite consistent across different patient groups and treatment settings;

3. Evidence does not indicate major differences in response rates between clinical subtypes of delirium; and
4. There are no significant differences in efficacy for haloperidol versus atypical agents (Meagher et al., 2013).

Regarding side-effect incidence, a meta-analysis of all randomized controlled trials in which SGAs have been compared with conventional drugs concluded that of the SGAs, only clozapine was associated with significantly fewer extrapyramidal symptoms (EPS ($p = 0.008$) and higher efficacy than low-potency conventional drugs. A reduced frequency of EPS was noted with olanzapine, which was of borderline significance ($p = 0.07$) (Leucht, Wahlbeck, Hamann, & Kissling, 2003). Another study analyzed the data on neuroleptics acquired in the German multicenter drug surveillance program database (Projekt “Arzneimittelsicherheit in der Psychiatrie”) program from 1993 to 2000 and found that severe adverse drug reactions (ADRs) occurred in 1.1% of the patients (Bender, Grohmann, et al., 2004). In contrast to the results from controlled trials, atypical neuroleptics caused more severe ADRs than did typical neuroleptics. Overall, SGAs were found to be superior in EPS and urological ADRs, but when clozapine is excluded, typicals and SGAs have similar occurrence rates of severe ADRs. Other problems to consider when choosing an alternative agent include the fact that SGAs may be associated with weight gain, dyslipidemia, high blood pressure, and ultimately with cardiovascular disease, diabetes, and metabolic syndrome (Henderson, 2008). Therefore, when considering the use of SGAs, clinicians must consider these factors and weigh potential risks and benefits before prescribing these agents to a critically ill patient. Finally, there have been numerous reports attributing the onset of delirium to the use of SGAs (e.g., clozapine, olanzapine), probably due to their anticholinergic potential (Bender, Grohmann, et al., 2004). But these data are limited to small case reports (see Box 41.7).

Box 41.7 CASE REPORTS LINKING SGA TO DELIRIUM GENERATION

- Case reports implicating risperidone use in causing delirium:
 - Kato et al. (2005), *Psychosomatics*
 - Morikawa and Kishimoto (2002), *Canadian Journal of Psychology*
 - Tavcar and Dernovsek (1998), *Canadian Journal of Psychology*
 - Chen Chen and Cardasis (1996), *American Journal of Psychology*
- Case reports implicating quetiapine use in causing the delirium:
 - Sim, Brunet, and Conacher (2000), *Canadian Journal of Psychology* - Balit et al. (2003), *Annals of Emergency Medicine*
 - Miodownik et al. (2008), *Clinical Neuropharmacology*
- Case reports implicating olanzapine use in causing the delirium:
 - Robinson, Burk, & Raman (2003), *Journal of Postgraduate Medicine*
 - Steil (2003) *Der Nervenarzt*
 - Samuels and Fang (2004), *Journal of Clinical Psychology* - Morita et al. (2004) *Journal of Pain & Symptom Management*
 - Prommer (2005) *Journal of Pain & Symptom Management*
 - Tuglu, Erdogan, & Ebay (2005) *Journal of Korean Medicine*
 - Weizberg et al. (2006) *Clinical Toxicology*
 - Lim, Travino, & Tampi (2006), *Annals of Pharmacotherapy*

Please note that antipsychotic agents should only be used short-term for treating agitation in the cognitively impaired individual. Serious concerns have been raised about the stroke and mortality risk of atypical antipsychotics when administered long-term for the management of agitation in patients with dementia. The dementia antipsychotic withdrawal trial (DART-AD) found that at 12 months, the cumulative probability of survival was similar in the active group and the placebo group (70% versus 77%; $p = ns$) (Ballard, Hanney, et al., 2009). Yet, there was a reduction in survival of the patients who continued to receive antipsychotics (after 12 months) compared with those who received placebo (24-month survival 46% vs. 71%; 36-month survival 30% vs. 59%).

Regarding concerns for QTc prolongation, data from the FDA Division of CardioRenal Drug Products Consultation suggested that all antipsychotic agents lengthen the QTc to varying degrees. They based their conclusions on a study of antipsychotic agents in psychotic subjects with normal baseline ECGs who were titrated to the “highest tolerated dose” of one of six antipsychotic agents (see Table 41.14) (FDA, 2000; Huffman & Stern, 2003). It may be reasonable to assume the doses used may have been substantially lower than the doses used for the treatment of hyperactive delirium. We also need to consider the fact that when these agents are used for the management of delirium, patients often received parenteral formulations (when available) due to noncompliance, and they often experience a number of comorbid medical issues (Huffman & Stern, 2003). When antipsychotic agents are recommended, it is wise to review the patient’s medication list and identify any other agents with the ability to prolong QTc. If possible, avoid other medications known to increase QTc and/or inhibitors of CPY3A4. Before and during the use of continuous antipsychotic management, you should obtain a 12-lead ECG, and measure QTc and electrolytes. All electrolyte abnormalities should be corrected (especially K⁺ and Mg⁺) and the QTc pattern monitored. Recommendations

Table 41.14 EFFECTS OF ORALLY ADMINISTERED ANTIPSYCHOTICS ON THE QTc INTERVAL^a

DRUG	MEAN INCREASE IN QTc (MS)	% OF SUBJECTS WITH > 60 MS INCREASE IN QTc
Thioridazine	35.8	29
Ziprasidone	20.6	21
Quetiapine	14.5	11
Risperidone	10.0	4
Olanzapine	6.4	4
Haloperidol	4.7	4

Data from Huffman JC, Stern TA. (2003). QTc Prolongation and the use of antipsychotics: A case discussion. *Primary Care Companion to the Journal of Clinical Psychiatry*, 5(6), 278–81.

^a Data adapted from the U.S. Food and Drug Administration’s Center for Drug Evaluation and Research, Psychopharmacological Drugs Advisory Committee (FDA, 2000), adapted by Huffman & Stern, 2003.

are to discontinue antipsychotic use if QTc increases to >25% of baseline or >500 msec. Of note, studies suggest that haloperidol may have the lowest ratio of cardiac death among all dopamine-antagonist agents, both typical and atypical (Hatta, Takahashi, et al., 2001; Harrigan, Miceli, et al., 2004).

Our recommended schedule in the case of hyperactive states is to use antipsychotic agents (e.g., haloperidol, risperidone, quetiapine) at one of the following time schedules: “TID” (thrice daily) schedule (0600 hrs, 1000, 2000) or “QID” (four times a day) schedule (0600, 1000, 1600, 2200). The idea is to enhance behavioral control during the daytime and help promote better nighttime rest without causing oversedation. Therefore, daytime doses are significantly lower than the nighttime dose (e.g., a 20 mg/d haloperidol dose will be distributed as 5 mg IV q 0600, 1000, and 1600; plus 10 mg at 2200 hrs).

When treating hypoactive delirium, we recommend doses in the very low range (i.e., haloperidol and risperidone in the 0.25 to 1 mg/24 hr). Data available suggest that the dopamine excess observed in delirious subjects occurs in all cases, even hypoactive forms. The same data demonstrate that antipsychotic use helps prevent and treat all forms of deliria, including the hypoactive type. In these cases, it is usually given as a single nighttime dose, just before sundown. Given their hypoactive state, very sedating agents (e.g., quetiapine, olanzapine) are usually not recommended. In the experience of the author, aripiprazole may prove to be a particularly good choice for hypoactive cases (usually starting at doses as low as 1 mg at bedtime), probably due to its partial dopamine antagonist-agonist properties that may have positive effects on attention, concentration, and sleep–wake cycle reversal in delirium, and its minimal muscarinic and histaminic antagonist activity (thus minimizing adverse cognitive effects). Recent reports seem to support this clinical experience, confirming the usefulness of aripiprazole, particularly in hypoactive delirium (Alao & Moskowitz, 2006; Straker, Shapiro, & Muskin, 2006; Boettger & Breitbart, 2011). Aripiprazole had enjoyed the reputation of being the only SGA not to be associated with QTc-prolongation or TdP, confirmed by both clinical trials data and clinical experience (Gulisano, Cali, et al., 2011; Germano, Italiano, et al., 2014; Li, Luo, et al., 2014; Marder et al., 2003). Yet there are at least two case reports of aripiprazole-induced cardiac arrest due to TdP, when it was used as a single agent (Nelson & Leung, 2013). There is at least one case report of aripiprazole-associated QTc prolongation in a geriatric patient (Hategan & Bourgeois, 2014). Before this, all other cases of QTc prolongation had either been associated with concomitant use of another antipsychotic agent or occurred after an overdose (LoVecchio, Watts, & Winchell, 2005; Nelson & Leung, 2013).

Norepinephrine Excess

α₂-Adrenergic Receptors Agonists versus Conventional Sedative Agents: Effect on Delirium Prevention

There have been several randomized clinical trials looking at anesthetic practice and delirium prevention (see Table 41.15).

Table 41.15 A₂-ADRENERGIC RECEPTORS AGONISTS AND ALTERNATIVE SEDATIVE AGENTS VERSUS CONVENTIONAL ANESTHETICS: EFFECT ON DELIRIUM PREVENTION AND TREATMENT

The earliest study examined epidural versus halothane anesthesia to assess postoperative delirium and found no difference between the two approaches (Berggren et al., 1987). A second study compared the effects of continuous epidural bupivacaine plus fentanyl versus continuous IV fentanyl anesthesia on postoperative delirium, and again found no differences between these approaches (Williams-Russo et al., 1992).

The majority of patients in the ICU, particularly those who are mechanically ventilated, receive some form of sedation to reduce their anxiety, encourage sleep, and increase tolerance of the critical care environment, including multiple IV lines, pain management, endotracheal tubes, and ventilators. Sedative and analgesic drugs are among the most commonly prescribed medications in the ICU (Farina, Levati, & Tognoni, 1981). As discussed, sedative agents (mostly GABA-ergic) and opioids may contribute to the development of delirium by one of six mechanisms: interfering with physiological sleep patterns; interfering with central cholinergic function; increasing compensatory upregulation of NMDA and kainite receptors and Ca^{2+} channels; disrupting the circadian rhythm of melatonin release; disrupting thalamic gating function; and leading to CNS-depressant dependence and withdrawal. Therefore, sedating alternatives have been thought promising in decreasing medication/sedation-induced delirium.

The first study involving ketamine in delirium prevention was a DBRPCT involving children undergoing dental repair in sevoflurane-induced anesthesia (Abu-Shahwan & Chowdary, 2007). The study demonstrated a substantially lower incidence of emergence agitation in the ketamine group compared with placebo (16.6% vs. 34.2%), but no difference in time to meet recovery room discharge criteria between the two groups. A second study compared the effects of IV ketamine versus placebo on postoperative delirium in patients undergoing acute type-A aortic dissection repair, which found a significant reduction in the incidence of delirium in patients in the ketamine group (3% vs. 31%, $p = 0.01$) (Hudetz et al., 2009). Postoperative C-reactive protein concentration was also lower ($p < 0.05$) in the ketamine-treated patients compared with the placebo-treated patients.

In an attempt to demonstrate that different sedative strategies may achieve delirium reduction, the author and his team (Maldonado, 2003) were the first to report on the use of the novel sedative agent dexmedetomidine (DEX) as an alternative to the use of benzodiazepines and related agents (e.g., midazolam [MID], propofol [PRO]) during the postoperative state (Maldonado, 2003; Maldonado et al., 2003, 2004). Post-cardiotomy patients were selected, given the high incidence of delirium in such patients (around 57%) nationwide (Ebert, Walzer, Huth, & Herrmann, 2001). We studied patients ($n = 118$) undergoing cardiac surgery (i.e., repair or replacement) with cardiopulmonary bypass (Maldonado et al., 2009). Intraoperative anesthesia for the surgical procedures was standardized for all subjects in all three studied groups. All procedures were performed via median sternotomy in conjunction with CPB and induction of moderate hypothermia. After successful weaning from CPB, patients were started on one of three randomly assigned, postoperative sedation regimens: DEX (loading dose: $0.4 \mu\text{g}/\text{kg}$, followed by a maintenance drip of $0.2\text{--}0.7 \mu\text{g}/\text{kg}/\text{hour}$), PRO drip ($25\text{--}50 \mu\text{g}/$

kg/minute), or MID drip ($0.5\text{--}2 \text{ mg}/\text{hour}$), all titrated to achieve a target sedation level (i.e., a Ramsay Sedation Score of 3 before extubation and 2 after extubation). Upon arrival at the ICU, a standardized protocol for postoperative care was implemented for all patients. Study results showed there were no significant preoperative or intraoperative differences between treatment groups (e.g., age, sex, American Society of Anesthesiology classification, bypass time, clamp time, or lowest temperature achieved) (see Table 41.16). The only real difference in management between groups was the type of postoperative sedation. Final results demonstrated an incidence of delirium of 3% for patients on DEX, compared to 50% for PRO and 50% for MID ($p < .01$). The absolute risk reduction in the incidence of delirium associated with using DEX was 47% (95% CI 28%–66%) corresponding to a number-to-treat of 2.1 patients (95% CI 1.5–3.6). Similarly, the number of delirious days was also significantly lower in the DEX group compared to PRO and MID (1% vs. 16% vs. 29%, respectively; $p < .001$).

Since then, two DBRPCT have confirmed the original findings and demonstrated the delirium-sparing effects of DEX. The first of these compared DEX with lorazepam (LOR) in the ICU on mechanical ventilation. The study found that DEX-treated patients had more delirium-free days (7 days vs. 3 days, $p = .01$), had a lower prevalence of coma ($p < 0.001$), and spent more time within sedation goals ($p = .04$) than LOR-treated subjects (Pandharipande et al., 2007). Similarly, a second, much larger trial (i.e., 68 ICUs in five countries) compared the incidence of delirium among ICU-ventilated subjects sedated with either DEX or MID and found a lower delirium incidence (54% vs. 76.6%, $p < .001$), shorter intubation time (median time to extubation was 3.7 days DEX vs. 5.6 days MID; $p = .01$), and less tachycardia and hypertension in the DEX-treated group (Riker et al., 2009).

A study assessing the effects of different classes of sedative agents compared variable doses of morphine or dexmedetomidine, with open-label propofol titrated to effect (Shehabi et al., 2009). This study found that the incidence of delirium was comparable between morphine 22 (15.0%) and DEX 13 (8.6%) (95% CI: 0.256–1.099, $p = .088$). Yet DEX-managed patients spent 3 fewer days (2 vs. 5) delirious (95% CI: 1.09–6.67, $p = .0317$), were more likely to be extubated earlier (95% CI: 1.01–1.60, $p = .040$), experienced less systolic hypotension (23% vs. 38.1%, $p = .006$), and required less norepinephrine ($p < 0.001$), than morphine-treated patients.

Finally, a subsequent study assessed the role of clonidine IV ($0.5 \text{ microg}/\text{kg}$ bolus, followed by continuous infusion at $1\text{--}2 \text{ microg}/\text{kg}/\text{hr}$) versus placebo on delirium in post-cardiotomy patients and found no significant difference in the incidence of delirium between groups (33% vs. 40%, $p = 0.705$) (Rubino et al., 2010). Yet, delirium scores were significantly lower in patients treated with clonidine compared to placebo ($P = 0.001$), suggesting that the beneficial effects in delirium prevention previously seen with DEX may extend to all alpha-2 agonists (Rubino et al., 2010).

Despite evidence demonstrating that prophylactic use of DEX in reducing the incidence of delirium and plenty of clinical evidence that it is useful in the management of agitation related to hyperactive delirium, there is no study to

date confirming its potential in the treatment of delirium. A randomized, open-label trial of agitated delirium assigned subjects to receive an infusion of either haloperidol 0.5–2.0 mg/hour or dexmedetomidine 0.2–0.7 µg/kg/hr (Reade et al., 2009). Results found that DEX significantly shortened median time to extubation (from 42.5 to 19.9 hours; *P* = 0.016), significantly decreased ICU length of stay (from 6.5 to 1.5 days; *P* = 0.004), and, in patients requiring ongoing sedation, DEX cut in half the time propofol was needed (79.5% vs. 41.2%; *P* = 0.05). Finally, a recent meta-analysis including all postoperative prevention strategies found that DEX sedation was associated with less delirium compared to sedation produced by other drugs (2 RCTs with 415 patients, pooled RR = 0.39; 95% CI = 0.16–0.95) (Zhang et al., 2013).

The detailed proposed mechanisms for delirium reduction have been described elsewhere (Maldonado, 2008a). They can be summarized in six postulated theories: The first suggests

that DEX has an intrinsic *delirium-sparing effects*, which may be explained by DEX's pharmacological characteristics. The second theory suggests that the reason patients had significantly less delirium in the DEX group was not because of its use per se, but because those patients were not exposed to other sedative agents with much greater delirium potential (e.g., GABA-ergic agents, such as propofol and midazolam, and lower doses of opioid agents). Third, data suggest that the neuroprotective effect of DEX is mediated by activation of the alpha2A adrenergic receptor subtype (Ma et al., 2004). Fourth, it is worth noticing that DEX has been shown to have significant neuroprotective effect, in vivo and in vitro, against glutamate-induced damage via an increased astrocyte expression of BDNF through an extracellular signal-regulated kinase-dependent pathway (Engelhard et al., 2003; Ma et al., 2004; Sato, Kimura, Nishikawa, Tobe, & Masaki, 2010; Degos et al., 2013). Fifth, it is also hypothesized that DEX

increases the expression of active (autophosphorylated) focal adhesion kinase, a non-receptor tyrosine kinase playing a pivotal role in cellular plasticity and survival (Dahmani, Rouelle, Gressens, & Mantz, 2005). The sixth theory involves DEX's unique mechanism for inducing sleep. Data suggest that DEX induces a qualitatively similar pattern of c-Fos expression as seen during normal NREM sleep by acting on endogenous sleep pathways (i.e., a decrease in the locus ceruleus and tuberomammillary nucleus and an increase in the ventrolateral pre-optic nucleus) (Nelson et al., 2003).

It is certainly possible that a combination of any or all of these six mechanisms work together, leading to the results obtained in the above-mentioned studies. It is this author's experience that all centrally acting α_2 -adrenergic receptors agonists are to some extent useful in the management of hyperactive delirium. In fact, our team uses clonidine to help transition patients off IV-DEX with good success (see Table 41.17). We also use clonidine, orally and transdermally, for prevention of alcohol withdrawal, with excellent results. Another α_2 -adrenergic receptor agonist worth considering is guanfacine. This agent is even more α_2/α_1 selective and is available in oral dose form. This makes it an excellent alternative to DEX (which requires an IV drip and a monitored bed) and is less hypotensive than clonidine. Our team has been using this agent, as we have clonidine, both as adjunct treatment of hyperactive delirium and as a primary agent in the prevention and treatment of alcohol withdrawal.

Glutamate Excess

Glutamate Antagonists and Ca+ Channel Modulators for Delirium Management

A number of agents with antiglutamatergic and Ca+ channel blocking qualities are worth considering here: lamotrigine, amantadine, memantine, gabapentin, and valproic acid (VPA) (see Table 41.18).

Both amantadine and memantine have been recognized as having neuroprotective effects, probably mediated by their protection from glutamate-induced exocytosis (by blocking excessive N-methyl-D-aspartic acid receptors without disrupting

physiological synaptic activity, thus preventing excessive calcium influx into neurons—believed to be the key early step in GLU-induced exocytosis); reducing the release of proinflammatory factors from activated microglia; inducing expression of neurotrophic factors, such as glial cell line-derived neurotrophic factor in astroglia; and limiting oxidative injury and dendritic degeneration induced by anticholinesterase neurotoxicity (Giacino & Whyte, 2003; Zaja-Milatovic, Gupta, Aschner, & Milatovic, 2009; Ossola et al., 2011; Kutzing, Luo, & Firestein, 2012). Thus, it makes sense to consider their use in various syndromes associated with excess glutamate and subsequent cognitive decline (e.g., traumatic brain injury, stroke, delirium). In fact, studies have demonstrated that memantine may be effective in reducing the damage induced by acute ischemia/reperfusion (Yigit et al., 2011), while amantadine has been shown to enhance cognitive recovery and minimize delirium after severe TBI in humans (Giacino et al., 2012).

A DBPCRT compared the use of gabapentin as an add-on agent in the treatment of postoperative pain (i.e., spine surgery under general anesthesia) to reduce the occurrence of postoperative delirium (Leung et al., 2006). Subjects received either placebo or gabapentin 900 mg administered orally one to two hours before surgery, and continued once a day for the first 3 postoperative days. Results demonstrated that gabapentin was superior to placebo in reducing delirium occurrence (0% vs. 42%, $p = 0.045$). Even though the study authors attributed this to gabapentin's opioid-sparing effect, they failed to consider gabapentin's true modes of action (i.e., modulation of voltage-sensitive Ca2+ channels, NMDA receptor antagonism, activation of spinal alpha-2 receptors, attenuation of Na+ dependent action potentials) as potential mediators of its deliriolytic effect.

Even though many of us routinely use VPA (either oral or IV) in the management of agitated delirious patients who either are not responsive or cannot tolerate conventional treatment, there is very little literature investigating the effectiveness of this practice. In fact, there are no RCT or even OL studies on the matter. The only published report on the effectiveness of VPA for delirium treatment comes from a report of six cases (Bourgeois, Koike, Simmons, Telles, & Egglestone,

2005). The authors reported that “in all six cases, the use of VPA combined with conventional antidelirium medications resulted in improved control of behavioral symptoms without significant side effects.” In all cases, standard psychotropic medication regimens commonly used for the management of delirium and/or nonspecific agitation in the general hospital setting (i.e., antipsychotics and/or benzodiazepines) had initially been tried with limited success, and in all cases the addition of VPA to the existing regimens resulted in improved clinical response. Daily doses ranged between 0.5 to 2.5 grams in divided doses, without significant side effects and with discernible therapeutic benefits.

Similarly, the Stanford’s Psychosomatic Medicine Research Lab presented a larger case series ($n = 16$) equally demonstrating the usefulness and safety of VPA in the management of agitated/hyperactive delirium, as an add-on to ineffective response to conventional therapy (Sher, Lolak, Miller, & Maldonado, 2013). In this series, the dose ranged between 0.5 to 3.0 grams per day in divided doses. All subjects in this case series improved in their clinical status with eventual resolution of delirium. In the case of intubated patients,

addition of VPA frequently allowed prompt extubation, since agitation and related desaturation were better controlled. No significant side effects were identified in any of the subjects, with the exception of nonclinically significant decreases in the number of platelets in few subjects. Of note, as in the case of SGAs, there have been case reports on VPA-induced delirium. The availability of IV (Depacon) and elixir (Depakene, ideal for administration via feeding tube, if needed) forms allow administration in non-cooperative subjects, or those intubated and unable to take PO medication. The IV formulation even allows for loading to quickly establish therapeutic serum levels, then continuing for maintenance or converting to PO when medically indicated. Others have described the usefulness of VPA in the management of destructive and aggressive behavior associated with brain injury (Wroblewski, Joseph, Kupfer, & Kalliel, 1997) and dementia (Haas, Vincent, Holt, & Lippmann, 1997; Narayan & Nelson, 1997; Tariot, 1999; Porsteinsson, Tariot, et al., 2003; Sival, Duivenvoorden, et al., 2004). As in any patient receiving VPA, close monitoring of liver function tests, bilirubin, platelet count, and amylase are advisable, especially in the critically ill patient.

Cholinergic Deficit

Acetylcholinesterase Inhibitors for Delirium Prevention

Despite the logical premise behind the prophylactic use of acetylcholinesterase inhibitor agents, studies have not consistently demonstrated positive results (see Table 41.19). The first publication suggesting the promise of acetylcholinesterase inhibitors in delirium prevention comes from a study on the use of rivastigmine for delirium prevention among hospitalized elderly patients who had been chronically treated with rivastigmine for dementia (Dautzenberg, Mulder, Olde Rikkert, Wouters, & Loonen, 2004). A retrospective chart review showed that those on rivastigmine had a significantly lower incidence of delirium compared to subjects not treated (45.5% vs. 88.9%; $p < 0.05$). Similarly, a prospective study of elderly subjects suffering from vascular dementia randomly placed patients on either rivastigmine (6 mg/d) or aspirin (100 mg/d) and followed them at regular intervals for 24 months (Moretti, Torre, Antonello, Cattaruzza, & Cazzato, 2004). The results suggested that those on rivastigmine had a substantially lower incidence of delirium compared to aspirin

(40% vs. 62%; $p < 0.001$). Also of significance, when subjects developed delirium, the mean duration of delirium was shorter (mean duration 4 ± 1.71 days vs. 7.86 ± 2.73 days; $p < 0.01$), and the use of benzodiazepine and neuroleptic agents for management of agitation was significantly less in the rivastigmine group ($p < 0.05$). Furthermore, analysis of behavioral data (as measured by Behavioral Pathology in Alzheimer's Disease (BEHAVE-AD) scale), found that total scores in the rivastigmine group were significantly improved over baseline and at the end of the study (all $p < 0.001$). Further sub-analysis of the BEHAVE-AD individual items indicated that rivastigmine provided benefits on all items of the scale, except for delusions, throughout the study.

Unfortunately, the only DBRCT of rivastigmine failed to demonstrate efficacy in the prevention of postoperative delirium. In a study in cardiac surgery patients comparing rivastigmine (1.5 mg/d for 3 days preoperatively) against placebo found no benefits of the active drug use (Gamberini et al., 2009).

Similarly, results have been negative with the use of donepezil. The first study was a DBRPCT involving elderly patients undergoing elective total joint replacement surgery

Table 41.19 ACETYLCHOLINESTERASE INHIBITORS IN DELIRIUM PREVENTION

STUDY (N = 7)	POPULATION	INTERVENTION	DELIRIUM DEFINITION	DELIRIUM INCIDENCE %		
				CONTROL	INTERVENTION	P-VALUE
Dautzenberg et al., 2004 OL, Retrospective review, $n = 51$	(P) ≥ 65 y/o hospitalized demented patients	Patients who used rivastigmine chronically with a randomly selected subgroup of all patients not treated	Retrospective chart review of geriatric service consultations	88.9 (26/29)	45.5 (4/11)	$P < 0.05$
Moretti et al., 2004 RCT, $n = 230$	(P) ≥ 65 y/o—o/p, w/ vasc dementia (24-month f/u)	Cardioaspirin vs. rivastigmine PO qD	CAM BEHAVE-AD	62 (71/115)	40 (46/115)	$P < 0.001$
Liptzin et al., 2005 DBRPCT $n = 80$	(P) Elderly elective total joint replacement	PBO vs. donepezil (14 days pre + 14 days post Sx)	DSM-IV	17.1 (7/41)	20.5 (8/39)	$p = 0.69$
Sampson et al., 2007 DBRPCT, $n = 33$	(P) Elderly elective hip replacement	PBO vs. donepezil 5 mg immediately p-Sx + 3 days	DSI	35.7 (5/14)	9.5 (2/19)	$p = 0.08$
Oldenbeuving et al., 2008 $N = 26$	(P) Delirium p CVA	Rivastigmine 3→ 12 mg/d; no PBO	DRS ≥ 12	In 16/17 (94%) delirium severity improved; mean decrease 14.8→8.5; mean duration: 6.7 days; no side effects		
Gamberini et al., 2009 DBRPCT, $n = 120$	(P) Cardiac Sx under CPB	PBO vs. PO rivastigmine 1.5 ¹ pre-op, until POD #6	CAM	30 (17/57)	32 (18/56)	$p = 0.8$
van Eijk et al., 2010 DBRPCT, $n = 109$	(Tx) > 18 y/o in ICU	2 arms, both receiving haloperidol, trial PBO vs. rivastigmine	CAM-ICU	3d	5d	$p = 0.06$
				Above refers to delirium duration in days; trial halted due to mortality in rivastigmine ($n = 12$, 22%) was > than in placebo group ($n = 4$, 8%; $p = 0.07$)		

¹ Rivastigmine-treated patients who experienced delirium had a shorter duration, lower use of benzodiazepine and neuroleptic for management of agitation, and improvement in all behavioral aspects measured by the BEHAVE-AD.

(Liptzin, Laki, Garb, Fingerroth, & Krushell, 2005). Subjects in the active treatment group received donepezil or placebo for 14 days before surgery and 14 days afterward, and no significant differences between groups were found ($p = 0.69$). A second RCT also failed to demonstrate efficacy of donepezil (5 mg immediately postoperatively and every 24 hrs thereafter for the first 3 postoperative days) over placebo in preventing postoperative delirium after elective total hip replacement surgery in older people without preexisting dementia (9.5% donepezil vs. 35.7% PBO; $p = 0.08$) (Sampson et al., 2007). Even though this was a negative study, the trend was in the right direction (lower incidence of delirium; shorter length of stay [9.9 vs. 12.1 days; $p = 0.09$] and shorter delirium duration [1.5 vs. 1.8 days; $p = 0.83$]), and the study had Type-II errors (i.e., it was grossly underpowered).

The results of the acetylcholinesterase trials seem to suggest that these agents are either (a) just not good for delirium prevention; or (b) they need to be used for much longer periods of time (as in the case of Dautzenberg and Moretti's study); or (c) they need to be used at doses much higher than we currently use them in order to achieve acute clinical efficacy.

A note of warning: more recently a DBRPCT comparing rivastigmine to placebo was stopped after members of the data safety and monitoring board unblinded the results and performed an interim analysis, halting the study due to concerns about a higher mortality rate in the rivastigmine group ($p = 0.07$) (van Eijk et al., 2010). The authors failed to explain the mechanism by which rivastigmine use may have led to the higher mortality reported. It is difficult to interpret their report, as less than 25% of the sample had been studied, and the causes of death for those on the study drug were heterogeneous. It is clear that the study relied on a very fast rivastigmine titration (essentially doubling the dose every 3 days until reaching the goal of 6 mg BID by day 10). This could have contributed to untoward side effects, which could have potentially worsened underlying cardiovascular or metabolic processes. Unlike in other delirium studies, the population in this study was not homogeneous, as it involved patients with all types of disease in the ICU. As the authors reported, "we cannot exclude that the recorded difference in mortality is due to chance" (van Eijk et al., 2010, p.1835).

Acetylcholinesterase Inhibitors for Delirium Treatment

Addressing the theory that proposes that delirium is caused by a central cholinergic deficiency state, some researchers and clinicians have experimented with the use of acetylcholinesterase inhibitor agents. Most of the published data consist of small series of case reports associated with the use of rivastigmine in the treatment of delirium in older persons (Dautzenberg, Mulder, et al., 2004; van den Blik & Maas, 2004)(van den Blik and Maas 2004). There have been at least 19 papers, mostly case reports, suggesting that acetylcholinesterase inhibitor agents (e.g., donepezil, galantamine, physostigmine, rivastigmine) may be effective in the treatment of delirium (see Box 41.8).

Physostigmine and Delirium

Acetylcholine deficiency has been postulated as one of the potential causes of delirium; whether this is caused by normal physiological causes (e.g., aging) or due to exogenous factors (e.g., use of anticholinergic substances). Thus, among the tools to treat delirium, particularly when it is presumed to be due to the ingestion of substances with anticholinergic potential, we should consider the potential use of physostigmine. Physostigmine, a short-acting acetylcholinesterase inhibitor, increases synaptic acetylcholine concentrations and can overcome the postsynaptic muscarinic receptor-blockade produced by anticholinergic agents. As a tertiary amine, it can pass freely into the CNS and reverse both central and peripheral anticholinergic effects.

Many reports have demonstrated its utility and safety in cases when delirium has been caused by medication overdose (whether accidental or intentional) (Stern, 1983); Lipowski, 1992; Beaver & Gavin, 1998; Richardson, Williams, & Carstairs, 2004; Eyer et al., 2011; Hail, Obafemi, & Kleinschmidt, 2013). Physostigmine has been successfully used to treat emergence delirium in both adults (Brown, Heller, & Barkin, 2004; Haase & Rundshagen, 2007) and pediatric patients (Funk, Hollnberger, & Geroldinger, 2008). It has been reported that physostigmine attenuates several withdrawal states, especially alcohol delirium and opiate and nitrous oxide withdrawal syndromes; and it may offer a protective mechanism against hypoxic damage of the brain (Powers, Decoskey, & Kahrilas, 1981; Ruprecht, Schneck, & Dworacek, 1989).

Despite many psychiatrists' concerns about physostigmine administration, its use as a diagnostic test appears to be rather safe. In a series of 39 adults treated with varying doses of physostigmine (range 0.5–2.0 mg), 56% of all cases experienced full reversal of delirium. Among the cases known to be antimuscarinic in etiology (e.g., overdose with a known substance) 100% of patients experience full reversal. In this sample, no patient experience dysrhythmias or signs of cholinergic excess, or required the administration of atropine. One (2.6%) in 39 patients experienced a brief convulsion, with no known adverse sequelae (Schneir et al., 2003). Similarly, others have reported that among 52 consecutive patients with suspected anticholinergic delirium, physostigmine controlled agitation and reversed delirium in 96% and 87% of cases, respectively (Burns, Linden Gaudins, Brown, & Fletcher, 2000). Again, no significant side effects were reported.

Given its safety profile and effectiveness, physostigmine should be considered when a delirious patient's examination exhibits signs of a central anticholinergic state (e.g., confusion, sinus tachycardia, markedly dilated and fixed pupils, dry mouth, hypoactive bowels sounds, dry and flushed skin; see Box 41.9) and/or when it is known that the patient's altered mental status is due to the use of known anticholinergic substances (e.g., diphenhydramine). An initial physostigmine dose of 1–2 mg (0.5 mg in children) given intravenously over 3 to 5 minutes is the recommended dose. If the response is incomplete, additional doses of 0.5–1.0 mg every 5 minutes may be given until delirium resolves or there are signs of cholinergic excess (e.g., diaphoresis, salivation, vomiting, diarrhea). A prolonged PR interval (>200 ms) or QRS complex (>100 ms and not related to bundle branch block) interval on ECG are considered the only absolute contraindications for physostigmine use.

Melatonin and Sleep Deficit

Sleep deprivation is one of the major theories on the development of delirium, whether caused by medication effect, environmental factors, or patient characteristics. Many sedative and hypnotic agents may worsen sleep and thus are not recommended. As described in the prevention section, various sedative hypnotic agents are commonly used in the medical setting, but most of them have significant problems, including causing or worsening delirium, cognitive clouding, and respiratory depression.

Box 41.9 ANTICHOLINERGIC SIDE EFFECTS

Cognitive impairment
Delirium
Dilated and fixed pupils, blurred vision
Dry and flushed skin
Dry mouth
Fever
Hallucinations
Hypoactive bowels sounds, constipation, ileus
Sinus tachycardia
Urinary retention

Various sedative hypnotic agents are commonly used in the medical setting. Nevertheless, benzodiazepines and the benzodiazepine-receptor agonists (e.g., zolpidem) may cause or exacerbate delirium. Other sedating agents, such as antidepressants (e.g., trazodone, mirtazapine) and antipsychotics (e.g., olanzapine) have been used off-label to promote sleep, but these agents have not been tested in the critically ill population. Clinicians must also consider factors such as drug–drug interaction and medication half-lives when prescribing. For example, mirtazapine and trazodone may indeed promote night sleep, but their effects may last well into the next day, interfering with cognition, attention, and concentration. Sedative agents with high anticholinergic load, such as antihistaminic agents (e.g., diphenhydramine, hydroxyzine) or tricyclic antidepressants (e.g., amitriptyline) should be avoided, as they will aggravate delirium even if they are immediately effective in promoting sleep. Similarly, benzodiazepines should also be avoided if at all possible.

An alternative to these is the use of non-benzodiazepine agents, such as melatonin or melatonin agonists (i.e., ramelteon). Melatonin has been shown to play an important role in the regulation of circadian rhythm and maintenance of a physiological, well-regulated sleep-wake pattern (Brzezinski, 1997). Multiple studies have demonstrated a number of abnormalities linking melatonin and delirium, including (a) irregular patterns of melatonin circadian rhythm (Miyazaki et al., 2003; Olofsson, Alling, Lundberg, & Malmros, 2004); and (b) decreased melatonin secretion (Shigeta et al., 2001; Guo, Kuzumi, Charman, & Vuylsteke, 2002) and abnormalities in the 24-hour urinary excretion of 6-sulphatoxymelatonin (6-SMT); the chief metabolite of melatonin (Balan, Leibovitz, et al., 2003). (See Table 41.20 for publications on melatonin abnormalities in delirium.) It is also theorized that melatonin may have protective effects, at least in cases of global cerebral ischemia/reperfusion injury, which may have implications for delirium onset (Sun, Lin, et al., 2002; Zhang, Guo, et al., 2002; Cheung, 2003; Cervantes, Morali, et al., 2008). In fact, melatonin may have a number of beneficial physiological effects which may prove beneficial in the management of medically ill, delirious patients (see Box 41.10).

Melatonin in Delirium Prevention

Several case reports have described the successful use of melatonin in preventing postoperative delirium (Hanania & Kitain, 2002). A small DBRPCT demonstrated that the use of melatonin (10 mg q HS) was associated with longer and better sleep quality ($p = 0.04$) (Bourne et al., 2008). A recent DBRPCT ($n = 222$) compared the effects of melatonin versus placebo among elderly patients undergoing hip arthroplasty under spinal anesthesia and found that those receiving melatonin showed a statistically significant decrease in the percentage of postoperative delirium (9.43% vs. 2.65%, $p = 0.003$) (Sultan, 2010). Similarly, a recent DBRPCT ($n = 145$) among tertiary-care medicine service elderly individuals demonstrated that the administration of low-dose (i.e., 0.5 mg) melatonin was associated with a lower risk of delirium (12.0% vs. 31.0%, $p = 0.014$), adjusted for dementia and other comorbidities (Al-Aama et al., 2011).

Table 41.20 DELIRIUM-ASSOCIATED MELATONIN ABNORMALITIES

STUDY	POPULATION	INTERVENTION	DELIRIUM DEFINITION	RESULTS
Shigeta et al., 2001 <i>N</i> = 29	Men and women undergoing laparotomy for digestive disease	None; observational	CAM	All patients without delirium showed nearly identical preoperative and postoperative melatonin secretion for 24 hours. Conclusions: Abnormal melatonin secretion may be involved in postoperative sleep disturbances, which triggered delirium in elderly patients.
Guo et al., 2002 <i>N</i> = 12	Males undergoing elective CABG with CPB	None; observational		Only three patients regained circadian secretion of cortisol. Conclusion: melatonin and cortisol secretion were disrupted during cardiac surgery with CPB and in the immediate postoperative period
Miyazaki et al., 2003 <i>N</i> = 41	s/p esophagectomy for CA	None; observational	CE	A significant correlation was seen between ICU psychosis and an irregular melatonin circadian rhythm (<i>P</i> = .0001).
Balan et al., 2003 <i>N</i> = 31	Patients who developed delirium during hospitalization	None; patients were divided into: hyperactive (7), hypoactive (10), mixed (14)	ICD-10 DRS	24-hr urinary excretion of 6-sulphatoxymelatonin (6-SMT)—the chief metabolite of melatonin. Among hyperactive patients, the levels of 6-SMT were lower during the acute delirium than after recovery (<i>p</i> < 0.001). Among hypoactive patients, 6-SMT levels were higher during the acute delirium than after recovery (<i>p</i> < 0.01). No difference in mixed.
Yoshitaka, Egi, et al., 2013 <i>N</i> = 40	40 postoperative patients in intensive care unit	None; observational	CAM	There was no difference in preoperative melatonin concentration. The Δ melatonin concentration at 1-hr post-op was significantly lower in patients with delirium than in those without delirium (<i>P</i> = .036). After adjustment of relevant confounders, Δ melatonin concentration was independently associated with risk of delirium (OR, 0.50; <i>P</i> = .047).

Melatonin and Melatonin Agonists in Delirium Treatment

Several case reports have described the successful use of melatonin in treating severe postoperative delirium unresponsive to antipsychotics or benzodiazepines (Hanania & Kitain, 2002). As part of the Sultan (2010) DBRPCT noted above

(*n* = 222), comparing the effects of melatonin versus placebo among elderly patients undergoing hip arthroplasty under spinal anesthesia, a number of subjects developed postoperative delirium and received postoperative melatonin for treatment (*n* = 62). It was found that 58% of subjects experienced delirium resolution after treatment administration (Sultan, 2010).

Box 41.10 MELATONIN PHYSIOLOGICAL EFFECTS

- Melatonin plays important roles in multiple bodily functions, which may have implications for the development of delirium in the medically ill:
 - Chronobiotic effect (affecting aspects of biological time structure)
 - Sleep–wake cycle regulatory effects
 - Helps reset circadian rhythm disturbances
 - Extensive antioxidant activity (with a particular role in the protection of nuclear and mitochondrial DNA)
 - Extensive antiinflammatory activity
 - Anti-nociceptive and analgesic effects
 - Melatonin receptors appear to be important in mechanisms of learning and memory
 - Inhibits the aggregation of the amyloid beta protein into neurotoxic microaggregates responsible for the neurofibrillary tangles characteristics of Alzheimer’s disease, and it prevents the hyperphosphorylation of the tau protein.

Adapted from Maldonado (Maldonado, 2008a).

Darlington, L. G., C. M. Forrest, G. M. Mackay, R. A. Smith, A. J. Smith, N. Stoy and T. W. Stone (2010). “On the Biological Importance of the 3-hydroxyanthranilic Acid: Anthranilic Acid Ratio.” *Int J Tryptophan Res* 3: 51–59.

Of note, a systematic literature search of all papers published on the use of melatonin for the treatment in dementia revealed a significant improvement in sundowning/agitated behavior (de Jonghe, Korevaar, van Munster, & de Rooij, 2010). This may be particularly important given the presence of circadian rhythm disturbances, like sundowning, in both dementia and delirium. Similarly, case reports have suggested the usefulness of ramelteon, a melatonin agonist, in the treatment of delirium (Kimura et al., 2011).

Similarly, there are two case reports of the successful use of ramelteon (a novel selective melatonin-receptor agonist) in the treatment of patients with delirium (Kimura et al., 2011; Furuya et al., 2012). (See Table 41.21 for a summary of published case reports and studies on the use of melatonin for the treatment of delirium.)

When it comes to sleep and delirium, the clinician must consider both risks and benefits of the intervention.

In general, lack of sleep may lead to delirium, especially in patients at high risk (e.g., the elderly; the seriously medically ill); thus, promoting sleep is paramount. The first step, as always, is prevention. Therefore, the implementation of nonpharmacological sleep protocols as described above is important. If the patient still has difficulty sleeping, the use of melatonin (or melatonin agonists) is probably the best first pharmacological option. When this is not enough, clinicians should consider the use of trazodone, followed by mirtazapine. If needed, zolpidem may be an acceptable choice. Compared to conventional benzodiazepine agents, zolpidem may have a lower deliriogenic potential. Certainly, some of the other delirium treatment alternatives already discussed above may be beneficial for sleep promotion, such as the use of nighttime gabapentin or VPA or the use of low-dose quetiapine. As a general rule, it is advisable to avoid the use of diphenhydramine due to its anticholinergic effects. Although

Table 41.21 MELATONIN AND ANALOG FOR DELIRIUM MANAGEMENT

STUDY <i>N</i> = 7	POPULATION	INTERVENTION	DELIRIUM DEFINITION	RESULTS
Bourne et al., 2008 <i>N</i> = 24 DBPCT	S/p tracheostomy to assist weaning from vent	Melatonin (MEL) 10 mg PO @ 2000	Bispectral index (BIS)	Melatonin use was associated with a 1-hour increase in nocturnal sleep ($P = 0.09$) and a decrease in BIS AUC indicating “better” sleep. Melatonin use was associated with increased nocturnal sleep efficiency.
Al-Aama, Brymer, et al., 2011 <i>N</i> = 145	Individuals aged ≥ 65 y/o admitted through the ED to a medical unit	Randomized to MEL 0.5 mg vs. PBO every night for 14 days or until discharge.	CAM	Melatonin was associated with a lower risk of delirium (12.0% vs. 31.0%, $p = 0.014$).
Sultan, 2010 <i>N</i> = 300	≥ 65 y/o scheduled for hip arthroplasty under spinal anesthesia	Randomized to: 1. PBO 2. Melatonin 5 mg 3. Midazolam 7.5 mg 4. Clonidine 100 μ g	Abbreviated Mental Test (AMT)	The melatonin group showed a statistically significant decrease in the percentage of postoperative delirium to 9.43%. POD: PBO—32.7 %; MEL—9.4 % ($p = 0.003$); MID—44 and ($p = 0.245$) CLO—37.3 % ($p = 0.629$); Melatonin was successful in treating 58.06% of patients who suffered postoperative delirium.
de Jonghe et al., 2010 Review	Meta-analysis		Various	Nine papers, including RCTs ($n = 243$), and five case series ($n = 87$) were reviewed. Two of the RCTs found a significant improvement on sundowning/agitated behavior. All five case series found an improvement.
de Jonghe, van Munster, et al., 2011 <i>N</i> = 452	≥ 65 y/o admitted for surgical repair of hip fracture	Randomized to: PBO Melatonin 3 mg @ 2100	CAM	Ongoing
Kimura et al., 2011 <i>N</i> = 3 (case report)	Pts > 59 y/o, medically ill	Open label; ramelteon 8 mg q HS	DSM-IV-TR MDAS-Jap	All three cases demonstrated significant improvement in delirium scores as measured by MDAS, with steady improvement over 7 days, ramelteon 8 mg at HS.
Furuya et al., 2012 <i>N</i> = 5 (case report)	Mostly demented, medically ill patients	Open label; ramelteon 8 mg	DSM-IV-TR	Authors reported the successful treatment of five cases of delirium within 1 day, after ramelteon 8 mg at HS.

Abbreviations: MEL=melatonin; BIS= Bispectral index (BIS) monitor.

low-dose doxepin is an excellent alternative for many adult patients, it is unclear if it would still have enough anticholinergic effect to make it wise avoid it. Certainly, the use of conventional benzodiazepine agents is discouraged due to their inherent deliriogenic effect.

SLEEP RESTORATION IN DELIRIUM TREATMENT

As described above, in delirium treatment we highly recommend starting with the implementation of nonpharmacological sleep protocols. If the patient still has difficulty sleeping, the use of melatonin (or melatonin agonists) is probably the best first pharmacological option (e.g., 3 mg PO q, 2000; for prophylaxis). Several case reports have described the successful use of melatonin (e.g., 1–36 mg HS PO, for treatment) and melatonin agonists in treating severe postoperative delirium that is unresponsive to antipsychotics or benzodiazepines (Sultan, 2010; Kimura et al., 2011; Furuya et al., 2012).

If that fails, clinicians should consider the use of non-benzodiazepine agents, such as trazodone or mirtazapine. If absolutely necessary, zolpidem may be an acceptable choice, but take into consideration the moderately high incidence of disordered sleep behaviors while on zolpidem and similar drugs. Given its short half-life and high sedation effect, low-dose quetiapine may also be an acceptable short-term solution, especially in patients experiencing sundowning.

OTHER AGENTS THAT HAVE SHOWN SOME PROMISE IN DELIRIUM MANAGEMENT

Some have theorized that an impaired serotonin metabolism may play a role in the development of delirium (Maldonado, 2008a,b). The original open-label study found that the antiemetic agent ondansetron, a selective serotonin 5-HT₃-type receptor antagonist, may be effective in the treatment of “hyperactive delirium” ($P=0.001$) (Bayindir, Guden Akpınar, Sanisoglu, & Sagbas, 2001). More recently, there was a second study (DBRCT; $n=80$) comparing ondansetron (8 mg IV) to haloperidol (5 mg IV) in the treatment of post-cardiotomy “delirium.” The authors reported no significant baseline difference between the groups and similar clinical improvement, from delirious baseline, in both groups ($p<0.01$). Unfortunately, this study did not use a standardized and validated delirium severity measure. The nonvalidated “scale” used by these researchers (different in each case) appeared to have been more a nonstandardized measure of agitation, rather than delirium. It is also not clear how the groups were randomly assessed, and it is difficult to make sense pharmacologically of the time for assessment, given very different pharmacokinetics of both agents (e.g., after IV administration, haloperidol’s half-life is 10–20 hrs., vs. ondansetron’s 5 hrs.; onset of action is also expected to be quite varied). Given the nature of these studies, and the fact it did not rely on the use of a validated diagnostic method, further, better designed studies are needed.

Finally, an open-label, prospective NRCT of patients undergoing cardiac surgery compared placebo versus statin administration for prevention of delirium in elderly patients (Katznelson et al., 2009). The authors remarked that statin administration has been shown to decrease morbidity and mortality after cardiac and major noncardiac surgery, and that animal and human studies have demonstrated the beneficial effect of statins in central neural system injury. Thus they theorized that the antithrombotic, antiinflammatory, and immunomodulatory properties of statins may be responsible for these protective effects, and that the same qualities may help protect against delirium. In fact, their study demonstrated that the administration of statins had a significant protective effect, reducing the odds of delirium by 46% among patients 60 years old and older. Of interest, these delirium-sparing effects did not manifest in patients younger than 60 years old.

DELIRIUM MANAGEMENT: SUMMARY

In summary, in order to prevent delirium, we recommend incorporating nonpharmacological and pharmacological approaches. Key among the possible interventions is the minimization of prolonged and uninterrupted sedation, by scheduling daily sedation holidays and titration of sedation to a targeted goal, assisted by the use of sedation scales. The choice of sedative and analgesic agents may also make a significant difference. It is important to be mindful of the additive effect that certain pharmacological agents may have, including sedative, deliriogenic, and anticholinergic potential. A good prevention strategy is the routine inspection of the patient’s medication list, wise choice of agents (avoiding anticholinergic and benzodiazepine agents, if possible) and eliminating all unnecessary agents. Remember the rule: the greater the number of pharmacological agents the patient is exposed to, the greater the risk for delirium. The implementation of delirium surveillance methods (such as any of the widely available delirium detection tools) enables the early recognition of delirium, and sometimes the detection of subsyndromal forms of delirium, allowing for prompt action before a full-blown syndrome has developed. Early mobilization is paramount. As a rule, the more vertical and restriction-free a patient is, the lower the incidence of delirium. It is important to eliminate restrictive devices and to reduce or eliminate sedation and analgesia as soon as medically appropriate and safe, and to promote getting patients mobilized and out of bed as soon as possible. Once they are capable of leaving the bed, patients should be encouraged to eat all meals sitting at the bedside chair rather than in bed. The implementation of a multicomponent, nonpharmacological protocol (especially with training and involvement of family and friends) may make a big difference for many patients, their family, and hospital staff. When safe, family and staff should be encouraged to get the patient out of the unit and to see that the patient receives as much direct sunlight as possible. This will assist the process of normalizing the sleep–wake cycle naturally by manipulating the amount of ambient light. When this is not possible, consider the use of melatonin or a melatonin-agonist, as well as

any of a whole host of nonpharmacological sleep-promoting interventions (e.g., avoid scheduling unnecessary blood draws and vital sign checks in the middle of the night [if the patient's medical condition allows it], minimize ambient noise and unnecessary light exposure, limit the amount of TV-watching after a certain time of day, and offer ear plugs and eye masks to enhance the patient's comfort). Melatonin and melatonin agonists may offer more benefit and fewer side effects than conventional sedative agents. The selective use of prophylactic antipsychotic agents should be considered, particularly in patients at high risk or those with a prior history of developing delirium in the medical environment. When delirium has already developed, the judicious use of dopamine antagonist agents seems to have the most evidence for a prompt recovery. When it comes to the use of acetylcholinesterase inhibitors, the data available seem to suggest that they work only in patients who have been on them long-term (i.e., for dementia). Thus their use may be considered in patients with moderate to severe cognitive impairment who suffer from multiple medical and chronic medical issues and who are expected to repeatedly return to the medical environment. Yet, data suggest that physostigmine is an underutilized therapeutic option we should consider in obvious cases of anticholinergic delirium.

SUMMARY

Delirium is a neurobehavioral syndrome caused by the transient disruption of normal neuronal activity secondary to systemic disturbances, and is the most common psychiatric syndrome found in the general hospital setting. In addition to causing distress to patients, families, and medical caregivers, the development of delirium has been associated with increased morbidity and mortality, increased cost of care, increased hospital-acquired complications, poor functional and cognitive recovery, decreased quality of life, prolonged hospital stays, and increased placement in specialized intermediate and long-term care facilities.

Clinical experience and research data suggest that once delirium has occurred, it is possible the patients may not return to their pre-delirium cognitive functional level. In fact, data suggests delirium the occurrence of delirium is associated with an increased risk of dementia, and acceleration in the rate of cognitive decline in those demented patients who develop delirium. Therefore, given increasing evidence that delirium is not always reversible, and given the potentially numerous negative sequelae associated with its development, physicians must do everything possible to prevent its occurrence.

The data also suggest that there may be a "dose-effect" for delirium, meaning that the longer a patient is delirious, the worse is the expected outcome. This is particularly true of hypoactive delirium, which unfortunately is the most commonly occurring type, particularly in the elderly. Therefore, clinicians are encouraged to implement as many prevention strategies as are available to them in order to improve patient outcome and prevent or minimize the occurrence of delirium, thus minimizing its morbidity.

Because delirium is common, it is important that physicians be mindful and implement surveillance and monitoring strategies to allow for early detection and the implementation of techniques that may shorten its duration. When delirium occurs, it is important to immediately correct the underlying contributing causes and use treatment strategies directed at preventing harm to the patient and others and to shorten the duration of the delirium episode, thus improving the odds of recovering baseline functional status.

The psychosomatic medicine specialist has much to contribute to the diagnosis, treatment, and study of delirium. In the author's experience, better results at implementing change, fostering psychiatric consultation, and greater involvement of our services come from getting involved in multidisciplinary quality-improvement projects that involve physicians, nurses, and ancillary staff in the process of recognition and treatment of delirious patients. Active participation in educational programs (e.g., continuing education, grand rounds, clinical case conferences) and development of a multidisciplinary task force charged with assessing the problem and developing an action plan are key to being recognized as an expert in the field, the one to go to for advice. At our institution, we developed a "CNS Pharmacotherapy Task-Force" that developed protocols for the ICU in sedation, pain management, neurological assessment, and delirium monitoring, prevention, and treatment. Its success has led to this model being replicated throughout the institution, with a greater recognition of delirium as a problem and of psychosomatic medicine specialists as the experts in the field. The author's team has implemented regular didactic sessions for nursing, regular rounding sessions in the MICU and SICU, and a monthly "psychiatric mortality and morbidity" review in the internal medicine program that has been invaluable in helping the medical staff change their perception and practice toward delirium, leading to greater joint participation between psychiatry and medico-surgical services.

CLINICAL PEARLS

- Four important non-modifiable factors for delirium are older age, baseline cognitive impairment, severity of underlying medical illness, and preexisting mental disorders.
- Among patients with preexisting mental disorders, patients with bipolar disorder had the highest incidence of delirium.
- Opioids, corticosteroids, and benzodiazepines are major contributors to delirium see Figure 41.7 (Gaudreau, Gagnon, et al., 2005b).
- A study of adult patients admitted to inpatient medicine wards showed that those who developed delirium had significantly elevated levels (i.e., above the detection limit) of IL-6 (53% versus 31%) and IL-8 (45% versus 22%), compared with patients who did not develop delirium, even after adjusting for infection, age, and cognitive

impairment (de Rooij, van Munster, Korevaar, & Levi, 2007). This is the first study to show a relationship between peripherally measured cytokine levels and delirium as a symptom of sickness behavior in acutely admitted elderly.

- Three core domains of delirium are *cognitive deficits* (characterized by attention and vigilance disturbances), *circadian rhythm dysregulation* (characterized by fragmentation of the sleep–wake cycle), and *higher cortical dysfunction* (characterized by semantic and comprehension deficits, executive dysfunction, and thought-process disturbances) (Meagher et al., 2007).
- Hypoactive delirium is often missed or misdiagnosed as depression (Liptzin & Levkoff 1992), and these patients have experienced the worst prognosis (e.g., prolonged hospital stay, higher morbidity and mortality) (Kiely et al., 2007).
- The severity scales of delirium may provide an added benefit—the ability to diagnose subsyndromal delirium.
- In our clinical experience, patients with delirium tend to exhibit a reemergence of primitive signs (see Box 41.5).
- Although the EEG is nonspecific and difficult to obtain in agitated patients, it can be useful in differentiating delirium from other conditions such as catatonic states, seizure activity, somatoform disorders, and malingering.

DEMENTIA: DIAGNOSIS AND TREATMENT

Scott McGinnis

INTRODUCTION

Dementia is a highly prevalent and ever-increasing cause of morbidity and mortality throughout the world. At present it is already one of the leading causes of years lost due to disability and healthcare expenditures in high-income countries; and with the rapidly growing older segments of the population developing dementia, the number of affected individuals will increase exponentially (*The Global Burden of Disease: 2004 Report*; Hebert, Scherr, Bienias, Bennett, & Evans, 2003). Dementia likewise stands ready to produce a significant public health challenge to the developing world, in which the number of affected individuals is rising most rapidly (Ferri et al., 2005). Medical practitioners in most disciplines encounter patients with dementia; it particularly behooves general practitioners, geriatricians, neurologists, psychiatrists, and psychologists to have a thorough understanding of its diagnosis and management.

Dementia is defined as a progressive impairment in cognition or behavior of sufficient severity to interfere with one's usual activities, and occurring in the absence of delirium. As such, it can present with a variety of different clinical manifestations and can be due to a variety of underlying brain conditions. Increasing knowledge about the phenotypes and pathophysiologies of neurodegenerative dementias, coupled with increasing availability of disease-specific biomarkers, has revolutionized diagnostic practice. Old practices of excluding reversible causes and lumping any remaining cases under the headings of "senile dementia" or "Alzheimer's disease" have given way to a process of proactively identifying specific clinical syndromes and attempting to determine neuropathology *in vivo*. The value of this new process is not purely academic, as identification of a specific condition carries both important prognostic and educational value for patients and caregivers and significant ramifications regarding strategies for symptomatic treatment. Identification of pathology *in vivo* also forms a critical component in the development and application of disease-modifying treatments for neurodegenerative dementia.

This chapter first reviews a general approach to diagnosis of dementia, focusing on the use of history and examination to localize cognitive dysfunction and to establish its time course and severity. A discussion of the differential diagnosis of dementia follows, including the epidemiology, genetics, clinical manifestations, diagnostic studies, clinical/pathological

associations, and treatments for specific clinical syndromes. The chapter closes by presenting strategies for management of dementia cases in general.

APPROACH TO DIAGNOSIS: GENERAL PRINCIPLES

As with any neurological or psychiatric illness, a detailed history and examination provide the most important diagnostic information in the assessment of a patient with suspected cognitive impairment or dementia (see Chapters 1–4 of this volume). Goals of the history and examination include localizing the impairment to regions and/or large-scale networks in the brain, establishing the time course and severity of symptoms, reviewing potentially modifiable contributing medical and psychiatric factors, and reviewing pertinent aspects of the patient's developmental, social, and family histories.

LOCALIZATION OF COGNITIVE DYSFUNCTION

Important considerations when localizing cognitive dysfunction include determining whether a pattern of deficits is predominantly *cortical* or *subcortical*, determining whether deficits are focal, multifocal, or diffuse, and determining which large-scale networks in the brain are implicated. Cortical cognitive symptoms or signs reflect dysfunction in networks containing at least one node in a cortical zone, such as limbic, paralimbic, heteromodal, or unimodal association cortex (Marsel Mesulam, 2000). Examples of cortical deficits include, but are not limited to, amnesia, aphasia, alexia, apraxia, and agnosia. Cortical deficits may be *unimodal* (confined to processing in a single sensory/motor modality) or *transmodal* (involving multiple modalities), depending on whether dysfunction exists in unimodal or transmodal regions of the brain. Neurodegenerative illnesses with cortical pathology such as Alzheimer disease (AD) and dementia with Lewy bodies (DLB) are the most common causes of cortical dementia.

In contrast to cortical dementias, subcortical dementias present with a profile of slowed processing speed, impaired attention, apathy, mood symptoms, and motor symptoms (Albert, Feldman, & Willis, 1974). Subcortical dementias are associated with forgetfulness, but in contrast to the

temporolimbic amnesia of a condition such as AD, memory difficulties are predominantly at levels of encoding and retrieving information, so recognition and cued memory are preserved. Subcortical dementias localize to subcortical white matter and/or deep gray structures. Examples of conditions producing subcortical dementia include vascular dementia (VaD), HIV-associated dementia, progressive supranuclear palsy (PSP), normal pressure hydrocephalus (NPH), and gliomatosis cerebri.¹

Our understanding of the organization of large-scale networks in the brain has grown dramatically in recent years with the availability of new technologies, including functional connectivity magnetic resonance imaging (fcMRI) and diffusion tensor imaging (DTI; Yeo et al., 2011). For purposes of clinical care, it is useful to employ a simplified approach and categorize networks broadly by the cognitive functions they subserve. In this scheme, one can consider cognitive domains such as episodic memory, language, complex attention/executive functions, visuospatial functions, and behavioral regulation/social cognition. Language functions localize to the perisylvian networks in the dominant (usually left) hemisphere (Hickok & Poeppel, 2007). Visuospatial functions localize to two visual streams, a dorsal occipitoparietal stream important for localization of items in space and integration with one's own sense of body position, and a ventral occipitoparietal stream important for the identification of items (Ungerleider & Haxby, 1994). The domain of complex attention and executive functions, comprising numerous component processes, localizes predominantly to frontoparietal and frontal/subcortical networks in the brain (Cummings, 1993). Episodic memory localizes both to temporolimbic networks (important for encoding, retrieval, and storage), and frontal networks (important for encoding and retrieval) (Budson & Price, 2005). Behavioral regulation and social cognitive processes recruit networks predominantly involving paralimbic regions such as the orbitofrontal cortex, anterior cingulate cortex, and insula (Gleichgerricht, Ibanez, Roca, Torralva, & Manes, 2010). In the case of each of these networks, connectivity exists between cortical nodes and other cortical nodes, cortical nodes and subcortical structures (striatum, thalamus), and between subcortical structures (Marsel Mesulam, 2000). Lesions at any point in the network can give rise to dysfunction, producing (in uncommon instances) cortical deficits from subcortical lesions.

Localization of cognitive symptoms to large-scale networks in the brain has particular value in the approach to dementia because neurodegenerative processes appear to target specific networks early in the course of the illness. Specific types of misfolded proteins accumulate with a limited range of possible distributions, starting focally and spreading along particular anatomical lines until there is diffuse involvement of the brain at the later stages of illness (Pievani, de Haan, Wu, Seeley, & Frisoni, 2011).² Additionally, circumscribed patterns

of atrophy in specific neurodegenerative syndromes correspond to regions of the brain that are highly structurally and functionally connected. These findings have given rise to the *network degeneration hypothesis*, which postulates that neurodegenerative processes target large-scale networks in the brain to produce characteristic progressions of neurodegeneration and clinical symptoms that depend on the pathology and networks targeted (Seeley, Crawford, Zhou, Miller, & Greicius, 2009). Further research is required to delineate the roles of misfolded proteins in the pathogenesis of specific diseases, the factors underlying network specificity, and the relationship between distribution of misfolded proteins and the distribution of neurodegeneration as marked by cell death and atrophy.

Despite enormous progress in recent years, there remain limitations to the approach of attempting to determine pathology in any given patient on the basis of history, examination, and structural neuroimaging alone. Such limitations arise from the following factors:

1. A single clinical syndrome or phenotype may be observed with different types of underlying pathology with varying probabilities, reflecting the fact that large-scale networks may be targeted by more than one type of disease process;
2. Clinical syndromes that share common underlying pathologies frequently overlap (e.g., a single patient may have features of multiple syndromes)³;
3. Different neurodegenerative pathologies frequently coexist within the same individual, and with vascular pathology (Schneider, Arvanitakis, Bang, & Bennett, 2007); and
4. Very old age (90 years old or greater) increases not only the probability that AD pathology will be found in the non-demented, but also the probability that amnestic dementia will be found in the absence of AD pathology (Savva et al., 2009).

These limitations highlight the need to further develop *in vivo* biomarkers of pathology. Efforts at present are most advanced for AD, for which cerebrospinal fluid (CSF) analysis of β -amyloid, total tau (t-tau), and phosphorylated tau (p-tau) is already available for clinical use, and amyloid positron emission tomography (PET) imaging may become available in the near future.

TIME COURSE AND SEVERITY

The usual time course of a neurodegenerative dementia is one of insidious onset and gradual progression over months to

1. See Chapters 46, 49, and 63 for detailed discussions of NPH, gliomas, and HIV-associated dementia, respectively.

2. Misfolded proteins in neurodegenerative dementia include (but are not limited to) β -amyloid, tau, α -synuclein, TAR DNA-binding protein 43 (TDP-43),

fused in sarcoma protein (FUS), and prion protein. See Table 42.3 and the text for specific clinical and pathological correlations.

3. Examples of overlapping clinical syndromes include those associated with AD pathology (amnestic AD, posterior cortical atrophy, logopenic primary progressive aphasia), those associated with Lewy body pathology (DLB and Parkinson disease dementia), and those associated with primary tau pathology (agrammatic primary progressive aphasia, behavioral-variant frontotemporal dementia, corticobasal syndrome, PSP syndrome).

Table 42.1 DIFFERENTIAL DIAGNOSIS OF DEMENTIA

PROCESS	CONDITIONS
Vascular	Infarcts (strategic or disseminated)*, ischemia, CNS vasculitis, CAA, non-inflammatory vasculopathy, hyperviscosity states, subdural hematomas, venous sinus thrombosis, dural AVF
Infectious	Viral (HIV*, PML, HSV, others), bacterial (CNS Whipple, <i>Bartonella</i> , TB, neurosyphilis, Lyme), fungal, parasitic
Toxic	Alcohol, heavy metals, organic solvents, heroin
Autoimmune/inflammatory [†]	Multiple sclerosis, antibody-associated encephalitis (paraneoplastic or non-paraneoplastic), HE, other NAIM, neurosarcoidosis, Beçhet disease, celiac disease
Metabolic	Thyroid dysfunction, uremia, hepatic encephalopathy, vitamin deficiency (B ₁₂ , thiamine, niacin, vitamin E), porphyria
Iatrogenic	Medications, chemotherapy, radiation therapy
Neoplastic [†]	Primary CNS lymphoma, intravascular lymphoma, gliomatosis cerebri*, lymphomatoid granulomatosis, metastases
Structural	Hydrocephalus (obstructive or normal pressure)*, FTBSS
Genetic	Hereditary leukodystrophies, lysosomal disorders, mitochondrial encephalopathies
Psychiatric	Catatonia, psychosis, severe melancholic depression, somatoform disorders, malingering
Degenerative [†]	AD, PCA, FTD (bv-FTD, PPA-S, PPA-G, FTDP, FTD-ALS, CBS, PSP*), PPA-L, PDD, DLB, HD, prion diseases

Abbreviations: AVF = arteriovenous fistula; PML = progressive multifocal leukoencephalopathy; HSV = herpes simplex virus; TB = tuberculosis; FTBSS = frontotemporal brain sagging syndrome; FTDP = frontotemporal dementia with Parkinsonism; HD = Huntington disease. Please refer to chapter text for other abbreviations.

* Denotes conditions commonly associated with subcortical dementia.

[†] Denotes conditions associated with rapidly progressive dementia.

years. Atypical, rapid progression over days to weeks may occur in individuals with prion disease, autoimmune or inflammatory encephalitides, atypical forms of neurodegenerative conditions that usually progress more slowly, certain infections, or other rare causes of dementia (Table 42.1). Sudden onset of symptoms occurs most frequently with vascular conditions such as ischemic stroke or hemorrhage, although the absence of a sudden onset and/or stepwise progression does not exclude vascular disease as a primary or contributing factor. It is likewise important to note that, for any given neurodegenerative condition such as AD, there is considerable variability between individuals in terms of how quickly symptoms progress, as well as variability within the same individual in different stages of illness (Doody et al., 2010). A static time course or a course of fluctuating cognitive impairment without steady progression may occur in a variety of medical and psychiatric conditions⁴ (Millan et al., 2012).

Numerous methods have been devised to rate the severity of cognitive dysfunction and dementia. A general distinction can be made between individuals with normal cognition for their age and education, those with cognitive dysfunction

beyond what can be attributed to aging that nevertheless does not interfere with their usual activities, and those whose performance in usual activities has been disrupted by cognitive dysfunction. Individuals with impaired cognition that does not interfere with usual activities may be classified as having mild cognitive impairment (MCI), conceptualized as an intermediate stage between normal aging and dementia⁵ (Petersen, 2004). Individuals with MCI are at an increased risk of progressing to a diagnosis of dementia when compared with cognitively normal individuals; the annual rate of progression in community-based populations has been estimated at 5–10%, the annual rate in specialty clinics at 10–15% (Petersen, 2011).

There are no strict guidelines that distinguish between mild, moderate, and severe dementia, although multiple schemes provide a conceptual framework for such classification. The Clinical Dementia Rating scale (CDR) is a widely used measure applicable to AD that relies on a semi-structured clinical interview and examination with a patient and reliable informant (Morris et al., 1997). Application of this scale generates ratings ranging from 0.5 (questionable

4. A thorough discussion of cognitive dysfunction associated with medical and psychiatric illness is beyond the scope of this chapter. Common mimics of dementia are discussed below in the section “Differential Diagnosis of Dementia.” For review of the cognitive dysfunction associated with psychiatric illness, see Millan et al., 2012.

5. More specifically, standard criteria for MCI require a report of cognitive impairment by a patient (or caregiver) and evidence by history with or without exam that the individual is not normal for age, not demented, has sustained a decline in cognition, and has essentially normal functional activities. MCI may be further classified according to whether or not there is memory impairment (amnesic vs. non-amnesic) and whether a single domain or multiple domains of cognition have been affected (Petersen, 2004).

or very mild dementia), to 1 (mild dementia), 2 (moderate dementia) or 3 (severe dementia) for the domains of memory, orientation, judgement and problem solving, community affairs, home and hobbies, and personal care.⁶ Various brief cognitive batteries including, but not limited to, the Montreal Cognitive Assessment (MoCA), the Mini-Mental State Exam (MMSE), the Kokmen Short Test of Mental Status, and the Addenbrooke's Cognitive Examination (ACE-R) are available to provide a longitudinal measure of global cognitive function and performance within selected sub-domains of cognition (Folstein, Folstein, & McHugh, 1975; Kokmen, Naessens, & Offord, 1987; Mioshi, Dawson, Mitchell, Arnold, & Hodges, 2006; Nasreddine et al., 2005). Each has its strengths and weaknesses; for example, the MoCA is relatively sensitive for attentional and executive dysfunction, whereas the ACE-R offers a more thorough examination of language and semantic processing. It is best to gain familiarity with a measure and to use it consistently so as to provide an index of change.

Increasing attention in research is being paid to the *pre-clinical* stage of neurodegenerative dementias, defined as the stage in which pathophysiological processes are active but have yet to produce clinically apparent symptoms. For AD, this stage may last for ten years or more prior to the onset of symptoms (Morris, 2005). Identification of neurodegenerative illness in the preclinical stage by definition requires the use of biomarkers of the pathophysiological process. At present, for AD, investigators have proposed models for the presence and progression of different biomarkers (Jack et al., 2010). Studies that will allow us to further refine these models and thus improve our ability to use biomarkers clinically are currently underway (Trojanowski et al., 2010).

DIFFERENTIAL DIAGNOSIS OF DEMENTIA

Table 42.1 lists causes of cognitive dysfunction and dementia categorized by the mechanism of illness: vascular, infectious, toxic, autoimmune/inflammatory, metabolic, iatrogenic, neoplastic, structural, genetic, psychiatric, and degenerative. A key question in formulating the differential diagnosis for a particular patient is whether or not the presentation suggests a relatively common condition such as AD, VaD, or cognitive dysfunction in the setting of general medical or psychiatric illness. Certain *red flags* that may suggest a less common cause of cognitive dysfunction include a non-amnestic cognitive profile, rapid progression of symptoms over days to weeks, or the early presence of additional

neurological symptoms such as pyramidal or extrapyramidal motor signs, myoclonus, cerebellar signs, apraxia, psychosis, autonomic dysfunction, rapid-eye-movement (REM) sleep behavior disorder, or seizures. Other red flags of note include young age (onset of symptoms before age 65, and especially before age 50), a family history suggestive of an autosomal dominant mode of inheritance, and prominent evidence of systemic medical or organ-specific illness not yet accounted for.

In a practice parameter for diagnosis of dementia, the Quality Standards Subcommittee of the American Academy of Neurology (AAN) recommended structural neuroimaging of the brain with computed tomography (CT) or magnetic resonance imaging (MRI), as well as routine screening for depression, vitamin B₁₂ deficiency, and hypothyroidism as a part of one's routine evaluation (Knopman et al., 2001). Many practitioners also obtain additional laboratory measures such as comprehensive metabolic profile, complete blood count (CBC), and urinalysis. Table 42.2 lists selected additional labs and studies available for use in cases of diagnostic uncertainty.

The vast majority of late-onset dementias (onset of symptoms at age ≥ 65) are attributable to neurodegenerative pathology, vascular disease, or mixed degenerative/vascular pathology (Jellinger, Danielczyk, Fischer, & Gabriel, 1990; Schneider et al., 2007). Of the degenerative pathologies, AD is by far the most common in this age group, followed by Lewy body pathology. In the population of individuals with early-onset dementia (onset of symptoms between ages 45 and 65), AD and VaD continue to represent the most common etiologies, but a much higher proportion of cases are due to frontotemporal lobar degeneration (FTLD) pathology than in the population with late-onset dementia (Garre-Olmo et al., 2010; Picard, Pasquier, Martinaud, Hannequin, & Godefroy, 2011).

Table 42.3 summarizes the epidemiology, genetics, neuropsychology, imaging, and associated pathologies for selected neurodegenerative dementia phenotypes. One should note that nomenclature in the literature and in clinical practice has been inconsistent and rapidly evolving. This chapter groups the primary progressive aphasia (PPAs) together due to their common involvement of language, while noting that semantic PPA (PPA-S) and agrammatic PPA are also frequently classified as frontotemporal dementias (FTDs) due to their anatomical distributions and associations with FTLD pathology⁷ (Josephs et al., 2011). PSP syndrome (PSPS) and corticobasal syndrome (CBS) are considered together as extrapyramidal syndromes frequently associated with FTLD-tau pathology.

6. From these ratings, a global dementia score and "sum of box scores" are derived. Examples of guiding criteria include the specification that patients with moderate dementia may appear well enough to be taken to functions outside of the home, are not able to function independently outside the home, perform only simple chores, have very restricted interests, and often require assistance in matters of dressing and personal hygiene. Individuals with severe dementia appear too ill to be taken to most functions outside of the home, require near-total assistance for functions within the home, and require much help with personal care.

7. FTLD pathology broadly comprises three specific subtypes based upon type of protein inclusion: FTLD-tau, FTLD-TDP, and FTLD-FUS. There are, at present, six subtypes of FTLD-tau (Pick, PSP, corticobasal degeneration, argyrophilic grain disease, multisystem tauopathy, diffuse neurofibrillary tangle with calcifications), four subtypes of FTLD-TDP (FTLD-TDP1-4), and three subtypes of FTLD-FUS (neuronal intermediate filament inclusion disease, basophilic inclusion body disease, atypical FTLD with ubiquitin-only immunoreactive changes). See Josephs et al., 2011, for review.

Table 42.2 ANCILLARY STUDIES IN THE DIAGNOSIS OF DEMENTIA

STUDY	INDICATIONS
Neuropsychological examination	Inadequate mental status examination; need for more detailed delineation of cognitive profile
Blood: RPR, HIV, Lyme Ab, other infection labs	Epidemiological setting for exposure; clinical evidence of infection ¹
Blood: ANA, ESR, CRP, anti-thyroid Abs, encephalitis Abs, other rheumatological labs	Suspicion for autoimmune/inflammatory causes of dementia ²
Blood: thrombophilia labs, toxicology, copper/ceruloplasmin, homocysteine, MMA, vitamins, other metabolic labs	Suspicion for underlying condition
Blood: genetic tests for neurodegenerative conditions, CADASIL, leukodystrophies, lysosomal, mitochondrial disorders	Family history suggestive of autosomal dominant inheritance (if applicable); suspicion for underlying condition ³
Urine: toxicology screen, copper, heavy metals, metabolic labs	Suspicion for toxic or metabolic condition ⁴
CSF: cell counts, protein, glucose, infection labs, IgG synthesis/index, oligoclonal bands, paraneoplastic Abs, cytology/flow cytometry	Suspicion for autoimmune/inflammatory, infectious, neoplastic cause of dementia
CSF: β -amyloid, t-tau, p-tau, 14-3-3 protein	Suspicion for AD pathology or CJD
Imaging: CXR, CT C/A/P \pm PET, mammography, echocardiography	Suspected systemic condition, including infection, inflammatory, neoplasm
Imaging: cerebral angiography (CT, MR, or conventional), CNIS, MR spectroscopy	Suspected vasculitis, vasculopathy, neoplasm
Imaging: brain FDG-PET or SPECT, PiB or AV-45 amyloid PET ⁵	Biomarker evidence for AD vs. other degenerative dementias
DAT PET or SPECT, MIBG myocardial scintigraphy, polysomnography	Evidence for degenerative cause of Parkinsonism, DLB, sleep disorder
EEG, EMG/NCS, autonomic studies	Suspicion for seizures, HE/NAIM, CJD, neuropathy, MND, dysautonomia
Brain biopsy	Other studies non-diagnostic; note low sensitivity (~55–65%) ⁶

Abbreviations: Ab = antibody; C/A/P = chest/abdomen/pelvis; CNIS = carotid noninvasive ultrasound; PiB = Pittsburgh Compound B; DAT = dopamine transporter. Please refer to chapter text for other abbreviations.

ALZHEIMER DISEASE

Epidemiology and Genetics of Alzheimer Disease

AD is the most common cause of dementia, constituting approximately 50–70% of late-onset dementias and 20–40% of early-onset dementias diagnosed clinically (Garre-Olmo et al., 2010; Jellinger et al., 1990; Picard et al., 2011). Age is the primary risk factor for AD and for all-cause dementia; the incidences of AD and all-cause dementia increase exponentially after the age of 65 (Corrada, Brookmeyer, Paganini-Hill, Berlau, & Kawas, 2010; Jorm & Jolley, 1998). The current prevalence of AD in the United States is estimated to be 13% in individuals 65 and over, increasing to approximately 43% in

individuals 85 and over (Thies & Bleiler, 2011). The estimated number of persons older than 65 with AD in the United States is projected to increase from approximately 5.1 million in 2010 to 13.2 million in 2050 (Hebert et al., 2003).

Approximately 94–99% of AD cases are late-onset (Bird, 2008). The average lifetime risk of AD in the general population is approximately 10–12% in a 75–80-year lifespan (Goldman et al., 2011). This risk at least doubles when one has a first-degree relative with AD. Although multiple candidate genes are under investigation, the only well-documented genetic association for late-onset AD is with the apolipoprotein E (*APOE*) gene, of which there are three isoforms: $\epsilon 2$, $\epsilon 3$, and $\epsilon 4$. Multiple studies have reported that approximately

Clinical Manifestations and Diagnosis of Alzheimer Disease

50–70% of people with late-onset AD carry at least one $\epsilon 4$ allele, suggesting a two- to three-fold increase in risk of AD for *APOE* $\epsilon 4$ heterozygotes. However, these results may be biased by oversampling “younger-old” individuals, as other studies imply that the $\epsilon 4$ allele shifts the onset of AD towards an earlier age without altering one’s overall lifetime risk (Khachaturian, Corcoran, Mayer, Zandi, & Breitner, 2004). Because of its lack of sensitivity and specificity, testing for *APOE* status is not recommended as part of a routine work-up for dementia or AD.

Approximately 60% of early-onset AD is familial (defined by the presence of two or more family members affected), and approximately 13% of cases appear to be inherited in an autosomal dominant fashion (suggested by \geq three generations affected) (Campion et al., 1999). Familial autosomal dominant early-onset AD thus constitutes < 2% of all cases of AD (Bird, 2008). The three known gene associations for familial autosomal dominant early-onset AD involve the presenilin-1 gene on chromosome 14 (*PSEN1*), the amyloid precursor protein gene on chromosome 21 (*APP*), and the presenilin-2 gene on chromosome 1 (*PSEN2*). Mutations in *PSEN1* account for 20–70% of cases, mutations in *APP* for 10–15% of cases, and mutations in *PSEN2* are rare. Essentially all individuals with Down syndrome develop AD pathology after age 40, presumably because they have three copies of the *APP* gene. Experts recommend that testing for gene mutations associated with familial autosomal dominant early-onset AD be offered to individuals with early-onset AD and family history of dementia (or unknown family history), individuals with a family history suggestive of autosomal dominant dementia and at least one case of early-onset AD, and individuals with a relative who has a known gene mutation (Goldman et al., 2011). Referral to a genetic counselor is imperative for all individuals who desire testing, and recommended for those who are undecided and would like to discuss the issue further.

Strong medical or environmental risk factors for AD have yet to be established. There is some suggestion from epidemiological data that vascular risk factors increase one’s risk for cognitive decline or AD, independent of stroke. Observational studies have demonstrated a correlation between hypertension in middle age (40–60 years of age) and cognitive impairment later in life (Whitmer, Sidney, Selby, Johnston, & Yaffe, 2005). Similarly, type 2 diabetes mellitus and obesity appear to independently increase one’s risk of AD (Profenno, Porsteinsson, & Faraone, 2010). Although data regarding cholesterol levels and AD have been inconsistent, most studies involving individuals assessed in middle age have suggested that high blood levels of total cholesterol and/or low density lipoprotein (LDL) cholesterol confer increased risk of AD later in life (Shepardson, Shankar, & Selkoe, 2011). Some, but not all, studies concerning head trauma and risk of AD later in life have suggested an association, particularly in men and in individuals with a family history of dementia (Fleminger, Oliver, Lovestone, Rabe-Hesketh, & Giora, 2003).

AD most commonly presents with insidious onset and gradual progression of difficulty with memory for recent events. Early impairments in language (usually difficulty finding words), executive functioning, and/or visuospatial functioning of varying severity are also frequently present. Although comportment and social demeanor are typically preserved until late in the course of the illness, neuropsychiatric features including mild apathy, social withdrawal, anxiety, and irritability are common early (Lyketsos et al., 2011). Insight into deficits is variable between patients, but at least somewhat reduced as a rule, and (as with other deficits) it worsens with the progression of the disease (McDaniel, Edland, & Heyman, 1995). Behavioral agitation is estimated to occur in approximately 80% of patients with AD, typically later in the disease course (Jost & Grossberg, 1996). Additional neurological manifestations such as seizures, myoclonus, and pyramidal or extrapyramidal motor signs usually do not occur until later stages of illness (Friedman, Honig, & Scarmeas, 2011; Portet, Scarmeas, Cosentino, Helzner, & Stern, 2009).

A clinical diagnosis of dementia due to probable AD is usually made by establishing a history of progressive cognitive impairment of sufficient severity to interfere with usual activities, with deficits in memory and at least one other cognitive domain apparent on examination, in the absence of other causative conditions (McKhann et al., 2011). Supportive features from mental status examination (MSE) or neuropsychological examination of a patient with mild dementia due to AD include impairments in episodic memory (encoding, retrieval, and storage), confrontation naming, semantic fluency, and, frequently, impairments on more challenging tests of complex attention/executive function and/or visuospatial function (see Chapter 3). Structural neuroimaging commonly reveals focal atrophy in the medial temporal and/or posterior temporoparietal regions, progressing to generalized atrophy with progression of disease and correlating with density of neurofibrillary tangles at autopsy (Figure 42.1) (Jack et al., 2004; Whitwell et al., 2008).

Figure 42.1 Coronal T1-weighted MRI of a patient with Alzheimer disease. This image demonstrates severe atrophy of the bilateral medial temporal cortices.

In uncommon instances, AD presents with symptoms other than memory impairment as the most prominent initial symptom. Examples include situations in which executive dysfunction, language, or visuospatial symptoms predominate. Cases of posterior cortical atrophy (PCA) and logopenic PPA due to AD pathology represent extreme versions of this situation, discussed in greater detail below. Even more rarely, AD pathology is uncovered to be the principal pathology in patients with the clinical syndromes of behavioral-variant FTD (bvFTD), PPA-S, or CBS (Alladi et al., 2007). Non-amnestic presentations appear to occur more frequently in the population with early-onset AD (Balasa et al., 2011; Koedam et al., 2010).

In cases of diagnostic ambiguity, biomarker evidence for AD can be obtained with 18-fluorodeoxyglucose positron emission tomography (FDG-PET), perfusion single-photon emission computed tomography (SPECT), or CSF analysis of β -amyloid 42, t-tau, and p-tau levels. FDG-PET or perfusion SPECT in AD reveals a characteristic pattern of hypometabolism or hypoperfusion in bilateral temporoparietal and posterior cingulate/precuneus cortex with variable involvement of the lobes and sparing of primary sensorimotor cortices. Elements of this pattern have yielded diagnostic sensitivities in the range of 86–94% and specificities ranging from 63–93% comparing AD with other degenerative dementias in studies with pathological confirmation of diagnosis (Devous, 2002; O'Brien, 2007).

The characteristic CSF profile of AD consists of a low level of β -amyloid 42 and elevated levels of t-tau and p-tau. CSF data from a cohort of 56 subjects with autopsy-confirmed AD and 52 age-matched controls revealed a diagnostic sensitivity of approximately 96% for low β -amyloid 42 levels (Shaw et al., 2009). Levels of t-tau had the greatest specificity (92%) in distinguishing AD from controls. Limited data comparing CSF biomarkers in AD compared to other neurodegenerative dementias with pathological confirmation suggest that combined use of β -amyloid 42 and p-tau levels yields a sensitivity of over 95% and a specificity of over 80% (Schoonenboom et al., 2012).

The availability of biomarker evidence of the AD pathophysiological process is one factor that prompted a revision of clinical diagnostic criteria for AD by the National Institute on Aging–Alzheimer's Association (NIA-AA) workgroups on diagnostic guidelines for Alzheimer's disease (Albert et al., 2011; McKhann et al., 2011). The new criteria allow for diagnosis of “probable AD dementia with evidence of the AD pathophysiological process” as well as “MCI due to AD.” For each of these diagnoses, one must meet a set of core criteria for either probable AD dementia or MCI, and on top of that possess biomarkers of β -amyloid deposition and/or downstream neuronal degeneration or injury.⁸ While not recommended for routine clinical use at this juncture, AD biomarker tests may be offered to patients for whom greater

diagnostic certainty sooner rather than later is likely to alter the plan of care.

Pathology and Pathophysiology of Alzheimer Disease

As with every neurodegenerative dementia, pathology represents the gold standard for the diagnosis of AD. Various criteria for the pathological diagnosis of AD have been proposed over the past several decades, each requiring a progression of extracellular fibrillar β -amyloid (senile plaques, and in particular a subset called neuritic plaques) and intracellular neurofibrillary tangles (NFTs) (Braak & Braak, 1991; Hyman et al., 2012; Hyman & Trojanowski, 1997; Khachaturian, 1985). Clinical and pathological studies have suggested that a clinical diagnosis of dementia due to AD predicts underlying AD pathology in approximately 85–95% of cases (Gearing et al., 1995; Jellinger et al., 1990; Mayeux et al., 1998; Schneider et al., 2007).

Despite the clearly established pathology of AD, questions remain about its fundamental etiology and pathophysiology. The amyloid hypothesis is based on evidence that accumulation of β -amyloid occurs as an upstream event preceding neurodegeneration, and the fact that the only gene mutations known to cause AD lead directly to overproduction of β -amyloid 42. Research has suggested that oligomeric forms of β -amyloid are toxic to synapses (Shankar et al., 2008) and that accumulation of β -amyloid directly or indirectly causes downstream events including inflammation, oxidative injury, tau hyperphosphorylation, and neuronal dysfunction and death (Hardy & Selkoe, 2002). It is possible that other mechanisms such as factors pertaining to neuronal energy metabolism, changes in intracellular and synaptic functions, and/or chronic neuroinflammatory response to an inciting injury occur upstream of or concomitantly with β -amyloid accumulation (Bero et al., 2011; Herrup, 2010; Pimplikar, Nixon, Robakis, Shen, & Tsai, 2010).

Compatible with a network-based model of neurodegeneration, amyloid deposition appears to target the default mode network—a network of brain regions including the medial temporal cortex, medial temporal cortex, temporoparietal cortex, and posterior cingulate/precuneus cortex (Buckner et al., 2005). Recent research has also suggested that once the cascade of tau hyperphosphorylation and NFT formation has been initiated, tau pathology spreads outward from entorhinal cortex along network lines via trans-synaptic mechanisms (Liu et al., 2012).

Treatment of Alzheimer Disease

Despite recent advances in our understanding of the pathophysiology of AD, disease-modifying therapies aimed at slowing or reversing the pathophysiological process have remained elusive. There are two types of symptomatic medications currently approved for use in dementia due to AD: cholinesterase inhibitors and memantine (Table 42.4).

In addition to the neuropathology of AD reviewed above, postmortem studies have revealed that the illness is associated with a significant loss of neurons in the basal forebrain—specifically

8. Current biomarkers of β -amyloid deposition include CSF β -amyloid 42 and PET amyloid imaging. Biomarkers of neuronal injury include CSF t-tau/p-tau, quantitative structural MRI measures, FDG-PET, SPECT, and other less well validated biomarkers (see Albert et al., 2011).

Table 42.4 SELECTED MEDICATIONS IN THE SYMPTOMATIC TREATMENT OF DEMENTIA

TYPE	INDICATIONS	EXAMPLES	STARTING DOSE	MAINTENANCE DOSE	COMMENTS
Cholinesterase inhibitors	AD, DLB/PDD, VaD*; cognition, mood, apathy, anxiety, psychosis	donepezil rivastigmine galantamine ER	5 mg QHS 1.5 mg BID† 8 mg QD	10 mg QHS 6 mg BID† 16–24 mg QD	Monitor GI s/e, sleep, HR, muscle cramps, fatigue
Memantine	AD, DLB/PDD*, VaD*, PPA*, bvFTD*; cognition, apathy*, agitation*	memantine	5 mg QD	10 mg BID	Monitor GI s/e, HA, dizziness, BP
SSRIs	mood*, anxiety*, irritability*, agitation*	sertraline citalopram	12.5 mg QD 5 mg QD	lowest effective (up to 200 mg QD) lowest effective (up to 40 mg QD)	Monitor QTc, GI s/e, HA, sleep, tremor, sexual s/e, fatigue, apathy
SNRIs	mood*, anxiety*	venlafaxine ER	37.5 mg QD	lowest effective (up to 225 mg QD)	Monitor GI s/e, HA, sleep, BP, diaphoresis
Bupropion	mood*, apathy*	bupropion SR	100 mg QD	lowest effective (up to 200 mg BID)	Monitor GI s/e, HA, sleep, tremor, anxiety
Mood stabilizers	mood lability*, agitation*	carbamazepine ER lamotrigine	100 mg BID 25 mg QD	lowest effective (up to 800 mg BID) lowest effective (up to 200 mg QD)	Monitor labs, GI s/e, HA, sleep, tremor, ataxia, fatigue, rash‡
Melatonin receptor agonists	insomnia*	melatonin ramelteon	3 mg QHS 8 mg QHS	lowest effective (up to 12 mg QHS) 8 mg QHS	Take within 30 minutes of bedtime
Stimulants	apathy*	methylphenidate	5 mg QD	lowest effective (up to 60 mg QD)	Monitor weight, sleep, anxiety, HR, BP
Atypical antipsychotics	aggressive agitation* (short term), psychosis*, insomnia*	quetiapine olanzapine aripiprazole	12.5 mg QHS 2.5 mg QHS 2 mg QD	lowest effective (up to 400 mg BID) lowest effective (up to 20 mg QHS) lowest effective (up to 30 mg QD)	Monitor QTc, weight, GI s/e, fatigue, extrapyramidal s/e [§] ; note ↑ risk of stroke, mortality in older pts

Abbreviations: s/e = side effects; HR = heart rate; HA = headache; BP = blood pressure; QTc = QTc interval on electrocardiogram. Please refer to chapter text for additional abbreviations.

* Indicates off-label use and/or weaker evidence of efficacy.

† Also available in transdermal patch, which may reduce risk of GI s/e; starting dose 4.6 mg/24 hour, maintenance dose 9.5 mg/24 hour.

‡ Carbamazepine requires monitoring of CBC, BUN/creatinine, liver function tests, TSH, urinalysis; lamotrigine requires monitoring for Stevens-Johnson syndrome, and slow dose escalation (e.g., 25 mg QD × 2 weeks → 50 mg QD × 2 weeks → 100 mg QD × 1 week → 200 mg QD).

§ Patients with DLB or PDD may demonstrate severe sensitivity to neuroleptic medications. Only agents with low dopamine receptor antagonism (e.g., quetiapine, clozapine) should be used, and when used, used with caution.

the nucleus basalis of Meynert—that provide cholinergic projects to widespread areas of the cerebral cortex (Whitehouse et al., 1982). Cholinesterase inhibitors act by reducing the breakdown of acetylcholine, a neurotransmitter important for the modulation of attentional, memory, and sensory processing in the brain (Bentley, Driver, & Dolan, 2011). Studies have revealed modest but significant treatment effects of cholinesterase inhibitors vs. placebo in subjects with dementia due to AD on measures of cognition, behavior, and daily functioning (Raina et al., 2008). Response to treatment in any given individual is variable. More extensive data are available for mild to moderate dementia, but some studies suggest modest efficacy in severe dementia as well. Although selected subsets of patients with MCI may benefit, studies have not suggested that treatment with cholinesterase inhibitors delays progression to dementia in the population of individuals with MCI on the whole (Raschetti, Albanese, Vanacore, & Maggini, 2007).

Available data do not suggest clear superiority of any one of the three cholinesterase inhibitors currently in wide use (donepezil, galantamine, rivastigmine). The most common side effects associated with cholinesterase inhibitors include gastrointestinal (GI) side effects (diarrhea, nausea, vomiting, and loss of appetite), muscle cramps, insomnia, and fatigue. One should exercise caution in patients with significant bradycardia or heart block, history of ulcers or occult gastrointestinal bleeding, or severe obstructive pulmonary disease.

Memantine acts as a low to moderate affinity antagonist to glutamate NMDA (*N*-methyl-D-aspartate) receptors. Small beneficial effects on measures of cognition and behavior have been observed in treatment trials involving subjects with AD dementia, most apparent in moderate to severe disease (Smith, Wells, & Borrie, 2006). Combination therapy with both a cholinesterase inhibitor and memantine appears to provide benefit beyond treatment with just a cholinesterase inhibitor (Atri, Shaughnessy, Locascio, & Growdon, 2008). Potential side effects of memantine include dizziness, headache, GI side effects, hypertension, and confusion.

The Future of the Field: Disease-Modifying Therapies

Significant efforts to develop disease-modifying therapies for AD have been underway in recent years. Many strategies have centered on reducing β -amyloid formation, blocking its aggregation, or hastening its clearance from the brain. Other strategies have focused on inhibiting the phosphorylation and aggregation of tau, or on neuroprotection via reduction of oxidative stress, inflammation, or mitochondrial dysfunction.

Amyloid-based therapies have included inhibitors of the enzymes β -secretase and γ -secretase (responsible for cleaving the trans-membrane amyloid precursor protein into fragments of toxic β -amyloid) and active or passive immunization against β -amyloid. Thus far, there is good evidence from human and non-human studies that these agents do indeed lower levels of fibrillar β -amyloid in the brain, but completed studies to date have demonstrated either no or equivocal clinical efficacy (Citron, 2010; Rafii & Aisen, 2009). One hypothesis for why this has been the case is that studies to date have been conducted predominantly in subjects with mild to

moderate dementia due to AD, stages in which the pathological burden is considerable and in which pathophysiological mechanisms downstream of β -amyloid accumulation may be less responsive to its reduction (Sperling, Jack, & Aisen, 2011). Multiple large-scale studies of amyloid-based therapies are ongoing at the time of this review, and additional studies are in the planning phases. Such studies are increasingly using biomarkers to establish the diagnosis of AD at the stages of MCI or preclinical illness.

POSTERIOR CORTICAL ATROPHY

The clinical syndrome of posterior cortical atrophy (PCA) involves insidious onset and gradual progression of visual deficits and/or apraxia, usually but not always associated with underlying AD pathology. Visual deficits include visuospatial impairments localizing to the dorsal (occipitoparietal) visual stream, visuoperceptual deficits localizing to the ventral (occipitotemporal) visual stream, and/or visual field cuts localizing to primary visual cortex. Accurate data regarding prevalence and incidence of PCA are currently lacking due to poor general awareness of the syndrome and a lack of consistent diagnostic criteria (Crutch et al., 2012). Most studies have suggested a younger average age of onset (50s to early 60s) for PCA compared to amnesic AD, in keeping with the hypothesis that non-amnesic presentations are more likely to occur as early-onset dementias.

Patients with PCA frequently present with problems navigating in space, reading, or carrying out arithmetic, although a subset may present to an ophthalmologist for evaluation regarding more basic elements of vision. Examination commonly reveals elements of the syndromes of Bálint (simultagnosia, optic ataxia, and oculomotor apraxia) and Gerstmann (agraphia, acalculia, left-right confusion, and finger agnosia⁹). Impairments in executive functions, language, and memory are variable early in the course of illness, but memory storage is frequently preserved. PCA patients commonly report visual hallucinations and/or positive perceptual phenomena, including color after-images, reverse size phenomena, perception of movement of static stimuli, and visual crowding (Crutch et al., 2012). Depression and anxiety are highly prevalent in this population, perhaps because insight into deficits tends to be more preserved than in amnesic AD (Mendez, Ghajranian, & Perryman, 2002). Structural neuroimaging with MRI in patients with PCA usually reveals atrophy in the bilateral parietal and occipital lobes that is apparent on gross inspection (Figure 42.2).

Limited clinical/pathological correlation series have suggested that AD pathology is found in approximately 80% of cases of PCA, with other associated pathologies including Lewy body pathology, corticobasal degeneration pathology, prion pathology, and subcortical gliosis each being found in 10% or fewer of cases (Crutch et al., 2012). Series involving

9. Finger agnosia, defined as an inability to distinguish, name, or recognize fingers, usually occurs in the setting of a more generalized disturbance in awareness of body parts and their orientation, also associated with disturbances in balance and/or dressing apraxia.

Figure 42.2 Axial FLAIR (fluid attenuated inversion recovery) MRI of a patient with posterior cortical atrophy. This image demonstrates severe atrophy of the posterior parietal and occipital cortices.

CSF analysis of AD biomarkers have revealed a profile suggestive of AD in a similar proportion of cases.

There are, at present, no medications with proven benefit for the visual and cognitive symptoms associated with PCA. Due to the pathological association between PCA and AD and information from case reports suggesting a potential benefit, many practitioners institute empirical trials of cholinesterase inhibitors for their patients. Treatment with antidepressant medications, anti-anxiety medications (Table 42.4), and/or symptomatic medications for Parkinsonism may provide benefit in appropriate circumstances. Occupational therapists and/or vision therapists can often provide strategies for modifying the home environment to optimize recognition of important objects or locations, along with other practical coping strategies and resources for the visually impaired.

DEMENTIA WITH LEWY BODIES AND PARKINSON DISEASE DEMENTIA

Dementias associated with Lewy body pathology—Parkinson disease dementia (PDD) and dementia with Lewy bodies (DLB)—are the second most common type of neurodegenerative dementia after AD (McKeith et al., 2004). Although epidemiological studies have been hindered by a lack of pathological criteria to distinguish between the two and (until recently) a lack of validated clinical diagnostic criteria for PDD, population-based clinical studies have estimated the prevalences of DLB and PDD to be 0.7% and 0.3%, respectively, in the population of individuals aged 65 and older. These estimates are in keeping with a prevalence of 10–15% for DLB in hospital-based autopsy series of dementia.

DLB and PDD frequently share clinical features and are distinguished somewhat arbitrarily by the timing of Parkinsonian symptoms relative to the onset of dementia; individuals with onset of dementia within one year of Parkinsonism are considered to have DLB. As no single individual symptom reliably distinguishes between DLB and PDD, and certain gene mutations have produced kindreds containing both disorders, experts have argued that they may exist along a spectrum of Lewy body disease with distribution of neurodegeneration determining phenotype (McKeith et al., 2004). The cognitive profile of both PDD and DLB usually involves early dysfunction in complex attention, executive functions, and visuospatial processing (Bradshaw, Saling, Anderson, Hopwood, & Brodtmann, 2006; Mosimann et al., 2004). Fluctuations in attention, alertness, or cognition of varying intensity and duration are considered to be a *core* feature of DLB (present in 50–75% of cases), but are also observed frequently in PDD (McKeith et al., 2005).¹⁰ The other two core features of DLB are visual hallucinations that are often vivid, three-dimensional hallucinations of animate objects, and Parkinsonism, which is present in 25–50% of patients at diagnosis and develops in approximately 75% throughout the course of the illness. Visual hallucinations occur in an estimated 50% of patients with idiopathic Parkinson disease (Aarsland et al., 2007). Other neuropsychiatric symptoms common to both disorders include depression, anxiety, apathy, and delusions.

In comparison to the Parkinsonism of idiopathic PD, the Parkinsonism of DLB tends to be more bilaterally symmetrical and less responsive to treatment with levodopa (Molloy, McKeith, O'Brien, & Burn, 2005). Tremor is less common and less severe in DLB than in idiopathic PD, which is interesting in light of the fact that individuals with idiopathic PD and prominent early resting tremor are less likely to develop cognitive impairment than those with more prominent instability of posture and impaired gait (Burn et al., 2006). Additional features that may be present in both DLB and PDD (but that are more commonly present in DLB) include REM sleep behavior disorder, severe sensitivity to neuroleptic medications, and autonomic dysfunction. REM sleep behavior disorder manifests as vivid dreams without accompanying muscle atonia, leading to an individual's "acting out" dreams. REM sleep behavior disorder may precede other symptoms of DLB, PD, or multiple system atrophy (another α -synucleinopathy) by years or even decades (Iranzo et al., 2006). Autonomic dysfunction often produces orthostatic hypotension (with concomitant lightheadedness or syncope), urinary retention or incontinence, constipation, or impotence.

Structural neuroimaging demonstrating relative sparing of medial temporal lobe volume and/or thickness supports a diagnosis of DLB rather than AD in the correct clinical context, as does hypoperfusion or hypometabolism in the occipital and posterior temporoparietal cortices with sparing of the posterior cingulate/precuneus on perfusion SPECT or FDG-PET imaging (Kantarci et al., 2011). Dopamine

10. The third report of the DLB Consortium outlines clinical criteria for the diagnosis of "probable DLB" and "possible DLB" (McKeith et al., 2005).

transporter PET or SPECT and myocardial scintigraphy with 123-I-metaiodobenzylguanidine (MIBG) are approved imaging modalities with diagnostic utility for DLB and limited but increasing availability in the clinical setting (McKeith et al., 2007; Yoshita et al., 2006).

DLB and PDD are both associated with Lewy bodies—filamentous intraneuronal protein inclusions containing the protein α -synuclein, distributed throughout the central, peripheral, and autonomic nervous systems. Staging schemes have been proposed for both DLB (McKeith et al., 2005) and PD (Braak et al., 2003), based on the quantity and distribution of α -synuclein pathology in brainstem, subcortical, limbic, and neocortical brain regions. However, whether and to what degree the quantity and distribution of this pathology correlates with symptom type, severity, and progression in Lewy body disorders remains a matter of debate (Burke, Dauer, & Vonsattel, 2008; Jellinger, 2008). Synaptic dysfunction and/or cell loss may provide better correlates of clinical dysfunction. Most patients with DLB have some level of AD pathology, with burden of tangle pathology influencing the likelihood of Alzheimer-type manifestations.

Treatment of DLB and PDD centers on pharmacological and non-pharmacological management of cognitive, neuropsychiatric, motor, and autonomic symptoms. Multiple studies, including a randomized placebo-controlled study with rivastigmine, have suggested efficacy of cholinesterase inhibitors for treatment of cognition, and neuropsychiatric symptoms (McKeith et al., 2000; Samuel et al., 2000). One should be mindful of the potential for these medications to exacerbate postural hypotension, falls, and hypersalivation in patients with DLB. Fewer data are available regarding memantine, but some studies suggest benefits on global clinical status and behavioral symptoms in patients with mild to moderate DLB (Emre et al., 2010). Because of the potential for neuroleptic sensitivity, antipsychotic medications should be avoided in this patient population when possible. If psychotic symptoms are very intrusive and do not respond to cholinesterase inhibitors, memantine, or behavioral strategies, low doses of atypical antipsychotics with low dopamine receptor antagonism (e.g., quetiapine or clozapine) should be used with caution (see Table 42.4). Parkinsonian symptoms may be treated with carbidopa/levodopa monotherapy, starting at low doses and increasing gradually with monitoring for worsening psychotic symptoms in particular. Low-dose melatonin (3 mg at bedtime [QHS]) or clonazepam (0.25 mg QHS) may be effective for REM sleep behavior disorder. Fludricortisone and/or midodrine may be useful in the treatment of orthostatic hypotension. Modafinil has been studied on a limited basis for treatment of fatigue and daytime somnolence in PD, with some suggestion of benefit (Tyne, Taylor, Baker, & Steiger, 2010).

PRIMARY PROGRESSIVE APHASIA

Primary progressive aphasia (PPA) is a neurodegenerative syndrome characterized by early degeneration of left hemisphere perisylvian language networks. Capturing the specificity of

early PPA for language, standard diagnostic criteria require that a patient present with a prominent isolated impairment of language, and that this impairment start insidiously, progress gradually, and account for all major limitations in activities of daily living for the initial phase of the illness (Mesulam, 2001).¹¹ Although PPAs may exist on a continuum in which various aspects of language such as word finding, object naming, syntax, or word comprehension may be more or less affected, most cases of PPA can be categorized in the early stages primarily as disorders of grammatical processing (PPA-G), semantic processing (PPA-S), or reduced verbal output with word-finding difficulties and frequently impaired repetition of sentences or phrases (logopenic PPA, or PPA-L) (Gorno-Tempini et al., 2011). There is a paucity of epidemiological data directly pertaining to PPA and its subtypes, but inference from the literature on FTLT and PPA-L suggests a prevalence on the order of 1–6 cases per 100,000, an annual incidence on the order of 0.4–1.4 cases per 100,000 person-years, and an average age of onset in the 50s or early 60s (Grossman, 2010; Mesulam, 2008).

PPA-G is characterized by effortful, non-fluent speech with impaired syntax and grammar. Apraxia of speech (AOS), a motor-based disorder of speech that produces speech sound errors, errors of stress assignment, and trial-and-error attempts to correct articulation, is frequently present (Josephs, Duffy, et al., 2006). Whereas comprehension of syntactically complex sentences is often impaired, comprehension of single words and knowledge of objects are typically preserved. Structural and functional imaging studies suggest that the left posterior frontal cortex (including premotor, supplementary motor area, and posterior inferior frontal areas) and insula degenerate early (Gorno-Tempini et al., 2004; Josephs, Duffy, et al., 2006). The majority of PPA-G cases examined pathologically have exhibited underlying FTLT-tau pathology, particularly when associated with AOS. Less frequently, PPA-G has been associated with underlying AD pathology or FTLT-TDP pathology (Grossman, 2010; Josephs, Duffy et al., 2006; M. Mesulam, 2008).

PPA-S is characterized by fluent, grammatical speech with dramatic early impairments in confrontation naming and understanding the meaning of single words. Examination frequently reveals additional features such as impaired reading or spelling of orthographically irregular words (i.e., surface dyslexia or dysgraphia), and impaired object knowledge (Gorno-Tempini et al., 2011). Neuropsychiatric features including obsessive-compulsive tendencies and behavioral disinhibition frequently follow language dysfunction (Seeley et al., 2005). Significant early atrophy and hypometabolism/hypoperfusion in PPA-S occurs in the anterior temporal lobes, usually ventral, lateral, and asymmetrical, left greater than right (Figure 42.3) (Gorno-Tempini et al., 2011). Patients with asymmetrical right greater than left early anterior temporal degeneration more frequently develop behavioral symptoms, topographical disorientation, or prosopagnosia prior to language impairment (Chan et al., 2009; Josephs,

11. See Mesulam, 2001; and Gorno-Tempini et al., 2011, for full diagnostic criteria.

Whitwell, et al., 2009). Neuropathological studies have suggested that the majority of PPA-S cases have underlying FTLTD-TDP pathology (Grossman, 2010).

PPA-L is characterized by significant word-retrieval difficulties poor repetition of phrases and sentences, phonological errors in speech, but preserved grammar, motor output, and repetition and comprehension of single words (Gorno-Tempini et al., 2004). Imaging evidence consists of atrophy and/or hypoperfusion or hypometabolism in left posterior perisylvian temporal and parietal cortex (Gorno-Tempini et al., 2011). There are few clinical/pathological reports pertaining to logopenic PPA, but the data available suggest that a majority of cases exhibit underlying AD pathology (Grossman, 2010; M. Mesulam, 2008).

To date no medications have proven symptomatic benefit for PPA. Additional data are required to determine whether or not cholinesterase inhibitors and/or memantine may have benefit for subsets of patients (Boxer et al., 2009; Johnson et al., 2010; Kertesz et al., 2008). Speech and language therapy may provide patients and their families with compensatory strategies for coping with changes and optimizing language function.

BEHAVIORAL-VARIANT FRONTOTEMPORAL DEMENTIA

Unlike most other neurodegenerative dementias, the behavioral-variant of frontotemporal dementia (bvFTD) produces dramatic early changes in personality, comportment, and demeanor. Such changes frequently take the form of apathy, disinhibition, stereotyped or stimulus-bound behaviors, perseveration, mental rigidity, hoarding, loss of empathy, blunted affect, and changes in food preference, typically towards sweet foods. Insight into cognitive and behavioral changes is typically quite limited. Early diagnosis can be challenging because of the overlap between bvFTD and psychiatric disorders and because cognitive difficulties are usually overshadowed by behavioral changes. A subset of patients, usually male, who meet

behavioral criteria for a diagnosis of bvFTD but remain stable as opposed to progressing to incapacitating dementia may have developmental disorders on the spectrum of Asperger syndrome with decompensation in middle age related to altered life circumstances (Davies et al., 2006; Piguet, Hornberger, Mioshi, & Hodges, 2011). Documentation of clear impairment on neuropsychological measures of executive function, unambiguous progression, and abnormalities on structural or functional neuroimaging increase the likelihood of progressive, degenerative bvFTD¹² (Rascovsky et al., 2007).

The incidence of bvFTD is highest in the group of individuals with early-onset dementia (aged 45–64), although less common cases occur in the very young (20s–30s) or the very old. Epidemiological studies suggest a prevalence of 3.5–15 cases per 100,000 for all syndromes associated with FTLTD (bvFTD, PPA-S, PPA-G) in the age group 45–64, of which approximately 60–80% of cases are bvFTD (Grossman et al., 2007; Knopman et al., 2005; Snowden, Neary, & Mann, 2007). Gene mutations account for about 10–20% of cases, with an autosomal dominant pattern of inheritance clear in about 10% (Piguet et al., 2011). Mutations in the genes encoding tau and progranulin (*MAPT* and *GRN*) account for the greatest proportion of genetic cases. Genetic counseling and screening for mutations in these genes may be offered to individuals with one or more first degree relatives with an illness in the FTD spectrum. A smaller proportion of genetic cases are due to mutations in the genes *C9ORF72*, *VCP*, *TARDBP*, or *CHMP2B*.

Performance on standard neuropsychological measures and on scales such as the MMSE may be largely preserved early, but selected tests of executive function, decision making, emotion detection, and theory of mind have utility (Torralva, Roca, Gleichgerricht, Bekinschtein, & Manes, 2009). General neurological examination may reveal evidence of motor neuron disease (frontotemporal dementia with amyotrophic lateral sclerosis, or FTD-ALS), which occurs concomitantly with bvFTD in approximately 10% of cases. Parkinsonism and bvFTD may coexist in cases with underlying FTLTD-tau pathology such as with *MAPT* mutations, CBD, or PSP, as well as familial cohorts with FTLTD-TDP pathology due to mutations in *GRN* or *C9ORF72*. Structural imaging findings in bvFTD series are heterogeneous but most frequently reveal atrophy of the mesial frontal, orbitofrontal and anterior insula cortices (Figure 42.4) (Seeley et al., 2008). Similarly, perfusion SPECT and FDG-PET reveal a frontal distribution of hypoperfusion or hypometabolism (Kanda et al., 2008; Varma et al., 2002).

In the future, quantitative imaging techniques may be available for clinical application to predict pathological

12. International consensus criteria for a diagnosis of “possible” bvFTD require evidence of progressive deterioration in behavior and/or cognition plus three or more of the following: (1) early behavioral disinhibition; (2) early apathy or inertia; (3) early loss of sympathy or empathy; (4) early perseverative, stereotyped, or compulsive/ritualistic behavior; (5) hyperorality and dietary changes; (6) neuropsychological profile with executive function deficits. Certainty can be increased to “probable” bvFTD by presence of significant functional decline and imaging results consistent with bvFTD. Certainty can be increased to “definite” bvFTD with histopathological evidence of FTLTD on post mortem examination or presence of a known pathogenic mutation.

Figure 42.4 Axial T1-weighted MRI of a patient with behavioral-variant frontotemporal dementia. This image demonstrates atrophy of the frontal lobes bilaterally.

subtype in bvFTD and other syndromes associated with FTLD pathology (Whitwell & Josephs, 2012). This would be particularly useful for bvFTD, a pathologically heterogeneous syndrome associated with FTLD-tau or FTLD-TDP pathologies in 90–95% of cases (in roughly equal proportions) and FTLD-FUS and other pathologies in the remainder of cases. In addition to being associated with these protein inclusions, bvFTD is characterized pathologically by bilateral frontotemporal atrophy, neuronal loss, microvacuolation, and varying degrees of astrocytic gliosis.

Few treatment trials have been conducted to assess the efficacy of pharmacological interventions in bvFTD. Mostly anecdotal evidence suggests some benefit from selective serotonin reuptake inhibitors (SSRIs) for treating impulsivity, repetitive or obsessive-compulsive behaviors, and eating disorders (Mendez, 2009). Atypical antipsychotics may be used in low doses for significant agitation, aggression, or psychosis. Cholinesterase inhibitors do not appear to be effective. Memantine has shown some promise in limited studies; further investigation with placebo-controlled trials is required (Boxer et al., 2009). Caregiver education and support are indispensable in the management of bvFTD, as strategies for dealing with problematic behaviors are required and caregiver burden is very high compared to other types of dementia (Riedijk et al., 2006).

CORTICOBASAL SYNDROME AND PROGRESSIVE SUPRANUCLEAR PALSY

Corticobasal syndrome (CBS) and progressive supranuclear palsy syndrome (PSPS) are syndromes characterized by atypical parkinsonism with varying levels of cognitive impairment and dementia. The hallmarks of CBS are asymmetrical

apraxia and extrapyramidal symptoms (rigidity, bradykinesia, tremor, dystonia) accompanied by signs of cortical involvement such as alien limb syndrome, cortical sensory loss, hemisensory neglect, visuospatial deficits, or myoclonus (Kouri, Whitwell, Josephs, Rademakers, & Dickson, 2011; Rebeiz, Kolodny, & Richardson, 1968). Other aspects of cognitive dysfunction including executive dysfunction, aphasia, and memory loss are highly variable but not uncommon (Murray et al., 2007; Wenning et al., 1998). PSPS characteristically involves severe early postural instability and falls, supranuclear gaze impairment that manifests with decreased saccade velocity or ophthalmoplegia, and an extrapyramidal syndrome with prominent axial rigidity (Steele, Richardson, & Olszewski, 1964; D. R. Williams & Lees, 2009). A majority of patients with PSPS develop a dementia syndrome with frontal and subcortical features such as disinhibition or impulsivity, apathy, social withdrawal, stimulus bound/imitative/utilization behavior, psychomotor slowing, executive dysfunction, and pseudobulbar affect (Golbe & Ohman-Strickland, 2007; Litvan, Mega, Cummings, & Fairbanks, 1996). As aforementioned, there can be substantial clinical overlap between the syndromes of CBS and PSPS in any given patient, as well as overlap with PPA-G and bvFTD (Kertesz, McMonagle, Blair, Davidson, & Munoz, 2005).

MRI in CBS characteristically reveals asymmetric atrophy of the perirolandic cortex and basal ganglia, whereas PSPS has been associated consistently with atrophy of the brainstem (particularly midbrain and superior cerebellar peduncle) and frontal white matter with lesser involvement of the frontal cortex (Boxer et al., 2006; Josephs et al., 2008). As with bvFTD, quantitative neuroimaging may help to determine underlying pathology in CBS and PSPS (Whitwell & Josephs, 2012). Although CBS is pathologically heterogeneous, focal atrophy of the posterior frontal cortex has been found to predict CBD (FTLD-tau) pathology, more widespread frontotemporal atrophy to predict FTLD-TAR DNA binding protein-43 (TDP) pathology, and more widespread temporoparietal atrophy to predict AD pathology (Whitwell et al., 2010). Unlike CBS, nearly all PSPS cases exhibit underlying FTLD-tau pathology, most commonly PSP pathology, less commonly CBD pathology (Josephs, Petersen, et al., 2006).

Pharmacological management of CBS and PSPS consists of symptomatic treatment of motor, cognitive, and mood dysfunction. One may do so in a manner analogous to that described for DLB and PDD above, noting that many CBS and PSPS patients will be less responsive to levodopa and cholinesterase inhibitors, and also less likely to demonstrate neuroleptic sensitivity. Disease-modifying therapies based on proposed pathophysiological mechanisms are being considered (Stamelou et al., 2010).

VASCULAR COGNITIVE IMPAIRMENT AND DEMENTIA

Vascular cognitive impairment (VCI) is an umbrella term that encompasses patients with MCI due to cerebrovascular disease (also termed VCI-no dementia), vascular dementia

(VaD), and mixed vascular-degenerative dementia. VaD is the second most common form of dementia in developed countries after AD (Fratiglioni et al., 2000; Lobo et al., 2000); about a third of dementia cases show significant vascular pathology at autopsy, and the estimated prevalence of VCI in people over 65 is about 5% (Moorhouse & Rockwood, 2008). Challenges in the diagnosis of VaD are posed by its pathophysiological heterogeneity, lack of a consensus pathological gold standard, and frequent coexistence with neurodegenerative pathology. Diverse processes such as large-vessel cerebrovascular disease, small-vessel disease, chronic non-infarct ischemic changes, and hemorrhage are all associated with VaD. Although both correlation between the time course of stroke and cognitive dysfunction and neuroimaging evidence of vascular disease can provide useful evidence of VaD, the sensitivity of these features has been demonstrated to be suboptimal (Gold et al., 2002).

The nature and severity of cognitive dysfunction depend on the volume, quantity, and location of infarctions, ischemia, and atrophy referable to vascular disease. Deficits may be predominantly cortical or subcortical. The time course of progression may be gradual or stepwise. Single strategic infarcts in the thalamus, angular gyrus, caudate, globus pallidus, basal forebrain, or hippocampus may be sufficient to produce dementia, but many cases of VaD arise due to the cumulative effects of multifocal cortical or subcortical infarcts. Leukoaraiosis, a term for non-specific signal changes in the white matter detectable by CT or MRI, is associated with cognitive and functional decline, but as of yet without clear associations with particular cognitive domains (Moorhouse & Rockwood, 2008). Although executive dysfunction is not uncommon in VaD, and diffuse subcortical infarcts or ischemia may produce a syndrome of subcortical dementia with prominent executive impairment, clinical/pathological studies suggest that executive dysfunction is neither sensitive nor specific for VaD and should not be employed as a diagnostic marker (Reed et al., 2007).

Diagnosis of VCI and VaD requires a clinical judgement that vascular disease is contributing significantly to a patient's cognitive or behavioral dysfunction. Such judgement is most frequently based on: (1) history (including history of stroke and risk factors for stroke); (2) examination (including examination of blood pressure, heart rate, body mass index, waist circumference, examination of the cardiovascular system, and examination for focal neurological signs in addition to a detailed MSE); and (3) neuroimaging, bearing in mind the lack of pathognomonic neuroimaging features¹³ and possible lack of correlation between infarct location and cognitive profile. Limitations in the current diagnostic criteria for VaD

most commonly used, the National Institute of Neurological Disorders and Stroke and Association Internationale pour la Recherche et l'Enseignement en Neurosciences (NINDS-AIREN) criteria, prompted the National Institute for Neurological Disorders and Stroke (NINDS) and the Canadian Stroke Network to recommend a comprehensive set of clinical and research standards for the description and study of VCI (Hachinski et al., 2006; Roman et al., 1993). These standards represent an important step in the direction of establishing a consensus diagnostic gold standard.

Treating modifiable risk factors for stroke such as hypertension, hypercholesterolemia, diabetes mellitus, smoking, and excessive alcohol intake is recommended in the treatment and prevention of VaD, although data demonstrating benefit with respect to primary and secondary prevention of stroke are more robust than data demonstrating direct benefits on cognition. Similarly, while antiplatelet therapy with aspirin, aspirin/dipyridamole, or clopidogrel offer benefit with respect to prevention of stroke in individuals at risk, no clinical trials have addressed the issue of efficacy for VaD (Williams, Spector, Orrell, & Rands, 2000). Randomized controlled trials of cholinesterase inhibitors and memantine over six months in mild to moderate VaD have suggested small benefits of uncertain clinical significance (Kavirajan & Schneider, 2007). Further studies are required to determine whether subgroups of patients might benefit.

RAPIDLY PROGRESSIVE DEMENTIAS

Rapidly progressive dementias (RPDs) involve progression of cognitive dysfunction sub-acutely over days, weeks, or several months as opposed to the progression over months to years usually witnessed with degenerative dementias. Rapid progression should prompt consideration of a differential diagnosis highlighting prion diseases, autoimmune/inflammatory encephalopathies, and unusual presentations of typically chronic neurodegenerative dementias.

Prion Diseases

Prion diseases account for the majority of cases of RPD (Geschwind, Shu, Haman, Sejvar, & Miller, 2008; Josephs, Ahlskog, et al., 2009). Human prion diseases include Creutzfeldt-Jakob disease (CJD), variant Creutzfeldt-Jakob disease (vCJD; "mad cow disease"), kuru, familial fatal insomnia, and Gerstmann-Sträussler-Scheinker syndrome (GSS). Prion diseases most frequently occur sporadically, but may also be transmitted genetically (due to autosomal dominant mutations in the prion protein gene), iatrogenically (via contaminated surgical instruments, tissue grafts, or use of cadaveric pituitary hormones), or, in cases of kuru or variant CJD, by ingestion of contaminated tissues. Sporadic CJD (sCJD) constitutes the most common form of human prion disease, with an incidence of approximately one case per million individuals per year worldwide (Ladogana et al., 2005).

Characteristic features of CJD, in addition to rapid cognitive decline, include focal higher cortical signs (such as apraxia, agnosia, or aphasia), akinetic mutism, myoclonus, pyramidal

13. In selected uncommon circumstances such as VCI/VaD due to cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL) or cerebral amyloid angiopathy (CAA), MRI results have high sensitivity and specificity. CADASIL characteristically produces T2 hyperintensities in the temporal poles and external capsules. CAA characteristically produces multiple hemorrhages (apparent on gradient echo or susceptibility weighted MRI) restricted to lobar, cortical, or cortico-subcortical regions. See Knudsen et al. (2001), *Neurology* 56(4), 537–539; O'Sullivan et al. (2001), *Neurology* 56(5), 628–634.

Figure 42.5 Diffusion-weighted MRI of a patient with Creutzfeldt-Jakob disease. This image demonstrates restricted diffusion diffusely along the cortical ribbon and in the basal ganglia.

or extrapyramidal signs, cerebellar signs, and visual dysfunction. The presence of restricted diffusion along the cortical ribbon and/or within deep gray structures (striatum and/or thalamus) is both sensitive and specific for CJD (Figure 42.5) (Vitali et al., 2011; Young et al., 2005). Diagnosis may be supported by the presence of periodic sharp wave complexes (PSWCs) on EEG and/or 14-3-3 protein in the CSF. Median survival is five months from onset of symptoms (Collins et al., 2006). Disease phenotype, including symptoms, signs, distribution of MRI signal abnormalities, EEG results, CSF results, and disease duration, is influenced considerably by the molecular subtype of illness (Parchi et al., 1999).¹⁴

Prion diseases have characteristic pathological features, including neuronal loss, glial proliferation, vacuoles in the neuropil (producing a “spongiform” appearance), and absence of inflammation (Prusiner, 1998). Pathophysiology involves the transformation of a normal cellular prion protein (PRPc) to a pathogenic isoform (PRPsc) via a three-dimensional conformational change. Pathogenic PRPsc spreads rapidly through the brain via trans-synaptic mechanisms. There are no treatments with established efficacy for prion diseases.

Autoimmune/Inflammatory Encephalopathies

Autoimmune or inflammatory causes of dementia merit consideration in the appropriate clinical setting, especially because they may respond to treatment more dramatically than other types of dementia such as neurodegenerative illness. The spectrum of autoimmune dementias is large; in some instances specific autoantibodies have been defined and pathogenic mechanisms relatively well delineated, while in others, disease mechanisms remain poorly defined and

the presence of autoimmunity is inferred on the basis of responsiveness to immunosuppression (Flanagan et al., 2010; Rosenbloom, Smith, Akdal, & Geschwind, 2009). Clinical features that should prompt consideration of an autoimmune cause of dementia include subacute onset and rapid progression of cognitive dysfunction, fluctuating course, coexisting organ-specific autoimmunity, evidence of inflammation in the CSF, or MRI suggestive of encephalitis.

Hashimoto encephalopathy (HE) and antibody-associated encephalitis (AAE) are two types of autoimmune illness particularly noteworthy in the context of RPD. HE is defined by cognitive dysfunction in the setting of high titers of anti-thyroid antibodies (anti-thyroid peroxidase, anti-thyroglobulin, or anti-microsomal antibodies), and absence of any other clear etiology for the cognitive dysfunction (Brain, Jellinek, & Ball, 1966; Chong, Rowland, & Utiger, 2003). The majority of individuals with HE have a fluctuating, relapsing, and remitting course; the minority, a subacute progressive course. Transient aphasia, tremor, seizures, gait ataxia, and hypersomnolence are frequently observed features, although the presentation is highly variable and numerous other signs and symptoms have been reported (Marshall & Doyle, 2006). Approximately 80% of cases exhibit elevated levels of total protein in the CSF; much fewer have elevated leukocytes, oligoclonal bands, or elevated IgG synthesis or index. Greater than 90% of reported cases have EEG abnormalities, most frequently consisting of generalized slowing, less frequently of focal slowing, epileptiform changes, or triphasic waves. MRI findings have consisted of normal or nonspecific findings in the majority of reported cases, although a few reported cases have demonstrated diffuse T2 hyperintensities in white matter.

The pathogenesis of HE remains unclear, as does the role, if any, anti-thyroid antibodies play in the encephalopathy. Limited pathological studies have most commonly revealed perivascular lymphocytic infiltrates in the brain parenchyma and/or leptomeninges, with or without gliosis. Similar clinical characteristics and pathology have been reported in encephalopathies in patients with other autoimmune diseases such as Sjögren syndrome and systemic lupus erythematosus, leading some authors to group these conditions under the rubric of nonvasculitic autoimmune inflammatory meningoencephalitis (NAIM) (Caselli, Boeve, Scheithauer, O'Duffy, & Hunder, 1999; Lyons, Caselli, & Parisi, 2008). Clinicians have most frequently treated HE and NAIM with high-dose intravenous corticosteroids as a first line of therapy (Castillo et al., 2006), additionally treating hypothyroidism and seizures as necessary. Alternative immunomodulatory treatments, including cyclophosphamide, azathioprine, methotrexate, intravenous immunoglobulin (IVIg), and plasmapheresis, have been employed with some success in cases where corticosteroids were not effective or were contraindicated (Marshall & Doyle, 2006).

Antibody-associated encephalitis (AAE) are encephalitis associated with antibodies reactive to neuronal antigens. Several such antibodies have been established, including (but not limited to) anti-Hu, anti-Ma2, anti-CV2, anti-VGKC, anti-amphiphysin, anti-Yo, anti-nCMAg, anti-Ma1, anti-Ri,

14. Subtypes, defined by the methionine-valine polymorphism at codon 129 of the prion protein and by the type of prion protein (type 1 or type 2): MM1 and MV1 (“classic”), VV2 (“ataxic”), MV2 (“kuru plaque”), MM2-cortical, MM2-thalamic, and VV1. MM1 and MV1 account for ~70% of cases and are characterized most frequently by cognitive deficits, myoclonus, ataxia, pyramidal signs, PSWCs on EEG, and 14-3-3 protein in CSF.

anti-GAD65, anti-NMDAR, and anti-neuropil antibodies. In many cases, AAE is paraneoplastic, either preceding or following the diagnosis of cancer by weeks, months, or rarely, one to several years. The most common neoplasms associated with paraneoplastic AAE include small-cell lung cancer, germ-cell tumors, thymoma, Hodgkin's lymphoma, and breast cancer (Gultekin et al., 2000). Age of onset of AAE ranges from childhood to older adulthood, depending in part upon the tumor and antibody associations involved.

AAE may occur as focal limbic encephalitis or be associated with more widespread involvement of the nervous system (i.e., brainstem, cerebellum, spinal cord). Limbic encephalitis frequently presents as a subacute amnesic syndrome with accompanying neuropsychiatric symptoms (depression, personality changes, anxiety, emotional lability) and seizures. More than 80% of these patients have an abnormality in the CSF, most frequently a mild elevation in protein with or without a mild pleocytosis (Daffner, Sherman, Gonzalez, & Hasserjian, 2008). Over 90% demonstrate abnormalities on EEG, including focal or generalized slowing and/or epileptiform activity. Only about 50–65% demonstrate MRI abnormalities of increased T2 signal in the medial temporal lobes and/or other limbic structures.

Comprehensive workup to evaluate for an underlying neoplasm is indicated in all cases of suspected or confirmed AAE. This workup may include CT scanning of the whole body, with and without contrast; PET scanning of the whole body; tests for tumor markers in the blood; mammography; and ultrasound studies. Aggressive treatment of an underlying neoplasm in conjunction with immunomodulatory therapies with IVIg, plasmapheresis, corticosteroids, or cytotoxic agents provides benefit to a subset of patients. Presence of antibodies reactive to cell membrane antigens (anti-VGKC, anti-NMDAR) may confer a more favorable prognosis than presence of antibodies reactive to intracellular antigens (Bataller et al., 2007).

COMMON DEMENTIA MIMICS

A fair proportion of individuals presenting for evaluation of cognitive changes turn out to have potentially reversible medical or psychiatric illness. Though not entirely specific, potential concern about symptoms by the patient exceeding that of loved ones is one predictive factor of non-progressive, non-degenerative illness. As noted above, one should screen for symptoms of depression, anxiety, and bipolar disease as a routine part of the cognitive assessment. Such symptoms may not be superficially apparent in patients who have cognitive dysfunction related to a maladaptive response to significant life stressors. This syndrome may exist on a spectrum with post-traumatic stress disorder. Characteristics include elements of dissociation and a cognitive profile suggestive of attentional/executive dysfunction, and poor memory encoding and retrieval.

This cognitive profile is common to other medical and psychiatric causes of cognitive dysfunction (Millan et al., 2012). Relatively common medical contributing factors include obstructive sleep apnea, history of chemotherapy, and chronic

pain (Aloia, Arnedt, Davis, Riggs, & Byrd, 2004; Kannarkat, Lasher, & Schiff, 2007). Severe melancholic and/or psychotic depression in older individuals can cause dementia but be mistaken for neurodegenerative illness, especially when it is not responsive to antidepressant medications (Wagner, McClintock, Rosenquist, McCall, & Kahn, 2011). Electroconvulsive therapy may provide cognitive as well as mood benefits in such patients.

TREATMENT OF DEMENTIA

This section discusses treatment issues pertaining to dementia patients in general, specifically: (1) behavioral and lifestyle recommendations; (2) management of the neuropsychiatric symptoms of dementia; and (3) use of ancillary services and providers.

BEHAVIORAL AND LIFESTYLE RECOMMENDATIONS

Cognitive Performance and Quality of Life

In most cases, a diagnosis of dementia induces substantial fear and dread about what the future holds for patients and their families. Direct but compassionate communication by the provider about the diagnosis and what can and cannot be predicted is essential to address preconceived notions and to advocate for an active, safe lifestyle. Components of an active lifestyle that may provide psychological, physical, and even cognitive benefits include regular exercise, stimulating cognitive activities, social activities, and a healthy diet. In making lifestyle recommendations to patients and caregivers, it is important to remain aware that apathy and anxiety concerning reduced functionality are very frequent features of dementia that may lead to resistance to activities by the patient. Goals should therefore be realistic, adaptable, and always in keeping with a positive subjective experience for the patient.

Multiple studies have examined the effects of exercise on cognitive, behavioral, and psychiatric symptoms in dementia, with positive results. Exercise may improve physical functioning in patients with dementia and reduce problems related to agitation, wandering, and insomnia (Potter, Ellard, Rees, & Thorogood, 2011; Thune-Boyle, Iliffe, Cerga-Pashoja, Lowery, & Warner, 2011). A recent meta-analysis of studies pertaining to aerobic exercise and cognition suggested that exercise not only reduces risk of future MCI and dementia in healthy individuals, but it also improves cognitive scores and imaging biomarkers of cognition after 6 to 12 months in patients with MCI or dementia, compared with sedentary controls (Ahlskog, Geda, Graff-Radford, & Petersen, 2011).

As with exercise, accumulating evidence suggests that a healthy diet not only reduces risk for cardiovascular and cerebrovascular disease, but also may influence the risk and rate of progression of neurodegenerative pathology. Specifically, adherence to a “Mediterranean-type” diet appears to reduce the risk of cognitive impairment and dementia in healthy individuals, and it may slow cognitive decline in individuals diagnosed

with MCI or AD (Solfrizzi et al., 2011). The Mediterranean diet emphasizes consumption of vegetables, fruits, unrefined whole-grain foods, and fish, while limiting foods containing trans-fat, cholesterol, added sugars, and salt.

Data from trials support the notion that activities that offer cognitive and social stimulation to patients with dementia are more likely to provide benefit than those that do not. Cognitive stimulation, an intervention usually presenting a range of activities aimed at general enhancement of cognitive and social functioning in a small-group setting, appears to consistently promote cognition, and possibly overall quality of life in patients with mild to moderate dementia (Buschert, Bokde, & Hampel, 2010; Woods, Aguirre, Spector, & Orrell, 2012). These data are consistent with studies in healthy older people suggesting that cognitively stimulating activities and social activity are associated with a lower risk of incipient dementia (James, Wilson, Barnes, & Bennett, 2011; Wilson et al., 2003).

Safety

The loss of independence inherently associated with dementia is one of the most challenging aspects of the condition for both patients and caregivers. Continued performance of routine activities within a patient's capabilities should be encouraged, as long as the safety of the patient or of others is not compromised. Driving is perhaps the most common example of an activity that poses substantial risk, usually not recognized by the patient. More than loss of memory, impairments in attention, executive functions, and visuospatial functions increase one's risk of accidents (Silva, Laks, & Engelhardt, 2009). An AAN practice parameter published in 2010 identified the following factors as predictive for unsafe driving: (1) dementia severity, including CDR global score of 1 or greater and/or MMSE of 24 or below; (2) self-reported situational avoidance or reduced driving mileage; (3) caregiver's rating of driving as "marginal" or "unsafe"; (4) a history of accidents or citations; and (5) impulsive or aggressive personality characteristics (Iverson et al., 2010). Individuals with dementia at low to moderate risk of accidents should be strongly encouraged to consider voluntary surrender of driving privileges or to undergo a professional driving evaluation. Noncompliant patients determined to be at high risk of accidents should be subject to intervention per applicable laws.

Examples of other potentially unsafe situations or activities include cooking without supervision when there is the potential to leave a stove or oven on, operating power tools or appliances during which a lapse in attention could cause significant bodily harm, and keeping firearms or other weapons in the house. Patients with dementia who have a propensity to wander but who do not require 24-hour supervision for other indications may benefit from wearing a monitor and/or from measures to prevent them from leaving the house unsupervised. Patient self-administration of medications should be monitored for errors, and assistance provided when necessary. Pill boxes with designated slots for different days and times may help reduce confusion about what medications should be taken when.

MANAGEMENT OF THE NEUROPSYCHIATRIC SYMPTOMS OF DEMENTIA

As reviewed above for specific dementia syndromes, neuropsychiatric symptoms of dementia (also termed "behavioral and psychological symptoms of dementia," or BPSD, in the literature) arise in nearly every dementia patient. Neuropsychiatric symptoms tend to cluster into syndromes of agitation, psychosis, or mood disorders, but these syndromes frequently coexist in the same patient (Ballard & Corbett, 2010). Pharmacological and non-pharmacological treatment strategies should be tailored to the type and severity of symptoms.

Depression, Anxiety, and Apathy

Despite the high prevalence of depression in dementia, relatively few randomized, controlled clinical trials have assessed the efficacy of the antidepressant medications most widely used in clinical practice. Those that have—for example, recent trials evaluating the efficacy of sertraline or mirtazapine for depressive symptoms in patients with AD—have not suggested benefit vs. placebo and have suggested a relatively high rate of side effects (Banerjee et al., 2011; Rosenberg et al., 2010). For this reason, consideration should be given to non-pharmacological treatments as a first line of therapy unless depression is severe. Non-pharmacological treatments may include cognitive stimulation, psychotherapy, exercise, occupational therapy with attention to environmental factors contributing to mood, and teaching caregivers behavioral management techniques (Brodaty, 2011). If not already started for enhancement of cognition, a cholinesterase inhibitor may also enhance mood, particularly in AD or Lewy body disorders (Ballard & Corbett, 2010). SSRIs may have greater efficacy for treatment of anxiety and irritability in dementia, although most data on the issue pertain to patients with more severe agitation and aggression (discussed below).

Most of the available evidence for pharmacological treatment of apathy in dementia comes from studies in which the primary endpoints involved other symptoms of dementia and measures of apathy were embedded in behavioral scales such as the Neuropsychiatric Inventory (Berman, Brodaty, Withall, & Seeher, 2012). From these studies, conducted largely in patients with AD, cholinesterase inhibitors demonstrated the clearest and most consistent benefits. Limited studies containing apathy measures that evaluated memantine or methylphenidate have likewise suggested benefit (Dolder, Davis, & McKinsey, 2010). Although available data do not suggest considerable benefit from antidepressant medications, those studied have not included the more "activating" antidepressants such as bupropion or serotonin-norepinephrine reuptake inhibitors (SNRIs). Dopamine agonists have been used off-label with some success for treating apathy related to other neurological conditions, such as stroke (Kohn et al., 2010), but have not been widely studied in dementia. Non-pharmacological treatments for apathy in dementia, including cognitive stimulation, cognitive-communication

therapy, and multisensory stimulation, require further investigation (Roth, Flashman, & McAllister, 2007).

Insomnia

Disturbances of sleep are highly prevalent in dementia, and may be due to any number of factors, such as effects of the neurodegenerative process on neural mechanisms underlying the circadian rhythm, primary sleep disorders occurring concomitantly with the dementia, medical or psychiatric comorbidities, medication side effects, and environmental or behavioral factors. Accordingly, one's first step in managing insomnia in a patient with dementia should be to identify and treat the specific factors contributing to insomnia in that particular patient. Polysomnography may be useful to identify sleep disorders such as restless legs syndrome (RLS), periodic limb movements in sleep, REM sleep behavior disorder, and obstructive or central sleep apnea. Non-essential medications associated with insomnia, including cholinesterase inhibitors and anti-Parkinsonian medications, should be discontinued. Non-pharmacological therapies such as light therapy, daytime exercise, and behavioral interventions¹⁵ should be employed prior to the use of medications.

There is no clear standard of care in the pharmacological treatment of insomnia in dementia. Of the available options, melatonin and the melatonin receptor agonist ramelteon have the lowest likelihood of adverse cognitive effects, although some studies have suggested limited efficacy (Serfaty, Kennell-Webb, Warner, Blizard, & Raven, 2002; Singer et al., 2003). Antihistamines should be avoided due to frequent side effects such as anticholinergic effects that can exacerbate cognitive impairment. Despite its widespread use, evidence for the efficacy of trazodone in insomnia is scant (Mendelson, 2005). Other options, including non-benzodiazepine hypnotics (zolpidem, zaleplon, eszopiclone) and atypical antipsychotics (e.g., quetiapine or olanzapine) should be used with caution and closely monitored for potential side effects. As a rule, the lowest possible effective dose should be sought over a time-limited trial, employing "as needed" rather than scheduled dosing.

Agitation and Aggression

Like insomnia, agitation and aggression occur in dementia with a multitude of possible underlying factors. Pharmacological treatment should be employed only as a last resort for patients with distressing symptoms of agitation or aggression that are unresponsive to non-pharmacological measures, unless there is imminent risk of harm to self or others. A recommended strategy is to first assess for infections, pain, constipation, or dehydration; to optimize treatment of visual and auditory

impairment; and to address potential environmental triggers such as low light or extreme noise levels (Ballard & Corbett, 2010). Non-essential medications with the potential to cause or exacerbate confusion should be eliminated, as should a patient's access to alcohol. As recommended above, the patient's sleep cycle should be reinforced via adherence to a regular schedule with good sleep hygiene.

Where possible, situations that provoke anger or agitation should be identified and avoided. For example, if a certain mode of bathing or showering is not well tolerated, alternative modes should be explored, in particular those that foster a greater sense of relative autonomy in the patient. Rather than attempt to reason with a demented patient in situations of resistance or disagreement, a caregiver should distract or gently redirect the patient. Agitation frequently arises as a response to a perceived threat, so a calm demeanor and a predictable environment with cues that promote relaxation such as music and warm lighting may provide benefit. Patient stress may also be alleviated by routine exercise in moderation, "pet" therapy with animals, validation therapy, structured social interaction, other individualized meaningful activities, and aromatherapy with lavender oil or *Melissa officinalis* lemon balm (Ballard, O'Brien, Reichelt, & Perry, 2002).

When medications are required, atypical antipsychotics have the best evidence of benefit for short-term (up to 12 weeks) treatment of aggression (Ballard & Corbett, 2010). Potential adverse reactions include extrapyramidal symptoms, drowsiness, peripheral edema, stroke, acceleration in the rate of cognitive decline, and increase in mortality. Other types of medication, including memantine, carbamazepine, or SSRIs, have limited, but better evidence for treatment of non-aggressive agitation (Gauthier, Loft, & Cummings, 2008; Pollock et al., 2007; Tariot, Loy, Ryan, Porsteinsson, & Ismail, 2002). Benzodiazepines often exacerbate cognitive and motor difficulties and may cause frank confusion or paradoxical agitation.

USE OF ANCILLARY SERVICES AND PRACTITIONERS

As reviewed above, dementia poses a variety of different medical, psychological, and social challenges. A team-based approach to treatment offers the advantage of expertise in specialized areas of treatment. Such an approach works best when one physician is the point-person for the patient and his or her caregivers, coordinating the plan of care and facilitating communication between parties when necessary.

Education about a patient's illness, its expected sequelae, and common issues it raises frequently reduces stress in patients and their caregivers. Social workers with expertise in dementia, neuropsychiatry, and/or geriatric medicine can often provide information above and beyond that offered by the primary treating physician. They may also offer strategies for dealing with specific stressors or recurrent problematic situations, psychotherapy, guidance regarding financial and legal planning, and referral information for resources in the community. Information and support are also frequently available through nonprofit organizations such as the Alzheimer's Association,

15. Behavioral interventions include maintaining consistent bedtimes and rising times; following a relaxing bedtime routine; limiting daytime napping and time spent in bed; exposing the patient to bright light (preferably sunlight) in the day; keeping sleep areas dark, quiet, and temperate at night; avoiding caffeine, alcohol, and nicotine; establishing regular meal times; avoiding excessive fluid intake in the evening; emptying the bladder before bed; and treating musculoskeletal pain.

the Association for Frontotemporal Degeneration, the Lewy Body Dementia Association, and other disease-specific groups. Certain patients and caregivers, in particular those with uncommon or lesser-known conditions, often benefit from attending support groups, where people can discuss common experiences and strategies.

Symptom-specific rehabilitation provides a stimulus for attempting to maintain function and, when this is not possible, methods for compensation. Physical therapy (PT) and occupational therapy (OT) directly address changes in motor function, including loss of dexterity, difficulty completing skilled movements or tasks, and problems with balance and gait. Assessments and plans often include recommendations regarding exercise programs and guidance about when a walking-assistance device (e.g., a cane or walker) is indicated. Home safety evaluations, frequently conducted by OT, identify modifiable features of the home environment that increase a patient's risk for falls or other potential sources of harm. Speech and language therapy targets language and other aspects of cognition. Numerous studies have suggested therapeutic benefits and adaptive brain changes associated with cognitive intervention programs in MCI and mild to moderate dementia due to AD (Buschert et al., 2010).

As with any area of medicine, knowing one's own breadth of expertise and "comfort zone" in evaluating and treating specific problems is essential so that consultation with other providers will be obtained when necessary. In the case of dementia, specific consultations within medical, neurological, or psychiatric subspecialties may be sought, depending upon the circumstance. Geriatric psychopharmacologists can provide guidance with respect to the use of medications. Various types of individual and group psychotherapy are available for consideration and selection when appropriate.

Part of the art of dementia care consists of maintaining focus on the present while simultaneously addressing selected key matters of the future in advance. A patient's wishes pertaining to end-of-life care and surrogate medical and financial decision-making should be discussed while he or she has capacity to make decisions in these areas. Legal consultation with an elder law attorney may be appropriate. Longitudinal care of the dementia patient importantly requires longitudinal monitoring of caregiver resources and stress. When a need for increased supervision or services arises, options include home care, day programs, assisted living, and nursing home care. Selecting from among these options requires careful consideration of a patient's specific needs, desires, and resources (see Chapter 83).

SUMMARY

Dementia is a major source of morbidity and mortality worldwide. Most dementias are neurodegenerative, with age being the primary risk factor. Clinical evaluation of the patient presenting with change in cognition centers on determining the dysfunction of large-scale brain networks, establishing

the time course and severity, and utilizing selected laboratory and imaging data to support one's hypothesis regarding underlying etiology. Familiarity with the key features of common causes of dementia such as AD and VaD assists in the process, as does familiarity with the salient features of less common causes including Lewy body disorders, PCA, FTD, PPA, common causes of rapidly progressive dementia, and medical and psychiatric illnesses that can cause or mimic dementia.

Symptomatic treatment of dementia includes behavioral and lifestyle modifications; optimization of factors that contribute to cognition, such as mood, anxiety, sleep, pain, and concomitant medical illness; attention to issues of safety and quality of life; and use of medications for symptomatic enhancement of cognition. Cholinesterase inhibitors and/or memantine may provide modest cognitive and behavioral benefit for patients with AD, Lewy body disorders, and possibly subgroups of patients with other types of dementia. Non-pharmacological strategies are generally preferred in the management of neuropsychiatric symptoms of dementia. When necessary and when potential benefits outweigh risks, SSRIs, other antidepressants, mood stabilizers, stimulants, and atypical antipsychotics may be useful. One should use such medications with close monitoring for side effects.

There are no disease-modifying therapies currently available for neurodegenerative dementias. Recent research has focused on the neurodegenerative process as targeting large-scale brain networks in a focal manner early in the course of illness and spreading along the lines of these networks as illnesses progress. The specific role of pathologically misfolded proteins, a feature common to the pathology of different neurodegenerative illnesses, remains unclear. Lack of efficacy of drugs targeting β -amyloid in clinical trials for patients with dementia due to AD may be due to intervention at stages that are too advanced to provide benefit. Accordingly, efforts are underway to intervene at the stages of MCI or preclinical disease, using biomarkers to establish the diagnosis. As our understanding of neurodegenerative dementias continues to expand at an incredibly rapid rate, the future holds significant promise for more effective interventions.

CLINICAL PEARLS

- Old practices of excluding reversible causes and lumping remaining cases under the headings of "senile dementia" or "Alzheimer's disease" have given way to a process of proactively identifying specific clinical syndromes and attempting to determine neuropathology *in vivo*.
- When localizing cognitive dysfunction, determine whether a pattern of deficits is predominantly *cortical* or *subcortical*; determine whether deficits are focal, multifocal, or diffuse; and determine which large-scale networks in the brain are implicated.
- In contrast to cortical dementias, subcortical dementias present with a profile of slowed processing speed, impaired attention, apathy, mood symptoms, and motor symptoms

(Albert, Feldman, & Willis, 1974). Subcortical dementias are associated with forgetfulness, but memory difficulties are predominantly at levels of encoding and retrieving information so that recognition and cued memory are preserved.

- The domain of complex attention and executive functions localizes predominantly to frontoparietal and frontal/subcortical networks in the brain (Cummings, 1993). Episodic memory localizes both to temporolimbic networks (important for encoding, retrieval, and storage), and frontal networks (important for encoding and retrieval) (Budson & Price, 2005). Behavioral regulation and social cognitive processes recruit networks predominantly involving paralimbic regions such as the orbitofrontal cortex, anterior cingulate cortex, and insula (Gleicher, Ibanez, Roca, Torralva, & Manes, 2010).
- Specific types of misfolded proteins accumulate with a limited range of possible distributions, starting focally and spreading along particular anatomical lines until there is diffuse involvement of the brain at the later stages of illness.
- The *network degeneration hypothesis* postulates that neurodegenerative processes target large-scale networks in the brain to produce characteristic progressions of neurodegeneration and clinical symptoms that depend on the pathology and networks targeted (Seeley, Crawford, Zhou, Miller, & Greicius, 2009).
- There is a need to further develop *in vivo* biomarkers of pathology. Efforts now are most advanced for AD, for which CSF analysis of β -amyloid, total tau (t-tau), and phosphorylated tau (p-tau) are already available for clinical use, and amyloid PET imaging may become available in the near future.
- Certain *red flags* suggest a less common cause of cognitive dysfunction: a non-amnesic cognitive profile, rapid progression of symptoms over days to weeks, or the early presence of additional neurological symptoms such as pyramidal or extrapyramidal motor signs, myoclonus, cerebellar signs, apraxia, psychosis, autonomic dysfunction, REM sleep behavior disorder, or seizures. Other red flags include young age (onset of symptoms before age 65 and especially before age 50), a family history suggesting autosomal dominant mode of inheritance, and prominent evidence of systemic medical or organ-specific illness not yet accounted for.
- For a diagnosis of dementia, the Quality Standards Subcommittee of the American Academy of Neurology (AAN) recommended structural neuroimaging of the brain with CT or MRI, routine screening for depression, vitamin B₁₂ deficiency, and hypothyroidism as part of a routine evaluation (Knopman et al., 2001). Many practitioners also obtain a comprehensive metabolic profile, CBC, and urinalysis (see Table 42.2).
- In the population of those with early-onset dementia (onset of symptoms between the ages of 45 and 65),

Alzheimer's disease and vascular dementia continue to be the most common etiologies, but a much higher proportion of cases is due to frontotemporal lobar degeneration (FTLD) pathology compared to the population with late-onset dementia (Garre-Olmo et al., 2010; Picard, Pasquier, Martinaud, Hannequin, & Godefroy, 2011).

- Experts recommend offering testing for gene mutations associated with familial, autosomal dominant, early-onset AD to individuals with early-onset AD and a family history of dementia (or unknown family history); individuals with a family history suggestive of autosomal dominant dementia and at least one case of early-onset AD, and individuals with a relative who has a known gene mutation (Goldman et al., 2011). Referral to a genetic counselor is imperative for all individuals who desire testing, and recommended for those who are undecided and would like to discuss the issue further.
- Although comportment and social demeanor are typically preserved until late in the course of AD, neuropsychiatric features such as mild apathy, social withdrawal, anxiety, and irritability are common early (Lyketsos et al., 2011).
- Available data do not suggest clear superiority of any one of the three cholinesterase inhibitors currently in wide use (donepezil, galantamine, rivastigmine).
- Limited data on CSF biomarkers in AD compared to other neurodegenerative dementias with pathological confirmation suggest that combined use of β -amyloid 42 and p-tau levels yields a sensitivity of over 95% and a specificity of over 80% (Schoonenboom et al., 2012).
- Combination therapy with both a cholinesterase inhibitor and memantine appears to provide benefit beyond treatment with just a cholinesterase inhibitor (Atri, Shaughnessy, Locascio, & Growdon, 2008). Potential side effects of memantine include dizziness, headache, GI side effects, hypertension, and confusion.
- Examination of patients with posterior cortical atrophy (PCA) commonly reveals elements of the syndromes of Bálint (simultagnosia, optic ataxia, and oculomotor apraxia) and Gerstmann (agraphia, acalculia, left-right confusion, and finger agnosia¹⁶). Impairments in executive functions, language, and memory are variable early in the course of illness, but memory storage is frequently preserved. PCA patients commonly report visual hallucinations and/or positive perceptual phenomena, including color after-images, reverse size phenomena, perception of movement of static stimuli, and visual crowding (Crutch et al., 2012). Treatment for depression, anxiety, and Parkinsonism may provide benefit in some cases.

16. Finger agnosia, defined as an inability to distinguish, name, or recognize fingers, usually occurs in the setting of a more generalized disturbance in awareness of body parts and their orientation, and is also associated with disturbances in balance and/or dressing apraxia.

- The cognitive profile of both PDD and DLB usually involves early dysfunction in complex attention, executive functions, and visuospatial processing (Bradshaw, Saling, Anderson, Hopwood, & Brodtmann, 2006; Mosimann et al., 2004). Fluctuations in attention, alertness, or cognition of varying intensity and duration are considered to be a *core* feature of DLB (present in 50–75% of cases), but are also observed frequently in PDD (McKeith et al., 2005).¹⁷ The other two core features of DLB are visual hallucinations that are often vivid, three-dimensional hallucinations of animate objects, and parkinsonism.
- Additional features that may be present in both DLB and PDD (but that are more commonly present in DLB) include REM sleep behavior disorder, severe sensitivity to neuroleptic medications, and autonomic dysfunction.
- Unlike most other neurodegenerative dementias, the behavioral-variant of frontotemporal dementia (bvFTD) produces dramatic early changes in personality, comportment, and demeanor, in the form of apathy, disinhibition, stereotyped or stimulus-bound behaviors, perseveration, mental rigidity, hoarding, loss of empathy, blunted affect, and changes in food preference, typically towards sweet foods. The patient's insight into these cognitive and behavioral changes is typically quite limited.
- Hashimoto encephalopathy (HE) and antibody-associated encephalitis (AAE) are two types of autoimmune illness. HE is defined by cognitive dysfunction in the setting of high titers of anti-thyroid antibodies (anti-thyroid peroxidase, anti-thyroglobulin, or anti-microsomal antibodies), and absence of any other clear etiology for the cognitive dysfunction (Brain, Jellinek, & Ball, 1966; Chong, Rowland, & Utiger, 2003).
- The most common neoplasms associated with paraneoplastic AAE include small-cell lung cancer, germ-cell tumors, thymoma, Hodgkin lymphoma, and breast cancer (Gultekin et al., 2000).

EPILEPSY AND SEIZURES

W. Curt LaFrance, Jr., and Andres M. Kanner

INTRODUCTION

When evaluating a patient with seizures, the first step is to establish whether the paroxysmal episodes are in fact epileptic seizures or physiological non-epileptic events or psychogenic non-epileptic seizures (Kaplan & Fisher, 2005; Schachter & LaFrance Jr., 2010). Indeed, one out of every four to five patients admitted to an epilepsy center with a diagnosis of treatment-resistant epilepsy (TRE) does not suffer from epilepsy. Several physiological non-epileptic events must be considered; such as sleep disorders, syncope, migraines, or transient ischemic attacks, as well as movement disorders. If the patient has epilepsy, it is essential to establish the type of epileptic syndrome and the type of seizures. As with any other neurological or psychiatric disorder, a detailed history of the paroxysmal events is of the essence.

The initial workup of the patient with seizures includes an electroencephalogram (EEG) with awake and asleep recordings and activation procedures, structural neuroimaging, and also an evaluation of the psychiatric comorbidities in epilepsy. If the routine EEG study coupled with the clinical history and neurological exam does not provide enough information to reach an adequate diagnosis, a prolonged (24–72-hour) EEG study can be considered, either as an ambulatory outpatient study or an inpatient one, preferably with video. Patients with focal epilepsy or refractory seizures should undergo pre-surgical evaluation (Fountain, Van Ness, Swain-Eng, Tonn, & Bever, 2010). A list of anti-seizure medications used for treatment of epilepsy and their pharmacological activity is found in Tables 43.1 and 43.2.

COMORBID DISORDERS IN EPILEPSY

Patients with epilepsy (PWE) have been found to be at higher risk of suffering from mood, anxiety, psychotic, and attention-deficit disorders and non-epileptic seizures (Benbadis, Agrawal, & Tatum IV, 2001; Benbadis & Hauser, 2000;; Bredkjaer, Mortensen, & Parnas, 1998; Brown et al., 2001; Currie, Heathfield, Henson, & Scott, 1971; Edeh & Toone, 1987; Ettinger et al., 2005; Jacoby, Baker, Steen, Potts, & Chadwick, 1996; Kessler et al., 1994; Kogeorgos, Fonagy, & Scott, 1982; McDermott et al., 1995; Mendez, Cummings, & Benson, 1986; O'Donoghue, Goodridge, Redhead, Sander, & Duncan, 1999; Onuma, Adachi, Ishida,

Katou, & Uesugi, 1995; Pariente, Lepine, & Lellouch, 1991; Perini et al., 1996; Regier et al., 1993; Roy-Byrne et al., 1999; Rutter et al., 1970; Schmitz & Wolf, 1995; Semrud-Clikeman & Wical, 1999; Walsh et al., 1986). (See Table 43.3.) The wide ranges of prevalence reflect the different patient populations surveyed and the different assessment techniques.

By the same token, there is evidence of a bidirectional relationship between some psychiatric disorders and epilepsy. Patients with a history of major depressive disorders or suicidality (independent of a major depressive disorder) have a four- to seven-fold greater risk of developing epilepsy (Forsgren & Nystrom, 1990; Hesdorffer, Hauser, Annegers, & Cascino, 2000; Hesdorffer, Hauser, Olafsson, Ludvigsson, & Kjartansson, 2006). Furthermore, children with a history of attention-deficit disorder of the inattentive type have a 3.7-fold higher risk of developing epilepsy (Hesdorffer et al., 2004). Further support of the bidirectional relationship model comes from a study of patients with chronic temporal lobe epilepsy (TLE), revealing progression of psychiatric comorbidity even after controlling for pre-morbid psychiatric history (Jones, Bell, et al., 2007). Jones et al. (Jones, Watson, et al., 2007) found that 45% of adolescents with new-onset epilepsy met criteria for an Axis I diagnosis according to the *Diagnostic and Statistical Manual of Mental Disorders IV Text Revision* (DSM-IV-TR) classification, while McAfee et al. reported that children with a psychiatric comorbid diagnosis were almost three times more likely to develop epilepsy than those without (McAfee et al., 2007). Clearly, the relationship between psychiatric disorders and epilepsy is complex and is not only the consequence of the epileptic disorder.

BIDIRECTIONAL RELATIONSHIP AND ANIMAL MODELS

Experimental animal data have supported the bidirectional relationship between epilepsy and depression. The assessment of "symptoms of depression" in rats (Sillaber, Holsboer, & Wotjak, 2009) has been carried out with two tests, among others: the quantification of saccharin in water (saccharin consumption test [SCT]), where a lower consumption is considered to be equivalent to anhedonia, as rats love this ingredient. The second test, known as the freezing swim test (FST), is based on the rats' dislike of swimming in water and their tendency to "freeze" when placed in a container of water. It consists of a measurement of immobility time when

Table 43.1 CHOICE OF AEDS FOR SPECIFIC SEIZURE/ EPILEPSY TYPES

EPILEPSY TYPE	FIRST LINE	SECOND LINE	THIRD LINE
Focal (Partial)	Carbamazepine	Gabapentin	Phenobarbital
	Phenytoin	Lamotrigine	Primidone
	Valproate	Topiramate	Felbamate
	Tiagabine	Ezogabine	
	Ethotoin	Levetiracetam	
	Oxcarbazepine	Zonisamide	
	Primidone	Lacosamide	
Idiopathic Generalized:			
Absence	Ethosuximide	Methsuximide	
	Valproate	Clonazepam	
	Methsuximide		
Myoclonic	Valproate	Clonazepam	
	Lamotrigine	Levetiracetam	
	Topiramate		
	Primidone		
Tonic-clonic	Valproate	Lamotrigine	Phenobarbital
	Phenytoin	Topiramate	Primidone
	Carbamazepine	Levetiracetam	
	Primidone		
	Ethotoin		
Symptomatic Generalized:			
	Valproate	Clonazepam	Felbamate
		Lamotrigine	
		Topiramate	
		Levetiracetam	

Primidone: generalized “grand mal”, psychomotor, focal
Rufinamide/clobazam—adjunctive for treatment of seizures associated with Lennox-Gastaut syndrome
Idiopathic generalized epilepsy: Levetiracetam

placed in a container with water. A long period of immobility when placed in a water container is considered to be a symptom equivalent of “despair.” Finally, separation of newly born rats from their dam has also been used as an animal model of depression. The assessment of “symptoms of anxiety” in rats is done by measuring the time spent in the open arms of the elevated plus maze, a behavioral experimental paradigm. A reduced time spent in the open arms is considered to be equivalent to symptoms of anxiety.

Epilepsy Facilitates the Development of Phenomena Equivalent to Depression in Animal Models

Using a common animal model of temporal lobe epilepsy (TLE), the lithium and pilocarpine-induced status epilepticus (SE) model with male Wistar rats, Mazarati et al. (Mazarati et al., 2008) demonstrated an increase in immobility time in the FST and decreased consumption of saccharin in the SCT in post-SE animals. This finding was associated with a decrease of serotonin (5-HT) concentrations and turnover in

the hippocampus, and of 5-HT release from the hippocampus in response to raphe nuclei stimulation.

Depression Facilitates the Development of Epileptic Activity

Three studies have shown that early maternal separation (MS) of rats or cross-fostering at birth can accelerate the kindling process. In two of the three studies, male and female non-epileptic rats underwent MS on postnatal days 2–14 for 180 min/day or early handling (EH) and brief separation (15 min/day). At seven weeks of age, rats of both genders exposed to MS displayed significantly increased anxiety, as evidenced by reduced time spent in the open arms of the elevated plus maze compared with EH rats. In females, but not in males, fewer stimulations were required following MS than EH to reach the fully kindled state (39.6 +/- 6.4 vs. 67.1 +/- 9.4; p < 0.0001) (Jones et al., 2009; Salzberg et al., 2007). Likewise, in the third study, cross-fostering was used as a model for early-life stress in seizure-prone (FAST) and seizure resistant (SLOW) rats. The animals underwent amygdala kindling (where repeated stimulation generated seizures), until six Class V seizures were recorded. An increased kindling rate was observed among all cross-fostered rats compared to non-fostered rats (Gilby et al., 2009).

Comorbidity of epilepsy and depressive and anxiety disorders has also been identified in other animal models. The genetically epilepsy-prone rat (GEPR) with its two strains, GEPR3 and GEPR9, is an animal model of epilepsy with comorbid behaviors equivalent to depressive symptomatology manifested by decreased sucrose consumption in the SCT and increased immobility time in the FST (Jobe, 2006). The GEPR harbors inborn defects in pre- and post-synaptic transmission of both serotonin (5-HT) and norepinephrine (NE), resulting from deficient arborization of noradrenergic and serotonergic neurons arising from the locus ceruleus and raphe nuclei (Jobe et al., 1994). Likewise, the Genetic Absence Epilepsy Rats from Strasbourg (GAERS) illustrate the existence of epilepsy semiology (or characteristics of the seizure) and comorbid symptoms equivalent to symptoms of depression and anxiety in an animal model of generalized epilepsy (Jones et al., 2008). One study of 47 GAERS and 73 control rats without epilepsy (CwoE) were subjected to behavioral measures of depression (Sucrose Preference Test [SPT]) and anxiety (Elevated Plus Maze [EPM]), and the Open Field Arena (OFA) at 7 and 13 weeks of age, ages prior to and after seizure onset. The GAERS exhibited significantly greater levels of behaviors equivalent to symptoms of depression and anxiety on these measures, including reduced consumption of sucrose solution in the SPT, shorter time in the open arms of the EPM, and reduced exploratory activity and less time spent in the inner area of the OFA. These differences were evident preceding and following the onset of epilepsy. Clearly, increased anxiety- and depressive-like behaviors in GAERS were not a consequence of seizures, but rather an expression of comorbid neurological and psychiatric-like conditions.

Table 43.2 ANTIEPILEPTIC DRUGS (AEDS)

DRUG	MECHANISM	METABOLISM	PROTEIN BINDING	HALF LIFE (HOURS)*	DOSE (P-PEDIATRIC; A-ADULT)
Phenobarbital	1, 2	Hepatic	50%	96	P: 2–5 mg/kg A: 90–120 mg
Phenytoin (Dilantin)	1	Hepatic	85–90%	12–36	P: 4–7 mg/kg A: 200–500 mg
Ethosuximide (Zarontin)	5	Hepatic	<5%	30–60	P: 15–40 mg/kg A: 500–2000 mg
Clonazepam (Klonopin)	1, 2	Hepatic	47%	18–50	P: 0.1–0.2 mg A: 2–6 mg
Carbamazepine (Tegretol)	1	Hepatic	65–90%	14–27	P: 5–20 mg/kg A: 600–1600 mg
Valproic acid (Depakene, Depakote)	1, 2	Hepatic	80–95%	6–15	P: 30–80 mg/kg A: 1–3 g
Gabapentin (Neurontin)	6	Renal	None	6–8	P: 30–60 mg/kg A: 1800–3600 mg
Lamotrigine (Lamictal)	1, 3	Hepatic	55%	12–48†	P: 5–15 mg/kg A: 200–700 mg
Felbamate (Felbatol)	1, 3	Hepatic	25%	20–23	P: 15–45 mg/kg A: 1800–4800 mg
Topiramate (Topamax)	1, 2, 3, 4	Renal	15%	12–23	P: 5–10 mg/kg A: 100–400 mg
Tiagabine (Gabitril)	2	Hepatic	96%	7–9	P: 0.5–0.8 mg A: 32–56 mg
Vigabatrin (Sabril)	2	Renal	None	7	P: 50–60 mg/kg A: 2–5 g
Ezogabine (Potiga)	7, 8	Hepatic	45–80%	6–10	P: not established A: 600–1200 mg
Zonisamide (Zonegran)	9, 5 (6?)	Hepatic	40%	63 (50–68)	P: 200–400 mg A: 200–400 mg
Lacosamide (Vimpat)	9.a, 18	Hepatic	<15%	13	P: 200–400 mg A: 200–400 mg
Levetiracetam (Keppra)	15 (6?)	Hepatic	<10%	7	P: 60 mg/kg or 3000 mg A: 1000–3000 mg
Rufinamide (Banzel)	1 (6?)	Hepatic	34%	6–10	P: 45 mg/kg or 3200 mg A: 1600–3200 mg
Ethotoin (Peganone)	1 (6?)	Hepatic		3–9	P: 500–1000 mg A: 2–3 g
Primidone (Mysoline)	1 (6?)	Hepatic	25%	10–12	P: 750 mg or 10–25 mg/kg A: 750 mg–2 g
Methsuximide (Celontin)	16, 17	Hepatic	not significant	3	P: 600 mg–1.2 g A: 600 mg–1.2 g

(continued)

Table 43.2 (CONTINUED)

DRUG	MECHANISM	METABOLISM	PROTEIN BINDING	HALF LIFE (HOURS)*	DOSE (P-PEDIATRIC; A-ADULT)
Oxcarbazepine (Trileptal, Novartis)	9.b, 1, 12	Hepatic	40%	2–9	P: 900–1800 mg A: 1200–2400 mg
Pregabalin (Lyrica)	6, 13	Negligible/minimal (<2%)	None	6.3	P: not established A: 300–600 mg
Clobazam (Frisium)	14 (6?)	Hepatic	80–90%	36–42	P: 20 mg A: 20–40 mg

*Half-lives in children are typically 50% of adult.

†Dependent on co-therapy.

1. Stabilizes voltage-dependent sodium channel.
2. Enhances GABA-ergic inhibition.
3. Glutamate receptor antagonist.
4. Carbonic anhydrase inhibitor.
5. Inhibits T-calcium currents.
6. Unknown.
7. Augmentation of GABA-mediated currents.
8. Opens potassium-channels.
9. Inhibits sodium channels. (9.a. Inactivates sodium-channels).
10. Modulation of collapsing response mediator protein-2.
11. Prolongation of inactive state of sodium-channel.
12. Increased potassium conductance.
13. Binds to $\alpha 2$ -delta site (voltage-gated calcium channels).
14. Opening of GABA channel.
15. Inhibits burst firing.
16. Suppresses paroxysmal three cycle/second spike and wave activity.
17. Depresses motor cortex evaluation of CNS threshold to convulsive stimuli.
18. Binding to collapsing response mediator protein-2 (CRMP-2).

Some General Principles in Addressing Psychiatric Aspects of Epilepsy

A recent consensus statement from representatives from the International League Against Epilepsy underscored the importance of the neuropsychiatric aspects of epilepsy and treatment approaches (Kerr et al., 2011). The evaluation of any type of psychopathology in PWE must be approached with the following questions in mind.

1. Is this psychiatric disturbance temporally related to the occurrence of seizures?
2. Is the onset of psychiatric symptoms associated with the remission of seizures?

We consider the peri-ictal psychiatric symptoms (pre-ictal and post-ictal) as well as inter-ictal symptoms associated with the onset or remission of seizures as an expression of a para-ictal process.

3. Are the psychiatric symptoms the result of the introduction of an anti-epileptic drug (AED) with potential

Table 43.3 PREVALENCE OF PSYCHIATRIC DISORDERS IN EPILEPSY AND THE GENERAL POPULATION

PSYCHIATRIC DISORDER	PREVALENCE	
	<i>Epilepsy</i>	<i>General Population</i>
Depression	11–80%	3.3%: Dysthymia 4.9–17%: Major Depression
Psychosis	2–9.1%	1%: Schizophrenia 0.2%: Schizophreniform Disorder
Generalized Anxiety Disorders	15–25%	5.1–7.2%
Panic Disorder	4.9–21%	0.5–3%
ADHD	12–37%	4–12%
Psychogenic Non-Epileptic Seizures	10–20%	.03%

negative psychotropic properties, or did they appear after discontinuation of an AED with positive psychotropic properties (mood stabilizing, antidepressant, and anxiolytic properties)?

4. Do the symptoms meet diagnostic criteria of the DSM-IV or the *International Classification of Diseases* (ICD), or do these symptoms present as an atypical disorder?
5. What is the impact of the psychiatric disorder at hand on the quality of life of patients?
6. What is the treatment for the psychiatric disorder? If pharmacotherapy is required, how do psychotropic drugs interact with AEDs, and what is the impact of psychotropic drugs on the seizure threshold?

Tables 43.4–43.7 summarize side effects and interactions of AEDs and psychotropic medications.

Psychiatric comorbid diagnoses have had a noted association with focal epilepsy—in particular, temporal and frontal lobe epilepsies—while little attention has been paid to comorbid psychiatric conditions in idiopathic generalized epilepsy (IGE). In fact, some researchers have hypothesized that patients with temporal lobe epilepsy (TLE) with involvement of temporomesial limbic structures show more psychiatric symptoms compared with extra-TLE patients. While some researchers showed higher depression scores in localization related epilepsies (Quiske, Helmstaedter, Lux, & Elger, 2000), other researchers did not find symptomatic differences between patients with TLE and extra-TLE patients (Swinkels, van Emde Boas, Kuyk, van Dyck, & Spinhoven, 2006). Furthermore, an increasing literature has shown a relatively high prevalence of psychiatric comorbidities in pediatric and adult patients with IGE. For example, in a comparison

of 100 patients with juvenile myoclonic epilepsy (JME) with 100 healthy controls, psychiatric diagnoses were found in 49 patients with JME. Anxiety and mood disorders, present in 23 and 19 patients, respectively, were the most frequently observed, and 20 of the JME group had personality disorders (de Araujo Filho et al., 2007). Psychiatric comorbidity has been associated with the frontal lobe dysfunction found in JME and other types of IGE, such as childhood and juvenile absence epilepsy.

DEPRESSION IN EPILEPSY

Depression is the most frequent psychiatric disorder in PWE. In three community-based studies, prevalence rates of depression ranged between 21% and 33% among patients with persistent seizures and from 4–6% among seizure-free patients (Edeh & Toone, 1987; Jacoby et al., 1996; O'Donoghue et al., 1999). Similar results were found in a recent Canadian population-based study of psychiatric disorders in PWE (Tellez-Zenteno, Patten, Jette, Williams, & Wiebe, 2007). Ettinger et al. reported the results of a population-based survey that investigated a lifetime prevalence of depression, epilepsy, diabetes, and asthma in 185,000 households (Ettinger, Reed, & Cramer, 2004). Among the 2,900 PWE, 32% reported having experienced at least one episode of depression. This contrasted with 8.6% prevalence among healthy respondents, 13% among patients with diabetes, and 16% among people with asthma. Using the same population, these investigators found that 13% of patients with epilepsy had experienced symptoms of manic-depressive illness, compared to 2% of healthy controls (Ettinger, Reed, Goldberg, & Hirschfeld, 2005).

Depression is more common in patients with partial seizure disorders of temporal or frontal lobe origin and among patients with poorly controlled seizures (Edeh & Toone, 1987; Jacoby et al., 1996; Mendez et al., 1986; O'Donoghue et al., 1999). Yet depression is also a predictor of worse seizure control, both with pharmacotherapy with AEDs and epilepsy surgery. For example, in a study of 780 patients with new-onset epilepsy, individuals with a history of psychiatric disorders, and particularly depression, were half as likely to be seizure-free with AEDs after a median follow-up period of 79 months, compared to patients without a psychiatric history (Hitiris, Mohanraj, Norrie, Sills, & Brodie, 2007). Likewise, in a prospective study of 138 patients with new-onset epilepsy, those with symptoms of depression and anxiety at the time of diagnosis of epilepsy were significantly less likely to be seizure-free at the one-year follow-up evaluation (Petrovski et al., 2010).

Several studies have found a worse post-surgical seizure outcome in patients with a lifetime history of psychiatric disorders and, in particular, depression. For example, in a study of 100 consecutive patients with treatment-resistant TLE who had an antero-temporal lobectomy, those with a lifetime history of depression were significantly less likely to achieve complete freedom from auras and disabling seizures (Kanner, Byrne, Chicharro, Wu, & Frey, 2009).

Table 43.4 MAJOR PRESCRIPTION MEDICATIONS THAT MAY CAUSE SEIZURES OR SYNCOPE

<i>Seizures</i>	<i>Syncope</i>
Antihistamines	Beta blockers
Penicillin	Calcium channel blockers
Beta blockers	Nitrates
Baclofen	Tricyclic antidepressants
Theophylline	Clonidine
Tricyclic antidepressants	Clozapine
Sympathomimetics	Trazodone
Isoniazid	Thioridazine
Chlorpromazine	Chlorpromazine
Amoxapine	
Loxapine	
Clozapine	
Maprotiline	
Meperidine	

Table 43.5 NEUROPSYCHIATRIC SIDE EFFECTS OF ANTIEPILEPTIC DRUGS (MOST DOSE-DEPENDENT)

Clonazepam	Lethargy, ataxia, irritability, depression, psychosis
Ethosuximide	Psychosis, Parkinsonian changes
Phenobarbital	Lethargy, depression, memory loss, irritability, paradoxical excitation/agitation
Phenytoin	Lethargy. When toxic—delirium, seizures, psychosis, choreoathetosis
Carbamazepine	Lethargy, depression, irritability, agitation, psychosis, delirium, seizures, aggression
Valproic acid/Valproate	Lethargy, depression, hallucinosis, delirium, pseudodementia, hearing loss
Felbamate	Insomnia, fatigue anxiety, depression, agitation
Gabapentin	Lethargy, fatigue, aggression
Lamotrigine	Dizziness, lethargy, insomnia, seizures, agitation
Topiramate	Lethargy, confusion, trouble concentrating, word-finding difficulties
Tiagabine	Dizziness, fatigue, lethargy, nervousness, irritability, difficulty with concentration, depression
Vigabatrin	Lethargy, psychosis, depression anxiety, irritability, confusion, hyperactivity (children)
Ezogabine	Dizziness, somnolence, fatigue, confusion, asthenia, psychotic symptoms, hallucinations
Zonisamide	Dizziness, ataxia, concentration/ memory difficulties, agitation/ irritability, insomnia, somnolence, fatigue, depression, anxiety, speech problems
Levetiracetam	Somnolence, asthenia, dizziness, nervousness, vertigo, ataxia, irritability, depression, fatigue, coordination difficulties and abnormalities
Rufinamide	Somnolence, fatigue, dizziness, tremor, ataxia, blurred vision, coordination abnormalities, gait disturbances
Ethotoin	Ataxia, dizziness, fatigue, insomnia
Lacosamide	Dizziness, fatigue, vertigo, somnolence, ataxia, tremor, balance disorder, blurred vision
Primidone	Ataxia, vertigo, irritability, drowsiness, dizziness
Methsuximide	Drowsiness, ataxia, dizziness, seizures
Oxcarbazepine	Dizziness, somnolence, fatigue, ataxia, tremor, abnormal vision, abnormal gait
Pregabalin	Somnolence, dizziness, ataxia, blurred vision, abnormal thinking, fatigue, euphoric mood
Clobazam	Dizziness, agitation, fatigue, slurred speech, somnolence, aggression, irritability, insomnia, ataxia

The Neurological Disorders Depression Inventory for Epilepsy (NDDI-E), a brief six-item self-report screening tool for depression in epilepsy, has been shown to identify depressive symptoms exclusive of the neurovegetative side effects of AEDs (Gilliam et al., 2006). Screening questions include: Everything is a struggle, Nothing I do is right, Feel guilty, Better off dead, Frustrated, and Difficulty finding pleasure.

SUICIDALITY IN PATIENTS WITH EPILEPSY

The suicide rate in depressed PWE is 9–25 times higher in patients with partial seizures of temporal lobe origin than expected in the overall population (Nilsson, Tomson, Farahmand, Diwan, & Persson, 1997; Rafnsson, Olafsson, Hauser, & Gudmundsson, 2001; Robertson, 1997). In a Danish population-based study, patients with epilepsy had twice the risk of committing suicide in the absence

of any psychosocial obstacles. A comorbid mood disorder increased the risk by 32-fold, while an anxiety disorder increased the risk by 12-fold. The highest risk of suicide in PWE occurred within six months after a new diagnosis of epilepsy was made (Christensen, Vestergaard, Mortensen, Sidenius, & Agerbo, 2007). In a review of the literature, Gilliam and Kanner concluded that suicide has one of the highest standardized mortality rates (SMR) of all causes of death in PWE (Gilliam & Kanner, 2002). Robertson reviewed 17 studies pertaining to mortality in epilepsy and found that suicide was ten times more frequent than in the general population (Robertson, 1997). Rafnsson et al. reported the results of a population-based incidence cohort study in PWE from Iceland in which suicide had the highest SMR (5.8) of all causes of death (Rafnsson et al., 2001). A Swedish study of cause specific mortality among 9,000 previously hospitalized PWE found an SMR of 3.5 (Nilsson et al., 1997).

Table 43.6 ANTI-EPILEPTIC DRUG (AED) INTERACTIONS

AED	DECREASE	INCREASE
Phenobarbital (PB)	DPH ¹ , CBZ ¹ , VPA, ESX, CZP, TGB, OXC, RFM, ZNS	
Clonazepam (CZP)	No consistent changes. OXC ZNS	No consistent changes

DEPRESSION AS A PARA-ICTAL PHENOMENON

Pre-ictal symptoms of depression and depressive episodes typically present as a dysphoric mood in which the prodromal symptoms may extend for hours or even one to three days prior to the onset of a seizure. In children, this dysphoric mood often takes the form of irritability, poor frustration

tolerance, and aggressive behavior. Blanchet and Frommer (1986) assessed mood changes during 56 days in 27 PWE who rated their mood on a daily basis. Mood ratings pointed to a dysphoric state three days prior to a seizure in 22 (81%) patients. This change in mood was greatest during the 24 hours preceding the seizure. Patients or parents of children

Table 43.7 SOME REPORTED PHARMACOKINETIC INTERACTIONS BETWEEN PSYCHOTROPIC DRUGS AND AEDS

EFFECT ON BLOOD LEVELS OF DRUG LISTED BELOW RESULTING FROM INTERACTION WITH DRUG LISTED ON THE LEFT

with epilepsy often report that dysphoric symptoms completely resolve the day after the ictus.

Post-ictal symptoms of depressive and depressive episodes have been recognized for decades but have been investigated in a systematic manner in only one study (Kanner, Soto, & Gross-Kanner, 2004). The presence of post-ictal symptoms of depression was identified in 43 of 100 consecutive patients with refractory partial seizure disorders. These symptoms occurred after more than 50% of seizures, and their duration ranged from 0.5–108 hours, with a median duration of 24 hours. Other studies have shown that symptoms of depression can outlast the ictus for up to two weeks, and, at times, have led patients to suicide (Anatassopoulos & Kokkini, 1969; Hancock & Bevilacqua, 1971). Likewise, inter-ictal symptoms can worsen in severity during the post-ictal period. For example, in the study by Kanner et al. (Kanner et al., 2004) post-ictal exacerbation in severity of inter-ictal symptoms was identified in up to 30% of patients. In fact, some patients whose inter-ictal mood disorder was in remission with antidepressant medication experienced breakthrough symptoms of depression in the post-ictal period.

Ictal symptoms of depression or a depressive episode are the clinical expression of a simple partial seizure in which the depressive symptoms are the sole (or predominant) semiology. Ictal symptoms of depression ranked second after symptoms of anxiety or fear as the most common type of

ictal affect in one study (Williams, 1956). This presentation occurred in 21% of 100 PWE who reported auras consisting of psychiatric symptoms (Daly, 1958; Weil, 1955). Yet, the actual prevalence of ictal symptoms of depression is yet to be established in larger studies. The most frequent symptoms include feelings of anhedonia, guilt, and suicidal ideation. Such mood changes are typically brief, stereotypical, occur out of context, and are associated with other ictal phenomena. More typically, however, ictal symptoms of depression are followed by an alteration of consciousness as the ictus evolves from a simple to a complex partial seizure.

DEPRESSION AS COMORBID DISORDER: INTER-ICTAL DEPRESSIVE DISORDERS

Inter-ictal forms of depression in epilepsy can be identical to depressive disorders described in non-epileptic patients (i.e., major depression, bipolar disorder, cyclothymia, dysthymia, and minor depression). Nevertheless, a review of the literature has clearly shown an atypical clinical presentation of inter-ictal depressive episodes that fail to meet any of the DSM categories. Blumer coined the term “inter-ictal dysphoric disorder” to describe this atypical presentation, found in about one-third of patients with mood disorders in epilepsy (Blumer, Altshuler, 1998). It is characterized by

a chronic “dysthymic-like” state, where symptoms tend to occur intermittently, intermixed with brief euphoric moods, explosive irritability, anxiety, paranoid feelings, and somatoform symptoms (anergia, atypical pain, and insomnia). This type of depression is often unrecognized.

A significant number of patients with epilepsy present with depressive episodes that fail to meet the DSM diagnostic criteria and often present as sub-syndromic episodes. Even though this may be a less severe form of depression than a major depressive episode, sub-syndromic depressive episodes have a very negative impact on the quality of life of people with epilepsy (Kanner, Barry, Gilliam, Hermann, & Meador, 2010).

Depressive disorders often occur along with anxiety disorders. For example, in a study of 188 consecutive patients with epilepsy, 31 patients met DSM-IV criteria of a current major depressive episode (MDE). Twenty-one of these patients had a mixed MDE and an anxiety disorder (Kanner et al., 2010). Recognition of such comorbidity is of the essence, as failure to target the anxiety disorder in the treatment of these patients can result in recurrence of the depressive disorder. In addition, comorbid depressive and anxiety disorders in patients with and without epilepsy are associated with a worse course of the depressive disorder.

DEPRESSION AS AN IATROGENIC PROCESS

AEDs can cause psychiatric symptoms (McConnell & Duncan, 1998). AEDs with GABA-ergic properties, primarily phenobarbital, primidone, the benzodiazepines, tiagabine, and vigabatrin are more likely to cause depression (Barabas & Matthews, 1988; Brent, Crumrine, Varma, Allan, & Allman, 1987; Ferrari, Barabas, & Matthews, 1983; Ring & Reynolds, 1990; Smith et al., 1987). Other AEDs that have been linked to depression include felbamate, topiramate, levetiracetam, and zonisamide (Kanner, Faught, French, et al., 2000; McConnell et al., 1996; Mula & Trimble, 2003). A careful review of the data suggests that the occurrence of psychiatric adverse events is more likely to be identified in patients susceptible to developing psychiatric disorders, such as patients with a past psychiatric history or with a family psychiatric history (Mula & Trimble, 2003).

The addition of AEDs with mood-stabilizing properties, such as carbamazepine, valproic acid, and lamotrigine, can occasionally cause depressive episodes, albeit with a significantly lower frequency than other AEDs. More often than not, these AEDs are associated with the occurrence of depression *upon their discontinuation* in patients with a prior history of depression or panic disorder, which had been kept in remission by these AEDs (Ketter et al., 1994).

The Food and Drug Administration (FDA) announced in 2008 that it would require manufacturers of AEDs to add a warning to their labeling indicating that use of the drugs increases risk for suicidal thoughts and behaviors (Barclay, 2008). The announcement was based on an FDA review of 199 clinical trials of 11 AEDs, which reported risk for suicidal behavior or thoughts was nearly doubled for patients receiving AEDs vs. placebo (0.43% vs. 0.24%). A critique of the FDA

analysis included the fact that the methodological approach including lumping all AEDs, which have different mechanisms of action, into one class, and basing the recommendation on adverse-event data rather than on systematically acquired data (Hesdorffer & Kanner, 2009). The authors concluded that the risk of adverse effects from uncontrolled seizures almost certainly outweighs the small risk of suicidality, and they emphasized the need for practitioners to screen for mood and anxiety disorders in PWE. Furthermore, attempts to replicate the data from the FDA meta-analysis in five large studies yielded contradictory findings. Therefore, certain, but not all, AEDs can cause psychiatric adverse events that can lead to suicidal ideation and behavior, but this is likely to occur in patients with a predisposition for psychiatric illness. Thus, before starting an AED like topiramate, zonisamide, vigabatrin, barbiturate, or levetiracetam, it is essential to inquire about a prior personal or psychiatric history.

DEPRESSION FOLLOWING EPILEPSY SURGERY

There has been an increasing number of reports of depressive disorders following an antero-temporal lobectomy (Savard, Andermann, Reutens, & Andermann, 1998). It is not unusual to see “mood lability” within the initial six weeks to three months after surgery. Often these symptoms subside, but in up to 30% of patients, overt symptoms of depression become apparent within the first six months. Characteristically, symptoms of depression vary in severity from mild to very severe, including suicidal attempts. In most instances, these depressive disorders respond readily to pharmacological treatment with antidepressant drugs (see depression treatment section). Patients with a prior history of depression are at greater risk. A German study found that patients with personality disorders are at higher risk of suffering from post-operative psychiatric complications compared with patients with other preoperative psychiatric conditions (such as depression) or with patients with no preoperative psychiatric diagnosis whatsoever (Koch-Stoecker, 2002). While some studies have not found a relationship between depression with the post-surgical control of seizures, others have (Kanner & Balabanov, 2008; Pintor et al., 2007). All patients undergoing epilepsy surgery, therefore, should be advised of this potential complication, *prior to surgery*.

TREATMENT OF DEPRESSION IN EPILEPSY

There is a lack of controlled studies on the treatment of depression in epilepsy. In their absence, a consensus statement has been published, outlining pharmacological and psychotherapeutic approaches for PWE with affective disorders (Barry, Ettinger, et al., 2008). Before starting a patient on an antidepressant drug (AD), it is important to determine if the seizures may be related to starting or stopping an AED.

In all cases inquiry into suicidality is mandatory.

Do antidepressant drugs worsen seizures? A review of the literature has found an increased incidence of seizures with the

use of four specific antidepressant drugs. These are: maprotiline, amoxepine, clomipramine, and bupropion (McConnell & Duncan, 1998; Swinkels, Jonghe, 1995). Increased seizures have been identified in patients without epilepsy taking tricyclic antidepressants (TCA), but these seizures have been associated with the following variables: (1) Overdoses and/or high plasma serum concentrations, (2) rapid dose increments, (3) the presence of other drugs with pro-convulsant properties, and (4) the presence of central nervous system (CNS) pathology, abnormal EEG, and personal and family history of epilepsy (Curran & de Pauw, 1998; Preskorn & Fast, 1992; Rosenstein, Nelson, & Jacobs, 1993; Swinkels, Jonghe, 1995). Based on the evidence suggesting a bidirectional relationship between depression and epilepsy, and a higher incidence of seizures in patients with depression, it is important to reconsider the question of whether antidepressants increase the risk of seizures, or whether we are identifying the seizure occurrence associated with such increased risk. A study appears to challenge the notion of proconvulsant effect of antidepressants. Alper et al. (Alper, Schwartz, Kolts, & Khan, 2007) compared the incidence of seizures between depressed patients in trials randomized to selective serotonin-reuptake inhibitors (SSRIs), serotonin-norepinephrine reuptake inhibitors (SNRIs), mirtazapine, or placebo in the course of multicenter placebo-controlled studies of these drugs submitted to the FDA for approval. Compared to the expected incidence of seizures of the general population, all depressed patients had a higher incidence of seizures. Nonetheless, patients randomized to placebo had a significantly higher incidence of seizures than those treated with the actual antidepressant drug.

In general, the SSRI class of drugs is safe in patients with epilepsy. In one study, sertraline was found to *definitely* worsen seizures in *only one* out of 100 patients with refractory epilepsy (Kanner, Kozak, & Frey, 2000). Blumer has also reported using TCAs alone and in combination with SSRIs in epileptic patients, without seizure exacerbation (Blumer, Zielinski, 1988). Monoamine-oxidase inhibitors (MAO-I) are not known to cause seizures in patients without epilepsy. Patients treated with TCAs should be started at low doses with small increments until the desired clinical response is reached. This will minimize the risk of causing or exacerbating seizures. (See Table 43.4.)

PHARMACOKINETIC INTERACTIONS BETWEEN ANTIDEPRESSANT DRUGS AND AEDS

Most antidepressants are metabolized in the liver, and their metabolism is accelerated in the presence of AEDs with enzyme-inducing properties, which include phenytoin, carbamazepine, phenobarbital, primidone at regular doses, and oxcarbazepine and topiramate at doses above 900 mg/day and 300 mg/day, respectively. This pharmacokinetic effect is not observed with the new AEDs gabapentin, lamotrigine, tiagabine, levetiracetam, zonisamide, pregabalin, vigabatrin, and ezogabine. Conversely, some of the SSRIs are inhibitors of one or more isoenzymes of the cytochrome P450 (CYP 450) system. These include fluoxetine, paroxetine, fluvoxamine,

and, to a lesser degree, sertraline (Fritze, Unsorg, & Lanczik, 1991; Grimsley, Jann, Carter, D'Mello, & D'Souza, 1991; Pearson, 1990). Citalopram, on the other hand, does not have pharmacokinetic interactions with AEDs (McConnell & Duncan, 1998). Sertraline has been shown rarely to increase phenytoin levels, and this is thought to be associated with displacement by tight protein binding, or by inhibition of the CYP 450 system (Haselberger, Freedman, & Tolbert, 1997; Thomson, 2006).

CHOICE OF ANTIDEPRESSANT

The SSRI class of drugs should be considered the first-line treatment in depressed PWE. They are safe with respect to seizure propensity, are less likely to result in fatalities after an overdose, and generally have a favorable adverse-effects profile. Furthermore, their efficacy in dysthymic disorders and in symptoms of irritability and poor frustration tolerance makes this class of AEDs more attractive among PWE who have atypical forms of depression. SSRIs with no or minimal effects on CYP 450 isoenzymes, such as citalopram and sertraline, should be considered in patients taking hepatically metabolized AEDs to avoid pharmacokinetic interactions.

In open, uncontrolled trials, TCAs have also been reported to yield a good clinical response, but the cardiotoxic effects and severe complications seen in overdose make these drugs a second-line antidepressant choice. Blumer has anecdotal reports of the utility of low-dose TCAs in PWE and inter-ictal dysphoric disorder (Blumer, Zielinski, 1988).

A cautionary note is in order. Before starting an antidepressant, clinicians must rule out a history of any manic or hypomanic episodes that may be suggestive of a bipolar disorder, as antidepressants can potentially trigger a manic or hypomanic episode in the short term, and they may worsen the course of the bipolar disorder in the long term, particularly in the case of rapidly cycling bipolar disease. In such cases, an AED with mood-stabilizing and antidepressant properties such as lamotrigine must be considered. Carbamazepine and valproate may be added in case of persistent symptoms. Lithium should be considered if these AEDs cannot yield a euthymic state. If an antidepressant is required, it should not be started in the absence of a mood-stabilizing drug.

OTHER TYPES OF PSYCHIATRIC TREATMENTS

Lithium was the first mood-stabilizing drug used for the treatment of patients with bipolar disorder. Its use in epileptic patients with affective disorders, however, has been fraught with several problems, including changes in EEG recordings and pro-convulsant effects at therapeutic serum concentrations in patients without epilepsy (Bell, Cole, Eccleston, & Ferrier, 1993). Lithium's neurotoxicity and related increase in seizure risk are exacerbated with the concurrent use of neuroleptic drugs, in the presence of EEG abnormalities, and with a history of a central nervous system disorder.

Electroconvulsive therapy (ECT) is *not* contraindicated in depressed PWE (Fink, Kellner, & Sackeim, 1999; Regenold, Weintraub, & Taller, 1998; Sackeim, Decina, Prohovnik,

Malitz, & Resor, 1983). It is a well-tolerated treatment and is worth considering in PWE with very severe depression that fails to respond to antidepressant drugs. Furthermore, there is no evidence that ECT increases the risk of epilepsy (Blackwood, Cull, Freeman, Evans, & Mawdsley, 1980).

Vagal nerve stimulation (VNS) is used as adjunctive treatment for epilepsy and has also shown longer-term mood effects (Marangell et al., 2002). The impact of other neurostimulation interventions, such as deep brain stimulation (DBS) or transcranial magnetic stimulation (TMS), on mood in patients with epilepsy has not been studied in controlled trials.

In addition to pharmacological intervention, the value of psychotherapy for the treatment of depression in PWE should not be overlooked. Surveys reveal that fear of the next seizure is rated as the greatest concern in PWE (Fisher et al., 2000). Counseling and psychotherapy can be useful in helping the patient deal with the stresses and limitations of living with epilepsy (Ramaratnam, Baker, & Goldstein, 2008).

ANXIETY DISORDERS IN EPILEPSY

Anxiety is the second most common psychiatric comorbid diagnosis in PWE, with an estimated prevalence between 15% and 25% (Edeh & Toone, 1987; Jacoby et al., 1996; Jones et al., 2003; O'Donoghue et al., 1999; Vazquez & Devinsky, 2003). In 174 consecutive patients with epilepsy from five epilepsy centers, a current DSM-IV diagnosis of anxiety disorder was found in 30% of patients (Jones et al., 2003).

The various forms of anxiety disorders (generalized anxiety disorder, panic disorder, phobias, obsessive-compulsive disorder, and post-traumatic stress disorder) can present *inter-ictally* with the same clinical manifestations as anxiety disorders in the general population. The peri-ictal presentations of anxiety symptoms often differ from their inter-ictal manifestations, however.

ANXIETY EPISODES AS PARA-ICTAL PROCESSES

Ictal fear or panic is the most frequent ictal psychiatric symptom. It is the sole or predominant clinical expression of a simple partial seizure (aura) or the initial symptom of a complex partial seizure, and it usually has a mesial temporal lobe origin. Seizures of mesial frontal origin involving the cingulate gyrus can also be associated with an anxious feeling, but not a panic attack, as an expression of the aura. Relying on electrographic inter-ictal and ictal data to document a diagnosis often yields false negative results. Indeed, simple partial seizures originating from mesial frontal regions are often undetected in scalp EEG recordings, as the location of the epileptogenic zone (in cingulate gyrus) relative to the angle subtended by scalp electrodes positioned at the midline and over suprasylvian regions may not permit the detection of the epileptiform discharges or ictal patterns. Likewise, scalp recordings are unlikely to detect any epileptiform activity from simple partial seizures of mesial temporal lobe origin, particularly those in which the epileptogenic area is in the amygdala, as this structure

generates epileptiform discharges with a very narrow electric field. By the same token, inter-ictal recordings may fail to recode any inter-ictal discharges, even with the use of basal and antero-temporal electrodes. In these instances, the use of sphenoidal electrodes placed under fluoroscopic guidance will be necessary. It should be emphasized that the placement of sphenoidal electrodes without fluoroscopic guidance does not yield any advantage over antero-temporal and basal temporal electrodes (Kanner & Jones, 1997).

A careful history can help distinguish inter-ictal from ictal panic. Ictal panic is typically less than 30 seconds in duration, is stereotypical, occurs out of the context of concurrent events, and is associated with other ictal phenomena such as periods of confusion of variable duration and subtle or overt automatisms. The intensity of the sensation of fear is mild to moderate and rarely reaches the intensity of a panic attack. On the other hand, inter-ictal panic attacks consist of episodes of 5–20 minutes' duration, which at times may persist for several hours. The feeling of fear or panic is very intense ("feeling of impending doom") and is associated with a variety of autonomic symptoms, including tachycardia, diffuse diaphoresis, and dyspnea. Patients may become so completely absorbed by the panic that they may not be able to report what is going on around them; however, there is no confusion or loss of consciousness, as seen in complex partial seizures. It is not infrequent for patients to develop agoraphobia due to the fear of experiencing a panic attack. As stated above, EEG recordings with sphenoidal electrodes placed under fluoroscopic guidance may be necessary to demonstrate the mesial temporal lobe epileptiform activity that generates ictal panic (Kanner & Jones, 1997; Kanner, Ramirez, & Jones, 1995).

Patients with ictal panic may also suffer from inter-ictal panic attacks, which have been identified in up to 25% of patients with epilepsy (Vazquez & Devinsky, 2003).

Post-ictal symptoms of anxiety can be relatively frequent among patients with refractory partial epilepsy. In a study of 100 consecutive patients with pharmaco-resistant partial epilepsy, we identified a mean of 2 ± 1 post-ictal symptoms of anxiety (range: 1–5; median = 2) in 45 patients (Kanner et al., 2004). These symptoms occurred after more than 50% of their seizures and had a median duration of 24 hours (range: 0.5–148.0 hours). Thirty-two patients reported symptoms of generalized anxiety and/or panic; an additional ten patients also reported symptoms of compulsions, and 29 patients experienced post-ictal symptoms of agoraphobia. In 44 of these 45 patients, post-ictal symptoms of depression were also reported, which included anhedonia, feelings of helplessness, crying bouts, suicidal ideation, and feelings of guilt.

TREATMENT OF ANXIETY DISORDERS IN EPILEPSY

Antidepressants belonging to the SSRI class can prevent the occurrence of inter-ictal panic attacks as well as treat generalized anxiety disorders. On the other hand, there is as of yet no evidence that these drugs have any impact

on post-ictal psychiatric symptoms. Antidepressant drugs of the SNRI family have been also been used with success, but no controlled studies exist in patients with epilepsy. Benzodiazepines have been used for years in the management of anxiety disorders. We do not recommend their chronic use because of the development of tolerance and sedating adverse events. However, short trials with clonazepam can be quite effective.

PSYCHOSIS OF EPILEPSY

Psychotic disorders are more frequent in PWE than in the general population, with some studies suggesting prevalence rates of up to 10%. Psychotic disorders can present as a schizophreniform disorder, indistinguishable from those of patients without epilepsy. However, the term “psychosis of epilepsy” implies the presence of certain characteristics that distinguish these disorders from those of patients without epilepsy.

POST-ICTAL PSYCHOTIC SYMPTOMS AND PSYCHOTIC EPISODES

Post-ictal psychotic phenomena can present in the form of isolated symptoms or as psychotic episodes, defined as a cluster of symptoms of at least 24 hours' duration. The prevalence of post-ictal psychotic disorders in PWE is yet to be established, but has been estimated to range between 6% and 10% (Dongier, 1959; Kanner, Stagno, Kotagal, & Morris, 1996). Recurrent post-ictal psychotic symptoms have been found in 7% of 100 consecutive patients with refractory partial epilepsy (Kanner et al., 2004). Common findings include:

1. A delay between the onset of psychiatric symptoms and the time of the last seizure.
2. A relatively short duration (from hours up to a few weeks long).
3. An affect-laden symptomatology.
4. The clustering of symptoms into delusional and affective-like psychosis.
5. An increase in the frequency of secondarily generalized tonic-clonic seizures preceding the onset of post-ictal psychosis (PIP).
6. The onset of PIP after having seizures for a mean period of more than ten years.
7. A prompt response to low-dose neuroleptic medication or benzodiazepines (Devinsky et al., 1995; Kanner et al., 1996; Lancman, Craven, Asconape, & Penry, 1994; Logsdail & Toone, 1988; Umbricht et al., 1995).

In a study with eight years of follow-up on patients with PIP, 3 developed chronic psychosis and 4 of 14 patients died (Logsdail & Toone, 1988).

In most cases, insomnia is the initial presenting symptom. In patients with recurrent post-ictal psychotic episodes, families need to learn to recognize these symptoms so that a timely administration of 1–2 mgs of risperidone may avert the episode. It should be given for two to five days and then discontinued.

The occurrence of post-ictal psychotic episodes also has important localizing implications. PIP suggests the presence of bilateral independent ictal *foci* (Devinsky et al., 1995; Logsdail & Toone, 1988; Umbricht et al., 1995). A 2008 study (Kanner & Ostrovskaya, 2008a) demonstrated that the presence of post-ictal psychotic episodes (PIPE) suggests the presence of bilateral ictal foci in close to 90% of patients with refractory partial epilepsy. Accordingly, patients undergoing surgical evaluation may require longer video EEG (vEEG) monitoring studies and possibly the use of intracranial electrodes. If recordings with depth or subdural electrodes are used, prophylactic treatment with low-dose risperidone or haloperidol can avert the occurrence of such episodes during the invasive vEEG monitoring studies (Kanner et al., 1996).

PIP can also lead to the development of inter-ictal psychotic episodes (IPE). Various authors have reported on the development of IPE following PIPE (Adachi et al., 2003; Adachi et al., 2002; Tarulli, Devinsky, & Alper, 2001). For example, Tarulli et al. found that 6 of 43 patients with PIPE met all the criteria for both PIPE and IPE (Tarulli et al., 2001). Five of the six patients had multiple documented PIPEs before they became chronically psychotic. The range of length of time between PIPE and IPE was 7 to 96 months. Kanner and Ostrovskaya found that 7 of 18 patients with PIPE went on to develop IPE, compared to 1 of 18 controls (Kanner & Ostrovskaya, 2008b). Other investigators have reported PIPEs preceding and/or following the occurrence of IPE (Adachi et al., 2003; Adachi et al., 2002).

Ictal psychotic symptoms or episodes should always be considered in the differential diagnosis of PIP and psychosis of epilepsy, as a whole. It is typically due to non-convulsive status epilepticus. The presence of unresponsiveness and automatisms should increase the suspicion. Yet confirmation with EEG recordings is of the essence, as certain psychotic processes, such as catatonic states, can be associated with unresponsiveness and mannerisms that mimic automatisms.

ALTERNATIVE PSYCHOSIS OR “FORCED NORMALIZATION”

The concept of alternative psychosis, developed from observations by Landoldt in 1953, (Landoldt, 1953; Blanchet & Frommer, 1986) implies an inverse relationship between seizure control and psychotic symptom occurrence. He described a “normalization” of EEG recordings with the appearance of psychiatric symptoms and coined the term “forced normalization.” Forced normalization has been reported in patients with TLE and generalized epilepsies. Dongier reported the disappearance of a focal discharge during a psychotic episode

in 15% of 318 patients with peri-ictal psychoses (Dongier, 1959). Prevalence rates of alternative psychosis are reported to be 11–25% (Janz, 2002). As with other forms of psychosis of epilepsy, the psychotic manifestations were identified after a 15-year history of epilepsy in 23 patients reported by Wolf (Wolf & Trimble, 1985). The dopamine (DA) system has been implicated in forced normalization. DA antagonists provoke seizures, and DA agonists have anticonvulsant properties but may precipitate psychosis. Both Landoldt and Wolf reported a pleomorphic clinical presentation with a paranoid psychosis without clouding of consciousness as being the most frequent manifestation. A premonitory phase involving insomnia, anxiety, a feeling of oppression, and social withdrawal may occur in a prodromal phase. Forced normalization may then manifest as psychosis, conversion symptoms, hypochondriasis, depression, or mania.

Inter-ictal psychotic disorders can present with delusions, hallucinations, referential thinking, and thought disorders, as in patients without epilepsy. Slater coined the term “inter-ictal psychosis of epilepsy” (POE) to describe certain clinical characteristics, particularly psychotic episodes seen inter-ictally in patients with chronic epilepsy (Slater, Beard, & Glithero, 1963). The description of these cases is remarkable for *the absence* of negative symptoms, better premorbid history, and less common deterioration of the patients’ personality. The psychosis is less severe and more responsive to therapy.

IATROGENIC PSYCHOTIC DISORDERS

AED-RELATED PSYCHOSIS

Psychotic disorder as an expression of a drug toxicity has been reported with several AEDs, most prominently ethosuximide, phenobarbital, and primidone, as well as the newer AEDs topiramate and levetiracetam (McConnell & Duncan, 1998). Psychotic disorders can occasionally follow the discontinuation of AEDs, particularly those with mood-stabilizing properties. Ketter et al. reported the development of some cases of psychosis among 32 inpatients who were withdrawn from carbamazepine, phenytoin, and valproic acid (Ketter et al., 1994). Acute withdrawal from benzodiazepines is well known to result sometimes in an acute psychotic episode (Sironi, Franzini, Ravagnati, & Marossero, 1979).

PSYCHOSIS FOLLOWING TEMPORAL LOBECTOMY

Temporal lobectomy has been associated with postoperative psychosis. In a series of 100 of Falconer’s patients, Taylor reported seven with *de novo* postoperative psychosis (Taylor, 1972). Jensen and Vaernet reported *de novo* psychotic disorders in 9 of 74 patients (Jensen & Vaernet, 1977). Trimble calculated postoperative *de novo* psychoses to range between 3.8–35.7% (mean, 7.6%) of patients and suggested that, in at least some cases, a causal relationship by way of forced normalization was possible (Trimble, 1992).

Many epilepsy centers currently do not consider patients with a preoperative history of psychosis to be candidates for epilepsy surgery. Thus, more recent reports of postsurgical psychosis in patients are primarily *de novo* psychoses, which would be expected to be of lower incidence than postoperative exacerbations of preexisting psychosis. Yet a history of psychosis should not be considered an absolute contraindication to epilepsy surgery, provided that the patient can cooperate during the presurgical evaluation, has a clear understanding of the nature of the surgical procedure, and can provide a fully informed consent.

DRUG TREATMENT OF PSYCHOSIS IN EPILEPSY PATIENTS

Antipsychotic drugs (APD) are necessary in the management of psychotic disorders in epilepsy patients, despite their proconvulsant properties. While the risk of seizure occurrence must always be carefully considered when starting antipsychotic drugs in these patients, it should never be a reason not to treat a patient in need of antipsychotic medication. Antipsychotic drugs can be separated into two classes: the typical antipsychotic drugs, and the atypical. The former include 18 drugs developed between the 1950s and the 1970s. Their mechanism of action resides in their ability to block dopamine (DA-2) receptors, at the level of meso-cortical, nigrostriatal, and tubero-infundibular DA pathways (Stahl, 2000). Blockade of the DA receptors at the former pathways is responsible for their antipsychotic effect, but it results as well in emotional blunting and cognitive symptoms that often lead to confusion with the negative symptoms of schizophrenia. Blockade at the nigrostriatal pathways results in acute and chronic movement disorders, presenting as Parkinsonian symptoms, as well as dystonic and dyskinetic movements, while blockade at the tubero-infundibular pathways results in increased secretion of prolactin. In addition to their DA-blockade properties, most of the typical antipsychotics have muscarinic cholinergic, α -1, and histaminic blocking properties, responsible for anticholinergic adverse effects, weight gain, sedation, dizziness, and orthostatic hypotension.

Atypical antipsychotic drugs (AAPD) are dopamine-serotonin antagonists that target DA-2 and 5HT-2A receptors (Stahl, 2000). Their main difference with conventional antipsychotic drugs (CAPDs) is the absence or mild occurrence of extrapyramidal adverse events and of hyperprolactinemia. In addition, this class of drugs has a lesser blunting of affect, and several of these AAPDs have mood-stabilizing properties. Hence, AAPDs have in large part replaced CAPDs. Today, six AAPDs have been introduced in the United States: clozapine (Clozaril), risperidone (Risperdal), olanzapine (Zyprexa), ziprasidone (Geodon), quetiapine (Seroquel), and aripiprazole (Abilify).

The seizure rate associated with the use of antipsychotic drugs has ranged from 0.5% to 1.2% among non-epileptic patients (Whitworth & Fleischhacker, 1995). The risk is higher with certain drugs, and higher in the presence of the following factors: (1) a history of epilepsy; (2) abnormal EEG recordings; (3) history of central nervous system disorder;

(4) rapid titration of the APD dose; (5) high doses of antipsychotic drugs; and (6) the presence of other drugs that lower the seizure threshold (McConnell & Duncan, 1998). For example, when chlorpromazine is used at doses above 1000 mgs/day, the incidence of seizures was reported to increase to 9%, in contrast to a 0.5% incidence when lower doses are taken (Logothetis, 1967). Clozapine has been reported to cause seizures in 4.4% when used at doses above 600 mgs/day, while at a doses lower than 300 mgs, the incidence of seizures is less than 1% (Toth & Frankenburg, 1994). While these two drugs have been associated with the higher frequencies of seizures, most antipsychotic drugs have been associated with seizure occurrence in the presence of the risk factors cited above.

With the exception of clozapine, atypical antipsychotic drug-related seizure incidence has not been higher than expected in the general population (Toth & Frankenburg, 1994). This finding was confirmed by Alper et al. in a study comparing the incidence of seizures of psychotic patients without epilepsy randomized to either placebo or one of the atypical antipsychotic drugs (risperidone, olanzapine, quetiapine, and aripiprazole) in regulatory studies submitted to the FDA. Thus, during pre-marketing studies of non-epilepsy patients taking antipsychotic drugs, seizures were reported in 0.3% of patients given risperidone, 0.9% given olanzapine, 0.8% given quetiapine (vs. 0.5% on placebo), and 0.4% of patients treated with ziprasidone (data in PDR, 2002).

The risk of seizure occurrence or worsening of seizures with atypical antipsychotic drugs in PWE has not been well studied. Pacia and Devinsky reviewed the incidence of seizures among 5,629 patients treated with clozapine (Pacia & Devinsky, 1994). Sixteen of these patients had epilepsy before the start of this antipsychotic drug, and all patients experienced worsening of seizures while on the drug: eight patients at doses lower than 300 mgs/day, three patients at doses between 300 and 600 mgs/day, and five at doses higher than 600 mgs/day. Higher doses of clozapine were associated with greater risk of seizures than lower dose therapy (Pacia & Devinsky, 1994). It goes without saying that clozapine should be avoided, or used in exceptional circumstances with extreme caution, in patients with epilepsy.

Most antipsychotic drugs can cause EEG changes consisting of slowing of the background activity, particularly when used at high doses. In addition, some of these drugs, particularly clozapine, can cause paroxysmal electrographic changes in the form of inter-ictal sharp waves and spikes. This type of epileptiform activity, however, is not predictive of seizure occurrence. Data from studies by Tiihonen et al. suggest that a severe disorganization of the EEG recordings is a better predictor of seizure occurrence (Tiihonen et al., 1991).

Clozapine followed by chlorpromazine and loxapine are the three antipsychotic drugs with the highest risk of seizure occurrence. Those with a lower seizure risk include haloperidol, molindone, fluphenazine, perphenazine, trifluoperazine, and the atypical, risperidone. The PDR data available on the atypicals report seizures during clinical trials occurring with olanzapine (0.9%), quetiapine (0.8%), risperidone (0.3%), and ziprasidone (0.4%) (PDR, 2002). Whether the presence of

AEDs at adequate levels protects patients with epilepsy from breakthrough seizures upon the introduction of antipsychotic drugs with proconvulsant properties is yet to be established. AEDs are sometimes started when clozapine is used at greater than 600 mg/d.

In addition to the proconvulsant properties of antipsychotic drugs, clinicians must also consider the pharmacokinetic and pharmacodynamic interactions between these and AEDs. Induction of hepatic enzymes upon the introduction of enzyme-inducing AEDs may result in an increase of the clearance of most antipsychotics. By the same token, discontinuation of an AED with enzyme-inducing properties may result in a decrease in the clearance of the antipsychotic drug, which in turn can lead to extrapyramidal side effects caused by an increase of their serum concentrations. Finally, certain antiepileptic drugs, like valproic acid, can inhibit the glucuronidation metabolism of APDs like clozapine.

ATTENTION-DEFICIT DISORDERS AND BEHAVIOR DISTURBANCES

While the adult epilepsy literature has characterized the full spectrum of DSM- and ICD-defined psychiatric disorders (Swinkels, Kuyk, van Dyck, & Spinhoven, 2005), similar efforts in the pediatric epilepsy literature have essentially just begun (Caplan et al., 2005; Jones, Watson, et al., 2007; McLellan et al., 2005; Ott et al., 2001), again with a focus on children with chronic epilepsy. Of the potential psychiatric comorbid diagnoses of childhood epilepsy, attention-deficit hyperactivity disorder (ADHD) has been of longstanding interest. Ounsted (1955) was among the first to call attention to the syndrome of hyperkinetic disorder and its complications in children with epilepsy. A growing literature has characterized disorders of attention in youth with epilepsy using diverse methods, including proxy (parent, teacher) rating scales, behavioral checklists, or formal cognitive tests (Dunn & Kronenberger, 2005). However, only three investigations determined the rate of ADHD and its subtypes in pediatric epilepsy using contemporary diagnostic criteria that now recognize specific subtypes of the disorder (DSM-IV) (Task Force on DSM-IV, 1994). One of these studies was population-based (Hesdorffer et al., 2004), while the others were derived from tertiary care clinical settings (Dunn, Austin, Harezlak, & Ambrosius, 2003; Sherman, Slick, Connolly, & Eyrl, 2007). All studies reported a significantly elevated rate of ADHD in childhood epilepsy with an over-representation of the inattentive subtype; a distribution that appears different from clinically derived samples of ADHD children seen in tertiary care centers where the combined subtype predominates (Barkley, 2006). None of the studies of ADHD in epilepsy examined the neurobehavioral or neuroradiological complications compared to children with epilepsy without ADHD or healthy controls.

In a population-based study carried out in the Isle of Wight in Great Britain, Rutter and collaborators found behavioral disorders in 28.6% of children with uncomplicated seizures, and 58.3% of children with both seizures

and additional central nervous system pathology (Rutter, 1970). In a separate, population-based study of children with seizures, cardiac disorders, and controls, McDermott and collaborators found that children with epilepsy had more behavioral problems than either the children with cardiac disease or the controls. The children with epilepsy presented with higher rates of hyperactive behavior (28.1% vs. 12.6% in cardiac children and 4.9% in controls), headstrong or oppositional behavior (28.1% vs. 18.3% of cardiac children and 8.6% of controls), and antisocial behavior (18.2% vs. 11.6% of cardiac children and 8.8% of controls) (McDermott, 1995).

PRE-ICTAL SYMPTOMS AND EPISODES

Pre-ictal irritability, impulsive behavior, and poor frustration tolerance have been frequently reported by parents of children with epilepsy without ADHD. Their actual prevalence rates have yet to be established, however. Blanchet and Frommer identified pre-ictal irritability as a prominent symptom, associated with symptoms of depression (Blanchet & Frommer, 1986). These changes were more accentuated during the 24 hours preceding the seizure.

POST-ICTAL SYMPTOMS OF ADHD AND BEHAVIORAL DISTURBANCES

In the study on clinical characteristics and prevalence of post-ictal psychiatric symptoms cited above (Kanner et al., 2004), we found post-ictal irritability in 30 patients and poor frustration tolerance in 36, with a median duration of 24 hours for each symptom (range: 0.5–108 hours).

ADHD AND BEHAVIOR DISTURBANCES AS AN EXPRESSION OF PARA-ICTAL PROCESSES

Behavior disturbances and ADHD are frequent expressions of para-ictal processes, remitting or improving significantly upon reaching seizure control. Examples include “epileptic encephalopathies” such as the acquired epileptic aphasia of childhood (also known as Landau-Kleffner syndrome) (Morrell et al., 1995).

Aggressive behavior and ADHD can be seen in children with gelastic seizures associated with hypothalamic hamartomas. These psychiatric symptoms remit with cessation of epileptic seizures (Fohlen, Lellouch, & Delalande, 2003).

ADHD AND BEHAVIORAL DISTURBANCES AS AN INTER-ICTAL COMORBID DISORDER

The prevalence of ADHD in PWE is reported to range between 10 and 40% (McDermott, 1995; Rutter, 1970; Semrud-Clikeman & Wical, 1999). These data reflect statistics from pediatric populations with epilepsy. In fact, there are no data on the incidence or prevalence of ADHD in adults with epilepsy. Theoretically, if ADHD were to follow the same natural course in PWE than primary ADHD, 50% to 75% of children with epilepsy and ADHD would be expected

to display symptoms of ADHD when entering adulthood. This question will need to be answered in future studies. Furthermore, the clinical manifestations of ADHD in adults with epilepsy are yet to be described in a systematic manner (see Chapter 50 on ADHD).

IATROGENIC ADHD

Many of the AEDs can cause symptoms of behavioral disturbances. The most frequent offenders include GABA-ergic drugs such as the barbiturates, benzodiazepines, and vigabatrin. Among the newer AEDs, topiramate and levetiracetam have been implicated. Valproic acid can cause behavioral disturbances at higher doses, and encephalopathy even with therapeutic doses.

TREATMENT OF ADHD IN PEOPLE WITH EPILEPSY

The pharmacological treatment of ADHD in PWE is the same as that of patients without seizures. In general, there is no pharmacokinetic interaction between CNS stimulants and AEDs, though there have been two reports that methylphenidate can increase blood levels of phenytoin and phenobarbital (McConnell & Duncan, 1998).

PSYCHOSOCIAL CONSEQUENCES FOR PEOPLE WITH EPILEPSY

IMPACT OF DEPRESSION ON QUALITY OF LIFE IN EPILEPSY PATIENTS

Psychiatric symptoms in general are found to have a greater impact on quality of life in patients with TLE than in healthy controls (Hermann et al., 2000). Depression, specifically, has a significantly negative impact on the quality of life of PWE. Lehrner et al. (Lehrner et al., 1999) found that depression was the single strongest predictor for each domain of health-related quality of life that persisted after controlling for seizure frequency, seizure severity, and other psychosocial variables. Perrine et al. (Perrine et al., 1995) found that mood had the highest correlations with scales of the Quality of Life in Epilepsy Inventory–89 (QOLIE-89) and was the strongest predictor of poor quality of life in regression analyses. In a study of patients with pharmaco-resistant TLE, Gilliam et al. found that high ratings of depression and neurotoxicity from AEDs were the only independent variables significantly associated with poor quality of life scores on the QOLIE-89 summary score. The authors *did not* find any correlation between the type and/or the frequency of seizures. Gilliam et al. also found that mood status was the strongest predictor of the patients’ assessment of their own health status in a group of 125 patients more than one year after temporal lobe surgery (Gilliam, 2002; Gilliam et al., 1997). In a recent study, Kanner et al. (Kanner et al., 2010) found that sub-syndromic forms of depression had as negative an impact on quality of life as major depressive episodes and

anxiety disorders. Furthermore, the comorbidity of a major depressive episode and more than one anxiety disorder was associated with a worse impact on quality of life.

STIGMA

The statement that “treating the seizure is not the sum of treating the patient with epilepsy” is most apparent in the psychosocial consequences and familial impact of epilepsy. While the practice of “sterilization of the epileptic” seems archaic, laws were in place in four American states in the early twentieth century that ratified this policy (Friedlander, 2001). Sadly, in the twenty-first century, research in developing countries reveals that the stigma of epilepsy still affects women. Santosh et al. point out that “The psychosocial consequences of the stigma potentials of epilepsy are nowhere more evident than in the case of women with epilepsy of the marriageable age in a developing country.” They examined the prevalence of concealment or disclosure of the history of epilepsy and its consequences on the married life of women with epilepsy in southern India (Santosh, Kumar, Sarma, & Radhakrishnan, 2007). The authors found that 55% of 82 women with epilepsy concealed their history of epilepsy before marriage, and 38% of those who concealed it were separated or divorced. Concealment was described as a coping strategy for anticipated negative consequences of disclosure of the stigmatized disease. Unfortunately, this attitude is not solely a reflection of a developing country’s practice. Researchers in Japan who studied marital statistics in a population of 278 patients with epilepsy found that in one-quarter of PWE who divorced, the reason for divorce was epilepsy (Wada et al., 2004). Kleinman et al. found that family, marriage, financial, and moral consequences of the social experience of epilepsy as a chronic disease demonstrated the importance of the social impact of epilepsy (Kleinman et al., 1995).

Along with the stigma of epilepsy itself, the comorbidities of epilepsy, including depression, anxiety, and non-epileptic seizures, impose a psychosocial burden themselves. Because of stigmatizing attitudes, patients may avoid or delay medical care and treatment for their mental health problems (Andrews, Henderson, & Hall, 2001). In a survey of 1,400 respondents with depression and anxiety, one-quarter of individuals did not present their symptoms to a physician, with reasons including fear of stigma (Meltzer et al., 2003). The importance of early detection of mental illness in patients with chronic somatic disorders is paramount in order to initiate psychiatric treatment to prevent chronification (Gatchel, Polatin, & Kinney, 1995). Freidl et al. investigated the impact of perceptions of stigma in patients with epilepsy, with non-epileptic seizures, and somatoform pain disorders in 101 inpatients and outpatients (Freidl et al., 2007). The authors found a high stigmatization concerning psychiatry, even in patients with epilepsy and somatoform/dissociative symptoms with psychiatric comorbidity, and concluded that perceived stigma is a barrier to recovery. In the next section, another significant comorbidity in epilepsy, non-epileptic seizures, is discussed.

NON-EPILEPTIC SEIZURES

Non-epileptic events are either physiological or psychological in origin (Schachter & LaFrance Jr., 2010). Psychogenic non-epileptic seizures (NES) resemble epileptic seizures presenting as a sudden, involuntary, time-limited alteration in behavior, motor activity, autonomic function, consciousness, or sensation. However, unlike epilepsy, NES do not result from epileptogenic pathology and are not accompanied by an epileptiform electrographic ictal pattern. Patients with NES are often disabled and difficult to treat.

EPIDEMIOLOGY AND COSTS

Of the 1% of the U.S. population diagnosed with epilepsy, 5–20% have NES (Gates, Luciano, & Devinsky, 1991). They are usually women (~80%) and most are between 15 and 35 years old (~80%) (Shen, Bowman, & Markand, 1990), though young children and the elderly can develop NES. The patients, their families, and society bear an enormous cost if psychiatric care is not provided or if inappropriate neurological therapy is instituted (LaFrance & Benbadis, 2006). Patients with NES take double the number of medications compared to patients with epilepsy (Hantke, Doherty, & Haltiner, 2007), and while NES are not responsive to AEDs, most patients with NES receive unnecessary AEDs (de Timary et al., 2002), having been presumed epileptic. Extensive observational data suggest that AEDs are ineffective or may even worsen NES (Krumholz, Niedermeyer, Alkaitis, & Morel, 1980). In some cases, potentially dangerous invasive diagnostic studies, toxic parenteral medications, or emergency intubation are administered. Diagnostic and therapeutic challenges are complicated by the 10–30% rate of comorbid NES and epileptic seizures (ES). Misdiagnosis and mistreatment of NES as ES costs an estimated \$110–\$920 million annually on diagnostic evaluations, inappropriate administration of AEDs, and emergency department utilization (Martin, Gilliam, Kilgore, Faught, & Kuzniecky, 1998).

PATHOLOGY OF NON-EPILEPTIC SEIZURES

While there is not a specific focal “lesion” that produces NES, we do have an understanding of the comorbid psychopathology in patients with NES. The phenomenology of NES, formerly referred to as “pseudoseizures,” is well defined, with systematic assessments of diagnostic comorbidities and psychological testing (Gates & Rowan, 2000; Gram, Johannessen, Oterman, & Sillanpää, 1993). Studies have informed us of risk factors for NES (e.g., sexual or physical abuse, head injury) (Alper, Devinsky, Perrine, Vazquez, & Luciano, 1993; Westbrook, Devinsky, & Geocadin, 1998), and good prognostic features for NES resolution (e.g., female, independent lifestyle, short duration of NES) (Chabolla, Krahn, So, & Rummans, 1996; Bowman, 1999; Barry, 2001; Ettinger, Dhoon, Weisbrot, & Devinsky, 1999). Negative prognostic factors include longer duration of NES, comorbid neurological and/or psychiatric disease, and pending litigation, among others. Interestingly, CNS pathology

and abnormal EEG did not predict outcome in two studies (Lelliott & Fenwick, 1991; Kanner et al., 1999).

There are two main “causes” of NES: post-traumatic and developmental (Kalogjera-Sackellares, 1996). Post-traumatic NES are thought to develop in response to acute or chronic exposure to traumatic experience(s), such as physical or psychological trauma, and sexual or physical abuse. “Developmental NES” refers to coping difficulties with tasks and milestones along the individual’s continuum of psychosocial development. NES are clinically classified under different DSM-5 diagnoses, including *Conversion*, and *Dissociation disorders*. A much smaller percentage (<5%), present as *Factitious disorder and malingering*. A psychosocial stressor (e.g., sexual or physical abuse, loss of a relationship, work stress, parental divorce) (Wyllie, Glazer, Benbadis, Kotagal, & Wolgamuth, 1999) is often identified but may take time to uncover. Many patients with NES also suffer from mood (12–100%), anxiety (11–80%), personality (33–66%), non-seizure conversion/somatoform (20–100%), and non-seizure dissociative disorders (up to 90%) co-occurring with their primary NES diagnosis of conversion, somatoform, or dissociative disorder (Bowman, 1999).

DIAGNOSIS OF NON-EPILEPTIC SEIZURES

Obtaining an accurate diagnosis of NES is the essential first step for instituting proper therapy and avoiding unnecessary and potentially dangerous therapies. Clinical features of ES and NES overlap, however, and there is no one clinical feature that reliably distinguishes ES from NES. Subjective visceral, sensory, or psychic phenomena, alterations in responsiveness, and convulsive motor activity can be present in both disorders. Ictal presentations range from uncoordinated, disorganized motor activity to unresponsiveness without motor signs in NES. Clinical differentiation between NES and epilepsy has also been based on other identifiers such as the presence of pre-ictal pseudosleep (where the patient reports being asleep but EEG shows them to be awake), geotropic eye movements (forced downward deviation of the eyes toward the floor, with head turning), eye closure and post-ictal whispering with NES, and the presence of post-ictal headache and post-ictal nose rubbing with epilepsy. The use of suggestion to both provoke and stop NES is documented. With the issue of disclosure and informed consent, provocative procedures (e.g., saline injection) have drawn fire recently as a potentially unethical intervention (Smith et al., 1997). However, it is argued that when properly employed, seizure induction can act as a “stepping stone” to appropriate treatment if the patient develops insight into the events (i.e., that they are not epileptic) (Devinsky & Fisher, 1996). The distinction between physiological non-epileptic events and psychological NES is based on the combination of thorough history, physical exam in the peri-ictal period, and neurophysiological monitoring (Benbadis & LaFrance Jr., 2010). (See Table 43.8.)

Video-electroencephalographic monitoring (vEEG) led to an explosion of NES knowledge beginning in the 1980s (Boon & Williamson, 1993; Desai, Porter, & Penry, 1979; Jedrejczak, Owczarek, & Majkowski, 1999; Penin, 1968).

An article reviewing the diagnostic tests, including EEG, neuroimaging, prolactin levels, and personality testing, provides the sensitivities and specificities for each of these tests (Cragar, Berry, Fakhoury, Cibula, & Schmitt, 2002). It was once thought that absence of physical injury sustained during a seizure was a diagnostic indicator differentiating NES from ES; however, more than half of all patients with NES actually do have physical injuries associated with their NES (Kanner, 2003). Other injuries occur as a result of iatrogenic issues, which are also prevalent in NES, and death has resulted from medically aggressive treatment of NES (Reuber, Baker, Gill, Smith, & Chadwick, 2004). Up to half of NES patients have had “non-epileptic psychogenic status” (Dworetzky, Bubrick, & Szaflarski, 2010), and 27.8% of patients with NES are admitted to intensive care units inappropriately for treatment (Reuber et al., 2003).

NES are not associated with epileptiform discharges on vEEG recordings, the gold standard for NES diagnosis (Ghougassian, d’Souza, Cook, & O’Brien, 2004). Studies of inter-rater reliability (IRR) in vEEG show moderate to excellent IRR for NES diagnosis (Benbadis et al., 2009; Syed et al., 2011). Humility in diagnosing NES without vEEG—and sometimes with vEEG—is critical. In one study, prediction of the nature of unusual seizures by the admitting neurologist was accurate in only 67% of cases. When observing these events without accompanying EEG, determination from observations of unit personnel and neurologists was correct in less than 80% of episodes (King et al., 1982). Lancman et al. strongly assert that “No matter how suggestive the clinical manifestation of a paroxysmal event may be of pseudoseizures, such diagnosis should never be made without electrographic confirmation” (Lancman, Lambrakis, & Steinhart, 2001). The co-occurrence of ES and NES in a patient, present in 10% of patients with NES (Benbadis et al., 2001), further potentially complicates diagnosis and therapy. The diagnosis comes through careful history and thorough review of medical records that can identify different episode types and assess the supportive data.

EEG abnormalities in patients with NES do not necessarily confirm the diagnosis of ES. For example, EEGs showing “sharpish waves” or paroxysmal slowing provide little support of ES. Normal variants are also misinterpreted as inter-ictal epileptiform discharges in patients without epilepsy (Benbadis & Lin, 2008). A positive neurological history was present in a quarter of patients with NES, and a positive family history of epilepsy was present in 37.6% of NES patients (Lancman, Brotherton, Asconape, & Penry, 1993). While neurological signs, symptoms, and history are important to note in seizure patients, they are in no way pathognomonic in distinguishing NES from ES. A 2004 paper described three criteria in NES patients admitted for vEEG, yielding a positive predictive value of 85% (Davis, 2004). The criteria were (1) at least two NES per week, (2) refractory to at least two AEDs, and (3) at least two EEGs without epileptiform activity. Using “the rule of 2’s” documenting seizure frequency, EEG abnormalities, and drug-treatment response prior to vEEG may help with definitive diagnosis of NES. An International League Against Epilepsy commissioned paper provided diagnostic

Table 43.8 BEHAVIORS TO HELP DISTINGUISH PSYCHOGENIC NON-EPILEPTIC AND EPILEPTIC SEIZURES

	PSYCHOGENIC NON-EPILEPTIC SEIZURES	EPILEPTIC SEIZURES
<i>Observation</i>		
Situational onset	Occasional	Rare
Gradual onset	Common	Rare
Precipitated by stimuli (noise, light)	Occasional	Rare
Purposeful movements	Occasional	Very rare
Opisthotonus “ <i>arc de cercle</i> ”	Occasional	Very rare
Tongue biting (tip)	Occasional	Rare
Tongue biting (side)	Rare	Common
Prolonged ictal atonia	Occasional	Very rare
Vocalization during “tonic-clonic” phase	Occasional	Very rare
Reactivity during “unconsciousness”	Occasional	Very rare
Rapid post-ictal reorientation	Common	Unusual
Undulating motor activity	Common	Very rare
Asynchronous limb movements	Common	Rare
Rhythmic pelvic movements	Occasional	Rare
Side-to-side head shaking	Common	Rare
Ictal crying	Occasional	Very rare
Ictal stuttering	Occasional	Rare
Post-ictal whispering	Occasional	Not present
Closed mouth in “tonic phase”	Occasional	Very rare
Closed eyelids during seizure onset	Very common	Rare
Convulsion >2 minutes	Common	Very rare
Resisted lid opening	Common	Very rare
Pupillary light reflex	Usually retained	Commonly absent
Lack of cyanosis	Common	Rare
Ictal grasping	Rare	Occurs in FLE and TLE
Post-ictal nose rubbing	Not present	Can occur in TLE
Stertorous breathing post-ictally	Not present	Common
Self-injury	May be present (especially excoriations)	May be present (especially lacerations)
Incontinence	May be present	May be present

Abbreviations: FLE, frontal lobe epilepsy; TLE, temporal lobe epilepsy.

levels of certainty for NES based on history, event semiology and studies (with vEEG being the gold standard) (LaFrance et al., 2013).

TREATMENT LITERATURE

Along with diagnostic advances and a solid understanding of NES phenomenology, there is a growing evidence base for treatments for NES. Historically, the literature provided divergent views on natural history and outcome, as well as the value of psychotherapy, psychotropic medication, and other interventions for NES (Barry, 2001; Ramani, 2000; Aboukasm, Mahr, Gahry, Thomas, & Barkley, 1998; Walczak et al., 1995). More than a century after this disorder was clearly identified, there is now only one Class I, randomized, clinical trial (RCT) for treatment of NES (LaFrance et al., 2014) (discussed below). More controlled studies on treating this costly and disabling disorder are needed.

The NES treatment literature has been systematically reviewed (LaFrance & Devinsky, 2004; LaFrance & Barry, 2005; Baker, Brooks, Goodfellow, Bodde, & Aldenkamp, 2007; LaFrance, Reuber & Goldstein, 2013). There is a growing number of prospective series in the NES treatment literature published. Ataoglu et al. (Ataoglu, Ozcetin, Icmeli, & Ozbulut, 2003) randomized 30 patients with NES: half to paradoxical intention (PI) inpatient psychotherapy, and the other half to oral benzodiazepine therapy. PI consists of the therapist's suggesting that the patient engage in the undesired activity intentionally. The authors found greater improvements in anxiety scores and mildly better seizure control in the PI group than in the diazepam group. More recently, two prospective open trials of cognitive behavioral therapy (CBT) (Goldstein, Deale, Mitchell-O'Malley, Toone, & Mellers, 2004; LaFrance et al., 2009) and another two using group psychotherapy showed reduction in NES frequency and post-traumatic symptoms, respectively (Barry, Wittenberg, et al., 2008; Zaroff, Myers, Barr, Luciano, & Devinsky, 2004).

In a follow-up cohort study, 11 of 14 (79%) inpatients with NES experienced cessation or significant improvement after receiving a combination of hypnosis, group therapy, family therapy, and individual therapy (Kim, Barry, & Zeifert, 1998). A follow-up study at a comprehensive epilepsy center (CEP) (Aboukasm et al., 1998) suggested that CEP psychotherapists and CEP neurologists have similar favorable treatment outcomes, underscoring the beneficial impact of continuity of care and explanation of the nature of the seizures. The study also showed that the absence of communication with a NES patient about the diagnosis yields no improvement or worsening in their seizures. Rusch et al. (Rusch, Morris, Allen, & Lathrop, 2001) found that matching specific psychotherapies to the patient's comorbid diagnoses produced greater seizure-free rates, with 21 of 33 patients (63%) reaching event-free status at the end of treatment.

Moving beyond open-label data, more recently, two pilot RCTs were published comparing treatments to control groups. Goldstein et al. enrolled 66 patients with NES who were randomized to either CBT (plus standard medical care [SMC])

or SMC alone, scheduled to occur over four months. They found a reduction in the CBT-treated group, compared to the SMC group (Goldstein et al., 2010). LaFrance et al. enrolled 38 patients with NES in a double-blind pilot RCT who were randomized to either flexible-dose sertraline or placebo. They found a 45% reduction in NES in the SSRI-treated group and an 8% increase in the placebo group (LaFrance et al., 2010). As noted above, a multicenter pilot RCT enrolling 38 patients compared a CBT-informed psychotherapy (CBT-ip), CBT-ip and sertraline, sertraline alone and Treatment As Usual (TAU/SMC) and found the two psychotherapy arms showed a significant reduction in NES, comorbid symptoms (depression and anxiety) and improvement in functioning and quality of life. Ements in depression. Medication alone showed improvements in depression. The TAU/SMC arm showed no improvement in NES or secondary measures (LaFrance et al., 2014). Along with providing evidence for a manualized therapy for NES (Reiter et al., 2015), the study underscored that the current standard is not adequately treating patients with NES. More large-scale clinical trials are greatly needed to provide more Class I efficacy data for treatments for NES.

TREATMENT OF NON-EPILEPTIC SEIZURES

Prior to recent years, there was a lack of systematic intervention studies for NES. The void of generalizable, effective treatments for NES left only consensus recommendations (Ramani, 2000). Although psychotherapy is the mainstay of treatment recommendations, (Ramani, 2000; Aboukasm et al., 1998) its efficacy had been unproven with controlled data. Furthermore, no medications had proven effective in the treatment of NES. Clinicians do, however, use psychotropic medications to treat comorbid mood, anxiety, and elements of personality disorders, which often occur in patients with NES.

TREATMENT THEORIES

Etiological approaches for NES include *biomedical*, *psychodynamic*, *cognitive behavioral*, and *family theory* models (Ziegler & Imboden, 1962; Swingle, 1998; Krawetz et al., 2001). Precursors to psychogenic NES include childhood sexual abuse, physical abuse, comorbid psychiatric conditions, minor head trauma, disability claims, and reinforced behavioral patterns, among others. In identifying signs, symptoms, and situations that are associated with NES in a patient, we can formulate predisposing, precipitating and perpetuating factors that then inform interventions to promote the mental, physical, and social health of the patient (LaFrance & Devinsky, 2002).

Biomedical approaches highlight the absence of epileptiform activity during NES, demonstrating a functional-neuroanatomical dissociation model for NES (Brown & Trimble, 2000; Blumer, 2000). AEDs do not treat NES, and in some patients can worsen NES (Niedermeyer, Blumer, Holscher, & Walker, 1970). Conversely, withdrawal

of AEDs has been shown to be safe in patients with lone NES (Oto, Espie, Pelosi, Selkirk, & Duncan, 2005). Anti-depressant, anti-anxiety, and antipsychotic therapies (e.g., medication, relaxation techniques) can treat symptomatic comorbid disorders and are currently being studied to evaluate whether medications may indirectly improve NES frequency or severity (LaFrance, Blum, Miller, Ryan, & Keitner, 2007).

NES are currently treated as a neuropsychiatric illness with psychological underpinnings. Both psychotherapeutic and psychopharmacological interventions are used to treat psychological conflicts and to treat the psychiatric comorbid diagnoses. These approaches fall under the headings of psychodynamic psychotherapy, cognitive behavioral therapies, family systems therapies, behavioral modification (mainly for mentally handicapped individuals), and biological psychiatric treatments.

CONCEPTUALIZATION FOR TREATMENT RECOMMENDATIONS

Bowman recommends the “4 E’s” for interventions by neurologists: Explanation, Exploration, Exportation (for treatment), and do not Exile. The circumspect neurologist will exercise caution when deciding whether or not to “explore” a patient’s trauma history. The “exile” issue is of greatest importance because it must be realized that once the vEEG diagnosis of NES is confirmed by the neurologist, the difficult work of collaboratively treating the patient with psychiatry has just begun.

Treatment and outcome vary considerably with the underlying psychopathology. Patients with NES generally have poor to fair treatment outcomes, but children and adolescents tend to do better than adults. In one study, outcome was significantly better for the younger patients at 1, 2, and 3 years after diagnosis (seizure-free percentages: children, 73%, 75%, 81%; and adults, 25%, 25%, 40%, respectively). The authors proposed that different psychological mechanisms at different ages of onset and greater effectiveness with earlier intervention may be factors leading to better outcome for children and adolescents (Wyllie et al., 1991).

The higher success rates are noted in the treatment articles and chapters describing longer inpatient admissions where patients were managed by a multidisciplinary team familiar with NES (Ramani & Gumnit, 1982). More recent reviews, however, reveal that roughly one-third of the patients have NES cessation, and another third have reduction in their NES (Reuber & Elger, 2003). In one NES outcome study, 71% of patients reported persistence of their seizures, in spite of 41% of the patients’ having had inpatient psychiatric treatment (Reuber et al., 2003). Of the patients with lone NES, 40% continued to receive AEDs inappropriately, impacting their quality of life. Patients with NES rate their quality of life more poorly than those with epilepsy (Testa, Schefft, Szaflarski, Yeh, & Privitera, 2007). Quigg et al. found that quality of life measures improve, however, when patients reach NES freedom, and not when their NES are merely reduced (Quigg, Armstrong, Farace, & Fountain, 2002). Even with NES improvement, up to half of the patients remain on government or family support and are unemployed (Krawetz et al., 2001), and patients with NES generally do not expect

to return to work (Pestana, Foldvary-Shaefer, Marsillio, & Morris, 2003). One study found that patients with NES scored higher on hypochondriasis and somatic-complaint scales of the Minnesota Multiphasic Personality Inventory (MMPI) compared with patients with epilepsy, reflective of a focus on bodily function and neurological complaints (Owczarek, 2003). Poor quality of life in patients with NES may partly result from their somatic focus. A factor analysis of predictors of health-related quality of life revealed that patients with NES had more bodily concern than those with epilepsy (Testa, Szaflarski, Fargo, Dulay, & Schefft, 2003), and that somatic focus may influence health-related quality of life.

Noting the good prognosis if NES has a recent onset, Gates suggested that psychiatric treatment be based on NES chronicity: short-term psychotherapy for those with NES for less than six months, and more intensive inpatient therapy for those with longstanding NES (Gates, 1998). Although patients who receive feedback about their diagnosis and psychotherapy have better outcomes than those who do not (Aboukasm et al., 1998), the difference may reflect baseline characteristics of the groups, rather than the effects of intervention.

Based on the clinical and research reports to date, we suggest the following assessment and treatment approach by a multi-specialty neuropsychiatric team:

1. Proper diagnosis—vEEG for each patient with suspected NES, refractory, or pharmaco-resistant seizures.
2. Presentation—explain the NES diagnosis in a clear, positive, non-pejorative manner. The patient may make the diagnosis presentation to the family members if cognitively and emotionally capable. This process helps reveal the level of understanding and initial acceptance of the diagnosis by the patient. Clarifications can be made by the physician who is present. Communicate the diagnosis unambiguously to the referring physician and explain the need to eliminate unnecessary medications.
3. Psychiatric treatment—conduct a thorough psychiatric assessment to identify predisposing factors (including comorbid psychiatric disorders), seizure precipitants, and perpetuating factors. As diagnosis informs treatment, a dual-armed approach ensues with pharmacotherapy and/or psychotherapy, as indicated by the individual needs of the patient with NES.

Psychopharmacology begins with tapering and discontinuing ineffective AEDs for patients with lone NES, unless a specific AED has a documented beneficial psychopharmacological effect in the patient. In patients with mixed ES/NES, reduce high-dose or multiple AED therapy if possible. Use psychopharmacological agents to treat mood, anxiety, or psychotic disorders (LaFrance & Devinsky, 2002).

Psychogenic NES are likely to be the result of a complex interaction between psychiatric disorders, psychosocial stressors, dysfunctional coping styles, and CNS vulnerability (Mökleby et al., 2002). Identifying the underlying stressors and providing supportive psychotherapy can help some patients, but this is often insufficient or ineffective. Studies

consistently identify three main comorbid diagnoses in patients with NES: *Major depressive disorder*, *Post-traumatic stress disorder*, and *Cluster B personality traits characterized by impulsivity/hostility* (Bowman & Markand, 1996), (Rechlin, Loew, & Joraschky, 1997). Three additional critical areas of dysfunction in the NES population are emotion regulation, family dynamics, and unemployment/disability (Walczak et al., 1995; Holmes et al., 2001; Griffith, Polles, & Griffith, 1998). Poorer outcomes of treatment may be associated with the high number of comorbid psychiatric disorders and psychosocial stressors (Carson, Ringbauer, MacKenzie, Warlow, & Sharpe, 2000). Therefore, therapy for patients with NES may require combined psychological education, psychotherapy, and pharmacotherapy, while simultaneously eliminating ineffective AEDs. A National Institute of Neurological Disorders and Stroke (NINDS)/National Institute of Mental Health (NIMH)/American Epilepsy Society (AES) workshop emphasized that there is a great need for these interventions to be studied in randomized, controlled trials (LaFrance et al., 2006).

Prior published treatment reports reveal that coordination between neurologists and psychiatrists/psychologists with accurate diagnosis and prompt initiation of psychotherapy and communication between care providers, patients and families yields higher treatment success.

SUMMARY

In conclusion, a significant number of PWE have psychiatric disorders that accompany their seizures, and/or integrated mood/anxiety/psychotic and personality integrated symptoms secondary to their epilepsy. Quality of life and stigma associated with epilepsy have a significant impact on the lives of PWE. Management of epilepsy is also complicated by the presence of NES. Further research in these areas is needed to inform diagnosis, pathophysiology, and treatment of these neuropsychiatric aspects of epilepsy.

CLINICAL PEARLS

- Among the physiological non-epileptic events that must be considered in the differential diagnosis of treatment-resistant epilepsy are several sleep disorders, syncope, migraines, or transient ischemic attacks.
- Comorbid psychiatric disorders commonly occur in patients with epilepsy.
- The evaluation of any type of psychopathology in patients with epilepsy must be approached with the following questions in mind:
 - Is this psychiatric disturbance temporally related to the occurrence of seizures? Is the onset of psychiatric symptoms associated with the remission of seizures? (We consider the peri-ictal psychiatric symptoms (pre-ictal and post-ictal) as well as inter-ictal symptoms associated with the onset or remission of seizures an expression of a para-ictal process.)
- Are the psychiatric symptoms the result of the introduction of an antiepileptic drug (AED) with potentially negative psychotropic properties, or did they appear after discontinuation of an AED with positive psychotropic properties (mood stabilizing, antidepressant, and anxiolytic properties)?
- Do the symptoms meet diagnostic criteria of the DSM or the ICD, or do these symptoms present as an atypical disorder?
- What is the impact of the psychiatric disorder at hand on the quality of life of patients?
- What is the treatment for the psychiatric disorder?
- If pharmacotherapy is required, how do psychotropic drugs interact with AEDs, and what is the impact of psychotropic drugs on the seizure threshold?
- Depression is the most frequent psychiatric disorder in patients with epilepsy: more common in patients with partial seizure disorders of temporal or frontal lobe origin and among patients with poorly controlled seizures (Edeh & Toone, 1987; Jacoby et al., 1996; Mendez et al., 1986; O'Donoghue et al., 1999).
- The suicide rate in depressed PWE is 9–25 times higher in patients with partial seizures of temporal lobe origin than expected in the overall population (Nilsson, Tomson, Farahmand, Diwan, & Persson, 1997; Rafnsson, Olafsson, Hauser, & Gudmundsson, 2001; Robertson, 1997).
- Pre-ictal symptoms of depression and depressive episodes typically present as a dysphoric mood in which the prodromal symptoms may extend for hours or even one to three days prior to the onset of a seizure.
- Depressive disorders often occur with anxiety disorders. Recognition of such comorbidity is critical, as failure to target the anxiety disorder in the treatment of these patients can result in recurrence of the depressive disorder.
- The addition of AEDs with mood-stabilizing properties, such as carbamazepine, valproic acid, and lamotrigine, can occasionally cause depressive episodes, albeit with a significantly lower frequency than other AEDs. More often than not, these AEDs are associated with the occurrence of depression *upon their discontinuation* in patients with a prior history of depression or panic disorder, which had been kept in remission by these AEDs (Ketter et al., 1994).
- Depressive disorder may follow antero-temporal lobectomy (Savard, Andermann, Reutens, & Andermann, 1998); patients with a prior history of depression are at greater risk.
- SSRIs are safe in general in patients with epilepsy.
- Most antidepressants are metabolized in the liver, and their metabolism is accelerated in the presence of AEDs with enzyme-inducing properties, which include

- phenytoin, carbamazepine, phenobarbital, primidone at regular doses, and oxcarbazepine and topiramate at doses above 900 mg/day and 300 mg/day, respectively. This pharmacokinetic effect is not observed with the new AEDs gabapentin, lamotrigine, tiagabine, levetiracetam, zonisamide, pregabalin, vigabatrin, and ezogabine.
- Electroconvulsive therapy (ECT) is not contraindicated in depressed PWE (Fink, Kellner, & Sackeim, 1999; Regenold, Weintraub, & Taller, 1998; Sackeim, Decina, Prohovnik, Malitz, & Resor, 1983).
 - Vagal nerve stimulation (VNS) is used as adjunctive treatment for epilepsy and has also shown longer-term mood effects (Marangell et al., 2002).
 - Ictal fear or panic is the most frequent ictal psychiatric symptom. It is the sole or predominant clinical expression of a simple partial epileptic seizure (aura) or the initial symptom of a complex partial epileptic seizure, and it usually has a mesial temporal lobe origin.
 - A careful history can help distinguish inter-ictal from ictal panic. Ictal panic is typically less than 30 seconds in duration, is stereotypical, occurs out of context with concurrent events, and is associated with other ictal phenomena, such as periods of confusion of variable duration and subtle or overt automatisms. The intensity of the sensation of fear is mild to moderate and rarely reaches the intensity of a panic attack.
 - SSRIs can prevent the occurrence of inter-ictal panic attacks and generalized anxiety disorder, but there is as of yet no evidence that these drugs have any impact on post-ictal psychiatric symptoms.
 - In most cases, insomnia is the initial presenting symptom. In patients with recurrent post-ictal psychotic episodes, families need to learn to recognize these symptoms so that a timely administration of 1–2 mgs of risperidone may avert the episode. It should be given for two to five days and then discontinued.
 - *Ictal psychotic symptoms or episodes* should always be considered in the differential diagnosis of post-ictal psychosis and psychosis of epilepsy as a whole.
 - Psychotic disorder as an expression of a drug toxicity has been reported with several AEDs, most prominently ethosuximide, phenobarbital, and primidone, as well as the newer AEDs topiramate and levetiracetam (McConnell & Duncan, 1998). Psychotic disorders can occasionally follow the discontinuation of AEDs, particularly those with mood-stabilizing properties.
 - Antipsychotic drugs (APD) are necessary in the management of psychotic disorders in epilepsy patients despite their proconvulsant properties. While the risk of seizure occurrence must always be carefully considered when starting antipsychotic drugs in these patients, it should never be a reason not to treat a patient in need of antipsychotic medication.
 - There is no pharmacokinetic interaction between CNS stimulants and most AEDs.
 - Clinical differentiation between non-epileptic seizures and epilepsy has also been based on other identifiers such as the presence of pre-ictal pseudosleep (where the patient reports being asleep but EEG shows them to be awake), geotropic eye movements (forced downward deviation of the eyes toward the floor with head turning), eye closure, and post-ictal whispering with NES; and the presence of post-ictal headache and post-ictal nose-rubbing with epilepsy.
 - Non-epileptic seizures are currently treated as a neuropsychiatric illness with psychological underpinnings. Psychotherapeutic interventions are used to address psychological conflicts, and psychopharmacological interventions are used to treat comorbid psychiatric diagnoses.
 - Validated, manualized treatment for patients with NES has been shown to reduce NES frequency, improve comorbid symptoms, quality of life and functioning.

DISCLOSURE STATEMENTS

Dr. LaFrance has received research support from the National Institutes of Health (NINDS 5K23NS45902 [PI]), the American Epilepsy Society, the Epilepsy Foundation, Rhode Island Hospital, and the Siravo Foundation; has acted a legal expert; serves on the editorial board of *Epilepsy & Behavior*; is chair of the American Epilepsy Society (AES) and International League Against Epilepsy (ILAE) NES Task Forces; and receives royalties from the publication of *Gates and Rowan's Nonepileptic Seizures*, 3rd ed. (New York: Cambridge University Press, 2010). Dr. Kanner has received research funding from Pfizer Laboratories.

DIAGNOSIS AND TREATMENT OF HEADACHE

Elizabeth W. Loder

INTRODUCTION

Mild, occasional headaches are among the common aches and pains of life. These ordinary headaches are infrequent, respond well to simple over-the-counter treatments and do not require medical attention. When headaches are severe, frequent, or disabling, however, sufferers often seek medical care. Headache is among the most common outpatient complaints and a common reason for emergency department visits. Physicians in nearly every specialty can expect to encounter patients with troublesome headaches. Because a number of chronic headache conditions are comorbid with certain psychiatric disorders, however, psychiatrists are especially likely to encounter patients with complaints of headache. This chapter focuses on the diagnosis and management of recurrent headache.

HEADACHE DIAGNOSIS

Headache diagnosis depends heavily upon the patient's description of typical headache features. *The International Classification of Headache Disorders* (ICHD) has many features in common with the diagnostic system used in psychiatry: diagnosis is clinical, and is based on inclusion and exclusion criteria (Headache Classification Subcommittee of the International Headache Society, 2013). The diagnostic criteria focus on headache location, intensity, duration, and the presence or absence of typical aggravating or associated features. In addition to inquiring about these characteristics of headache, a complete headache history should include information about prescription and non-prescription medicines used now and in the past to treat headaches, a family history of headaches, and other medical conditions and medications.

ICHD divides headaches into two major categories. *Primary* headaches are those for which no other disorder can be identified as responsible for the headache. The three major primary headache disorders are migraine, tension-type, and cluster headaches. Boxes 44.1–44.3 list diagnostic criteria for these disorders. A fourth group of “other” primary headaches includes less common syndromes such as hemicrania continua and new daily persistent headache. When patients meet criteria for a primary headache disorder and have a normal neurological examination, additional testing generally is not needed or recommended (Bartleson, 2006).

Secondary headaches, in contrast, are those in which the headache is due to an underlying problem such as head injury, tumor, or infection. When there is suspicion of a secondary headache disorder on the basis of the history or physical examination, additional investigation is needed (Detsky et al., 2006). Table 44.1 lists worrisome or “red flag” symptoms or signs that generally should prompt further testing, and the specific diagnoses of concern. The testing necessary depends upon the disorder that is suspected, and might include computed tomography (CT) or magnetic resonance imaging (MRI) of the head or cervical spine, blood tests, or a lumbar puncture to assess cerebrospinal fluid pressure and composition (Evans & Silberstein, 2002). With the exception of situations in which acute cerebral bleeding or other unusual problems are suspected, MRI is the preferred imaging test. MRI is more sensitive than CT for a variety of abnormalities, and provides a better look at posterior brain structures. An MR angiogram (MRA) or venogram (MRV) can be useful to detect arterial or venous abnormalities responsible for headache (Mehndiratta, Garg, & Gurnani, 2006).

HEADACHE MISDIAGNOSIS AND TREATMENT ERRORS

It can sometimes be difficult to distinguish between primary and secondary disorders, and the two may coexist. Because the primary headache disorder of migraine is so common in the population, for example, many people who experience head trauma have a prior history of migraine, which may worsen in relation to the head injury. It can be difficult to distinguish the relative contributions of the two problems in such cases. Primary headache disorders such as migraine are often incorrectly attributed to medical disorders such as sinus pathology. The misdiagnosis of migraine as “sinus” headache is a well-known phenomenon (Silberstein, 2004a). In clinical practice it is not uncommon to see patients who have had multiple unsuccessful sinus surgeries for recurrent or frequent headaches, and who respond well to triptans or other specific anti-migraine therapies when those are tried. The confusion between sinus headaches and migraine probably stems from the fact that migraine can be accompanied by nasal congestion or stuffiness and can also produce facial pain. Migraine attacks can last several days, and if the symptoms are incorrectly attributed to sinus pathology, a course of antibiotics may be started

Box 44.1 DIAGNOSTIC CRITERIA FOR THE THREE SUBTYPES OF TENSION-TYPE HEADACHE (ICHD-3 BETA) (HEADACHE CLASSIFICATION SUBCOMMITTEE OF THE INTERNATIONAL HEADACHE SOCIETY, 2013). REPRODUCED WITH PERMISSION OF THE INTERNATIONAL SOCIETY OF HEADACHE

Infrequent episodic tension-Type headache

- A. At least ten episodes occurring on <1 day per month on average (<12 days per year) and fulfilling criteria B–D
- B. Headache lasting from 30 minutes to 7 days
- C. Headache has at least two of the following characteristics:
 - 1. Bilateral location
 - 2. Pressing/tightening (non-pulsating) quality
 - 3. Mild or moderate intensity
 - 4. Not aggravated by routine physical activity such as walking or climbing stairs
- D. Both of the following:
 - 1. No nausea or vomiting (anorexia may occur)
 - 2. No more than one of photophobia or phonophobia
- E. Not better accounted for by another ICHD-3 diagnosis

Frequent episodic tension-Type headache

Like *Infrequent episodic tension-type headache*, except for:

- A. At least ten episodes occurring on ≥ 1 but <15 days per month for at least 3 months (≥ 12 and <180 days per year) and fulfilling criteria B–D

Chronic tension-Type headache

- A. Headache occurring on ≥ 15 days per month on average for >3 months (≥ 180 days per year)¹ and fulfilling criteria B–D
- B. Headache lasts hours to days or may be unremitting
- C. Headache has at least two of the following characteristics:
 - 1. Bilateral location
 - 2. Pressing/tightening (non-pulsating) quality
 - 3. Mild or moderate intensity
 - 4. Not aggravated by routine physical activity such as walking or climbing stairs
- D. Both of the following:
 - 1. No more than one of photophobia, phonophobia or mild nausea
 - 2. Neither moderate nor severe nausea, nor vomiting
- E. Not attributed to another ICHD-3 diagnosis

Note: Code 2.3, *Chronic tension-type headache*, evolves over time from episodic tension-type headache; when these criteria A–E are fulfilled by headache that, unambiguously, is daily and unremitting within three days of its first onset, code as 4.8, *New daily-persistent headache*.

Box 44.2 DIAGNOSTIC CRITERIA FOR MIGRAINE WITH AND WITHOUT AURA AND CHRONIC MIGRAINE (ICHD-3 BETA) (HEADACHE CLASSIFICATION SUBCOMMITTEE OF THE INTERNATIONAL HEADACHE SOCIETY 2013). REPRODUCED WITH PERMISSION OF THE INTERNATIONAL SOCIETY OF HEADACHE

Migraine without aura

- A. At least five attacks fulfilling criteria B–D
- B. Headache lasting 4 to 72 hours (untreated or unsuccessfully treated)
- C. Headache has at least two of the following characteristics:
 - 1. Unilateral location
 - 2. Pulsating quality
 - 3. Moderate or severe pain intensity (inhibits or prohibits daily activities)
 - 4. Aggravation by, or causing avoidance of, routine physical activity such as walking stairs or similar routine physical activity
- D. During headache, at least one of the following occurs:
 - 1. Nausea and/or vomiting
 - 2. Photophobia and phonophobia
- E. At least one of the following is present:
 - 1. History and physical and neurological examinations do not suggest an organic disorder
 - 2. History and/or physical and/or neurological examinations do suggest such disorder, but it is ruled out by appropriate investigations
 - 3. Such disorder is present, but migraine attacks do not occur for the first time in close temporal relation to the disorder

Migraine with aura

- A. At least two attacks fulfilling criteria B and C
- B. One or more of the following fully reversible aura symptoms:
 - 1. Visual
 - 2. Sensory
 - 3. Speech and/or language
 - 4. Motor
 - 5. Brainstem
 - 6. Retinal
- C. At least two of the following four characteristics are present:
 - 1. At least one aura symptom *develops gradually* over more than 5 minutes, and/or two or more symptoms occur in succession
 - 2. No single aura symptom *lasts less than 5 minutes or more than 60 minutes*
 - 3. At least one aura symptom is unilateral

4. *Headache follows aura* with a free interval of less than 60 minutes (it also may begin before or simultaneously with the aura)

D. Not better accounted for by another ICHD-3 diagnosis, and history, physical examination, and, where appropriate, diagnostic tests exclude a secondary cause

Chronic migraine

DIAGNOSTIC CRITERIA

A. Headache fulfilling criteria B and C for 1.1, *Migraine without aura*, on ≥ 15 days/month for >3 months which has the features of migraine headache on ≥ 8 days/month

B. Not better accounted for by another ICHD-3 diagnosis

Note:

1. History and physical and neurological examinations do not suggest any of the disorders listed in groups 5–12, or history and/or physical and/or neurological examinations do suggest such disorder, but it is ruled out by appropriate investigations, or such disorder is present, but headache does not occur for the first time in close temporal relation to the disorder.

2. When medication overuse is present and fulfils criterion B for any of the subforms of 8.2 *Medication-overuse headache*, it is uncertain whether this criterion B is fulfilled until 2 months after medication has been withdrawn without improvement (see *Comments*).

Comments:

Most cases of chronic migraine start as 1.1 *Migraine without aura*. Therefore, chronicity may be regarded as a complication of episodic migraine. As chronicity develops, headache tends to lose its attack-wise (episodic) presentation, although it has not been clearly demonstrated that this is always so.

and appear to be effective when the headache naturally wanes. Additionally, vasoconstrictive decongestant medications and mild analgesics contained in over-the-counter sinus medications can also be effective for migraine, which then reinforces the idea that the problem was due to sinus pathology.

Migraine is also often misdiagnosed as tension-type headache. In patients who develop daily or near-daily headache, there may be an evolution in headache characteristics over time. Typically, accompanying symptoms such as nausea and vomiting become less prominent as patients get older and as headache frequency increases. The clinical picture can be mistaken for tension-type headache if a full history of early attack characteristics is not obtained. One study carried out in general practice showed that most physician diagnoses of tension-type headache turned out to be incorrect. When longitudinal diary information was obtained, most patients initially diagnosed with tension-type headache turned out to have migraine (Lipton, Cady, Stewart, Wilks, & Hall, 2002).

Diagnostic delay is common in cluster headache. In one study, the mean delay before correct diagnosis was 2.6 years, and patients consulted an average of three physicians before a correct diagnosis was identified (Bahra & Goadsby, 2004). The most common misdiagnosis of cluster headache is migraine; there is

Box 44.3 DIAGNOSTIC CRITERIA FOR EPISODIC AND CHRONIC CLUSTER HEADACHE (ICHD-3 BETA) (HEADACHE CLASSIFICATION SUBCOMMITTEE OF THE INTERNATIONAL HEADACHE SOCIETY 2013). REPRODUCED WITH PERMISSION OF THE INTERNATIONAL SOCIETY OF HEADACHE.

Episodic Cluster Headache

A. At least five attacks fulfilling criteria B–D

B. Severe or very severe unilateral orbital, supraorbital, and/or temporal pain lasting 15–180 minutes if untreated

C. Either or both of the following:

1. At least one of the following symptoms or signs ipsilateral to the headache:
 - a. Ipsilateral conjunctival injection and/or lacrimation
 - b. Ipsilateral nasal congestion and/or rhinorrhea
 - c. Ipsilateral eyelid edema
 - d. Ipsilateral forehead and facial sweating
 - e. Ipsilateral forehead and facial flushing
 - f. Sensation of fullness in the ear
 - g. Ipsilateral miosis and/or ptosis

2. A sense of restlessness or agitation

D. Attacks have a frequency from one every other day to eight per day

E. Not attributed to another disorder

Chronic Cluster Headache

A. Attacks fulfilling criteria A–E for 3.1 *Cluster headache*

B. Attacks recur over >1 year without remission periods or with remission periods lasting <1 month

Comments:

Chronic cluster headache may arise *de novo* (previously referred to as *Primary chronic cluster headache*) or evolve from the episodic subtype (previously referred to as *Secondary chronic cluster headache*). Some patients may switch from chronic to episodic cluster headache.

some overlap in treatments for the two conditions (sumatriptan is effective for acute treatment of both disorders, for example), but there are also many differences. Preventive treatments such as beta blockers that are helpful for migraine are not effective for cluster headache, so diagnostic delay exposes some patients to many years of ineffective treatments. Patients with cluster headaches are also often thought to have dental problems, and many undergo unnecessary tooth extractions.

Misdiagnosis of headaches can lead to inappropriate treatment or missed treatment opportunities. Other causes

Table 44.1 “RED FLAG” OR WORRISOME HEADACHE FEATURES AND SUGGESTED EVALUATION

WORRISOME FEATURE	DIFFERENTIAL DIAGNOSIS	POSSIBLE EVALUATION
Acute onset of extremely severe headache	Subarachnoid hemorrhage, cerebral venous thrombosis, reversible cerebral vasoconstrictive syndrome	Computed tomography (CT) scan followed by a lumbar puncture if negative; Magnetic resonance angiography (MRA), Magnetic resonance venography (MRV), or CT angiogram in selected patients
Aura symptoms lasting longer than an hour	Stroke	MRI or CT scan to assess for ischemic lesion
New headache in a patient over 50	Temporal arteritis, neoplasm, other secondary headaches	Detailed history, CT or MRI, as well as selected blood tests
Headache with Valsalva, cough, sneezing	Chiari malformation or other occipital lesion	MRI
Progressive headache with focal neurological findings	Intracranial neoplasm	Detailed examination and CT or MRI
Chronic headache with tinnitus and transient visual disturbances	Idiopathic intracranial hypertension	MRA, MRV, followed by lumbar puncture to assess cerebrospinal fluid (CSF) pressure

of treatment errors include drug interactions, serious side effects, and inappropriate medication use in pregnant women. Perhaps the most common treatment errors in headache stem from prolonged use of nonsteroidal anti-inflammatory medications, with resulting gastrointestinal toxicity and bleeding. Vasoactive medications such as triptans and ergot compounds can occasionally produce vasoconstrictive complications, including myocardial infarction. Drug dependence and addiction syndromes can develop in patients who are prescribed habit-forming medications such as barbiturate-containing combination medications or opioids for the treatment of headache. Barbiturate dependence and addiction is no longer as common a problem as it was prior to the advent of the triptan medications for migraine treatment; opioid dependence and addiction, however, has increased in frequency among headache patients over the last decade (Loder, 2006). This coincides with a movement to use these medications more liberally for the treatment of chronic, non-malignant pain syndromes.

HEADACHE EPIDEMIOLOGY AND GENETICS

Most forms of headache are more common in women than in men, and women far outnumber men among those who

seek specialty care for headache. This is because the clinical expression of the most common form of benign recurrent headache—migraine—is strongly influenced by cycling ovarian steroid hormone levels. At all ages past puberty, for example, the prevalence of migraine is higher in females than in males, and women are more likely than men to experience longer, more intense headaches and to be more disabled by migraine. The prevalence of headache also varies with age. In both sexes, the prevalence of primary headache disorders such as migraine increases throughout early adulthood, plateaus in the middle years, and gradually declines thereafter. Secondary headaches become relatively more common as people age (Lipton & Bigal, 2005). It is unusual for primary headache disorders to begin after the age of 50, and new onset headaches in someone over this age require a thoughtful work-up to exclude dangerous underlying sources of pain.

Many of the primary headache disorders have a genetic basis. The familial form of a rare subtype of migraine with aura, known as familial hemiplegic migraine, is an autosomal dominant condition. Three mutations that can lead to this disorder have been identified. These appear to increase brain susceptibility to cortical spreading depression, a neurological event that is thought to underlie migraine aura (Russell & Ducros, 2011). Genome-wide association and other studies have identified other loci that may be involved in more common forms of migraine (Anttila et al., 2010; Ligthart et al., 2011). At present, these findings have few clinical implications, but they are exciting because they validate the biological underpinnings of some of the primary headache disorders. They also provide targets for the development of drugs to treat these disorders.

PSYCHIATRIC DISORDERS AND HEADACHE

Psychiatric disorders are common in patients who are referred to specialty headache care. This may reflect an increased occurrence of headache in patients with chronic headache disorders. It may also reflect the fact that psychiatric disorders may interfere with adherence to recommended headache treatments or the development of a good working relationship with physicians (Saper & Lake, 2002). The term “comorbidity” is commonly used to indicate a clinical situation in which two disorders coexist at a frequency greater than would be expected based on chance alone. Affective disorders such as anxiety disorders and depression are more common in patients who have migraine, and the reverse situation is also true. This bidirectional association of affective spectrum disorders and migraine strongly suggests an underlying shared predisposition to both disorders, perhaps based on serotonergic abnormalities in the central nervous system. A longitudinal cohort study suggested that these disorders, when they coexist, appear in a fixed order, with the onset of anxiety preceding that of migraine, which in turn precedes the onset of depression (Merikangas, Whitaker, Isler, & Angst, 1994).

Psychiatric comorbidity has been most extensively studied in patients with migraine. Studies suggest that the odds of having major depression are roughly in the range of 2–4 for those with migraine compared with non-migraineurs. The risk of

other affective spectrum disorders such as generalized anxiety disorder, bipolar disorder, or panic attacks is also increased in those who have migraine compared with those who do not. Suicide also appears to be more common in migraineurs compared with non-migraineurs (Breslau, Merikangas, & Bowden, 1994; Breslau, Chilcoat, & Andreski, 1996; Breslau, 1998; Breslau, Schultz, Stewart, Lipton, & Welch, 2001). The risk of depression and anxiety may be elevated in those with high-frequency migraine (Zwart et al., 2003).

The presence of a psychiatric disorder in a patient with headache can complicate treatment. Certain antidepressants may trigger a manic or hypomanic episode. There is also concern about the possibility of “serotonin syndrome” with combined use of triptans and selective serotonin reuptake inhibitors (SSRI) or selective serotonin norepinephrine reuptake inhibitors (SNRI). Serotonin syndrome has also been reported with triptan monotherapy (Soldin, Tonning, & Obstetric-Fetal Pharmacology Research Unit Network, 2008). The risk appears low, and the number of case reports is low and of variable credibility (Evans, 2007, 2008). However, the Food and Drug Administration (FDA) has issued an advisory regarding the possibility of serotonin syndrome with combined triptan and SSRI or SNRI treatment. A position paper from the American Headache Society concludes that available evidence is not sufficient to warrant limiting the use of these drugs; however, they recommend that clinicians using the combination be “vigilant” for signs or symptoms of serotonin syndrome (Evans, Tepper, Shapiro, Sun-Edelstein, & Tietjen, 2010).

Case reports and adverse event information from clinical trials suggest that certain medications used for psychiatric conditions may occasionally produce headache as a side effect, or aggravate preexisting headache. Low-grade, featureless headache or worsening of migraine have been reported as side effects of SSRI or SNRI therapy, for example (Bickel, Kornhuber, Maihofner, & Ropohl, 2005). There are no evidence-based strategies or treatments for this complication, but clinical experience suggests that the headache may wane over time, even if the patient remains on the offending drug; alternatively, switching to another drug in the same class may relieve the headache. On the other hand, there is some evidence that certain antidepressants can be helpful as treatment for headache, though none is FDA-approved for that purpose (Tarlaci, 2009).

GENERAL PRINCIPLES OF HEADACHE MANAGEMENT

Most patients with headaches should be encouraged to keep a simple headache diary where they record the frequency and severity of the headaches and any medications used to treat them (Russell et al., 1992). In general a single daily composite rating of headache intensity is sufficient to guide treatment decisions. More complex diaries that require multiple daily entries have not been shown to be superior to simpler diaries, and may promote somatic preoccupation. The website of the American Headache Society provides several simple diaries that can be easily downloaded.

Patients prone to recurrent, troublesome headaches should be advised to get sufficient and regular amounts of sleep, eat regular meals, and get regular exercise. Sleep disruption, emotional upset, hormonal fluctuations, and alcohol may trigger migraine attacks. Alcohol and napping are triggers for cluster headache. There is good evidence that relaxation training, biofeedback, and stress-management techniques may be useful adjuncts to an overall management plan for migraine and tension-type headache, but they are less useful for cluster headache (Sandor & Afra, 2005).

Many patients with primary headache disorders can be treated successfully in general practice. Referral to a headache specialist should be considered when the patient has complex medical comorbidities, unusually frequent or debilitating headaches, or is poorly responsive to treatment attempts.

TENSION-TYPE HEADACHE

Tension-type headache (TTH) is a mild or moderate, non-descript headache that is usually bilateral, with pain that is “pressing” or “tightening.” It is usually not associated with migrainous features such as nausea or vomiting, or photo- or phonophobia (Table 44.2). It is divided into episodic and chronic forms, depending on the frequency of headaches. The second edition of the ICHD provides criteria for: (1) infrequent episodic TTH (fewer than 12 headache days per year), (2) frequent episodic TTH (between 12 and 180 days per year) and (3) chronic TTH (at least 180 days per year). These can be further subdivided according to the presence or absence of muscle tenderness. Although the name implies that muscle or emotional tension might be the underlying

Table 44.2 ABORTIVE AND PREVENTIVE TREATMENT OPTIONS FOR TENSION-TYPE HEADACHE

ABORTIVE AGENTS
Over-the-counter drugs
Aspirin
Acetaminophen

Prescription drugs
Tramadol
Aspirin (or acetaminophen)-butalbital-caffeine combinations
Preventive agents for tension-type headache
Agent: Typical dose
Amitriptyline: 25–100 mg/day
NSAIDs, e.g. naproxen sodium: 550 mg bid

cause of these headaches, evidence is lacking to support this view. For example, people with migraine have higher muscle tension on average than do those who meet criteria for tension-type headache. Because TTH can mimic secondary types of headache, it is a diagnosis that should be made only after consideration has been given to organic disorders. This requires a general and neurological examination and in some cases the examination of headache diaries. It is a clinical diagnosis; there are no laboratory or radiological studies that can rule in a diagnosis of TTH. Manual palpation of the pericranial muscles and their insertions can sometimes demonstrate muscle pathology that is contributing to the headaches (Couppe, Torelli, Fuglsang-Frederiksen, Andersen, & Jensen, 2007; Jensen, 1999; Bendtsen, 2000).

It can sometimes be difficult to distinguish tension-type headaches from migraine. Almost all patients with migraine also experience at least occasional TTH, and roughly half have frequent TTH (Lyngberg, Rasmussen, Jorgensen, & Jensen, 2005a). Migraine and tension-type headache share many common triggers, such as lack of sleep and emotional stress or tension (Rasmussen, 1993). In contrast to migraine, which is a severe headache (if untreated), tension-type headaches may interfere with function but are rarely incapacitating. Occasional tension-type headaches are generally self-managed; most tension-type headache sufferers who seek care do so because the headaches are very frequent. Also in contrast to migraine, tension-type headaches are not associated with prominent associated features such as nausea, vomiting, or photo- or phonophobia.

Tension-type headache is the most prevalent form of primary headache, with a lifetime prevalence above 90%. For the individual sufferer, it is less severe and disabling than migraine, but at the population level, it is responsible for a substantial amount of missed work and decreased work function simply because it is so common (Lyngberg, Rasmussen, Jorgensen, & Jensen, 2005b; Lyngberg, Rasmussen, Jorgensen, & Jensen, 2005c). A recent comprehensive review showed that disability attributable to TTH exceeds that due to migraine, and several studies show a higher number of missed workdays due to TTH compared with migraine (Schwartz, Stewart, & Lipton, 1997; Stovner & Hagen, 2006). Unsurprisingly, this burden is concentrated in the small proportion of patients who have TTH and comorbidities. Most sufferers do not seek medical attention unless headaches are chronic or associated with other disorders such as depression, which may render the additional burden of headache more difficult to tolerate (Holroyd et al., 2000).

TREATMENT OF TENSION-TYPE HEADACHE

Far less research attention has been devoted to the development of treatments for tension-type headache than to migraine. Table 44.3 lists commonly used abortive and preventive medications for tension-type headache. There is relatively old evidence suggesting that tricyclic antidepressants are probably effective, with amitriptyline being the best studied and therefore the most commonly used (Bendtsen & Jensen, 2000; Bryson & Wilde, 1996; Diamond & Baltes, 1971). The doses used are lower than those used for the treatment of

Table 44.3 ABORTIVE AND PREVENTIVE TREATMENT OPTIONS FOR MIGRAINE

ABORTIVE AGENTS	
<i>Over-the-counter drugs for mild-moderate attacks</i>	
Aspirin	
Acetaminophen	
Ketoprofen	
Naproxen sodium	
Aspirin-acetaminophen-caffeine	
<i>Prescription drugs for mild-moderate attacks</i>	
Tramadol	
Aspirin (or acetaminophen)-butalbital-caffeine combinations	
<i>Prescription drugs for moderate-severe attacks</i>	
Sumatriptan	
Rizatriptan	
Zolmitriptan	
Eletriptan	
Almotriptan	
Naratriptan	
Frovatriptan	
Ergotamine preparations	
Opioids	
<i>Drugs to treat associated nausea/vomiting</i>	
Metoclopramide	
Hydroxyzine	
Prochlorperazine	
<i>Preventive agents for migraine</i>	
Agent	Typical dose
Low-dose tricyclic antidepressants, e.g. amitriptyline	25–100 mg/day
Beta blockers, e.g. propranolol*	80–160 mg/day
Divalproex sodium*	250 mg bid–500 mg bid
Topiramate*	15–25 mg po q hs to initiate; increase as tolerated to 50 mg po bid
Calcium blockers, e.g. verapamil	80–240 mg/day
Cyproheptadine	4–8 mg bid

(continued)

Table 44.3 (CONTINUED)

ABORTIVE AGENTS	
NSAIDs, e.g. naproxen sodium	550 mg bid
Lisinopril/Candesartan	5–10 mg qd/20 mg qd
Onabotulinum toxin type A injections*	155 units IM in pericranial muscles

* Approved by the FDA for prevention of migraine

depression, and are typically in the range of 25 mg to 100 mg per day, generally given as a single dose in the evening.

Anticholinergic side effects such as dry mouth, sedation, and constipation may be treatment-limiting. Appetite increase and weight gain are particularly troublesome long-term side effects. Starting with a low dose of medication, such as 10 mg nightly, and working up slowly to a higher dose is helpful, since some patients develop tolerance to these effects. A “start low and go slow” approach also enables patients to identify the lowest dose that successfully treats their problem. Preventive medications for headache commonly take weeks to months to show their full benefits, however. As is true in other headache disorders, treatment benefits are best identified through the use of carefully kept headache diaries or calendars. Total eradication of headache is unlikely; instead, the goal of treatment is to reduce headaches to a manageable frequency. If amitriptyline is effective for headache but poorly tolerated, it may be worthwhile to systematically try other tricyclics, which may have fewer side effects. Although many of them have not been systematically studied for the treatment of headache, there is a strong clinical impression that they are effective.

In contrast to the tricyclic antidepressants, there is not strong evidence to support the use of SSRIs or SNRIs for the treatment of chronic tension-type headache, although fluvoxamine may be an exception (Langemark & Olesen, 1994; Manna, Bolino, & Di Cicco, 1994).

Non-pharmacological treatments such as physical therapy or other physical treatments are commonly used for tension-type headaches. These include the use of heat, cold, massage, and exercise-based physical treatments. In general, there is no strong evidence to support or refute the benefits of such treatments, but they do not appear to be harmful.

Relaxation therapies such as biofeedback training may be useful for tension-type headache. Biofeedback training provides the patient with feedback about muscle tension or finger temperature. Lower levels of muscle tension or higher finger temperatures are generally correlated with a more relaxed state; over time, with such feedback most patients are able to achieve a state of relaxation. Typically, they are then expected to practice biofeedback techniques daily (Nicholson, Buse, Andrasik, & Lipton, 2011).

MIGRAINE

Migraine is also a highly prevalent primary headache disorder, with a cumulative lifetime incidence of 43% in women and 28% in men. This high disease burden is explained by the fact

that migraine is a chronic condition of long duration, with peak incidence in the late teens or early twenties (Stewart et al., 2008). Migraine is more prevalent than many other conditions commonly seen in neurology, yet it is often missed or incorrectly diagnosed as “sinus” or “tension” headache. In contrast to tension-type headaches, the pain of migraine is usually moderate or severe in intensity, and the headaches are usually associated with accompanying symptoms such as nausea, vomiting, photophobia, or phonophobia. Headaches can last up to 72 hours (and occasionally even longer, a situation known as *status migrainosus*). In a subset of patients with migraine, the disorder is progressive, and over time, intermittent attacks may become more frequent and develop into *chronic migraine*, a condition in which attacks occur 15 or more days per month (Lipton, 2009) (Table 44.4).

Migraine pain is often experienced on one side of the head, usually in the temporal area, and the affected side may vary from attack to attack. Most patients report that the pain is “throbbing” or “pulsating.” Sensitivity to sound and light are common, and some patients report that strong sensory experiences (smells, sound, light) can trigger an attack. The pain is commonly aggravated by physical activity, and sufferers generally prefer to lie still, often in a dark, quiet room. Migraine attacks in children may be shorter than those in adults, and vomiting is often a more prominent symptom. Many children and some adults report that vomiting partially relieves the headache.

Migraine, especially migraine with aura, is increasingly recognized to have medical implications. It is associated with an increased prevalence of ischemic stroke, coronary heart disease, patent foramen ovale, and affective disorders such as depression and anxiety (Breslau et al., 1994; Diener, Kurth, & Dodick, 2007; Kurth, 2010; Kurth, Kase, Schurks, Tzourio, & Buring, 2010; Schurks et al., 2009). In women, it is associated with an increased risk of preeclampsia and peri-pregnancy stroke (Bushnell, Jamison, & James, 2009; Facchinetti et al., 2009; James, Bushnell, Jamison, & Myers, 2005). It is a relative contraindication to the use of exogenous estrogens after the age of 35, or at any age when aura is present (Loder, Buse, & Golub, 2005).

Many women with migraine report that headaches are more common, severe, and long-lasting around the time of menstruation. This menstrual susceptibility to headache is probably caused by declining estrogen levels. Headaches seem particularly likely to occur when these falling estrogen levels occur after a prolonged period of relatively high levels of estrogen. Some evidence suggests that efforts to minimize or eliminate this drop in estrogen levels (for example, continuous rather than interrupted oral contraceptive regimens) may reduce the frequency or intensity of menstrual migraines. At present, however, the harm-to-benefit balance of such treatment has not been carefully studied, and there are no hormonal treatment regimens that have an FDA indication for the treatment of migraine (Loder, 2004).

Emotional stress or tension is among the most commonly mentioned triggers of migraine attacks. A hallmark of migraine is that the headache often comes *after* rather than *during* a stressful event (Kelman, 2007) (AMPP) (Pearfield,

Table 44.4 NEWER PRESCRIPTION MEDICATIONS FOR TREATMENT OF MIGRAINE

DRUG	ADVANTAGES	SIDE EFFECTS	INTERACTIONS WITH PSYCHOPHARMACOLOGICAL MEDICATIONS	COMMENT
Candesartan	Can be useful in patients with concomitant hypertension	Hypotension, fatigue	Few that are clinically important, although many CNS drugs such as anxiolytics or sedatives can produce hypotensive or orthostatic side effects; additive effects may occur when they are used with blood pressure medications	Not FDA-approved for migraine prevention, but use is supported by randomized trials
Lisinopril	Can be useful in patients with concomitant hypertension	Pedal edema, chronic cough, angioedema (rare)	As above	Not FDA-approved for migraine prevention, but use is supported by randomized trials
Topiramate	Reduction of migraine frequency and severity in roughly half of trial subjects; not associated with weight gain	Memory and word-finding difficulties; paresthesias; kidney stones; acute glaucoma (rare); associated with cleft deformities when used in pregnancy	Caution recommended when used in conjunction with other CNS depressants; no specific reported interactions with antidepressants	FDA-approved for migraine prevention. Used off-label for mood stabilization. Psychiatric adverse effects have been reported, including acute mood changes and suicidal thoughts. The package insert states that "Antiepileptic drugs (AEDs), including Topiramate, increase the risk of suicidal thoughts or behavior in patients taking these drugs for any indication. Patients treated with any AED for any indication should be monitored for the emergence or worsening of depression, suicidal thoughts or behavior, and/or any unusual changes in mood or behavior."
Onabotulinum toxin type A	Administered as intramuscular injections to sites in the head and neck every three months; no need to take daily oral medications	Local irritation, injection reactions. Muscle weakness is expected and can occasionally produce unwanted ptosis or neck pain that improve as the medication wears off over 2–3 months. Rare cases reported of possible toxin spread with botulism-like symptoms—none in patients who have received treatment for headache	None	FDA-approved for treatment of chronic migraine (migraine 15 or more days per month). Not effective in episodic forms of the disorder

1995). Other commonly mentioned triggers of migraine include dietary substances such as alcohol, aged cheeses, chocolate, or food additives, especially monosodium glutamate. It is difficult to establish the relationship between dietary practices and headache. Patients with migraine vary in their susceptibility to dietary triggers. Strict elimination diets to treat headaches, although popular, lack strong scientific support for their specific benefits (Blau, 1992; Mitchell et al., 2011; Zencirci, 2010).

Caffeine is a special case, since it can be a treatment for headache, or, when it is withdrawn, a cause of headache. In

small amounts, caffeine augments the effects of mild analgesics such as aspirin or acetaminophen, and it is a common ingredient in both over-the-counter and prescription combination headache medications. Taken too frequently, however, caffeine is suspected of aggravating migraine, and its abrupt withdrawal may produce a caffeine-withdrawal headache (Wolpow, 2010). It has even been suggested that caffeine is the "trigger" for ischemic stroke associated with migraine, and caffeine intake is associated with the development of chronic daily headache (Logroscino & Kurth, 2010; Scher, Stewart, & Lipton, 2004). For all of these reasons, it should be used

judiciously in people with migraine, whether it is ingested as a drug or in drinks.

Physical activity or exertion, including sexual activity, can also aggravate or trigger headache in those with migraine. Exercise-induced migraine usually comes on after sustained exertion, rather than immediately upon onset of exercise, and can sometimes be modified or eliminated by a change in exercise routine or intensity. A variety of serious causes of exertional headaches must be ruled out by appropriate investigation (Mokri, 2002).

MIGRAINE AURA

Only about a third of migraineurs experience the focal neurological symptoms that constitute aura. Visual aura is by far the most common form of aura, followed by auras consisting of sensory or speech disturbances. In typical visual aura, the visual symptoms precede the headache, come on gradually, and fade away within an hour as the headache begins. They may consist of partial or complete homonymous loss of vision, or visual abnormalities such as flickering, glittery zig-zag lines, sometimes referred to as a “scintillating scotoma.” These abnormalities usually begin near the center of the visual field, then expand and enlarge before fading away (Eriksen, Thomsen, & Olesen, 2005).

Sensory auras often consist of paresthesias, commonly beginning in one hand and traveling upwards to the arm and face on the same side. This stereotyped “march” of symptoms is sometimes referred to as the “cheiro-oral syndrome.” In this case, too, symptoms usually develop and fade away gradually, to be followed by the headache. It can be difficult for patients to distinguish between numbness and weakness.

Aura can also take the form of muscle weakness, usually unilateral, and patients may experience a dense and sometimes prolonged hemiplegia. These syndromes, although rare, are of interest because they are frequently familial, with autosomal dominant inheritance. Three genes associated with these rare hemiplegic migraine syndromes have been identified, all of which appear to affect neuronal excitability (Russell & Ducros, 2011).

The underlying cause of migraine aura is thought to be a process called *cortical spreading depression*. This term refers to a wave of initial activation of neurons, followed by a prolonged depression of neuronal activity. This process spreads across the surface of the brain at a rate of approximately 3 mm per minute, a time course consistent with the progression of the neurological events of aura. A decrease in cerebral blood flow may occur, but it is thought to reflect these changes in neuronal activity rather than produce them. These decreases in blood flow rarely reach a level sufficient to cause ischemia of brain tissue (Sanchez-Del-Rio, Reuter, & Moskowitz, 2006).

There is, however, a small increased risk of ischemic stroke in people who have migraine with aura. Whether this is due to rare circumstances in which dehydration or platelet activation are sufficient to aggravate low blood-flow levels is not entirely clear. While the elevated risk of ischemic stroke in migraineurs with aura is high relative to that in people without migraine (or even those who have migraine without aura),

the absolute risk of stroke is low, meaning that patients should not panic. Rather, it is reason to emphasize the importance of minimizing other risk factors for stroke such as smoking or hypertension. In women of childbearing age, the combined stroke risk from aura and the use of estrogen-containing contraceptives is generally felt to be unacceptable; official guidelines from a number of authoritative bodies recommend that women with aura should not use estrogen-containing contraceptives or other forms of exogenous estrogen (Loder, 2009).

TREATMENT TO ABORT A MIGRAINE ATTACK

Treatment for migraine can be aimed at terminating an individual attack (abortive treatment) or at preventing migraine attacks (preventive treatment). Many patients need both forms of treatment. Abortive treatment alone is appropriate for patients who have intermittent attacks of migraine, whereas those who have frequent attacks are candidates for preventive treatment in addition to abortive therapy. There are no hard and fast rules about when preventive treatment should be considered; in general, patients are candidates for preventive treatment if they have more than one attack of migraine a week, or do not respond to or cannot tolerate abortive therapy.

Abortive treatment of migraine is initiated at the onset of or during an attack. The primary goals of acute treatment are to resolve headache pain and associated symptoms as rapidly as possible and restore function with minimal side effects. Some older medications relieve pain but can worsen disability because they produce sedation or side effects such as nausea and vomiting. Secondary goals of acute treatment include minimization of the need for rescue medication (backup medications used at home by patients when the usual treatment fails to relieve pain) and trips to the doctor’s office or emergency department.

Abortive treatment is most effective when used early in an attack while pain is still mild (Foley et al., 2005). This approach should be recommended in patients who have intermittent attacks of headache. An emphasis on early treatment can backfire, however, in patients who have frequent attacks of headache, since it may lead to medication overuse. Patients with frequent headaches need to limit use of abortive medications and may need to pick and choose which attacks are treated pharmacologically. Some patients, particularly those with anxiety disorders, may medicate in anticipation of headache, another situation that can easily lead to medication overuse. They may need instructions to postpone treatment until headache reaches a predetermined pain intensity.

Table 44.5 lists commonly used abortive treatments for migraine. Abortive treatments for migraine can be divided into nonspecific and specific medications. Nonspecific medications are those that are effective for many different kinds of pain, not just migraine. These include nonsteroidal anti-inflammatory agents (NSAIDs), acetaminophen, opioids, and various combination analgesics such as the barbiturate-containing medications (e.g., Fiorinal, Esgic, Phrenelin) (Cutrer, Mitsikostas, Ayata, & Sanchez-del-Rio, 1999; Mett & Tfelt-Hansen, 2008; Tfelt-Hansen, 2008).

**Table 44.5 ACUTE AND PREVENTIVE TREATMENT
OPTIONS FOR CLUSTER HEADACHE**

ABORTIVE AGENTS FOR CLUSTER HEADACHE		
Parenteral sumatriptan*, nasal spray triptans, or dihydroergotamine		
100% oxygen at 10–12 liters via face mask		
<i>Preventive Agents Commonly Used for Cluster Headache</i>		
Agent	Typical dose	
Verapamil	240 mg SR daily or above	240 SR po qd-bid (check EKG)
Lithium	Lithium carbonate 300 mg po tid; dose adjusted to achieve response	

* FDA-approved for cluster headache treatment

These medications, particularly NSAIDs, can be effective for migraine, but the combination medications and opioids are associated with overuse, dependence, and addiction. The combination medications and opioids also may produce sedation that limits the ability of patients to carry out daily activities or remain at work (Martin & Goldstein, 2005; Silberstein & McCrory, 2001). Isometheptene-containing combination medications are an exception to this rule, as they usually do not produce substantial fatigue. Isometheptene is a vasoconstrictive agent that is usually combined with acetaminophen and the mildly sedative medication dichloralphenazone (Freitag et al., 2001). However, isometheptene combination products are now difficult to obtain from commercial sources. At the time of this writing, only one company is manufacturing the drug, although it can be compounded.

Nausea and vomiting are prominent symptoms of migraine and can be debilitating in their own right. They are thus sometimes targets of treatment. For many patients, triptans successfully treat the nausea associated with migraine. When that is not the case, nausea can be treated with the use of the prokinetic dopamine antagonist metoclopramide, or with ondansetron, which is a serotonin agonist. These two medications typically do not produce sedation, and they can be taken early in an attack to help prevent or minimize the development of nausea. There is some evidence that metoclopramide or other anti-dopaminergic anti-nausea medications are effective for migraine pain in addition to their effects on nausea (Allena, Magis, & Schoenen, 2005; Azzopardi & Brooks, 2008; Friedman et al., 2005).

Specific medications are those that are effective for migraine or related headache disorders but are generally ineffective for

other types of pain. The two categories of specific migraine medications in use are the ergots and triptans. Ergotamine and its derivatives, such as dihydroergotamine, have a complex pharmacology. In many cases, side effects such as nausea and vasoconstrictive complications limit their usefulness (Tfelt-Hansen & Koehler, 2008). The triptans are selective serotonin 5-hydroxytryptamine (5HT) 1B/D agonists. The 5HT_{1B} receptors are located postsynaptically on the cerebral blood vessel's smooth muscle. Stimulation of these receptors by triptans produces cranial vasoconstriction. The 5HT_{1D} receptors are located presynaptically on the nerve fibers, and stimulation of these receptors inhibits the release of inflammatory neurotransmitters. Although the triptans are highly selective for the cerebral vasculature, a small degree of coronary arterial constriction can occur, possibly through their activity with 5HT_{2A} receptors. For this reason, they should generally not be used in patients who have underlying coronary artery disease or who are at high risk for occult coronary artery disease, on the basis of risk-factor stratification. In cases where there is doubt about the patient's coronary status, evaluation prior to triptan prescription may be prudent; however, there is no clear evidence to underpin the decision about what sort of evaluation is needed.

The triptans came into widespread use in the 1990s and are the abortive treatment of choice for patients without cardiovascular disease. Seven triptans are available in the United States (Table 44.5). All are available as oral tablets. Only one, sumatriptan, is available in a parenteral formulation, which is ideal for patients with rapid onset, severe headaches or those in whom nausea or vomiting preclude the use of oral medication. Two triptans are available as nasal sprays; two as orally dissolving tablets. Nasal spray administration of triptans has the advantage of convenience, but much of the dose is actually swallowed and absorbed orally, so the pharmacokinetic advantages of this route of administration are slight. Some of the medication drips down the back of the throat, and many patients complain of a bitter taste from the medication. Orally dissolving tablets are placed on the tongue and can be taken without water. Although patients perceive that these tablets work more quickly than those that are swallowed, objective measures of drug absorption do not clearly support the idea that this is so. The choice of formulation and dose depends upon patient preference and the circumstances of headaches. Most oral triptans can be repeated after two hours; the maximum daily dose varies, depending upon the drug (Loder, 2010).

Most patients who use triptans have a strong preference for oral treatment. A meta-analysis that compared the seven orally available triptans showed comparable efficacy for the marketed doses of most of them; the exceptions were naratriptan and frovatriptan. The marketed doses of those two drugs have lower rates of pain relief than do the others. They have the advantage of longer half-lives, however, so that duration of action may be prolonged, making them reasonable treatment choices for patients with long-duration moderate headaches (Mett & Tfelt-Hansen, 2008).

In general the triptans are well tolerated. Common non-serious side effects include occasional fatigue or nausea. So-called triptan sensations are more common with injectable

sumatriptan, probably because of the rapid increase in plasma levels of the drug. This can include transient neck or chest tightness. If patients are unprepared for this side effect, they may worry that they are experiencing cardiac problems; however, studies of coronary perfusion do not support the idea that these side effects reflect decreased coronary perfusion.

Several drug–drug interactions are worth noting. Of most relevance to psychiatrists, the U.S. Food and Drug Administration issued an advisory regarding the concomitant use of triptans and other serotonergic drugs (e.g., lithium, SSRIs, or SNRIs). In clinical practice, however, this side effect appears to be extremely rare and should not inhibit use of these drugs; rather, vigilance for this complication should be maintained (Evans et al., 2010).

If oral treatment of a migraine attack is not successful, non-oral routes of administration should be considered. Injectable treatment with subcutaneous sumatriptan is one option; sumatriptan comes in an autoinjector that can be easily used by most patients, even those with no medical experience. Prefilled cartridges are inserted into the reusable autoinjector. When the medication first came onto the market, these cartridges contained 6 mg of sumatriptan; recently, cartridges containing 4 mg of the medication have become available (Wendt et al., 2006). The efficacy of the sumatriptan 6 mg injection is 77% when evaluated as the proportion of patients who have a decrease from moderate or severe headache to mild or no headache within 1 hour of treatment (Cady et al., 1991). The injection can be repeated, if necessary, after 1 hour. When administered during migraine aura, the sumatriptan injection does not prolong aura but may not be optimally effective for the subsequent headache (Aurora, Barrodale, McDonald, Jakubowski, & Burstein, 2009; Bates et al., 1994). Consequently, many physicians instruct patients with aura who use the sumatriptan injection to delay dosing until headache is present.

Ketorolac is also available in prefilled syringes (though not in an autoinjector). It must be given intramuscularly; consequently, its use is limited to patients who have some medical training or who are willing and able to learn intramuscular injection technique.

Rectal suppositories are another possible treatment approach. Indomethacin is available as a 50 mg rectal suppository and is a highly effective treatment for many patients (Sah & Saini, 2008). It is well to remember that administration of NSAIDs through non-oral routes does not reduce the risk of gastrointestinal complications or bleeding; those side effects are mediated systemically and not through direct mucosal irritation. Dihydroergotamine (DHE) is available as a nasal spray, but its administration is cumbersome, and as with the triptan nasal spray, many patients complain of a bad taste (Ziegler et al., 1994).

A pulmonary inhaler version of DHE may soon become commercially available, but at the time of this writing it has not yet been approved by the FDA. DHE has vasoconstrictive properties and, like the triptans and other ergot preparations, should not be used in patients with known coronary artery disease or those who are at high risk for cardiovascular disease (Aurora, Rozen, Kori, & Shrewsbury, 2009; Shrewsbury, Kori, Miller, Pedinoff, & Weinstein, 2008).

RESCUE TREATMENT FOR MIGRAINE

Headache attacks vary in intensity, and there are times when abortive medication is ineffective. If patients have backup rescue treatment they can self-administer, they may be able to avoid a trip to the physician's office or emergency department. Non-oral rescue therapies are typically used where possible, to reduce the risk that nausea or vomiting will interfere with use. Opioids have a place as rescue treatment for patients with contraindications to triptan use, but in general they should be used only occasionally. Options for rescue therapy include subcutaneous sumatriptan or dihydroergotamine-45, injectable ketorolac, butorphanol nasal spray, hydromorphone suppositories, acetaminophen in combination with opioids, and phenothiazine suppositories (Whyte, Tepper, & Evans, 2010).

PREVENTIVE MIGRAINE TREATMENT

Only a subset of patients with migraine will be candidates for preventive (prophylactic) treatments. These are medications that are administered on a daily basis with the intention of reducing the frequency, duration, or severity of migraine overall. In general, currently available medications rarely eliminate all migraine attacks; rather, a common standard applied to indicate success with preventive migraine therapy is a reduction in attack frequency of 50%. Preventive medications are used by only about 5% of migraineurs (Diamond et al., 2007).

Preventive treatment should usually be offered to patients who cannot use or who do not benefit from abortive therapy, as well as those who have frequent headaches. A commonly used cutoff point for headache frequency at which prevention should be considered is one headache per week. Other special circumstances, such as prolonged headaches, even if infrequent, may merit consideration of prophylactic therapy as well. In general, treatment choices are based on a consideration of side effect profiles and any other benefits that might be obtained from a particular medication. For example, in patients with hypertension, one of the antihypertensive medications with anti-migraine efficacy may be a good choice.

While no preventive medication is effective for every patient in whom it is tried, a common reason for failure is an inadequate trial of the drug. Preventive medications for migraine typically take effect over weeks or even months. Migraine is a condition that naturally waxes and wanes, so that it can be difficult to distinguish true drug effects from the natural history of the illness.

Five drugs are approved by the U.S. Food and Drug Administration for the prevention of migraine (Table 44.5). These are timolol, propranolol, methysergide, divalproex sodium, and topiramate (Bigal & Lipton, 2006). Methysergide is no longer commercially available, and timolol is rarely used. Fibrotic complications curbed enthusiasm for use of methysergide, which was otherwise a remarkably effective drug. The remaining medications seem to have roughly similar efficacy in clinical practice; that is, in about half of patients they reduce headache frequency by roughly 50%. Treatment

is usually attempted with a single drug, but combinations of drugs can be tried in refractory cases. No clinical trials support this practice, however, and it is important to note that a recent trial of the combination of topiramate and propranolol failed to show any augmented benefit from the combination over topiramate alone.

Table 44.6 lists selected newer agents used for prevention of migraine, and provides additional details about drug-specific characteristics. Onabotulinum toxin type A is approved for the prevention of chronic migraine, which is migraine occurring 15 or more days per month. It does not appear to be effective for the prevention of episodic migraine, which suggests that mechanisms targeted by the drug become active only after the

transition to the chronic form of the disorder (Dodick et al., 2005; Gobel & Heinze, 2011). Other drugs are used off-label, with varying degrees of evidence of benefit. Commonly used off-label treatments include amitriptyline, verapamil, gabapentin, lisinopril, riboflavin (vitamin B2) and cyproheptadine. Preventive medication must be used sparingly and with great caution in women likely to become pregnant. Some, such as divalproex and topiramate, are teratogenic.

The mechanisms of action of preventive treatments for migraine are not firmly established. Many probably work to inhibit cortical spreading depression, but some may also block neurogenic inflammation or peripheral or central sensitization. Table 44.7 lists some commonly used preventive agents

Table 44.6 NEWER PRESCRIPTION MEDICATIONS FOR TREATMENT OF MIGRAINE

DRUG	ADVANTAGES	SIDE EFFECTS	INTERACTIONS WITH PSYCHOPHARMACOLOGIC MEDICATIONS	COMMENT
Candesartan	Can be useful in patients with concomitant hypertension	Hypotension, fatigue	Few that are clinically important, although many CNS drugs such as anxiolytics or sedatives can produce hypotensive or orthostatic side effects; additive effects may occur when they are used with blood pressure medications.	Not FDA approved for migraine prevention, but use is supported by randomized trials
Lisinopril	Can be useful in patients with concomitant hypertension	Pedal edema, chronic cough, angioedema (rare)	As above.	Not FDA approved for migraine prevention, but use is supported by randomized trials
Topiramate	Reduction of migraine frequency and severity in roughly half of trial subjects; not associated with weight gain	Memory and word-finding difficulties; paresthesias; kidney stones; acute glaucoma (rare); associated with cleft deformities when used in pregnancy	Caution recommended when used in conjunction with other CNS depressants; no specific reported interactions with antidepressants	FDA approved for migraine prevention. Used off-label for mood stabilization. Psychiatric adverse effects have been reported, including acute mood changes and suicidal thoughts. The package insert states that "Antiepileptic drugs (AEDs), including Topiramate, increase the risk of suicidal thoughts or behavior in patients taking these drugs for any indication. Patients treated with any AED for any indication should be monitored for the emergence or worsening of depression, suicidal thoughts or behavior, and/or any unusual changes in mood or behavior."
Onabotulinum toxin type A	Administered as intramuscular injections to sites in the head and neck every three months; no need to take daily oral medications.	Local irritation, injection reactions. Muscle weakness is expected and can occasionally produce unwanted ptosis or neck pain that improve as the medication wears off over 2-3 months. Rare cases reported of possible toxin spread with botulism-like symptoms – none in patients who have received treatment for headache	None	FDA approved for treatment of chronic migraine (migraine 15 or more days per month). Not effective in episodic forms of the disorder.

for migraine, while Table 44.8 provides more detail on newer preventive treatments that have come into use in the last decade.

Beta Blockers

Although propranolol and timolol are the beta blockers that are approved by the FDA for migraine prevention, some clinicians use atenolol, metoprolol, or nadolol. The typical dose range for propranolol is between 60 mg and 160 mg daily. Beta blockers with intrinsic sympathomimetic activity, such as pindolol, do not appear to be effective for migraine prevention. Beta blockers are a good choice in patients with concomitant hypertension, tremor disorders, mitral valve prolapse, or anxiety. They are typically avoided in patients who have asthma or Raynaud’s syndrome.

Table 44.7 DIAGNOSTIC CRITERIA FOR EPISODIC AND CHRONIC CLUSTER HEADACHE (ICHD-II) (HEADACHE CLASSIFICATION SUBCOMMITTEE OF THE INTERNATIONAL HEADACHE SOCIETY 2004). (HEADACHE CLASSIFICATION SUBCOMMITTEE OF THE INTERNATIONAL HEADACHE SOCIETY, 2004)

Episodic cluster headache
A. At least 5 attacks fulfilling criteria B-D
B. Severe or very severe unilateral orbital, supraorbital and/or temporal pain lasting 15–180 minutes if untreated
C. Headache is accompanied by at least one of the following:
1. ipsilateral conjunctival injection and/or lacrimation
2. ipsilateral nasal congestion and/or rhinorrhoea
3. ipsilateral eyelid edema
4. ipsilateral forehead and facial sweating
5. ipsilateral miosis and/or ptosis
6. a sense of restlessness or agitation
D. Attacks have a frequency from one every other day to 8 per day
E. Not attributed to another disorder
Chronic Cluster Headache
A. Attacks fulfilling criteria A-E for 3.1 Cluster headache
B. Attacks recur over >1 year without remission periods or with remission periods lasting <1 month
Comments:
Chronic cluster headache may arise de novo (previously referred to as primary chronic cluster headache) or evolve from the episodic subtype (previously referred to as secondary chronic cluster headache). Some patients may switch from chronic to episodic cluster headache.

Table 44.8 ACUTE AND PREVENTIVE TREATMENT OPTIONS FOR CLUSTER HEADACHE

Abortive Agents for Cluster Headache	
Parenteral sumatriptan*, nasal spray triptans or dihydroergotamine	
100% oxygen at 10-12 liters via face mask	
Preventive Agents Commonly Used for Cluster Headache	
Agent	Typical dose
Verapamil	240 mg SR daily or above 240 SR po qd-bid (check EKG)
Lithium	Lithium carbonate 300 mg po tid; dose adjusted to achieve response

Antidepressants

Antidepressants are commonly used for migraine prevention despite the fact that none has an FDA indication for the disorder. The best evidence is for amitriptyline (Buchanan & Ramadan, 2006). Doses used to prevent migraine are typically in the range of 25–100 mg daily, much lower than those used to treat depression. The anti-migraine effect of amitriptyline is independent of its effects on depression. The medication is commonly given in a single daily dose at bedtime. Side effects are frequently treatment-limiting; they include sedation, weight gain, dry mouth, hypotension, and constipation.

SSRIs do not seem effective as migraine preventive agents. Fluoxetine appeared helpful in one small study, but a larger trial showed no benefit (Adly, Straumanis, & Chesson, 1992; Saper, Silberstein, Lake, & Winters, 1995). Some of the SNRIs may be effective. Trials suggesting this are small, however, and suffer from a number of methodological problems. An additional problem with using antidepressants to prevent migraine is the theoretical risk of serotonin syndrome when these drugs are used concomitantly with triptans.

Monoamine oxidase inhibitors have been used in the preventive treatment of migraine, but this is no longer common practice, probably owing to concern about side effects and the availability of newer preventive drugs such as topiramate (Silberstein, 2006). Lithium is another drug that has been used in the past but is no longer commonly employed for migraine, although it remains useful in cluster headache.

Anticonvulsants

Various anti-seizure medications are effective for migraine prevention. Divalproex sodium and topiramate are FDA-approved for this indication. The typical daily dose of divalproex for migraine ranges from 500 mg to 1500 mg per day, lower doses than are typically used for epilepsy. An extended-release version of the drug is available that allows

once-daily dosing. Drug levels can be checked, but efficacy does not correlate with blood levels. Common side effects include weight gain, hair loss, and gastrointestinal problems such as nausea. Hepatotoxicity and pancreatitis are rare side effects. Divalproex is a known teratogen and thus a last resort in women of childbearing age, who should be strongly cautioned against becoming pregnant while on the drug (Modi & Lowder, 2006).

The target dose for topiramate is in most cases 100 mg per day, given as 50 mg twice daily. Most patients cannot tolerate this as a starting dose, however. A common practice is to begin with 25 mg at bedtime daily for a week, and then to increase the dose in 25 mg increments each week until the target level is achieved. Doses of 50 mg per day and up to 200 mg per day were evaluated in clinical trials and were more effective than placebo; in clinical practice, some patients do best at these extremes of the dosing range (Silberstein, 2004b).

Gabapentin does not have FDA approval for treatment of migraine, but is commonly used, perhaps because it is well tolerated and has few drug interactions. Side effects include fatigue. Typical doses range from 300 mg to 1200 mg, three times a day (Young, Siow, & Silberstein, 2004). Lamotrigine does not appear to be effective for prevention of migraine headaches, but it may have efficacy against aura; it is not FDA-approved for this indication, however, and the rare but serious side effect of Stevens-Johnson syndrome argues against its routine use for this purpose. Zonisamide is sometimes used off-label, as is leviratracetam (Young et al., 2004).

Calcium Channel Antagonists

No calcium channel antagonist is FDA-approved for migraine prevention. Verapamil, however, is frequently used and generally well tolerated. It is usually given in a dose of 120–240 mg per day in a sustained-release formulation. The most common side effect is constipation; peripheral edema can also occur (Black, 2006).

Several double-blind, placebo-controlled trials support the use of lisinopril for migraine prophylaxis. There is also some evidence for the angiotensin receptor blocker candesartan. These drugs are not, however, FDA-approved for migraine. They can cause fetal renal abnormalities when used during pregnancy, so must be used with caution in women of childbearing age (Gales, Bailey, Reed, & Gales, 2010).

Miscellaneous

Cyproheptadine is commonly used for pediatric migraine prevention, although evidence supporting this practice is sparse; the drug is, however, somewhat similar to methysergide in being a serotonin antagonist, and is well tolerated. It also has antihistaminic effects and is a modest calcium channel blocker (Rao, Das, Taraknath, & Sarma, 2000).

Vitamin B2 in doses of 400 mg once daily has demonstrated some migraine preventive effects in two double-blind, randomized trials. It turns the urine bright yellow but is well tolerated. There is likewise some modest evidence supporting the use of the herb butterbur for migraine prevention; a

recent meta-analysis suggested that the herb feverfew, long popular as a migraine preventive treatment, is probably ineffective. Evidence for the benefits of oral magnesium is mixed, and diarrhea is a treatment-limiting side effect (Evans & Taylor, 2006).

CLUSTER HEADACHE

Cluster headache is a distinct type of headache that is more common in men than in women. It is a relatively rare headache disorder, with estimates of its prevalence given as roughly 70 per 100,000. In contrast to migraine, cluster headache is a short-lived headache, with duration not exceeding three hours. It is a strictly unilateral headache with severe, stabbing pain localized in and behind the eye. It can, however, switch sides from one attack to the next, and occasionally even within an attack. It is associated with autonomic features on the same side as the pain, which can include ptosis, miosis, and nasal stuffiness or rhinorrhea (Table 44.7). Nausea, vomiting, photophobia and phonophobia, which are common accompaniments to headache in migraineurs, are not common in cluster headache. Aura has been reported in association with cluster headache but is not the rule (Kudrow, 1979).

Multiple attacks of cluster headache can occur per day. Cluster headache is so-called because attacks of headache cluster together for weeks to months in cluster “periods” or “episodes.” Most sufferers have episodic cluster headache and will have daily or near-daily attacks for several months, interspersed with remission periods during which they are headache-free for intervals of months to years. About 15% of sufferers, however, have chronic cluster headache, in which there are no or very short remission periods (Kudrow, 1982).

During a cluster episode, patients are commonly susceptible to a number of environmental triggers that can cause individual attacks of headache to occur. For example, ingestion of alcohol is commonly reported to trigger cluster headaches during a cluster period, while during remission periods, patients can drink with impunity. Many patients also experience cluster attacks in conjunction with rapid-eye-movement (REM) sleep, so that cluster headache is sometimes considered a parasomnia. Patients with cluster headache are usually physically restless during an attack, in contrast to migraine patients, who prefer to lie quiet and avoid motion.

TREATMENT OF CLUSTER HEADACHE

Patients with cluster headache usually do not have to be told to avoid triggers such as alcohol and napping during a cluster episode. Again in contrast to migraine, trigger avoidance and lifestyle alterations are not notably effective treatments for cluster headache. Because the headache occurs daily, sometimes multiple times per day, reliance on abortive therapy alone is typically not recommended; essentially, all patients with cluster headache should be offered concomitant preventive therapy in addition to abortive therapy of individual attacks. Table 44.8 lists commonly used treatments for cluster headache.

The sumatriptan injection is FDA-approved for the treatment of cluster headache. The 6 mg dose of sumatriptan aborts about three-quarters of cluster headaches within 15 minutes of treatment (Capobianco & Dodick, 2006). Side effects are those observed in the migraine trials and are mostly nonserious events such as flushing or nausea. As in migraine patients, triptans are contraindicated in uncontrolled hypertension and coronary artery disease. Although there is some evidence that nasal or oral administration of triptans is more effective than placebo for cluster headache, they are not preferred agents. Their onset of action is relatively slow, and the patient may suffer needlessly while waiting for them to take effect. Nonetheless, there may be some circumstances where these are appropriate therapies. Ergots, including DHE, can also be used, but there are few circumstances where they are preferred to the triptans.

Indomethacin suppositories can also be tried for patients with cluster headache, and they may be particularly helpful for patients who cannot take or do not benefit from sumatriptan injections. Oxygen inhalation has been shown to be effective for abortive treatment of cluster headache in two controlled trials; typically the oxygen should be administered through a non-rebreather mask at a rate of 8–10 liters per minute for 10–15 minutes at the onset of the attack. Roughly 80% of patients report benefit from oxygen treatment, and there are no major contraindications to its use aside from severe chronic obstructive pulmonary disease with carbon dioxide retention (Cohen, Burns, & Goadsby, 2009).

Preventive treatment of cluster headache is often remarkably effective. Unlike patients with migraine, those with cluster headache are commonly rendered headache-free by prophylaxis. There is good evidence of benefit for the preventive use of verapamil and lithium in the treatment of cluster headache, although neither is FDA-approved for treatment of cluster headache. Verapamil is effective for about three-quarters of patients with episodic cluster headache and slightly more than half with chronic cluster headache (Gabai & Spierings, 1989). The doses necessary to achieve benefit can be quite high, however—often in the range of 240 mg or above per day—and it is prudent to monitor the electrocardiogram to assess for conduction delay.

Lithium is effective in 87% of patients (Kudrow, 1977). It is typically given as lithium carbonate at a starting dose of 300 mg three times daily; most patients respond well to this dose and do not need upward titration. Monitoring of serum levels is not useful to guide therapy, which is based on clinical response, but can help avoid toxicity. Caution should be used if lithium is administered with diuretics or NSAIDs. Nausea and tremor are common side effects. Prolonged use can affect kidney and thyroid function. Fortunately, many patients need the medication for relatively short periods of time, thus minimizing the likelihood of toxicity with prolonged use.

Steroids such as prednisone are highly effective in the treatment of cluster headache, but serious side effects such as osteonecrosis limit the duration of their use. Therefore, they are most commonly employed as “bridging therapy” to cover the patient while he waits for preventive medication

with lithium or verapamil to become effective. Suppression of headaches may be dose-dependent, so that when patients taper from a high to a low dose of prednisone, for example, headaches may resume with dose reduction (Gaul, Diener, & Muller, 2011). Potential side effects are stomach pain, fluid retention, and insomnia.

Two promising new therapies are under investigation for medically refractory cluster headache. Occipital nerve blocks can temporarily relieve cluster headache, so trials are underway to see if implantable occipital nerve stimulators might provide longer lasting relief; results so far are encouraging but not definitive. Lead migration is the most common problem with the procedure, and infection is also a concern (Dodick, 2011; Leroux et al., 2011; Strand, Trentman, Vargas, & Dodick, 2011). Deep brain stimulation of the hypothalamus with implantable electrodes also appears effective in several case series, but severe complications can occur with this surgery; it is unlikely that this will ever be anything other than a last resort for treatment (Leone, Franzini, Cecchini, Broggi, & Bussone, 2010).

PAROXYSMAL HEMICRANIA

A variety of other headache syndromes have similarities to cluster headache. One is paroxysmal hemicranias, a condition in which headaches are unilateral and associated with autonomic features but briefer (10–30 minutes) and more frequent (up to 15 times daily) than cluster headache (Matharu, Boes, & Goadsby, 2003). These headaches are important to diagnose because they are very sensitive to scheduled treatment with indomethacin. Indomethacin is usually given initially as 25 mg orally, three times daily; the dose is doubled every three days until relief occurs or a maximum of 75 mg three times daily is reached. Drug benefit occurs quickly in susceptible patients, so that an indomethacin treatment trial can be completed within nine days. If indomethacin is not effective or tolerated, other treatments effective in cluster headache can be tried but do not commonly meet with success.

IDIOPATHIC STABBING HEADACHE

Patients with idiopathic stabbing headache, sometimes referred to as “icepick headache” or “jabs and jolts,” complain of short, sharp episodes of very intense pain, usually in the temples. Occasional jabs of pain are not uncommon in patients who have migraine, but these stabbing pains can also occur in isolation from other forms of headache. When they are only occasional, the only treatment needed is reassurance. Frequent volleys of pain, however, can be disabling. They usually respond well to treatment with indomethacin or sometimes other NSAIDs. Because they are so brief and can occur unpredictably throughout the day, this treatment must be administered on a continuous basis. A common practice is to give indomethacin 25 mg orally, three times daily, for several weeks. In many cases, when this treatment

is withdrawn, the headaches will not recur (Mukharesh & Jan, 2011).

This condition should be distinguished from short, sharp jabs of pain in the face, a situation in which trigeminal neuralgia must be considered. Trigeminal neuralgia is most common in older patients. Often the pain can be triggered by chewing or exposure to wind or cold. This triggerability is not a feature of idiopathic stabbing headaches. Medical treatment of trigeminal neuralgia usually consists of carbamazepine or other anticonvulsant medications. Some cases of ectatic blood vessels' compressing the nerve have been reported, and surgical decompression for such patients can be effective (Feinmann & Peatfield, 1993).

NEW DAILY PERSISTENT HEADACHE

New daily persistent headache (NDPH) is a headache that is constant from onset or within three days of onset, and continues for at least three months. It is defined as a headache that has few if any associated features such as nausea, or photo- or phonophobia, although a migrainous form is increasingly recognized. It is bilateral, pressing or tightening in quality, and mild to moderate in intensity. Its cause is unknown, although in some patients it is preceded by infection. Although it is similar in many ways to chronic tension-type headache, it is distinguished from that disorder by its sudden onset. There are no established treatments for NDPH, so treatment is usually that used for other headache disorders such as migraine or tension-type headache. Unfortunately, treatment is often ineffective (Goadsby & Boes, 2002).

HYPNIC HEADACHE

Hypnic headache is a dull headache that awakens the patient, usually over the age of 50, from sleep. It occurs 15 or more days a month and lasts at least 15 minutes. It is not associated with autonomic signs or symptoms, and is not associated with prominent migrainous features such as nausea, or photo- or phonophobia. It can be distinguished from cluster headache by its moderate intensity and lack of autonomic features. It often responds to caffeine or lithium carbonate 300 mg administered at bedtime. Indomethacin and melatonin can also be tried (Evers & Goadsby, 2003).

HEMICRANIA CONTINUA

Hemicrania continua is, as its name implies, a unilateral headache that is daily and continuous without pain-free periods or side-shift for at least three months. It is typically moderate in intensity, but most patients experience periodic exacerbations. During these periods of worsening, autonomic signs occur on the side of the pain. These may include conjunctival injection, tearing, nasal congestion, or ptosis. This is a headache that typically responds to indomethacin; in fact, diagnostic criteria require indomethacin response in order to make a definite diagnosis (Silberstein & Peres, 2002).

MEDICATION OVERUSE HEADACHE AND DRUG-INDUCED HEADACHE

Daily or near-daily intake of symptomatic pain medications is common in people with frequent headaches. This is undesirable for a number of reasons. Many commonly used symptomatic headache medications contain barbiturates or opioids, which can be habit-forming and produce sedation or impaired judgement that interfere with daily activities. The adverse effects of daily use of even simple analgesics such as acetaminophen or NSAIDs can also be important, and include abnormalities of liver or kidney function as well as gastrointestinal bleeding.

Finally, considerable observational evidence suggests that frequent use of short-acting pain-relieving medications can produce or perpetuate headache disorders, a clinical situation known as "medication overuse headache" (Bigal et al., 2008). Those with preexisting headache disorders seem most susceptible. This observational evidence, however, is likely to be confounded by severity of illness.

From a scientific point of view, it remains uncertain whether medication use drives headache progression, or whether those with severe progressive headaches are simply using a great deal of medication in response to their pain. A combination of these things is also possible, and it may be the case that only some headache patients are vulnerable to the disease-aggravating effects of too-frequent use of pain relievers. It is also unclear whether all short-term symptomatic medications are implicated in headache progression, or just some of them. Some experts, for example, believe that plain NSAIDs are unlikely to produce medication overuse headache (as opposed to combination medications that may contain NSAIDs along with other ingredients such as caffeine). Analysis of data from one longitudinal study, for example, suggested that regular use of aspirin might actually protect against the progression from episodic to chronic forms of headache (Ashina, Zeeberg, Jensen, & Ashina, 2006).

It is also uncertain whether overuse of symptomatic medications interferes with or prevents benefit from longer-term preventive headache strategies. There has long been a strong clinical impression that this is the case, with some experts claiming preventive treatment can only be effective once patients are withdrawn from overused short-term medications. Recent analyses of data from trials of preventive treatment with topiramate and onabotulinum toxin type A, however, did not show reduced benefit of those prophylactic treatments in subjects who were overusing short-acting headache relief medications. This suggests that not all patients must be withdrawn from overused medications in order to benefit from preventive headache therapy. There are still many other reasons, however, to attempt medication reduction or withdrawal in patients who are using these treatments frequently (Katsarava et al., 2005).

ICHD criteria for the diagnosis of medication overuse headache have frequently been altered, and expert opinion remains divided on the amount and type of symptomatic headache medication that is needed to produce medication overuse headache. From a practical clinical point of view, a

reasonable practice is to restrict the use of symptomatic medication to no more than three days of use per week (Silberstein et al., 2005).

It can be difficult to help patients with chronic headache disorders maintain reasonable limits on the use of symptomatic headache-relief medications. There is a tension between the desire for pain relief for individual headaches and the longer-term goal of prevention of headache worsening or the development of treatment-related morbidities. Disagreement between patients and their physicians about the type and amount of medication that should be used to treat individual headache episodes is a common cause of treatment difficulty. Treatment strategies that are appropriate for patients with occasional headaches—in particular, the emphasis on early, aggressive treatment of individual headache attacks—can be counterproductive for patients who have frequent headaches. Over time, some patients develop maladaptive beliefs and behaviors regarding medications; a common example is the belief that only a certain medication (such as meperidine) will help a bad headache (Kavuk et al., 2004; Usai et al., 2004).

Treatment agreements that limit the monthly amount of short-term pain medications that can be used by the patient are often the most successful approach to preventing medication overuse. Patients with chronic headache should be encouraged to use non-medication strategies to augment pharmacological treatment of headaches, and should understand that they may have to pick and choose which headaches to treat.

Treatment of patients whose medication overuse is an entrenched behavior can be difficult. It is not always easy to obtain an accurate history of medication intake. Patients may not disclose use of over-the-counter medications unless asked, for example. Thus it is essential that patients with frequent headaches, even those that are mild, be asked specifically about prescription and non-prescription medications, including details about the number of tablets taken and the number of times per day they are used. When medication reduction or withdrawal is necessary, the methods used depend upon the drug(s) being taken. If patients also are heavy consumers of caffeine in the form of caffeine-containing headache medications, cola drinks, energy drinks, or coffee, headache from caffeine withdrawal will make the treatment more difficult. In such cases, it may be worthwhile to taper and discontinue caffeine prior to beginning the rest of the medication taper.

From a behavioral point of view, non-barbiturate or non-opioid medications are best discontinued abruptly, in order to avoid perpetuating medication-taking behavior. Opioid or barbiturate withdrawal syndromes can be severe, and these medications must be withdrawn more slowly to avoid precipitating withdrawal seizures. Patients using these medications on an “as needed” basis should be converted to a regular schedule of use and the dose reduced gradually (Paemeleire, Crevits, Goadsby, & Kaube, 2006).

Severe withdrawal headache may occur when regular use of short-acting pain medications is discontinued. Typically, these withdrawal headaches will last two to three days. They may respond to the use of steroids such as decadron 4 mg three times daily for three days. Strong sedatives such as

prochlorperazine can be used to help patients tolerate the withdrawal headache and any nausea; they are particularly effective when given as rectal suppositories.

Following medication withdrawal, patients typically need considerable emotional support to avoid returning to previous patterns of medication use. Preventive treatments, including non-pharmacological methods of headache management, must be emphasized. Patients who are unable to withdraw on an outpatient basis from overused medications may require hospitalization. The most successful approach involves hospitalization in a dedicated headache unit, where the underlying headache disorder can be managed in addition to accomplishing medication withdrawal. Unfortunately, there are only a few such dedicated hospital programs remaining in the United States. The majority of headache patients requiring hospitalization for medication withdrawal will thus need to be treated in a general medical or detoxification unit or on an outpatient basis.

TREATMENT OF MEDICALLY REFRACTORY HEADACHE DISORDERS

The long-term management of patients with refractory benign headache is challenging. Organic causes must be ruled out before chronic daily headache can be considered a primary headache problem. These recommendations do not apply to patients who have chronic headache on the basis of head trauma, surgery, or other medical conditions. The following management principles can be helpful in treating patients whose headaches respond poorly to aggressive treatment.

The first principle is to rethink the goals of treatment, which should shift from the idea that a cure is possible and towards a philosophy of symptom management and preservation of functioning and quality of life. Depression, somatic preoccupation, inactivity, and medication overuse are important treatment targets. Patients who can tolerate the medications should be on prophylaxis for their condition, even in the absence of a clear decrease in headache frequency or severity. This may prevent worsening of headache and disease progression. A simple headache calendar can help guide treatment.

Use of most abortive medications for headache should be limited to two or three days per week. Disease-specific medications such as the triptans and ergots are preferable; opioids and barbiturate-containing drugs should be used with caution. Medications such as hydroxyzine, promethazine, or 4% lidocaine drops, and non-pharmacological methods of management (ice, heat, massage) can be used more often.

The role of maintenance opioids in chronic, benign headache is controversial. The only two long-term studies show benefit (as measured by decreased pain levels, decreased use of emergency department [ED]) in only 25% of patients; no reductions in abortive medication use, returns to work, or improvements in mood were found (Rothrock, 1999; Saper et al., 2004; Saper et al., 2010). Scheduled use of long-acting opioids may be most helpful as a time-limited bridging or respite treatment for three to six months in carefully selected patients. Considerable clinical experience is needed to select

patients with chronic headache who might benefit from opioid maintenance treatment (Saper et al., 2010).

CLINICAL PEARLS

- The misdiagnosis of migraine as “sinus” headache is a well-known phenomenon (Silberstein, 2004a).
- Preventive treatments, such as beta blockers, that are helpful for migraine are not effective for cluster headache, so diagnostic delay exposes some patients to many years of ineffective treatments.
- Perhaps the most common treatment errors in headache stem from prolonged use of nonsteroidal anti-inflammatory medications, with resulting gastrointestinal toxicity and bleeding.
- It is unusual for primary headache disorders to begin after the age of 50.
- Affective disorders such as anxiety disorders and depression are more common in patients who have migraine, and the reverse situation is also true.
- Studies suggest that the odds of having major depression are roughly in the range of 2–4 for those with migraine compared with non-migraineurs.
- Serotonin syndrome has also been reported with triptan monotherapy (Soldin, Tonning, & Obstetric-Fetal Pharmacology Research Unit Network, 2008). The risk appears low, and the number of case reports is low and of variable credibility (Evans, 2007, 2008). However, the FDA has issued an advisory regarding the possibility of serotonin syndrome with combined triptan and SSRI or SNRI treatment. A position paper from the American Headache Society concludes that available evidence is not sufficient to warrant limiting the use of these drugs; however, they recommend that clinicians using the combination be “vigilant” for signs or symptoms of the disorder (Evans, Tepper, Shapiro, Sun-Edelstein, & Tietjen, 2010).
- Low-grade, featureless headache or worsening of migraine have been reported as side effects of SSRI or SNRI therapy (Bickel, Kornhuber, Maihofner, & Ropohl, 2005). Clinical experience suggests that the headache may wane over time, even if the patient remains on the offending drug; alternatively, switching to another drug in the same class may relieve the headache.
- Unlike patients with migraine, those with cluster headache are commonly rendered headache-free by prophylaxis.
- Although the name implies that muscle or emotional tension might be the underlying cause of tension-type headaches, evidence is lacking to support this view.
- There is relatively old evidence suggesting that tricyclic antidepressants are probably effective for tension-type headaches, with amitriptyline being the best studied and

therefore the most commonly used (Bendtsen & Jensen, 2000; Bryson & Wilde, 1996; Diamond & Baltes, 1971).

- A hallmark of migraine is that the headache often comes after, rather than during, a stressful event.
- In women of childbearing age, the combined stroke risk from aura and the use of estrogen-containing contraceptives is generally felt to be unacceptable.
- So-called triptan sensations are more common with injectable sumatriptan, probably because of the rapid increase in plasma levels of the drug. This can include transient neck or chest tightness. If patients are unprepared for this side effect, they may worry that they are experiencing cardiac problems; however, studies of coronary perfusion do not support the idea that these side effects reflect decreased coronary perfusion.
- Opioid or barbiturate withdrawal syndromes can be severe, and these medications must be withdrawn more slowly to avoid precipitating withdrawal seizures. Patients using these medications on an “as needed” basis should be converted to a regular schedule of use and the dose reduced gradually (Paemeleire, Crevits, Goadsby, & Kaube, 2006).

TRAUMATIC BRAIN INJURY

EVALUATION AND MANAGEMENT FOR THE PSYCHIATRIC PHYSICIAN

Gregory J. O'Shanick, George T. Moses, and Nils R. Varney

INTRODUCTION

All psychiatrists practicing in medical settings, and most psychiatrists in community practice, will encounter patients who have sustained traumatic brain injuries (TBI) in their clinical practices. While in some situations the TBI is the cause for the initial psychiatric evaluation, frequently the TBI is not the presenting concern, but is an aspect of the medical history that has been neglected, or is unrecognized by the patient, their family, or their healthcare team. The presence of a prior neurological injury is always relevant information to be ascertained by the consulting psychiatric physician, who frequently is the only person caring for a patient who will take a sufficiently detailed history and perform a sufficiently detailed neurocognitive examination to establish the presence and relevance of TBI to the patient's condition (Table 45.1). The examination required once TBI is under consideration includes the assessment of auditory, visual perceptive, vestibular, and language functions. Absent such a focused neurological examination, deficits in these areas may go undetected. Without an appreciation of the context of a prior TBI, the deficits that are found might be misattributed to a primary psychiatric disorder or malingering. This chapter will assist the reader in the recognition of those salient post-TBI neuropsychiatric and neurosensory manifestations often seen, but under-recognized in these patients, and will focus on the recognition and management of late effects of TBI as they are encountered in psychiatric practice.

TBI has a far more important role for clinical psychiatry than determination of disability, as it causes or alters the symptoms of mood disorders. Seventeen to 61% of all TBI patients develop depression within two years of injury (Rapoport, 2012) and seek psychiatric care without considering the relevance of TBI. TBI-related mood disorders offer different diagnostic challenges, respond differently to medications, and can have substantially different outcomes than do "conventional" mood disorders. In an ideal setting, the patient's reporting that they have memory trouble, episodes of confusion, or anger problems would be adequate history from which to proceed. However, TBI patients may be involved in litigation, so clinical caution is necessary. Unfortunately, the issues generated by caution may produce wrong answers of their own. For example, the same TBI patient who has

suffered only a brief loss of consciousness (LOC) and has a normal magnetic resonance imaging (MRI) could be the same patient who experienced an intermittent post-traumatic amnesia (PTA) lasting three days and a quantitative PET scan showing right fronto-temporal hypometabolism (cf. Bigler, 2008). Thus, as diagnostic errors can cut either way, balanced caution is advisable.

CONTEXT OF TRAUMATIC BRAIN INJURY

TBI occurs in a variety of contexts (Faul, Xu, Wald, & Coronado, 2010). Falls remain the leading cause of TBI among civilians followed by motor vehicle accidents (MVA) and other blows to the head, including sports injuries and assaults. Assaults may be due to blunt objects such as body parts (fists, feet, elbows, knees, heads, etc.), edged weapons, or firearms. Penetrating TBI are associated with lower Glasgow Coma Scores (GCS) and higher acute mortality rates. The vast majority of TBI are closed, meaning no breach of the dura has occurred. TBI from MVA result from rapid acceleration/deceleration forces causing micro-shearing and diffuse axonal injury (DAI). DAI may appear on MRI as numerous, small, white matter lesions. Ischemic injury of brain tissue also can occur due to vasospasm, microvascular

Table 45.1 ESSENTIAL EQUIPMENT FOR TBI NEUROLOGICAL EXAMINATION

<i>Blindfold</i>	BESS and Fukuda Stepping Test for vestibular dysfunction
<i>Reflex hammer</i>	Deep tendon reflex assessment

occlusion, and/or the rupture of blood vessels. Intravascular coagulopathy, either immediate or delayed, is common in more severe cases of TBI, which adds an additional mechanism of injury (Stein, Chen, Sinson, & Smith, 2002; Harhangi, Kompanje, Leebeek, & Maas, 2008; Greuters, van den Berg, Franschman, Viersen, Beishuizen, Peerdeman, & Boer, 2011). With the exception of mine workers, injury from blast waves is uncommon among the civilian population. As a consequence of the high incidence of blast-induced neurotrauma among combat veterans, significant research efforts are now underway regarding this form of TBI (Cernak & Noble-Haeusslein, 2009; Lippa, Pastorek, Bengel, & Thornton, 2010; Luebeck, Bryan, Morrow, & Isler, 2011).

TBI can also be subdivided into primary and secondary brain injuries. The primary injuries occur at the time of the trauma. The secondary brain injuries are the result of a cascade of molecular injury mechanisms that unfold over hours and sometimes days following the acute event. This separation is likely an oversimplification, since secondary injury likely begins at the time of the mechanical injury and primary injury is often modulated by the immediate treatments (Moppett, 2007). Secondary injuries can occur following even mild TBI, and variability in their scope and severity is an important reason for the wide variation in symptoms and impairments that follow mild TBI (cf. Bigler & Maxwell, 2012). Inflammatory responses and glutamate-related excitotoxicity (including oxidative stress and damage to cell membranes by free radicals) are well-established mechanisms of secondary injury. Neuronal death by apoptosis following TBI has been demonstrated in animal models; it may be relevant to secondary injury in humans, particularly following severe TBI. Electrolyte imbalances are often the cause of secondary injury in severe head traumas. This injurious cascade continues for hours and potentially days. Inflammatory responses as well as glutamate mediated excitotoxicity causing free radical damage to cell membranes become part of the secondary TBI. The mechanism of trauma-related neuronal apoptosis remains to be definitively elucidated in humans.

EPIDEMIOLOGY

TBI remains a leading cause of injury, death, and disability in the United States. Persons of all ages, races, and socioeconomic backgrounds are at risk for TBI. From 1997 through 2007, the average annual incidence in US civilians of TBI severe enough to warrant medical attention or to contribute to mortality was 1.7 million. According to the Centers for Disease Control and Prevention (Faul et al., 2010), TBI contributes to over 52,000 deaths annually—about one-third of all deaths related to trauma. Annual emergency department (ED) visits due to TBI number over 1.3 million, which result in approximately 275,000 hospitalizations. The age groups most affected are children under 4, adolescents in their late teens, and older adults (over 65).

The incidence of TBI among active duty U.S. military personnel is quadruple the civilian rate, approximately 23 TBIs per 1000 service members. The majority of these injuries are

non-combat related, and over 80% are classified as mild. The incidence of TBI in the military has tripled since the beginning of this century with mild injuries accounting for almost all of the increase. The increasing incidence is due partly to increased ascertainment of TBI and improvements in body armor that now allow combatants to survive injuries that previously would have been lethal (Belmont, Schoenfeld, & Goodman, 2010; Capehart & Bass, 2011).

PROBABILITY ISSUES REGARDING TRAUMATIC BRAIN INJURY'S SIGNIFICANCE IN MENTAL HEALTH POPULATIONS

While it is commonly agreed that 2-million persons sustain mild TBIs annually, only 5% of these have significant residual mental status problems. However, it does not follow that only 5% of prospective psychiatric patients with mild TBI have “real” problems. These individuals are a self-selected subgroup because they are seeking and paying for psychiatric care rather than being selected at random from among the 2 million with mild TBI. In addition, this group would include the 100,000 persons who are expected to have neuropsychiatric symptoms each year, which is five percent of two million mild TBIs. From this perspective, the base rate of real patients with treatable symptoms is far higher than 5%.

DETERMINING SEVERITY

Three commonly used means for rating the severity of a TBI exist: The Glasgow Coma Scale (Teasdale & Jennett, 1974), the standards set by the American College of Rehabilitation Medicine (ACRM, 1993) and clinical, post-hoc observation. Each procedure employs highly selective rigorous inclusion criteria for moderate and severe TBI so that there can be no question about the reliability of each diagnosis. However, it does not follow that failure to meet these criteria demonstrates that a TBI is either mild or inconsequential.

GLASGOW COMA SCALE

This rating scale is based on best observed, verbal and motor responses recorded 30 minutes after a TBI occurs. However, as Teasdale, who co-authored the GCS, wrote, “the Glasgow Coma Scale was designed and should be used to assess the depth and duration coma (Teasdale et al., 1978). It is not, therefore, appropriate for determining the severity of TBIs in general. On the GCS, a TBI is rated as mild if the sum of points obtained regarding eye, motor, and speech responses is between 13 and 15. All such patients have their eyes open; the highest rated eye response. This would seem appropriate for the designation of mild for a coma, but does not indicate that the patient is capable of tracking a visual target or reading. In addition, patients with GCS scores of 13 could be insensible, disoriented and incoherent. A patient with a score of 14 would be much more responsive, but would remain confused.

A patient with an errorless score of 15 would be responsive and capable of comprehensible speech, but still might have conspicuous problems with thinking and memory, severe headache, or even such major symptoms as intermittent seizures or “organic” hallucinosis. Thus, while the GCS may have utility in an ED for triage and in an intensive care unit (ICU) for tracking a patient’s progress, a normal GCS score denotes only the absence of a coma and does not exclude a wide variety of major neurocognitive, neurosensory and neuropsychiatric symptoms.

AMERICAN CONGRESS OF REHABILITATION MEDICINE CRITERIA

Most TBIs are classified as mild to severe by standards set by the ACRM in 1993. Indeed, these could be regarded as the “gold standard” of TBI classification. These diagnostic criteria are based on duration of LOC or of PTA. In our experience, the diagnostic criteria based on PTA are neglected by many clinicians, who classify a TBI as more than mild only if the LOC is greater than 30 minutes. However, the ACRM criteria mandate that a TBI be rated as moderately severe if a patient has a PTA or period of altered consciousness lasting 24 hours or more. As a result of this oversight, the erroneous diagnosis of mild TBI is commonly made in patients who in actuality have sustained a moderately severe TBI, where lasting post-concussive symptoms are probable rather than rare (Bigler, 1990; Lezak et al., 2004).

Determining the duration of PTA can also be done incorrectly if the duration of PTA is determined by the patient’s first memory. It is not at all uncommon for patients to have shards of memory during the immediate post-impact stage of a PTA, or even over the next few days of recovery (especially memories of physical pain). Ritchie Russell (Russell & Smith, 1961), who defined PTA, said that PTA was over when continuous memory was restored; however, the presence of bits of recollection here and there are permitted and do not reflect resolution of PTA. Failure to consider PTA in rating a TBI can result in misclassification of moderate TBI as “mild.” This is particularly important with regard to TBIs from the wars in Iraq and Afghanistan, which are primarily the result of blast. Blast inflicts brain injury by passing through the body and thus rarely results in prolonged LOC, despite frequently causing prolonged PTA. (MacDonald et al., 2011).

CLINICAL OBSERVATION OF OUTCOME

Following TBI, patients improve to varying degrees. However, improvement does not alter the classification of the original injury as mild, moderate, or severe. This apparently obvious point, like the importance of PTA to rating TBI severity, frequently appears to be neglected in practice. The severity in the initial injury remains the best predictor of long-term prognosis; while at a particular point in recovery a patient with a moderate TBI may resemble one with a mild TBI, the likelihood of residual symptoms or impairments will be much higher in the former.

Kinematics

The debate over PTA and LOC in the classification of TBI severity overlooks a critical point; namely, that each is an outcome variable that is dependent. The independent variable that actually reflects the severity of physical impact to the brain should be expressed with reference to *kinematics*, the branch of physics concerned with objects in motion. That is, accelerations and decelerations expressed as g-forces describe and quantify the forces that cause a brain injury (Varney & Varney, 1995). The basic formula for describing the forces of a TBI as it affects the brain, derived from Newtonian physics, is: $a = v^2/(2s)$. This is a direct reflection of a law of physics (Newton’s Third Law), not an engineering formula. This numerical result is expressed in g-forces. That is, the severity of a TBI is a result both of how fast you were going and of how quickly you stop (Varney & Roberts, 1999). The relationship between velocity, stopping distance, and acceleration is shown in Figure 45.1. In this figure, stopping distance reflects the vehicle’s front-end collapse distance. Automakers such as Mercedes-Benz have developed break-away frame assemblies that cause the front end to collapse by up to four feet in a head-on impact. As shown in Figure 45.1, at 50 miles per hour, approximately 10 g’s are generated when the front end collapses to absorb the kinetic force, and this represents a safe amount for the occupants to experience. The car, however, would be a total wreck. Conversely, a vehicle with only a 0.5-foot collapse zone, such as would be seen in an armored car, would generate 200 g’s if it were to experience a front-end collision at 50 miles per hour. This is more than adequate for a serious brain damage to occur in the occupants of the vehicle. In this case, the vehicle would appear to be relatively undamaged. As the car absorbs more force, less force affects those inside. Until TBI classification reflects the forces that cause brain injury, and not outcome variables such as LOC and PTA, determination of the initial severity of TBI will remain inexact and imprecise.

IMAGING

Anatomic neuroimaging, computerized tomography (CT), and MRI of patients with acute TBI is the standard for the diagnosis of gross injuries and complications of neurosurgical

Figure 45.1 Acceleration as function of velocity.

magnitude such as subdural and epidural hematomas and life-threatening cerebral edema. However, their limited spatial resolution (CT, 2–3 mm; 1.5 Tesla MRI, 1 mm; 3 Tesla MRI–0.5 mm) makes them insensitive to two common consequences of closed TBI—cavitation and micro-shearing. These injuries have been observed in post-mortem studies of patients with TBI who have died from other causes (Bigler, 2004).

Anatomical neuroimaging offers no information about abnormal metabolic activity of injured neurons. Following brain contusions, the cortex shows diminished metabolic activity with associated cognitive impairments. Contusions may also produce irritable foci that result in intermittent sensory phenomena or memory disruption; metabolism in these areas may be increased either persistently or episodically. In the latter case, even functional imaging may miss a clinically significant lesion.

In the context of neuropsychiatric evaluation and treatment of patients with mild TBI, the limitations of neuroanatomical imaging frequently predominate, with “normal” structural studies as the usual finding in the face of unequivocally “organic” symptoms (cf. Shenton et al., 2012). Confident diagnoses can nonetheless be made without corroboration from neuroanatomical imaging, as indeed they were for most neurological disorders in the era that preceded the advent of CT scanning. The occurrence of typical constellations of symptoms, unfolding of the clinical course along typical lines, stereotypical symptoms (semiology), and valid and confirmatory neuropsychological test findings can add up to diagnostic confidence. Nonetheless, clinicians treating TBI patients frequently encounter the prejudice that neuroanatomical imaging is “objective” and all else is “subjective.”

ORBITAL FRONTAL PATIENTS: THE OTHER MASK OF SANITY

The most common area of tissue damage in typical closed TBI is the orbital frontal cortex, usually via lacerations, abrasions, and contusions of the cortex caused by friction of the ventral surface of the frontal lobe against the sharp, irregular ridges of the cribriform plate. Clinical awareness of this site of injury often is absent early on, because the symptoms and signs of orbital frontal injury may not be manifest in a typical diagnostic evaluation by an emergency medicine physician or even a general neurologist or psychiatrist. Patients with orbital frontal injury may have no conspicuous abnormality on mental status examination, may appear euthymic, and may have few spontaneous complaints (see Chapter xx on frontal lobe disorders, and the discussion of frontotemporal degeneration in Chapter xx on dementia). The seeming invisibility of the orbital frontal syndrome is caused by alexithymia, a condition of pathologically limited insight and self-perception. Patients with alexithymia either do not realize that they have psychological symptoms, or they simply do not care. They can be quite illogical in doing so. For example, patients may report suicidal ideation when asked (never with a specific plan), but then deny dysphoria. Typically, they fail to report symptoms

other than those that are immediately present, such as localized pain, and overlook severe migraine headaches, for example, that are not occurring at the time of the interview. An easy screening procedure for suspected alexithymia is to ask for the chief complaints without any prior discussion (i.e., no hints). The list generated independently by the patient will be badly impoverished, particularly regarding already documented problems such as headache, insomnia, temper, impotence, unemployment, and the like.

Experiencing alexithymia creates an interesting scenario with regard to evidence of malingering. Malingering, after all, is something that requires intact executive functioning to plan and execute a plausible symptom complaint. Although the alexithymic patient is not aware of his problems, he is still potentially influenced by the temptation of unearned money (as in a personal injury, disability determination, or worker’s compensation setting), but cannot generate an effective plan to fake symptoms. Thus, his alexithymia and executive dysfunction result in unnecessary and poorly executed transparent attempts at malingering (Ju & Varney, 2000).

The core disability of orbital frontal patients is that they think less (Varney & Menafee, 1993). Spontaneous decision-making becomes labored, less frequent, and less reliable, particularly with the multiple small decisions of ordinary life, such as deciding what to do next (Varney, 1999). Emotional responses are muted, and indifference is manifest. While this is virtually invisible to non-family members, these symptoms are wrenching to those who previously have enjoyed a close relationship with the patient. Severe anxiety and associated autonomic stress-related physical disorders are very common among family members (Chwalisz, 1999). Even among family members, long-delayed full recognition can take two or more years (Siders, 1999). Even the milder varieties of frontal symptoms may cause a disability based on problems with productivity and reliability of work product (Varney, 1988) without any loss of vocational knowledge.¹ Unfortunately, this is often viewed as the result of poor motivation; or, when legal or disability issues are involved, desire for “secondary gain” is suspected.

Patients with damage largely confined to the orbital frontal region and its connections typically do very well on conventional neuropsychological testing (Varney & Stewart, 2004), as many of the neuropsychological tests aimed at identifying frontal lobe disorders are more sensitive to dorsolateral frontal than to orbital frontal functioning. As stated by Heilman and Valenstein (2012), “unlike most artificial problems posed by neuropsychological tests, the relevant issues, rules of engagement and endpoints are not always clearly identified. Patients with frontal lobe damage who despite good IQ scores, cannot effectively deploy their intelligence in real world situations.”

With no obvious symptoms and no expressed complaints, orbital frontal patients can prove difficult to assess without also interviewing a collateral source such as a spouse, domestic

1. Eighty percent productivity and 5% errors of omission add up to a disability in most jobs. For example, a hotel housekeeper with 20 rooms to clean and 20 things to do in each room would be unable to clean more than 16 rooms and would overlook at least one important duty in each room.

partner, parent, or sibling. Ideally, this will be done apart from the patient, but with the patient's consent. The spontaneous complaints offered by the collateral source typically describe the syndrome and its impact on the family. Families may offer accounts of extreme behavior that are striking in view of the bland presentation of the patient; for example, a patient may watch television all day, literally without doing anything else—not even changing channels or eating.

Orbital frontal symptoms relating to activities of daily living (e.g., indecisiveness, mental inertia) and psychosocial symptoms (poor empathy, indifference) can be reliably determined by structured interview of a collateral informant (Varney, 1991). In functional neuroimaging studies (Varney & Bushnell, 1998; Varney et al., 1995; Varney et al., 2001), the correlation coefficient of gamma rays per voxel from the orbital frontal region and the interview test score was $-.61$.² Interview results did not correlate significantly with any other region. No score from seven neuropsychological measures of executive function correlated with orbital frontal activity, but each correlated significantly with metabolic activity in other frontal areas. Thus, with regard to descriptive symptoms not appropriate for formal neuropsychological testing, the relationship with orbital frontal activity was significant and specific.

Executive disability in patients with orbital frontal injury involves problems not detected by conventional neuropsychological testing (Martzke et al., 1991) which isolates individual abilities for testing. These injuries create problems with independent living due to several factors, including:

1. inability to recognize the need to execute daily activities such as meal planning and preparation, money management, and safety awareness;
2. inability to generate an internal means of goal-directed activity, such that they are directionless, and living on their own becomes bewildering;
3. vulnerability to exploitation and victimization, as they require others (who are often unscrupulous and predatory due to impaired risk-assessment by the patient) to assist them in decision-making and providing external structure; and
4. impaired insight into their own limitations and adaptability.

Neuropsychological testing in the typical structured format of assessment fails to demonstrate such relevant “real world” disability. To further complicate matters, seemingly similar tests of dysexecutive disability are not closely related to real-world functional independence and success in some patients (Varney & Stewart, 2004).

Psychological tests to demonstrate executive disability in orbital frontal patients are a relatively new area of assessment

in which there are no tests with high “hit rates” as validated against the patient's activities of daily living or a specific locus of lesion such as orbital frontal cortex. Lezak's Tinker Toy Test (Lezak et al., 2012) is an unconventional, but accurate, means of testing executive functioning. Superficially, this assessment appears so simple that most preschool age children could make a passing construction. The elements that render this test difficult for the patient with executive disability are (1) there are 100,000 potential “right answers” from which to select, and (2) the patient must independently choose one and persevere to its completion to “pass.” By contrast, Block Design, no matter how difficult, has only one correct solution. With indecisiveness being the hallmark of impaired executive functioning, the Tinker Toy Test can be failed by individuals who otherwise appear to be quite intelligent. Because of the elementary nature of the task, failure is a quite conspicuous and remarkable symptom with well-established prognostic significance (Bayless et al., 1989).

NEUROPSYCHOLOGICAL ASSESSMENT IN TRAUMATIC BRAIN INJURY: A CONSUMER'S GUIDE

A fundamental problem with contemporary neuropsychological assessment arises when an abnormal test score is viewed as a primary symptom rather than an indication of a known symptom. Tests are psychometric inventions that can be failed for a variety of reasons. For example, it might be correct to describe Block Design as a measure of non-verbal problem-solving; however, a defective Block Design score could reflect a variety of problems with no relevance to intelligence, such as confusion, constructional apraxia, optic ataxia, bradyphrenia, unilateral visual neglect, absence spells, poor mental focus, or morphopsia. The great majority of neuropsychologists now performing TBI assessments use the Wechsler tests to measure IQ and memory; new versions of these tests are published every five years.

The Wechsler Adult Intelligence Scale, Version IV (WAIS-IV) consists of a wide variety of different subtests, each of which measures a different ability. The results of each test are then converted into a scaled score, a statistical representation of each test performance that permits direct comparison of individual test scores. Averaging these test scores determines overall IQ, with selected groups of subtests defining verbal and performance IQ, and subsidiary index scoring such areas as verbal comprehension, working memory, or perceptual reasoning.

WAIS-IV presents a number of problems, including the following:

1. IQ and other composite scores can be misleading, as they average multiple individual test scores. While this may be useful in the assessment of normal school children for class placement, it can be misleading with a TBI patient. Put simply, various specific mental abilities can be selectively impaired from focal brain lesions such that averaging scores can obscure the presence of a specific symptom.

2. This Iowa Collateral Head Injury Interview measure looks for mild symptoms described following transorbital frontal leucotomy. This particular measure is standardized and covers well-established orbital frontal symptoms as described, including those that are much milder in transorbital frontal lobotomy patients.

2. A test score can be interpreted as being “within normal limits” if it falls above the ninth percentile, the very low end of normal (i.e., just above the level for mild mental retardation). It would follow, therefore, that 91% of testing subjects should score above the ninth percentile, making such a very low score acceptable for all of them as individuals. Consequently, the designation of a score as being “within normal limits” provides no diagnostically relevant information for the top half of the distribution of an individual ability.
3. It should be noted that the Wechsler tests are commercial products, developed and published by a for-profit company. As such, they do not reflect unbiased consensus within the scientific community as would be achieved in a non-profit setting (e.g., just as procedures for assessing and interpreting thyroid function are established separately from machinery to perform these assessments). Nevertheless, neuropsychology’s ethical guidelines state that it is “unethical” not to purchase the latest models from this line of products.

The Wechsler Memory Scale, Version IV (WMS-IV) is also made up of a number of specific subtests that measure immediate and delayed recall on a variety of verbal and non-verbal subtests. These test results can also be converted to scale scores and used in a manner similar to those described with regard to IQ. Most of the tasks that make up this battery involve memorization. This creates four problems:

1. They lack ecological validity because they are irrelevant to what a patient is expected to remember outside the clinic.
2. They are boring for patients to take, so there are no natural incentives to learn.
3. They offer no opportunity to assess the role of autonomic activation for memory retention and implicit memory.
4. They do not address issues that affect memory encoding, such as absentmindedness, distractibility, and fatigue.

Other controversies exist regarding evaluative methods commonly employed by neuropsychologists. The first involves effort or malingering testing. On the basis of one or more such tests, a patient may be labeled as deliberately producing poor scores or putting forth a suboptimal effort: such tests are purported to be essential in settings with the potential for personal injury litigation. A number of issues exist concerning the validity or fairness of these tests, resulting in their exclusion from assessments utilized for Social Security disability determination, where regulations specifically state, “Remove malingering and credibility tests from the list of test options (e.g., Test of Memory Malingering, Minnesota Multiphasic Personality Inventory [MMPI])” (Disability Determination Services Administrators’ Guide (DDSA), 2012). A similar prohibition against their utilization has been instituted by the United States Army (Office of the Surgeon General/US Army Medical Command [OTSG/MEDCOM] Policy 11-076, 2011).

The use of the MMPI as a measure of “emotional functioning” is another area of controversy in assessment of those

with TBI. The test purports to assess a variety of different dimensions of abnormal psychology (e.g., depression, hypochondriasis) to derive a profile that supports various psychological diagnoses. Many of these subsets generate inaccurate descriptions of the TBI patient’s psychiatric state, prognosis, and *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) diagnosis. The fundamental problem stems from the original intention of the MMPI, which was not for use with neuropsychiatric populations. Many items used to identify somatoform disorder, psychoses, and faking involve well-established neuropsychiatric symptoms such as absence spells or visual illusions associated with migraine headaches (Roberts et al., 1989). Thus, the misuse of the MMPI with TBI patients can result in highly pejorative psychiatric and psychological diagnoses for illness-appropriate symptoms.

SEIZURES

Although generalized tonic-clonic seizures are readily recognized, the existence of seizure events with absent or less overt motor manifestations may be overlooked in those with a history of TBI. Initial seizures following the acute TBI event occur in 10–15% of adults in the first week following severe TBI (Langendorf & Pedley, 1997). While less commonly than with severe TBI, both moderate and mild TBIs can precipitate acute seizure episodes. Similarly, the potential for late seizures is not limited to those with severe TBI. Longitudinal studies define increased lifetime seizure risk for those with mild, moderate, or severe TBI across the lifespan as ranging from a relative risk of 2.22 in those with mild closed TBI, to 7.4 in severe brain injury, to 2.17 in those with skull fracture (Christensen, Pedersen, Pedersen, Sidenius, Olsen, & Vestergaard, 2009). Evaluation of these events generally begins with either a routine or sleep-deprived electroencephalogram (EEG), the latter evaluation being more sensitive because of the effect of sleep deprivation on seizure threshold. While the specificity of EEG is high, the sensitivity is low, with studies indicating only a 30% likelihood of capturing an actual seizure discharge, even in those with diagnosed epilepsy. More extended EEG monitoring with either ambulatory recording or inpatient telemetry can be effective; however, in situations where the irritable focus is in either the frontal lobe or deep temporal regions, surface electrodes may still fail to detect abnormalities. The use of a structured diagnostic interview, such as the 40-item Iowa Inventory for Partial Seizure-like Symptoms (Roberts, 1999), will not only identify those whose events may be misdiagnosed, but, as it can be serially administered, it will also allow a method of tracking the therapeutic impact of anticonvulsant treatment over time. Table 45.2 outlines the historical elements that are of significance in assessing seizure presence.

NEUROPROTECTION

Using neuroprotective agents to mitigate the degree of residual damage after TBI has been the “Holy Grail” of neurotraumatologists since the 1980s saw the establishment of the

Table 45.2 “RED FLAG” SYMPTOM FREQUENCY
RESPONSES FOR PARTIAL SEIZURES FROM IIPSS
(ESTABLISHED WITH 5000 CONTROL SUBJECTS)

<i>Essential symptoms</i>	Episodic gaps in memory lasting over 5 minutes Absence spells (others noting transient “blank look” or reporting “spacing out” episodes watching TV)
<i>Corroborative symptoms</i>	Any symptom occurring more than once per week Sensory hallucinations (olfactory, gustatory, kinesthetic, tactile, visual, etc.) occurring more than once a week Unrecalled anger episodes occurring more than once a month

multi-center Traumatic Coma Data Bank. While the shearing effects of head impact or acceleration and deceleration forces created DAI in the acute phase (so-called cell murder), a delayed disconnection of axons from the cell body was recognized and termed “programmed cell death” or apoptosis (Povlishock & Katz, 2005). This secondary cause of DAI, termed “cell suicide” (Ucker, 1991), was recognized as a potential opportunity for secondary prevention of white matter damage and consequent disconnection of cortical regions. Unfortunately, large scale multi-centered international studies failed to define a universally effective pharmacological intervention that could be administered post-event. Lyeth and colleagues (1988) identified that the pre-injury use of an anticholinergic agent in a rat model of TBI would reduce injury severity, duration of coma, and favorably affect outcome. Unfortunately, this had little practical application in neurotrauma settings, as no benefit was obtained with post-injury administration. Only one study to date has shown efficacy of an agent when given to humans in clinical settings *following* TBI. The use of naturally derived progesterone was explored by Stein (2011) over a several-decade span in non-human settings and resulted in a large, multi-center study that defined significant benefit from post-injury-administered progesterone in severe TBI. In that study, progesterone’s neuroprotective benefits were realized even when the drug was administered 8 hours post-injury. Current multi-center studies aim to better define the parameters and limitations of progesterone therapy.

POST-TRAUMATIC HEADACHES
AND VERTIGO

Hines (1999), in his seminal treatise on post-traumatic headache (PTHA), identified six subtypes: (1) tension type, (2) local injury or scar-related pain, (3) migraine, (4) dysautonomic cephalgia, (5) cervicogenic, and (6) neuralgic. (Many patients have more than one mechanism for their headaches, and dissecting them may be difficult in patients who do not spontaneously provide an accurate and comprehensive account of their symptoms.) As with assessment of other neuropsychiatric symptoms following TBI, it is usually necessary

to interview collateral sources to fill in the history. In addition, a particularly careful physical and neurological examination of the head and neck may reveal findings not noted in a more cursory examination by a generalist physician. As atypical as this may seem for the psychiatrist, facility with evaluating temporomandibular joint functioning; assessing trigger points at the greater occipital notches, levator scapulae, and insertion of the splenius capitus; and evaluating deficits in oculomotor control, including teaming and saccades, will increase capture of subtle triggers of PTHA and permit more definitive intervention and symptom relief. Fatigue and poor sleep architecture further contribute to and complicate pain tolerance. Optimizing sleep efficiency to improve restorative sleep is essential to the comprehensive treatment of post-traumatic pain disorders, including headache.

NEUROSENSORY DEFICITS

Failure to appreciate neurosensory abnormalities following TBI can result in its misdiagnosis as a primary psychiatric syndrome and thus lead to ineffective and potentially damaging treatment. To identify these abnormalities, the psychiatric physician must be capable of performing a competent and accurate cranial nerve examination, including assessment of olfactory functioning. Visuo-perceptual dysfunctions and lateralized loss of visual awareness (due to non-dominant temporal-parietal damage) results in increased startle and reaction when the patient is approached from the dysfunctional side. Over time, this evolves into a subtle form of hypervigilance that may resemble paranoia. Coexistent orbital frontal damage results in faulty problem-solving/threat assessment, and potentially impulsive reactions may occur.

Damage to anterior or posterior tracts in the non-dominant hemisphere involved in prosodic aspects of language may be misattributed to either a severe depressive or even a schizophreniform loss of affective tone. Some patients with these deficits punctuate their communication with expletives, use physical gestures, or deliberately increase the volume of their speech in order to convey their intended affect. Damage to the dominant superior temporal gyrus creates an alteration in auditory processing that may resemble a primary attention-deficit disorder. Individuals with such asymmetrical functioning retain the capacity for focused attention in visual domains, but evidence problems with auditory figure-ground differentiation, sound localization, and sustained auditory attention. While such an auditory-processing dysfunction may be seen as a developmental issue in 10–20% of men (Cooper & Gates, 1991), its presence in women implies a high probability of some form of acquired central nervous system dysfunction. In addition, when auditory-processing disorders are misdiagnosed as a primary attention-deficit hyperactivity disorder (ADHD) and treated with stimulants, they may actually get worse.

Frequently seen with auditory-processing deficits, subtle balance disorders may result in the individual’s limiting social activities, especially in settings of visual complexity and movement. Normal balance functioning requires the integration of

vestibular, visual, and proprioceptive functions; at least two of the three must be functional for normal balance. Usually, vestibular functioning is the constant component and thus permits balance in settings of darkness (vestibular and proprioceptive) or shifting or soft surfaces (vestibular and visual). When vestibular asymmetry occurs following TBI, the individual is rendered reliant on vision and proprioceptive functions for all balance. Thus, one is unable to close one's eyes in the shower when shampooing, as the vestibular system is faulty. Such a "visually dependent" balance will result in patients' avoiding crowded settings such as grocery stores, where their point of visual fixation is intermittently blocked by passers-by. The internal signal of apprehension at loss of balance results in withdrawal from the setting, followed by relief from anxiety. This may be misinterpreted as agoraphobia, unless a thorough neurological examination is conducted, including the use of the Balance Error Scoring System (Riemann & Guskiewicz, 2000) or the Fukuda Stepping Test (Fukuda, 1959).

POST-TRAUMATIC HYDROCEPHALUS

Neurosurgeons and neurologists are the principal managers of post-traumatic hydrocephalus (PTH) developing in the acute phase following TBI. Psychiatric physicians more typically encounter PTH as a cause of progressive cognitive impairment in their differential diagnosis of any patient who presents with a dementing disorder who also has a history of intracranial hemorrhage of any type and severity. Chronic mismatch between normal rates of cerebrospinal fluid (CSF) production and reduced drainage (due to partial occlusion by residual blood products of arachnoid granulations, which are villous enlargements that protrude into dural sinuses or diploic veins and drain CSF) will not be evident immediately. Rather, much like the hair collected in the bottom of the shower drain, the longer the shower runs, the more the water backs up on the floor. The importance of this diagnosis is its usually gratifying response to lumbar drainage of CSF and definitive neurosurgical intervention, usually an extracranial shunt.

A diagnosis of PTH should be entertained whenever the patient presents with any evidence of the cardinal triad of urinary incontinence, cognitive decline, and balance disorder ("wet, weird, and wobbly"). Severity of urinary incontinence may range from slight leakage while sleeping or with coughing or sneezing, to more significant loss of control. This probably reflects subtle pressure effects in the mid-sagittal region of the frontal lobes. Balance disorder may appear initially to be suggestive of early Parkinsonian gaits, with reduced upper extremity-associated movements while walking, en bloc turning, petit march, and festination. Cog-wheeling elicited spontaneously or with recruitment may be an initial finding as well. Cognitive deficits may include impaired short-term memory, poor performance on multitasking, and apathy (see Chapter xx on apathy).

While fundoscopic examination may find papilledema or loss of previously present spontaneous venous pulsations, neuroimaging by CT scan is the initial diagnostic study of choice.

The presence of symmetrical ventriculomegaly, while consistent with PTH, is still not diagnostic, as following TBI the post-traumatic loss of cerebral tissue can result in *hydrocephalus ex vacuo*. CSF drainage in that setting would not help, and could even precipitate intracranial bleeding. Comparison with earlier CT scans is the best way to confirm progressive ventricular enlargement, making it worthwhile to track down scans that may have been done years ago, at other sites of care. Another option is the use of a computer-assisted volumetric measurement, NeuroQuant[®] (FDA 510(k)K061855, Cortech Labs, La Jolla, California), that uses a database of normal controls aged 50 to 100 to compare ventricular and regional volumes and express that as an age-based percentile. This software also permits intra-subject comparison of bilateral structures to assess for asymmetrical focal atrophy or ventriculomegaly. Generally, left and right volumetric measurements should vary no more than 30%, and findings in excess of this are reasonably viewed as evidence of asymmetry. In most hospital settings, serial lumbar drainage comparing baseline assessments of gait/balance and mental status for improvement is the next step in the evaluation and treatment of PTH. Videotaping gait pre- and post-drainage can detect subtle changes not appreciated in the immediate examination setting. The use of a structured mental status exam with alternate forms is necessary when mental status rather than gait or continence is the primary manifestation of the suspected hydrocephalus.

Select academic institutions with specialized hydrocephalus treatment programs will have available a more sophisticated computer-assisted analysis of CSF dynamic cerebral compliance through the use of a pressure volume infusion (PVI) study. This represents the ultimate "gold standard" for PTH diagnosis. In this procedure, CSF pressure is measured using an attached transducer at opening, after withdrawal of a quantity of CSF, and after the infusion of a small quantity of fluid isotonic with CSF. These three measurements then are used to calculate the "compliance," which is a reflection of the drainage capacities of the arachnoid granulations. PVI calculations then assist with determining the degree of shunt flow and which form of shunting is optimal for a given patient (cf. Czosnyka & Whitfield, 2006).

TAU NEURODEGENERATION

Dementia pugilistica, first described in 1928 by forensic pathologist Harrison Stanford Martland, remains the prototype for dementia seen following multiple concussive injuries. When compared to Alzheimer's-type dementia, the lack of beta-amyloid deposition on neuropathological study is the distinguishing difference in dementia known as chronic traumatic encephalopathy (CTE) (cf. Shively, Scher, Perl, & Diaz-Arrastia, 2012). While public attention regarding CTE has been drawn to tragic deaths seen in professional athletes, tau deposition has been seen at autopsy in youths in their teens with histories of far fewer concussive events. The lack of data regarding individual recovery variability and threshold for symptom development creates a conundrum for the psychiatrist confronted with the youth athlete who has sustained

a series of sports-related concussions that result in a persistence of post-concussive deficits. Apprehensive parents often expect the clinician to be the referee in deciding whether or not to end participation in contact sports. Unfortunately, no good data exist regarding cumulative risk for a given individual, although some effort has been made to generate a “hit count” (much like a “pitch count” for pitchers whose upper extremity is not fully developed) to limit exposure (Cantu & Nowinski, 2012).

In settings where the clinical history and examination is suggestive for CTE, no definitive treatment is currently available. Attention to factors that exacerbate cognitive dysfunction may help, including sleep quantity and quality, depression, pain, nutritional status, and endocrine status. Functional neuroimaging with PET usually does not show the biparietal hypometabolism typical of Alzheimer’s disease, but rather shows a multifocal, asymmetrical pattern of glucose hypometabolism consistent with multiple concussive events inflicted from multiple directions.

Pharmacological stabilization appears to be prudent in enhancing nutritional and vitamin stability, including the use of supplemental vitamin D, B₁₂, and tetrahydrofolate. Treatment of endocrine deficiencies such as thyroid, testosterone, insulin-like growth factor (IGF-1), and growth hormone may also be initiated, although no definitive data exist on their efficacy in delaying decline. Treatment with either N-Methyl-D-aspartate (NMDA) antagonists and/or cholinesterase inhibitors theoretically may slow the rate of decline, but no definitive studies have been done to date.

BRAIN INJURY AS A CHRONIC DISEASE

The majority of TBIs resolve without any noticeable residual symptoms. Despite this, even mild TBI results in temporary disruption in cognitive functioning and not infrequently produces some degree of permanent disability. After a mild TBI, some groups have reported that up to half are left with a moderate or severe disability (Thornhill et al., 2000; Moppett, 2007). This is primarily true for recurrent episodes of TBI, but it is much more common for moderate and severe TBI to result in significant, permanent disability. The disability resulting from TBI may be anything from a slight decrement in fine-motor coordination to quadriplegia with severe cognitive impairments. As the severity of the impairment increases, so do the comorbid medical and psychiatric problems. TBI patients frequently suffer with chronic pain, planning and motivation problems, depression, anxiety, or even psychosis. Patients with persistent symptoms of TBI may have a decreased ability and desire to engage in their usual socialization. As a result, many of these patients do not engage in regular exercise or consume a rational diet. Lacking the typical social support and feedback mechanisms to correct these deficiencies, they become long-term problems. The subsequent loss of muscle tone and weight gain predispose them to additional injuries, hypertension, diabetes, dyslipidemia, coronary artery disease, and gastrointestinal problems. TBI, along with the aforementioned problems, also predisposes these individuals to many

sleep-related problems. These factors combined result in a general decrease in the perceived quality of their lives, further exacerbating problems with motivation and resulting in a downward health spiral. In 2012, it was estimated that there were between 3 and 5 million persons in the United States living with significant long-term TBI-related disabilities. Conceptualizing TBI as a chronic disease that occurs in staggering numbers makes it easy to see how the economic cost of TBI in the United States reaches \$60 billion annually (cf. Masel & DeWitt, 2010).

LABORATORY EVALUATION OF TRAUMATIC BRAIN INJURY

When a patient presents with TBI acquired under suspicious circumstances (e.g., a serious fall in a person without a sensory or coordination problem or trauma from a single-car motor vehicle accident [MVA]), the laboratory evaluation should include levels of substances that are commonly used in suicide attempts. Such substances include not only sedatives and drugs of abuse but also acetaminophen, salicylates, and tricyclic antidepressants (TCA). Urine qualitative tests of TCA compounds and their metabolites are readily available in most hospital laboratories. They are not as sensitive or specific as the serologic tests but serve adequately as initial screening tests. An example of a potential confounding factor from using the less specific screen is that cyclobenzaprine may cause a positive TCA result.

Acute laboratory evaluation of the severe TBI patient will not be addressed other than as noted above since that is likely to be handled by an intensivist in the ICU. Specific laboratory evaluation of a patient with TBI will depend on the setting and the chronicity of the TBI.

In the acute setting, gonadotropic hormone levels will not be followed since they frequently are low but most commonly return to premorbid levels within a few months while even more return to normal within a year. During the rehabilitation phase, and certainly in a debilitated patient with a remote history of TBI, persistent hormonal deficiencies become more of a concern. Posterior pituitary damage is most often obvious in the acute stage, though it can manifest days after the initial trauma. This occasionally happens in those deemed to have only a mild TBI and turns what was thought to be a routine concussion into a life-threatening emergency. A screening battery is outlined in Box 45.1 (Elovic et al., 2005). Current guidelines suggest serial neuroendocrine evaluations annually for five years following TBI (Ghigo et al., 2005).

Studies relating to the incidence of TBI-associated anterior pituitary and pituitary stalk damage vary widely. Near universal agreement exists that there is a possibility of some degree of hypopituitarism after any TBI. Due to the compromise of anterior pituitary vascular structures, specific deficiencies can occur without panhypopituitarism such as hypothyroidism, hypogonadism, growth hormone deficiency, and adrenal failure with elevated prolactin. Growth hormone hyposecretion results in age-related IGF-1 deficiencies and may be the first anterior pituitary hormone deficiency seen in

Box 45.1 PITUITARY ASSESSMENT PROTOCOL
(ALL DRAWN AT 0800)

Cortisol levels (<12 mcg/dl → follow-up)
TSH—thyroid-stimulating hormone
Free T4—free thyroxin
LH—luteinizing hormone
FSH—follicle stimulating hormone
Testosterone (free and weakly bound)—males only
Estradiol—females only
IGF-1—insulin-like growth factor (<165 nG/mL in
<40 yo → follow-up)

non-acute TBI. When sex hormones are low due to TBI, the gonadotropins will not be elevated, highlighting the importance of ordering follicle-stimulating hormone (FSH) and luteinizing hormone (LH) when evaluating low testosterone or estradiol. When checking sex hormones, it is important to include the sex hormone-binding globulin (SHBG) to indicate the relative quantity of usable testosterone and estradiol. Elevated SHBG is also an important measure of risk for osteoporosis in men. (Note: SHBG may not be elevated in certain conditions, such as type II diabetes.)

Ordering only basal hormone studies will miss many neuroendocrine dysfunctions, though it will result in a significant increase in the number of such deficiencies that are identified. Most often, provocative testing is left to the endocrinologist.

Studies have shown that neuroendocrine disorders are common after TBI of any severity, with the majority resolving after 12 months. Any history of severe TBI should prompt a neuroendocrine evaluation, especially in patients that experience increased intracranial pressure (Klose, Juul, Poulsgaard, Kosteljanetz, Brennum, & Feldt-Rasmussen, 2007). Additionally, any history of TBI with severe residual symptoms that could be attributable to the neuroendocrine axis also warrants further investigation. Some authors advocate that “pituitary function after TBI should be assessed in all patients, regardless of the severity of the trauma” (Schneider, 2006).

Elevations in either creatine kinase (CK) and/or prolactin may occur during seizure activity. Both of these tests will be elevated after tonic-clonic seizures, though the prolactin level begins to fall approximately 20 minutes into the postictal state. The CK will also be elevated in patients fighting against physical restraints and in those that have experienced a dystonic reaction. Any patient with significant physical trauma will have elevated CK. Serially following of CK levels will give an objective measure of the healing process. If levels remain high, then neuropsychiatric manifestations can be expected since this is a measure of the severity of trauma to the entire individual.

Low levels of magnesium are associated with seizure activity, alcoholism, delirium, and agitation. Lactate dehydrogenase (LDH) is elevated in cerebral damage, seizures, megaloblastic anemia, hepatic disease, and infarctions of the

heart, lungs, and kidneys. Improper handling of the blood specimen may also elevate LDH. In many institutions, after the patient leaves the ICU arterial blood gasses are rarely performed. A normal pulse oximetry does not rule out cerebral hypercapnia, though this is more often a problem in early management of severe TBI. Sleep disorders of most types are increased in TBI, with hypercapnia occurring in many of these. Rarely is this sufficient to cause significant problems with mental status, but it is certainly worth considering when unexpected mental status changes occur.

Sleep disorders following any degree of TBI are the rule rather than the exception. Decreased CSF levels of hypocretin-1, a wakefulness-promoting neurotransmitter, have been observed in the acute TBI setting but tend to resolve within 6 months (Baumann, Werth, Stocker, Ludwig, Bassetti, 2007). Despite this, many patients suffer with hypersomnia, excessive daytime sleepiness, and fatigue after TBI. Overnight pulse oximetry is a convenient and inexpensive test that yields clinically useful information. If oxygen saturations fall below 88% throughout the night or if a significant drop in oxygen saturation occurs, intervention is needed. This can be in the form of continuous positive airway pressure (CPAP), supplemental oxygen, or an oral appliance that advances the mandible. Failure to correct aberrant cerebral oxygen and carbon dioxide levels may lead to useless and damaging treatments while the patient continues to fail.

Numerous biomarkers have been studied in TBI patients in attempts to predict morbidity, mortality, and effective rehabilitation strategies. Concentrations of neuron-specific enolase, S100B, myelin basic protein, cleaved tau, and brain natriuretic peptide as well as others have been followed serially in TBI patients. The usefulness of these biomarkers remains to be definitively elucidated (cf. Dash, Zhao, Hergenroeder, & Moore, 2010).

PSYCHOPHARMACOLOGY OF SUBACUTE AND CHRONIC TRAUMATIC BRAIN INJURY SEQUELAE

Currently, no FDA-approved pharmacological interventions exist for subacute and chronic TBI sequelae. Nonetheless, multiple treatment options exist that are “off-label.” Considering the frequency of these conditions, as well as the numerous medical and psychiatric sequelae associated with them, it is logical to presume that many hospitalized individuals suffer from TBI sequelae. As has been stated, the reason for the consult will probably not state an association with TBI, but the astute psychiatric physician must illuminate the true source of the malady resulting in a psychiatric consult for the medical patient.

Basic principles of psychopharmacology need to be observed when prescribing medications for TBI. Most medications used by psychiatrists lower the seizure threshold, which can be problematic for this population. Such medications may still be beneficial, but dosages may need to be lower than usually prescribed. While in the hospital, access to the complete medication list is readily available, which is rarely the case after discharge. When seen as an

out patient, even if you have been following the patient, another physician may have ordered or the patient may have started something new without informing you. When the full medication list is seen, it often contains potentially dangerous combinations.

BENZODIAZEPINES

Generally speaking, there is no role for the chronic use of benzodiazepines in patients with TBI-related sequelae, with the possible exception of clonazepam due primarily to its anti-epileptic properties and benefit for restless leg syndrome. One of the many problems with benzodiazepines is that once they are started the patients rarely want to stop them. If never started, no fight will occur with the patient about stopping a medication that is “working so well.” Frequently, patients with histories of alcohol and sedative abuse will be the ones that find them most “effective” and there are many less problematic options. An even more common problem associated with this class of medication is the cognitive slowing and associated memory impairment. This is especially problematic in patients with TBI who may be less able to articulate the decline they experience as a result of benzodiazepines. Often the spouse or other collateral informant will be the one to point out the decline associated with these or any other changes. Even typically well-tolerated benzodiazepines may be overly sedating in this population or cause unacceptable cognitive impairment.

ANTIPSYCHOTICS

As with benzodiazepines, antipsychotics play only a minor role in the treatment of TBI. Although they are effective chemical restraints, dopamine antagonists decrease neuronal regeneration (Feeney, Gonzalez, & Law, 1982), which may cause problems even a year after the initial insult. Use of antipsychotics is generally not advocated except in life-threatening settings where an actively violent patient is trying to harm himself or others, as may occur in the immediate post-acute phase. In those cases, antipsychotics commonly used in similar situations are appropriate with the added caveat of “start low and go slow.” Previously existing psychiatric conditions do not disappear once a person sustains a TBI and many predispose a person to incurring TBIs. Some believe that in the case of substance addiction, TBI should be assumed since rarely does such a person retain perfect memory of their traumatic experiences. If the patient had a condition that warranted antipsychotic use prior to TBI, it is certainly appropriate to continue such use. It should be noted that TBI often alters the way a person’s brain responds to certain medications, so previously effective medications may become ineffective or even intolerable.

SOPORIFICS

Sedative-hypnotics should be used sparingly in persons after TBI and in anyone in general. Sleep hygiene is always the first step in addressing insomnia. When starting a soporific agent,

the patient should always be informed that it is a short-term solution and that other agents or actions are more appropriate for chronic insomnia. While it has been shown in general populations that counseling is as effective as medication for sleep, similar studies in TBI populations are lacking. Anti-epileptic drugs or sedating antidepressants may be more beneficial in this population. Benzodiazepine derivatives often lose effectiveness quickly and should always be used with caution if an underlying sleep apnea is suspected as they will decrease muscle tone and worsen hypoxemia. Any soporific can be habit-forming, but zolpidem may be more problematic than other modern sleep aids in this respect. It may also cause more Zolpidem may be better at maintaining normal sleep architecture, but may cause amnesia and hallucinations than zaleplon or eszopiclone though may be better at maintaining normal sleep architecture. All of these can be effective in achieving sleep for brief, well-circumscribed periods. Although nightmares may occur with TBI, the patient with post-traumatic stress disorder (PTSD), which is not an uncommon comorbidity, is at greater risk. When this is the case, prazosin or clonidine may be useful for achieving sleep restoration and suppressing nightmares. If used during the day, they may also help curb the autonomic hyperreactivity often seen as a chronic symptom of TBI.

ANTIDEPRESSANTS

Older antidepressants, with the exception of trazodone, should generally be avoided in TBI patients. Low-dose tricyclics can be helpful in treating certain types of post-traumatic headaches and sleep, but the antidepressant doses are most often excessively anticholinergic, which limits their usefulness. Even the selective serotonin reuptake inhibitor (SSRI) and serotonin—norepinephrine reuptake inhibitor (SNRI) antidepressants are often not as beneficial as might be expected. Bupropion can be helpful for improving energy, concentration, mood, and motivation, but in doses above 300 mg it has more chance of lowering the seizure threshold than most other antidepressants. Patients being started on bupropion should be warned that the drug may cause them to be nervous, anxious, jittery, or “mean.” Generally, people who start out “mean” do not get “meaner” and often become calmer. Anxiety symptoms should be addressed with the SSRI or SNRI medications as opposed to the benzodiazepines or bupropion due to the considerations noted above.

PSYCHOSTIMULANTS

Various psychostimulants have been utilized to address post-TBI hypersomnia, inattention, and apathy. These attempts occasionally result in full resolution of symptoms, but this is very rare. Frequently there is little or no benefit and some symptoms may be worsened. When the hypersomnia, inattention, or apathy are severe and not addressed adequately by sleep hygiene, soporifics, antidepressants, and other treatments, then a trial of a psychostimulant or amantadine (an antiviral drug with stimulant properties in some individuals) is reasonable. As always in this population, starting at a lower than usual dosage is advisable, and

the titration schedule should also be conservative. It is common for a patient to report fabulous results initially only to report severe side effects at the next visit. Having an objective collateral source of information is invaluable in these situations. Any of the stimulants is a potential candidate for a trial with the patient exhibiting the above symptoms with the key to success often being the prescriber's comfort and confidence with a given stimulant. The wakefulness-promoting agents modafinil and armodafinil may offer a reasonable initial strategy for fatigue, though insurance considerations may prevent these as first-line agents as no supportive clinical research exists. Dextroamphetamine, mixed amphetamine salts, as well as the various methylphenidate compounds are all options.

COGNITIVE ENHANCERS

Acetylcholinesterase inhibitors—rivastigmine, donepezil, and galantamine—have demonstrated some degree of benefit in studies of TBI-related cognitive disorders. They may also improve apathy and fatigue associated with TBI. While the mechanisms for these benefits are unclear, some evidence indicates it is from an increase in IGF-1. Memantine, an NMDA-receptor antagonist with antagonistic effects at the 5-Hydroxytryptophan (5-HTP) receptor and nicotinic acetylcholine receptors, may also be tried. The proposed benefit in TBI is mainly from blocking the NMDA receptors from persistent activation by the excitatory amino acid glutamate, though the other mechanisms of action probably also play a role. Studies have shown that blocking glutamate activity early after TBI is counterproductive, but persistent activation of the NMDA receptors by glutamate is thought to play a role in secondary injury in TBI. Prescribing acetylcholinesterase inhibitors and memantine generally is not based on any empirical evidence, but more on logic and the symptom complex that is presented. If resources are no impediment, then serial neuropsychological testing can be utilized to determine the effectiveness of these strategies. If time and financial constraints are a problem, then patient reports, collateral interviews, and personal observations can suffice.

ANTI-EPILEPTIC DRUGS

Anti-epileptic drugs (AED) are often the best choice for TBI-related symptoms. Depending on the choice of AED, they may have efficacy for mood lability, migraine and other headache prophylaxis, sleep, restless leg/periodic limb movement syndromes, neuropathic pain, anxiety, etc. As with many psychotropic medications, they do not work immediately. The patients must be educated about this, since many will stop their medications after a few days since they are not seeing benefits or are having mild side effects without commensurate symptom relief. An undervalued AED is gabapentin, often a better choice for treating restless leg syndrome than clonazepam. While it may not be as rapidly effective as clonazepam, on occasion a first-night benefit is observed. Rarely, patients may find gabapentin stimulating and hence abusable, but the abuse risks are much less than

with the benzodiazepines. The same caution applies to pregabalin, with the added concern that it may cause teratogenesis via spermatogenic mechanisms. (Note: barrier protection is mandatory for sexually active males with fertile partners.) In many TBI patients, gabapentin can be especially helpful for concentration, although this is not often seen in the non-TBI population. Patients with other forms of cerebral insults, such as anoxia or febrile brain injury, may also find similar benefits. This is not a benefit that occurs reliably, but it is not unusual either. Gabapentin, pregabalin, and tiagabine may also help a patient achieve deeper stages of sleep. Considering the restorative benefits of sleep as well as the hormonal benefits of deep sleep in light of the chronic sleep disturbances in this population, these are certainly good choices for many. Frequently, AED combinations are required. Certain combinations seem more helpful than others. Gabapentin and tiagabine tend to have a synergistic effect, as does gabapentin and levetiracetam. Pregabalin and gabapentin also do well together, despite their similar-sounding names. Older AEDs are also very effective, but they have more side effects and more requirements for monitoring. Often these older medications are necessary since they are much more affordable than branded formulations. Encouraging patients without medication coverage to shop for the best price at local pharmacies, discount super stores, and member warehouse stores is also a beneficial intervention to suggest as frontal lobe problem-solving strategies may be impaired.

OVER THE COUNTER (OTC) PREPARATIONS

Melatonin is often a good choice when dealing with sleep-related issues shortly after TBI. Patients are usually comfortable with using an OTC preparation and often do not require more intervention than this. Dosages can range from 3–10 mg at bedtime and can be repeated if middle insomnia occurs. Rarely is residual daytime sedation observed, although it is not unheard of. It is not recommended in pregnancy, but few other restrictions apply. Melatonin may even be effective in chronic TBI for achieving sleep and for ameliorating middle insomnia, if taken when the awakening occurs. Valerian root does not have significant literature to substantiate its use in insomnia from any condition. Despite this, many tout its therapeutic properties in decreasing anxiety and insomnia. When used in recommended dosages and for short periods of time, some TBI patients may find it effective. Caution with the concomitant use of AEDs is advised. Typical OTC sleep aids contain diphenhydramine and are generally not recommended. As with prescription anticholinergic agents, diphenhydramine may worsen some cognitive symptoms associated with TBI. Despite this warning, some find it to be very helpful in the short term, and diphenhydramine is usually acceptable in pregnancy. In a patient unwilling to take prescription sleep aids, preferring OTC agents, or with positive expectations of success due to pre-TBI response, a trial may be appropriate with the patient being well aware of the risks and following a clear documentation of the discussion.

SPECIAL CONSIDERATIONS

The elderly always present special challenges, and TBI is no exception. While moderate and severe TBI are associated with a higher statistical likelihood of dementia, the precise mechanism is unknown. As discussed above, CTE, following multiple repetitive concussive injuries, is known to induce a tau-opathy.

TBI may also result in side effects to previously well-tolerated medications and alter alcohol tolerance. These issues are confusing to patients and often result in questions about losing their sanity. Sometimes these changes are temporary, but occasionally they become longstanding. Either way, reassurance will go far to comfort the elderly TBI patient. Depending on the acuity and severity of the TBI, the reassurance may need to be repeated often.

As previously noted, when a person with any psychiatric condition sustains a TBI, their psychiatric condition does not disappear. It is not unusual for the premorbid condition to be changed, but it will not disappear, unless the TBI is so severe as to render the person insensible. Frequently, the premorbid condition will be relegated to a less prominent position during the early stages of TBI, but it may later become more severe than it was premorbidly. Frequently, the person with a mild TBI who does not return to baseline will experience further psychiatric symptoms and possibly an entirely new condition. These nascent conditions must be dealt with in the appropriate clinical fashion, while keeping in mind the aforementioned precautions.

SUMMARY

Given the known epidemiology of TBI, it is certain that individuals with a history of TBI will be evaluated by the practicing psychiatrist. Such a past event may influence treatment response to conventional interventions, be misclassified as denial or treatment resistance, or be erroneously labeled as noncompliance or malingering. It is incumbent upon the psychiatric physicians to familiarize themselves with the evaluation and treatment of these organically based disorders to prevent needlessly increasing morbidity and mortality for the patients they serve.

CLINICAL PEARLS

- The examination required once TBI is under consideration includes assessment of auditory, visual perceptual, vestibular, and language function.
- Seventeen to 61% of all TBI patients develop depression within two years of injury (Rapoport, 2012) and seek psychiatric care without considering the relevance of TBI.
- Falls remain the leading cause of TBI among civilians, followed by motor vehicle accidents and other blows to the head, including sports injuries and assaults.

- TBI from motor vehicle accidents results from rapid acceleration and deceleration forces causing micro-shearing and DAI. DAI may appear on MRI as numerous small white matter lesions.
- Secondary brain injuries are the result of a cascade of molecular injury mechanisms that unfold over hours and sometimes days following the acute event.
- The Glasgow Coma Scale was designed and should be used to assess the depth and duration coma (Teasdale et al., 1978). It is not, therefore, appropriate for determining the severity of TBIs in general.
- ACRM criteria mandate that a TBI be rated as moderately severe if a patient has a PTA or a period of altered consciousness lasting 24 hours or more.
- The severity of the initial injury remains the best predictor of long-term prognosis.
- The basic formula for describing the forces of a TBI as it affects the brain is derived from Newtonian physics: $a = v^2/(2s)$. This means that the severity of a TBI is a result both of how fast you were going and of how quickly you stop.
- Head CT and MRI are insensitive to two common consequences of closed TBI—cavitation and micro-shearing.
- Following brain contusions, the cortex shows diminished metabolic activity with associated cognitive impairments. Contusions may also produce irritable foci that result in intermittent sensory phenomena or memory disruption.
- The most common area of tissue damage in typical closed TBI is the orbital frontal cortex, usually via lacerations, abrasions, and contusions of the cortex caused by friction of the ventral surface of the frontal lobe against the sharp, irregular ridges of the cribriform plate.
- The core disability of orbital frontal patients is that they think less (Varney & Menafee, 1993). Spontaneous decision-making becomes labored, less frequent, and less reliable, particularly with the multiple small decisions of ordinary life, e.g., “what to do next” (Varney, 1999).
- Orbital frontal symptoms relating to activities of daily living (e.g., indecisiveness, mental inertia) and psychosocial symptoms (poor empathy, indifference) can be reliably determined by structured interview of a collateral informant (Varney, 1991).
- Executive disability in patients with orbital frontal injury involves problems not detected by conventional neuropsychological testing (Martzke et al., 1991), which isolates individual abilities for testing.
- Initial seizures following the acute TBI event occur in 10–15% of adults in the first week following severe TBI (Langendorf & Pedley, 1997).

- Longitudinal studies define increased lifetime seizure risk for those with mild, moderate, or severe TBI across the lifespan ranging from a relative risk of 2.22 in those with mild closed TBI, to 7.4 in severe brain injury, to 2.17 in those with skull fracture (Christensen et al., 2009).
- To identify neurosensory dysfunction, the psychiatric physician must be capable of performing a competent and accurate cranial nerve examination, including assessment of olfactory functioning.
- Visuo-perceptual dysfunctions and lateralized loss of visual awareness (due to non-dominant temporal-parietal damage) results in increased startle and reaction when the patient is approached from the dysfunctional side. Over time, this evolves into a subtle form of hypervigilance that may resemble paranoia.
- When auditory-processing disorders are misdiagnosed as a primary ADHD and treated with stimulants, they may actually get worse.
- When vestibular asymmetry follows TBI, the individual must rely on vision and proprioceptive functions for all balance. Such a visually dependent balance will result in patients' avoiding crowded settings such as grocery stores, where the point of visual fixation is intermittently blocked by passers-by.
- Current guidelines suggest serial neuroendocrine evaluations annually for five years following TBI (Ghigo et al., 2005).
- Sleep disorders following any degree of TBI are the rule rather than the exception.
- Generally speaking, there is no role for chronic use of benzodiazepines in patients with TBI-related sequelae.
- When hypersomnia, inattention, or apathy are severe and not addressed adequately by sleep hygiene, soporifics, antidepressants, and other treatments, then a trial of a psychostimulant or amantadine (an antiviral drug with stimulant properties in some individuals) is reasonable.

DISCLOSURE STATEMENTS

Dr. O'Shanick has served as a consultant and expert for Avanir, Cephalon, and Ceretec and has received payment for those services. He is also the sole owner of a private outpatient brain injury medicine program (Center for Neurorehabilitation Services, PC) in Richmond, Virginia.

Dr. Moses has received speaker bureau fees from Pamlabs, Inc, maker of Cerefolin NAC, Deplin & Metanx.

Dr. Varney has nothing to disclose.

FRONTAL SYSTEMS AND DYSFUNCTIONS

Kimiko Domoto-Reilly, Paul Malloy, Deborah A. Cahn-Weiner, and Thomas Markham Brown

INTRODUCTION

The frontal lobes comprise about one-third of the cerebrum and have extensive connections with other brain regions. Frontal systems, therefore, are susceptible to injury from a wide variety of diseases and insults; because the frontal lobes are responsible for orchestrating many higher cognitive abilities, impairment may result in devastating effects on socially adaptive behavior. This chapter reviews the functional neuroanatomy of the frontal lobes, the cognitive and behavioral features of frontal lobe syndromes, evaluation techniques, and treatment options. Social and legal implications are also briefly discussed.

CAUSES OF FRONTAL SYSTEM DYSFUNCTION

Degenerative disorders can have their earliest and most dramatic effects on the frontal lobes, including frontotemporal dementia and Alzheimer's disease. A number of the so-called subcortical dementias disturb both motor and executive/frontal systems (e.g., Parkinson's, Huntington's disease; Goldberg et al., 1990; Gotham, Brown, & Marsden, 1988). Some developmental conditions such as attention-deficit hyperactivity disorder (ADHD) and autism spectrum disorders feature prominent frontal system disruption. Many psychiatric illnesses are associated with frontal system dysfunction, including but not limited to: Tourette's syndrome, major depression, schizophrenia, and obsessive-compulsive disorder.

The frontal lobes are often involved in stroke. The middle cerebral artery serves the frontal convexity and is the most common territory for large vessel ischemic stroke. The anterior communicating artery is a common site for aneurysm, and hemorrhage can cause a severe frontal syndrome due to mesial and basal frontal damage. The watershed zone between the anterior and middle cerebral arteries is also at risk in settings of decreased intracranial blood flow, such as in cardiac arrest.

Other disorders may not affect frontal cortex directly but will disrupt frontal systems through destruction of white matter connections to posterior and subcortical structures (e.g., multiple sclerosis, small vessel cerebrovascular disease). These diffuse connections render the frontal systems particularly vulnerable to so-called toxic/metabolic dysfunction, which

can have multiple etiologies, including sepsis, sleep deprivation, medications, seizures, and intoxication. Infections such as HIV and syphilis (tertiary) produce frontal system dysfunction. Mass lesions such as tumors can exert local and/or diffuse effects via focal expansion, axonal disruption, and hydrocephalus. Treatment with radiation and/or chemotherapy can result in delayed degenerative effects. The frontal lobes are also particularly prone to damage in head injury, due to the high incidence of direct contusion and of disruption of critical connections from other regions of the brain. Normal aging also contributes to frontal system dysfunction (D'Esposito & Gazzaley, 2011; Prakash et al., 2009).

FUNCTIONAL NEUROANATOMY OF THE FRONTAL LOBES

The functional subdivisions of the frontal lobes include the primary motor area, premotor area, frontal eye fields, dorsolateral area, orbital/basal area, and anterior cingulate gyrus/supplementary motor areas (SMA). The primary motor area subserves pyramidal motor functions; the premotor area is involved in sensorimotor integration and praxis; and the frontal eye fields control volitional eye movement and visual search. Damage to these zones generally results in relatively simple disorders of motor functioning (e.g., hemiparesis, volitional gaze disturbance). The dorsolateral, orbital, and mesial (cingulate/SMA) subdivisions are involved in higher cognitive functions. These *prefrontal* cortical regions have been of greatest interest to psychiatrists, behavioral neurologists, and neuropsychologists because of the striking personality and behavioral changes that can result from insults to these areas.

Each prefrontal zone has extensive connections with posterior cortical, thalamic, and basal ganglia structures that play an important role in their expression of complex behavioral patterns. The dorsolateral and orbital frontal areas, for example, receive input from distinct posterior association areas in each sensory modality. Parallel but separate subcortical connections exist as well (e.g., the dorsolateral area is connected to dorsolateral caudate nucleus, while the orbital area is connected to ventromedial caudate). The insular cortex, the ancient "hidden lobe of the brain" buried under the frontal and temporal opercula, has emerged as an area intimately connected with the frontal lobe, and contributing to interoception, emotional awareness, and cognitive

abilities traditionally ascribed to the frontal lobe such as performance-monitoring and decision-making (Craig, 2009). Thus, frontal cortical areas act in concert with other cortical and subcortical structures to form distinct frontal systems (Cummings, 1993). Current models of cognition consider behavior in the setting of networks, reflecting the functional connectivity of specific, distributed brain regions implicated in task performance.

SPECIFIC FRONTAL LOBE SYNDROMES

For practical teaching purposes, this section will treat the syndromes of frontal lobe damage as though each were distinct. The reader must keep in mind, however, that patients may suffer damage to multiple frontal zones as well as damage to other cortical and subcortical areas, and hence may display deficits reflecting disruption of several behavioral subsystems. Furthermore, these subsystems act in concert (not isolation) in facilitating normal behavior.

EXECUTIVE FUNCTION

Dysexecutive syndrome refers to cognitive and organizational functions subserved primarily by dorsolateral frontal systems. Executive functions include the ability to integrate sensory information from multiple modalities, formulate goals with due regard for long-term consequences, generate multiple response alternatives, and choose appropriate goal-directed behavior. As a behavior sequence progresses, executive functions continue to play a role in self-monitoring of the adequacy and correctness of the behavior, and to modify behaviors when conditions change. Executive abilities allow us either to change a plan or to persist in the face of distractions and shifting circumstances.

Lesions of the dorsolateral prefrontal region can result in a stereotyped or limited response repertoire, easy loss of task set, perseverative or inflexible behavior, inability to integrate disparate sensory elements into a coherent whole, and lack of self-monitoring of errors. Problems with behavioral switching can cause a lack of response flexibility, such that the patient becomes rigidly “stuck in set” (i.e., stuck in a set of behaviors; Luria, 1980; Stuss, 1993). It is not difficult to see how such problems could interfere with one’s ability to problem-solve when task demands are high.

Dysexecutive problems may affect performance in other cognitive domains. For example, poor organization may lead the patient with frontal lobe functional injury to fail clock-drawing tests, by drawing a series of numbers around the periphery without concern for spatial placement, or continuing beyond 12 due to poor self-monitoring. Patients with frontal dysfunction may also make concrete errors in setting the hands on the clock face (for example, when asked to set the hands to “ten after eleven,” the patient may draw the hands to the “10” and the “11”). Perseverative tendencies may cause patients to reuse an earlier item or response during a later task. For example, when asked to name a book and then name a house, the patient may say “book.” The examiner must be

aware of the underlying frontal deficit so that these errors are not mistaken for primary difficulties in language functions. Hence, it is usually desirable to interrogate frontal functions early in the assessment.

Executive deficits may also affect memory performance. Frontal system damage can result in inefficient learning due to failure to make use of active learning strategies, reduced memory for temporal/situational context, and a tendency to make perseverative errors (Vilkkii, 1989). These deficits have usually been characterized as a failure of working memory. *Working memory* is thought of as the ability to take information in for short-term storage, manipulate it over a brief period of time, and organize it for permanent memory encoding. Frontal system injury patients perform particularly poorly when the memory task includes test-controlled distractions or interference techniques (Parkin & Walter, 1992) because they are unable to simultaneously hold the items in temporary storage and ignore the distraction.

DISINHIBITION SYNDROME

Disinhibited behavior is commonly associated with damage to the orbital area, which is thought to result in disruption of frontolimbic connections. Disinhibited personality changes, amnesia with confabulation, and failure on neuropsychological tests of inhibition are signs of orbitofrontal damage (Malloy et al., 1993). Lesions of this subsystem result in disruption of inhibitory and emotional mechanisms, with consequent impulsive and socially inappropriate behavior. A patient may be aware that a particular behavior is inappropriate, but may still be unable to inhibit the behavior. Disorders of emotional reactivity can include emotional incontinence, mood lability, and irritability, culminating in situationally inappropriate reactions. Disinhibition can also result in “stimulus-bound behavior,” in which the patient is unable to control the attentional “pull” to a stimulus. The patient may also exhibit increased distractibility by irrelevant stimuli, paralleled by diminished sustained attention.

Disinhibition is perhaps most disruptive and embarrassing to the patient’s caregiver, particularly because the patient often lacks insight into the inappropriateness of the behavior. Some family members may be confused and disturbed by a patient’s sudden irritability and insensitivity towards them, in contrast to their previous mild-mannered personality. Unfortunately, this behavior can sometimes be misinterpreted as intentionally provocative and malicious.

APATHETIC/AKINETIC SYNDROME

Akinetic syndromes most often result from damage to the mesial cingulate-supplementary motor system subserving drive and motivation. Lesions to the anterior cingulate gyrus can result in *akinetic mutism*, in which the patient fails to respond to environmental stimuli and remains inert. Bilateral lesions frequently result in persistent akinesia, whereas unilateral lesions produce typically transient akinetic symptoms. Lesions to the supplementary motor area and corpus callosum can result in “alien hand syndrome” in which the

patient may seize objects, throw things, or otherwise explore the environment in a disinhibited fashion (typically with the non-dominant hand) (Goldberg & Bloom, 1990). The patient may report having no control over movements of the hand. Such behavior is likely attributable to initiation of action by the right hemisphere while disconnected from the verbal left hemisphere.

Diminished responsiveness can manifest itself in problems with initiating or persisting in behavior, without reaching the severity of akinetic mutism. Patients with frontal lobe damage may often begin a task correctly, but then stop prior to completion, requiring repeated prompts from the examiner to continue. *Impersistence* refers to the failure to maintain a particular response despite reinforcement, feedback, cues, or other signals indicating that additional responses are necessary. The patient may be described as not “following through” with chores or tasks at work.

Flat or diminished affect may be seen. Some patients become docile, apathetic, abulic, or even akinetic. Patients may have lowered responsiveness to environmental triggers, or may have a preserved motivation to act, but be unable to organize these impulses into directed drives, action plans, or response sequences. Such changes often lead to profound disruption of interpersonal relationships.

ADDITIONAL BEHAVIORAL FINDINGS

Anosognosia and neglect are other common behavioral features. *Anosognosia* refers to patients’ lack of awareness, or disregard, of their deficits. Patients with frontal dysfunction vary in their degree of awareness of their deficit. Such deficits can profoundly affect treatment and responsiveness to rehabilitative efforts. *Neglect* is the inability to attend to a particular aspect of one’s environment. Neglect can be specific to a body part or space, and has been reported in association with right dorsolateral prefrontal and anterior cingulate lesions in humans (Heilman & Valenstein, 1972).

Environmental dependency is a syndrome in which the patient responds in a habitual or perseverative way to stimuli in the surrounding area, without regard to the necessity or appropriateness of the response. *Utilization behavior* is a subtype of environmental dependency in which the patient uses encountered objects without a specific goal or need (e.g., donning a stethoscope left on the table in the examination room). Environmental dependency has been conceptualized as the release of parietal lobe exploratory behavior due to absence of frontal inhibition (Lhermitte, 1986). In a somewhat similar fashion, with *imitation behavior*, the patient may find it difficult to stop himself from mimicking the actions of the examiner, even when specifically instructed not to do so.

Various psychiatric symptoms can also emerge. Patients with frontal lobe damage are at greater risk to develop disturbances of mood and affective expression, ranging from intermittent mood lability to major depression or mania (Mayberg, 1994; Robinson et al., 1988). The challenge for the clinician is to differentiate these possible affective disturbances from the frontal lobe syndromes of apathy and disinhibition. Damage to structures functionally connected to the orbitofrontal

cortex, mainly in the right hemisphere, seems to be associated with secondary mania in traumatic brain injury (Starkstein et al., 1988). New onset of anxiety disorders, personality disorders, sexual dysfunction, and obsessive-compulsive disorder have also been reported after closed head injury (Max et al., 1995; van Reekum et al., 1996; Bryant & Harvey, 1998).

DISEASE FOCUS: FRONTOTEMPORAL DEMENTIA

Frontotemporal dementia (FTD) is a neurodegenerative disease characterized by progressive atrophy of the frontal and anterior temporal lobes. FTD can present with several distinct clinical syndromes involving disturbances in personality, judgement and insight, and/or language function (Gorno-Tempini et al., 2011; Rascovsky et al., 2011). Roughly 15% of all patients with dementia carry a diagnosis of FTD; among patients under 65 years old, it has been estimated that FTD is as common as Alzheimer’s disease (Rascovsky et al., 2005). Current classification comprises a behavioral variant (bvFTD), which accounts for roughly 50% of FTD cases, and two language subtypes. This disease has proven to be a heartbreaking demonstration of the profound disabilities rendered by progressive dissolution of frontal systems. Patients can present with insidious onset of abnormal social behaviors, including poor hygiene, inappropriate remarks, increased risk-taking (gambling, stealing, speeding), diminished social engagement, and ritualistic behaviors. Involvement of the insula is thought to account in part for dietary changes such as binge eating. Language disturbances related to frontal lobe atrophy include speech apraxia and agrammatism.

ASSESSMENT OF FRONTAL SYSTEMS

This section provides a brief overview of clinical assessment techniques for evaluating patients with frontal lobe syndromes. The interested reader is referred to more comprehensive articles on assessment such as those by Levin and Malloy (Levin & Kraus, 1994; Malloy & Richardson, 1994).

The clinical interview can provide a great deal of information about the integrity of frontal systems. A relatively unstructured initial interview may be very useful in eliciting abnormal behaviors such as reduced initiative and drive, poor insight into deficits, inappropriate social behavior, environmental dependency, poor self-monitoring of errors, and labile affect. A disinhibited personality may become apparent during the interview, with the patient interrupting with inappropriate questions or intrusive comments. The patient may be distracted by extraneous stimuli in the environment, or require repeated reminders to answer a specific question, because of either off-topic remarks or lack of response.

The examiner should pay particular attention to discrepancies between patients’ and caregivers’ reports of problems. An important caveat is that some patients respond well to the formal clinical setting, and may perform well in such a structured environment; the family’s description of the patient’s daily behavior in various daily social settings provides valuable

insight. Obtaining a comprehensive history from a close informant is essential, as the patient may be unable to recount the complete history of events or to provide a valid report of behavioral changes. Asking specifically about risky and inappropriate behaviors such as gambling or sexual exploits is also important, as families are sometimes reluctant to volunteer such information, or do not realize that it is relevant.

Physical appearance may provide the clinician with some information about a patient's executive functioning and reflective insight. For example, patients may wear clothes that are mismatched or inappropriate for the season, neglect personal hygiene, or show no concern over incontinence. Some patients may develop perseverative or stereotyped behaviors, such as finger tapping, pacing, or phrase repetition. Altered food preferences and binge eating may lead to significant weight gain; some patients may attempt to consume non-food items.

Neurological assessment, including the elicitation of "frontal release signs" (e.g., grasp, snout, palmomental), can be useful for the assessment of frontal lobe dysfunction. The presence of these "primitive" reflexes may be an indication that motor/premotor portions of the frontal lobe have been damaged; however, these reflexes can often be seen in elderly individuals without neurological disease (Tweedy et al., 1982). Patients may have difficulty initiating or inhibiting eye movements towards a target, or sustaining fixation; frontal eye fields in particular are implicated in antisaccade abilities (Everling et al., 1998). Basic language assessment of patients with frontal lobe dysfunction can reveal dysarthria, grammatical errors in production and comprehension, and variable but effortful production of speech sounds and prosody (speech apraxia), especially with increasing articulatory complexity (Brazis et al., 2007).

Difficulties with motor programming can be observed with motor impersistence (e.g., unable to keep eyes closed or tongue protruded for 10 seconds), gait disturbance (e.g., initiation and continued ambulation, foot elevation and forward propulsion), despite the preservation of isolated components of the motor sequence. Patients may have difficulty coordinating bimanual movements, or inhibiting movements of the contralateral limb. Traditional motor assessment often includes Luria sequencing (three meaningless hand movements performed in sequence) and ramparts drawing (see Figure 46.1a), which are often useful means of assessing patients with diffuse brain damage, as the demand on language comprehension is minimal. Frontal system dysfunction errors on these tasks include perseveration and pull to stimulus (e.g., grasping at the examiner's hands, or copying directly over a figure; see Figure 46.1b).

Although a formal mental status examination may provide additional useful information, the bedside evaluation of frontal dysfunction should not be limited to such instruments. Measures such as the Mini-Mental State Examination (MMSE) have been shown to be inadequate and inexact for assessment of frontal/executive abilities (Malloy et al., 1998; Royall et al., 1992). It is also important to recognize that large frontal lesions may be relatively clinically silent, and only revealed with skilled evaluation, including a detailed history of social and interpersonal changes.

Figure 46.1 Examples of frontal-system errors on ramparts drawing (A), demonstrating set loss, and figure copying (B), demonstrating pull to stimulus.

Tests commonly used by neuropsychologists to evaluate the integrity of frontal systems include the Controlled Oral Word Association test (COWA) (Benton, 1968), which requires the patient to produce as many words as possible in one minute beginning with specified letters. This task requires multiple-response generation as well as maintenance of a complex task set, and permits the examiner to observe perseverative and intrusive response styles. The Stroop Test, requiring the patient to name the color of the ink in which color names are printed, measures selective attention and cognitive flexibility, and gives information about the patient's ability to inhibit a habitual response (Golden, 1976). These tests represent only a few of the numerous tests available to neuropsychologists in the assessment of frontal systems. More detailed description of the neuropsychological assessment can be found in Chapter <??>.

Neuroimaging can be extremely useful in determining the location and extent of frontal damage. A brief overview is offered here regarding imaging techniques that would be most commonly encountered in the clinical setting; technical capabilities, especially in structural and functional MRI, are rapidly expanding. Computed tomography (CT) scan may be the first structural imaging method employed, as it is typically easily tolerated and is usually adequate for the detection of large contusions, hemorrhage, hydrocephalus, and projectile wounds. Metal artifacts may obscure specific structures, however, and the resolution of routine clinical CT scans limits detection of small lesions and subtler atrophy patterns.

Diffuse axonal injuries, for example, are better seen on T2-weighted MRI scans as small areas of hyperintensity in the cerebral white matter. Diffusion tensor imaging is emerging as a specific MR sequence for assessment of white matter tract integrity. MRI is superior in detecting cerebral edema as well as earlier detection of ischemic injury and malignancies (the latter with contrast media). MRI is also superior in imaging lesions close to bone (e.g., orbitofrontal areas) due to beam-hardening artifact on CT scan.

Figure 46.2 Structural (MR) and functional (PET) imaging findings in a patient with frontotemporal dementia, with sagittal views of focal frontal atrophy (B) and hypometabolism (C), respectively, in comparison to a healthy individual (A).

In addition to the structural findings on CT and MRI (compare the brain MRI of a healthy individual (Figure 46.2a) to the profound frontal lobe atrophy of an individual with FTD (Figure 46.2b)), functional imaging scans such as single-photon emission computed tomography (SPECT) and positron emission tomography (PET) can provide important diagnostic insights. Each of these technologies requires administration of a radioactively tagged nucleotide. Spatial resolution is superior with PET, but SPECT radiotracers typically have longer half-lives and thus may be more readily accessible in the clinical setting (Wahl et al., 2011). Relevant findings on these scans include increased tracer uptake in tumors, regional hypometabolism in neurodegenerative diseases (see Figure 46.2c for an illustration of frontal lobe hypometabolism in a patient with FTD), and peri-ictal hyperperfusion in focal epilepsy.

Additional clinical assessment may include laboratory testing for suspected toxic or disease exposure. Patients suspected of obstructive sleep apnea or other sleep disorders should undergo a polysomnogram. Electroencephalogram (EEG) is indispensable in the work-up of suspected seizures; frontal lobe seizures in particular have a heterogeneous semiology, including fencing posture, pelvic thrusting, motor automatisms, olfactory hallucinations, speech arrest, bipedal movements, and urinary incontinence (O’Muircheartaigh & Richardson, 2012).

TREATMENT STRATEGIES

Treatments have primarily been aimed at reducing undesirable or disruptive behaviors, based on hypotheses about underlying neurophysiological substrates.

PHARMACOLOGICAL TREATMENT

The treatment of behavioral, emotional, and cognitive disturbances in frontal systems dysfunction can be complicated by the abnormal condition of the tissues that are the targets of pharmacological interventions. Damaged brain tissue may disrupt circuits necessary not just for normal functioning, but also for normal responses to medication. Additionally, thorough and ongoing review of the patient’s medications is necessary to ensure that substances that can contribute to cognitive dysfunction are eliminated. Targeted neurotransmitter enhancements include norepinephrine for arousal, dopamine

for motivation and working memory, and acetylcholine for attention (Daffner & Wolk, 2010). The clinician must be careful to distinguish between behavioral symptomatology and mood disorders in order to direct treatment appropriately.

AGGRESSION AND IMPULSIVITY

Inappropriate jocularity, disinhibition, and aggression may result from a decreased ability to recognize and respond appropriately to social cues. In addition, such behaviors may be the secondary products of depression, mania, anxiety, or psychosis. The clinician must determine the origin of the disturbed behavior and intervene accordingly. Beta blockers, usually in high dose ranges, have proven effective, although onset of action may be delayed. Valproic acid can also be helpful, and often is well tolerated; it has been shown to be effective in reducing destructive and aggressive behaviors in patients with brain injury and dementia, although results are mixed and side effects such as over-sedation and lightheadedness can occur (Dolder & McKinsey, 2010; Wroblewski et al., 1993). Selective serotonin-reuptake inhibitors (SSRIs) can be helpful in neurodegenerative conditions such as FTD (Vossel & Miller, 2008); conversely, cholinesterase inhibitors may exacerbate disinhibition, irritability, and impulsivity in FTD (Mendez et al., 2007).

DEPRESSION AND MANIA

The choice of agent is guided mainly by side effects and the particular neurological susceptibilities of the patient in question. Depression may respond to SSRIs, and mood lability may respond well to mood stabilizers such as lithium, carbamazepine, and sodium valproate (Sloan et al., 1992; Wroblewski et al., 1996). Mania in patients with traumatic brain injury (TBI) has been successfully treated with lithium carbonate, carbamazepine, valproic acid, clonidine, and electroconvulsive therapy (ECT). Lithium management requires careful oversight; the risks of confusion, nausea, tremor, ataxia, and lethargy in a patient with frontal system dysfunction are worth considering carefully (Brown & Stoudemire, 1998; Schiff et al., 1982). Lithium may also lower the seizure threshold (Massey & Folger, 1984). Under controlled circumstances in which the drug may be reliably administered and

serum levels monitored closely, lithium can prove quite effective for behavioral problems, but benefits should be weighed against the risk of an exacerbation of cognitive dysfunction.

ATTENTION AND AROUSAL

Patients with frontal lobe syndrome can display severe decrements in arousal, energy, and motivation. Apathy may become pathological, and can interfere with attempts at rehabilitation. It has been hypothesized that such apathetic behaviors result from dysfunction of the mesolimbic/mesocortical dopamine projections to the frontal lobes. Hence, pharmacotherapy for patients with decreased energy and motivation has frequently involved the use of dopamine-system-enhancing agents such as bromocriptine and pramipexole. Amantadine, an N-methyl-D-aspartate (NMDA) receptor antagonist, may also enhance dopaminergic systems via indirect mechanisms; a recent study in patients with severe, non-penetrating TBI and prolonged disturbances in level of consciousness suggests that amantadine may increase the rate of behavioral recovery (Giacino et al., 2012). One potential consequence of using dopamine agonists in this patient population, however, is a risk of developing psychosis or other hypervigilant states (Gualtieri & Evans, 1988). Therefore, these medications should be administered with careful dose escalation and monitoring for emergent psychotic behavior.

Additional problems include disruptions of impulsivity, disinhibition, and planning, and it has been theorized that dopaminergic agents may be useful in minimizing these behavioral disturbances and in improving attention span and information processing speed. At least some studies have reported positive effects on cognitive functioning with dopaminergic agents (Kraus & Maki, 1997a, 1997b).

Some studies have found that stimulant medications, such as methylphenidate and dextroamphetamine, result in improved cognitive functioning (Gualtieri & Evans, 1988; Wroblewski, 1993), although findings have been mixed (Speech et al., 1993). Modafinil is a newer agent with a different (and incompletely understood) mechanism of action, and may be better tolerated.

Acetylcholine is known to play a role in attentional systems, although the precise mechanisms remain unclear (Furey et al., 2008; Taverni et al., 1998), and studies involving cholinesterase inhibitors such as donepezil or rivastigmine have produced mixed results. Patients with multiple sclerosis often complain of cognitive fatigue and have difficulties with tasks requiring sustained attention (Kujala et al., 1995), and a recent study investigating administration of rivastigmine showed improvement in processing speed (Huolman et al., 2011). Anticholinergic agents such as bladder antispasmodics may exacerbate cognitive impairments and should be carefully screened for in medication review.

BEHAVIORAL TREATMENT

Sohlberg and colleagues (Sohlberg et al., 1993) have presented a model for rehabilitation following TBI that provides a

theoretical framework for understanding the patient's executive deficits. These authors also identify intervention options for managing executive dysfunction and provide decision rules for selecting the most appropriate interventions for these patients. Briefly, their treatment model includes environmental modification (e.g., labeling cupboard contents and organizing physical space), specific skill training (e.g., using a written or computerized organizational system), communication skills (e.g., turn taking), overtraining task-specific routines (e.g., grooming), external compensatory training (e.g., organizational or memory books), and training in metacognitive skills. Sohlberg's work represents a pioneering effort in devising a behavioral treatment program for patients with frontal lobe injuries secondary to TBI.

Socially inappropriate or disruptive behaviors may respond well to behavior modification techniques such as *response cost* and *differential reinforcement of other behaviors* (DRO). Response cost involves defining situations in which certain responses will cost the patient opportunities for other reinforcers. For example, "If you interrupt other group members during meeting, you will not be allowed to watch television in the afternoon." DRO involves positively reinforcing an alternative, appropriate behavior. Differential reinforcement can be geared towards any other behavior that takes up time (e.g., any interaction with a stranger that is not sexual), a specific alternative behavior (e.g., shaking hands with a stranger), or an incompatible behavior (e.g., not speaking with the stranger). It is generally most practical to first use behavioral modification for those with disinhibitory behavior, and apply specific cognitive rehabilitation techniques to those with obvious specific deficits after problem behaviors have decreased. There is some evidence that cognitive-behavioral interventions, at least in patients with mild TBI, can shorten the duration of symptoms following injury (Mittenberg et al., 1996).

Behavioral interventions include the development of compensatory strategies and the manipulation of the patient's environment in an attempt to reduce unwanted behaviors and shape more desirable ones. These techniques can be helpful not only in eliminating problem behaviors but also in reducing caregiver burden. Many patients find comfort in daily routines; indeed, disruption can lead to behavioral outbursts. If the cognitive impairment or behavioral issues necessitate institutionalization, the family may be pleasantly relieved to find that the patient is much more at ease in the standardized predictability.

ENVIRONMENTAL INTERVENTIONS

Clinicians have also devised interventions based on the knowledge that patients with frontal systems dysfunction tend to respond impulsively in many situations and fail on tasks when working memory is taxed. Clinicians can restructure the environment to provide salient operant cues and greater external executive control, and work with patients on overlearning adaptive responses so they have a high probability of occurring in problem situations. External or environmental interventions can be particularly effective with severely impaired patients who cannot benefit from cognitive retraining. An

example of a simple environmental intervention would be setting a timer alarm on an electronic watch as a reminder to check an assignment book.

With recent advances in technology, there has been a proliferation of rehabilitative devices and technologies. Such developments include computer-assisted cognitive rehabilitation (Chen et al., 1997), electronic reminder devices for patients with planning and organizational disabilities secondary to frontal lobe damage (Wilson et al., 1997), and telephone intervention and follow-up (Dombovy & Olek, 1997). Microcomputer devices show great promise as executive prosthetic devices, which can provide the organization and self-monitoring skills that many frontal patients lack. Chute and colleagues have done extensive work on computerized speech devices and computer-controlled household devices (Chute, 2002). For example, a computer attached to a wheelchair can provide synthetic speech cues to guide patients through a task step-by-step, prompting them to check the correctness of each response against a model. Unfortunately, little research has been conducted in the area of executive prosthetics, and user-friendly interfaces are still lacking.

LEGAL IMPLICATIONS AND CAREGIVER BURDEN

As described above, patients with frontal lobe disorders are often unaware of their deficits. Additionally, even when help is offered, patients may either not understand why it is necessary, or may outright refuse intervention. Some patients only come to medical attention after breaking the law, such as with reckless driving or illicit drug use. Families may become bankrupt if the patient makes impulsive or irrational decisions with investments. Decision-making competence entails an ability to understand the situation at hand and the implications of the consequences, and to behave according to the expressed reasoning behind a decision. Impaired decision-making can lead to life-threatening situations, as illustrated by the following story: a patient with bvFTD was speaking with her husband on the phone, and he heard an alarm in the background. When he asked her what the sound was, she reported that the fire alarm was going off; he had to instruct her to leave the house (which unfortunately burned to the ground). The fire had been set by her cigarette, as she had been compulsively smoking. Standardized tests such as the MMSE often do not capture executive dysfunction, and thus the clinician must be attuned to the appropriate assessment of such impairments.

CLINICAL PEARLS

- Patients with frontal lobe damage may often begin a task correctly, but then stop prior to completion, requiring repeated prompts from the examiner to continue. *Impersistence* refers to the failure to maintain a particular response despite reinforcement.
- In frontotemporal dementia (FTD), patients can present with insidious onset of abnormal social behaviors,

including poor hygiene, inappropriate remarks, increased risk-taking (gambling, stealing, speeding), diminished social engagement, and ritualistic behaviors.

- *Anosognosia* refers to patients' lack of awareness or disregard of their deficits. Patients with frontal dysfunction vary in their degree of awareness of their deficit. Such deficits can profoundly affect treatment and responsiveness to rehabilitative efforts.
- Clinicians can restructure the environment to provide salient operant cues and greater external executive control, and work with patients on overlearning adaptive responses so they have a high probability of occurring in problem situations.

DISCLOSURE STATEMENTS

This chapter is a modification of Chapter 41, "Frontal Lobe Syndromes and Traumatic Brain Injury," by Paul Malloy, Deborah Cahn-Weiner, and Thomas Markham Brown, from *Psychiatric Care of the Medical Patient*, Second Edition.

Dr. Domoto-Reilly has nothing to disclose.

MOVEMENT DISORDERS

Shreya Raj and Jeremiah M. Scharf

INTRODUCTION

The basal ganglia are composed of deep subcortical nuclei (caudate, putamen, globus pallidus, subthalamic nucleus, substantia nigra, nucleus accumbens, and extended amygdala) that participate in action selection and reinforcement learning. Disorders of basal ganglia circuits are classically defined based on resulting motor output, where disruptions cause either too little movement (hypokinetic disorders, e.g., Parkinsonism) or too much movement (hyperkinetic disorders, e.g., chorea, dystonia, myoclonus, and tics) (Albin, Young, & Penney, 1989). For many years, movement disorders were thought to be entirely motor phenomena; however, it is now known that the basal ganglia also mediate selection and regulation of cognitive, behavioral, and affective processes via parallel loops of cortico-striato-thalamo-cortical (CSTC) circuits (Alexander, DeLong, & Strick, 1986). Subsequently, clinical researchers have demonstrated that disorders arising from basal ganglia dysfunction have cognitive, behavioral, and affective symptoms that parallel their motor abnormalities. Until recently, these symptoms have been overlooked, but they can often cause significant morbidity unless treated. In this chapter, we highlight psychiatric features of three paradigmatic basal ganglia disorders (Huntington disease, Parkinson disease, Tourette syndrome); however, any neurological or systemic conditions that affect basal ganglia function (e.g., focal stroke, trauma, infection, neoplasm, toxic/metabolic injury, endocrine disturbances) will also cause psychiatric disturbances that require evaluation and treatment.

HUNTINGTON DISEASE

Huntington disease (HD) is a progressive, inherited neuropsychiatric illness with characteristic motor, cognitive, and psychiatric dysfunction. It has a prevalence of 4 to 10 per 100,000 in populations of European ancestry, and equal rates among men and women (Ross & Tabrizi, 2011). The mean age of onset is approximately 40 years old, and death typically occurs 15 to 20 years after diagnosis. However, there is a juvenile form, the Westphal variant, which is associated with slowed movements, rigidity, dystonia, myoclonus, seizures, and a more rapidly progressive course.

ETIOLOGY

HD is an autosomal dominant genetic disorder caused by an expanded CAG trinucleotide repeat within the huntingtin (*HTT*) gene on chromosome 4. The *HTT* gene codes for the protein huntingtin, and CAG expansion results in long stretches of poly-glutamine repeats within this protein. The functions of both normal and mutant huntingtin are still unclear, though the CAG expansion appears to cause a gain-of-function toxicity to neurons that results in neurodegeneration. While unaffected individuals have up to 36 CAG repeats within the *HTT* gene, individuals with CAG repeat lengths above 36 are at risk for developing HD. People with repeat CAG lengths of 36 to 39 may or may not develop HD, whereas individuals with 40 or more will almost certainly develop the disease by age 65. In general, longer CAG repeat lengths are associated with earlier disease onset, and also associated to a lesser degree with motor and cognitive disease progression (Rosenblatt et al., 2012). However, neither the type nor the severity of associated behavioral or psychiatric syndromes is associated with repeat codon length (Weigell-Weber, Schmid, & Spiegel, 1996; Zappacosta et al., 1996). The number of CAG repeats can increase with successive generations, resulting in an earlier age of onset in children of affected parents, a process called “genetic anticipation.”

CLINICAL FEATURES

HD is characterized by symptoms in the motor, cognitive, and psychiatric domains. Disease onset is declared when motor symptoms develop. However, many patients may go through a “prodromal period,” experiencing substantial cognitive or behavioral disturbances years before motor signs become evident.

MOTOR SIGNS

Motor signs can be classified as (1) involuntary movements, specifically chorea, and (2) altered voluntary movements. Chorea is commonly treated with dopamine-blocking (antipsychotic) or dopamine-depleting (tetrabenazine) drugs. Tetrabenazine is the only U.S. Food and Drug Administration (FDA) approved drug for HD, with an indication for chorea (Frank & Jankovic, 2010). Its mechanism of action is dopamine depletion at the presynaptic vesicles.

Common adverse side effects include sedation, insomnia, weight gain, depressed mood, akathisia, and Parkinsonism. All patients on tetrabenazine should be monitored for signs of depression, which can occur in 15–20% of patients on the medication (Kenney, Hunter, Mejia, & Jankovic, 2006), as well as for suicidality. Although both typical and atypical neuroleptics are also used in clinical practice, there are few double-blind, placebo-controlled studies evaluating the efficacy and safety of neuroleptic medications in HD. These medications may also cause apathy and akathisia, both of which can be difficult to distinguish from the “organic” effects of HD. Atypical antipsychotics may be better tolerated than typical neuroleptics, and small studies have looked at olanzapine, quetiapine, clozapine, and aripiprazole. Clozapine usage was complicated by drowsiness, fatigue, anticholinergic side effects, and exacerbation of gait problems. Aripiprazole was found to help with chorea at a level comparable to tetrabenazine but has not been tested in larger, randomized trials. Other medications studied for management of chorea include amantadine and benzodiazepines. Amantadine, an N-methyl-D-aspartate (NMDA)-receptor antagonist, significantly reduced chorea in one of two studies, but has been associated with increased irritability, aggression, and hallucinations (Armstrong & Miyasaki, 2012). Benzodiazepines can be helpful with anxiety and chorea, but require higher doses that risk sedation.

COGNITIVE SYMPTOMS

Cognitive symptoms in HD patients often begin before motor findings are recognized, and include impairment in memory, concentration, judgement, insight, and learning (Jason et al., 1997; Salmon, Granholm, McCullough, Butters, & Grant, 1989). HD patients characteristically describe problems with attention and executive function early in the disease (e.g., multitasking, sustained attention). A 2010 study compared 575 pre-motor HD patients to 160 non-CAG expansion controls in various neuropsychological tests of executive functioning, memory, visuospatial perception, and processing speed (Duff et al., 2010). They found approximately 40% of pre-HD individuals met criteria for mild cognitive impairment (MCI), and individuals closer to HD diagnosis had higher rates of MCI. Within this group, non-amnesic MCI was more common than amnesic MCI, and single-domain MCI was more common than multiple-domain MCI. In the non-amnesic single-domain subtype, impairments in processing speed were most frequent.

PSYCHIATRIC

There is a wide range of psychiatric syndromes found in patients with HD, which can often precede diagnosis and be a major source of functional impairment throughout the disease. In general, there is a lack of controlled clinical trials for treatment of HD-related psychiatric symptoms; thus, most recommendations come from case reports and clinician experience.

Depression is the most common psychiatric disorder in HD. A 2005 study involving 2,835 patients with an established diagnosis of HD found over 40% of subjects endorsed significant depressive symptoms, and more than half had sought treatment for depression in the past (Paulsen et al., 2005). Many studies cite a lifetime prevalence of 30–40% (Rosenblatt, 2007). Diagnosis can be complicated by the overlap between symptoms of HD and depression—namely, fatigue, cognitive problems, weight loss, and apathy.

A critical feature of depression in HD is the increased suicide rate among individuals with HD, which has been estimated to be 4 to 6 times higher than found in the general population (Roos, 2010). Suicidal behavior is likely to be impulsive, and at times may even occur in the absence of active depression. Two particularly risky times for suicide attempts are around the gene test and when increased symptom severity leads to loss of independence.

Despite the high prevalence of depression in HD, there is a general lack of controlled clinical trials to guide its treatment, and the majority of treatment recommendations come from case studies. In general, management recommendations adhere to those in non-HD depression. Selective-serotonin reuptake inhibitors (SSRI) are commonly used as first-line treatment, given the relatively benign side-effect profile and safety in overdose. One caveat is that individuals with HD tend to be more sensitive to medication side effects, so therapies should be started at low doses and titrated slowly. In addition, medications with anticholinergic properties may worsen motor function due to changes in the dopaminergic–cholinergic balance. If trials of SSRIs are ineffective, one could consider venlafaxine or mirtazapine. Electroconvulsive therapy (ECT) is also an accepted therapy for depression in HD.

APATHY

Apathy is highly associated with HD. Unlike depression and anxiety, its progression can be related to disease stage. Apathy is so characteristic of HD that the disease has been termed the “apathetic dementia” (Burns, Folstein, Brandt, & Folstein, 1990). Inertia, lack of interest, impersistence, and lack of initiative may precede other signs by years. Progression of apathy to a terminal state of global self-neglect, inertness, and mutism may leave the patient completely inaccessible. Apathy in HD is usually attributed to the impaired arousal, attention, and concentration that mark relative disconnection of the frontal lobes and the striatum (Caine & Shoulson, 1983).

There have been no gold-standard, or even particularly efficacious, treatments identified thus far for apathy (see Chapter 34). A literature review reveals anecdotal reports about use of amantadine, amphetamines, bromocriptine, bupropion, methylphenidate, and selegiline. One could also consider non-sedating SSRIs like fluoxetine, sertraline, or citalopram. Non-pharmacological interventions include avoiding open-ended questions, providing cues, maintaining a regular schedule, increasing environmental stimulation, and limiting expectations of the patient.

IMPULSE DYSCONTROL

Irritability and aggression are also often seen in HD patients. Again, there are no controlled clinical trials to guide treatment. However, physicians use a wide variety of medication classes, including neuroleptics, mood stabilizers, and SSRIs, to manage these symptoms. Beta blockers have been used to decrease autonomic arousal. Pindolol may be better tolerated than propranolol, as the latter can cause bradycardia and hypotension (Abrahamsen, Digranes, & Gisholt, 1990).

MANIA

The lifetime prevalence estimate of mania in HD is between 5% and 10% (Rosenblatt, 2007). Mainstays of treatment are anticonvulsants or neuroleptics. Interestingly, lithium does not seem to work in HD patients; there is a poor response, and HD patients are at greater risk for lithium toxicity. Better choices may be valproate, lamotrigine, or carbamazepine (Novak & Tabrizi, 2010).

PSYCHOSIS

Psychosis can manifest as delusions or hallucinations. The most common psychotic presentation in HD is of poorly organized paranoia, and it may be considered part of executive dysfunction seen in the disease. Any sort of psychotic symptoms are usually treated with neuroleptics, and atypicals are preferred due to the more tolerable side-effect profile.

OBSESSIVE-COMPULSIVE DISORDER

Obsessive-compulsive disorder (OCD) does not have a clearly defined prevalence in HD, but studies have shown 22–50% of patients endorsing some kind of obsession or compulsion. Pharmacological agents used include SSRIs and clomipramine, while non-pharmacological behavioral management techniques utilize distraction, setting a routine, and cognitive behavioral therapy (CBT; although CBT may become impossible as cognitive dysfunction worsens).

ALCOHOLISM

Increased rates of alcoholism have been associated with HD, but most reports are methodologically flawed (Mayeux, 1984). The best studies report figures that match rates found in contemporaneous control populations (King, 1985).

PARKINSON DISEASE

There are numerous psychiatric and cognitive disturbances seen in Parkinson disease (PD). Some of the more common include depression, anxiety, apathy, psychosis, and dementia/dysexecutive syndromes. Diagnosing mood disorders in PD can be complicated by the fact that many of the disorder's cardinal features often mimic the somatic symptoms of psychiatric disorders. These include apathy, fatigue, sleep

disturbances, motor slowing/retardation, weight gain/loss, and changes in appetite. Mood symptoms can also be caused or exacerbated by the dopaminergic medications commonly used for PD treatment.

DEPRESSION

In a systematic review of 36 PD studies, the average prevalence of major depressive disorder (MDD) was 17%, minor depression was 22%, and 13% of patients had dysthymia. Clinically significant depressive symptoms (irrespective of a *Diagnostic and Statistical Manual of Mental Disorders* [DSM] diagnosis) were endorsed by 35% of PD patients (Reijnders, Ehrt, Weber, Aarsland, & Leentjens, 2008). The DSM IV maintains that any symptoms associated with a "general medical condition" must be excluded when assessing for depression. However, this requirement runs the risk of missing clinically significant mood disorders that often adversely affect the lives and functionality of PD patients. In 2006, a workgroup put together by the National Institute of Neurologic Diseases and Stroke (NINDS) and National Institute of Mental Health (NIMH) recommend eliminating this DSM IV exclusion criterion in the assessing for depression in PD (Blonder & Slevin, 2011).

Risk factors for depression in PD include female sex, a personal or family history of depression, early-onset PD, "atypical" Parkinsonism, and the presence of other psychiatric comorbidities. Compared to non-PD depression, affected Parkinson's patients may have higher rates of anxiety, pessimism, and suicidal ideation, but less guilt or self-reproach (Weintraub & Burn, 2011).

There are no clear guidelines as to which treatment is most efficacious in PD depression. A National Institutes of Health (NIH)-funded eight-week, randomized, and placebo-controlled pilot study by Menza and colleagues (Menza et al., 2009) involved 52 PD patients with major depression or dysthymia. They were given paroxetine controlled release (CR), nortriptyline, or placebo. Nortriptyline was effective at reducing depressive symptoms, while paroxetine CR was not different from placebo. A randomized, placebo-controlled pilot study by Devos and colleagues (Devos et al., 2008) of 48 PD patients with major depression compared the effects of citalopram, desipramine, and placebo. The results suggested that both citalopram and desipramine were more effective than placebo at the end of the 30-day trial. Although desipramine showed a greater reduction in depressive symptoms at the study midpoint (day 14) relative to citalopram, this difference did not persist at the end of the trial, and desipramine was not as well tolerated overall, primarily due to anticholinergic side effects such as dry mouth, constipation, and orthostatic hypotension. There is still a dearth of published serotonin-norepinephrine reuptake inhibitor (SNRI) studies, although a recent NINDS-funded study comparing paroxetine and extended-release venlafaxine (Richard et al., 2012) found evidence of efficacy for both medications.

Some treatment considerations for depression in PD include the side-effect profile of various antidepressant classes. PD patients are already at risk of dysautonomic symptoms, and

the anticholinergic properties of tricyclic antidepressants may exacerbate these symptoms, in particular constipation and orthostatic hypotension. In addition, anticholinergic agents can worsen cognitive impairment and predispose PD patients to delirium. In general, most treaters start with an SSRI given the relatively benign side-effect profiles and track record with non-PD patients (Blonder & Slevin, 2011), though SSRIs can worsen bradykinesia or apathy in some cases (Gerber & Lynd, 1998). Although SSRIs given in conjunction with monoamine oxidase B (MAO-B) inhibitors (such as selegiline and rasagiline) theoretically increase the risk of serotonin syndrome, in practice this is rarely observed, as there is not significant MAO-A inhibition at therapeutic doses of selective MAO-B inhibitors (Gallagher & Schrag, 2012).

ANXIETY

Up to 40% of PD patients report anxiety symptoms. In fact, anxiety disorders may predate diagnosis of a movement disorder by up to 20 years, possibly due to reduction of dopaminergic neurons in the earliest stages of the disease (Gallagher & Schrag, 2012). Commonly seen diagnoses include panic disorder, social phobia, generalized anxiety disorder, and anxiety not otherwise specified (NOS). There are correlations to the on/off phenomenon observed with the motor fluctuations; anxiety is most often associated with “off” periods. The prevalence of anxiety in PD patients exceeds that seen in both the general population and in patients with other chronic medical conditions; as such, it cannot be explained away simply as a reactive phenomenon. In addition, rates of anxiety in relatives of PD are also greater than those observed in the general population (Arabia et al., 2007). There are no systematic assessments or large placebo-controlled trials for the management of anxiety in PD. Various drug classes have been used in everyday practice, including benzodiazepines, tricyclic antidepressants (TCAs), SSRIs, atypical cyclic antidepressants (such as trazodone), non-selective monoamine oxidase inhibitors (MAOIs), and buspirone. When choosing a pharmacological strategy, the major consideration is side effects of certain medications. For example, benzodiazepines are commonly used for anxiety in the general population; in PD patients, however, their sedative and autonomic effects can be troublesome. TCAs have anticholinergic side effects that can dull cognition or exacerbate PD-associated dysautonomia. SSRIs are well tolerated and have a relatively benign side-effect profile, but there are no studies clearly demonstrating their efficacy in PD anxiety.

APATHY

Parkinsonian apathy is recognized as a distinct clinical entity from depression. It is highly prevalent in its own right, affecting up to 60% of PD patients (Gallagher & Schrag, 2012). It is generally characterized by a diminishment in goal-directed behavior, speech, and emotional engagement. Comorbidities of Parkinsonian apathy include depression, cognitive impairment, and dysexecutive syndromes. Apathy may also be associated with a more rapid progression in motor and cognitive decline (Blonder & Slevin, 2011).

In treating apathy, one should first address any depressive symptoms beforehand, as the two are so closely related. Beyond that, treatment guidelines are based on a number of case reports and smaller studies. Pharmacological agents studied include cholinesterase inhibitors, stimulants, and testosterone replacement. McKeith and colleagues performed a double-blind, placebo-controlled study that demonstrated improvement in apathy and indifference in patients with dementia with Lewy bodies (DLB) using rivastigmine (McKeith et al., 2000). In 2004, Ready and colleagues (Ready, Friedman, Grace, & Fernandez, 2004) showed a significant inverse correlation between free testosterone levels and apathy in elderly male PD patients. This was independent of disease severity, suggesting a possible role for testosterone replacement. Unfortunately, this hypothesis was not confirmed in later studies. Chatterjee and Fahn successfully alleviated apathy with methylphenidate, but this was a single case study (Chatterjee & Fahn, 2002).

PSYCHOSIS

Psychotic symptoms such as hallucinations and delusions are common in PD patients, although they tend to arise late in the course of the disease (on average, after ten years) (Zahodne & Fernandez, 2008). The estimated prevalence of visual hallucinations is 22–38%. Other examples include minor psychotic symptoms (for example, illusions of presence and visual illusions) in 17–72% and delusions in 1–7% (Gallagher & Schrag, 2012). Risk factors include cognitive impairment, age greater than 65, advanced disease status, concurrent sleep disorders or depression, and use of dopamine agonists (Eng & Welty, 2010). The first step in addressing psychotic symptoms is the reduction of any nonessential PD medications. If the patient is on multiple agents, one could try reducing or removing PD medications in the following order (from first discontinuation to last): anticholinergics, selegiline, amantadine, dopamine agonists, catechol-O-methyltransferase (COMT) inhibitors, and lastly, levodopa (Zahodne & Fernandez, 2008). Antipsychotics can be used in refractory cases. Although both quetiapine and clozapine are commonly used in practice, only the latter is recommended by the American Academy of Neurology guidelines (Miyasaki et al., 2006). These guidelines recommend avoiding olanzapine, as it has failed to show benefit, and worsened PD symptoms in some studies. Of note, PD patients can experience therapeutic benefit at clozapine doses as low as 6.25 mg/day (Zahodne & Fernandez, 2008). At higher doses, patients may experience sedation, orthostatic hypotension, and sialorrhea due to the anticholinergic effects of clozapine.

DEMENTIA/DYSEXECUTIVE SYNDROMES

Cognitive dysfunction is a frequently seen outcome in PD. Up to 80% of PD patients may experience cognitive decline as the disease progresses, and up to 25% of non-demented PD patients can meet MCI criteria (Weintraub & Burn, 2011). There can be measurable cognitive deficits even prior to the diagnosis of PD, which often involve executive and visuospatial dysfunction. Despite the widespread prevalence of PD

MCI and dementia, there have been few trials demonstrating efficacious treatment with cognitive enhancers. Emre and associates showed statistically significant but clinically modest cognitive improvement in PD patients on rivastigmine (Emre et al., 2004). Trials of donepezil have not shown sufficient evidence for treatment of PD dementia based on primary endpoints (Alzheimer Disease Assessment Scale-Cognitive [ADAS-Cog]), but the American Academy of Neurology (AAN) Practice Parameter concluded that donepezil is “probably effective,” based on secondary endpoint improvements in Mini-Mental Status Exam (MMSE) (Dubois et al., 2012; Miyasaki et al., 2006).

IMPULSE CONTROL DISORDERS

Impulse control disorders (ICD) in PD are common, with an incidence of 13.7%. Subtypes include problematic and pathological gambling, compulsive sexual behavior, compulsive buying, and binge-eating disorders. There is an association between ICDs and dopamine agonists, as patients on dopaminergic medications are up to 3.3 times more likely to have an ICD than those who are not taking them (Weintraub et al., 2010). Risk factors for the development of ICDs include early onset of disease, younger age, higher doses of dopaminergic drugs (especially dopamine agonists), history of psychiatric disorder, and recreational drug or alcohol abuse (Kummer & Teixeira, 2009). Careful evaluation and psychoeducation before starting dopaminergic medications may be helpful in staving off an ICD. Patients and caregivers should be advised of the warning signs at the start of treatment, and again at follow-up. This is especially important if the patient has a history of behavioral or substance addictions (Voon et al., 2011). If an ICD does develop, the first step should be to reduce dopaminergic medications where possible. Close monitoring is needed, as patients who have been exposed to high doses of dopamine agonists are at risk of a withdrawal syndrome, characterized by anxiety, dysphoria or depression, fatigue, autonomic symptoms, and drug cravings (Rabinak & Nirenberg, 2010).

PUNDING

Punding refers to a diverse set of non-goal-directed, stereotyped actions or behaviors. The type of behavior is often related to the individual’s interests or former occupation: for example, an office worker repetitively shuffling papers, or a beautician brushing hair (Spencer, Rickards, Fasano, & Cavanna, 2011). Other common examples include sorting buttons and assembling or disassembling watches or other household items. Punding has been associated with dopaminergic therapy, although there is no clear pathophysiology established. Punding behaviors are most often described in the PD literature, but they have also been observed in other patient groups on dopaminergic drugs (e.g., patients treated for restless leg syndrome) (Spencer et al., 2011). While there are superficial similarities to the compulsions observed in OCD, punding behaviors lack a distressing ego-dystonic quality. Rather, PD patients appear to find them soothing.

Problems arise with the amount of time devoted to punding, which can lead to social withdrawal or ignoring of other important activities of daily living. Like ICDs, there are no clear treatment guidelines for punding other than decreasing dopaminergic medications.

DEMENTIA WITH LEWY BODIES

DLB and dementia associated with Parkinson disease (PDD) have traditionally been considered different disorders, but it is more likely that they represent two conditions along a disease continuum rather than distinct entities. The differentiation between DLB and PDD is made on the basis of the onset of cognitive dysfunction relative to onset of motor symptoms: DLB should be diagnosed when dementia occurs before or concurrently with the onset of Parkinsonism, while PDD requires that the dementia develop in the context of an established PD (classically, more than one year after onset of motor symptoms) (McKeith et al., 2005).

DLB is formally characterized by cognitive fluctuations, visual hallucinations, and Parkinsonism. Fluctuations take the form of changes in alertness or attention. These may be difficult to observe during a time-limited office visit, so collateral information from family members or a caregiver is crucial. The visual hallucinations are generally well formed and often non-frightening to the patient. Motor symptoms, similar to those found in PD, include bradykinesia, rigidity, postural instability, and masked facies. A tremor may also be present, although often not as pronounced as in PD. Motor symptoms may also be more symmetrical in DLB patients compared to those with PD, and responses to levodopa are often less robust (see also Chapter 42).

Another hallmark of DLB is exquisite sensitivity to neuroleptics. Reactions may include delirium, acute psychosis, and exacerbation of Parkinsonian motor symptoms. On the other hand, DLB patients typically have a very good response to cholinesterase inhibitors. These agents can dramatically improve cognition (to a degree beyond what is observed in Alzheimer’s disease patients), and may alleviate visual hallucinations by improving attentional systems (McKeith, Wesnes, Perry, & Ferrara, 2004). Both the marked response to cholinesterase inhibitors and the sensitivity to anticholinergic drugs are thought to be related to a pathological deficit of cortical cholinergic function in DLB (Tiraboschi et al., 2000).

ATYPICAL PARKINSON SYNDROMES

Atypical Parkinsonian syndromes include DLB, progressive supranuclear palsy (PSP), corticobasal syndromes (CBS), and multiple system atrophy (MSA), the latter of which is divided into three subtypes based on whether the predominant symptom is Parkinsonism (MSA-P, previously called striatonigral degeneration), cerebellar (MSA-C, also known as olivopontocerebellar atrophy), or dysautonomic (MSA-A, also known as Shy-Drager syndrome). Clinical features that can help differentiate an atypical syndrome from primary

PD include symmetry of motor symptoms at onset, a more rapid course of progression, early dysautonomia and postural instability, as well as partial or non-responsiveness to dopaminergic medications. Careful consideration of these syndromes is important not only for precise diagnosis, but also to guide treatment choices. In particular, patients with atypical Parkinsonian syndromes often have significant sensitivity to the side effects of anticholinergic medications, including exacerbation of constipation, orthostatic hypotension, and postural instability leading to an increased rate of falls. Furthermore, urinary frequency or urgency is commonly observed in PD and atypical PD-related dysautonomia, but most of the anticholinergic medications that are typically used as anti-spasmodic agents can worsen cognitive dysfunction. Thus, treatment of PD-related bladder dysfunction should be limited to the agents with the least central nervous system penetration, such as darifenacin or trospium chloride.

TOURETTE SYNDROME

Tourette syndrome (TS) is a childhood-onset neurodevelopmental disorder characterized by the presence of waxing and waning motor and vocal tics. *Tics* are classically described as brief, rapid, non-rhythmic, involuntary movements or sounds. They may be simple (e.g., eye blinking, grimacing, coughing, sniffing, or grunting) or complex. Complex tics vary widely and include coordinated movements of multiple muscle groups, slower dystonic (posturing) movements; more purposeful-appearing movements with compulsive (touching/tapping) or aggressive/self-injurious (poking or punching) features; as well as syllables, words, phrases, and complex utterances such as repeating oneself (palilalia), repeating others (echolalia), and socially inappropriate utterances (coprolalia). Of note, coprolalia is only present in 10–20% of TS patients (McNaught & Mink, 2011). Tics are most commonly associated with an uncomfortable premonitory sensation/urge and are briefly suppressible, with subsequent buildup of the urge until the tic is released. Tics can worsen with a variety of external triggers, including stress, anxiety, excitement, or systemic infection.

Current DSM classification separates tic disorders based on length of symptoms, age of onset, and tic types (American Psychiatric Association [APA], 2000). Transient tic disorder (TTD) (now called *Provisional tic disorder* in DSM-5) requires that single or multiple tics be present for more than four weeks, but less than one year. Chronic motor or vocal tic disorder (CT) is defined by the presence of either multiple motor or vocal tics (but not both) that are present for more than one year, while TS (*Tourette disorder* in DSM-IV-TR and DSM-5) requires that both motor and vocal tics be present, though not necessarily concurrently. This distinction between CT and TS is somewhat arbitrary, since vocal tics are merely motor contractions of oropharyngeal, laryngeal, and diaphragmatic muscles resulting in sounds (Singer, 2010). Thus TS and CT may best be considered part of a continuous spectrum of developmental tic disorders. Lastly, TTD,

CT, and TS are required to have onset prior to age 18; otherwise they are classified as *Tic disorder, not otherwise specified* (TD-NOS).

TS prevalence estimates have ranged widely between 0.05–3% of the pediatric population, though more recent community-based studies using larger sample sizes and multistage assessment procedures have provided more consistent estimates of 0.3–0.7% in school-age children (“Prevalence of diagnosed Tourette syndrome in persons aged 6–17 years—United States, 2007,” 2009). Higher rates are observed in special education populations. The average onset age of tics is 5–7 years old, with peak severity typically in early adolescence (mean age of 10, with significant variability between individual patients). The majority of TS patients experience reduction in symptoms in late adolescence or early adulthood (Leckman et al., 1998). Singer’s “rule of thirds” estimates that, by early adulthood, a third of tic disorders have disappeared, a third have improved, and the final third continue or worsen (Singer, 2006). Approximately 15% have persistent, disabling tics as adults (Bloch, Peterson, et al., 2006).

The etiology of TS and other developmental tic disorders is still unclear, though imaging studies have implicated dysfunction in CSTC circuitry, in particular impaired frontal CSTC circuits mediating cognitive control as well as overactive motor CSTC circuits (Wang et al., 2011). Although the presence of high rates of TS, CMT, and OCD in first-degree relatives of TS patients indicates a significant genetic predisposition, researchers have thus far only identified a small number of strong candidate susceptibility genes (O’Rourke, Scharf, Yu, & Pauls, 2009). Many environmental risk factors have been proposed, but none have been consistently replicated across studies.

TREATMENT

The decision to treat tics is based on the extent to which tics cause impairment in physical, social, educational, or occupational functioning. Medication choice can be guided by the severity of tics and effectiveness in treating comorbid conditions (Singer, 2010). Treatment algorithms generally aim to use a step-wise approach, with the goal of using medications with the lowest side-effect risk first, as described in the tiers below.

Tier 1: Alpha-2 Agonists

Alpha-2 agonists, including clonidine or guanfacine, should be the first-line treatment, especially for tics of mild severity. Guanfacine is sometimes better tolerated due to less sedation and a longer half-life. However, clonidine may be more effective in some patients, based on anecdotal experience. Both agents can reduce hyperactivity and impulsivity and can improve attention to some degree, and therefore can be helpful in patients with TS and attention-deficit hyperactivity disorder (ADHD). Alpha-2 agonist side effects include sedation, dry mouth, stomachaches, headaches, hypotension/dizziness, and (rare) bradyarrhythmias.

Tier 2: Atypical Neuroleptics

Neuroleptics (dopamine D2 receptor antagonists) may be necessary for more severe or refractory tics. In general, higher D2-blockade correlates with increased efficacy in tic reduction. Common side effects of atypical neuroleptics include weight gain, hyperlipidemia, impaired glucose tolerance, and sedation. Less often, they can cause Parkinsonism, acute dystonic reactions, akathisia, and tardive dyskinesia. Patients on atypical neuroleptics should have fasting lipids and glucose levels checked prior to initiation, and every three to six months, depending on the clinical context.

Tier 3: Typical Neuroleptics

The only FDA-approved medications for tics are haloperidol and pimozide, which along with fluphenazine are the three typical neuroleptics with the highest D2-receptor potency. Typical neuroleptics can be highly effective in treating tics, but are often not tolerated due to their severe side-effect profiles, including weight gain, cognitive dulling, extrapyramidal symptoms, akathisia, and tardive dyskinesia. In general, typical neuroleptics should be reserved for refractory tics.

Other medications also used to treat tics include clonazepam, topiramate, baclofen, levetiracetam, dopamine agonists (ropinirole and pramipexole), and tetrabenazine. Clonazepam is sedating, which often limits its use and can be associated with physiological dependence. Topiramate may be considered as an alternate Tier 1 medication prior to a neuroleptic trial, though it can exacerbate executive dysfunction in patients with comorbid ADHD and can cause (reversible) word-finding difficulties. Tetrabenazine, an inhibitor of the vesicular monoamine transporter (VMAT) resulting in pre-synaptic dopamine depletion, can be very effective in treating tics, and has a lower risk of tardive dyskinesia than neuroleptics. However, it can also cause significant weight gain, sedation, and reversible Parkinsonism, as well as depression in up to 25% of patients. It is contraindicated in patients who are actively suicidal, have impaired hepatic function, or are taking MAOIs (Lyon, Shprecher, Coffey, & Kurlan, 2010). For the latter, there should be a minimum two- to three-week “wash-out” period between use of MAOIs and tetrabenazine to avoid hypertensive crises. Neurologists have also had success with use of botulinum toxin in treating eye blinking and neck tics as well as simple vocal tics, in collaboration with specialists in otorhinolaryngology.

Behavioral Therapy

Given that tics are preceded by a premonitory sensory urge that is temporarily relieved by tic completion, behavioral therapy—specifically habit-reversal training (HRT)—can be an effective, non-pharmacological treatment for tics. Based on the known role of the basal ganglia in both motor learning and reinforcement learning of “habits,” HRT teaches patients to respond to a premonitory urge with a “competing response” (CR) that is physically incompatible with the tic (Azrin & Peterson, 1988). While urges temporarily increase with CR

implementation, over time, premonitory urges habituate in a manner akin to reduction of obsessive-compulsive symptoms in exposure-ritual prevention therapy for OCD. HRT has been demonstrated to be effective in reducing tics in multiple randomized clinical trials, in both children and adults (Wilhelm et al., 2012; Piacentini et al., 2010) and currently is formulated in the context of a “comprehensive behavioral intervention for tics (CBIT),” which incorporates several modalities, including psychoeducation, relaxation training, functional analysis to identify and mitigate common tic triggers, and HRT (Piacentini et al., 2010).

NEUROPSYCHIATRIC COMORBIDITIES

TS rarely occurs as an isolated tic disorder. A large, clinic-based, multi-center registry study of 3,500 patients found only 12% of TS patients without any comorbidities (Freeman et al., 2000). The most common neuropsychiatric comorbidities in TS are ADHD and OCD. Other co-occurring conditions include ICD, anxiety and mood disorders, sleep disorders, and learning disabilities. For the sake of concision, we have limited the review below to the more frequently found conditions.

Attention-Deficit Hyperactivity Disorder

ADHD is characterized either by an impaired ability to sustain attention (inattentive subtype), by the presence of impulsivity and hyperactivity (hyperactive/impulsive subtype), or by both sets of symptoms (combined subtype) (APA, 2000). It is the most common comorbid disorder in TS, with a prevalence of up to 60–80% of clinically referred patients (Cavanna, Servo, Monaco, & Robertson, 2009). ADHD usually precedes onset of tics by two or three years. Comorbid TS and ADHD are associated with increased tic severity and impairment. In addition, patients with TS plus ADHD often have additional comorbid disorders, including oppositional defiant disorder, conduct disorder, and episodic explosive episodes (“rage” attacks). A 2006 study comparing behavioral symptoms in children with TS alone, TS plus ADHD, ADHD alone, and an unaffected population found that while children with TS alone did not differ from unaffected children with respect to aggression, delinquency, or conduct difficulties, children with TS plus ADHD had significantly higher scores on indices of disruptive behaviors and scored similarly to children with ADHD alone (Sukhodolsky et al., 2003). Diagnosing ADHD within the TS population requires a careful assessment of other potential causes of executive dysfunction that can mimic ADHD, such as constant inward focus on tic suppression, prominent obsessional or non-obsessional anxiety, and sedative side effects of many tic-suppressant medications.

Stimulants are the treatment of choice in ADHD, but many physicians remain leery of using them in patients with tics disorders for fear of worsening tics. However, controlled clinical trials have found that this concern is unwarranted for most TS patients. The 2002 Treatment of ADHD in Children with Tics (TACT) study randomized 136 children with comorbid chronic tic disorder and ADHD into

four treatment groups: (1) clonidine, (2) methylphenidate, (3) methylphenidate and clonidine, and (4) placebo (Tourette Syndrome Study Group [TSSG], 2002). For ADHD symptoms, all three medication arms were significantly improved compared to placebo at the end of the 16-week trial, but the greatest improvement was observed in the combined methylphenidate and clonidine group. A secondary measure of tic severity also demonstrated decreased tic severity in all three treatment groups (including methylphenidate alone) compared to placebo. Lastly, tic-worsening occurred in the same number of children in each group (20% on methylphenidate, 26% on clonidine, and 22% on placebo).

These data suggest that stimulants are not contraindicated in patients with tic disorders, and, when started at low doses and titrated up slowly, can successfully treat ADHD without concomitant tic-worsening. Another randomized controlled trial has demonstrated success in treating ADHD symptoms with the non-stimulant medication atomoxetine without associated tic-worsening (Allen et al., 2005).

Obsessive-Compulsive Disorder

The lifetime prevalence of OCD in the general population is thought to be between 1.9% and 3.2%. However, OCD has been observed at much higher rates in TS patients, though prevalence estimates vary widely (20–89%) (Singer, 2010). There is a preponderance of evidence to suggest a shared genetic susceptibility between OCD and tic disorders (Pauls et al., 1986; Pauls, Raymond, Stevenson, & Leckman, 1991). OCD symptoms generally emerge several years after the onset of tics and are more likely to persist over time than tics (Bloch, Peterson, et al., 2006). OCD symptoms in TS usually include a need for order or routine, a requirement for things to be symmetrical or “just so,” and “evening-up” rituals (Cavanna et al., 2009). Some compulsions overlap with complex tics, requiring a mindful evaluation and in many cases treatment targeting both OCD and tic suppression. Studies have also described phenomenological differences between OCD alone and OCD with comorbid TS. For example, individuals with OCD in the absence of tics tend to have cognitive obsessions preceding compulsions; while individuals with both TS and OCD more often have a sensorimotor phenomenon, such as focal or generalized body sensations (usually tactile, musculoskeletal/visceral, or both, often described as feelings of pressure, aching, itching, or tension) occurring either before or during the patient’s performance of the repetitive behaviors (Ferrao et al., 2012; Leckman et al., 1993; Miguel et al., 2000). Mental sensations, defined as “general, uncomfortable feelings or perceptions” (Miguel et al., 2000) (including urge only, energy release, sense of incompleteness, and just-right perceptions) were also observed at higher rates in patients with TS and OCD than in those with OCD only. Another study noted that obsessions in OCD and TS tended to include sexual, religious, aggressive, and symmetrical themes, while individuals with OCD were more likely to report obsessions related to contamination, bad things happening, or becoming ill (Leckman et al., 1994).

The pharmacological first-line treatment for concurrent OCD and TS is SSRIs (Goodman, Storch, Geffken, &

Murphy, 2006; Lombroso & Scahill, 2008). Patients with OCD will typically need higher doses than one would normally use for depression, and up to 25% of OCD patients show no meaningful improvement on SSRIs alone and may require augmentation. In such cases, neuroleptics are often the agent of choice. A 2006 systematic review and meta-analysis of antipsychotic augmentation studies in adults with refractory OCD demonstrated a significant benefit of neuroleptic augmentation, particularly in patients with comorbid tic disorders (Bloch, Landeros-Weisenberger, et al., 2006). Clomipramine continues to remain the most effective pharmacological treatment for OCD, though it is usually used as a second-line agent due to its side-effect profile (weight gain, anticholinergic side effects, electrocardiogram QT interval prolongation).

Psychotherapeutic interventions, specifically CBT involving exposure and ritual prevention (ERP), have been demonstrated in multi-center randomized controlled trials to be effective treatments for OCD both in children and adults. These studies suggest that the combination of CBT and medications (either SSRIs or clomipramine) may be more effective than either treatment alone. Current guidelines recommend initial non-pharmacological interventions for mild-to-moderate OCD, with the addition of medications in refractory or more severe cases (“Treatment of Obsessive-Compulsive Disorder,” 1997).

Anxiety/Depression

Non-obsessional anxiety and depression frequently co-occur in patients with TS and chronic tic disorder, with estimates in the TS clinical population averaging roughly 20% for both anxiety and depression, but as high as 40% each in some clinical cohorts (Freeman et al., 2000). In general, anxiety and depression are treated with the same interventions in tic disorder patients as they are in the general population (i.e., CBT and pharmacotherapy). However, they are important to evaluate and monitor, since untreated depression and anxiety can increase tic severity; therefore, targeting these two common psychiatric disorders can sometimes reduce mild tics to such a degree that tic-specific treatments are not necessary. Given the high rates of comorbid OCD, SSRIs are often the pharmacological therapy of choice for TS-related anxiety and depression. Caution may also be needed when prescribing antidepressants with noradrenergic activity, such as SNRIs or bupropion, both of which can exacerbate tics. Lastly, physicians should be aware of the pharmacokinetic interactions between many SSRIs and the common dopamine antagonists used for tic suppression, such as fluoxetine, paroxetine, or bupropion with aripiprazole (via the CYP2D6 enzyme), fluoxetine with haloperidol (via CYP2D6), and fluoxetine, fluvoxamine, citalopram/escitalopram or (to a lesser degree) sertraline with pimozide (via CYP1A2 and/or CYP3A4).

Episodic Dyscontrol/Intermittent Explosive Disorder (IED)

Explosive outbursts are characterized by unpredictable and abrupt displays of aggression out of proportion to provoking stimuli (Budman, Bruun, Park, Lesser, & Olson, 2000).

There is often a preceding sense of tension or increased arousal, relieved by the outburst. They can be present in 15–30% of TS patients and can often be the most impairing symptom of the disorder. Explosive outbursts are associated with high family distress, problematic interpersonal relationships, impaired functioning, and increased rates of psychiatric hospitalization (Budman et al., 2008). A 2000 study by Budman and colleagues found the probability of explosive outburst in TS was greatly associated with comorbid disorders (including ADHD and OCD), and its likelihood rose with the number of comorbidities. Neither the presence of mood disorders nor tic severity was correlated with the number of explosive episodes in the population studied (Budman et al., 2000). While no randomized controlled trials have been conducted on treatment of IED in patients with tic disorders, experts currently recommend the following: (1) treatment of underlying triggers that may exacerbate outbursts (untreated/incompletely treated tics, OCD, ADHD, depression or non-obsessional anxiety); (2) behavioral therapy targeting anger; and (3) pharmacotherapy, including SSRIs and atypical neuroleptics.

In the same vein, TS patients have higher rates of self-injurious behaviors (SIB) than found in the general population. SIBs have been observed in up to 33% of TS patients (Robertson, Trimble, & Lees, 1989). Although the range of severity varies, some patients do have very serious manifestations that result in injury or even life-threatening consequences. A study of 332 TS patients seen at a single clinic during a three-year period found that 5.1% met criteria for “malignant TS,” defined as two or more emergency-room visits or one or more inpatient admissions for TS-related issues (Cheung, Shahed, & Jankovic, 2007).

CLINICAL PEARLS

- Apathy is so characteristic of Huntington’s disease that it has been termed the “apathetic dementia” (Folstein, 1989). Inertia, lack of interest, impersistence, and lack of initiative may precede other signs by years.
- A critical feature of depression in Huntington’s disease is the increased suicide rate among individuals with HD, which has been estimated to be four to six times higher than found in the general population. Suicidal behavior is likely to be impulsive, and at times may even occur in the absence of active depression. Two particularly risky times for suicide attempts are around the gene test, and when increased symptom severity leads to loss of independence.
- OCD does not have a clearly defined prevalence in HD, but studies have shown 22% to 50% of patients endorsing some kind of obsession or compulsion.
- In general, most treaters of depression in Parkinson’s disease start with an SSRI, though SSRIs can worsen bradykinesia or apathy in some cases. Although SSRIs given in conjunction with MAO-B inhibitors (such as selegiline and rasagiline) theoretically increase the risk of serotonin syndrome, in practice this is rarely observed, as there is not significant MAO-A inhibition at therapeutic doses of selective MAO-B inhibitors.
- Punding is a diverse set of non-goal-directed, stereotyped actions or behaviors associated with dopaminergic therapy, although there is no clear pathophysiology established. PD patients appear to find punding soothing. The type of behavior is often related to the individual’s interests or former occupation: for example, an office worker repetitively shuffling papers or a beautician brushing hair. Like ICD, there are no clear treatment guidelines for punding other than decreasing dopaminergic medications.
- Up to 40% of PD patients report anxiety symptoms. In fact, anxiety disorders may predate diagnosis of a movement disorder by up to 20 years.
- Comorbidities of Parkinsonian apathy include depression, cognitive impairment, and dysexecutive syndromes. Apathy may also be associated with a more rapid progression in motor and cognitive decline.
- Although both quetiapine and clozapine are commonly used in practice for PD dementia, only the latter is recommended by the American Academy of Neurology guidelines (Miyasaki et al., 2006). These guidelines recommend avoiding olanzapine, as it has failed to show benefit and even worsened PD symptoms in some studies. Of note, PD patients can experience therapeutic benefit at clozapine doses as low as 6.25 mg/day.
- McKeith and colleagues performed a double-blind, placebo-controlled study that demonstrated improvement in apathy and indifference in patients with DLB using rivastigmine.
- DLB is formally characterized by cognitive fluctuations, visual hallucinations, and Parkinsonism. Fluctuations take the form of changes in alertness or attention. These may be difficult to observe during a time-limited office visit, so collateral information from family members or a caregiver is crucial. The visual hallucinations are generally well formed and often non-frightening to the patient.
- Another hallmark of DLB is exquisite sensitivity to neuroleptics. Reactions may include delirium, acute psychosis, and exacerbation of Parkinsonian motor symptoms. On the other hand, DLB patients typically have a very good response to cholinesterase inhibitors.
- Patients with atypical Parkinsonian syndromes often have significant sensitivity to the side effects of anticholinergic medications, including exacerbation of constipation, orthostatic hypotension, and postural instability leading to an increased rate of falls.
- Of note, coprolalia is only present in 10–20% of TS patients.
- Alpha-2 agonists, including clonidine or guanfacine, should be the first-line pharmacological treatment for TS, especially for tics of mild severity. While haloperidol and

pimozide are the only two FDA-approved medications for tics, they are now considered third-line agents due to their side-effect profile.

- Cognitive Behavioral Intervention for Tics (CBIT), which includes Habit Reversal Training (HRT) has been demonstrated in multi-center randomized controlled trials to be effective for reducing tics both in children and adults and should also be considered first-line treatment when available.
- Pimozide (Orap) is not clearly more effective than haloperidol and fluphenazine, since all three have equally high D2-receptor potency; pimozide has many drug–drug interactions that affect the QT interval, which limits its utility in practice.
- The most common neuropsychiatric comorbidities in TS are ADHD and OCD, though anxiety, depression, and impulse dyscontrol/anger outbursts also frequently occur and often cause more impairment than the tics themselves.
- Diagnosing ADHD within the TS population requires a careful assessment of other potential causes of executive dysfunction that can mimic ADHD, such as constant inward focus on tic suppression, prominent obsessional or non-obsessional anxiety, and sedative side effects of many tic-suppressant medications.
- Stimulants are the treatment of choice in ADHD, but many physicians remain leery of using them in patients with tics disorders for fear of worsening tics. However, controlled clinical trials have found that this concern is unwarranted for most TS patients.

DISCLOSURE STATEMENTS

Dr. Raj has no potential conflicts to disclose.

Dr. Scharf has received grant support from the American Academy of Neurology Brain Foundation, the Tourette Syndrome Association, the Trichotillomania Learning Center, National Human Genome Research Institute (NHGRI), National Institute of Mental Health (NIMH) and NINDS. He has also received travel support from a joint education grant from the Tourette Syndrome Association and Centers for Disease Control and is a member of the Tourette Syndrome Association Scientific Advisory Board. He has no other potential conflicts to disclose.

NEUROPSYCHIATRIC ASPECTS OF FOCAL NEUROLOGICAL DISEASE

CEREBROVASCULAR DISEASE AND MULTIPLE SCLEROSIS

Ruchi Aggarwal and Mario F. Mendez

INTRODUCTION

For most of the last century, brain injury has been about location. The specific focal area of a brain injury primarily determines the manifestations of the neurological disease, regardless of the pathophysiological process. Basic brain-behavior principles include cerebral dominance and hemispheric specialization. Lesions in the left hemisphere result in aphasia, alexia, agraphia, ideomotor apraxia, and forms of acalculia. Some left-hemisphere lesions alter the ability to localize sensations on one's body or to recognize objects by looking at them. In contrast, lesions in the right hemisphere result in visuospatial difficulties, face-discrimination problems, environmental disorientation, and even amusia (the inability to recognize musical tones or to reproduce them). Disturbances in the frontal lobes can produce executive and personality changes; in the temporal lobes, memory and language changes; and in the parietal lobe, spatial and attentional changes. Although we now know that cognition is organized in more distributed and interactive networks throughout the brain, we still use these basic brain-behavior principles to localize and understand the consequences of focal neurological disease.

In contrast to cognitive deficits, clinicians and investigators are less aware of the focal psychiatric manifestations of brain lesions. As a general rule, any cognitive deficit can result from any focal neurological disease, depending on the focality and location. Psychiatric symptoms, however, may be more complicated. Yet psychiatric symptoms may be just as common as cognitive dysfunction. For example, common neurological causes of depression include left frontal strokes, multiple sclerosis, Parkinson's disease, Huntington's disease, Alzheimer's disease and other dementias, and epilepsy. Neurological causes of mania are right-hemisphere strokes, multiple sclerosis, Parkinson's disease after dopaminergic treatment, Huntington's disease, and trauma. Delusions and obsessive-compulsive symptoms may result from many of these disorders as well as from other neurological diseases.

This chapter focuses on the psychiatric manifestations of stroke and other cerebrovascular diseases and on multiple sclerosis, disorders that exemplify focal and multifocal diseases of the brain. While the effect on basic cognition is

highly dependent on the location of the lesions, the psychiatric manifestations may result from other mechanisms as well. An understanding of these behaviors and their causes, and the need to evaluate neurological patients for psychiatric symptoms, can greatly facilitate the management of these patients.

CEREBROVASCULAR DISEASE

Cerebrovascular disease is associated with depression, mania, and a range of other psychiatric symptoms (see Table 48.1). In the United States, cerebrovascular disease is the third leading cause of mortality among those age 50 and older, preceded only by heart disease and cancer. Cerebrovascular disease encompasses a range of disorders, most prominently stroke, or a sudden loss of blood supply to the brain leading to permanent tissue damage. According to the American Stroke Association, approximately 795,000 Americans each year will suffer a new or recurrent stroke. Although other forms of cerebrovascular disease, including transient ischemic attack and chronic subcortical white matter change, may display neuropsychiatric symptoms, the systematic study and review of psychiatric disease in stroke has been the overwhelmingly predominant theme in the literature and will therefore be the focus of our review.

Strokes are often divided in terms of their pathophysiology, or, alternatively, by the site of damage. The pathophysiology of stroke can be ischemic (both thrombotic and embolic events) or hemorrhagic. Ischemic events constitute approximately 85% of cerebrovascular accidents, while hemorrhagic events are estimated to make up the rest. No matter what the cause of stroke, psychiatric manifestations are a well-recognized consequence.

DEPRESSION

PREVALENCE

Among all the possible psychiatric or behavioral manifestations post-stroke, depression is consistently the most prevalent. The prevalence of post-stroke depression (PSD) is approximately 33%, a rate much higher than that of depression in the

Table 48.1 NEUROPSYCHIATRIC SYMPTOMS ASSOCIATED WITH STROKE

SYNDROME	CLINICAL SYMPTOM	ASSOCIATED LESION LOCATION	COURSE AND PROGNOSIS	TREATMENT
Vascular Dementia	Cognitive decline demonstrated by loss of memory and at least one other deficit in domain of aphasia, apraxia, agnosia, or executive function	Multiple ischemic lesions	Current stroke with associated deterioration of cognitive function; influenced by: hypertension, hypotension, atherosclerotic heart disease, cigarette smoke, hyperlipidemia, diabetes	Anticoagulation effective to reduce risk of recurrence, antiplatelet aggregate drugs effective in secondary prevention of stroke, antihypertensives, lipid-lowering agents, smoking cessation, and prevention or management of diabetes mellitus; for pre-dementia (history of transient ischemic attacks, stroke, previous cognitive impairment), prevention may include carotid endarterectomy (when carotid stenosis is from 70–99%); patients in dementia stage (cognitive decline in several areas of intellectual functioning) treatment may include antidepressants, antihypertensive, cholinergic agonists, antiplatelet aggregation agents, statins, and neurotrophic factors
Major Depression	Depressed mood, diurnal mood variation, loss of energy, anxiety, restlessness, worry, weight loss, decreased appetite, early-morning awakening, delayed sleep onset, social withdrawal, and irritability	Left frontal lobe or left basal ganglia during first 2 mos. post-stroke	Mean duration of 40 weeks, minority develop long prolonged depression post-stroke, increased mortality	Nortriptyline showed significantly greater improvement in Hamilton Rating Scale for Depression (HAMD) vs. placebo but side effects were severe enough to require discontinuation; Citalopram (SSRI) showed a response rate of 59% to placebo 28% on HAMD; Recent study showed that patients treated with nortriptyline showed significantly greater decrease in HAMD score than either placebo or fluoxetine treated patients, no significant difference between fluoxetine and placebo
Minor Depression	See Major Depression; less severe; no suicidal ideation	Right basotemporal or right orbitofrontal lesions; right subcortical lesions; left posterior lesions	Mean duration of 12 weeks, increased mortality	See Major Depression
Mania	Elevated mood, increased energy, decreased sleep, feelings of well-being, pressured speech, flight of ideas, grandiose thoughts	Right basotemporal or right orbitofrontal lesions or right subcortical lesions	Not systematically studied	Effective treatments have not been established

Anxiety Disorder	Symptoms of major depression, intense worry, and anxious foreboding in addition to depression, associated light-headedness or palpitations and muscle tension or restlessness, and difficulty concentrating or falling asleep	Left cortical lesions, usually dorsal lateral frontal lobe; anxiety alone with right hemisphere lesions	Early onset (during acute in-hospital evaluation) but not late onset associated with psychiatric history including alcohol abuse, with mean duration of 1.5 months, delayed generalized onset mean duration of 3 months; Patients with GAD and depression had mean duration of depression significantly longer than duration of depression without GAD	SSRIs; benzodiazepines common for GAD, very conservative dosage and careful monitoring must be used; patients receiving nortriptyline treatment showed significantly greater improvement in HAMA and Hamilton Rating Scale for Anxiety (HAMA) scales than placebo group; furthermore, anxiety symptoms showed earlier improvement than depressive symptoms; buspirone may be useful in reducing anxiety without many of the adverse side effects, such as sedation, and without the risk of development of tolerance; however, this medication has not been empirically evaluated to treat post-stroke anxiety disorders
Psychotic Disorder	Hallucinations or delusions	Right temporal parietal occipital junction	Not systematically studied	No controlled treatment trials; anecdotal reports suggest two basic approaches, one using anticonvulsant therapy and the other neuroleptic therapy (use of anticonvulsants has its rationale in the frequent coexistence of seizures with psychotic disorders after stroke)
Apathy	Loss of drive, motivation, interest, low energy, unconcern	Posterior internal capsule or cingulate gyrus ventral striation and dorsomedial thalamus	Not systematically studied	No controlled trials for treatment; Patients have been treated with nortriptyline, apomorphine, and amphetamine with some success
Catastrophic Reaction	Anxiety, reaction, tears, aggressive behavior, swearing, refusal, renouncement, and compensatory boasting	Left anterior subcortical	Not systematically studied	Effective treatments have not been established
Pathological Laughing and Crying	Frequent, usually brief laughing or crying; crying not caused by sadness or out of proportion to it; and social withdrawal secondary to emotional outbursts	Frequently bilateral hemispheric lesions; lesions involving the frontopontine cerebellar pathways with almost any lesion location	Not systematically studied	Patients on nortriptyline showed significantly greater improvement in Pathological Laughter and Crying Scale (PLACS) compared to placebo group, significant improvements in depression scores were also observed; however, PLACS scores were significant for both depressed and non-depressed patients; All citalopram-treated patients reported greater than 50 percent reduction in the number of crying episodes; Hamilton scores dropped significantly during treatment as well

general population. Patients hospitalized at the time of a survey tended to have a higher frequency of PSD, at about 40%, as compared to community samples where the frequency was about 20% (Kaplan & Sadock, 1995). The prevalence of PSD among patients with left anterior strokes is as high as 70% (Robinson, 1986).

RISK FACTORS

Investigators have studied many risk factors for PSD. The significance of individual risk factors varies from study to study, probably reflecting the multifactorial nature of PSD. In addition, there is a bidirectional relationship or reciprocal correlation between stroke and depression. In other words, depression itself has also been found to be associated with an increased risk of stroke (Dong, Zhang, et al., 2011).

Among the identified risk factors, the presence of left anterior stroke lesions may be the most important. Clinicians have long observed a relationship between left-sided lesions and depression and between right-sided lesions and mania. The high prevalence of PSD allows for greater certainty of a relationship with left-sided lesions, but the relationship of mania to right-sided lesions is not as firm. Furthermore, the severity of depression in the acute post-stroke period is related to distance of the anterior border of the lesion from the left frontal pole (Robinson, Kubos, et al., 1984; Kaplan & Sadock, 1995; Narushima, Kosier, et al., 2003). Conversely, in the case of late-onset PSD, evidence for an association with lesion location has not held true in meta-analysis (Carson, MacHale, et al., 2000) (see Figure 48.1).

Other variables that may increase the risk for PSD include generalized cerebral atrophy, subcortical atrophy, dysphasia, living alone or with poor social support, pre-stroke psychopathology, and low level of functioning (Astrom, Adolfsson, et al., 1993). The relationship with impaired level

of functioning is particularly evident among hospitalized patients. However, the relationship here is also bidirectional in that depression leads to poor performance in activities of daily living (ADLs) and decreased participation in rehabilitation (Parikh, Robinson, et al., 1990). A self-defeating cycle of depression, poor recovery, and worsening depression can be an unfortunate and dangerous consequence of untreated PSD. In contrast, severity of stroke has not been consistently correlated with the development of PSD.

DIAGNOSIS

The diagnosis of PSD can be challenging. This helps explain the varied rates of depression found across studies. PSD is can be very similar to primary depression, except that the patient exhibits less guilt and more somatic or vegetative symptoms (Lokk & Delbari, 2010). In some cases, however, it may be impossible to know if somatic symptoms such as low energy, insomnia, poor appetite, and cognitive dysfunction are related to depression or to other factors such as the physical sequelae of stroke itself, medications being used, or comorbid medical illnesses. In addition, deficits such as aphasia, dysarthria, neglect, and anosognosia (the lack of awareness of deficit) complicate the ability of stroke survivors to communicate their symptoms. Patients with depression specifically associated with cerebral microvascular disease or extensive deep white matter and periventricular hyperintensities on magnetic resonance imaging (MRI) have prominent psychomotor slowing, executive function deficits, and relatively poor long-term outcomes (Yamashita, Fujikawa, et al., 2010).

The *Diagnostic and Statistical Manual of Mental Disorders-IV* (DSM-IV) criteria for *Depression secondary to a general medical condition* provide some general guidance for the diagnosis of PSD. For a diagnosis of *Major depression*, patients must demonstrate a depressed mood and four

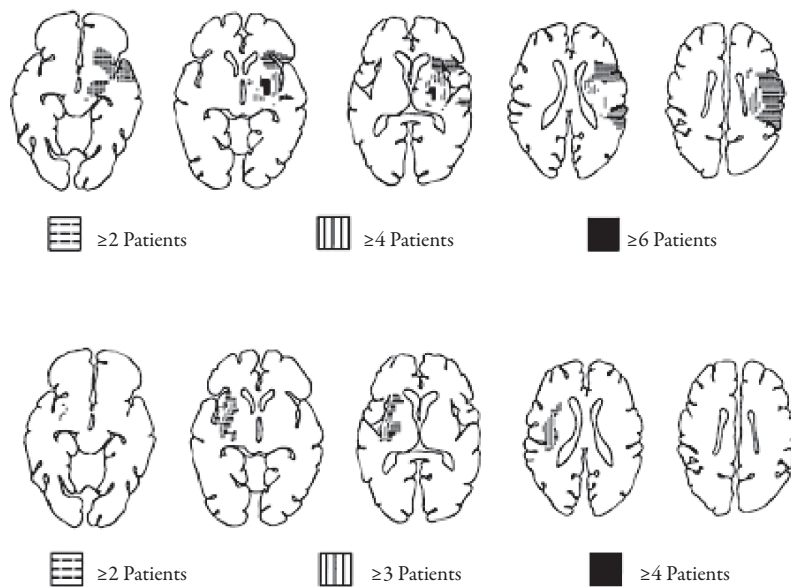

Figure 48.1 Schematic representation of superimposed lesions in patients with depressive disorders after stroke. Top, Nine patients with major depression and left hemisphere stroke. Bottom, Five patients with “minor depression” and right hemisphere stroke. Reproduced with permission (Herrmann, Bartels, et al., 1995).

additional symptoms from the following list: change in appetite, insomnia or hypersomnia, decreased interest or pleasure, psychomotor changes, decreased energy, feelings of guilt or worthlessness, poor concentration, and suicidal thoughts. *Minor depression* requires at least two but fewer than four of the above criteria, along with depressed mood or loss of interest. For *Dysthymia*, the DSM-IV criteria specify minor depression with a duration of at least two years (American Psychiatric Association Task Force on DSM-IV, 2000).

Several scales or screening instruments are available to measure and monitor depression severity. The Geriatric Depression Scale (Yesavage, Brink, et al., 1982) may be beneficial in the diagnosis of depression after a stroke as it focuses more on core symptoms of depression than on somatic symptoms alone. It is not designed for use in patients with cognitive impairment or aphasia. Other screening instruments include the Patient Health Questionnaire (PHQ-9), the Montgomery-Asberg Depression Rating Scale (MADRS), and the Hamilton Rating Scale for Depression (HRSD). Although all of these scales are acceptable screening instruments in PSD, their sensitivity and specificity are difficult to determine as there is no existing gold standard for the diagnosis of PSD beyond DSM-IV criteria. The Aphasic Depression Rating Scale (ADRS) is a useful tool and has been validated in patients both with and without aphasia (Benaim, Cailly, et al., 2004). It can be administered by the treating or rehabilitation team as it is based on observable behaviors, and therefore does not depend on the input of a family member or the patient. Finally, the Stroke Inpatient Depression Inventory (SIDI) is a scale specifically designed for PSD (Roger & Johnson-Greene, 2009). It is helpful even in the acute hospital setting, where questions regarding decreased interest in usual activities may be difficult to interpret, or even meaningless.

No matter what technique is used to evaluate PSD, the screening of all stroke patients for depression is better than the common practice of evaluating patients only if they display obvious symptomatology. In addition, evaluation of depression post-stroke should always include evaluation for suicidal ideation, plans, and intent. Suicidal thoughts are frequent after a stroke, as evidenced by an overall rate of suicidal ideation of 15% (Santos, Caeiro, et al., 2012).

CLINICAL COURSE

Acute-onset PSD occurring days to less than three months after a stroke may remit; however, late-onset PSD occurring after three months is likely to persist and display a more chronic course (Lokk & Delbari, 2010). The duration of post-stroke major versus minor depression is variable across studies. In general, whether acute-onset or late-onset, of minor or major intensity, PSD has the potential to become chronic, with symptoms lasting up to or more than three years. In one longitudinal study of post-stroke major depression, researchers found that, among patients with acute depression immediately following stroke, 60% had remission of symptoms by the one-year follow-up (Astrom, Adolfsson, et al., 1993). In this same study, if not remitted by one to two years, patients were unlikely to be remitted at the three-year follow-up.

Finally, PSD has an impact on ADLs and functional recovery, and PSD increases the risk of death (Morris, Robinson, et al., 1993).

ETIOLOGY

The different course, prognosis, and risk factors in acute-onset PSD versus late-onset PSD suggest a different underlying pathophysiology in these conditions. Acute-onset PSD may be more biologically mediated, while late-onset or chronic forms of PSD may be more psychologically mediated. Major and minor depressions have also been proposed to have different etiologies. A study conducted by Robinson and colleagues found that major depression was more likely to be found after left anterior lesions, whereas left posterior lesions were more likely to account for the emergence of minor depression after stroke (Robinson, Kubos, et al., 1984). While psychosocial factors certainly play a role in the etiology of PSD, biological factors are of key importance.

Disruption in corticolimbic circuits, especially with left anterior lesions, is a proposed mechanism for PSD. Numerous researchers have found a strong correlation between a left-sided frontal or left basal ganglia location of strokes and acute-onset PSD. Destruction of neurons and circuits in this area may lead to decreased ability to produce neurotransmitters, including serotonin (Narushima, Kosier, et al., 2003). Patients with PSD have reduced levels of 5-hydroxyindoleacetic acid (5-HIAA) in their cerebrospinal fluid (CSF) compared to matched controls (Spalletta, Bossu, et al., 2006).

An increase in the production and circulation of cytokines forms the basis of another major theory for PSD. As part of the inflammatory response, certain proinflammatory cytokines are increased after an acute stroke. Specifically, cytokine interleukin-1 (IL-1) plays an important role in the initiation and maintenance of inflammatory and immune responses following ischemic injury (Spalletta, Bossu et al., 2006). Additional cytokines involved in this acute response may include tumor necrosis factor alpha (TNF-alpha), IL-6, IL-8, and IL-18 and may be overproduced in patients with depression. Other cytokines, when administered to mice, can induce a syndrome similar to depression. The proposed mechanisms by which these cytokines lead to depressive symptoms include theories on alterations in the hypothalamic-pituitary-adrenal (HPA) axis with decreased production or change in neurotransmitters. Some of the cytokines, IL-1 included, are indeed potent stimulators of the HPA axis. Other cytokines may cause increased degradation or metabolism of tryptophan, resulting in a reduced ability to produce serotonin. Spalletta and colleagues have discussed a "cytokine-serotonin interaction" and the cycle that may lead to decreased overall production of serotonin, thus leading to depression (Spalletta, Bossu, et al., 2006).

The presence of genetic vulnerability is a further biological factor in PSD. Recent findings indicate that PSD is more common in those patients with certain serotonin transporter (*SERT*) gene polymorphisms (Kohen, Cain, et al., 2008). The *SERT* gene is located on chromosome 17q and encodes for the SERT protein. This SERT protein

is located on presynaptic membranes of serotonergic neurons and controls serotonergic signaling by uptake of serotonin into the synapse. Therefore, variations in expression of this gene may lead to increased susceptibility of mental illnesses, including major depressive disorder (Kohen, Cain, et al., 2008).

TREATMENT

The literature on treatment of PSD includes several randomized control trials with selective serotonin-reuptake inhibitors (SSRIs) and with nortriptyline (Kaplan & Sadock, 1995). Both types of antidepressants have shown promising results in the treatment of PSD, with findings of improved level of functioning compared to untreated depressed patients. Additionally, research suggests the long-term benefit of treating depression immediately after stroke (Kaplan & Sadock, 1995) (see Figure 48.2).

Due to the high prevalence of PSD and the improvement in prognosis with antidepressants, some researchers have studied the prophylactic use of antidepressants in stroke. Their findings indicate a possible benefit of antidepressants, even in patients who were not found to have clinical depression (Chen, Patel, et al., 2007). However, not enough data are available to recommend the use of antidepressants as prophylactic agents in stroke patients.

Stimulant medications are also used in PSD, especially in patients with comorbid apathy and fatigue. For patients whose participation in rehabilitation is essential to good recovery and where quick onset is needed, stimulant medication may be the best option. The most studied stimulant is methylphenidate, with data supporting its use with a low incidence of side effects (Lokk & Delbari, 2010).

Nonpharmacological strategies include social support, cognitive-behavioral therapy, behavioral activation therapy, electroconvulsive therapy, and rehabilitation strategies. Given that poor social support or living alone are consistent risk factors for chronic depression in the literature, social support and the involvement of family or other support

networks is vital. Psychological interventions such as behavioral activation therapy remain the treatment of choice for minor depression or for those who cannot tolerate antidepressants (Lokk & Delbari, 2010). Cognitive-behavioral therapy in the treatment of PSD has not shown a robust response, and it is of limited use in those whose cognitive impairment or aphasia is too severe for them to actively participate. Although electroconvulsive therapy is often effective in severe or treatment-resistant cases, adverse events and risks in the post-stroke period limit its use (Lokk & Delbari, 2010).

MANIA

Prevalence

As post-stroke mania is much less frequent than PSD, data on its prevalence rates, etiology, risk factors, and treatment are limited. Estimated prevalence rates are less than 1% (Santos, Caeiro, et al., 2011). Nevertheless, given a high prevalence of silent stroke and the possibility for mania to present late after a stroke, post-stroke mania should be in the differential diagnosis of late-onset bipolar disorders. In fact, among patients with new-onset mania after the age of 50, more than half have “asymptomatic” or “silent” cerebral infarctions on MRI of the brain (Fujikawa, Yamawaki, et al., 1995).

Risk Factors

Stroke location, but not family history, may predispose to post-stroke mania (Santos, Caeiro, et al., 2011). Despite debate, mania after stroke tends to be more frequent after right-sided lesions involving frontal lobe, temporal lobe, or caudate nucleus. These lesions may be evident on MRI but not on computerized tomography (Cummings & Mendez, 1984). As with many of the other psychiatric manifestations post-stroke, subcortical atrophy may pose an increased risk for development of mania (Robinson & Starkstein, 1989). As with PSD, mania after stroke is not clearly related to a family history of affective and bipolar disorder. Although several reports suggested an increased risk of post-stroke mania in those with a positive family history of bipolar disorder, a recent review of the literature by Santos and colleagues (2011) did not support such a relationship.

Diagnosis

Case reports have described the symptoms of post-stroke mania as indistinguishable from those seen in patients with primary mania. DSM-IV criteria for *Manic episode* provide a useful guideline. Criteria include elevated, expansive, or irritable mood lasting for at least one week, accompanied by at least three (four if the mood is only “irritable”) of the following symptoms: inflated self-esteem or grandiosity, decreased need for sleep, more talkative or pressure to keep talking, flight of ideas or racing thoughts, distractibility, increase in goal-directed activity or psychomotor agitation, and excessive

Figure 48.2 Survival rates over 9-year follow-up of acute stroke patients who received a 12-week post-stroke course of antidepressants or placebo. Reproduced with permission (Jorge, Robinson, et al., 2003).

involvement in pleasurable activities that have high potential for negative consequences (American Psychiatric Association Task Force on DSM-IV, 2000).

Another diagnostic tool is the criteria for secondary mania proposed by Krauthammer and Klerman (1978). The core criteria are similar to that of mania as diagnosed by DSM-IV, with the addition of the requirement that there be no prior history of mania or affective illness (Krauthammer & Klerman, 1978). As with DSM-IV criteria for *Mood disorder due to a general medical condition*, the symptoms cannot be present during the course of a delirium alone.

Clinical Course

The temporal relationship of mania or bipolar spectrum illness after stroke can vary from a very acute presentation to delayed mania for up to two years. The majority of cases do appear immediately after the stroke, with approximately 53% occurring in the first few days (Santos, Caeiro, et al., 2011). Another 23% of mania cases occur within the first month following the stroke (Santos, Caeiro, et al., 2011). Secondary mania associated with stroke or “vascular mania” is more difficult to treat than primary mania, as it may not respond to conventional mood stabilizers or antipsychotic medications. However, the mania often resolves without recurrence of further manic episodes (Cummings & Mendez, 1984). In the majority of cases reviewed in the literature, manic symptoms lasted from 1 to 12 weeks (Santos, Caeiro, et al., 2011).

Etiology

The increased risk with right-sided lesions is consistent with studies of primary mania showing decreased perfusion in the right hemisphere (Migliorelli, Starkstein, et al., 1993). Predominantly, right-sided lesions in the frontal lobe, especially in the orbitofrontal cortex, temporal lobe, caudate nucleus, and thalamus, are all implicated in the etiology for post-stroke mania. Consequently, a leading hypothesis for the origin of post-stroke mania is the interruption or dysfunction of frontolimbic circuits necessary for mood regulation (Santos, Caeiro, et al., 2011). Increase in serotonin receptor binding found after right-sided, but not left-sided, strokes has been one proposed mechanism for the development of mania in this population (Robinson & Starkstein, 1989).

Treatment

No randomized control studies are available for treatment of mania after stroke. Case reports do describe the resolution of symptoms with mood stabilizers, as used in primary mania (Cummings & Mendez, 1984). Mood stabilizers such as lithium or valproic acid and atypical antipsychotics for mania with psychotic features may be effective (Santos, Caeiro, et al., 2011). As the majority of the cases of post-stroke mania are thought to remit without recurrence, prolonged treatment is usually unnecessary.

ANXIETY

Prevalence

The rate of anxiety after stroke is about 25% across studies. The most likely anxiety diagnosis given is generalized anxiety disorder (GAD) or GAD due to stroke. As in primary anxiety, post-stroke anxiety is often comorbid with depression. Of those with post-stroke anxiety, approximately 75% are felt to have concomitant depression (Chemerinski & Levine, 2006). If anxiety and depression are comorbid, the severity and prognosis of depression is worse (Astrom, 1996). Studies on anxiety after stroke are few, with work focusing almost exclusively on GAD.

Risk Factors

Risk factors for anxiety after stroke, especially in chronic anxiety, include both predisposing factors and either cortical or subcortical atrophy (Astrom, Adolfsson, et al., 1993; Astrom, 1996). Patients with early-onset anxiety after stroke often have a previous psychiatric history or a history of alcohol abuse (Castillo, Starkstein, et al., 1993). Lesion location may also have an associated risk, with findings that right-hemisphere strokes are more likely to present with anxiety alone versus left-hemisphere strokes that present with both anxiety and depression (Castillo, Starkstein, et al., 1993).

Diagnosis and Clinical Course

DSM-IV criteria form the basis for diagnosis in GAD secondary to stroke. Excessive worrying for at least six months, with related symptoms including restlessness, decreased energy, concentration difficulties, irritability, muscle tension, and/or sleep disturbances, make up the diagnostic criteria (American Psychiatric Association Task Force on DSM-IV, 2000). Anxiety has approximately the same time course and presentation of symptoms after stroke as with depressive disorders.

Treatment

As with the other psychiatric manifestations related to stroke, treatment is currently guided and limited to what is known for primary psychiatric disorders. SSRIs are the primary treatment of choice, and buspirone may be helpful as well. Benzodiazepines, although effective in some cases, should be used with caution due to side effects, especially in an elderly population (Chemerinski & Levine, 2006).

APATHY

Prevalence

Although apathy, defined as lack of motivation or reduced goal-directed behaviors and cognition, can be associated with depression, it is often a separate condition. Apathy or abulia is frequently the first or most prominent sign of the development of vascular dementia. The frequency of apathy following stroke is 20–25% (Jorge, Starkstein, et al., 2010).

Risk Factors

There are several risk factors for post-stroke apathy. It is most frequent among patients with some degree of cognitive impairment, as demonstrated by lower scores on the Mini-Mental State Examination (Jorge, Starkstein, et al., 2010). However, there is not a direct correlation here, as even patients with severe dementia may not be apathetic. Other factors associated with apathy may include older age, impairment in ADLs, and frontal lobe and other lesion locations.

Diagnosis

Clinicians can document the signs of decreased spontaneous behavior and engagement with an apathy scale. The Apathy Evaluation Scale by Marin and colleagues is one such reliable measure for apathy (Marin, Biedrzycki, et al., 1991). It has three available versions, with one version a self-rated scale to be filled out by the patient, another a caregiver scale, and a third version a clinician-administered scale. There are 18 items designed to measure signs and symptoms associated with apathy, including reduced levels of goal-directed behavior; reduced goal-directed cognition, such as decreased interests, lack of plans and goals, and lack of concern about one's own health or functional status; and reduced emotional expressions as manifested by flat affect, indifference, and restricted responses to events. Alternative apathy measures include the Starkstein Structured Interview for Apathy (Jorge, Starkstein, et al., 2010).

Clinical Course and Etiology

Apathy occurs most often as a late presentation after stroke and seems to have a chronic course. The chronic nature of apathy is also associated with continued decline in level of functioning and poor recovery. Strokes involving the medial frontal region and anterior cingulate and the caudate nuclei can result in a frontal apathic-abulic state. After finding that lesions of the posterior limb of the internal capsule were also associated with apathy, Starkstein and colleagues concluded that damage to the frontal-subcortical networks plays a prominent role in the development of this condition (Jorge, Starkstein, et al., 2010).

Treatment

The literature on treatment of apathy is mostly limited to case reports. The mainstays of pharmacological treatment have been dopamine agonists or stimulant medications (Jorge, Starkstein, et al., 2010). Unfortunately, although apathy is often associated with depression, use of antidepressant medications such as SSRIs may worsen the symptoms of apathy.

Other Neuropsychiatric Manifestations

Other neuropsychiatric manifestations of cerebrovascular disease include catastrophic reaction, pathological laughter and crying, psychosis, anosognosia, irritability/agitation,

disinhibition, and cognitive deficits, including vascular dementia (Kaplan & Sadock, 1995; Chemerinski & Levine, 2006) (see Table 48.2).

MULTIPLE SCLEROSIS

Multiple sclerosis (MS) is a chronic, often unpredictable, autoimmune, demyelinating neurological illness. After trauma, MS is the most common cause of neurological disability in young and middle-aged adults. The prevalence of MS is approximately 1 per 1,000 in the United States population, with about twice as many women affected as men (Vattakatuchery, Rickards, et al., 2011). Curiously, the prevalence of MS increases as the distance from the equator increases (Kaplan & Sadock, 1995). As any of the myelin sheaths in the central nervous system is susceptible to destruction by this disease, MS can have a variety of presentations and manifestations (see Table 48.2). The diagnosis requires at least two episodes of neurological disturbance with lesions separated in time and space (see Table 48.3).

The three main types of MS are divided by their clinical course into relapsing-remitting, secondary progressive, and primary progressive multiple sclerosis. Another category of multiple sclerosis, which is less studied, is "benign MS." Neuropsychiatric symptoms can occur any time in the course of the illness, with some case reports describing behavioral manifestations as the only presenting symptom. Comorbid psychiatric diagnoses are common and have long been recognized as part of the disease. In fact, as early as 1877, Jean-Martin Charcot first described a common presentation he observed in MS patients as "cheerful indifference."

DEPRESSION

Prevalence

Historically, early investigators and clinicians described MS as resulting in eutonia or euphoria with relative immunity from depression. This has subsequently proven to be incorrect. As in stroke, depression is one of the most common neuropsychiatric manifestations of MS, with an estimated 50% of MS patients suffering from depression across studies (Feinstein, 2004). The prevalence of depression is in fact more common in MS than in several other neurological diseases, even in diseases with comparable or similar amounts of loss in function, suggesting that a biological mechanism is involved. In addition, risk of suicide is unfortunately high compared with other neurological disorders (Goldman Consensus Group, 2005).

Risk Factors

Lesion load, location of lesion, and brain involvement may be risk factors for depression in MS. In this disorder, patients with brain involvement are more likely to be depressed than patients with spinal cord lesions alone (Schiffer, Caine, et al., 1983). Poor functional status and cognitive impairment are other risk factors for depression. In some samples, younger

Table 48.2 NEUROPSYCHIATRIC MANIFESTATIONS OF MULTIPLE SCLEROSIS

SYNDROME	LIFETIME PREVALENCE	CLINICAL SYMPTOMS	TREATMENT
Depression	50%	Depressed mood and other symptoms of primary depression, irritability, less guilt	SSRIs as first line; treatment guided by what is known for primary depression
Mania and Bipolar Disorders	2% (approximately twice that of general population)	Similar to primary mania: flight of ideas, expansive mood, reduced sleep, grandiosity, etc.	Mood stabilizers; antipsychotics; immunomodulatory/disease-modifying therapies
Euphoria	15–25%; more common in patients with cognitive dysfunction and heavier lesion load, esp. in frontal lobes	State of mental and physical (euforia, sclerotic) well-being or optimism despite significant disability; “cheerful indifference”	No recommended pharmacological treatment for euphoria alone
Anxiety	14–40%	Similar to primary anxiety disorders	SSRIs
Fatigue	75%–90%	Divided into: – motor fatigue: physical weakness following sustained activity – mental fatigue: feeling tired or exhausted out of proportion to level of activity	Dopamine agonists, amantadine, modafinil; exercise training programs Also, treat any underlying sleep disorders, pain, or comorbid depression
Psychosis	1–2% (controversial as to whether it is more prevalent than in the general population)	Hallucinations/delusions	Antipsychotics
Pathological Laughter and Crying (PLC)	10%	Spontaneous, uncontrollable outbursts of either crying or laughing, often inappropriate to situation or incongruent with actual mood	SSRIs; nortriptyline; dextromethorphan-quinidine
Cognitive Impairments	43–70%	Deficits in complex attention, information processing and speed, executive functioning, encoding, visual processing; can progress to subcortical dementia; language may be spared	Acetylcholinesterase inhibitors; disease-modifying therapies incl. INF- β Cognitive rehabilitation programs

age of onset and recent diagnosis (shorter disease duration) of MS are also associated with increased risk of depression (Paparrigopoulos, Ferentinos, et al., 2010).

Risk factors for suicide and suicidal ideation are similar to those seen in the general population and include male gender, social isolation, substance abuse, and younger age of onset of MS (Paparrigopoulos, Ferentinos, et al., 2010). The most important risk factor for completed suicide in MS is depression, underscoring the importance of detecting depression in this disorder (Goldman Consensus Group, 2005).

Diagnosis

As is the case for stroke and other neurological diseases, depression in MS can be a diagnostic challenge. Many of the symptoms that may be inherent with MS, including fatigue, appetite changes, insomnia, and problems with concentration or cognition, overlap with the symptoms of depression. This may account for the missed diagnosis of depression among known MS patients as “just a natural part of their illness” or, alternatively, the misdiagnosis of MS as depression.

Depression in MS often presents with less guilt than seen in primary depression. In addition, MS-related depression may present with more irritability, discouragement, and frustration (Feinstein, 2004).

Diagnosis is again guided by DSM-IV criteria for *Mood disorder secondary to a general medical condition*. Scales used in measuring primary depression are also used in the study of depression in MS. Examples of scales used include the Beck Depression Inventory and the Hamilton Depression Rating Scale. According to the Goldman Consensus Group, the best approach to screening depression in MS is by using the Beck Inventory, with a cutoff score of 13 indicating depression (Goldman Consensus Group, 2005). Concern about overdiagnosis of depression in MS has led to the development and administration of scales that can separate vegetative symptoms from other symptoms of depression. For example, the Chicago Multiscale Depression Inventory may be useful in patients with medical illnesses such as MS, as it has three separate sub-scales to evaluate depression, including vegetative, mood, and evaluative/cognitive scales. It is self-administered by patients and asks them to score how closely a given statement or phrase describes them

Table 48.3 MULTIPLE SCLEROSIS

Multiple Sclerosis	Clinical Definition		Etiology
	The presence of two attacks, involving different parts of the CNS, separated by a period of at least 1 month, and lasting a minimum of 24 hours		T cells, and to a lesser extent, B lymphocytes invade the CNS, destroying axons; damage to myelin leads to an inflammatory reaction, and resolution of this to plaque formation
Symptoms	<i>Initial symptoms</i> Heterogeneous; may include a broad range of somatosensory, ocular, and motor symptoms	<i>Motor symptoms</i> Include transient hemiparesis and various forms of seizure, among others	<i>Symptoms of cerebellar dysfunction</i> May occur, including scanning speech, gait ataxia, and various tremors
Common Courses	<i>Relapsing-remitting form</i> Most common; patient has relapses of illness that can present with a broad range of neurological symptoms leading to remission and almost complete recovery with each episode	<i>Secondary progressive form</i> May evolve from relapsing-remitting form, leading to incomplete recovery after acute exacerbation of illness	<i>Primary progressive type</i> Quite uncommon, occurring in no more than 10% of cases; steady worsening of course from the outset of the disease; may be rapidly progressing and is rarely seen in patients younger than 40 years of age
Treatment	<i>Nonspecific symptomatic treatments</i> Neuropsychiatric symptom treatment as per Table 48.1; Glucocorticoids used to treat acute inflammatory responses associated with damage to the myelin sheath; although causing symptomatic relief, they do not impact the long-term course or outcome of the disorder		<i>Interferon (immunosuppressive/immunomodulatory agents)</i> <i>Interferon- β-1b</i> : shown to reduce annual relapse rates, in addition to changing the course of the disorder, there are preliminary data that this compound may also ameliorate the cognitive symptoms associated with MS; <i>Interferon- β-1a</i> : shown to reduce disability and relapse in patients, and may also have beneficial effects on cognitive function; <i>Glatiramer acetate</i> : effects on reducing relapse and improving disability, and, like the others, also has stabilizing effects on MRI changes

(Arnett & Randolph, 2006). The limitation of using screening instruments to diagnose depression in any condition, including MS, emphasizes that depression is a clinical diagnosis, and good clinical judgement in conjunction with instruments is the ideal approach. Finally, failure to suppress in the dexamethasone suppression test in MS is similar to findings seen in primary major depressive disorder (Goldman Consensus Group, 2005).

Clinical Course

According to the Goldman Consensus Group statement on depression in MS, depression does contribute to functional impairment in this disorder (Goldman Consensus Group, 2005). Study findings vary on the amount of functional impairment caused. There are reported associations with depression and decreased compliance with medications, decreased cognitive function, increased time off from work and disability, and disruption in family support systems. It is still not clear if emotional stress or depression can actually lead to increased progression of MS as measured by new gadolinium-enhancing lesions on MRI (2005). Unlike after acute stroke, depression in MS seems to have a chronic and possibly even worsening progressive course (2005).

Etiology

Depression in MS may be multifactorial. There are studies of lesion-related anatomical, autoimmune, inflammatory, and

psychological factors (Vattakatuchery, Rickards, et al., 2011). Given evidence for and against the many different proposed mechanisms, it is very likely that the etiology of depression differs from patient to patient and that multiple factors may be involved even in the same patient.

Study findings on the correlation of depression with lesion location are inconsistent. Some report a correlation of depression with left-sided lesions, others with right-sided lesions, and others find no correlation at all (Vattakatuchery, Rickards, et al., 2011). Improvement in imaging techniques for MS and future studies may help clarify the relationship between lesion location and depressive symptomatology. Among the studies that have found a correlation with lesion location, the left arcuate fasciculus, the right parietal lobe, periventricular and frontal areas, temporal lobes, right frontal lobe, left medial inferior frontal cortex, and right medial inferior frontal regions have been variably implicated (Vattakatuchery, Rickards, et al., 2011). Brain atrophy, especially in the frontal lobes, could also play a role in increased risk of depression (Vattakatuchery, Rickards, et al., 2011) (see Figure 48.3, left and right).

Inflammatory and immune mechanisms may be the common link between the pathogenesis of depression and MS, as was suggested in the case of stroke. Proinflammatory cytokines are increased in patients with MS as well as in patients with primary depression (Vattakatuchery, Rickards, et al., 2011). Although small sample sizes limit definitive

Figure 48.3 Patient with chronic dysthymia and multiple sclerosis. MRI on left shows axial flair image; MRI on right shows coronal T1 image.

conclusions, a few studies have found a correlation between the production of interferon gamma (INF- γ) and TNF- α in MS-related depression (Kahl, Kruse, et al., 2002). The mechanism by which cytokines cause depression may be related to cytokine modulation of serotonin. In animal and experimental models, cytokines such as TNF- α are found to upregulate the expression of the SERT protein, which in turn decreases availability of serotonin in the synapse (Vattakatuchery, Rickards, et al., 2011).

Complicating the relationship between depression and MS is the finding of worsening depression in patients treated with interferon. Immunomodulatory therapies remain a mainstay of treatment of MS, and one of these treatments, INF- β , had been associated with an increased risk of depression. While subsequent studies have not shown INF-beta to cause depression, INF- α used in treatment of diseases such as hepatitis C does result in depression in some patients (Myint, Schwarz, et al., 2009). These findings help support the idea that cytokines are involved in etiology of depression. In addition, the finding that this is specific to certain interferon treatments, but not to INF- β used in MS, helps differentiate MS-related depression from iatrogenic or treatment-induced depression (Vattakatuchery, Rickards, et al., 2011).

There are additional psychological factors in the etiology of MS-related depression. Although studies investigating a relationship between severity of illness and depression have found conflicting results, there is no doubt that MS leads to loss of functioning and that the unpredictable nature of the illness can leave patients feeling hopeless or out of control (Vattakatuchery, Rickards, et al., 2011). The types of coping strategies employed by patients can have a significant impact on the development of depression. Specifically, escape-avoidance strategies lead to higher incidence of depression, compared to cognitive reframing and active problem-solving strategies that lead to decreased depression (Mohr, Goodkin, et al., 1997). The finding that anxiety and depression are higher in patients during the first year after the diagnosis of MS supports the

“illness representation” model of dealing with disease. In other words, the patient’s view of the illness and beliefs about their own personal identity can influence the likelihood of developing anxiety and depression (Vattakatuchery, Rickards, et al., 2011).

Treatment

The Goldman Consensus Group statement on depression in MS advocates a combined psychotherapeutic and pharmacological approach to this disease (Goldman Consensus Group, 2005). As with primary depression, cognitive-behavioral therapy can play an important therapeutic role (Larcombe & Wilson, 1984). In moderate to severe cases of major depressive disorder in MS, antidepressants are recommended and usually effective; however, the only two double-blind randomized placebo-controlled trials of antidepressants in MS-related depression, one with desipramine and one with paroxetine, showed only modest to questionable benefit (Koch, Glazenborg, et al., 2011). Tolerability may have been a limiting factor in these studies; tricyclic antidepressants (TCAs) such as desipramine and paroxetine are often associated with more side effects than non-paroxetine SSRIs. In general, tolerability of the anticholinergic properties of TCAs may be an issue in MS patients, many of whom already deal with bladder dysfunction. The sexual dysfunction related to SSRIs can also pose a problem in this sensitive patient population.

Electroconvulsive therapy (ECT) has alleviated depression in some patients with MS. Although the majority of case studies suggest that ECT is safe, effective, and well tolerated in this population (Rasmussen & Keegan, 2007; Pontikes & Dinwiddie, 2010), there is one report of a depressed patient with active MS lesions who had a worsened neurological outcome after ECT. Before the use of ECT for MS-related depression, patients should undergo a gadolinium-enhanced MRI scan to rule out active lesions (Mattingly, Baker, et al., 1992).

Prevalence and Risk Factors

The rates of bipolar disorder and mania are estimated to be twice as common, at approximately 2% in MS versus 1% in the general population. Although other symptoms in MS, such as pathological laughter and crying, euphoria, and corticosteroid-induced mania, may be mistakenly diagnosed as bipolar disorder, studies that have taken this into account still find higher rates of bipolar illness among patients with MS (Iacovides & Andreoulakis, 2011). Unlike in the case of depression, bipolar disorder in MS does seem to be more prevalent in those with a family history of bipolar disease (Feinstein, 2004).

Diagnosis and Clinical Course

Mania in MS may be indistinguishable from mania in primary bipolar disorder. There are several case reports describing patients with the initial presentation of mania who were misdiagnosed with primary bipolar disorder. A key study by Lyoo and colleagues (1996) found that, of 2,783 patients admitted to a mental hospital over a six-year period, 23 (0.83%) had findings consistent with MS on MRI. Many of these patients had mania or bipolar symptoms. The authors also found that the patients with likely MS had a greater length of hospital stay on index admission compared to those without the MS lesion findings (Lyoo, Seol, et al., 1996). This result suggests that, in patients whose manic symptoms do not resolve within expected time frames, a search for secondary causes such as MS is indicated.

Several case reports indicate the resolution of manic episodes with traditional treatments for bipolar disorder, including mood stabilizers. Unlike in stroke patients, mania can be part of a bipolar course with multiple episodes of mania occurring throughout the lifetime. Manic and euphoric episodes in MS are also associated with increased cognitive decline (Feinstein, 2004).

Etiology

As is the case with all psychiatric disorders, including bipolar disorder, found in the setting of MS, the etiology is likely to be multifactorial. Genetic predisposition, lesion location, and cortical atrophy all play a role. Genetic factors include the presence of certain Human Leukocyte Antigen (HLA) antigens in families with both MS and bipolar illness (Schiffer, Weitkamp, et al., 1988; Bozikas, Anagnostouli, et al., 2003). While studies are inconclusive, psychotic mania appears to be associated with MS plaques in the bilateral temporal lobes, possibly due to limbic involvement (Paparrigopoulos, Ferentinos, et al., 2010). As with stroke, lesions of the right frontal lobe can result in manic symptoms. In addition, the demyelination of orbitofrontal circuits can lead to mania-like behavior from disinhibition, impulsivity, and socially inappropriate acts (Asghar-Ali, Taber, et al., 2004). There may be a further association between cortical atrophy and reduced overall gray matter volume and the development of euphoria in MS (Paparrigopoulos, Ferentinos, et al., 2010).

Mood stabilizers and antipsychotics are the primarily interventions for MS-related mania. Lithium has been effective in managing mania in many patients with MS. In contrast, patients with mania due to MS may show delayed or limited response to conventional psychotropic medications (Asghar-Ali, Taber, et al., 2004). There may be an additional benefit of treating the underlying MS with high-dose corticosteroids or immunomodulatory therapies (Asghar-Ali, Taber, et al., 2004; Thone & Kessler, 2008). Euphoria by itself, without mania or pathological affect, a much more frequent presentation of MS, may not require or respond to psychopharmacological intervention (Feinstein, 2004).

FATIGUE

Prevalence and Diagnosis

Perhaps the most common symptom of MS is fatigue, occurring in at least 75% of patients at some point in the course of their illness (Braley & Chervin, 2010). Fatigue contributes to substantial disability and loss of work hours. No universal definition of fatigue exists, as it is more of a subjective experience. Some definitions found in the literature include a "subjective feeling of exhaustion, not improved by bed rest," "lack of energy," and "tiredness." Many authors divide fatigue into mental and physical varieties. Alternatively, fatigue can be divided into central and peripheral types, with MS fatigue representing a central fatigue because it results from central nervous system disease (Cantor, 2010). In contrast, peripheral nervous system fatigue, such as that found in myasthenia gravis, is more easily understood and quantified (Cantor, 2010).

In asking patients about fatigue, a positive answer should be followed by questions to look for depression or primary sleep disorders. Scales for fatigue can be helpful, such as the Krupp's Fatigue Severity Scale and the Modified Fatigue Impact Scale, both of whom have been validated in MS patients; the Epworth Sleepiness Scale; and the Chalder Fatigue Scale (Braley & Chervin, 2010). After other conditions are ruled out, one of these above scales may be useful to monitor the level of fatigue and the treatment response.

Etiology

Among patients with MS, some of the same mechanisms involved in the production of depression play a role in their fatigue. These include cytokine and endocrine changes. Among the cytokines, INF- γ and TNF- α are potential contributors to fatigue as they are increased in MS patients with fatigue compared to those without fatigue (Braley & Chervin, 2010). The HPA axis is also implicated, as low cortisol and Dehydroepiandrosterone (DHEA) levels occur in chronic fatigue syndrome. Axonal loss with resulting decreased or altered cerebral metabolism can contribute to fatigue (Braley & Chervin, 2010). MRI studies suggest that frontal or parietal cortical atrophy plays a role in MS-related fatigue (Pellicano, Gallo, et al., 2010). Positron emission tomography (PET)

imaging shows decreased glucose metabolism in frontal cortex and basal ganglia in MS patients with fatigue compared to those without fatigue (Roelcke, Kappos, et al., 1997).

Sleep disorders are another potential contributor to fatigue, with poor-quality sleep leading to daytime fatigue. The prevalence of restless leg syndrome in MS is greater than that of the general population, and this contributes to disrupted sleep. If an MS lesion is located in the medullary respiratory centers of the reticular formation, it can lead to central type sleep apnea (Braley & Chervin, 2010). Sleep disruption is also related to medications, pain, depression, anxiety, and spasticity (Braley & Chervin, 2010).

Treatment

There have been several studies investigating amantidine, modafinil, pemoline, and other medications for the treatment of fatigue in MS. Pemoline has not proven to be of any benefit in this condition, but studies with this drug are limited. Placebo-controlled trials for both amantidine and modafinil show some modest, but positive results (Braley & Chervin, 2010). There are no clear data on the use of methylphenidate or amphetamine in MS-related fatigue. The effectiveness of these medications can be enhanced in combination with non-pharmacological interventions, including exercise programs and cooling devices (Braley & Chervin, 2010).

OTHER NEUROPSYCHIATRIC MANIFESTATIONS

Other behavioral manifestations of MS are catatonia, pathological laughter and crying, euphoria, anxiety, psychosis, and personality changes beyond eutonia or euphoria (Feinstein, 2004). In addition, cognitive dysfunction is a key neuropsychiatric complication of MS (Kaplan & Sadock, 1995; Feinstein, 2004).

CLINICAL PEARLS

- Common neurological causes of depression include left frontal strokes, MS, Parkinson's disease, Huntington's disease, Alzheimer's disease and other dementias, and epilepsy.
- Neurological causes of mania are right hemisphere strokes, MS, Parkinson's disease after dopaminergic treatment, Huntington's disease, and trauma.
- Among all the possible psychiatric or behavioral manifestations, post-stroke, depression is consistently the most prevalent. The prevalence of PSD is approximately 33%, a rate much higher than in the general population.
- Depression itself has also been found to be associated with an increased risk of stroke (Dong, Zhang, et al., 2011).
- The severity of depression in the acute post-stroke period is related to distance of the anterior border of the lesion from the left frontal pole (Robinson, Kubos, et al., 1984; Kaplan & Sadock, 1995; Narushima, Kosier, et al., 2003).
- Patients with depression specifically associated with cerebral microvascular disease or extensive deep white matter and periventricular hyperintensities on MRI have prominent psychomotor slowing, executive function deficits, and relatively poor long-term outcome (Yamashita, Fujikawa, et al., 2010).
- The SIDI is a scale specifically designed for PSD (Roger & Johnson-Greene, 2009).
- Acute-onset PSD occurring days to less than three months after a stroke may remit; however, late-onset PSD occurring after three months is likely to persist and display a more chronic course (Lokk & Delbari, 2010).
- Suicidal thoughts are frequent after a stroke, as evidenced by an overall rate of suicidal ideation of 15% (Santos, Caeiro et al., 2012).
- PSD is more common in those patients with certain *SERT* gene polymorphisms (Kohen, Cain, et al., 2008).
- Despite debate, mania after stroke tends to be more frequent after right-sided lesions involving frontal lobe, temporal lobe, or caudate nucleus.
- The majority of cases of mania appear immediately after the stroke, with approximately 53% occurring in the first few days. Another 23% of mania cases occur within the first month following the stroke (Santos, Caeiro, et al., 2011).
- Strokes involving the medial frontal region and anterior cingulate and the caudate nuclei can result in a frontal apathic-abulic state. After finding that lesions of the posterior limb of the internal capsule were also associated with apathy, Starkstein and associates concluded that damage to the frontal-subcortical networks plays a prominent role in the development of this condition (Jorge, Starkstein, et al., 2010).
- The prevalence of depression is more common in MS than in several other neurological diseases, even in diseases with a comparable amount of loss in function, suggesting that a biological mechanism is involved. In addition, risk of suicide is unfortunately high compared with other neurological disorders (Goldman Consensus Group, 2005).
- Although other symptoms in MS, such as pathological laughter and crying, euphoria, and corticosteroid-induced mania, may be mistakenly diagnosed as bipolar disorder, studies that have taken this into account still find higher rates of bipolar illness among patients with MS (Iacovides & Andreoulakis, 2011).
- Demyelination of orbitofrontal circuits can lead to mania-like behavior from disinhibition, impulsivity, and socially inappropriate acts (Asghar-Ali, Taber, et al., 2004).

- Prevalence of restless leg syndrome in MS is increased compared to that of the general population.
- In MS-related fatigue, placebo-controlled trials for both amantadine and modafinil show some modest, but positive results (Braley & Chervin, 2010). There are no clear data on the use of methylphenidate or amphetamine in MS-related fatigue.

BRAIN TUMOR

Donna B. Greenberg

INTRODUCTION

Patients with brain tumors face the emotional challenge of cancer and mortality along with a threat to their neurological function and their very identity. The great variability in the likelihood of tumor progression and its pace brings anxiety and uncertainty. Some brain tumors have a relatively benign prognosis and cause problems disproportionately less than the fears they engender in patients and their families. The poor prognosis of others makes palliative care an early consideration. Finally, brain tumors can be histologically benign but cause major symptoms and functional impairments because of their location in the brain.

PRIMARY BRAIN TUMORS

Primary brain and other nervous system tumors are relatively rare (incidence of 8 per 100,000) compared to lung cancer, for instance (85 per 100,000). More than 213,500 primary brain and nervous system tumors were diagnosed between 2004 and 2007, and 36% were malignant. The incidence of neuroepithelial malignant brain and nervous system tumors has been essentially stable over the 20 years from 1987 to 2007. Risk is related to hereditary tumor syndromes like neurofibromatosis, increased familial risk, and ionizing radiation (Kohler et al., 2011). There is no evidence for short-term risk of cellular telephones producing brain cancer, and the long-term risk is yet to be fully studied (Corle et al., 2012). The known risk factors highlight the importance of family history and personal history of brain cancer as well as history of radiation exposure in judging who would be more likely to develop a brain tumor.

Primary neuroepithelial tumors include astrocytic, oligodendroglia, and oligoastrocytic tumors, and ependymal and choroid plexus tumors. There are also neuronal and mixed neuronal-glial tumors, pineal tumors, embryonal tumors like medulloblastoma, and primitive neuroectodermal tumors (PNET). In addition, lymphomas and germ-cell tumors can present in the central nervous system (CNS); and craniopharyngiomas develop in the region of the sella. Here we will focus on primary meningiomas and gliomas, then CNS lymphoma, and brain metastases.

MENINGIOMAS

Meningiomas are the most common primary brain tumor. They arise from the dura and most are intracranial. The majority are found in parasagittal regions, the sphenoid ridge, tubercle of the sella turcica, and in the convexity of the brain. The lateral ventricle, olfactory groove, falx, cerebellar tentorium, middle fossa, and orbits are less common sites (Fathi & Roelcke, 2013). The incidence rises with advancing age (Niira et al., 2000; Go, Taylor, & Kimmel, 1998). Most are asymptomatic and remain the same size or grow very slowly. They are resected for symptoms. Meningiomas may recur once resected and may (rarely) be malignant. Half of patients with neurofibromatosis type 2 develop meningiomas. Those that grow large may have diffuse effects and behavioral symptoms, especially when affecting the frontal or temporal lobe. While patients are anxious before surgery, rates of depression after successful surgery are similar to population norms (Goebel & Mehdorn, 2013).

GLIOMAS

Gliomas are tumors of the neuroglia, the cells that surround and support the neurons of the brain. Gliomas are graded according to their histology and described by their location, size, and grade. Gliomas can begin as low-grade tumors that grow slowly over many years, then transform into (secondary) highly malignant, rapidly progressive tumors. Gliomas infiltrate the brain, so that resection of the visible tumor often is insufficient to completely remove the malignancy. These low-grade gliomas (World Health Organization [WHO] grades I and II)—diffuse astrocytomas, oligodendrogliomas, and mixed oligoastrocytomas—include about 15% of primary brain tumors. The 10-year cumulative survival of supratentorial low-grade gliomas is 43%, and 20-year survival is 26%, so for many they act as a chronic neurological disease (Claus & Black, 2006). The best prognosis occurs with complete resection and with frontal and parietal locations. Low-grade gliomas may be biopsied, resected (Batchelor, 2014), followed with imaging, and treated with chemotherapy intermittently when growth is noted. More rapid growth may occur as time goes on, and then chemotherapy treatments are intensified.

High-grade, rapidly progressive gliomas include anaplastic oligodendroglioma, mixed anaplastic oligoastrocytoma, anaplastic astrocytomas (WHO grade III), and glioblastoma (WHO grade IV). Pure oligodendroglioma has the best outcome and responsiveness to treatment (Stupp et al., 2014). Isocitrate dehydrogenase gene (IDH) mutations are associated with better prognosis. The standard of care for aggressive tumors like glioblastoma includes immediate upfront multi-modal treatment with surgery, radiation, and chemotherapy.

CNS LYMPHOMA

Primary CNS lymphoma represents 4% of newly diagnosed brain tumors. Because lymphoma occurs in the setting of immunodeficiency, the incidence rose when HIV/AIDS was more rampant and untreated, peaking in the mid-1990s. Psychiatric presentations occur in 43% as insidious personality changes, depression, apathy, psychosis, or confusion. Visual hallucinations may be related to infiltration of visual pathways, eye, or leptomeninges (Bataille et al., 2000; Hochberg et al., 2014). If primary CNS lymphoma is suspected, a brain biopsy should precede use of corticosteroids that might alter the biopsy, preventing specific diagnosis.

BRAIN METASTASES

More than half of all brain tumors are metastases from a primary tumor. Now that systemic treatment has improved, and patients live longer, there is more opportunity for brain metastases to develop. The majority occur in the cerebral hemispheres. Metastases occur preferentially at the junction of gray and white matter where the diameter of vessels decreases and traps clumps of tumor cells. They are more common in the watershed areas or border zones between areas of cerebral circulation (Gavrilovic & Posner, 2005).

The rate that brain metastases are diagnosed in life is 20% for lung cancer, 7% for melanoma and renal, 5% for breast, 1–2% in colorectal cancers (Barnholtz-Sloan et al., 2004). The metastatic brain tumors most likely to bleed and therefore to present with stroke are melanoma, choriocarcinoma, thyroid, and renal cancers (Lacy et al., 2012). Brain metastases occur rarely in ovarian cancer, prostate cancer, testicular cancer, esophageal cancer, soft tissue sarcoma, and thyroid cancer (Gavrilovic & Posner, 2005).

PRESENTING SYMPTOMS OF BRAIN TUMORS

Headache occurs in almost half of patients with primary brain tumor, most often tension-type headache, more rarely migrainous headache, typically bifrontal but worse on one side. Nausea and vomiting, a change in headache characteristics or temporal pattern from those the patient has had in the past, and positional worsening with bending forward are clues to a mass. Classic early morning headaches are uncommon as

a presenting sign (Forsyth & Posner, 1993), but the headache may awaken the patient from sleep (Omuro & De Angelis, 2013). Change in personality or memory problems are presenting factors in 30–35% (Chang et al., 2005). Less often, stroke from hemorrhage is a presenting symptom in tumors with the tendency to bleed. Nausea, vomiting, papilledema, lethargy, confusion, and signs of increased intracranial pressure require imaging to rule out brain tumor regardless of age (Sivani et al., 2011).

TUMORS HIDDEN BEHIND PSYCHIATRIC ILLNESS

To the extent that patients with brain tumors can present with psychiatric syndromes and a relative absence of neurological findings, psychiatrists are concerned about missing the diagnosis. Chronic persistent headache, a change in headache, or cognitive impairment—slowed thinking, memory loss, and difficulty with multitasking—accompanying more common affective symptoms may be clues. Atypical presentations of typical psychiatric syndromes, treatment resistance, and a recent change in psychiatric presentation should add to suspicion (Madhusoodanan et al., 2007). The availability of imaging in the modern day may have eased worry about a missed diagnosis, but some patients are labeled as having non-organic psychiatric illness without brain imaging, and it is the psychiatrist who must make a decision to look at the patient with a full neurological examination, neuropsychiatric testing, neurological consultation, or to get a brain MRI with contrast. A recent large meta-analysis of published case studies (Subramoniam et al., 2010) did not find a link between specific psychiatric symptoms and location of the tumor in most cases, but found that early mental symptoms occurred in 18% of patients with supratentorial tumors and 5% of infratentorial tumors. Anorectic symptoms and consideration of anorexia nervosa were significantly associated with hypothalamic tumors (Goddard et al., 2013). The neurobehavioral findings of patients with frontal lobe tumors include abulia, personality change, and depression, in contrast to patients with temporolimbic tumors, who present with auditory and visual hallucinations, mania, panic attacks, or amnesia (Fillee & Kleinschmidt-DeMasters, 1995).

TREATMENT

SURGERY

The neurosurgeon in planning treatment for a brain tumor considers the anatomy and the tumor's proximity to vital structures. The quality of a biopsy is key to treatment planning in the modern day—for both reliable tumor-grading and for full molecular characterization. In glioblastoma patients, resection is the first goal; the extent of resection is a predictor of survival (Huang et al., 2013). Surgical resection leads to the best outcome for low-grade glioma as well (Jakola et al., 2012). In patients with benign tumors, the decision for resection

depends on whether symptoms can be alleviated and comorbid complications minimized.

Surgery is a consideration for an isolated brain metastasis in the setting of a younger patient with good function (Kalkanis et al., 2010). Furthermore, resection of multiple lesions or recurrent lesions is a consideration with or without whole-brain radiation treatment if the tumor is causing a mass effect, if it is accessible, and if it is larger than 30–40 mm. Surgery is coordinated with options for radiation treatment. It is also used when the diagnosis is uncertain and the pathology is known to be radiation-resistant (Owonikoko et al., 2014). Surgical resection may be the only approach to cerebellar lesions particularly if they are large and threaten to cause herniation.

Advances including the use of an operating microscope, real-time correlation of intra-operative findings with intra-operative MRI, and intra-operative dyes that highlight neoplastic tissue have refined the precision of biopsy and tumor removal. Language centers can be preserved if identified by cortical mapping and stimulation when the patient is awake and asleep. Subcortical mapping and diffusion tensor imaging-based tractography map motor pathways.

RADIATION TREATMENT

External beam radiation treatment (RT) requires positioning of the patient on a flat table and immobilization with a thermoplastic mask. The table can move such that more than one beam can aim at the targeted tumor, with the most intense radiation occurring at the intersection of the beams (Huang et al., 2013). Computerized tomography information describes the shape of the tumor and relative density of tissues, so that an RT-planning computer can devise the program. Three-dimensional conformal RT or intensity modulated radiation treatment (IMRT) modulates the intensity of each beam and delivers doses that match complex tumor shapes to reduce damage to healthy tissues near the tumor. Thin beams of radiation of different intensities are aimed at the tumor from many angles. Imaging techniques can be combined with planning to offer image-guided radiotherapy. This treatment is typically done five days per week for several weeks. Stereotactic radiosurgery (SRS) is a form of RT, delivering high doses with precision, using a rigid immobilization device, like a head frame or face mask. The goal is obliteration of a tumor less than 3 cm in a one- to five-day treatment. Sometimes automated robotic devices adjust the patient's position (Huang et al., 2013). SRS is used on focal metastatic lesions to limit or to delay toxicity from whole-brain radiation. It has shown benefit for patients with one to three lesions and is considered for patients with more than three (Owonikoko et al., 2014).

These treatments are difficult for patients who have claustrophobia or anxiety about being immobilized. Several technical modifications for claustrophobic patients have been evaluated (Kim et al., 2004). Relaxation training, urgent behavioral treatments, and/or premedication with benzodiazepines can help phobic patients tolerate the treatment. All these psychological modalities may be used in advance to reduce anticipatory anxiety and to facilitate treatment as it is planned.

CHEMOTHERAPY

Some chemotherapy drugs, like temozolomide, cross the blood–brain barrier, but others have been delivered by intrathecal or intraventricular methods or by chemotherapy-impregnated wafers.

Glioblastoma

In a practice-changing study in 2005, the addition of temozolomide to radiotherapy for newly diagnosed glioblastoma led to a clinically meaningful and statistically significant survival benefit with minimal toxicity (Stupp et al., 2005). That regimen of chemoradiation—post-operative radiation (60 gray [Gy] divided in 30 fractions) with temozolomide initially and then adjuvant six cycles of five days of temozolomide every four weeks—prolonged progression-free and overall survival and is currently the preferred treatment for all age groups (Stupp et al., 2005; Stupp et al., 2009; Hart et al., 2013). In the signal study, with radiation and chemotherapy, the two-year survival rate was 27%, versus 10% with only radiotherapy. The prognosis is still poor, however, with a five-year survival rate of 17% in patients younger than 50. Tumors with methylation of the promoter for methylguanine methyltransferase (MGMT) were more responsive to temozolomide. The outcome for glioblastoma with radiation and temozolomide for the MGMT-positive group was a 49% two-year survival (Stupp et al., 2009). A similar treatment is often recommended for anaplastic astrocytoma, but the contributions of chemotherapy and/or radiation treatment are not yet clear. The third category, anaplastic oligodendroglioma, has a somewhat better prognosis than anaplastic astrocytoma (Batchelor, 2014; Stupp et al., 2014). Salvage chemotherapy includes bevacizumab; temozolomide again; carmustine, lomustine, and carboplatin (Omuro & De Angelis, 2013). Other targeted drugs are under development.

Half of patients with glioblastoma are over age 65, and their prognosis is related to performance status and age. For the older patient with other medical comorbidities, treatment can include temozolomide alone, hypofractionated RT alone, best supportive care, or whole-brain RT for urgent relief of symptoms (Arvold & Reardon, 2014).

Primary CNS Lymphoma

Methotrexate, high-dose systemic treatment, is the backbone of induction treatment for CNS lymphoma. This may be combined with cytarabine, or a combination of rituximab and temozolomide (Hochberg & Batchelor, 2014). RT is deferred.

Brain Metastases

Systemic chemotherapy and targeted drugs that offer hope of treating brain metastases, often as part of the treatment for systemic disease, include gefitinib, erlotinib, and crizotinib in non-small cell lung cancer; and lapatinib and capecitabine for human epidermal growth factor receptor (HER)-2 positive breast cancer. Dabrafenib and vemurafenib,

(BRAF)-inhibitors used for BRAF-mutant melanoma and ipilimumab, have shown promise in treating CNS disease in melanoma (Owonikoko, 2014).

ISSUES IN CARE

PROGRESSION VS. PSEUDOPROGRESSION

One of the difficulties of care for patients with glioblastoma and their physicians is that the assessment of the response to treatment or the progression of tumors can be ambiguous. *Pseudoprogession* is transient radiographic worsening occurring up to four months after RT. This occurred in 21% of patients in the glioblastoma treatment study (Stupp et al., 2005) with RT and temozolomide compared to 90% with RT alone. More pseudoprogession is seen in MGMT-positive patients. Treatment is often continued if progression is not definitive (Batchelor & Loeffler, 2014). The patient has regularly repeated scans to assess the state of the tumor, and coping with ambiguity and uncertainty is a regular challenge for the patient and family.

THROMBOEMBOLIC DISEASE

Patients with brain tumor are at greater risk of veno-occlusive disease and pulmonary embolism. Therefore, clinicians should be alert to signs of clots. The risk of spontaneous bleeding in the tumor is low, except in patients with metastases of tumors prone to hemorrhage, including melanoma, choriocarcinoma, thyroid carcinoma, and renal carcinoma. Prophylactic anticoagulation is not recommended but the presence of a brain tumor does not contraindicate anticoagulant treatment for thrombosis that has been proven (Jenkins et al., 2010; Gerber et al., 2006; Stupp et al., 2014).

SEIZURES

Brain tumor patients present with a seizure 20–40% of the time, and another 20% have at least one or more during their course of treatment. Primary tumors are more apt to cause seizure than metastases (Wen, 2006; Lacy et al., 2012). The most benign neuroepithelial tumors have the highest risk of seizure. If the tumor is in the temporal and insular cortex, the rate of developing epilepsy is higher (Kerkhof & Vecht, 2013).

Low-grade gliomas have a 70–90% incidence of seizure, while glioblastoma rates of seizure range from 30% to 62% (Kerkhof & Vecht, 2013; Lote et al., 1998). Both simple and complex seizures with or without generalization are seen. An electroencephalogram has two roles: to see if unexplained symptoms may be caused by subclinical seizures and to determine if delirium is caused by status epilepticus (Omuro & De Angelis, 2013). Management of persistent seizures is key to quality of life in low-grade glioma patients who have a chronic course (Shields & Choucair, 2014).

Short-term prophylaxis with a newer anti-epileptic drug is appropriate for patients having brain surgery, to prevent early post-operative seizures (Rossetti & Stupp, 2010; Glantz et al.,

2000). Levetiracetam is the most common drug currently used. How long the drug is continued is not well defined, (Chang et al., 2005), but generally anti-seizure drugs are tapered beginning one or two weeks after tumor resection and discontinued in those who do not have a seizure (Kuijlen et al., 1996; Chang et al., 2008; Fuller et al., 2013).

In patients with brain tumors who have not had a seizure, anti-epileptic drugs are not recommended, as there is no evidence of prophylactic benefit (Sirven et al., 2004; Mikkelsen et al., 2010; Tremont-Lukats et al., 2008; Stupp et al., 2014). Anti-epileptic drugs are not required for posterior fossa tumors (Wen et al., 2006). For those who have had a seizure, anticonvulsants are continued as long as the brain tumor is present, better at low doses in the setting of partial resection, with stable and controlled seizures (Rossetti & Stupp, 2010; Drappatz et al., 2014).

When anticonvulsants are required, levetiracetam, pregabalin, lamotrigine, lacosamide, and topiramate are preferred rather than older anticonvulsants like valproate that affect the cytochrome P450 system and have more drug interactions and toxicity (Lacy et al., 2012).

For the psychiatrist following a patient with a brain tumor who is on levetiracetam, the most common clinical question is whether irritability is due to this drug and whether an anticonvulsant switch is warranted. Irritability is reported in 6–12% of patients on levetiracetam. In a study comparing phenytoin and levetiracetam perioperatively, levetiracetam had only mild mood effects (Fuller et al., 2013). Helmstaedter and colleagues (2008) found a moderate increase in aggression, loss of self-control, restlessness, and sleep problems in 25 percent of 288 consecutive epilepsy patients taking levetiracetam and more severe symptoms in 12%. These symptoms were independent of dose, but associated with poorer seizure control, mental retardation, and a psychiatric disposition of impulsivity. When irritability and aggression are problematic symptoms in patients with brain tumors, it is worth considering a change of anticonvulsant; however, the ease of treatment with levetiracetam, and the lack of need for frequent blood levels, has made it the default choice. Lamotrigine is an alternative that has beneficial effects on mood. Reports related to anxiety for most anticonvulsants are mixed (Piedad et al., 2012).

CEREBRAL EDEMA

Cerebral edema comes with tumor presentation, tumor progression, RT, and steroid withdrawal. The vessels in the brain are more permeable when the blood–brain barrier is disrupted, so that plasma fluid and proteins move into the brain parenchyma and interstitial fluid. Headache, lethargy, and confusion are symptoms. The symptom of dizziness can increase with the Valsalva maneuver or upon standing, due to transient increases in pressure associated with near syncope. The risk is herniation of the cerebellar tonsils through the foramen magnum and death (Lacy et al., 2012). Disruption of the blood–brain barrier is noted when gadolinium seeps through breaks in blood–brain barrier into areas of parenchymal enhancement noted on

post-contrast T1 sequences of the MRI. Edema is seen as hyperintensity on T2 images and fluid attenuated inversion recovery (FLAIR) sequences without contrast. To complicate matters, hyperintensity is also seen with infiltrative non-enhancing tumor or post-treatment gliosis (Lacy et al., 2012).

CORTICOSTEROIDS

Dexamethasone is the treatment of choice for cerebral edema. Dexamethasone 4 mg orally every 6 hours is usually given for moderate symptoms. If herniation is not a risk, 4 mg or 8 mg per day may work and can be used for mild symptoms (Vecht et al., 1994). The half-life of dexamethasone is actually longer than six hours. Improvement occurs within hours to several days. A taper should occur at 50% reduction of the previous dose, tapered to the dose that preserves neurological function.

Toxicity of steroids is related to dose and duration. After 7 or 28 days of the full dose of 16 mg per day, brain tumor patients suffer proximal weakness (38%), peripheral edema (26%), hypertension 26%, gastrointestinal (GI) side effects, and change in mental status 21% (Vecht et al., 1994). Hyperglycemia is common.

Gastrointestinal Side Effects

Proton pump inhibitors as prophylaxis against ulcer or gastritis are preferred for patients with a history of ulcer, in the perioperative period and in patients taking non-steroidal anti-inflammatory agents (Kostaras et al., 2014; Lacy et al., 2012).

Psychiatric Side Effects

The medical psychiatrist can be helpful in evaluation and treatment of psychiatric side effects of corticosteroids. With steroids alone, in the absence of the trauma and disability of a brain tumor, patients can develop insomnia, manic-like symptoms, psychosis, and depression. Mood stabilizers like atypical antipsychotics may be helpful for emotional lability. Antidepressants may be necessary for typical syndromes of major depressive disorder. Cessation of steroids does not cause immediate improvement of psychiatric side effects, so psychotropic drugs have a role in the interval.

Steroid Myopathy

Steroid myopathy correlates with Cushingoid appearance and tends to occur after two to twelve weeks of treatment. Weakness is seen in proximal muscles bilaterally, in the legs more than in the arms. Therefore, patients may need help getting up from a low seat and have trouble climbing stairs; they may have difficulty doing things with their arms above their heads. Although the role of exercise in repair of myopathy is limited, physical therapy may be an important factor in the maintenance of mobility and quality of life (Pereira & de Carvalho, 2010).

Pneumocystis Prophylaxis

Patients under treatment with chemotherapy and RT, often also on corticosteroids, are immunodeficient and prone to pneumocystis pneumonia. Prophylaxis against pneumocystis makes trimethoprim-sulfamethoxazole, atovaquone, dapsone, or pentamidine a recommended part of the treatment (Kelly & Cronin, 2014).

COMPLICATIONS OF SURGERY

Infection and hematoma are common complications of surgery; others (less common) are hydrocephalus, pseudomeningocele, and posterior fossa syndrome (mutism, emotional lability, difficulties initiating movement). Posterior fossa syndrome is seen mostly in children after posterior fossa surgery; for instance, for medulloblastoma. Children with midline tumors and brainstem invasion are more at risk. Language, thinking, and balance disturbances may persist beyond one year, with incomplete recovery (Korah et al., 2010). Risperidone has been used in these children for irritability and difficulty with speech; study of its benefit is in progress.

COMPLICATIONS OF RADIATION TREATMENT

Side effects of RT depend on treatment location, fraction size, total dose, target volume, and technique. The dose and type of radiation are defined to minimize injury to normal tissue. Radiation is avoided in children less than three years old. Partial brain radiotherapy with doses of 50 to 60 Gy is associated with a low incidence of late neurocognitive decline (Armstrong et al., 2002; Brown, 2003). SRS treatment without whole-brain radiation causes less neurocognitive decline in function than does whole-brain RT with SRS (Tsao et al., 2012). Studies of hippocampal-sparing techniques are now in progress to reduce the neurocognitive toxicity of whole-brain radiation (Gondi et al., 2010; 2012).

The acute side effects of brain radiation include cerebral edema, and then within a few weeks, early demyelination. Corticosteroids are the main treatment for the symptoms of headache, neurocognitive and focal neurological deficits, and seizures. Patients can develop a transient cognitive decline, fatigue during treatment, and somnolence, which can persist for several months. Pseudoprogession, as noted above, is a radiation effect that tends to occur in the first three months after treatment, sometimes with neurological findings. Because the symptoms are sleepiness and exacerbation of tumor-related symptoms, the syndrome is difficult to distinguish from tumor growth (Wen et al., 2010; Patel et al., 2011). Complications six months to three years after whole-brain RT include asymptomatic white matter lesions, and diffuse white matter injury.

Leukoencephalopathy after whole-brain RT has an incidence of 34% if the patient is followed for more than six months; older age is a risk factor (Ebi et al., 2013). The process is thought to be related to accelerated atherosclerosis and mineralizing microangiopathy from small-vessel disease.

Gradual pituitary-hypothalamus dysfunction, hypothyroidism, hypogonadism, and growth hormone deficiency are also seen as a consequence of radiation. An endocrinologist is often consulted for management of thyroid hormones, reproductive hormones, corticosteroids, and growth hormone replacement. Brain tumor survivors who suffered growth hormone deficiency after treatment have been shown to be similar to patients with growth hormone deficiency from other pituitary pathologies. Their quality of life improved when growth hormone was replaced (Mukherjee et al., 2005).

Radiation necrosis with mass effect and associated progressive neurological dysfunction (Fink et al., 2012) is related to microvascular degeneration and loss of capillary endothelial cells. On imaging, white matter change, ventricular dilatation, and cortical atrophy are noted. While the first treatment for radiation necrosis is typically corticosteroids or sometimes surgery for symptoms, bevacizumab at doses lower than the anti-tumor dose for four treatments has been used (Levin et al., 2011).

Vascular effects of radiation may present as stroke-like migraine attacks. These effects are due to radiation injury, endothelial injury, and their direct effect on oligodendritic progenitor cells (Lacy et al., 2012).

BEVACIZUMAB

Bevacizumab is an antiangiogenic medication often used in the setting of malignant glioma in the hope of blocking microvessel sprout growth and proliferation of endothelial cues in the tumor. In the treatment of recurrent glioblastoma, contrast enhancement can be reduced in hours or days after initiation of bevacizumab. It is unclear whether this is related to tumor response or to treatment-induced reduction of the blood-brain barrier, or both. Furthermore, it is unclear if this drug will alter the pattern of spread of the tumor (Armstrong et al., 2012).

Side effects of bevacizumab include hypertension and proteinuria. Hypertension is best treated with the same principles as general hypertension. The preferred antihypertensive drugs (due to a lack of drug interactions) are amlodipine and felodipine. Angiotensin-converting enzyme (ACE) inhibitors are used when hypertension requires rapid response, and this class of drugs is useful for proteinuria as well.

A complication of bevacizumab is posterior reversible encephalopathy syndrome (PRES). This syndrome is associated with VEGF-sequestering agents and with tyrosine kinase inhibitors targeting VEGF. It resolves with treatment of hypertension and removal of the causative agent. It presents with headache, seizure, confusion, and often cortical blindness. MRI shows T2/FLAIR hyperintensities, mostly in white matter. Lesions are more often seen in the posterior cerebral hemisphere or posterior fossa. The pathogenesis is presumed to be related to cerebral vasomotor autoregulation or preeclampsia-like endothelial damage.

The risk of hemorrhage is increased with bevacizumab. This ranges from epistaxis to more serious bleeding. The risk of intracerebral hemorrhage remains low in patients with brain metastasis, with the exception of tumors like melanoma that

have higher rates of hemorrhage. Because of impaired wound healing, bevacizumab is stopped around surgery. Venous and arterial thromboembolism and bowel perforation are also considerations.

PSYCHIATRIC SIDE EFFECTS AND THEIR TREATMENTS

DEPRESSION AND ANXIETY

Depressive symptoms are common in patients with brain tumors, as many of the symptoms of the tumor or treatment include fatigue, poor concentration, and the challenge of coping with the predicament of diagnosis; as many at 44% are reported to be depressed (Ford et al., 2012). In one series of about 600 patients with high-grade gliomas, 93% reported depressive symptoms (Litofsky et al., 2004). About 15% reported explicitly that they were depressed, and their symptoms increased after surgery. Patients with high-grade gliomas worry about starting treatment and what will ensue; they are demoralized by hair loss, weight gain, fatigue, and lower function (Kilbride et al., 2007). Loss of autonomy is a major difficulty for many patients (Sterckx et al., 2013). In the first six months, radiation effect complicates the diagnosis of major depressive disorder.

Preoperative depression was independently associated with decreased survival in a retrospective review of more than 1,000 astrocytoma patients (Gathinji et al., 2009; and depressive symptoms have also been linked to shorter survival among patients with low-grade glioma (Mainio et al., 2005; Mainio et al., 2006). Patients with low-grade gliomas also have a high prevalence of generalized anxiety, phobia and obsessionality (Arnold et al., 2008; Mainio, 2011). The risk of hospitalization for depression in the first year after a cancer diagnosis was highest for men with brain cancer in a nationwide, population based study of cancer patients in Denmark (Dalton et al., 2009).

COGNITIVE IMPAIRMENT AND INATTENTION

Cognitive impairment may come with subclinical tumor progression and before radiological changes, interfering with patients' communication and ability to make decisions (Ford et al., 2012). The specific impairments vary according to location of the tumor and treatment. One study of patients with brain metastases documented deficits in 91% of patients at baseline, with some improvement in executive function and memory after treatment with fractionated whole-brain radiation. Cognitive function before treatment was inversely related to tumor volume and correlated with better survival (Meyers et al., 2004).

Patients with low-grade gliomas experience long-term cognitive deficits related to the tumor, but also to epilepsy, disease progression, surgery, and radiation therapy (Surma-aho et al., 2001; Taphoorn, 2003). In patients with CNS lymphoma, the cognitive deficits associated with methotrexate-induced leukoencephalopathy, especially when combined with radiation,

have been followed with a standardized battery measuring attention, executive function, memory, and psychomotor speed (Correa et al., 2007).

Patients with tumors in the frontal and temporal lobes are often referred to psychiatry because of the behavioral symptoms and poor executive function that may be associated with their lesion. Disability often leads to loss of a job or profession. Neuropsychiatric testing can highlight particular deficits in memory or attention. The combined power of cognitive rehabilitation, vocational rehabilitation, and individualized psychopharmacological treatment of depression, anxiety, and irritability can be brought to bear by the medical psychiatrist. In children who had multi-modal treatment for brain tumors, cognitive rehabilitation (including attention process training, strategy acquisition, and cognitive behavioral therapy) has been shown to improve academic achievement (Lagenbahn et al., 2013). The data for adults are also suggestive (Butler & Copeland, 2002; Butler & Copeland, 2008; Gehring et al., 2009). Both cognitive deficits and behavioral challenges, including inertia, anger, and inappropriate behavior, have been tackled by teaching the patient self-management skills and compensatory strategies and educating the family and staff, the people around the patient, techniques of behavioral management (Whiting et al., 2012).

Modafinil (Kaleita et al., 2006) has been used for attention and energy (Gehring et al., 2012; Meyers et al., 1998; Weitzner et al., 1995). However, one recent multi-center randomized controlled trial with a crossover design evaluating modafinil up to 400 mg per day did not find that modafinil improvement exceeded that of placebo (Boele et al., 2013).

Methylphenidate has improved attention and energy in adult brain tumor survivors and has also been shown to have benefits of sustained attention over a year for childhood cancer survivors (Conklin et al., 2010). A randomized, double-blind, placebo-controlled crossover trial of methylphenidate in child cancer survivors identified as having attention deficits and learning problems showed a better response with moderate-dose methylphenidate (0.6 mg/kg) in the patients whom parents and teachers noted as having more problems.

Donepezil, an anticholinesterase (AChE) inhibitor, has been tested for treatment of cognitive impairment after radiation. Survivors who have had brain radiation complain of decreased attention and concentration, poor short-term memory, and difficulty with expressive language. A pilot study of patients, mostly with low-grade glioma, more than six months after treatment, given donepezil 5 mg per day for six weeks and then 10 mg per day for 18 weeks, found improved attention/concentration, verbal memory and figural memory, and a trend for verbal fluency (Shaw et al., 2006). Another small, open-trial pilot study of childhood brain tumor survivors more than one year from cancer treatment who had received cranial radiation found that donepezil led to executive function and memory improvements. Some had initial vomiting and diarrhea (Castellino et al., 2012).

Memantine acts as an N-methyl-D-aspartate (NMDA) receptor antagonist and is used for Alzheimer's disease. The Radiation Therapy Oncology Group (RTOG) compared whole-brain radiation treatment with memantine to

whole-brain radiation treatment with placebo, and found less neurocognitive decline in the memantine group (Brown et al., 2013). The dose of memantine began with 5 mg the first week and was increased to 5 mg twice daily in week 2, 10 mg in the mornings and 5 mg in the evenings in week 3, until the 10 mg twice-a-day dose was reached at week 4. That full dose was continued for 24 weeks. Those taking memantine had delayed decline in cognition over time in memory, executive function, and processing speed.

CARE OF CAREGIVERS

The mental well-being of caregivers has a profound effect on the well-being of patients with brain tumors, so consideration of caregiver mental health is an important aspect of psychiatric care. More than 40% of caregivers have depression and anxiety, and patients' mood correlates with their caregivers' mood. Caregivers report challenges like the difficulty of telling others about the diagnosis, and worrying about their role change in a marriage. Relationships have to be renegotiated. Caregivers worry that their loved one might have recurrent seizures and therefore sometimes limit their activities with the patient for fear of seizures. They often find the patient's mood change, change of personality, and cognitive decline more difficult to bear than their physical disabilities. Cognitive impairment increases as the disease progresses, and the loss of the loved one's identity, memory, and awareness, the sense that the patient is "absent," is a major source of grief (Schmer et al., 2008; McConigley et al., 2010; Sterckx et al., 2013).

END OF LIFE

Drowsiness and loss of consciousness are the most common symptoms in the last weeks; in addition, poor communication, focal neurological deficits, seizures, dysphagia, and headaches are frequent (Walbert & Khan, 2014). Steroids are often used in the last weeks. Anticonvulsants may be compounded as a rectal suppository; intranasal or buccal midazolam has also been used to stop seizures (Nakken & Lossius, 2011). Decisions are required around tube feeding, hydration, steroid discontinuation, and palliative sedation (Pace et al., 2009). Dissolving wafers, sublingual and transdermal medications are important in the last days when dysphagia is prominent. Headaches are treated with non-steroidal medications and steroids. Most patients are not deemed competent for decisions in the last weeks. Dying with dignity depends on timely treatment of symptoms, good communication, defining preferences before the patient can no longer communicate, and fewer transitions in the last month of life (Sizoo et al., 2013).

CONCLUSION

In sum, the medical psychiatrist and psychologist have the role of helping the patient deal with existential anxiety in the setting of a malignant brain tumor diagnosis, whether preparing for a short or long course. They remain alert to pharmacological treatment of major depressive disorder as it occurs

in this stressful setting. Distinct attention to the psychiatric side effects of corticosteroids and treatment with mood stabilizers may be critical at times. The organizing structure of physical therapy, particularly for steroid myopathy as the steroids are tapered, can make a difference in the patients' quality of life. Psychotherapeutic discussion includes grief, anger at the illness or between loved ones, adjustments in lifestyle, conservation of emotional and physical energy, and the need to "put things in order" in the context of the patient's values. The factors that sustain a patient's ability to drive a car or require adjustment to the loss of driving, even temporarily, are pertinent. Treatments of anxiety, behavioral and pharmacological, may be particularly important in patients with low-grade tumors who face a chronic course. Anxiety disorder may predate the brain tumor, and the added contribution to the patient's current anxiety may not be as evident to the medical team. For patients who have cognitive deficits after tumor resection or radiation, psychiatrists optimize treatment of depression, clarify cognitive deficits, and make referrals for cognitive rehabilitation. Methylphenidate and modafinil have a role, especially for attentional deficits in survivors. Pituitary dysfunction should not be missed; consideration of hypothyroidism, hypogonadism, adrenal dysfunction, or growth hormone deficiency is something to remember for survivors. The role of memantine and donepezil for preserving or improving memory after brain radiation is under further study.

CLINICAL PEARLS

- The incidence of meningioma rises with advancing age (Niiri et al., 2000; Go et al., 1998). Most are asymptomatic and remain the same size or grow very slowly.
- The rate of brain metastases diagnosed in life is 20% for lung, 7% for melanoma and renal, 5% for breast, 1–2% in colorectal cancers (Barnholtz-Sloan, 2004).
- The metastatic brain tumors most likely to bleed and therefore to present with stroke are melanoma, choriocarcinoma, and thyroid and renal tumors (Lacy et al., 2012).
- Headache, occurring in almost half of patients with primary brain tumor, is most often a tension-type headache, (more rarely) migrainous headache, typically bifrontal but worse on one side. Nausea and vomiting, a change in headache characteristics or temporal pattern from those the patient has had in the past, and positional worsening with bending forward are clues to a mass (Forsyth & Posner, 1993).
- Anti-seizure medication to prevent seizure in a patient with a brain tumor who never had a seizure is not necessary.
- Memantine may have a role in preventing cognitive decline from whole-brain radiation.
- Attentional deficits after treatment may be treated with cognitive rehabilitation and stimulants.

- Hormonal deficits like thyroid, growth hormone, corticosteroids, and reproductive hormones warrant monitoring and endocrine referral after treatment for brain tumor.

ATTENTION-DEFICIT HYPERACTIVITY DISORDER IN MEDICAL ILLNESS

Anna M. Georgiopoulos and Craig B. H. Surman

INTRODUCTION

Attention-deficit hyperactivity disorder (ADHD) is a syndrome involving broad impairment in self-regulation and impacting many dimensions of life pertinent to the comprehensive management of medical patients. ADHD is diagnosed by the presence of functionally impairing inattention, impulsivity, and/or hyperactivity, and its biological basis has been elucidated at a genetic, neurostructural, and neuro-functional level. ADHD occurs in up to 7–9% of children and adolescents (American Psychiatric Association [APA], 2000; Faraone, Sergeant, Gillberg, & Biederman, 2003) and 4–5% of adults (Kessler et al., 2006), but it may be more common in some medically ill populations. In addition to its impact on educational, occupational, and social functioning, ADHD can create barriers to adherence with medical treatment and difficulties in navigating medical systems of care. Psychopharmacological and non-psychopharmacological therapies can substantially reduce associated morbidity.

ADHD DIAGNOSIS ACROSS THE LIFESPAN

The diagnosis of ADHD using *Diagnostic and Statistical Manual of Mental Disorders–5* (DSM-5) criteria requires impairment in two or more life settings (such as school, work, home, or social environments) due to persistent symptoms of inattention, impulsivity, and/or hyperactivity. Symptoms must begin in childhood and not be caused by another medical or psychiatric condition. Diagnostic criteria for ADHD continue to evolve. The majority of intervention research has relied on the DSM-IV definition, which specifically required onset of symptoms by age seven, and at least six current inattentive or impulsive/hyperactive symptoms. Inattentive symptoms include having trouble keeping focused attention on tasks, distractibility, being prone to careless mistakes, appearing not to listen in conversation, lack of follow-through, trouble with organizing activities, avoidance of effortful activities such as homework, losing things, and forgetfulness. Hyperactive symptoms include fidgetiness,

having trouble remaining seated, motor restlessness, trouble playing or relaxing quietly, feeling “on the go,” and talkativeness. Impulsivity can manifest verbally or behaviorally, and includes interrupting, becoming highly impatient when needing to wait, and blurting things out (American Psychiatric Association, 2000).

Third-party reports are useful in understanding the impact of ADHD in both children and adults but are essential to its identification in children; young children, along with some adolescents and adults, may have limited insight into their ADHD symptoms. In addition, adults often cannot fully recall childhood symptoms. Difficulties beyond those described in the core symptoms commonly occur, including sleep dysregulation, emotional reactivity, and poor organizational behavior (Biederman, Petty et al., 2006; Murphy, Barkley, & Bush, 2001; Surman et al., 2009; Surman et al., 2011).

The chief complaints of individuals with ADHD are diverse due to the heterogeneity of the functional problems they face. Children with ADHD are often brought to clinical attention for disruptive behavior or academic difficulty at school, or for impulsive or seemingly oppositional behaviors at home. Symptoms of impulsivity and hyperactivity typically decrease across the lifespan. While physical restlessness, talkativeness, and impatience commonly occur in both children and adults with ADHD, adults tend to have more socially acceptable manifestations. For example, while a child with ADHD may be out of his seat frequently during class time, as an adult he may be able to stay seated through a meeting but report feeling bored, restless, and “tuned out,” missing important material due to disengagement, or stepping out to answer non-urgent calls. Similarly, a teenager with ADHD may constantly interrupt family conversations and be disruptively loud in the library; as an adult, she may alienate coworkers by persisting with social conversation at unwelcome times or talking so much during work meetings that it is difficult for others to participate.

Compensatory capacities and effort may mask the burden of ADHD. While it is adaptive for individuals to learn ways to get tasks done despite their ADHD-related challenges, such compensatory efforts may require large investments

of time and energy. An individual with ADHD may be able to accomplish tasks requiring attention and control of behavior only with great difficulty, often needing to work harder or differently than his peers in order to achieve the same goals. Patients may spend longer hours than peers at study or work due to wandering thoughts, frequent breaks, or time spent checking for mistakes. Disorganization and forgetfulness may require heavy reliance on organizational systems, such as extensive checklists to ensure completion of simple tasks such as small shopping trips, or frequent use of alarms as reminders of appointments or tasks. Reliance on others is another form of compensatory burden. A patient who accomplishes the seemingly routine task of arriving at a scheduled medical appointment on time, for example, may be straining his marital relationship because he is reliant on his wife to call the medical office to schedule the follow-up visit, enter the information into the family calendar, and remind him repeatedly on the day of the appointment. Medical patients with ADHD with poorer compensatory supports may not follow through with care and become lost to follow-up.

The burden of ADHD also includes tendency to defer or avoid activities that strain an individual's capacities. For example, an individual with impulsive/hyperactive traits may avoid jobs requiring prolonged sitting, or drive longer and more time-consuming routes to avoid waiting in traffic. The otherwise capable individual may also simply avoid pursuing a promotion, higher education, or relationship that would tax his or her capacities.

The manifestation of ADHD symptoms varies according to each individual's challenges, strengths, and evolving psychosocial context. For example, a student with ADHD who also struggles with learning disabilities or low cognitive abilities may disengage from class more frequently, particularly without sufficient educational accommodations. A relative strength in academic performance may mask the impact of ADHD until vulnerable capacities—such as relative weaknesses in executive functioning—are strained by new demands (Antshel et al., 2009; Antshel et al., 2010). In many cases of apparently late-onset ADHD, childhood symptoms, while present, had been well compensated for by caregiving adults in highly structured environments, minimizing apparent functional impairment. While it is common for ADHD to be diagnosed for the first time following the transition to middle school, high school, college, or a new job, transfer to an educational or occupational setting that better fits an individual's strengths can also result in fewer impairing symptoms. The need for support should be reevaluated over time and at new developmental stages.

Revisions to the DSM-IV diagnostic criteria for ADHD during the 2013 update to the psychiatric diagnostic manual, DSM-5, included:

1. Moving away from separate diagnostic categories for subtypes of ADHD in DSM-IV (inattentive, impulsive/hyperactive, combined), and instead conceptualizing these to all be different “presentations” of ADHD, by using specifiers to note these symptom patterns;

2. Adopting onset before age twelve as a more appropriate historical criterion than on set before age seven;
3. Allowing simultaneous diagnosis of ADHD and pervasive developmental disorders or autism;
4. Enhancing descriptions of ADHD symptoms (American Psychiatric Association, 2013);
5. Reduction of number of current symptoms of either the inattentive presentation or impulsive/hyperactive presentation required in individuals over age 17, from 6 to 5.

It is clinically relevant to consider the reason for reduction of current symptom threshold for adult diagnosis in DSM-5. When children with full ADHD grow to have fewer than six current symptoms within an ADHD subtype category as adults, functional impairment may nevertheless remain significant (Faraone, Biederman, & Mick, 2006). Patients with onset by adolescence and four or more current symptoms in the “inattentive” or “hyperactive” category also often have effectively the same life problems as those with full ADHD (Barkley, Murphy, & Fischer, 2008; Faraone, Biederman, Spencer, et al., 2006). ADHD presentations that are clearly impairing but sub-threshold for full diagnostic criteria because of fewer current symptoms or difficulty in documenting age of onset may often warrant intervention. Under the new DSM-5 classification system, these presentations can be categorized as *ADHD not elsewhere classified*. The utility and implications of the DSM-5 revisions to ADHD diagnostic criteria will emerge with further research.

ASSESSMENT OF ADHD

Table 50.1 summarizes several rating scales that may be used for assessing baseline symptoms and tracking treatment progress. In children, a variety of ADHD measures is available for clinical use, including the ADHD-Rating Scale (DuPaul, Power, Anastopoulos, & Reed, 1998; Faries, Yalcin, Harder, & Heiligenstein, 2001), the Vanderbilt ADHD Parent Rating Scale (Wolraich et al., 2003), and Conners' Parent Rating Scale—Revised (S) (Conners, 1997). Self-report scales that offer indication of likelihood of diagnosis of ADHD are also available for children and adults (Brown, 1995; Conners, Erhardt, & Sparrow, 1999). The websites Schoolpsychiatry.org and CAPPCNY.org contain information and links to ADHD scales. A useful screening tool for adults, the Adult ADHD Self Report Scale (ASRS—v1.1), has been adopted by the World Health Organization (WHO; Kessler, Adler, Ames, Demler et al., 2005) (Figure 50.1). Like all disease-specific rating scales, it could be more likely to produce false positives in populations with high rates of comorbidity. The ASRS screener is a 6-item subset of the ASRS 18-item self-report form, which has a question for each of the 18 symptoms of inattention or impulsivity/hyperactivity.

Screening tools and rating scales should be supplemented with interviews and the collection of related information to confirm that an individual meets full criteria for

Table 50.1 SELECTED ADHD RATING SCALES

RATING SCALE	AGE GROUPS	REFERENCES	AVAILABILITY	FORMAT	ADVANTAGES/ DISADVANTAGES
ADHD-Rating Scale-IV	Pediatric	DuPaul 1998, Faries 2001	Purchase online, includes permission to reproduce forms	Parent and teacher versions	Maps onto DSM-IV-TR criteria.
Vanderbilt	Pediatric	Wolraich 2004	Free online at www.cappcn.org or www.schoolpsychiatry.org	Parent and teacher versions	Some items track non-ADHD disruptive symptoms (oppositional-defiant/conduct), anxiety and mood.
Conners	Pediatric Adult	Conners 1997, Conners 1999	Purchase online	Parent, teacher, and self-report versions	Short and long versions. Clearly delineated subscales for non-ADHD disruptive symptoms (oppositional-defiant/conduct).
Brown	Preschool through Adult	Brown 1995	Purchase online	Parent, teacher, and self-report versions	Scoring correlates with clinical diagnosis. Items emphasize organizational difficulties.
Adult ADHD Self-Report Scale (ASRS-v1.1)	Adult	Kessler 2005	Free online at www.cappcn.org	Self-report	First six items can be used as a screener. Full 18-item version useful for review of DSM-IV-TR current symptoms.

Please answer the questions below, rating yourself on each of the criteria shown using the scale on the right side of the page. As you answer each question, place an X in the box that best describes how you have felt and conducted yourself over the past 6 months. Please give this completed checklist to your healthcare professional to discuss during today's appointment					
	Never	Rarely	Sometimes	Often	Very Often
1. How often do you have trouble wrapping up the final details of a project, once the challenging parts have been done?					
2. How often do you have difficulty getting things in order when you have to do a task that requires organization?					
3. How often do you have problems remembering appointments or obligations?					
4. When you have a task that requires a lot of thought, how often do you avoid or delay getting started?					
5. How often do you fidget or squirm with your hands or feet when you have to sit down for a long time?					
6. How often, do you feel overly active and compelled to do things, like you were driven by a motor?					

Figure 50.1 Adult ADHD Self-Report Scale (ASRS-v1.1) Symptom Checklist. If four or more marks appear in the darkly shaded boxes within Part A, then the patient has symptoms highly consistent with ADHD in adults and further investigation is warranted (Kessler, Adler, Ames, Demler et al., 2005; World Health Organization, 2005).

ADHD. There is no “test” for ADHD. The clinical diagnosis of ADHD can be made by any clinician who is familiar with the syndrome and familiar with alternative explanations of mental and behavioral problems (Subcommittee on Attention-Deficit/Hyperactivity Disorder, 2011). In cases with complex psychiatric or psychosocial comorbidity, or when standard treatments have not been effective, psychiatric consultation may be helpful to confirm the diagnosis. While neuropsychological testing is highly useful for characterization of learning disabilities or cognitive impairments and may be required by schools or other institutions for

disability documentation, it demonstrates significant deficits in only a subset of clinically confirmed cases of ADHD (Seidman, 2006) and is not required to make the clinical diagnosis of ADHD.

NEUROBIOLOGY

Converging evidence demonstrates that ADHD has a heterogeneous etiology. Structural and functional differences from controls have been found using imaging techniques

in children and adults with ADHD, including prefrontal, cingulate, basal ganglia, and cerebellar regions (Bush, 2011; Seidman, Valera, & Bush, 2004). The efficacy of catecholaminergic pharmacotherapies and imaging studies implicate deficits in dopamine and norepinephrine pathways and also a role of these pathways in the effects of pharmacotherapies. ADHD is a genetic condition, as demonstrated by high familiality: the heritability coefficient is 0.76 based on twin studies (Faraone et al., 2005). Individual genes appear to contribute low risk for ADHD, but multiple genes, including those expressing catecholaminergic pathway components, may contribute to ADHD. Environmental (Banerjee, Middleton, & Faraone, 2007) and familial factors may have an impact on the expression of ADHD (Faraone, 2004). ADHD probably has heterogeneous neurobiological trajectories, and initial research demonstrates that genetic variation between individuals contributes to these trajectories (Shaw et al., 2007).

FUNCTIONAL IMPAIRMENT

ADHD is associated with significant deficits in both children and adults, including educational and occupational underperformance (Loe & Feldman, 2007); low frustration tolerance and antisocial behavior; poor relationships with peers, family members, and authorities; and more frequent traffic violations, accidents, and injuries (Barkley, 1997, 2004; Barkley, Guvremont, Anastopoulos, DuPaul, & Shelton, 1993; Barkley, Murphy, & Kwasnik, 1996; Barkley & Cox, 2007; Barkley & Murphy, 2010; Barkley et al., 2008; Biederman & Faraone, 2006; Biederman et al., 2006; Brown, 2000; Weiss & Hechtman, 1993). Between absence and underperformance at work, ADHD is associated with workforce inefficiency that costs the United States \$19.6 billion (Kessler, Adler, Ames, Barkley, et al., 2005) to \$116 billion (Biederman & Faraone, 2005) per year. A case-control study of 173 adults with and 134 adults without ADHD demonstrated a large impact of ADHD on overall quality of life (Mick, Spencer, Faraone, Biederman, & Zhang, 2007). The National Comorbidity Survey Replication (Kessler et al., 2006) confirmed on an epidemiological level that ADHD confers significant disability in all dimensions of functioning considered: self-care, mobility, cognition, days out of role, productive role functioning, and social role functioning.

PSYCHIATRIC COMORBIDITY AND DIFFERENTIAL DIAGNOSIS

Psychiatric comorbidity is common in both children and adults with ADHD (Barkley, 1997; Biederman et al., 1999; Kessler et al., 2006). Oppositional defiant disorder, conduct disorder, and developmental disorders such as Tourette's syndrome, enuresis/encopresis, and learning disabilities are common in children with ADHD (Biederman et al., 2010; Germano, Gagliano, & Curatolo, 2010). Pediatric ADHD confers higher risk for the onset of antisocial, mood, anxiety, substance use, and eating disorders as children age into

adolescence and adulthood (Biederman et al., 2010). Case-control studies also demonstrate higher rates of antisocial, mood, anxiety, and substance abuse disorders in adults with ADHD (Biederman et al., 2004; Biederman et al., 1994; McGough et al., 2005). ADHD may increase risk for bulimia nervosa (Surman, Randell, & Biederman, 2006). Sleep disorders are strongly associated with ADHD across the lifespan (Choi, Yoon, Kim, Chung, & Yoo, 2010; Cortese, Faraone, Konofal, & Lecendreux, 2009; Surman et al., 2009). Because of the high rates of comorbid mental health disorders in ADHD patients, and of ADHD in patients with other mental health disorders, ADHD patients should be screened for co-occurring mental health conditions, and ADHD should be considered in patients presenting with other psychiatric concerns. If potential concern for ADHD is raised by a review of a patient's social history (i.e., history of educational, occupational, or legal difficulties) or by such symptoms as poor concentration, distractibility, or impulsive behavior on psychiatric review of systems, more detailed evaluation for ADHD should be conducted.

When another condition that robustly impairs concentration and controlled behavior is present—such as major depression, acute agitation or panic, mania/hypomania, or substance intoxication—it is typically appropriate to defer confirmation of ADHD and address the priority condition first. The diagnosis of ADHD is facilitated by identifying that the criteria are fully met, and that the hallmarks of alternate conditions are absent. Examples of conditions that can present with symptoms similar to ADHD are presented in Table 50.2. ADHD may often be differentiated from other mental health conditions by the persistence of symptoms since childhood, continuation of ADHD symptoms during non-comorbid periods (i.e., when the patient is in full remission from depression), and the presence of non-overlapping symptoms. In the differential diagnosis of ADHD and bipolar disorder, for example, talkativeness, impulsivity, tangential speech, physical restlessness, and high energy occur in both conditions. However, impairing mood elevation or irritability, grandiosity, hypersexuality, and psychosis are hallmarks of bipolar disorder, not ADHD. When impulsivity, the amount or rapidity of speech, or other overlapping symptoms are not consistently present over time and seem largely driven by mood state, bipolar disorder should be considered. While sleep can be chronically dysregulated in ADHD patients, a change in sleep patterns may also signal a mood disorder. The sudden development of early morning insomnia is uncommon in ADHD, but it is a hallmark of major depression. Decreased need for sleep (total sleep time substantially decreased from a patient's own baseline without effort to stay awake, or daytime sleepiness) is uncommon in ADHD but can be indicative of mania.

Low mood or anxiety can create internal distraction, complicating the diagnosis of ADHD. For example, a patient who reports having trouble paying attention in conversations at work might further explain that he is thinking constantly about whether people respect or like him; prior to treating him for ADHD, it would be important to build evidence that ADHD symptoms were present in contexts less vulnerable to

Table 50.2 DIFFERENTIAL DIAGNOSIS: OTHER CONDITIONS PRESENTING WITH ADHD-LIKE TRAITS

CONDITION	DIFFERENTIATING DIAGNOSTIC TOOLS	DIFFERENTIATING FEATURES ON HISTORY, EXAMINATION
Autism spectrum disorder	Standardized diagnostic interview	Social reciprocity deficits
Dementia	Neuropsychological testing	Late onset; worsening course; memory impairment
Delirium	Diagnostic evaluation for occult medical conditions (e.g., chest X-ray, urinalysis)	Change in level of consciousness; waxing and waning symptoms; physical illness
Executive dysfunction without ADHD	Neuropsychological testing and behavioral interview	Absence of full ADHD criteria; prominent disorganization
Genetic, metabolic, or other acquired neurological syndromes (e.g., fetal alcohol syndrome)	Brain imaging, genetic testing, laboratory evaluation as suggested by symptoms	Temporal pattern; family history; developmental delay; mental status severity; neurological findings
Learning disability	Neuropsychological testing	Impairment in particular academic skills
Mental illness (e.g., mood, anxiety, psychotic disorders)	Psychiatric screening instruments	New onset; intermittent or worsening course; non-ADHD psychiatric symptoms, family history
Movement disorders (e.g., ataxias, chorea)	Electromyography, laboratory evaluations	Motor activity pattern; neurological findings
Poisoning (e.g., lead, pesticide)	Toxicology screen	Environmental exposure; new onset; associated symptoms
Seizure disorder (e.g., absence, partial seizure)	Sleep-deprived electroencephalography	New onset; intermittent symptoms; inability to respond during symptoms
Sensory impairment	Hearing, vision testing	Contextual symptoms (e.g., when seated in back of classroom only)
Sleep disorder (e.g., insomnia, restless leg syndrome, sleep apnea, narcolepsy)	Sleep study, sleep diary	Temporal pattern; associated symptoms (e.g., snoring, daytime somnolence)
Substance abuse	Toxicology screen	Worsening course; substance-centered behavior
Thyroid disorder	Laboratory testing	Cognitive decline; physical symptoms (e.g., weight change, heat/cold intolerance, poor growth)
Traumatic brain injury; post-concussive symptoms	Brain imaging	History of head trauma; acute onset

his self-critical and socially anxious mindset. Other neuropsychiatric challenges, such as learning disabilities, can also exacerbate or mimic ADHD traits. A student with dyslexia may find it harder to concentrate on reading, for example, regardless of the presence of ADHD.

Psychological distress not severe enough to merit diagnosis with another major psychiatric disorder is also common in ADHD patients. Circumscribed feelings of guilt, sadness, lack of hope, lack of interest, or anxiety may all be experienced relative to the domains of life that are a struggle for patients with ADHD. In some cases of highly impairing ADHD, successful treatment of comorbid psychiatric conditions can prove difficult until ADHD is appropriately addressed. When prioritizing the order of psychopharmacology interventions, typically depression or anxiety should be treated before comorbid ADHD. However, when impairment from ADHD is judged to be much more longstanding and severe, and when symptoms of anxiety or dysphoria seem

related substantially to sequelae of ADHD, initiating ADHD treatment first can be an effective strategy that minimizes the need for additional medication to treat mood and anxiety. Very limited evidence supports the cautious introduction of ADHD pharmacotherapy in children or adults with bipolar illness and comorbid ADHD, but typically this should be attempted only once their mood has been well stabilized (Bond et al., 2012; Chang, Nayar, Howe, & Rana, 2009; Joshi & Georgiopoulos, 2012).

PHARMACOLOGICAL TREATMENT

All agents approved by the Food and Drug Administration (FDA) to treat ADHD (Table 50.3) have catecholaminergic properties and are thought to work by increasing available norepinephrine or dopamine, particularly in prefrontal regions. Patients should always be warned that distressing

Table 50.3 FDA-APPROVED MEDICATIONS FOR ADHD

MEDICATION	FDA STARTING DOSE	FDA MAXIMUM DAILY DOSE	AACAP OFF-LABEL MAXIMUM DAILY DOSE ^a	TYPICAL DURATION OF EFFECT ^b	REPRESENTATIVE BRAND NAMES/ COMMENTS
<i>Stimulants: Amphetamines</i>					
Dextroamphetamine (immediate release)	2.5 mg (age 3–5) 5 mg (age 6+)	40 mg	60 mg	5 h	Dexedrine Dextrostat Liquadd (liquid formulation)
Dextroamphetamine ER	5 mg qam	40 mg	60 mg	8 h	Dexedrine Spansules (capsule can be opened and sprinkled)
Mixed amphetamine salts (immediate release)	2.5 mg (age 3–5) 5 mg (age 6+)	40 mg	60 mg	5 h	Adderall
Mixed amphetamine salts extended release ^c	10 mg qam	30 mg	60 mg	12 h	Adderall XR (capsule can be opened and sprinkled) Consider 5 mg starting dose for smaller children
Lisdexamfetamine ^c	30 mg qam	70 mg	n/a	12 h	Vyvanse; Consider 20 mg starting dose for smaller children
<i>Stimulants: Methylphenidates</i>					
Methylphenidate (immediate release)	5 mg bid	60 mg in divided doses	100 mg	4 h	Ritalin Methylin (includes chewable and liquid formulations)
Dexmethylphenidate (immediate release)	2.5 mg bid	10 mg bid	50 mg	5 h	Focalin
Methylphenidate SR/ER	10–20 mg qam	60 mg	100 mg	8 h	Metadate CD (capsule can be opened and sprinkled) Metadate ER Methylin ER Ritalin SR Ritalin LA
OROS methylphenidate ^c	18 mg qam (pediatric) 18–36 mg qam (adult)	54 mg (age 6–12) 72 mg (age 13+)	108 mg	12 h	Concerta
Dexmethylphenidate extended release ^c	5 mg qam (age 6–17) 10 mg qam (adult)	30 mg (age 6–17) 40 mg (adult)	50 mg	12 h	Focalin XR
Methylphenidate patch	10 mg qam	30 mg	n/a	9–12 h	Daytrana (patch may be removed early to shorten duration)
<i>Non-stimulants</i>					
Atomoxetine ^c	Pediatric: 0.5 mg/kg/day Adult: 40 mg/day	Lesser of 1.4 mg/kg or 100 mg	Lesser of 1.8 mg/kg or 100 mg	24 h	Strattera 25–50% dose-reduction in hepatic impairment
Clonidine extended-release	0.1 mg qhs	0.2 mg bid	n/a	24 h	Kapvay ER (immediate-release and patch formulations may be used off-label)
Guanfacine extended-release	1 mg	4 mg or 0.12 mg/kg/day	n/a	24 h	Intuniv (immediate-release formulation may be used off-label)

* Indicates FDA approval in adults as well as in children; other listed medications are FDA-approved in children only but are commonly used off-label in adults.

^a Adapted from AACAP ADHD Practice Parameter for pediatric care (Pliszka, 2007). In clinical practice, doses of stimulants above FDA limits may be indicated where meaningful incremental benefit has occurred with dose increase. Experience suggests that doses of most racemic methylphenidates up to 2 mg/kg/day, and doses of amphetamines (and dexmethylphenidate) up to 1 mg/kg/day may be well tolerated.

^b Based on average clinical duration; may vary in individuals.

thoughts and feelings (i.e., anxiety, irritability, agitation, or suicidal thoughts) as well as physical discomforts are possible side effects of medications that work on the brain. These agents also have peripheral nervous system side effects. Some medications commonly used for ADHD do not carry an FDA indication for use in adults, and others are commonly used off-label (i.e., without an FDA approval for use in ADHD), even in children and adolescents; the American Academy of Child and Adolescent Psychiatry ADHD Practice Parameter contains specific information about medications often used off-label for ADHD (Pliszka & AACAP, 2007). Before prescribing ADHD therapies, particularly non-stimulants, to patients taking other medications, it is advisable to check for specific drug–drug interactions (Table 50.4).

STIMULANT TREATMENT

In an ADHD patient with no contraindicating conditions, stimulants are typically the first choice over non-stimulant medications because of their more robust efficacy for ADHD management. A meta-analysis of adult trials showed greater effect size for stimulants (0.91 for immediate-release and 0.95 for long-acting) than for non-stimulant treatments (0.62) (Faraone, Biederman, Spencer, & Aleardi, 2006). Several methylphenidate and amphetamine drug products are available, with differing release patterns and duration of effect. For example, long-acting methylphenidate products typically acting for 12 hours include osmotic-release, layered bead, and patch formulations. Individuals may tolerate one formulation of a stimulant agent better than another.

Long-acting stimulants are preferable to immediate-release agents for many patients. Stimulants can be misused or abused. Among college-age individuals, studies suggest that

5–35% misuse non-prescribed stimulants, but long-acting agents are less likely to be abused (Wilens et al., 2008). An extended-release form of dextroamphetamine, lisdexamfetamine, is a pro-drug requiring enzymatic activation, which may further decrease its potential for abuse. Due to the convenience of once-daily dosing, long-acting formulations may also be preferable to promote treatment adherence. For young children or others unable to swallow pills, liquid formulations, extended-release formulations with capsules that may be opened and sprinkled on food, crushable short-acting agents, or the methylphenidate patch may be helpful.

While stimulants are typically well tolerated in use with other medications, some interactions are possible. Stimulants should be avoided for patients taking monoamine-oxidase (MAO)-inhibitor antidepressants. Methylphenidate may increase the effects of warfarin, phenobarbital, phenytoin, and primidone. The plasma level of amphetamine agents is lowered by acidifying agents, and treatments that lower acidity, such as proton pump inhibitors, can increase serum levels. This may vary by release mechanism, as a study demonstrated, for example, that levels of lisdexamfetamine were not changed in the presence of omeprazole, but that extended-release mixed amphetamine salts had a different time to maximum concentration in half of subjects studied (Haffey et al., 2009). Stimulants can also potentiate the effects of opiates, but they have not been proven to cause significant interaction when used with methadone or buprenorphine (McCance-Katz, 2009).

NON-STIMULANT TREATMENT

Because of their lower potential for abuse, non-stimulants are favorable for treatment of ADHD when the patient also has an active problem with substance abuse or dependence. Most also

Table 50.4 DRUG–DRUG INTERACTIONS IN ADHD AND MEDICAL ILLNESS

MEDICATION	ADHD PHARMACOTHERAPY	INTERACTION
MAO-inhibitor antidepressant	Stimulants, atomoxetine, bupropion	Contraindicated due to hypertensive reaction.
MAO-inhibitor antidepressant	Tricyclic antidepressants (desipramine, imipramine, nortriptyline)	Contraindicated due to hypertensive reaction, serotonin syndrome.
Linezolid (weak MAO-inhibitor)	Stimulants, atomoxetine, bupropion, tricyclic antidepressants (desipramine, imipramine, nortriptyline)	Risk of hypertensive reaction, serotonin syndrome. Use with caution and informed consent when clinically necessary.
Warfarin, phenobarbital, phenytoin, primidone	Methylphenidate	Stimulant increases effects of other medication; adjust doses as needed.
Proton pump inhibitors	Amphetamines	Increased serum levels of stimulant; adjust doses as needed.
Fluoxetine, paroxetine, quinidine, and other CYP2D6 inhibitors	Atomoxetine	Increased levels of atomoxetine; reduce atomoxetine dose as needed.
Fluoxetine, paroxetine, quinidine, other CYP2D6 inhibitors	Tricyclic antidepressants (desipramine, imipramine, nortriptyline)	Increased levels of tricyclic antidepressant, narrow therapeutic margin, fatal in overdose. Reduce tricyclic dose and monitor EKG and blood levels if concomitant use cannot be avoided.

have the advantage of 24-hour duration of effect. Atomoxetine is the only non-stimulant FDA-approved to treat ADHD in both children and adults. Slow titration and nighttime dosing can minimize the risk of sedation and gastrointestinal intolerance. Atomoxetine carries warnings about (very rare) liver failure, and the possibility of emerging suicidal ideation (Eli Lilly & Company, 2011). Atomoxetine is metabolized through the cytochrome P450 2D6 pathway, so other medicines using this pathway may affect atomoxetine levels; atomoxetine doses commonly need to be reduced by more than half when used concomitantly with fluoxetine, for example. Atomoxetine has anxiety-reducing properties for some patients, and one study demonstrated its efficacy for ADHD comorbid with social anxiety (Adler, Rubin, Qiao, Heinloth, & Durell, 2010).

While guanfacine and clonidine have been used off-label for ADHD in children for many years, newer extended-release formulations of both have received FDA approval. To date they have not been studied in adults. These agents are agonists at the alpha-2 adrenergic receptor, stimulation of which is thought to increase catecholaminergic activity in frontal regions. Side effects of short-acting alpha-2 agonists may include sedation, hypotension, and rebound hypertension, which can be minimized by gradual dose change for initiation or discontinuation. Short-acting preparations may be used for late-day ADHD symptoms interfering with bedtime routines. Extended-release formulations tend to be less sedating and provide 24-hour symptom coverage. They can be used as ADHD monotherapy, particularly in patients unable to tolerate stimulants due to exacerbation of comorbid anxiety, mania or tic disorders, low appetite, or insomnia.

The antidepressant bupropion (Wilens et al., 2005; Wilens et al., 2001) has demonstrated efficacy for ADHD in adults in double-blind clinical trials. Bupropion's efficacy for depression may make it an attractive option for patients presenting with both ADHD and impairing depressive symptoms. Bupropion should be avoided in patients at high risk for seizure, including binge drinkers and patients with bulimia nervosa.

There is also evidence to support the off-label use of tricyclic antidepressants for ADHD, including desipramine (Pataki, Carlson, Kelly, Rapport, & Biancaniello, 1993; Wilens et al., 1996), nortriptyline (Prince et al., 2000; Spencer, Biederman, Wilens, Steingard, & Geist, 1993; Wilens, Biederman, Geist, Steingard, & Spencer, 1993), or imipramine (Pliszka & AACAP, 2007). These medications can prolong the QT interval, be fatal in overdose, be subject to significant drug-drug interactions, and be associated with sedation and orthostatic hypotension (Riddle, Geller, & Ryan, 1993). As a result, tricyclics are most often considered in ADHD patients who cannot tolerate stimulants and FDA-approved non-stimulants, or in those with comorbid depression or anxiety. More commonly, however, a patient with comorbid depression and anxiety would be tried first with a combination of a selective serotonin reuptake inhibitor (SSRI) and a stimulant.

While modafinil has not been FDA-approved for ADHD, there is one published trial that demonstrates its efficacy in adults (Turner, Clark, Dowson, Robbins, & Sahakian, 2004). The side effects of this agent are similar to those of other sympathomimetics (Provigil, 1999), but it also carries warnings

of (rare) Stevens-Johnson syndrome, may not provide 24-hour symptom control, and can interfere with the effectiveness of oral contraceptives.

Like stimulants, atomoxetine, tricyclic antidepressants, and bupropion should be avoided in patients taking MAO-inhibitor antidepressants. While the antibiotic linezolid is a weak MAO-inhibitor with potential for interaction with psychotropic medications, a retrospective review revealed that only 1 out of 53 cases (1.8%) in which SSRIs were co-administered with linezolid experienced a serotonin syndrome (Lorenz, Vandenberg, & Canepa, 2008). In general, the combination is relatively well tolerated. Use of concomitant linezolid and ADHD medications may be considered with informed consent regarding the possibility of hypertensive reaction and/or serotonin syndrome, and if the risk-benefit ratio is favorable for a particular patient. If the use of linezolid will be time-limited and administered in a setting in which medical treatment adherence is unlikely to be affected by discontinuation of ADHD treatment (i.e., under parental supervision or in a hospital), the ADHD medication can readily be discontinued for the duration of linezolid therapy. However, when linezolid needs to be used over extended periods of time in patients with chronic infections or where underlying ADHD is so severe that discontinuation of ADHD pharmacotherapy is likely to result in non-adherence with life-saving medical treatment, a cautious trial of concomitant use of linezolid and ADHD medication may be necessary.

COMBINATION PHARMACOTHERAPY FOR ADHD

ADHD monotherapy may be ineffective in 30–40% of children (Wilens & Biederman, 1992). Combination therapies for ADHD (Hammerness, Georgiopoulos, et al., 2009; Pohl, Van Brunt, Ye, Stoops, & Johnston, 2009; Wilens et al., 2009) may be useful when monotherapies are only partially effective, when psychiatric comorbidities also require treatment, or to permit dose-reduction of one or both agents to minimize side effects. In addition to use as monotherapy, both extended-release guanfacine and clonidine have demonstrated effectiveness and recently received FDA approval as adjunctive agents in combination with stimulants (Palumbo et al., 2008; Spencer, Greenbaum, Ginsberg, & Murphy, 2009). In one study, significant improvement in ADHD with good tolerability was noted when osmotic controlled release oral delivery system (OROS) methylphenidate (OROS-MPH) was added in children who were partial responders to atomoxetine (Hammerness, Georgiopoulos et al., 2009; Wilens et al., 2009).

CARDIAC CONSIDERATIONS IN ADHD PHARMACOTHERAPY

The catecholaminergic effects of ADHD pharmacotherapies on heart rate, cardiac contractility, and blood pressure should be considered before administration. In most

patients, increased blood pressure and heart rate are not clinically significant, but some patients can be particularly vulnerable to them and require dose-reduction or discontinuation (Hammerness, Wilens et al., 2009). With the exception of the tricyclic antidepressants, there is little evidence of QT-prolongation from these agents. Coexisting conditions that could be exacerbated by sympathomimetic activity should be identified (Table 50.5). Depending on the potential consequences of exacerbation, these may represent absolute or relative contraindications.

Sudden death has been reported in individuals receiving stimulants or atomoxetine, and FDA-approved package inserts for these agents note this. The rate of sudden death while taking stimulant medication may be higher in patients with preexisting structural heart defects (Vetter et al., 2008), but an increase in the rate of sudden death has not been documented in otherwise healthy patients. Large retrospective population-based studies of pediatric and adult patients receiving ADHD pharmacotherapy showed no association with serious cardiovascular events, including myocardial infarction, stroke, and death (Cooper et al., 2011; Habel et al., 2011). The advisability of routine screening electrocardiograms to identify cardiac risk factors in children and adolescents has been

debated (American Academy of Pediatrics, 2000; Perrin, Friedman, & Knilans, 2008). Evaluation prior to initiating therapy for ADHD medication should include physical examination; personal history of cardiac symptoms such as chest pain, syncope or palpitations; and family history of pertinent cardiac risk factors, including hypertrophic cardiomyopathy, long QT syndrome, Wolff-Parkinson-White syndrome, or sudden death at an early age. Depending on these findings, electrocardiogram (EKG), echocardiography, or cardiology consultation may be indicated in some cases prior to initiating ADHD pharmacotherapy. The onset of symptoms suggestive of cardiac disorders during treatment for ADHD should lead to prompt evaluation (Hammerness, Perrin, Shelley-Abrahamson, & Wilens, 2011). Relatively few children (1–3%) will have persistent elevations of blood pressure or pulse while taking stimulants, but more research is required regarding the clinical significance over long-term use of stimulants in these outliers (Hammerness et al., 2011).

Sudden death, stroke, and myocardial infarction are more common in adults than in children, as are baseline cardiac risk factors. Particular caution is advised with ADHD pharmacotherapy in cases of poorly controlled hypertension, heart failure, recent myocardial infarction, or arrhythmia. One open-label study demonstrated that extended-release mixed amphetamine salts for ADHD were well tolerated by a small group of adults who were also taking anti-hypertensive treatment (Wilens et al., 2006). In adults, the most common condition that emerges during ADHD treatment and requires modification of therapeutic approach is the emergence of hypertension. When this occurs, there are several reasonable strategies, depending on the individual clinical scenario, including ADHD severity and other medical factors contributing to hypertension. These include dose-reduction of ADHD medication, use of the alpha-agonist ADHD treatments guanfacine or clonidine (indicated for hypertension but off-label in adults for ADHD, and requiring cautious monitoring for rebound hypertension in withdrawal), or treatment with other anti-hypertensive agents and continuation of stimulant medication.

Table 50.5 POTENTIAL CONTRAINDICATIONS TO ADHD PHARMACOTHERAPIES*

TYPE OF CONTRAINDICATION	RELEVANT AGENTS
Personal or family history of structural cardiac defect or arrhythmia	Tricyclic antidepressants may prolong QT interval; stimulants and atomoxetine may increase heart rate; alpha agonists may cause syncope, hypotension, bradycardia.
Agents with interaction/additive effects	MAOI antidepressants; sympathomimetics (e.g., caffeine, theophylline, pseudoephedrine).
Past or current psychosis (hallucinations, paranoia)	Stimulants and atomoxetine may exacerbate.
Past or current hypomania/mania	Stimulants, atomoxetine, and antidepressants may exacerbate.
Narrow angle glaucoma	Stimulants and atomoxetine may exacerbate.
Substance use or abuse	Stimulants may be abused.
Tic disorder	Stimulants (and rarely atomoxetine) may exacerbate; May improve with alpha-2 agonists.
Untreated hyperthyroidism	Stimulants and atomoxetine may exacerbate.
Untreated hypertension	Stimulants and atomoxetine may exacerbate.

* Incomplete list—stimulants may be contraindicated in any condition potentially exacerbated by sympathomimetic effects. Specialty consultation or management may allow safe treatment.

TREATMENT GOALS

It is useful to agree on treatment goals with a patient to focus treatment efforts. Asking a patient to identify the most important daily life tasks that would benefit from increased focus and reduced restlessness can generate treatment targets that can be tracked during intervention. Reasonable targets for ADHD pharmacotherapy include reduction of time spent looking for misplaced items; increased duration of concentration in reading, studying, or meetings; or reduction in missed content of conversations. Although pharmacotherapies for ADHD may robustly improve patients' capacities for attention and engagement, there are ADHD-related traits such as organizational abilities that may not benefit. An additional important goal is to learn to compensate for lack of these native skills. It may be useful to ask patients what they do

to organize their lives, such as setting aside time for planning and using a reminder system, and to encourage them to practice these skills. For example, a college student might ask his roommate to send him a reminder text message 30 minutes before a scheduled midterm examination, because he is afraid he will forget when it is scheduled or get distracted and miss it. With help, he may develop a system of entering such reminders into his cellphone, decreasing his dependence on others and increasing his consistency in meeting his obligations. Formation of new habits may be optimized by utilizing what has motivated behavior change and held the patient accountable in the past.

INITIATING PHARMACOTHERAPY

Rapid adjustment of medication occurs best with frequent visits at the outset of treatment. Gradually increasing sympathomimetic agents allows accommodation to peripheral effects such as dry mouth or decreased appetite. Some infrequent side effects of stimulants, such as mood or personality changes or muscle tension, are often reported only after several days of exposure. A typical dosing schedule calls for incremental increases in dose every few days to weeks, giving a long enough time for the patient and caregivers to monitor benefits and side effects of each dose. The rating scales described above, including the Conners, Vanderbilt, or ADHD-RS for children, or the 18-item ASRS for adults, may be used to monitor treatment response over time.

While the effects of stimulants may be experienced the same day they are taken, for non-stimulant agents, time to effect can vary from days to weeks. A typical strategy for atomoxetine is to start below 0.5 mg/kg/day, and increase every three to seven days, up to a maximum of 1.4 mg/kg/day. Because bupropion is thought to increase risk for seizures, it may be advisable to evaluate response at lower doses for several weeks before increasing the dose to a maximum of the 400–450 mg/day doses that have been studied in adults in clinical trials, or 6 mg/kg or 300 mg (whichever is lowest) if used off-label in children; if short-acting or sustained-release (SR) bupropion is used, split dosing with no single dose above 200 mg (150 mg in children) may also reduce this risk (Pliszka & AACAP, 2007).

Adults may require doses above FDA-approved limits for effective control of ADHD (Spencer et al., 2005). Limited study suggests that children requiring high doses do not demonstrate excessive plasma levels (Stevens, George, Fusillo, Stern, & Wilens, 2010). While optimal dosing cannot be predicted based on patient weight, it is reasonable to use weight to guide estimation of *maximum* dosing for stimulant treatment. Based on clinical experience, doses of methylphenidate up to 2 mg/kg/day, of dexamethylphenidate up to 1 mg/kg/day, and of amphetamine formulations up to 1 mg/kg/day may be well tolerated. However, it is advisable to increase the dose slowly, allowing several days to evaluate patient response carefully, particularly below or at the level of one-half of these suggested safety maximums. Further increase may be most prudent where there is incremental benefit at lower strengths.

Blood levels of stimulants are not typically monitored in clinical settings and may not be easily obtained from clinical laboratories.

MAINTAINING PHARMACOTHERAPY

Once treatment is stable, follow-up should occur on a time frame dictated by the outcomes being tracked. Uncomplicated patients can be followed every few months, or as dictated by local regulations for the monitoring of the medication employed. It is advisable to reevaluate need for medication treatment periodically. If patients have a change in circumstance that minimizes ADHD-related challenges, such as increase in how engaging or structured their daily activities are, this should also prompt reevaluation of need for ongoing treatment.

Some patients experience a change in the level of benefit over time. New environmental demands that render compensatory habits insufficient may merit stronger medication support. Weight gain, sleep deprivation, or decreased frequency of exercise (e.g., at the end of a sports season) may prompt reports of a changing level of benefit from treatment. Physiological transitions also necessitate alertness to possible need for dose adjustments. Pubertal patients may require increased doses due to their rapid increase in body size and environmental demands, or decreased doses, possibly due to frontal lobe maturation or slower medication clearance. Menopausal patients may complain of poorer attention and memory at menopause. Individuals may develop increased sensitivity to side effects or a need for dose-reduction with aging. Occasionally, patients appear to have tachyphylaxis to the effects of stimulants. Before raising dose in an established treatment, it is reasonable to address apparent tolerance by having patients take brief medication holidays. Patients who experience initiation or discontinuation side effects may need to taper doses up or down when there are breaks in treatment. Other patients with tachyphylaxis will benefit from switching at least temporarily to a different stimulant or to a non-stimulant. It is also important to consider the possibility that emerging psychiatric comorbidities such as depression could be resulting in a pattern of apparent loss of efficacy.

MONITORING AND MANAGING SIDE EFFECTS

Physical effects such as dry mouth, decreased appetite, insomnia, gastrointestinal upset, or other perturbations of peripheral nervous system function often occur with ADHD pharmacotherapies, and sometimes improve or resolve over a several-day period at a steady dose. Minimizing caffeine and sympathomimetic agents sometimes eliminates or reduces side effects, particularly early in a medication trial. Growth monitoring may prompt treatment holidays or non-stimulant treatment in children, as some studies associate stimulant treatment with effects on weight and height (Pliszka & AACAP, 2007). Blood pressure and heart rate should be monitored during the course

of ADHD pharmacotherapy. Patients should be prompted to report any detrimental changes in mood, thoughts, personality, mental function, or tics; these are expected to resolve with termination of treatment.

Some side effects may be managed by changing to an alternate form of the same active agent. For example, dry mouth may be less prominent on one form of long-acting methylphenidate than another for an individual patient, but switching between agents may also produce a new side effect. If a stimulant side effect occurs most at a particular time of day, changing to a different release pattern, or delaying the second daily dose by a small interval may eliminate the side effect. Tapering off stimulant doses by adding a smaller second dose later in the day to a long-acting agent given in the morning may limit wear-off effects such as fatigue or irritability. Changing the time of dose or dividing the dose can mitigate atomoxetine side effects, such as fatigue, sleep interruption, or gastrointestinal distress, in some cases.

NON-PSYCHOPHARMACOLOGICAL TREATMENT

While medications are often effective for reducing ADHD symptoms, non-medication interventions are important in order to minimize functional impairment and ADHD-related challenges such as executive function difficulties, distress over the consequences of ADHD, and comorbid mental health problems. Non-medication approaches to ADHD management include psychoeducation, cognitive-behavioral and parent training therapies, ADHD coaching, and disability accommodations. Effective pharmacotherapy may greatly facilitate adherence to non-medication interventions, and vice versa.

Patients benefit significantly from considering how ADHD impacts their lives via psychoeducation. Acknowledgement that ADHD is neurobiological condition that can be understood and compensated for can be very powerful for patients who have blamed themselves for a lifetime of underperformance relative to their potential. Helping loved ones understand how ADHD impacts their relationship, and how to best nurture the relationship given those challenges, can be very valuable. Community resources with helpful websites include organizations such as Children and Adults with ADHD (CHADD), and the Attention Deficit Disorder Association.

Structured cognitive-behavioral therapies (CBT) offer techniques to improve patients' compensatory strategies and change unhelpful beliefs (Safren et al., 2005; Safren et al., 2010; Solanto et al., 2010). A therapist's manual and client workbook are available (Safren, 2005a, 2005b). Training family members and teachers how to respond to behavior resulting from ADHD can be helpful. Parent training, for example, improved both child and parent functioning in some studies (Barkley, 2002; Pelham & Fabiano, 2008). Therapies and coaching for ADHD that foster new habits rely in part on establishing accountability. Groups can be another powerful context in which to teach new skills (Solanto et al., 2010).

Under the Americans with Disabilities Act, individuals with ADHD have a right to reasonable accommodations in work and school environments. Patients should be encouraged to explore what may be available for accommodation through the special education eligibility evaluation process in school districts, the college disability services office, or the human resources department at their job. Although neuropsychological testing is not necessary to confirm a DSM-IV diagnosis of ADHD, it can be a powerful tool for guiding patients toward interventions that will capitalize on their strengths and is often required to help secure educational or occupational accommodations.

MEDICAL SEQUELAE OF ADHD

Undiagnosed ADHD can significantly impact patients presenting for treatment of physical concerns. The impulsivity and lack of planning common in patients with ADHD may increase their risk for engaging in unhealthy behavior patterns. Impulsivity is linked to a shortened life expectancy (Friedman et al., 1995). ADHD is linked to higher rates of substance abuse, with lower quit rates, and thus to related medical sequelae (Biederman, Monuteaux, et al., 2006; Biederman et al., 1995; Pomerleau, Downey, Stelson, & Pomerleau, 1996; Wilens, 2006). ADHD may be associated with obesity in children (Kim, Mutyala, Agiovlasitis, & Fernhall, 2011) and adults (Cortese et al., 2008; Fleming, Levy, & Levitan, 2005).
