Patients seen in urgent and emergency care settings for trauma secondary to poorly regulated behavior may be suffering from ADHD. Preschool children hospitalized for mild traumatic brain injury are at increased risk for ADHD persisting through adolescence (McKinlay, Grace, Horwood, Fergusson, & MacFarlane, 2009). Children with ADHD symptoms are more likely to experience physical injuries (Schwebel et al., 2011). Older adolescents and young adults with ADHD are more likely to get into motor vehicle accidents (Barkley & Cox, 2007; Barkley, Murphy, Dupaul, & Bush, 2002). The possibility of ADHD should be considered in patients with reckless behavior and poor judgement—for example, a child on a burn unit who has been injured playing with firecrackers—but also in patients accidentally injured during repetitive or routine tasks that require sustained attention, such as a construction worker who shoots himself in the hand with a nail gun.

PREVALENCE OF ADHD IN MEDICAL ILLNESS

Patients with chronic medical illness are at increased risk for psychiatric illness (Wells, Golding, & Burnam, 1988). One study of psychiatric disorders in chronically ill children between 4 and 16 years of age revealed the presence of ADHD in 9.2%, versus 4.3% in controls (Cadman, Boyle, Szatmari, & Offord, 1987). While ADHD is strongly familial (Faraone, 2004), early medical insults could increase the likelihood of phenotypical expression of ADHD in genetically predisposed

patients. Plausible contributory factors include intrauterine growth retardation (Heinonen et al., 2010), perinatal hypoxia (Boksa & El-Khodor, 2003), malnutrition, and failure to thrive (Galler & Ramsey, 1989; Giglio, Candusso, D’Orazio, Mastella, & Faraguna, 1997), and tobacco, lead, or other environmental exposures (Froehlich et al., 2009). Psychosocial stressors resulting from chronic illness could also exacerbate functional impairment in patients with comorbid ADHD.

Differences in how cases have been ascertained in studies of ADHD across medical illness categories may be responsible for the high variability in ADHD prevalence rates found in pediatric cohorts (see Table 50.6). The high prevalence of ADHD in patients with some genetic syndromes (Lo-Castro, D’Agati, & Curatolo, 2010) raises the possibility of a common etiology. ADHD may be associated with particular alleles of the androgen receptor gene (Comings, Chen, Wu, & Muhleman, 1999). Specific patterns of increased ADHD symptoms may emerge in some medical illnesses. For example, inattentive symptoms may be more common in epileptic children (Bennett-Back, Keren, & Zelnik, 2011) and children with asthma (Yuksel, Sogut, & Yilmaz, 2008). On the other hand, pediatric migraine was found to be associated with hyperactive-impulsive, but not inattentive, ADHD symptoms (Bigal & Arruda, 2010).

ADHD-LIKE SYMPTOMS DUE TO MEDICAL ILLNESS OR TREATMENT

Neurocognitive effects of medical illness or its treatment, such as those experienced in HIV/AIDS, cancer, rheumatic conditions, endocrine disorders, and sleep disorders, may also result in impairment that should not be mistaken for ADHD. Hypertension may be associated with an increase in

executive function and attentional difficulties in adult and pediatric patients (Adams, Szilagyi, Gebhardt, & Lande, 2010). Options to address these conditions include improving treatment of the underlying medical illness (e.g., using an HIV medication that better penetrates the blood–brain barrier), altering medical treatments causing cognitive side effects (e.g., reducing steroid dose in inflammatory bowel disease), or by symptomatic treatment with stimulant (Conklin et al., 2009) or non-stimulant ADHD medications when appropriate.

It may sometimes be challenging to distinguish among symptoms related to the underlying medical disorder, side effects of medications, or comorbid ADHD. In the case of epilepsy, for example, comorbid ADHD is common, but imperfectly controlled seizures or anticonvulsants such as topiramate can also impair cognition and mimic or exacerbate inattentive symptoms. Family history of ADHD and documentation of ADHD symptom-onset prior to medical illness, when available, can be helpful in establishing ADHD as a separate comorbidity, but these factors are not clear or applicable in every medically complex case. Prospective tracking of ADHD-like symptoms with ADHD rating scales during systematic and, when possible, sequential rather than simultaneous trials of changes in medical treatments (e.g., increase, decrease, or change in anticonvulsant) or psychotropic treatments (e.g., empirical trial of an ADHD medication) can help to disentangle these effects and guide treatment.

ADHD DIAGNOSIS IN THE CONTEXT OF MEDICAL ILLNESS

ADHD may be challenging to diagnose in patients with chronic medical illness. Caregivers may fail to consider ADHD in medically ill children and adults, even when they

Table 50.6 VARIABILITY OF ADHD PREVALENCE IN PEDIATRIC MEDICAL ILLNESS

PEDIATRIC MEDICAL ILLNESS	PREVALENCE OF ADHD	REFERENCES
Fetal alcohol syndrome	>50%	Peadon 2010
Congenital heart disease	40–50%	Vetter 2008
Familial male precocious puberty	44.4%	Mueller 2010
Chromosome 18 abnormalities	41.7%	Zavala 2010
Velocardiofacial syndrome (22q11.2 deletion)	38%	Jolin 2009
Migraine	23.7% (hyperactive type only)	Bigal 2010
Congenital adrenal hyperplasia (males)	18.2%	Mueller 2010
Alopecia areata	14.3%	Ghanizadeh 2008
Complicated epilepsy	12.0%	Davies 2003
Cystic fibrosis	21% (disruptive behavior disorder) 9.6%	White 2009, Georgiopoulos 2011
Diabetes	2.1% 4%	Davies 2003, Levitt-Katz 2005

are having significant difficulty. In complex patients with medical illness, ADHD-related functional impairment may be misunderstood as being solely due to missing school or work frequently when ill, or to medical symptoms or treatment side effects such as pain or fatigue. A systematic search for persistent ADHD symptoms in multiple contexts over time will help establish the diagnosis.

CASE VIGNETTE

A six-year-old girl with cystic fibrosis (CF) is at nutritional risk due to poor weight gain. Pulmonary function tests cannot be completed reliably due to hyperkinesia. When specifically asked about her behavior in other settings, her mother reports that she won't sit at the table long enough to eat full meals; her teacher is concerned about inattention, and redirects her frequently in the classroom. On further assessment, she is found to meet criteria for *ADHD, combined type*. Atomoxetine improves her engagement at school, at home, and in medical care.

Adolescents with chronic illness may report lower rates of risky behavior than do adolescents in the general population (Britto et al., 1998). When these behaviors emerge in the setting of chronic illness, the presence of ADHD, some other psychiatric illness, or psychosocial stressors should be considered. Early identification and management of ADHD may better prepare children with chronic illness to pass through the high-risk stage of adolescence. The ability to meet educational and occupational demands is of key importance in the medically ill. In adults with CF, for example, psychological health and educational attainment may be more salient than pulmonary function for quality of life and the ability to continue working as they age and become sicker (Burker, Sedway, & Carone, 2004; Rieckert, Bartlett, Boyle, Krishnan, & Rand, 2007).

CASE VIGNETTE

A 16-year-old boy with Crohn's disease is brought to psychiatric attention for the first time and diagnosed with longstanding ADHD, oppositional defiant disorder, and possible learning disabilities. He refuses neuropsychological evaluation or ADHD treatment, stating that he is on too many medicines and sees too many doctors already. Within a year, he has dropped out of high school and is using marijuana daily and abusing alcohol in a binge pattern. He experiments with opiates, which he justifies as an attempt to manage his chronic diarrhea, coinciding with medical and functional decline with repeated inpatient medical hospitalization in young adulthood.

IMPACT OF ADHD ON MEDICAL TREATMENT ADHERENCE

In addition to school or work, home, and the social arena, patients with medical illness have an extra domain of functioning that may be pervasively affected by ADHD: medical self-care. Forgetfulness, avoidance, distractibility, and impulsive, restless behavior interfering with medical care

should prompt consideration of the presence of ADHD. Oppositional or defiant behavior, which often accompanies ADHD in childhood and may persist into adulthood (Harpold et al., 2007), can similarly confound consistent follow-through with medical recommendations.

Treatment adherence is often poor in chronic illness (Brown & Bussell, 2011; Modi et al., 2006; Zindani, Streetman, Streetman, & Nasr, 2006). There has been increasing recognition in the literature of psychological factors such as depression that may exacerbate non-adherence and affect medical outcomes (Cruz, Marciel, Quittner, & Schechter, 2009; Gonzalez et al., 2008; Kettler, Sawyer, Winefield, & Greville, 2002; Safren et al., 2009; Smith & Wood, 2007). Less studied are the effects of ADHD on adherence to medical care. Common barriers to adherence in chronic illness include oppositional behaviors, forgetting, and time-management difficulties, all of which are also prominent in ADHD (Dziuban, Saab-Abazeed, Chaudhry, Streetman, & Nasr, 2010; Modi & Quittner, 2006; Simons, McCormick, Devine, & Blount, 2010). The distractibility, avoidance of unpleasant tasks, and impairments in organization associated with ADHD may exacerbate the burden of medical self-care in chronic illness.

A trend between presence of externalizing disorders and non-adherence was noted in one study of children with CF (White, Miller, Smith, & McMahon, 2009). Georgiopoulos and Hua found that 61% of 18 pediatric CF patients with ADHD had non-adherence among the chief complaints at the time of initial evaluation; when effective ADHD treatment could be implemented, medical adherence often improved (Georgiopoulos & Hua, 2011). Examples of difficulties with medical adherence and navigating through systems of care that may be more common in patients with ADHD are found in Table 50.7.

ADHD TREATMENT IN THE MEDICALLY ILL PATIENT

The decision about whether and how to treat ADHD in medical illness requires careful consideration of each patient's psychiatric and medical status. There are limited data to suggest differential effectiveness of particular ADHD treatments in the context of medical illness. For example, there is preliminary evidence that stimulants, non-stimulants, and combination therapies are all useful treatment options in children with CF (Georgiopoulos & Hua, 2011).

Clinicians should consider that ADHD treatments could have unique adverse effects in patients with concurrent illness. In particular, some conditions could be exacerbated by their sympathomimetic activity. ADHD medication side effects should be considered if the intensity or character of symptoms differs from a patient's usual pattern or correlates with a new medication trial or dose adjustment. In cases of uncertain etiology of such symptoms, an on-off-on trial or dose-reduction of ADHD medication may be useful.

In medically ill patients, ADHD medication side effects may alter the usual risk-benefit ratios for these treatments on a case-by-case basis. For example, tricyclic antidepressants

Table 50.7 TYPICAL MANIFESTATIONS OF ADHD IN MEDICAL SETTINGS

ADHD SYMPTOM	SAMPLE MANIFESTATIONS IN MEDICAL SETTING
Forgetful	<p>Forgets to do treatments.</p> <p>Forgets to refill medication or ask for refills at time of visit.</p> <p>Forgets to come to appointments.</p> <p>Vague historian.</p> <p>Forgets to pay bills or do insurance paperwork.</p>
Loses things	<p>Misplaces prescriptions, medications, or important medical equipment.</p> <p>Loses medical correspondence, lab results.</p> <p>Loses cell phone, wallet with insurance cards, appointment cards.</p>
Leaves tasks unfinished	<p>Intends to but doesn't make follow-up appointments.</p> <p>Doesn't follow through on referrals or medical tests.</p> <p>Agrees to treatment plan but can't seem to follow through.</p>
Executive dysfunction (poor organization, time management, planning)	<p>Last-minute refill requests (i.e., runs out while on vacation).</p> <p>Doesn't anticipate adjustments in insurance, treatment providers, or treatment plan needed for major changes (moving to a new city, birth of child).</p> <p>Financial difficulties, runs out of money to buy medicines or make copays.</p> <p>Can't prioritize well in making medical decisions, seems to have poor "common sense."</p> <p>Late for appointments.</p> <p>Comes at wrong day or time.</p> <p>Difficult to determine chief complaint or main priority for visit.</p>
On the go, restless; inability to stay seated	<p>Doesn't comply with activity restrictions.</p> <p>Can't sit still for treatments.</p> <p>Leaves without treatment when has to wait.</p>
Poor listening and easily distracted	<p>Leaves office without fully understanding care instructions.</p> <p>Needs to hear or read instruction multiple times to retain information.</p> <p>Asks care providers to repeat instructions.</p>
Avoids difficult tasks	<p>Puts off medical treatments or important paperwork.</p> <p>Complexity of treatment plan feels overwhelming to patient.</p>
Talkativeness/interrupting	<p>Hard to keep conversation on track during visit.</p>
Trouble waiting their turn	<p>Excessive impatience or irritability with long waits.</p> <p>Heightened sense of urgency, demanding immediate intervention for medical problem.</p>
Careless mistakes	<p>Takes medication at wrong doses.</p> <p>Takes previously discontinued medication from wrong bottles.</p> <p>Injured or ill because of careless/risky behavior.</p> <p>Misses key steps of treatment plan.</p>

are often considered third-line ADHD agents, after stimulants and FDA-approved non-stimulants (Pliszka & AACAP, 2007), due to the potential for lethal overdose and cardiac side effects. The risk–benefit ratio for the use of tricyclics to treat ADHD would be even less favorable than usual in patients with unstable cardiac illness, but more favorable in the setting of medical illnesses like CF in which weight gain is welcome (Pedreira et al., 2005) and comorbid anxiety and depression are common.

Body mass index (BMI) percentile and gastrointestinal side effects should be carefully monitored in medically ill patients at high risk for weight loss and its consequences—as with some malignancies or gastrointestinal illnesses—who elect to try stimulants. Cyproheptadine (Daviss & Scott, 2004) or other agents can be added to increase appetite, and actively countering constipation, improving gastric motility, and/or better addressing malabsorption may be helpful. Nutritional consultation can be helpful in patients who need additional strategies to increase caloric intake—for example, by increasing caloric density, increasing frequency of food intake, or adding nutritional supplements. Alternatively, the combination of a non-stimulant and a stimulant may provide enough additional ADHD benefit to permit lowering the stimulant dose to stabilize weight.

Abdominal pain and nausea are common side effects of stimulants, atomoxetine, bupropion, and tricyclic antidepressants; in the presence of preexisting gastrointestinal disease, these side effects may be more bothersome and could contribute to unwanted appetite suppression. In addition, as noted above, there are reports of liver abnormalities with atomoxetine; it may be prudent to avoid introducing atomoxetine in patients with significant or unstable liver disease, and to consider active monitoring in patients who are also at risk of developing liver abnormalities due to their primary medical illness or the medications used to treat it. To prevent bowel obstruction, medications delivered with non-deformable capsules are not advised in the presence of preexisting severe gastrointestinal narrowing such as may occur, for example, in inflammatory bowel disease (McNeil Pediatrics, 2010).

Occasionally, normally minor side effects of ADHD medication can become significant due to medical comorbidity. Exacerbation of dry mouth by a stimulant or tricyclic antidepressant could be intolerable in a patient with Sjögren's syndrome. Muscle tension from a stimulant could exacerbate musculoskeletal pain. Urinary retention may be a positive side effect of atomoxetine for a child with nocturnal enuresis (Sumner, Schuh, Sutton, Lipetz, & Kelsey, 2006), but not for a middle-aged man with benign prostatic hypertrophy.

Patients with comorbid epilepsy and ADHD should be stabilized on anti-epileptic treatment to the extent possible prior to initiation of ADHD treatment. Such patients should be both cautioned about and monitored for any increase in seizure activity during therapy, as ADHD medications, like many drugs, may lower the seizure threshold. Similarly, patients with stable congenital cardiac malformations may tolerate ADHD treatment but should be closely monitored during treatment (Vetter et al., 2008).

ADHD TREATMENT IN PREGNANCY

Because there is potential risk to a developing fetus or infant with exposure to pharmacotherapies, pharmacotherapy should be used during pregnancy and lactation only in severe cases, where the mother's safety or well-being would be significantly compromised otherwise. When necessary, exposure should be minimized through as much of pregnancy as possible. Pregnancy may be an ideal time to explore and practice non-pharmacological strategies. Although stimulant abuse appears to correlate with adverse reproductive outcomes (Debooy, Seshia, Tenenbein, & Casiro, 1993; Golub et al., 2005; Plessinger & Woods, 1993), there are limited data to support the reproductive safety of use of amphetamines at doses prescribed for therapeutic use in humans (Golub et al.). While there are over 1,500 exposures to amphetamines during pregnancy reported in the literature, there is less evidence on the safety of methylphenidate, with reports of less than 70 cases in the literature (Humphreys, Garcia-Bournissen, Ito, & Koren, 2007). In one study of 237 pregnant women who took dextroamphetamine to control weight gain, birth weights were 4% lower than in non-users when the medication was used in the third trimester, but there was no increase in perinatal mortality (Naeye, 1983). In one observational study, amphetamines prescribed in the first trimester may have increased the occurrence of oral clefts, but not of severe congenital anomalies (Milkovich & van der Berg, 1977).

However, given the paucity of evidence regarding the safety of ADHD medication in pregnancy, discontinuation of ADHD medication is prudent in most pregnant women. For those with severely impairing symptoms, a switch from a stimulant to a tricyclic antidepressant, clonidine, guanfacine, or bupropion, for which there is more experience with use during pregnancy, could be considered (Milanovic, 2010). If a stimulant were required during pregnancy, an amphetamine product may be preferred to methylphenidate. Given the very limited data available for atomoxetine, it may be best avoided in pregnancy. Ideally, a strategy to switch ADHD medication during pregnancy would be developed during pre-conception planning and tested prior to pregnancy to avoid fetal exposure to a medication that may ultimately be ineffective for a given woman.

ADAPTING MEDICAL CARE TO PATIENTS WITH ADHD

ADHD can affect how patients care for themselves and interact with medical systems of care. Therapeutic interventions should target self-care behaviors with sensitivity to the impact of ADHD in patients with chronic medical illness (Table 50.8). Strategies for maintaining healthy sleep patterns, eating, exercise, and treatment adherence will foster health and minimize the burden of chronic illness. In patients with ADHD, adopting new or consistent routines may be particularly challenging. Difficulty initiating tasks, following through, and organizing behavior will have an impact on the ability of these patients to establish healthy routines.

Table 50.8 ADAPTATIONS TO MEDICAL CARE FOR PATIENTS WITH ADHD

ADHD-RELATED IMPAIRMENT	SAMPLE STRATEGIES TO ADAPT CARE FOR ADHD PATIENT
Inattention	— Expect inattention to interfere with verbal communication in your office. Ask the patient to repeat the treatment plan back to you to assess completeness of understanding.
Poor memory	— Write down instructions. Ask what reminder systems patients already use or can create, and apply them to medical self-care. — Expect details to be missed or avoided. Coach the patient on procedures for insurance approvals or refills.
Poor attention to detail	— Understand that medical treatment adherence may be difficult. Anticipate missed or late doses. When possible, select medicines that are less dangerous or ineffective when doses are missed.
Poor executive function	— Expect organizational challenges. At each visit, foster engagement in the organizational systems and social supports the patient needs to stay adherent.
Task avoidance, poor follow-through	— Expect motivation or interest in new strategies to decrease over time. — Help patients self-monitor their compliance with your recommendations, and establish external accountability for goals: computer or phone-based reminders, more frequent check-ins with your office, and the support of significant others may facilitate adherence.

- Expect inattention to interfere with verbal communication in your office. Ask the patient to repeat the treatment plan back to you to assess completeness of understanding.
- Expect memory challenges. Write down instructions for patients. Ask what reminder systems patients already use or can create, and apply them to medical self-care.
- Expect details to be missed or avoided. Coach the patients on procedures for insurance approvals or refills.
- Expect organizational challenges. At each visit, foster engagement in the organizational systems and social supports the patient needs to stay adherent.
- Understand that medical treatment adherence may be difficult. Anticipate missed or late doses. When possible, prescribe medicines which are less dangerous or ineffective when doses are missed.
- Expect their interest in or motivation with new strategies to decrease over time. Help patients self-monitor their compliance with your recommendations, and establish external accountability for goals: computer or phone-based reminders, more frequent check-ins with your office, and the support of significant others may facilitate adherence.

SUMMARY

ADHD is a common and well-characterized syndrome of self-regulatory difficulties with a high degree of familiarity and individual variation in presentation. A variety of screening and diagnosis instruments are available that are appropriate to help detect ADHD. The biological underpinnings of ADHD are becoming increasingly understood at the genetic, neurostructural, and neurofunctional levels. Pharmacological and psychosocial treatments can minimize the impact of the inattention, impulsivity, and hyperactivity associated with the syndrome. The functional impairments seen in medically

ill patients with ADHD may include challenges in self-care that can adversely affect physical health. Adaptations in the delivery of medical care may help increase medical treatment adherence in patients with ADHD.

CLINICAL PEARLS

- Methylphenidate may increase the effects of warfarin, phenobarbital, phenytoin, and primidone.
- The plasma level of amphetamine agents may be lowered by acidifying agents, and treatments that lower acidity, such as proton pump inhibitors, can increase serum levels.
- While optimal dosing cannot not be predicted based on weight, it is reasonable to use weight to guide your estimation of *maximum* dosing for stimulant treatment. Based on clinical experience, doses of methylphenidate up to 2 mg/kg/day, of dexamethylphenidate up to 1 mg/kg/day, and of amphetamine formulations up to 1 mg/kg/day may be well tolerated. However, it is advisable to increase the dose slowly, allowing several days to evaluate patient response carefully, particularly below or at the level of one-half of these suggested safety maximums. Further increase may be most prudent where there is incremental benefit at lower strengths.
- Therapies and coaching for ADHD that foster new habits rely in part on establishing accountability.
- The possibility of ADHD should be considered in patients with reckless behavior and poor judgement—for example, a child on a burn unit who has been injured playing with firecrackers—but also in patients accidentally injured during repetitive or routine tasks that require sustained attention, such as a construction worker who shoots himself in the hand with a nail gun.
- Patients should be encouraged to explore what may be available for accommodation through the special

education eligibility evaluation process in school districts, college disability services offices, or the human resources department at their job.

- Pediatric migraine was found to significantly increase the risk of hyperactive-impulsive, but not inattentive, ADHD symptoms.
- When risky behaviors emerge in the setting of chronic illness, the presence of ADHD, other psychiatric illness, or psychosocial stressors should be considered.
- Forgetfulness, avoidance, distractibility, and impulsive, restless behavior interfering with medical care should prompt consideration of the presence of ADHD.
- Ideally, a strategy to discontinue or switch ADHD medication during pregnancy would be developed during pre-conception planning and tested prior to pregnancy to avoid fetal exposure to a medication that may ultimately be ineffective for a given woman.

DISCLOSURE STATEMENT

Dr. Georgiopoulos has the following relationships to disclose during the period from July 2011–July 2014. Cystic Fibrosis Foundation: grant support, committee service, honoraria, travel reimbursement. European Cystic Fibrosis Society: committee service, travel reimbursement. U.S. Food and Drug Administration: employed for work unrelated to this chapter. Lippincott, Williams & Wilkins: royalties.

Craig Surman, MD discloses the following relationships through July 2014: Speaking or education supported by McNeil, Janssen, Janssen-Ortho, Novartis, Shire, and Reed/ MGH Academy (funded by multiple companies). Consulting to McNeil, Nutricia, Pfizer, Takeda, Shire, Somaxon. Research Support at the MGH Adult ADHD Program from Abbot, Cephalon, Hilda and Preston Davis Foundation, Eli Lilly, Magceutics, J & J / McNeil, Merck, Nordic Naturals, Nutricia, Pamlab, Pfizer, Organon, Shire, and Takeda. Royalties from Berkeley/Penguin for “FASTMINDS How to Thrive If You Have ADHD (or think you might)”, and from Humana/Springer for “ADHD in Adults: A Practical Guide to Evaluation and Management”.

THE PSYCHIATRIC CARE OF MEDICAL PATIENTS WITH AUTISM

Robert L. Doyle

At present, an estimated 1% of the general population suffers with some form of pervasive developmental disorder (Pasco, 2010). The spectrum of autistic people ranges from severely impaired individuals who appear aloof and apart from the world around them to those who are considered high-functioning and able to compensate for their social impairments by their substantial strength in other areas of life. At one end of this spectrum, the diagnosis is difficult to miss; but the higher functioning individuals may not be as easy to recognize, and their peculiar and concrete ways of dealing with the world can complicate medical care.

The disorders of the autism spectrum include pervasive difficulties in the domains of social interaction and communication, and stereotyped or restrictive repetitive behaviors, interests, and activities. The spectrum also includes what had been called Asperger's syndrome (AS), a condition with normal communication development but difficulties of social interaction and repetitive behaviors. Pervasive disorder not otherwise specified (PDD NOS) refers to patients with impairments in the three domains, but not sufficient to called autism and not meeting criteria for an alternative psychiatric diagnosis. Also in the spectrum is an uncommon condition that had been called "child disintegrative disorder" (CDD), characterized by loss in two autistic domains after two years of normal development. These children also had significant deficits in motor skills, bowel or bladder control, adaptive skills, or play before the age of ten years old. The autistic spectrum is more common in males.

Those who do not have stereotyped behaviors but have deficits in social communication are now diagnosed separately with "social communication disorder."

Rett's disorder, which was also grouped with autistic disorders, is characterized by social deficits and expressive and receptive language impairments that occurred after five months of normal development. Physical exam findings then included deceleration of head growth up to the age of four years, loss of purposeful hand movements until two and a half years old, along with gait or trunk coordination problems. It is distinct because it occurs almost exclusively in females.

Some cases of Rett's syndrome have been attributed to a mutation in the *MeCP2* gene, so these cases may eventually be categorized as a genetic disorder with autistic features, as has been the case with fragile X syndrome (Amir et al.,

1999). Since Rett's and childhood disintegrative disorders are "rare" to "very rare," the treatment studies have been scant and probably cannot be generalized. Therefore, clinicians often extrapolate information from larger studies on autism, which sometimes include individuals with Rett's disorder or childhood integrative disorder, but such extrapolations pose obvious shortcomings (APA, 2000). Due to the dearth of well-designed treatment studies on the rare conditions of Rett's disorder and childhood disintegrative disorder, this chapter will focus on treatments of the more commonly encountered diagnoses on the autism spectrum.

Psychiatrists, neurologists, and developmental pediatricians who specialize in treating children and adolescents routinely probe for symptoms all along the spectrum of autism. General psychiatrists and other physicians who exclusively treat adult patients encounter more difficulty with the nuanced presentations of autism in the higher functioning range, such as the individuals with Asperger's disorder or PDD NOS. Sometimes these very individuals slip through their childhood and adolescence without being formally diagnosed as belonging somewhere along the autism spectrum. Although the study of autism remains in its infancy, new information about the underpinnings of autism exponentially expands our understanding of this condition in each passing year. Nonetheless, no medication yet exists that can treat the core symptoms of the disorder.

Despite a lack of any behavioral or pharmacological treatment that shows robust improvements in the core symptoms, peripheral problems associated with autism can be improved with some existing interventions. Peripheral problems include common, co-occurring symptoms, such as self-injurious behaviors, poor concentration, insomnia, sensory integration issues, and even comorbid psychiatric conditions. Psychiatric disorders may be more difficult to recognize, due to communication problems that impair accurate descriptions of internal states in persons with autism. In addition, these psychiatric conditions may not respond as well to accepted treatments in the context of autism spectrum disorders, yet the same holds true whenever comorbid psychiatric conditions exist in the same person. Treating comorbid psychiatric conditions can be challenging and the outcomes suboptimal, but some improvement in the psychiatric symptoms can result in significant improvement in functioning.

At the very least, awareness of these problems will help develop more holistic treatment plans that will support patient adherence to the clinician's recommendations for care. For example, sensory integration issues related to tastes or textures could pose major challenges for persons on the autistic spectrum who are prescribed oral medications. The astute clinician treating autistic patients will have a close relationship with a compounding pharmacist, who can convert certain medications from pill form to solutions or suppository. The author recently evaluated two adolescent sisters with autism who have never been able to take oral medication due to sensory issues. Injections are not an option with their extreme needle phobia, but their aggressive behaviors have been successfully managed using specially compounded suppositories of risperidone.

This chapter will offer some advice on caring for patients with autism in the medical setting, but it cannot cover all scenarios that a clinician will encounter. Therefore, the reader is encouraged to consider creative ways to deal with the unique difficulties of autism while remembering that a simple and commonsense approach often gives the best outcome.

A cure for autism remains on the distant horizon; however, a number of interventions exist today that address coexisting problems as well as possible comorbid psychiatric disorders. Although treating "around the edges" may not improve core symptoms of autism per se, this approach can certainly improve the quality of life for persons with autism and the families who care for them. This chapter aims to address several common problems associated with autism spectrum disorder (ASD) that impair the delivery of optimal care in the medical setting.

AGGRESSION AND SELF-MUTILATION

First, aggression and self-mutilation occur frequently in persons with autism, and the *Diagnostic and Statistical Manual of Mental Disorders IV* (DSM-IV-TR) (APA, 2000) conceptualized these behaviors as core stereotypical symptoms. Nonetheless, such behaviors often increase during periods of medical illness, thereby serving as a sentinel of an underlying disease process. An exacerbation in self-injurious or aggressive behaviors without any recent change in the environment should warrant a medical work-up. The aggression and self-mutilation may be driven by the patient's need for medical attention, since he or she may not be able to communicate pain or distress verbally. As with delirium, the definitive treatment lies in treating the underlying medical condition as soon as possible.

ASSESSMENT OF COMORBID PSYCHIATRIC CONDITIONS

Second, assessing and treating comorbid conditions will be discussed. Failure to treat comorbid psychiatric conditions often sabotages medical treatments because far too often they go undiagnosed. Part of the problem lies in the tendency to attribute many difficult behaviors or other psychiatric symptoms to the pervasive developmental disorder

(PDD). Perhaps the term *pervasive developmental disorder* tricks one into thinking that every symptom or problem must be attributed to the pervasive nature of autism. Of course, teasing out the symptoms of other comorbid psychiatric disorders from a morass of autistic symptoms is more tedious than diagnosing these conditions in normally developing individuals, but the approach pays off with a better quality of life once the psychiatric condition is in remission. Consider the burden of untreated depression in persons with diabetes. That burden of illness becomes magnified if the person has autism in addition to the depression and diabetes, because the depression often goes unrecognized.

INSOMNIA

Insomnia is a third area that can complicate medical treatment. Sleep problems can be part of a comorbid psychiatric disorder, but most of the time insomnia occurs in the absence of comorbid psychopathology. Poor sleep leads to low energy, poor concentration, and, sometimes, increased irritability, so correcting sleep problems can be crucial to providing optimal medical care.

SENSORY INTEGRATION ISSUES

Children with autism sometimes have symptoms that are thought to be related to disruptions in how the children process and integrate information from other senses. Sensory integration theory suggests that inappropriate or deficient sensory processing is a developmental disorder or part of a developmental disorder amenable to treatment, and often referred to occupational therapists. A standard profile reporting children's sensory experiences illustrate how these symptoms present in children. Both social and non-social dimensions are noted. On the hyposensory-social dimension, children do not respond to their name, ignore new persons, or seek rough-housing play. On the hyposensory-non-social dimension, children stare at lights or objects; flap their arms, do not pay attention to novel objects, mouth objects, ignore loud noises, smell objects, do not respond to pain, and crave movement. The hypersensory-social dimension is captured in children who dislike being held, are distressed during grooming, are averse to social touch, avoid eye contact, and dislike tickling. The hypersensory-non-social children are sensitive to loud noises, avoid textures, are sensitive to light, averse to water, and avoid food with a strong taste/texture (Baranek, 2006). In order to deliver medical care to patients with milder forms of sensory idiosyncrasies, these traits can be taken into consideration. Patients may have distinct responses to restraints, to touching, to specific types of foods. Understanding this aspect of their makeup can facilitate care.

Occupational therapists have developed treatments for these symptoms. They use brushes, swings, balls, and other equipment with the hope of organizing sensory inputs and clarifying their role in developmental disorder and adaptation. The American Academy of Pediatrics (AAP) has written a policy statement to clarify the role of these treatments (AAP, 2012).

Before beginning, the clinician must be aware that persons with autism frequently exhibit finicky eating patterns. Sometimes these relate to sensory integration issues, as in the case of the sisters already mentioned. At other times, restricted or repetitive behaviors at the core of autism could result in a peculiar dietary regimen. For instance, a person on the autism spectrum may be stuck on foods of a certain color and end up eating a “beige” diet. Such restricted diets can lead to nutritional deficiencies, which could cause medical problems or slow recovery from a medical condition.

DIFFICULTY EXPRESSING INNER STATES

Since autism runs the range from nonverbal to the precocious verbal skills that some persons with Asperger’s disorder exhibit, a clinician may struggle to obtain information from most patients. Even those with impressive vocabularies might have great difficulty expressing their feelings or internal states. Any technique or technology that facilitates communication will make history-taking easier. This is not to be confused with “facilitated communication,” a therapy that once seemed to be a breakthrough in autism. “Facilitated communication” trained therapists to help guide the patient’s hand over a keyboard so that thoughts that could not be expressed verbally could be typed. The rationale was that the therapist could help the patients compensate for their fine motor deficits, but “facilitated communication” eventually fell from favor after scientific scrutiny showed significant flaws in its effectiveness. Nevertheless, numerous electronic devices have been invented to help nonverbal or nearly nonverbal persons with autism express themselves. As technology advances, these devices are becoming less expensive, more reliable, more compact, and easier to operate. At first, these devices were designed specifically for persons with communication problems and were limited to this application. Now, software programs can be downloaded into electronic pads and even pocket-sized smartphones with touchpad technologies. These can help in gathering more accurate histories and augment incomplete information provided by caregivers.

CONCRETE THINKING PATTERNS

Even persons on the autism spectrum without speech delays might still struggle with communication issues, given their concrete thinking patterns. Clinicians should remain aware that their patients with higher functioning autism are likely to interpret conversations in literal terms. The author recalls an interview in medical school in which the silver-haired and seasoned psychiatrist asked a patient if he heard voices. The patient responded, “Of course I do, how else could I be answering all your questions?” Although concrete and literal ways of thinking make for amusing moments, this sort of thinking may result in unintentional miscommunication of relevant clinical information. Therefore, carefully framing questions and accepting that responses may come from a person with a different frame of mind makes for more effective communication with the patient.

PROBLEMS IN THE LITERATURE

Even though research into ASDs has made many recent gains, most of the literature on treatment interventions suffers from a number of shortcomings. For instance, many studies include heterogeneous groups of patients on the autism spectrum, and the heterogeneity waters down results, thereby obscuring conclusive evidence that a homogeneous selection of patients would offer. Other studies are too poorly powered to make any clear assumptions about effectiveness, so the literature limps along, only hinting at the benefits of one treatment over another. Another common problem, which is magnified in poorly designed studies, is the high rate of placebo response in the autistic population. Several factors, such as reliance on caregiver’s reports and using inadequate rating scales that cannot accurately capture changes in autism symptoms over the short course of a clinical trial contribute to the placebo response problem. Some studies attempt to assess the treatment outcomes of comorbid conditions, such as depression or anxiety, but the standard rating scales that work well for the general population with depression or anxiety have not been validated in the autistic population. Moreover, most of the research into autism focuses on younger populations. Many other deficiencies exist; however, a few studies have met the gold standard seen in other areas of psychiatric research. These studies have provided the first two FDA-approved treatments for people with autism, even though these treatments do not treat the core symptoms of autism.

MEDICATIONS

IRRITABILITY, AGGRESSION, SELF-INJURIOUS BEHAVIORS

Two atypical antipsychotic agents, risperidone and aripiprazole, are approved for the treatment of “irritability,” defined as tantrums, aggressive behaviors, and self-mutilation in children with autism. These medications have improved the quality of life for these children and their families, but the core symptoms of autism, for the most part, remain unchanged. Although risperidone and aripiprazole do not improve the social and communication problems common to autism, one might argue that a reduction in certain forms of aggression or self-mutilation represents an improvement in stereotypical behaviors. Nevertheless, the medications target irritability, and some aspects of irritability are rhythmic and repetitive in the realm of stereotypes, or occur if such stereotypical behaviors are blocked (Aman et al., 2009; Marcus et al., 2009; Owen et al., 2009; Stigler et al., 2009). Take, for example, head banging, which fits criteria for stereotypy and improves with atypical neuroleptic treatment.

ATYPICAL NEUROLEPTICS

Risperidone

Risperidone was the first medication approved specifically for patients with autism. Information from several case series and double-blind, placebo-controlled studies indicated that

risperidone was effective in reducing irritability in children and adolescents with autism and related disorders (Posey & McDougale, 2008). The Research Units of Pediatric Psychopharmacology (RUPP) Autism Network showed foresight in conducting the first double-blind, placebo-controlled trial of risperidone in children and adolescents with autism. The eight-week study followed 101 youths (mean age, 8.8 years) who were randomly assigned to either risperidone or placebo. Subjects had “significant irritability,” defined by a score of 18 or greater on the Aberrant Behavior Checklist (ABC) Irritability subscale. A mean dosage of 1.8 mg per day provided a 57% reduction on the ABC Irritability subscale score, compared with a 14% in the placebo group (RUPP Autism Network, 2005a; Aman et al., 1985). With “response” defined as greater than 25% improvement on the ABC Irritability subscale score and a rating of “much improved” or “very much improved” on the Clinical Global Impressions–Improvement (CGI-I) scale, 69% on risperidone and 12% on the placebo were responders. An effect size of $d = 1.2$ in favor of risperidone on the main outcome measure was documented by the Research Units in Pediatric and Psychopharmacology (RUPP) Autism Network (Arnold et al., 2010). Even though improvements were seen on the Social Withdrawal and Inappropriate Speech subscales, these were not statistically significant. Risperidone was associated with a mean weight gain of 5.8 lbs., while the placebo group experienced a mean weight gain of 1.8 lbs. Drooling occurred more frequently with risperidone, yet extrapyramidal symptoms (EPS) and tardive dyskinesia (TD) showed no significant differences between the risperidone- and placebo-treated groups (RUPP Autism Network, 2005a).

An analysis of secondary outcome measures showed significant improvements in sensorimotor behaviors, affective reactions, and sensory responses on the modified Ritvo-Freeman Real Life Rating Scale (R-F RLRS), but no significant change appeared on the Social Relationship to People or Language subscales (McDougale et al., 2005; Freeman et al., 1986). The analysis of the Children’s Yale-Brown Obsessive Compulsive Scale (CY-BOCS) found risperidone to be more efficacious than placebo for reducing interfering repetitive behaviors (Scahill et al., 1997).

After the acute eight-week phase of the study, 63 responders entered the extended 16-week, open-label phase of the study (RUPP Autism Network, 2005a). Over the course of 16 weeks, two subjects discontinued taking the drug due to loss of effectiveness, and one due to an adverse event. The remainder of the subjects showed no clinically significant worsening of target symptoms while the mean dosage remained stable. Weight gain averaged 11.2 lbs. during the six months of risperidone treatment. Following the 16-week open-label phase, the 32 subjects who continued to be responders were randomized to either continued risperidone treatment or gradually switch to placebo over the course of three weeks. Of the 16 subjects switched to placebo, 62.5% showed significant worsening of symptoms, while only 12.5% of those continuing on risperidone worsened. Therefore, these results, along with those of another placebo-controlled discontinuation study, suggest that risperidone treatment beyond six months is probably necessary to prevent relapse (RUPP Autism Network, 2005a).

Recently, intention-to-treat (ITT) analyses were performed with suspected moderators and mediators entered into the regression equations (Arnold et al., 2010). The benefit–risk ratio of risperidone appeared better with greater symptom severity prior to treatment. Weight gain was not required for risperidone response, and it might even detract from it. Also, socioeconomic advantage, low prolactin, and absence of comorbid problems non-specifically gave better outcome (Arnold et al., 2010).

In addition to the RUPP study, a second multicenter, placebo-controlled study of risperidone in children and adolescents with PDDs completed the database needed to demonstrate requisite efficacy and tolerability to secure FDA approval (Posey & McDougale, 2008; Shea et al., 2004). This second study included 79 youths (mean age, 7.5 years) randomly assigned to risperidone (mean dose, 1.2 mg/d) or placebo (Shea et al., 2004). All subjects met criteria for PDD and scored greater than 30 on the Childhood Autism Rating Scale (CARS) (Shea et al., 2004; Shopler et al., 1980). The mean baseline score on the ABC Irritability subscale was 20. Risperidone-treated subjects experienced a 64% reduction in the ABC Irritability subscale score, while scores for subjects on placebo only decreased by 31%. Moreover, 53% of subjects on risperidone versus 18% on placebo showed an adequate response to the assigned treatment. Subjects given risperidone gained more weight than those given placebo (5.9 lbs. versus 2.2 lbs.), but extrapyramidal symptoms did not differ between groups over the eight-week study period (Shea et al., 2004).

In smaller study of 30 youths (ages, 8–18 years) treated with risperidone (0.01 mg/kg/d) versus haloperidol (0.01 mg/kg/d) under double-blinded conditions, the risperidone group showed significantly greater reductions in the total ABC scores, along with greater improvements in general behavior compared to a haloperidol group (Posey & McDougale, 2008; Miral et al., 2008). Subjects on risperidone experienced significant increases in prolactin levels (Posey & McDougale, 2008; Miral et al., 2008).

Although controlled studies of risperidone in adults with ASDs are needed, a placebo-controlled study of risperidone did focus on children down to the very young age of two years old (Nagaraj, Singhi, & Malhi, 2006). Children aged two to nine years received risperidone (1 mg/day) or placebo. Scores on the CARS and Children’s Global Assessment Scale showed risperidone to be highly efficacious (Posey & McDougale, 2008; Nagaraj, Singhi, & Malhi, 2006). On the other hand, a six-month, placebo-controlled study of 24 children with PDDs under six years old showed the risperidone dose range of 0.5–1.5 mg/day to be only minimally efficacious compared to placebo (Posey & McDougale, 2008; Luby et al., 2006). The low level of baseline irritability may have dampened the effect seen in other studies in which baseline irritability started substantially higher (Posey, 2008).

Emerging research involving 45 autistic patients treated for up to a year with risperidone monotherapy suggests that polymorphisms on certain candidate genes may help predict clinical improvement with risperidone (Corriea et al., 2010). Corriea and colleagues also found that polymorphisms on particular genes were associated with risperidone-induced

increases in prolactin levels and body mass index (BMI) (Corriea et al., 2010). These associations will require replication, but this early work may eventually lead to routine clinical tests that identify the drug that will work best with the fewest risks of adverse events for a given individual with autism.

Aripiprazole

The second medication approved for aggression and irritability in children with PDDs was aripiprazole. To evaluate the short-term efficacy and safety of aripiprazole in the treatment of irritability associated with autism, 218 children and adolescents (aged 6–17 years) were randomized 1:1:1 to aripiprazole (5, 10, 15 mg/day) or placebo in a double-blind, randomized, placebo-controlled, parallel group, eight-week study (Marcus et al., 2009). The efficacy was assessed with the (ABC) Irritability subscale (primary efficacy measure) and the clinician-rated Clinical Global Impression–Improvement score. All aripiprazole doses showed significantly better ABC Irritability subscale scores (5 mg/day, –12.4; 10 mg/day, –13.2; 15 mg/day, –14.4; versus placebo, –8.4; all, $p < 0.05$). Additionally, all aripiprazole doses delivered significantly greater improvements in the mean Clinical Global Impression–Improvement scores than the placebo group at week 8. Sedation was the most common cause for discontinuation. Mean weight gain was approximately 1 kg greater in each aripiprazole group (5 mg/day, 1.3 kg; 10 mg/day, 1.3 kg; 15 mg/day, 1.5 kg) compared to placebo (0.3 kg). Two serious adverse events—presyncope (5 mg/day) and aggression (10 mg/day)—occurred during the treatment phase. Overall, aripiprazole showed efficacy and was generally well tolerated (Marcus et al., 2009).

An eight-week double-blind, placebo-controlled trial of aripiprazole in 98 youths (aged 6–17 years) showed significantly greater improvement on the ABC Irritability subscale with aripiprazole treatment in a flexible dose range of either 5, 10, or 15 mg/day (Owen et al., 2009).

In a 14-week prospective open-label trial in patients with PDD NOS or Asperger's disorder, Stigler and colleagues noted significant improvement in 22 of 25 (88%) subjects with a dose range of 2.5 to 15 mg in 5–17-year-olds (Stigler et al., 2009). The ABC Irritability subscale dropped from a mean score of 29 at study start to 8.1 at study endpoint (Stigler et al., 2009). Weight gain was the most common adverse event (19/25 subjects, mean +2.3 lbs.) followed by tiredness (16/25 subjects, mild; 1/25 subjects, moderate) and extrapyramidal side effects (EPS) (9/25 subjects, mild) (Stigler et al., 2009).

The RUPP Autism Network implemented an elegantly designed multiple-site study with 124 children aged 4 to 13 who were diagnosed with PDDs accompanied by frequent tantrums, aggression, or self-injury (Aman et al., 2009). Subjects were randomly assigned to either risperidone monotherapy ranging from 0.5 to 3.5 mg/day (MED) or risperidone along with an average of 10.9 sessions of parent training (COMB). A positive clinical response was defined as a rating of “much or very much improved” on the Clinical Global Impression–Improvement subscale plus at least 25% reduction on the ABC Irritability subscale. If clinical response was not reached

by week 8, the risperidone was phased out and replaced with aripiprazole. The study sample was composed of 105 (85%) boys and 19 (15%) girls, with groups similar in terms of household income, parental education, and educational placement; however, the MED group had lower functional skills and was more likely to be treated with anticonvulsants. The COMB group's Home Situations Questionnaire Severity score decreased 71% compared to the MED groups score, resulting in an effect size of 0.34 by week 24. The effect-size differences between the MED and COMB groups were small up to week 16, but by week 24, the effect-size differences were in the medium range and favored the COMB group for the ABC Irritability and Hyperactivity/Noncompliance subscales (Aman et al., 2009a).

Olanzapine

Evidence for olanzapine's effectiveness is limited to one small placebo-controlled study and three open-label trials (Posey, 2008). The small, eight-week, placebo-controlled study enrolled 11 subjects (aged 6–14) randomly assigned to olanzapine (mean dose, 10 mg/day) or placebo (Hollander et al., 2006). While three of six (50%) subjects on olanzapine responded, one of 5 (20%) on placebo met response criteria. The olanzapine group gained substantially more weight (mean weight gain, 7.5 lbs., versus 1.5 lbs. on placebo) (Hollander et al., 2006).

A 12-week open-label study of olanzapine (mean dose, 7.8 mg/day) in eight individuals (mean age, 20.9 years; age range, 5–42 years) reported significant improvement irritability in six of the seven (86%) subjects completing the study (Potenza et al., 1999). Weight gain was significant in six subjects (mean weight gain, 18.4 lbs.), while three subjects experienced sedation (Potenza et al., 1999). Another six-week open-label study used a parallel group design to compare olanzapine (mean dose, 7.9 mg/day) versus haloperidol (mean dose, 1.4 mg/day) in 12 children with autism (mean age, 7.8 years) (Malone et al., 2001). Five of six (83%) subjects on olanzapine responded to treatment, whereas three of six (50%) improved on haloperidol. The olanzapine-treated subjects gained more weight (mean, 9 lbs.; range 5.9 to 15.8 lbs.) compared to those on haloperidol (mean 3.2 lbs.; range, –5.5 to +8.8 lbs.) (Malone et al., 2001).

On the other hand, a three-month open-label study of olanzapine (mean dose, 10.7 mg/day) in 25 children (mean age, 11.2 years) with PDD found it to be effective in only three (12%) subjects. As was the case in preschool-aged children treated with risperidone, low baseline scores on the ABC Irritability subscale may have contributed to the limited improvement in this study (Posey, 2008).

Quetiapine

Only two prospective and two retrospective studies have examined the benefits of quetiapine in persons with PDD (Posey & McDougale, 2008). In a 16-week open-label study (mean dose, 225mg/day), two of six (33%) of the youths (ages, 6–15 years) responded to treatment (Martin et al., 1999).

Of the nine subjects originally enrolled, two discontinued due to sedation or lack of response, and one due to a possible seizure (Martin et al., 1999). Weight gain ranged from 2 to 18 lbs. The other prospective study enrolled nine adolescents (age range, 12–17 years) for a 12-week trial on quetiapine (mean dose, 292 mg/day). Again, only six of nine subjects completed the study, with a mere two (22%) subjects considered responders (Findling et al., 2004). One of the subjects discontinued due to agitation and aggression, and weight gain and sedation were the most common adverse events in other subjects (Findling et al., 2004).

In the first published retrospective study, 20 subjects (mean age, 12.1 years; range 5–28 years) received monotherapy with quetiapine (mean dose, 249 mg/day; range, 25–600 mg/day) for at least four weeks (mean duration, 59.8 weeks; range, 4–180 weeks) (Corson et al., 2004). Although eight (40%) subjects responded, 15% of the subjects discontinued, while 50% reported adverse events (Corson et al., 2004). The other retrospective review included ten subjects (ages, 5–19 years) who were diagnosed with PDD and mental retardation (MR) (Hardan, Jou, & Handen, 2005). The mean dose of quetiapine was 477 mg/day, and concomitant medications were allowed as long as the dosages did not change during the period of observation on quetiapine. A response rate of 60% resulted from the intervention, with mild sedation, excessive salivation, and weight gain reported as adverse events (Hardan, Jou, & Handen, 2005).

Ziprasidone

Evidence for ziprasidone in treating irritability associated with PDD is limited to three published papers (Posey & McDougale, 2008). One six-week, prospective, open-label study of ziprasidone enrolled 12 adolescents (mean age, 14.5 years; range 12–18 years) with autism who were treated with ziprasidone (mean dose, 98.3 mg/day; range 20–160 mg/day) (Malone et al., 2007). At the study endpoint, 9 of the 12 subjects responded to treatment with reduction in irritability, aggression, and hyperactivity. Acute dystonic reaction occurred in two subjects, but ziprasidone treatment appeared to be weight-neutral. Electrocardiography recorded a mean prolongation in QTc of 14.7 milliseconds which should be considered in the context of the FDA warning about using ziprasidone with other drugs that may prolong QTc in individuals with known cardiac arrhythmias or a long QT syndrome. Total cholesterol decreased without any change in prolactin levels (Posey & McDougale, 2008; Malone et al., 2007).

The first retrospective review reported on 12 subjects (mean age, 11.6 years; range 8–20 years) receiving open-label treatment with ziprasidone (mean dose, 59.2 mg; range, 20–120 mg/day) for at least six weeks (mean duration, 14.2; range, 6–30 weeks) (McDougale, Kem, & Posey, 2002). Aggression, agitation, and irritability improved in six (50%) of the 12 subjects. Transient sedation was the most common adverse event, and no untoward cardiac effects were reported or observed. Although a mean weight loss of 5.8 lbs. (range, –35 to +6 lbs.) was documented, this probably occurred as a result of subjects'

being switched from other medications known to cause significant weight gain (McDougale, Kem, & Posey, 2002). The second retrospective study involved ten adults with autism and mental retardation who switched from clozapine, risperidone, or quetiapine to ziprasidone (Cohen et al., 2004). Weight gain most often prompted the switch, and ziprasidone resulted in a significant mean weight loss of 9.5 lbs. after six months of treatment. Maladaptive behaviors improved in six subjects, while three subjects experienced worsening, and one remained unchanged with respect to the maladaptive behaviors (Cohen et al., 2004).

Paliperidone

Paliperidone, approved by the FDA for schizophrenia in adults, is the major active metabolite of risperidone and the only atypical antipsychotic agent to use the Osmotic [Controlled] Release Oral System (OROS™) technology (Stigler et al., 2010). Unlike risperidone, cytochrome P450 2D6 (CYP2D6) has a limited role in the elimination of paliperidone, and most of the drug is excreted mainly unchanged in the urine. Recently, case reports of a 16-year-old Caucasian female and a 20-year-old Caucasian male with DSM-IV-TR-defined autism suggested that paliperidone may be an effective and well-tolerated treatment for severe irritability in adolescent and adult patients with autism (Stigler et al., 2010).

Clozapine

At the end of the list of atypical antipsychotic agents is clozapine. It rounds off the list as one the last medications to try, due to factors that make it an end-of-the-line treatment for schizophrenia. The main reason it is reserved as a last-ditch treatment is the risk of agranulocytosis. Many patients with autistic spectrum disorder struggle with venipuncture in conjunction with their yearly physical, so biweekly blood work would be out of the question. Since the prevalence of seizures ranges between 20% and 35% in adults and 17% and 14% in children and adolescents with ASD (Minshew, Sweeney, & Bauman, 1997; Rapin, 1996), clozapine would not be a first-line choice given its propensity to lower the seizure threshold (Posey & McDougale, 2008). Moreover, the literature only documents three reports of the use of clozapine in individuals with ASD. Three children ages 8 to 12 received treatment with clozapine 200–450 mg/day after they failed haloperidol treatment for eight months. Zudda and colleagues reported that decrease in aggression, hyperactivity, and negativism was sustained in two of the children, while the third child relapsed after five months (Zudda et al., 1996). These three children experienced transient sedation and enuresis (Zudda et al., 1996). Chen and colleagues treated a 17-year-old male inpatient with clozapine 275 mg/day and showed significant reduction in “overt tension,” hyperactivity, and stereotypies; however, the period of observation was only 15 days (Chen et al., 2001). A case report on a 32-year-old male patient with autism and profound mental retardation treated with clozapine 300 mg/day showed marked improvement in treatment-refractory aggression and social interactions over two months, with

further improvements over five years of treatment (Gobbi & Pulvirenti, 2001). This individual did not develop extrapyramidal syndrome (EPS) or agranulocytosis over the five years of treatment, but literature on clozapine's use in autistic spectrum disorder is scant and the risk of agranulocytosis serious, albeit uncommon, so it should remain delegated to a last-resort treatment until more substantial data are available.

On the other hand, EPS is much more common with typical antipsychotic agents, but they have been a mainstay of managing certain psychiatric conditions in the medical setting. The typical antipsychotic agents have a track record for rapid and reliable treatment stretching back decades. The typical antipsychotic agents often served as first-line treatments for aggression and agitation associated with delirium, psychotic disorders, and mania in the medical setting, given that they were less expensive than their non-generic atypical counterparts. In recent years, generic versions of atypical neuroleptics narrowed the price gap between the typical and atypical antipsychotic agents, so hospital formularies usually offer easy access to first-generation atypical agents, from aripiprazole to ziprasidone. Nonetheless, the typical antipsychotic agents still maintain an edge in the medical setting, because they can be rapidly titrated, and, in certain situations, intramuscular formulations can be used to expedite an effective dosage and thereby reduce patients' length of stay.

TYPICAL NEUROLEPTICS

Haloperidol

In hindsight, many of the earliest studies using typical antipsychotic agents to treat self-injurious behaviors (SIB) and aggression in individuals with autism contained flaws in methodology or diagnostic accuracy. The first well-designed research studies in this vein came from Campbell and colleagues, who systematically evaluated haloperidol in children with autism (Campbell et al., 1978). They first studied children with autism aged 2.6 to 7.2 years treated with haloperidol (mean dosage 1.7 mg/day) versus placebo in combination with one of two language-based training groups. Although sedation occurred in 12 and dystonia in 2 of the 20 subjects on haloperidol, significant improvement was noted in symptoms of withdrawal and stereotypy in the youths aged 4.5 years and older who were randomized to medication treatment (Campbell et al., 1978). Other studies showed that haloperidol targeted a range of maladaptive behaviors in youths, but acute dystonic reactions and dyskinesias consistently appeared in this treatment population (Posey & McDougale, 2008). Two larger studies focused on the association between haloperidol treatment and the frequency of dyskinesias. One study enrolled 60 children aged 2.3 to 7.9 years and randomly assigned them to either continuous or discontinuous (5 days on and 2 days off) treatment with haloperidol for six months, followed by one month on placebo. The other treated 118 children aged 2.3 to 8.2 years with haloperidol for six months, followed by one month on placebo. In both studies, withdrawal dyskinesias occurred more frequently and tended to be reversible; however, nine of ten subjects treated with the higher mean dosage of haloperidol 3.4 mg/

day developed dyskinesias in the latter study (Posey, 2008). In general, children and adolescents experience more movement disorders with the high-potency typical antipsychotic agents than do adult patients. Unfortunately, the high-potency typical neuroleptics such as haloperidol have not been studied systematically in adults with autism. Poor tolerability in terms of dyskinesias limits the use of high-potency and sedation the use of low-potency antipsychotic agents in children; however, the high-potency typical neuroleptics may have a role in the treatment of adults with autism, given that they have a long and successful history of treating agitation and aggression secondary to other conditions in adults.

ALPHA-2 ADRENERGIC AGONISTS

Guanfacine and Clonidine

Since irritability, agitation, and self-injurious behaviors cause such problems for persons with autism or those who care for them, a number of other medications have been studied. These medications may have offered a better side effect profile, but they proved to be less effective than the two FDA-approved atypical neuroleptics. Moreover, shortcomings in the design of these published reports limit one's ability to generalize the results. The largest of these studies retrospectively analyzed guanfacine (mean dosage 2.6 mg/day) treatment in 80 subjects aged 3 to 18 years (mean age 7.7 years) with PDD (Posey et al., 2004). Subjects diagnosed with Asperger's disorder or PDD NOS showed a greater response than those with autism; however, guanfacine was only effective in 10 of 69 (14%) subjects with significant aggression (Posey et al., 2004). In a six-week, double-blind, placebo-controlled crossover trial of clonidine (dosage range 0.04–0.10 mg/kg/day) in eight youths aged 5 to 13 (mean age, 8.1 years) with autism, significant improvements were noted on the Autism Behavior Checklist by teacher and parent ratings, but not by the clinician (Posey, 2008). A similarly designed four-week study with transdermal clonidine (dosage range 0.16 to 0.48 mg/day) in nine individuals aged 5 to 33 (mean age, 12.9 years) appeared beneficial for impulsivity, hyperarousal, and self-stimulation (Posey & McDougale, 2008). Sedation was the most common side effect in all the above studies with alpha-2 adrenergic agonists (Posey, 2008). Presently, long-acting formulations of guanfacine and clonidine have been approved for the treatment of attention-deficit hyperactivity disorder (ADHD) in children, and these may offer a better pharmacokinetic profile for individuals with autism. Nevertheless, these long-acting alpha-2 adrenergic agonists have not been systematically studied in the autistic population. Again, except for the few adult patients in the transdermal clonidine study above, the literature remains limited to the children and adolescents with autism.

ANTICONVULSANTS AND MOOD STABILIZERS

Divalproex

Given that mood stabilizers and certain anticonvulsants show efficacy in controlling agitation in manic states, these were a logical choice for possibly controlling agitated, aggressive

states in persons with autism. The most well-designed study of this group was an eight-week double-blind, placebo-controlled study of divalproex sodium in 30 subjects aged 6 to 20 years with PDD and significant aggression. Despite a mean serum trough level of 77.8 ug/mL, no significant difference between treatment and placebo groups was noted on the ABC Irritability subscale (Hellings et al., 2005). A smaller, open-label study of divalproex sodium (mean dosage, 768 mg/day) resulted in CGI-I ratings of “much improved” or “very much improved” in 10 of 14 subjects. Improvement was noted in impulsivity, aggression, and affective instability (Posey, 2008).

Lamotrigine

Although 8 of 13 (62%) youths initially prescribed lamotrigine for intractable epilepsy experienced a reduction in interfering behavioral symptoms, a double-blind, placebo-controlled trial in 14 youths aged 3 to 11 with autism demonstrated no differences between lamotrigine (5 mg/kg/d) and placebo groups on the Autism Behavior Checklist over the four weeks of treatment (Posey, 2008). In a small, naturalistic study of five patients aged 9 to 13 treated from 10 to 33 weeks (mean duration, 22 weeks) two of five responded with CGI-I ratings of “much improved” or “very much improved” for irritability, anger, and hyperactivity. Of note, two study patients received add-on sertraline at six months for obsessive behaviors, while another one was on long-term treatment with risperidone (Mazzone et al., 2006).

Levetiracetam

Rugino and colleagues investigated levetiracetam for the treatment of aggression, hyperactivity, mood lability, and impulsivity in ten children aged 4 to 10 with autism (Rugino & Samsock, 2002). Over the course of four weeks of treatment, only the subjects who were not recently weaned from drugs targeting aggression showed significant improvement in aggression. Nevertheless, a ten-week, double-blind, placebo-controlled study of levetiracetam (mean dosage, 862.5 mg/day) in 20 youths (age range, 5–17 years) with autism found no significant difference in parent and teacher ratings on the Autism Behavior Checklist between the levetiracetam and placebo group (Wasserman et al., 2006).

With estimates of seizure disorders of up to 35% of adults and 14% of children with autism, the appropriate anticonvulsant can be life-saving and offer improvement in functioning, but as a treatment solely targeting aggression and self-injurious behaviors without a comorbid seizures, these medications have shown inconsistent results (Bauman, 2010). At any rate, new-onset disruptive behaviors should make one consider the possibility that a seizure disorder might be emerging, particularly if caregivers cannot identify any changes in the environment or clinicians do not observe any other common medical issues that might provoke the change in behavior. Sensory issues may pose challenges to obtaining electroencephalography (EEG) in some individuals with autism, but the results can be a useful guide to the type of medication that should be employed, if EEG abnormalities appear. Be aware that the

partial complex seizures occur most frequently in individuals with ASD, and atypical behaviors and body movements associated with this type of seizure may be attributed to ASD. Temporal lobe seizures sometimes escape detection on regular EEG recordings, so clinical judgement should guide whether the patient could tolerate continuous monitoring with videography or the use of nasopharyngeal leads to confirm seizure activity.

Nonetheless, not all odd movements and mannerisms arise from abnormal EEG activity or stereotypical ASD symptoms. Other medical conditions, ranging from asthma to gastric reflux to acute sinusitis, could manifest in abnormal behaviors, particularly if the person with ASD struggles with expressing pain and distress (Buie, 2005).

Lithium

Lastly, one case report of lithium (900 mg/day) augmenting fluvoxamine therapy in an autistic patient without comorbid mania or bipolar disorder resulted in a marked decrease in aggression and impulsivity after two weeks of treatment (Epperson et al., 1994).

COMORBIDITY

Often, autistic symptoms predominate in the clinical picture, which causes clinicians and caregivers to overlook comorbid psychiatric and medical conditions and mistakenly attribute these to autism. A condition that could be addressed in conventional ways goes unrecognized and untreated. In the case of psychiatric disorders, a strong family history of mood, anxiety, or psychotic disorders should make clinicians vigilant to the emergence of such disorders in their patient with ASD.

For persons of normal intelligence with ASDs, estimates of coexisting psychiatric conditions vary considerably, from 9% to 89% (Hofvander et al., 2009). Hofvander and colleagues examined a sample of normal-intelligence individuals with ASD ($n = 122$) and noted that 80% of the of adult subjects met criteria for at least one other major Axis-I disorder, whereas all subjects in the Asperger's syndrome and PDD NOS subgroups carried at least one other comorbid Axis-I diagnosis (Hofvander et al., 2009). Several studies cite mood disorders along with anxiety disorders as common co-morbid psychiatric conditions (Hofvander et al., 2009). A lifetime incidence of mood disorder ranked highest of the comorbid psychiatric conditions ($n = 65$, 53%) with a third of the subjects ($n = 42$, 34%) having been prescribed antidepressant medications at least once in their lives, according to Hofvander's more recent work (Hofvander et al., 2009). Approximately 8% ($n = 10$) of the subjects with AS or PDD NOS in Hofvander's sample met criteria for bipolar disorder (Hofvander et al., 2009). The small sample size of subjects with ASD in this study prevented any accurate prediction of incidence rates in the larger population with ASD.

Anxiety disorders followed as the second most commonly encountered DSM-IV condition in individuals with normal intelligence and ASDs in Hofvander's study (Hofvander et al., 2009). The anxiety disorders in this sample included: generalized anxiety disorder ($n = 18$, 15%), social phobia ($n = 16$,

13%), panic disorder ($n = 13$, 11%), specific phobia ($n = 7$, 6%), post-traumatic stress disorder (PTSD) ($n = 2$, <2%), and anxiety disorder NOS ($n = 1$, <1%). Other studies note high rates of tic disorders, but tics are sometimes difficult to distinguish from stereotypical movements associated with ASDs (Posey, 2008). Substance use disorder (SUD) was more common in the PDD NOS group than the AD group, with alcohol listed as the most frequently abused substance (Hofvander et al., 2009). Fifteen percent ($n = 19$) of the subjects met criteria for SUD, while 12% ($n = 15$) reported alcohol as the substance of choice (Hofvander et al., 2009). Intermittent explosive disorder ranked at the top of the list for impulse control disorders, with an incidence rate of 6% ($n = 7$) (Hofvander et al., 2009). According to Hofvander and colleagues, about 12% ($n = 15$) of the adults in this sample met criteria for a psychotic disorder, and 15% ($n = 18$) had received neuroleptic medication at least once in their lives (Hofvander et al., 2009). In Hofvander and colleagues' sample, a substantial proportion ($n = 52$, 43%) met DSM-IV criteria for ADHD. The PDD NOS subgroup exhibited more symptoms of inattention and hyperactivity/impulsivity than their AS counterparts. About 14% ($n = 16$) had a reading disorder in combination with a disorder of written expression.

Larger prospective studies may provide more precise estimations of comorbid conditions in the future. At the present time, clinicians should be aware that comorbid conditions are a logical target for psychopharmacological interventions, even if this means extrapolating information from treatment studies performed on persons with various psychiatric disorders who were not diagnosed with an ASD.

Sometimes sorting out symptoms related to autism and those related to other comorbid conditions proves difficult. For instance, restrictive, repetitive behaviors and interests (RRBIs) resemble obsessions and compulsions typical of obsessive-compulsive disorder (OCD). The DSM-IV defines RRBIs as follows:

A preoccupation with stereotyped and restricted patterns of interest;
Inflexibility in adhering to routines and rituals;
Stereotyped and repetitive motor mannerisms;
Persistent preoccupations with parts of objects.

(Soorya, Kiarashi, & Hollander, 2008)

Neuropsychological, behavioral, and biological theories have been proposed to explain repetitive and restrictive behaviors in ASD. This chapter focuses on the biological theories, since double-blind, placebo-controlled trials of medications have tried to target the proposed dysregulation of serotonin or sensitivity to dopamine or endogenous opioids.

As for the RRBIs seen in autism, McDougle and colleagues reported differences in the Yale-Brown Obsessive Compulsive Scale (YBOCS) in autistic adults compared to those with OCD (Soorya, Kiarashi, & Hollander, 2008). Those with autism exhibited more compulsive behaviors than obsessions, and their obsessions were less likely to involve sex, religion, symmetry, contamination, and aggression compared to adults with only OCD (Soorya, Kiarashi, & Hollander, 2008). With

the similarities between RRBIs and OCD symptoms, drugs used for OCD treatment were tried for RRBIs in autistic individuals. A study by Shain, Freedman, and colleagues as well as other subsequent studies indicate that approximately a third of individuals with autism express elevated platelet levels of serotonin (Soorya, Kiarashi, & Hollander, 2008; Cook & Leventhal, 1996). McDougle and colleagues demonstrated that tryptophan depletion in adults with autism led to their exhibiting more repetitive behaviors such as whirling, flapping, pacing, banging, rocking, and self-injury. In addition, they showed that the sensitivity of the 5-HT_{1d} receptor positively correlated with the severity of repetitive behaviors (Soorya, Kiarashi, & Hollander, 2008). With this evidence, serotonin-reuptake inhibitors (SRIs) and selective serotonin-reuptake inhibitors (SSRIs) reuptake inhibitors received attention as possible interventions for the RRBIs associated with autism.

SEROTONIN-REUPTAKE INHIBITORS

Despite significant improvement in RRBIs in the double-blind, placebo-controlled trials of clomipramine, they lack approval for the treatment of the repetitive and restrictive aspects of autism due to the small size of the studies and tolerability issues. An early randomized, cross-over study of children with autism started with a two-week single-blind placebo phase followed by a crossover to ten weeks in either the clomipramine/placebo ($n = 12$) or the clomipramine/desipramine arm ($n = 12$). Clomipramine performed better than desipramine and placebo, as measured by the Autism subscale of the Children's Psychiatric Rating Scale and several outcome measures of OCD (Gordon et al., 1993). Although adverse events paralleled those seen in the treatment of OCD, one subject was dropped due to a seizure (Gordon et al., 1993). Other open-label and placebo-controlled studies showed less favorable outcomes (Posey, 2008). For example, clomipramine failed to separate from placebo in terms of decreased stereotypy on the ABC in a double-blind, placebo-controlled crossover trial of clomipramine, haloperidol, and placebo (Remington et al., 2001). High dropout rates occurred, with 20 of 32 subjects prematurely terminating in the clomipramine arm, vs. 10 out of 32 of those receiving haloperidol (Remington et al., 2001). Those receiving clomipramine reported high rates of fatigue, tremors, tachycardia, diaphoresis, and behavior problems (Remington et al., 2001). The need to monitor serum levels and electrocardiograms during treatment especially complicates treatment with SRI agents.

SELECTIVE SEROTONIN-REUPTAKE INHIBITORS

Since SSRI medications offered a more favorable side effect profile, a number of open-label studies with sertraline, citalopram, escitalopram, fluvoxamine, and fluoxetine attempted to demonstrate improvement in RRBIs associated with autism (Posey & McDougle, 2008). These open-label studies incorporated various designs, sample sizes, and durations

of treatment, but results tended to be positive in terms of decreasing RRBI (Posey & McDougle, 2008). Of note, the literature lacks studies of citalopram and escitalopram in adults with ASDs.

At present, double-blind placebo-controlled trials of fluvoxamine ($n = 30$) and fluoxetine ($n = 6$) in adults and fluoxetine ($n = 45$) in children and adolescents reported significant improvement in repetitive behaviors on YBOCS or Children's YBOCS (C-YBOCS), depending on the age group (Posey & McDougle, 2008). However, a double-blind, placebo-controlled study of fluvoxamine in children and adolescents ($n = 18$, mean age 9.5 years) with ASDs showed a poor response, with 14 of the subjects reporting notable adverse events (Posey & McDougle, 2008).

Unfortunately, limited information is available about the effect size, response rates, and other clinically pertinent points related to SSRIs in the treatment of major depression and other anxiety disorders. The same holds true for other classes of medications for mood disorders, including norepinephrine-reuptake inhibitors, tricyclic antidepressants, and monoamine oxidase inhibitors. Although not specifically studied in individuals with autism, the sedating properties of some of these classes of medication may address insomnia. For example, fluvoxamine, mirtazapine, and other medications could improve insomnia; however, trazodone probably should be avoided in males who cannot communicate, given the risk that priapism could occur and go untreated.

BENZODIAZEPINES

Clonazepam can be effective for non-rapid-eye-movement (REM) arousal disorders. It may be particularly helpful for individuals who exhibit repetitive, stereotyped, and rhythmic motor behaviors that impair their transition to sleep. Even though clonazepam does not always improve non-REM sleep disorder behaviors, it often helps REM sleep behavior disorders. Nonetheless, the use of benzodiazepines has not been extensively studied in persons with autistic spectrum disorders. Therefore, one must infer the benefits of benzodiazepines from studies performed with persons without autism. On the other hand, the risks, such as dependence, cognitive slowing, and reduced respiratory drive, are assumed to be at least as prevalent in persons with autism as in those without PDD. Paradoxical reactions can occur with benzodiazepines, and this may happen somewhat more frequently in persons with autism in this author's experience. Therefore, start benzodiazepines at a low dosage, and watch for disinhibition as the medication is slowly titrated.

Of course, non-pharmacological approaches to insomnia, such as attention to sleep hygiene, should be tried before turning to medications. Should these fail, a number of other prescription medications are now FDA-approved for the treatment of insomnia in adults, but few if any of the subjects in the studies had an ASD. Although no medication has FDA approval for the treatment of insomnia in children, two open-label trials of melatonin, one with immediate release (3 mg, $n = 15$), another combining immediate and controlled release (3–6 mg, $n = 16$), and a retrospective trial of melatonin ($n = 100$) in

children with ASD suggest that this supplement could reduce time to sleep onset and increase total sleep time (Posey, 2008). Like other over-the-counter supplements and herbal remedies, the purity and bioavailability of melatonin products may vary widely, as these are not regulated by the FDA.

DIETARY SUPPLEMENTS

Thus far, the literature on dietary supplements appears weak, and the few positive studies usually suffer from methodological flaws or small sample sizes. One of the better studies was a double-blind, placebo-controlled trial of l-carnitine 800 mg/day in 31 children with autism. In this study, a substantial improvement on the Gilliam Autism Rating Scale was seen over the eight-week trial (Crill & Helms, 2007). Although tryptophan depletion in adults diagnosed with autism resulted in worsening of their symptoms, no convincing evidence exists to suggest that supplementing with tryptophan or other amino acids improves autism symptoms. A 30-week, double-blind, placebo-controlled trial of vitamin C in 18 children with ASD showed positive results. A double-blind, placebo-controlled trial ($n = 18$ children) of supplementation with vitamin C for 30 weeks resulted in a reduction in stereotyped behaviors (Dolske et al., 1993). Another randomized, double-blind, placebo-controlled trial ($n = 13$ children) of omega 3 fatty acids reduced severe behavioral difficulties (Amminger et al., 2007). Supplementation with vitamin B₆ plus magnesium showed improvement in IQ and social quotient in one small study ($n = 8$); no change was noted in a slightly larger randomized, double-blind, placebo-controlled study ($n = 12$). Even though an open-label study of 33 children also showed improvement, all three studies contained methodological shortcomings (Posey & McDougle, 2008). Moreover, studies with supplements primarily focused on children, so even less is known about the use of dietary supplements in adults with autism. On the other hand, the use of vitamins and other supplements whenever a specific deficiency is present makes good clinical sense.

PSYCHOSTIMULANTS

In general, psychostimulants lack the robust effectiveness in treating attention deficits and impulsive behaviors in persons with ASD compared to those with typical ADHD, and side effects tend to be more common in the ASD group. Nonetheless, psychostimulants could improve adherence to treatment and increase functioning in some individuals on the ASD spectrum. Given the problems with tolerability, trials with psychostimulants should be deferred until after episodes of acute medical illness resolve. Patients in pain or distress from acute illnesses typically exhibit a reduced capacity for concentration, and their hyperactivity might be an attempt to find a body position that minimizes their physical discomfort. As always, clinicians should use every means available to ascertain whether a patient with ASD is suffering, then make every effort to relieve the physical pain. Once the patient is fully recovered from an illness, a reexamination of

his level of inattention, hyperactivity, and impulsivity can be considered.

The preponderance of studies on the benefits of stimulants in children with ASD was done with younger subjects, so scant information is available about the ways that adolescents or adults with ASD might respond to such treatments. The RUPP Autism Network conducted the best of these studies to date. The RUPP study sample included 72 youths between the ages of 5 and 14 years (RUPP Autism Network, 2005b). About 74% of the sample carried the diagnosis of autism, while another 26% had PDD NOS or Asperger's disorder as their diagnosis (RUPP Autism Network, 2005b). This double-blind, crossover, placebo-controlled study used one-week treatment phases with doses of methylphenidate (immediate release) approximating 0.125, 0.25, and 0.5 mg/kg (RUPP Autism Network, 2005b). The first two doses of the day were the same, while the last dose, given in the late afternoon, was smaller to improve tolerability (RUPP Autism Network, 2005b). The ABC as scored by parents served as the main outcome measure (RUPP Autism Network, 2005b). About half of the subjects (39/72) responded favorably to the methylphenidate, whereas 18% (13/72) dropped out of this study due to side effects (RUPP Autism Network, 2005b). Parent ratings showed significant improvement in their children on the Hyperactivity subscale, while their ratings on the Withdrawal subscale of the ABC was significantly worse on the higher dosage (RUPP Autism Network, 2005b). A subsequent analysis by Posey and his colleagues of those who completed the Swanson, Nolen, and Pelham (SNAP) rating scale reported that parents saw significant improvement at all three dosages, while teachers only appreciated significant improvement in the youths at the medium and high dosages on the Hyperactivity subscale (Posey, 2008). Irritability, emotional outbursts, and initial insomnia associated with methylphenidate caused the most problems for those who experienced side effects (Posey, 2008).

Beyond the RUPP study, the literature remains weak, with two small double-blind, placebo-controlled, crossover studies of methylphenidate ($n = 10$, mean age 8.5 years; $n = 13$, mean age 7.4 years), which suggested a trend toward improvement compared to placebo (Posey, 2008). In the smaller study of the two, a significant but modest improvement was noted on the Conners' Parent and Teacher Rating Scales and the clinician-completed ABC Hyperactivity subscale (Posey, 2008). The other study focused on results from the Conners' Abbreviated Symptom Questionnaire and the ABC Hyperactivity subscale completed by teachers (Posey, 2008). A few other small ($n = 9$ to 15), open-label studies with methylphenidate using Conners' Rating Scales or other instruments reported similar results compared to those above (Posey, 2008). Of note, two older studies in children ages 3 to 6 years using amphetamines (d-amphetamine, $n = 16$; and l-amphetamine, $n = 11$) were conducted with autistic children during inpatient hospitalizations (Posey, 2008). The d-amphetamine study employed an open-label design, while the l-amphetamine used a crossover design with levodopa; however, both studies showed worsening in the majority of the patients on the CGI scale (Posey & McDougale, 2008).

About half of the individuals with "ADHD but not PDD" continue to have symptoms as adults. With this in mind, one could expect that a number of adults with PDD and ADHD symptoms would follow a similar pattern and perhaps require treatment into adulthood. The bulk of research on stimulant use in persons with PDD focused on children and adolescents. If using stimulants in adults with PDD, be aware that this class of medication reliably increases blood pressure and pulse. This may cause problems in individuals with hypertension or borderline hypertension. The elevated heart rate could be construed as an anxiety symptom as well. Nevertheless, carefully monitoring adult patients who are prescribed stimulants provides the optimal level of care and predicts a better outcome.

Atomoxetine

The norepinephrine-reuptake inhibitor atomoxetine offers another approach to treating ADHD symptoms in the context of PDD. Arnold and colleagues used a randomized, double-blind, placebo-controlled, crossover design in their study with a one-week washout period (Posey & McDougale, 2008). Of the 16 children enrolled, one discontinued early due to adverse events, and two others due to lack of effect (Posey, 2008). Responder status (25% reduction on the ABC Hyperactivity subscale and a 1 or 2 on the CGI) was achieved by 56% ($n = 9$) of the children while 25% ($n = 4$) responded to placebo (Posey & McDougale, 2008). Although the response rate was lower than that found in larger studies of children with ADHD who did not have PDD, it produced a slightly better response rate than the RUPP study using methylphenidate cited above (Posey, 2008). Several small open-label studies using atomoxetine in children with ASD showed significant improvement on the Conners' Parent Rating Scale (Jou, Harden, & Handen, 2005), the parent-rated investigator-scored ADHD Rating Scale-IV (ADHD RS), and the ABC (Troost et al., 2006), and the CGI and SNAP (Posey, Wiegman, & Wilkerson, 2006). Although the literature is limited and mainly confined to studies of younger subjects, improving ADHD symptoms may be helpful in a number of ways.

SUMMARY

Given the paucity of effective treatments for persons with autism, clinicians face special challenges whenever they encounter persons on the autistic spectrum who present with medical problems. This chapter presents a few interventions that may lessen this challenge and provide better care for this population of patients. A major obstacle includes the difficulty of obtaining an accurate history. Verbal communication skills range from nonverbal on the severely autistic side of the spectrum, to those with precocious vocabularies at the Asperger's disorder end of the spectrum. Despite their impressive vocabularies, most of these patients still struggle with expressing internal states. This lack of a first-person description of internal states often obscures the clinical picture and

can hinder accurate reporting of adverse events. Since many young people show difficulty expressing internal states, child and adolescent psychopharmacologists adhere to the adage “Start low and go slow.” In treating persons of any age who carry a diagnosis of ASD, the prescribing clinician would be wise to start very low and go very slow, if possible.

Although studies can help guide treatment in youths with PDD and disruptive behaviors, the literature has neglected adults who continue to meet criteria for PDD and consistently or intermittently display aggressive, irritable, or disruptive behaviors. The clinician treating these issues in older persons on the PDD spectrum must rely on safety data from studies of these drugs in adults with other psychiatric disorders and presume that some measure of effectiveness of these drugs in dampening disruptive behaviors in children and adolescents will also apply to adults. Until well-controlled studies in the adults with PDD are done, extrapolating results from studies of youths with autism will be the best approach.

Lastly, less is known about the effective treatments for psychiatric disorders co-morbid with autism spectrum disorder. Study size, design flaws, and other limitations mean that clinicians will need to carefully extrapolate information from the scientific literature as they try to apply study results to the clinical setting. Of note, medications approved for certain psychiatric disorders show less robust response rates or appear less effective in studies that target mood, anxiety, or other psychiatric conditions in persons with autism. The population with PDD also experiences more adverse event in clinical trials compared to subjects in studies recruited from the general population. Despite these limitations, clinicians should take care to thoroughly assess their patients with autism to make sure that co-morbid psychiatric and medical conditions are appropriately diagnosed and adequately treated.

CLINICAL PEARLS

- Common symptoms occur with pervasive developmental disorder (PDD): self-injurious behaviors, poor concentration, insomnia, sensory integration issues, and other comorbid psychiatric conditions. These deserve separate consideration and attention.
- Sensory integration issues include:
 - Hyposensory-social: does not respond to own name, ignores new persons, seeks rough-housing play
 - Hyposensory-nonsocial: stares at lights/objects; flaps arms, does not give attention to novel objects, mouths objects, ignores loud noises, smells objects, does not respond to pain, craves movement
 - Hypersensory-social: dislikes being held, is distressed during grooming, is averse to social touch, avoids eye contact, dislikes tickling
 - Hypersensory-nonsocial: is sensitive to loud noises, avoids textures, is sensitive to lights, is averse to water, avoids food taste/texture (Baranek, 2006)

- Clinicians must be aware that people with autism frequently exhibit finicky eating patterns because of sensory integration issues or restrictive behavior. They are sensitive to tastes and textures of food.
- A person with autism may be “stuck” on eating foods of a certain color and stick to a “beige” diet. Such restricted diets can lead to dietary deficiencies.
- The astute clinician treating patients with autism should have a close relationship with a compounding pharmacist who can convert certain medications from pill form to solutions or suppositories.
- Even patients with autism who possess impressive vocabularies might display great difficulty in expressing their feelings or internal states.
- Clinicians should remain aware that their patients with higher functioning autism probably interpret conversations in literal terms with concrete thinking.
- Mood, anxiety, and other psychiatric disorders often go undiagnosed in the patient with autism.
- Alcohol is the most common substance abused among those with autism. ADHD is common.
- Repetitive behaviors include whirling, flapping, pacing, head banging, rocking, and self-injury.
- Insomnia is common and should be treated as a separate problem or as a component of a comorbid psychiatric disorder.
- Partial complex seizures and other seizures occur more frequently in individuals with autism spectrum disorder (ASD).
- Stimulants are not as effective in ASD as they are in attention-deficit disorder.
- Atypical antipsychotic agents can diminish disruptive behavior in patients with ASD.
- Restrictive repetitive behaviors and interests (RRBIs) resemble obsessions and compulsions typical of obsessive compulsive disorder (OCD). These include: a preoccupation with stereotyped and restricted patterns of interest; inflexibility in adhering to routines and rituals; stereotyped and repetitive motor mannerisms; and persistent preoccupations with parts of objects.

DISCLOSURE STATEMENT

Dr. Doyle has received honoraria for lectures presented at the Universite di Chieti in Italy and the Conferencia de Neurociencias in Bogota, Colombia. He also is a paid presenter for the American Physician’s Institute Board the Boards CME courses. Dr. Doyle also receives royalties from his book, *Almost Alcoholic*.

PART VI

MEDICAL SPECIALTIES

PSYCHIATRIC CARE OF THE PATIENT WITH HEART DISEASE

W. Victor R. Vieweg and Mehrul Hasnain*

INTRODUCTION

Depression will soon join atherosclerotic coronary artery disease (CAD) to produce the two leading causes of disability in the developed world (Murray & Lopez, 1997). When CAD expresses itself as coronary heart disease (CHD) clinically in the forms of angina pectoris, acute coronary syndrome (ACS), myocardial infarction (MI), and heart failure (HF), it may lead to interventions such as coronary arteriography, angioplasty and stent placement, coronary artery bypass graft (CABG) surgery, and cardiac transplantation. Recognized risk factors for CAD have largely remained stable over the past several decades. Those risk factors that may be altered include: (1) elevated low-density lipoprotein (LDL) cholesterol and fasting triglycerides, (2) hypertension, (3) diabetes mellitus (DM) and prediabetes, (4) overweight and obesity, (5) smoking, (6) lack of physical activity (sedentary lifestyle), (7) unhealthy diet, and (8) stress (variously defined and understood). Risk factors that cannot be altered include (9) age, (10) sex, and (11) family history.

The psychiatrist is commonly asked to evaluate and treat the depressed patient with CHD. Thus, depression will be the prototypical psychiatric syndrome and CHD the prototypical heart disease reviewed in this chapter. The same general principles will apply for CHD patients with anxiety disorders. Because atypical antipsychotic drugs raise many concerns and questions exist about cardiometabolic problems, we will discuss their use in patients with heart disease, even though psychosis is much less common in the general population than are depression and anxiety. Discussion of cardiac toxicity associated with antidepressant and antipsychotic medications will follow, with a focus on arrhythmias associated with these medications.

Additional issues we cover concern psychiatric aspects of arrhythmias, cardiac pacemakers, cardioverter defibrillators, and sudden cardiac death (SCD); hypotension, presyncope (symptomatic lightheadedness), and syncope (fainting); valvular heart disease; congenital heart disease; and pregnancy and heart disease.

BRAIN-HEART CONNECTION

Awareness of a connection between the heart and the mind dates to antiquity. Over 150 years ago, Claude Bernard hypothesized that the connection between these two organs was mediated via the vagus nerve (Thayer & Lane, 2009). The basis of this connection are now better understood. Functional neuroimaging suggests that the central neural circuitry of the brain–heart axis is the dorsal and subgenual regions of the anterior cingulate cortex, the insular cortex, and, to a lesser extent, the amygdala and basal ganglia. Brainstem regions, including the periaqueductal gray and the parabrachial nucleus, integrate afferent baroreceptor and mechanoreceptor information to shape the descending autonomic drive to the heart (Taggart, Critchley, & Lambiase, 2011).

We know that stress hormones, the autonomic nervous system, and inflammation play important roles in the bidirectional heart–brain association. Precise neurohormonal mechanisms linking heart and mind are still unknown, but stress is probably the shared underlying mechanism. In reviewing the influence of stress on heart disease, we (Vieweg et al., 2011a) reviewed the stressor effects of earthquakes on patients with and without CAD. For instance, earthquake victims experiencing SCD invariably had advanced atherosclerotic CAD. In contrast, patients developing stress-induced Takotsubo cardiomyopathy, a generally reversible cardiomyopathy (also known as left ventricular apical ballooning syndrome or broken heart syndrome—often precipitated by learning of an unexpected death of a loved one), were free of any form of CAD and most often survived the stressful event. These patients presented with symptoms and signs of MI and left ventricular hypokinesis, but recovery from stress-induced cardiomyopathy mediated by catecholamines commonly occurred during the weeks following its development. We hypothesized that stress was largely similar in both conditions but that the pre-morbid condition of the coronary arteries was distinctly different; that is, the pre-stress medical state better predicted the clinical outcome than the nature or magnitude of the stress.

* W. Victor Vieweg, MD, an author on this book chapter, died on October 7, 2013, in Charlottesville, Virginia. Dr. Vieweg, who began his career as a cardiologist, later specialized in psychiatry. He was a prolific researcher, especially in the interface of psychiatry and medicine, and often ahead of the times in conceptualizing disease and treatment models. In his death, both psychiatry and medicine have lost a great scholar and teacher.

Mind–heart connection also occurs at the behavioral level. Patients with mental illness are more likely to smoke, eat poorly, and exercise less than healthy individuals. There may be a genetic link to glucose dysregulation among individuals with major mental illness. The potentially adverse cardiometabolic effects of psychotropic medications further contribute to the link between brain and heart and will be emphasized in this chapter.

PSYCHOSOCIAL STRESSORS AND THE HEART

In the late eighteenth century, Dr. John Hunter, suffering from angina pectoris and CAD, stated “My life is at the mercy of any rogue who chooses to provoke me” (Skandalakis & Skandalakis, et al., 1992). Since at least the eighteenth century, clinicians have been interested in the relationship between psychosocial stressors and heart disease. We know that many psychosocial states may cause or contribute to adverse cardiac events, including: anger (Denollet et al., 2010), anger and hostility (Chida & Steptoe, 2009), anhedonia (Davidson et al., 2010), anxiety (Shen et al., 2008; Roest et al., 2010), anxiety-prone disposition (Shen et al., 2008), bereavement (Buckley et al., 2009), cynical hostility (Tindle et al., 2009), depression (Wulsin & Singal, 2003; Barth, Schumacher, & Herrmann-Lingen, 2004), depression and pain (Morone et al., 2010), early-onset anxiety (Janszky et al., 2010), episodic physical and sexual activity (Dahabreh & Paulus, 2011), generalized anxiety disorder (Martens et al., 2010a), natural and unnatural stress (such as naturally induced earthquakes and blizzards and humanly induced holiday events such as Christmas and New Year; Kloner, 2006), overtime work (Virtanen et al., 2010), panic disorder (Soh & Lee, 2010), phobia (Kawachi et al., 1994), phobic anxiety (Albert et al., 2005), post-traumatic stress disorder (Ahmadi et al., 2011), somatic symptoms of anxiety (Nabi et al., 2010), suppressed anger (Denollet et al., 2010), the “distressed” (Type D) personality (tendency towards negative affectivity and social inhibition (Denollet et al., 2009; Denollet, Schiffer, & Spek, 2010; Martens et al., 2010b), stressful work environment (Allesøe et al., 2010), and mixtures of anxiety and depression (Frasure-Smith & Lespérance, 2008). Not only may stress syndromes cause or exacerbate adverse cardiac events, but a panic attack may also mimic ACS or severe cardiac arrhythmia so well that they are indistinguishable from an actual cardiac event (Soh & Lee, 2010). Although better understanding of the impact of psychosocial stressors on the heart is still needed (Figueredo, 2009), Frasure-Smith and Lespérance (Frasure-Smith & Lespérance, 2008) have argued that a more general distress disorder may be the best way to link mental disorders and CHD.

CORONARY HEART DISEASE AND DEPRESSION

Depression is the most common stressor linked to CHD. This topic has been studied and reviewed frequently and may be found in both the psychiatric and the medical literature. (Lespérance &

Frasure-Smith, 2000; Frasure-Smith & Lespérance, 2006; de Jonge et al., 2006; Glassman, 2007; Marano et al., 2009; Pozuelo et al., 2009; Linke et al., 2009; Vieweg et al., 2010a; Vieweg et al., 2010b; Zuidersma, Thombs, & de Jonge, 2011). Several important points can be drawn from this literature.

1. Depression is about three times more common in patients after MI than the general population.
2. 15–20% of patient after MI meet *Diagnostic and Statistical Manual of Mental Disorders IV* (DSM-IV-TR) (American Psychiatric Association [APA], 2000) criteria for major depressive disorder and even a larger percentage will manifest depressive symptoms.
3. Women are at particularly high risk for depression following acute MI.
4. Major depressive disorder and elevated depressive symptoms link to a worse prognosis in patients with CHD in a dose-dependent manner.
5. Although it is suggested that ACS patients with first-time and new-onset depression are at particularly increased risk of worse prognosis, there is no consistent evidence to support such statements.
6. The nebulous boundaries of depression and the mismatch between the precision and reliability of instruments used to assess depression and those used to assess CHD are barriers to a better understanding of any link between depression and CHD.
7. Somatic symptoms of depression (in particular, sleep disturbances, fatigue, and appetite problems) have a stronger association with CHD prognosis than the cognitive symptoms.
8. Both biological and behavioral mechanisms have been offered to explain the link between depression and comorbid CHD.
9. Depressed patients with comorbid CHD have reduced medication compliance.
10. Screening for depression in CHD subjects is recommended (although we have argued for additional evidence before implementing such screening. (Hasnain et al., 2011).
11. The Patient Health Questionnaire (PHQ-2) (Wooley & Simon, 2000) provides two screening questions and may be followed by the PHQ-9 (Kroenke, Spitzer, & Williams, 2001) if either answer is positive.
12. If the PHQ-9 is consistent with a high probability of depression, the patient should be assessed further for depression.
13. Cardiologists should take depression into account when managing patients with CHD.
14. About one-half of cardiologists report that they treat depression in their patients.

15. There is no current evidence that screening for depression improves outcome in CHD patients.
16. Treatment options for major depression in patients with CHD include antidepressant drugs, cognitive behavioral therapy, and physical activity.
17. Interest is emerging in understanding the role of depressive symptoms in the pathogenesis of cardiovascular disease (CVD) among adolescents (Dietz & Matthews, 2011).

SCREENING FOR DEPRESSION AMONG PATIENTS WITH CHD

Depressed patients with CHD will reach the psychiatrist in a variety of ways. Probably, the most controversial pathway is screening CHD patients for depression. We discuss this topic because the psychiatrist may be asked by the cardiologist, internist, or primary care physician to assist in the screening process.

In 2008, the American Heart Association (AHA) Science Advisory published "Depression and Coronary Heart Disease: Recommendations for Screening, Referral, and Treatment" (Lichtman et al., 2008). This document arose from concerns that depression was highly prevalent in patients with CHD and was associated with suffering, poor CHD prognosis, and poor treatment compliance. It recommended initial screening using the PHQ-2 (Whooley & Simon, 2000; Kroenke, Spitzer, & Williams, 2003): [Over the past two weeks, how often have you been bothered by any of the following problems? (1) Little interest or pleasure in doing things. (2) Feeling down, depressed, or hopeless.] If the answer to either question is "yes," then refer the patient for a more complete evaluation by a mental healthcare profession or screening with the PHQ-9 (Kroenke, Spitzer, & Williams, 2001) that employs the nine major items used in the DSM-IV-R (American Psychiatric Association [APA], 2000) to diagnose major depressive disorder. The AHA advisory acknowledged the lack of data showing that screening led to improved outcome of patients with CHD. A meta-analysis underscored this point (Thombs et al., 2008). One difficulty is that 12% of patients report suicidal ideation on the PHQ-9, but only 0.45% will turn out to have suicidal intent (Shemesh et al., 2009). Having to immediately evaluate more than 10% of cardiology clinic patients for suicidal intent may place an enormous burden on cardiology clinic staff. As pointed out by Thombs et al. (Thombs et al., 2008) in their systematic review of screening for depression in cardiac patients, no studies have shown that screening for depression improves symptoms of depression or cardiac outcomes in patients with cardiac disease.

For readers having to grapple with this issue in more depth, see articles by Whooley, 2009; Ziegelstein et al., 2009; Larsen et al., 2010; Williams, 2010; Hasnain et al., 2011; Holmes, 2011; Ziegelstein & Thombs, 2011; Jelinek, 2011; and Huffman et al., 2011.

PSYCHOSOCIAL ADJUSTMENT AFTER ONSET OF ACS

Onset of ACS can be quite distressing and may generate grief-like symptoms. Higgins et al. (Higgins et al., 2007) conducted a semi-structured interview of 14 psychologists and social workers with extensive experience managing cardiac patients. The clinicians described the interactions among anxiety, depression, grief, loss, and denial; they also identified trauma, guilt, and anger as issues of concern in some patients. The perception of low support is associated with poor prognosis in patients with CHD, acts synergistically with depression, and may be more prominent in women (Lett et al., 2007; Leifheit-Limson et al., 2010; Chung et al., 2011). Psychoeducation and supportive counseling helps patients adjust after the onset of ACS. There is growing interest in home-based or telephone-delivered nursing psychosocial support interventions for patients post-ACS, but results have been mixed and inconclusive (Frasure-Smith et al., 1997; Cosette, Frasure-Smith, & Lespérance, 2001; Gallagher, McKinley, & Dracup, 2003; Bambauer et al., 2005). Face-to-face counseling offered in mental health or collaborative care settings is currently the best intervention for patients experiencing psychosocial adjustment difficulties after ACS (Huffman et al., 2011).

DEPRESSION AND HEART FAILURE

What used to be called congestive heart failure (CHF) is now called, for the most part, HF because "congestion" has been better managed (with diuretics and preload and afterload reduction) in HF (Braunwald & Bristow, 2000; Braunwald, 2008). Depression in HF patients with and without atrial fibrillation is associated with increased cardiac morbidity and mortality (Frasure-Smith et al., 2009; Sherwood et al., 2011). Persistent depression remains a major problem after implantable cardioverter defibrillator placement in HF patients (Pedersen et al., 2011). Shimizu et al. (Shimizu et al., 2011) recommend targeted treatment of depression in chronic HF as a strategy to improve cardiac function. Depression, but not treatment with antidepressant drugs, may be associated with increased mortality in HF patients (O'Connor et al., 2008). Conversely, HF is a risk factor for depression among the elderly (Luijendijk et al., 2010).

Depression reduces the effectiveness of a disease-management program in HF patients (Jaarsma et al., 2010); managing depression in HF patients is a formidable challenge for psychiatrists, even when working with a cardiologist who is both knowledgeable about and interested in the brain-heart interface. Side effects from antidepressants and antipsychotics drugs include: (1) hypotension, (2) hypertensive crisis, (3) arrhythmias such as those derived from QTc interval prolongation and bradycardia/tachycardia syndromes, (4) increases and decreases in prothrombin time and other parameters of anticoagulation monitoring, and (5) increases and decreases in myocardial contractility (Dimos et al., 2009; Silver, 2010). In the Sertraline AntiDepressant Heart Attack Randomized Trial-Congestive Heart Failure

(SADHART-CHF) study, sertraline was found safe but ineffective among depressed cardiac patients with HF and did not improve cardiac outcome (O'Connor et al., 2010). Tousoulis et al. (Tousoulis et al., 2010) speculated that selective serotonin reuptake inhibitors (SSRIs) may improve depression in HF patients.

DEPRESSION AFTER CORONARY ARTERY BYPASS SURGERY (CABG)

In a randomized controlled trial of nonpharmacological interventions in patients developing major or minor depression within a year of CABG, Freedland et al. (Freedland et al., 2009) found that both cognitive behavioral therapy (CBT) and supportive stress management, compared with usual care, improved depressive symptoms. CBT had greater and more durable effects on depression than did supportive stress management. The authors did not assess cardiac outcome.

Rollman et al. (Rollman et al., 2009), in a randomized, controlled trial, reported that telephone-delivered collaborative care to treat post-CABG depression, compared with usual care, improved depressive symptoms, mental health–related quality of life, and physical functioning at eighth-month follow-up. However, a substantial number of study patients did not benefit from this intervention. The authors argued for additional studies to better define favorable patient characteristics.

DEPRESSION AND CARDIAC REHABILITATION

The Ochsner Heart and Vascular Institute assessed the impact of cardiac rehabilitation on depression and CHD rehabilitation–associated mortality on consecutive CHD patients (Milani & Lavie, 2007). Cardiac rehabilitation reduced both depressive symptoms and excess CHD mortality (Milani & Lavie, 2007) in patients following major coronary events. In an earlier study (Lavie & Milani, 2006), the same group showed that young CHD patients with adverse psychological and coronary risk profiles benefited from a formal cardiac rehabilitation program. Specifically, metabolic syndrome parameters and psychological stress profiles among the study patients improved in response to a formal cardiac rehabilitation program. Participation in physical activity and improved physical fitness may explain the beneficial effects on both depression and CHD (Milani & Lavie, 2007).

In a prospective study of 195 patients entering outpatient cardiac rehabilitation, participants were screened by a trained researcher for depression with “The Structured Clinical Interview for DSM-IV Axis I Disorders, Non-patient Edition” under the supervision of a psychiatrist to ascertain the diagnosis of major depression (Swardfager et al., 2011). Patients with Center for Epidemiological Studies of Depression (CES-D) scores ≥ 16 , those voicing subjective mood complaints, or those showing objective signs of depression during cardiac rehabilitation visits were referred to a staff psychologist. Psychosocial interventions included

stress management seminars, group therapy sessions, individual counseling, and/or psychiatric referral as appropriate. Comprehensive lifestyle management resources were offered to all participants. Major depression was diagnosed in 22.1% and was associated with high rates of non-completion (44.2% versus 28.9%) and non-adherence (53% versus 34.9%). Also, individuals with major depression achieved poorer cardiopulmonary fitness increases and poorer body fat outcomes than individuals without major depression. Authors highlighted that, despite depression screening and structured psychosocial support, major depression remained a significant barrier to effective cardiac rehabilitation.

HEART RATE VARIABILITY (HRV) IN DEPRESSED CHD PATIENTS

Glassman et al (Glassman et al., 2007) sought to assess the influence of sertraline and mood improvement on heart rate variability (HRV) in ACS patients with major depressive disorder. Study subjects in the Sertraline AntiDepressant Heart Attack Randomized Trial (SADHART) underwent 24-hour Holter monitor electrocardiographic (EKG) assessment at baseline and at 16-week following up after randomization to sertraline or placebo. The authors found that both treatment with sertraline and depressive symptom improvement were associated with increased (improved) HRV. However, the clinical utility of this observation remains to be determined.

DIABETES MELLITUS (DM) AND CAD EQUIVALENT

In an often-referenced study published in 1998, Haffner et al. (Haffner et al., 1998) reported that patients with DM free of previous MI have as great a risk of a new MI as patients free of DM but with a previous MI. From these data flows the argument that treating risk factors for CAD is as important in patients with DM free of CHD as in patients with established CAD. Scherrer et al. (Scherrer et al., 2011), in a very large Department of Veterans Affairs database, showed that patients with combined type 2 DM and depression were at 30% increased likelihood of developing new-onset MI, compared with patients who only had type 2 DM or patients who only had major depressive disorder. This finding was undercut by a more recent meta-analysis of 45,000 subjects followed for 5 to 25 years showing that patients with DM without prior MI had a 43% lower risk of developing CHD than patients with previous MI free of DM (Bulugahapitiya et al., 2009). For purposes of this chapter about psychiatric patients with heart disease, we will not separate our remarks based on whether they do or do not have comorbid DM.

Less controversial is the observation that patients with depression and DM have increased CHD and all-cause morbidity and mortality (Katon et al., 2008; Pan et al., 2011). Given the overlap of psychotropic drug-induced weight gain, obesity, DM, and metabolic syndrome, the psychiatrist faces the challenge of treating patients with psychiatric problems and various metabolic disturbances.

PSYCHOTHERAPY IN CHD PATIENTS WITH DEPRESSION

Enhancing Recovery in Coronary Heart Disease (ENRICH) study tested the hypothesis that, in patients with acute MI and either low social support or depression, CBT would reduce the rates of subsequent deaths and recurrent MIs compared with patients receiving usual care (Writing Committee, 2003). The CBT intervention was delivered in individual or group treatment, or both. Most patients received between six and ten sessions of treatment. The treatment involved traditional elements of CBT, including cognitive restructuring, relaxation and skills training, and behavioral activation. With 2,481 patients, 334 of whom had a history of CHF, ENRICH was, to date, the largest trial by far in psychosomatic cardiology. While the primary trial hypothesis was not supported—there was no difference in mortality or the composite event rate—there was a small benefit of the CBT intervention regarding depression symptoms. Intervention-treated patients experienced a decline of about 10.1 points on the Hamilton Rating Scale for Depression, compared to about 8.4 points for patients in the usual care arm.

Cardiac Randomized Evaluation of Antidepressant and Psychotherapy Efficacy (CREATE) trial included depressed patients with stable CAD and sought to compare both the effects of citalopram versus placebo and the effects of interpersonal psychotherapy (IPT) versus clinical management (Lespérance et al., 2007). In IPT, treatment focuses on an interpersonal problem area associated with depression. Typically, these problems fall within the domains of grief, role disputes, role transitions, or interpersonal deficits. One or more domains may be targeted for intervention in patients with CHD. In CREATE, citalopram was more effective than placebo in reducing depressive symptoms and in achieving response and remission. In contrast, the patients who had IPT did not separate from clinical management (Lespérance et al., 2007).

ELECTROCONVULSIVE THERAPY (ECT) IN CHD PATIENTS WITH DEPRESSION

Electroconvulsive therapy (ECT) may be indicated in CHD patients with depression who are not responding to pharmacotherapy, when depressive symptoms pose a significant barrier to care, or when a patient prefers ECT to pharmacotherapy. ECT is associated with a transient increase in heart rate and blood pressures and a decrease in HRV. Although rare, adverse cardiovascular events during ECT are important causes of morbidity and mortality. Zielinski et al. (Zielinski et al., 1993) compared the rate of ECT-related cardiac complications in 40 patients with major depression and left ventricular impairment, ventricular arrhythmias, and/or conduction delay with a matched comparison group of 40 depressed patients without cardiac disease. The rate of complications (ventricular or arterial arrhythmias, bradycardia and/or ischemic event) was significantly higher in patients with cardiac disease than controls, but most of the complications

were transitory and did not prevent the completion of ECT (38 of the 40 cardiac patients completed the course of ECT). Case reports and case series describe successful ECT in patients with recent MI (Magid et al., 2005), recent CABG (Riesenman & Scanlan, 1995), hypertrophic cardiomyopathy (Adabag, Kim, & Aloul, 2008), cardiac pacemakers and implantable cardioverter defibrillators (Dolenc et al., 2004), and CHF and valvular diseases (Rayburn, 1997). Overall, ECT can be performed safely in most patients with underlying cardiac conditions, as long as such patients are identified ahead of time and are closely monitored for potential complications.

OBESITY, SICK FAT, GLUCOSE AND LIPID DYSREGULATION, AND THE METABOLIC SYNDROME

The major portion of this chapter focuses on the adverse cardiometabolic effects of antidepressant and antipsychotic drugs, with emphasis on those adverse effects among psychiatric patients with heart disease. In the United States, morbidity and mortality from CAD is decreasing, while both the prevalence of and mortality from schizophrenia have remained stable over the past several decades (Tiihonen et al., 2009) with life-expectancy shortened by 25 years or more, with most of this reduction due to CHD (Newcomer & Hennekens, 2007). This differential mortality gap is widening (Saha, Chant, & McGrath, 2007). Risk factors for CHD morbidity and mortality are more common in subjects with schizophrenia compared with the general population and include smoking, DM, dyslipidemia, hypertension, and obesity. Many of these risk factors appear as part of the metabolic syndrome, with its increased prevalence in schizophrenia (Meyer & Stahl, 2009). Thus, psychiatrists face the daunting task of improving the mental health of the many subjects suffering from depression, schizophrenia, and other psychiatric illnesses while employing psychotropic agents with substantial adverse cardiometabolic effects.

OBESITY

The most common parameter defining obesity in the United States is body mass index (BMI). In the metric system, BMI is determined by dividing body weight by body height squared (kg/m^2). When weight is measured in pounds, and height in feet and inches, BMI in kg/m^2 is $[\text{weight (pounds)}/\text{height}^2 (\text{inches})] \times 703.07$. A BMI less than $18.5 \text{ kg}/\text{m}^2$ is considered “underweight.” The “normal” range for BMI is 18.5 to $25 \text{ kg}/\text{m}^2$. A BMI greater than $25 \text{ kg}/\text{m}^2$ but less than $30 \text{ kg}/\text{m}^2$ is considered “overweight.” BMI $\geq 30 \text{ kg}/\text{m}^2$ is considered “obese.” Obesity may be graded [Grade 1, BMI $< 35 \text{ kg}/\text{m}^2$; Grade 2, BMI $< 40 \text{ kg}/\text{m}^2$; and Grade 3, BMI $\geq 40 \text{ kg}/\text{m}^2$ (morbid obesity)]. BMI in children and adolescents is measured as a percentile to adjust for the changes associated with growth. A variety of BMI calculators is available on the Internet, including BMI percentile charts for children and adolescents.

Because abdominal fat (apple shape) more than hip fat (pear shape) better links to cardiovascular morbidity and mortality, abdominal circumference may be a better index of sickness-related excess weight. Abdominal circumference is measured at the level of the umbilicus. For Caucasian adult men, at-risk abdominal circumference is 40 inches (102 cm). For Caucasian adult women, this value is 35 inches (88 cm). For Asian men and women, comparable values are 35 inches (88 cm) and 32 inches (80 cm), respectively.

SICK FAT

Adiposopathy (“sick fat”), as described in historical perspective by Bays (Bays, 2011), comprises pathogenic anatomical adipose tissue changes occurring with positive caloric balance (when caloric intake is greater than body requirements), resulting in pathophysiological endocrine and immune responses and subsequent metabolic disease. Visceral or abdominal fat arises within the abdominal cavity and embraces the stomach, liver, intestines, kidneys, etc. It differs from subcutaneous fat located under the skin and intramuscular fat located in skeletal muscles. Excess visceral fat explains central obesity and the protuberant abdomen. Central obesity is linked to CVD and type 2 DM, insulin resistance, inflammatory diseases, and other obesity-related conditions. Although pericardial fat is located in the thorax rather than the abdomen, it can be considered another form of visceral fat.

Among younger women, fat is commonly stored in the buttocks, thighs, and hips (pear shape) due to female sex hormones. When women reach menopause and estrogen production declines, fat migrates from their buttocks, hips, and thighs to the waist. Among men, fat is more commonly stored in the abdomen (apple shape) because of sex hormone differences. High-intensity exercise may reduce total abdominal (visceral) fat.

Operationally, obtaining patients’ weight and height is the most common practice to determine obesity and BMI. Obtaining vital signs, fasting glucose, fasting lipids, and triglycerides should be routine practice. Measurement of abdominal circumference can also be added. These findings will help determine patient education, drug selection, and extent of monitoring for CVD risk factors.

All too commonly, psychiatrists and other clinicians describe DM and hypertension as adequately controlled if “the numbers look good,” even among patients who are overweight or obese. The Food and Drug Administration (FDA) and pharmaceutical industry have selected “≥7% increase in body weight” to define excessive weight gain in phase 2 and phase 3 drug studies (Vieweg et al., 2011b). Thus, both individual clinicians and federal agencies may downplay the importance of reducing body fat, particularly visceral fat.

It is likely that personalized medicine will soon reach a level of sophistication and application warranting a detailed understanding of the role that obesity, visceral fat, and psychotropic drug-induced obesity play in psychiatric conditions with comorbid medical problems. Even at this point, casual acceptance of “modest” psychotropic drug-induced weight gain is no longer clinically appropriate in most cases.

GLUCOSE DYSREGULATION

The definition of DM is in transition (Table 52.1). Hemoglobin A1c (HbA1c) is gaining traction as another benchmark to diagnose DM (Malkani & Mordes, 2011). Table 52.2 depicts the correlation between HbA1c and mean serum glucose values over the preceding several weeks. HbA1c greater than or equal to 6.5% (≥48 mmol/mol in IFCC-standardized units) in Diabetes Control and Complications Trial (DCCT)-aligned units is a convenient benchmark to diagnose this condition. However, compared with fasting serum glucose or oral glucose-tolerance testing, it will miss some cases of DM. Thus, the presence of an elevated HbA1c is very useful to diagnosis DM, but the absence of an elevated value is not necessarily reassuring, and testing should move to fasting serum glucose measurements and glucose-tolerance testing.

METABOLIC SYNDROME

Reaven (Reaven, 1997; 2006) noted that several of the CVD risk factors (dyslipidemia, hypertension, hyperglycemia) commonly occur together and introduced the term *syndrome X* to describe this clustering. The syndrome, characterized by insulin resistance, is now called the *metabolic syndrome*. Its core features are obesity, atherogenic dyslipidemia (elevated triglycerides and low high-density lipoprotein [HDL] cholesterol), disturbed insulin and glucose metabolism, and

Table 52.1 SERUM GLUCOSE AND HBA1C VALUES FOR PREDIABETES AND DIABETES, AS DEFINED BY THE AMERICAN DIABETES ASSOCIATION (ADA, 2014)

CARBOHYDRATE LOADED STATE	SERUM GLUCOSE VALUES	DESCRIPTIVE STATE
<i>Fasting glucose</i>		
	100 mg/dl to 125 mg/dl	Prediabetes
	≥126 mg/dl	Diabetes
<i>Random glucose</i>		
	≥200 mg/dl	Diabetes
<i>2-hour post Oral Glucose Tolerance Test (OGTT)</i>		
	140 to 199 mg/dl	Prediabetes
	≥200 mg/dl	Diabetes
<i>HbA1c</i>		
	5.7 to 6.4%	Prediabetes
	≥ 6.5%	Diabetes

For clinicians using mmol/l (molarity) instead of mg/dl (weight dimension) to report serum glucose measurements, use the following principles of conversion:
Mg/dl × 0.0555 = mmol/l
Mmol/l × 18.0182 = mg/dl

Table 52.2 ESTIMATED MEAN SERUM GLUCOSE MEASUREMENTS OVER PRECEDING SEVERAL WEEKS BASED ON HBA1C DETERMINATIONS (NATHAN ET AL., 2008)

HBA1C	ESTIMATED MEAN SERUM GLUCOSE (MG/DL)
5	97 (76–120)
6	126 (100–152)
7	154 (123–185)
8	183 (147–217)
9	212 (170–249)
10	240 (193–282)
11	269 (217–314)
12	298 (240–347)

hypertension (Grundy, 2007; 2008). Individuals with these characteristics commonly manifest prothrombotic and pro-inflammatory states. It is associated with increased risk of type 2 DM, CVD (to a lesser extent), and all-cause mortality. However, the metabolic syndrome does not necessarily predict these adverse health risks to a greater extent than do the additive effects of its individual components. This observation has generated debate about its clinical utility (Sattar et al., 2008; Simmons et al., 2010).

DRUG-INDUCED WEIGHT GAIN AND OTHER METABOLIC PROBLEMS ASSOCIATED WITH ANTIDEPRESSANT AND ANTIPSYCHOTIC DRUG ADMINISTRATION

In recent publications (Vieweg et al., 2011b; Vieweg et al., 2008), we developed drug-induced weight gain tables comparing various psychotropic drugs, with a focus on antidepressant and antipsychotic drugs and drawing on information from more than 50 publications. These tables have been further modified and appear in Table 52.3. There has been much more interest in antipsychotic drug-induced weight gain than in antidepressant drug-induced weight gain, but management principles are the same for both drug types. Readers looking for a more detailed review of weight gain and glucose dysregulation with antidepressant and antipsychotic drugs are invited to a recent review by our group (Hasnain, Vieweg, & Hollett, 2012).

In 2004, the American Diabetes Association, the American Psychiatric Association, the American Association of Clinical Endocrinologists, and the North American Association for the Study of Obesity published the Consensus Development Conference on Antipsychotic Drugs and Obesity and Diabetes (American Diabetes Association et al., 2004). This consensus statement was an outgrowth of a variety of factors. The arrival of the second-generation (atypical) antipsychotic drugs (clozapine

in 1989, risperidone 1993, olanzapine 1996, quetiapine 1997, ziprasidone 2001, aripiprazole 2002, paliperidone 2006, iloperidone 2009, asenapine 2009, and lurasidone 2010) was thought to bring a more favorable side-effect profile than commonly used first-generation (typical) antipsychotic drugs such as chlorpromazine, perphenazine, trifluoperazine, thiothixene, haloperidol, and fluphenazine. However, emerging evidence revealed that serious problems with second-generation antipsychotic drugs included drug-induced weight gain. Opinions differ about the forthrightness of the pharmaceutical companies advising treating physicians and patients of this problem, and litigation has ensued (Berenson, 2007).

Antipsychotic drugs differ in their metabolic liability. Table 52.4 provides approximate relative likelihood of second-generation antipsychotic drugs' causing specific metabolic disturbances (Hasnain, Vieweg, & Hollett, 2012; Hasnain et al., 2009). Despite these differences, the FDA requires that all the manufacturers of second-generation antipsychotic drugs warn prescribers and patients of the potential for their drugs to induce hyperglycemia and DM (usually accompanied by weight gain). Table 52.5 outlines screening and monitoring guidelines for patients taking second-generation antipsychotic drugs.

RISK FACTORS FOR WEIGHT GAIN

Young age, low BMI at baseline, diagnosis of non-affective psychosis, and limited or no previous exposure to antipsychotic medications are predictors of weight gain (Álvarez-Jiménez et al., 2008; Saddicha, Ameen, & Akhtar, 2008; Gebhardt et al., 2009). Early weight gain may predict long-term weight gain (Kinon et al., 2005). Vigilant monitoring of weight gain early during antipsychotic drug treatment and appropriate interventions as indicated can limit long-term obesity and obesity-related complications. Education and encouraging a healthy lifestyle should be offered to all patients receiving antipsychotic medications. The suggested pharmacological intervention for patients who gain weight or develop metabolic complications is to switch the antipsychotic medication to one with lower metabolic liability (American Diabetes Association et al., 2004). Numerous anti-obesity and insulin-sensitizing agents have been studied for antipsychotic-induced weight gain and glucose metabolism dysregulation, but data do not support their routine use (Faulkner & Cohn, 2006; Baptista et al., 2008). Several recent studies suggest metformin may be a suitable option in young, high-risk patients who show a pattern of rapid weight gain early during treatment. For specific discussion on this topic, readers are invited to consult two recent publications by our group (Hasnain, Vieweg, & Fredrickson, 2010; Hasnain, Fredrickson, & Vieweg, 2011).

DIABETIC KETOACIDOSIS

Life-threatening hyperglycemia, with or without complications (diabetic ketoacidosis [DKA]), may appear after antipsychotic drug administration. Patients with DKA may be younger, less overweight at baseline, and, more commonly, female (Scheen & De Hert, 2007). The associated ranking

Table 52.3 PSYCHOTROPIC DRUG-INDUCED WEIGHT CHANGES SHOWING EXPECTED RELATIVE (WEIGHT BURDEN SCALE) AND APPROXIMATE ABSOLUTE (WEIGHT CHANGE/YEAR) WEIGHT ALTERATIONS (AFTER VIEWEG ET AL., 2011B)

WEIGHT BURDEN SCALE	-0.5	0	+0.5	+1.0	+1.5	+2.0

▼ Antipsychotic drugs that are investigational and/or not available in the United States
 — indicates lack of data

Table 52.5 SCREENING AND MONITORING GUIDELINES DURING ANTIPSYCHOTIC TREATMENT

RISK FACTOR	CONSENSUS STATEMENT FROM UNITED STATES	CONSENSUS STATEMENT FROM AUSTRALIA
Background risk assessment	Personal and family history of obesity, diabetes, dyslipidemia, hypertension, or CVD.	Assess risk factors for DM: Older age, family history of DM, CVD, or other cardiovascular risk factors, personal history of gestational DM or polycystic ovary syndrome, ethnic predisposition (e.g., indigenous Australian, Pacific Islander, Asian, African-American), lack of exercise, poor diet, obesity
Obesity	Measure weight, BMI, and waist circumference at baseline. Monitor weight and BMI every 4 weeks for 12 weeks, then quarterly. Monitor waist circumference annually.	Measure BMI and waist-hip ratio every visit or every 3 months
Glucose dysregulation	Check fasting serum glucose at baseline. Monitor at 12 weeks and then annually.	Measure serum glucose level (random or fasting): <ul style="list-style-type: none"> • Immediately on starting or changing antipsychotic medication and then every 3–6 months (ideally every month for 6 months) • Then minimum of twice yearly • Reassess earlier or more frequently if rapid weight gain/loss, polydipsia, or polyuria occur • Perform oral glucose tolerance test (OGTT) if fasting serum glucose 99.1–126.1 mg/dl (5.5–7.0 mmol/l) or random serum glucose 99.1–198.2 mg/dl (5.5–11.0 mmol/l)
Dyslipidemia	Check lipid profile at baseline. Monitor after 12 weeks and then every 5 years.	Check lipid profile every 6 months
Blood pressure	Measure blood pressure at baseline. Monitor after 12 weeks and then annually.	Blood pressure measurement every 6 months

Both guidelines advise intense monitoring in high-risk patients (American Diabetes Association et al., 2004; Lambert & Chapman, 2004).

strength is strong for clozapine and olanzapine, medium for quetiapine and risperidone, and low for ziprasidone and aripiprazole (DuMouchel et al., 2008). Educate patients about, and look for, symptoms and signs of DM and DKA during the first several months, especially in patients taking clozapine, olanzapine, quetiapine, or risperidone. The risk of new-onset DM persists throughout the course of therapy and is not necessarily restricted to the first few months or years of treatment. While weight gain usually precedes the development of glucose dysregulation, DM and DKA may develop in the absence of weight gain. Emerging weight loss is not necessarily a sign of metabolic improvement, but may be the harbinger of worsening glucose dysregulation. Remind patients that new-onset polydipsia and polyuria may be an early sign of DM.

ADVERSE CARDIAC EFFECTS OF ANTIDEPRESSANT AND ANTIPSYCHOTIC DRUGS

CHEMICAL CARDIOMYOPATHIES

Factors that determine cardiac vulnerability to the cardiotoxic effects of various medications and non-prescribed drugs, include: (1) direct toxic effects on myocyte structure and function, (2) pathological increases in sympathetic activation, and (3) myocyte oxidative stress (Figueredo, 2011). Drugs such as methamphetamine, clozapine, and methylphenidate are implicated in cardiomyopathy (Figueredo, 2011). Other agents used by psychiatric patients implicated in chemical cardiomyopathies are anabolic/androgenic steroids, catecholamines, cocaine, ethanol, and ma huang (ephedra). For a fuller list, see the table in the paper by Figueredo (Figueredo, 2011).

PROARRHYTHMIC EFFECTS OF ANTIDEPRESSANT AND ANTIPSYCHOTIC DRUGS

Box 52.3 provides detailed commentary on antidepressant and antipsychotic drug-induced EKG changes, including QTc interval prolongation, polymorphic ventricular tachycardia (PVT), and *torsade de pointes* (TdP). We encourage the reader to review this appendix at this time to better understand our comments below. Those interested in even more detail are referred to several of our recent papers on this topic (Vieweg et al., 2009; Vieweg et al., 2011c; Vieweg et al., 2012; Vieweg et al., 2013c; Hasnain et al., 2014).

General Comments

Case-control studies have produced conflicting evidence that tricyclic antidepressants (TCAs) and SSRIs lead to an increased risk of CVD (Meier, Schlienger, & Jick, 2001; Hippisley-Cox, et al., 2001; Sauer, Berlin, & Kimmel, 2003; Monster et al., 2004; Schlienger et al., 2004; Tata et al., 2005; Reid & Barbui, 2010). A paper by Hamer et al. (Hamer et al., 2011) described a prospective cohort study of 14,784

middle-aged adults free of CVD drawn from the Scottish Health Surveys. About 5% had used antidepressant drugs. Over an eight-year follow-up, TCAs were linked (hazard ratio [HR] 1.35, 95% confidence interval [CI], 1.03–1.77) to an increased risk of new-onset CVD. The link (HR 1.24, 95% CI, 0.87–1.75) between TCAs and CHD events did not reach statistical significance. SSRI use did not link to CVD. While recommending replication of this important prospective study showing a link between TCAs and CVD, the authors concluded that existing mental illness did not explain this link. Rather, TCA administration best explained the excess disease burden.

ANTIPSYCHOTIC DRUGS AND CARDIAC TOXICITY

Evidence linking antipsychotic drugs to SCD is compelling. In 2001, Ray et al. (Ray et al., 2001) studied 481,744 Tennessee Medicaid enrollees from January 1, 1988, through December 31, 1993 (before the introduction of risperidone and other newer [atypical] antipsychotic drugs) with 26,749 person-years for current moderate-dose antipsychotic drug use (>100 mg thioridazine equivalents), 31,864 person-years for current low-dose antipsychotic drug use (<100 mg thioridazine equivalents), 37,881 person-years for use in the past year only, and 1,186,501 person-years for no antipsychotic drug use. There were 1,487 confirmed SCDs in this cohort. Current moderate-dose use compared with nonuse yielded a risk ratio of 2.39 (95% CI, 1.77–3.22; $p < 0.001$). This risk ratio was greater than for current low-dose (1.30; 95% CI, 0.98–1.72; $p = 0.003$) and former use (1.20; 95% CI, 0.91–1.58; $p < 0.001$). However, among current moderate-dose users with severe CVD, the risk ratio was 3.53 (95% CI, 1.66–7.51), yielding an additional 367 SCDs per 10,000 person-years of follow-up. In an accompanying editorial, Zarate and Patel (Zarate & Patel, 2001) pointed out the following:

1. Newer antipsychotic drugs are no less cardiotoxic than older ones;
2. Antipsychotic drug cardiotoxicity may be missed in phase 2 and phase 3 clinical trials because of the small number of patients and short trial duration;
3. Psychotropic drugs, including TCAs and some antipsychotic drugs (particularly thioridazine), are known to prolong the EKG QTc interval (see Box 52.3) and may produce PVT and its subtype TdP;
4. QTc interval prolongation may be found in up to 8% of psychiatric patients with women and older patients at the greatest risk;
5. Antipsychotic drug-induced ventricular fibrillation is thought to be the main contributor to SCD among patients taking TCAs and antipsychotic drugs;
6. Additional risk factors including hypokalemia, hypomagnesemia, hypocalcemia, bradycardia, preexisting

CVD, congenital QTc interval prolongation, female sex, advancing age, baseline QTc interval prolongation, and co-administration of non-psychotropic drugs were associated with QTc interval prolongation;

7. Chronically psychotic patients have reduced life-expectancy independent of any drug administration; and
8. Depression may accompany psychosis and not be recognized, or depression may itself be a cardiovascular risk factor independent of antipsychotic drug treatment and contribute importantly to cardiac toxicity.

Strikingly absent from this editorial (written in 2001) is weight gain commonly associated with antidepressant and antipsychotic drug administration. In our observation, malpractice litigation is more likely to arise from psychotropic drug-induced metabolic problems than from psychotropic drug-induced cardiac arrhythmias.

In a 2009 paper, Ray et al. (Ray et al., 2009) extended their earlier work to look at patients taking newer (second-generation, atypical) antipsychotic drugs. They conducted a primary analysis in a retrospective cohort study of Tennessee Medicaid enrollees that included 44,218 and 46,089 baseline users of single typical and atypical antipsychotic drugs, respectively, and 186,600 matched nonusers. The authors performed a secondary analysis of users of antipsychotic drugs free of a baseline diagnosis of schizophrenia or related psychoses, and with whom nonusers were matched according to propensity score, to assess residual confounding due to factors linked to antipsychotic drug use. Ray et al. (Ray et al., 2009) found that current typical and atypical antipsychotic drug users had higher rates of SCD than did nonusers (adjusted incidence-rate ratio of 1.99; 95% CI, 1.68–2.34 and 2.26; 95% CI, 1.88–2.72, respectively). Users of atypical compared with typical antipsychotic drug users showed an incidence-rate ratio of 1.14 (95% CI, 0.94–1.39). There was no significantly increased risk of SCD for former antipsychotic drug users 1.13 (95% CI, 0.98–1.30). For both typical and atypical current antipsychotic drug users, the risk of SCD increased significantly with increasing dose. The incidence-rate ratios increased ($p < 0.001$) from 1.31 (95% CI, 0.97–1.77) for those taking low doses, to 2.42 (95% CI, 1.91–3.06) for those taking high doses of typical antipsychotic drugs. The incidence-rate ratios increased ($p = 0.01$) from 1.59 (95% CI, 1.03–2.46) for those taking low doses, to 2.86 (95% CI, 2.25–3.65) for those taking high doses of atypical antipsychotic drugs. In the cohort matched for propensity score, findings were similar. The authors concluded that both typical and atypical antipsychotic drug users had similar, dose-related increased risk of SCD.

Thus, a series of studies argues that psychiatrists and their patients face formidable cardiac challenges when considering prescribing and receiving TCAs and antipsychotic drugs. We review management approaches to those cardiac challenges in the following sections.

BRUGADA SYNDROME, SUDDEN CARDIAC DEATH, AND ANTIDEPRESSANT AND ANTIPSYCHOTIC DRUGS

We will briefly review antidepressant and antipsychotic drug-induced SCD in the Brugada syndrome (Sicouri & Antzelevitch, 2008). Brugada syndrome was first described in 1992 as a distinct EKG and clinical syndrome characterized by right bundle branch block (RBBB) and persistent ST-segment elevation in the right precordial leads plus SCD (Brugada & Brugada, 1992). Drug-induced Brugada syndrome is of intense interest (Postema et al., 2009; Yap, Behr, & Camm, 2009), with the website Brugada Drugs (www.brugadadrugs.org) dedicated to the drug-induced aspects of this syndrome. Drugs to be avoided or preferably avoided by Brugada syndrome patients are listed in Box 52.1 (Postema et al., 2009).

EKG manifestations of this syndrome may be intermittent. Therefore, a normal EKG does not rule it out. Fever and low heart rates may allow this syndrome to become manifest, and provocative testing with infusions of sodium channel (fast-channel) blocking drugs (flecainide, ajmaline, procainamide) may uncover the diagnostic EKG pattern. Drugs (e.g., quinidine) that block the myocardial cell action potential transient outward potassium current (see Vieweg et al., 2009) appear to reduce arrhythmias.

To diagnose an individual with the Brugada syndrome, look for the EKG pattern described above, with at least one clinical feature, including syncope, prior cardiac arrest, PVT or ventricular fibrillation, and/or a family history of SCD in member[s] under 45 years of age (Yap, Behr, & Camm, 2009). This syndrome is familial (more common among men, contrasted with *TdP*, more common among women), displaying an autosomal dominant transmission mode, with incomplete penetrance and an incidence of 5–66/10,000.

The Brugada syndrome is one of the ion-channel disorders, the so-called channelopathies, usually found in structurally normal hearts. Early interest was in the congenital long QT syndrome (Vincent, 1999), with subsequent attention paid to the Brugada syndrome. Now there is a short QT syndrome (Patel & Pavri, 2008), but this syndrome has not been linked to psychotropic drug administration.

CARDIAC RISKS OF ANTIDEPRESSANT DRUGS

Several years ago, we reviewed the cardiovascular side effects of newer antidepressant drugs (primarily SSRIs) (Fernandez, 2007) and pointed their superior cardiovascular safety

Box 52.1 DRUGS TO AVOID IN PATIENTS WITH BRUGADA SYNDROME (POSTEMA ET AL., 2009)

AVOID: amitriptyline, clomipramine, desipramine, lithium, loxapine, nortriptyline, trifluoperazine

Preferably AVOID: carbamazepine, cyamemazine, doxepin, fluoxetine, imipramine, maprotiline, perphenazine, phenytoin, thioridazine, antianginal drugs, and others.

compared with older antidepressant drugs, particularly TCAs. In this review, we described complications of SSRI administration, including the serotonin syndrome, tachycardia, arrhythmias, and other cardiovascular findings.

We reviewed antidepressant drug-induced blood pressure changes and their management in 1996 (Vieweg & Nicholson, 1996; Vieweg, 1996). TCAs have the most significant cardiovascular side effects of any of the antidepressant drugs currently available in the United States. These side effects are most manifest in subjects with preexisting CVD. Hypotension, with or without orthostasis, is the most common cardiovascular adverse effect, and conduction disturbances and ventricular arrhythmias are the most life-threatening side effects. TCAs' quinidine-like action accounts for conduction and rhythm disturbances. Monoamine oxidase inhibitors (MAOIs) commonly induce hypotension, with or without orthostasis. Hypertensive crises and the serotonin syndrome are the most serious cardiac adverse effects associated with MAOI administration, and patients using these agents require dietary and concomitant drug restrictions to minimize adverse effects. Rarely, spontaneous severe hypertension may occur without dietary or drug-drug interaction. Bupropion may increase blood pressure, particularly in those with preexisting hypertension. Trazodone may be associated with ventricular arrhythmias. Nefazodone (no longer used much in the U.S. because of adverse liver effects) and SSRIs may contribute to adverse cardiac drug-drug interactions. Co-administration of SSRIs and MAOIs may produce the serotonin syndrome and vasomotor instability. Venlafaxine may increase supine diastolic blood pressure, and, according to the manufacturer, such subjects require blood pressure monitoring. Periodic blood pressure assessment should probably be a routine part of patient care among those taking antidepressant drugs—particularly elderly patients. Recently, Mark et al. (Mark et al., 2011) documented that about half of geriatric patients receiving antidepressant drugs face drug-drug interactions.

QT INTERVAL PROLONGATION AND
TDP WITH NEWER ANTIPSYCHOTIC
ANTIDEPRESSANT DRUGS

Well known to be associated with some of the older antipsychotic and antidepressant drugs such as haloperidol and amitriptyline, QTc interval prolongation and *TdP* are also associated with some of the newer drugs from these categories. In 2011, an FDA Safety Announcement advised health care professionals and patients that citalopram should no longer be used at doses above 40mg/day because in higher doses the drug can unfavorably alter the electrical activity of the heart, and higher doses provide no additional benefit in the treatment of depression. The same year, the FDA directed the manufacturer to add a warning to the quetiapine (Seroquel) labeling about quetiapine-induced QTc interval prolongation and the potential for drug-induced *TdP*. Ziprasidone was associated with a dose-dependent QTc interval prolongation in the Pfizer 054 study specifically designed for this purpose (Psychopharmacological Drugs Advisory Committee, 2000). In a recent study (Potkin et al., 2013), iloperidone was associated with a greater increase

in QTc interval than competitor drugs (quetiapine and ziprasidone), but the increase was not clinically significant. Readers interested in more information are invited to the review by Hasnain and Vieweg (Hasnain & Vieweg, 2014).

Both citalopram and escitalopram cause dose-dependent QTc interval prolongation, which is greater for citalopram than escitalopram. While the FDA issued warning only for citalopram, the Medicines and Healthcare Products Regulatory Agency (MHRA) of the United Kingdom issued the same safety warning for both citalopram and escitalopram (Medicines and Healthcare Products Regulatory Agency 2011). The threshold for clinical significance of the QTc interval is an absolute duration of more than 500 milliseconds, or a change from baseline of more than 60 milliseconds (FDA, 2005). The warnings did not specify whether any subjects exceeded these thresholds for either drug.

We reviewed the literature and found no cases of citalopram-induced SCD among patients taking up to 60 mg/day of citalopram and free of risk factors for QTc interval prolongation and *TdP* (Vieweg et al., 2012). About 500 escitalopram overdoses and nearly 600 citalopram overdoses have been described, without serious cardiac sequelae or deaths due to either drug (Howland, 2011a; Howland, 2011b). Less than one-third of citalopram overdoses presented with QTc interval prolongation. In one study, 14% of escitalopram overdoses presented with QTc interval prolongation. In another study, the proportion of prolonged QTc intervals associated with escitalopram overdoses (1.7%) was not significantly different from that associated with citalopram overdoses (3.7%).

In several reviews of psychotropic drug-associated QTc interval prolongation and *TdP*, we noted that, while a drug may be associated with QTc interval prolongation, *TdP* occurs mostly when other risk factors besides the drug are present (Vieweg et al., 2012; Vieweg et al., 2013c; Kogut et al., 2013; Vieweg et al., 2013b, Hasnain & Vieweg, 2014). Box 52.2 lists the important risk factors. We will review each below.

Age

Su et al. (Su et al., 2006) assessed QT interval aging trends in healthy elderly Taiwanese. They manually measured the QT

Box 52.2 RISK FACTORS FOR QT INTERVAL PROLONGATION
1. Age—elderly at greatest risk
2. Circadian variation—nighttime period of greatest risk
3. Sex—women more vulnerable than men
4. Cardiovascular disease—presence considerably increases risk
5. Electrolyte abnormalities—particularly hypokalemia and hypomagnesemia
6. Pharmacodynamic and pharmacokinetic factors—drug-drug interaction, concomitant use of QTc interval-prolonging drugs, hepatic impairment, and poor metabolizer status

interval from the beginning of the QRS complex to the end of the T-wave. Study subjects comprised 115 persons (90 men and 25 women). Serial QTc interval measurements at baseline, two years, and four years were 422 ± 20 , 425 ± 21 , and 429 ± 27 msec, respectively. The QTc interval increased significantly during the four year follow-up ($p = 0.001$). The authors concluded that the QTc interval increases progressively with age.

However, conclusions and regulatory guidelines about drug-induced QTc interval prolongation in studies and clinical practice comprise periods of weeks and months, not years. Even though the FDA wants drug-induced group mean QTc interval lengthening not to exceed five msec before approving a medication for marketing (Darpo, Nebout, & Sager, 2006), individual patient/drug changes of less than 20 msec may not be clinically significant, due, in part, to differences in individual measurements (Camm, Malik, & Yap, 2004). Thus, changes in the QTc interval over four years as documented by Su et al. (Su et al., 2006) may have limited clinical utility.

Circadian Variation

The QTc interval varies throughout the day and night, with nighttime values about 20 msec longer than daytime measurements, due to differences in sympathetic and parasympathetic tone (Browne et al., 1983; Morganroth et al., 1991). In 20 normal subjects, daily QTc interval variation was 76 ± 19 msec (range 35–108 msec). However, CVD may increase this range (Morganroth et al., 1991).

Sex

Before puberty, the QTc interval is the same for both sexes (Tutar et al., 1998). Compared with adolescent girls, the QTc

interval in boys shortens by about 20 msec at puberty and this shortening appears to be androgen-driven. This sex difference remains until ages 50–55 years, when declining male testosterone values narrow these differences, but differences may continue even into old age. Based on the usual cardiovascular risk factors, we would expect about 45% of cases of *TdP* to occur in women; but, about 70% of cases of *TdP* occur in women, particularly older women (Vincent, 1999). In a recent review of subjects 60 years or older who developed QTc interval prolongation, PVT/*TdP*, and/or SCD while taking antidepressant or antipsychotic drugs or a combination of them, almost four-fifths of subjects were women (Vieweg et al., 2009).

Age and Cardiovascular Disease

Elderly men and women tend to have longer QTc intervals than their younger counterparts, even when both groups are free of CVD (Khan et al., 1998). Age-matched patients with CVD tend to have longer QTc intervals than those free of CVD (Khan et al., 1998).

Electrolytes

Electrolyte abnormalities, especially hypokalemia and hypomagnesemia, may cause or worsen QTc interval prolongation (Compton et al., 1996; Hatta et al., 1999; Hatta et al., 2000). Hypokalemia prolongs the cardiac action potential and may cause early afterdepolarizations (EADs) leading to *TdP* (see Box 52.3). Diuretics, especially the thiazides, are the most common cause of hypokalemia. Other causes include vomiting, diarrhea, postprandial states, exercise, and agitation.

Box 52.3 BASIC CARDIAC ELECTROPHYSIOLOGY FOR QTc INTERVAL PROLONGATION AND POLYMORPHIC VENTRICULAR TACHYCARDIA/TORSADE DE POINTES

Much of the material reported below is drawn from “Proarrhythmic Risk with Antipsychotic and Antidepressant Drugs: Implications in the Elderly” (Vieweg et al., 2009).

The Cardiac Conduction System and the Electrocardiogram

The heart has three important systems: (1) an energy system providing the force necessary to deliver cardiac contraction, (2) a conduction system consisting of special cardiac cells that electrically coordinate cardiac contraction to optimize cardiac output, and (3) the pump or (mechanical) pumping action itself. Antidepressant and antipsychotic drugs may have an impact on cardiac performance by altering any or all of these three systems. However, for purposes of this discussion, we will largely focus on the cardiac conduction system. This review is a condensation of several of our earlier publications on this topic (Vieweg et al., 2009; Vieweg et al., 2011c; Vieweg, 2002; Vieweg, 2003; Vieweg & McDaniel, 2003a; Vieweg & McDaniel, 2003b; Vieweg & McDaniel, 2003c; Vieweg & McDaniel, 2003d; Vieweg & Wood, 2004).

FIGURE 52.1

The standard EKG intervals (PR, QRS, and QT intervals) are usually best seen in limb lead II (voltage between the left leg electrode and the right arm electrode) and appear in Figure 52.1. The summed electrical charges generated within myocardial cells produce these EKG intervals. The QT interval and the effects that antidepressant and antipsychotic drugs have on it are of great interest to the psychiatrist.

(continued)

Figure 52.1 Representative lead II EKG showing standard intervals. The “P” wave is atrial electrical *depolarization* and just precedes mechanical right and left atrial contraction. The “QRS” interval is electrical ventricular *depolarization* and just precedes mechanical left and right ventricular contraction. The “ST” segment is the isoelectric portion of ventricular *repolarization*, and the “T” wave is the directional component of ventricular *repolarization*. The “QRS” interval, “ST” segment, and “T” wave on the surface EKG make up the “QT interval.” This interval consists of the “QRS” interval and “JT interval” (“ST” segment and “T” wave). Most of the “QT interval” represents ventricular *repolarization*.

FIGURE 52.2

The tangent method is the most popular way to calculate or measure the QT interval (Figure 52.2) (Postema et al., 2008). Not defined in the caption are U waves that are associated with hypokalemia and may fuse with the T-wave in severe hypokalemia (El-Sherif & Turitto, 2011). We know empirically that the length of the QT interval varies inversely with heart rate: the slower the heart rate, the longer the QT interval. Several group-derived formulae are used to correct (normalize) the QT interval (QTc interval) for heart rate (Goldenberg, Moss, & Zareba, 2006). The Bazett formula (Bazett, 1920) (QTc interval = QT interval in seconds divided by the square root of the RR interval in seconds) is the most popular current method used to calculate the QTc interval. The recommended Bazett-corrected QTc interval measurements in adults appear in Table 52.6 (Goldenberg, Moss, & Zareba, 2006). While seemingly beyond the expertise of the psychiatrist, accurately measuring the QTc interval may even be challenging for the internist or cardiologist (Viskin et al., 2005). Therefore, it behooves the psychiatrist to be familiar with the issues and language surrounding QTc interval calculation so as to best engage the assistance of the interested cardiac electrophysiologist as necessary.

Figure 52.2 Shown is the tangent method of measuring the QT interval using EKG lead II. See Figure 52.1 for definitions appearing in Figure 52.2 except for the “U” wave (see text). Draw a tangent to the steepest slope of the last limb of the “T” wave. The intersection of the tangent with the baseline defines the end of the “QT” interval. (Figure after Postema et al., 2008.)

Table 52.6 RECOMMENDED BAZETT-CORRECTED QTc MEASUREMENTS TO DIAGNOSE QT INTERVAL PROLONGATION, ACCORDING TO GOLDBERG AND COLLEAGUES (GOLDBERG, MOSS, & ZAREBA, 2006)

RATING	ADULT MEN (MSEC)	ADULT WOMEN (MSEC)
Normal	<430	<450
Borderline	430–450	450–470
Prolonged	>450	>470

(continued)

FIGURE 52.3

The action potential of a single ventricular muscle appears in Figure 52.3. Sodium (Na^+), calcium (Ca^{2+}), and potassium (K^+) ionic movements are very important in understanding the shape and direction of a cardiac cell action potential. These ions are unevenly distributed between the interstitium and interior of the cardiac myocyte due to its cell membrane that selectively limits ionic movement between the cell and interstitium (Fu, Clemon, & Ellenbogen, 1998). Ion channels are made of specialized proteins selective for certain ions. Ion channel activity is influenced by such factors as membrane potential, neurohormones, adenosine triphosphate supply, and certain drugs.

Cell *depolarization* (QRS interval or duration on the surface EKG; Figure 52.1) derives from a net inward flux of sodium and then calcium ions. Cell *repolarization* (JT interval on the surface EKG; Figure 52.1) derives from a net outward flux of potassium, mainly via the rapid delayed rectifier potassium channels (I_{Kr}). Reducing or slowing outward potassium currents by any agent, drug, condition, or process may prolong (lengthen or delay) *repolarization*, leaving the patient vulnerable to PVT or *TdP*.

Figure 52.3 Myocardial action potential. Shown is the action potential of a ventricular muscle cell. The numbers 0, 1, 2, 3, and 4 represent the phases of the action potential. The membrane resting potential is largely determined by the ratio of extracellular to intracellular potassium (phase 4). This phase is associated with ventricular diastole. The sudden surge of sodium (sodium “fast” channel) into the ventricular muscle cell (phase 0) represents the onset of cellular *depolarization* and is the rapid *depolarization* phase. The slope of phase 0 represents the maximum rate of *depolarization* of the cell and is known as V_{max} . Phase 0 is due to the opening of the fast sodium channels causing a rapid increase in the membrane conductance to sodium and the rapid influx of sodium ions into the cell, creating sodium current. The QRS interval (ventricular *depolarization*) on the surface EKG (see Figure 52.1) represents the initial electrical energy of the action potential of all the myocardial muscle cells.

Phase 1 of the action starts with the inactivation of the fast sodium channel. Following this phase, the “plateau” phase appears (phase 2) and is sustained by the inward movement of calcium (calcium “slow” channels) and outward movement of potassium through the slow, delayed rectifier potassium channels. During phase 3 (*repolarization*), the outward flow of potassium using the rapid delayed rectifier potassium channel (I_{Kr}) is the main ion channel causing the cell to repolarize and return to the membrane resting potential (phase 4).

FIGURE 52.4

Sequential changes on the surface EKG and cardiac cell action potential leading to PVT/*TdP* appear in Figure 52.4 (Viskin et al., 2003). Enhancing inward sodium or calcium currents or decreasing outward potassium currents may lead to QT interval prolongation (Tan et al., 1995). The most common mechanism of drug-induced PVT and *TdP* is potassium channel blockade.

The antipsychotic drug thioridazine of the phenothiazine family primarily blocks the rapid component (I_{Kr}) of outward potassium flow, causing inhomogeneous lengthening of the cardiac cell action potential, QT interval prolongation, early after depolarizations (EADs), and *TdP* (Yap & Camm, 2000). The quinidine-like (ion blocking) properties of TCAs primarily act on sodium influx during the early phase of the cardiac cell action potential (phase “0” or sodium “fast” channel) and may produce QRS widening as found in TCA overdose (Boehnert & Lovejoy, 1985). Secondly, TCAs may block calcium influx (calcium “slow” channel) and potassium efflux during phase 3 (Figure 52.3) of the cardiac myocyte action potential, leading to JT interval (Figure 52.1) lengthening with subsequent prolongation of the QT interval. Therefore, QT interval prolongation may occur after TCA administration by at least two mechanisms: (1) widening of the

(continued)

Figure 52.4 EKG, myocardial cell action potential, and *TdP* (data from Viskin et al., 2003). Abbreviations: EKG = electrocardiogram; AP = action potential; Na^+ = sodium; K^+ = potassium; Ca^{++} = calcium; I_{T0} = transient outward potassium current; I_{Kr} = rapid delayed rectifier potassium current; I_{Ks} = slow delayed rectifier potassium current; LQTS = long QT syndrome; EAD = early after depolarization of the AP; PVC = premature ventricular contraction

QRS interval during *depolarization*, and (2) lengthening of the JT interval during *repolarization*. It is lengthening of the JT interval rather than widening of the QRS complex that leaves the patient vulnerable to PVT and *TdP*. Summation of TCA secondary effects on the QT interval and thioridazine-like primary effects on the QT interval may act together to further lengthen the QT interval and lead to PVT and *TdP*.

FIGURE 52.5

The typical EKG features of PVT of the *TdP* type appear in Figure 52.5. The ventricular complexes appear wide and ventricular beats appearing close together. Cyclic alterations of the QRS electrical axis (due to migrating electrical foci) best explain the varying QRS morphology (twisting of the points—*torsade de pointes*) in *TdP*. Both the QT and QTc interval commonly exceed 500 ms in *TdP* (Bednar et al., 2001), and the most common QTc interval is 600–649 msec.

Figure 52.5 *Torsade de pointes*. Shown is the typical pattern found in *TdP* type of PVT. A sinus beat with a normal QRS interval (1) is followed by premature ventricular contraction (PVC) (2) with a short coupling interval. After a compensatory pause, another sinus beat (3) with a normal QRS interval is followed by another PVC (4) with a short coupling interval. The second PVC (4) is the first beat in a PVT of the *TdP* type. The sequence of beats 1–4 comprises the typical EKG features of short-long-short R-R intervals followed by *TdP*.

Pharmacodynamic and Pharmacokinetic Factors

Pharmacokinetic and pharmacodynamic factors that may potentiate (or inhibit) the effect of a drug are of utmost importance when prescribing drugs associated with QTc interval prolongation. Combining drugs with a potential to cause QTc interval prolongation would theoretically increase the risk of QTc prolongation and should be avoided. Metabolic inhibition of a drug would increase its blood level and thus increase the risk of toxicity (except in rare cases when a metabolite is associated with the risk). Drug–drug interactions are the most common reason for metabolic inhibition. Hepatic impairment is another reason for metabolic inhibition. Renal impairment would be pertinent to consider for drugs primarily excreted renally. Five to 10% of European Americans are “poor metabolizers” (pharmacokinetic factor) for certain drugs, with the CYP450 isoenzyme 2D6 most commonly

explaining these differences in metabolism. This possibility should be entertained if a patient does not tolerate the usual doses of a drug well.

HOSPITAL SETTINGS

Recently, a scientific statement from the American Heart Association and the American College of Cardiology Foundation that focused on prevention of *TdP* in hospital settings was published jointly in *Circulation* (Drew et al., 2010a) and the *Journal of the American College of Cardiology* (Drew et al., 2010b). Box 52.4 provides their list of drugs having a risk of causing *TdP*. For readers interested in a more detailed list of medications associated with QTc interval prolongation and risk of *TdP*, visit the CredibleMeds website, www.qtdrugs.org, provided by the Arizona Center for Education and Research on Therapeutics (AZCERT) website.

Box 52.4 DRUGS THAT HAVE A RISK OF CAUSING *TdP* (DREW ET AL., 2010A; DREW ET AL., 2010B)

GENERIC NAME	BRAND NAME(S)	CLINICAL USE
Arsenic trioxide	Trisenox	Cancer/leukemia
Bepidil	Vascor	Antianginal
Chloroquine	Aralen	Antimalarial
Chlorpromazine	Thorazine	Antipsychotic, schizophrenia, antiemetic
Cisapride	Propulsid	Gastrointestinal stimulant
Clarithromycin	Biaxin	Antibiotic
Disopyramide	Norpace	Antiarrhythmic
Dofetilide	Tikosyn	Antiarrhythmic
Droperidol	Inapsine	Sedative, antiemetic
Erythromycin	E.E.S., Erythrocin	Antibiotic, increase gastrointestinal motility
Halofantrine	Halfan	Antimalarial
Haloperidol	Haldol	Antipsychotic, schizophrenia, agitation
Ibutilide	Covert	Antiarrhythmic
Levomethadyl	Orlaam	Opiate agonist, pain control, narcotic dependence
Mesoridazine	Serentil	Antipsychotic, schizophrenia
Methadone	Dolophine, Methadose	Opiate agonist, pain control, narcotic dependence
Pentamidine	NebuPent, Pentam	Antiinfective, pneumocystis pneumonia
Pimozide	Orap	Antipsychotic, Tourette tics
Procainamide	Pronestyl, Procan	Antiarrhythmic
Quinidine	Quinaglute, Cardioquin	Antiarrhythmic
Sotalol	Betapace	Antiarrhythmic
Sparfloxacin	Zagam	Antibiotic
Thioridazine	Mellaril	Antipsychotic, schizophrenia

HYPERTROPHIC CARDIOMYOPATHY

Although not traditionally considered a risk factor for QTc interval prolongation among subjects receiving antidepressant and antipsychotic drugs, cardiac hypertrophy and left ventricular outflow tract obstruction may delay ventricular depolarization and repolarization, thereby prolonging the QT and QTc intervals (Johnson et al., 2011). Johnson et al. (Johnson et al., 2011) found QTc interval prolongation (>480 msec) in one out of eight subjects with hypertrophic cardiomyopathy. Therefore, when considering administration of psychotropic drugs with the potential to prolong the QTc interval to subjects with hypertrophic cardiomyopathy, obtain a baseline EKG.

ILLNESS SEVERITY

Recently, our group has looked at macrolide antibiotics and their relationship with QTc interval prolongation and *TdP* in an effort to study a more uniform population (Vieweg et al., 2013a; Hancox et al., 2013a; Hancox et al., 2013b). These papers include more than 60 case reports. Elderly women with heart disease are particularly vulnerable to QTc interval prolongation and *TdP*. Also, we developed an illness severity scale, as follows: (1) 1+ managed as outpatient, (2) 2+ required hospitalization, (3) 3+ required admission to the ICU and/or careful cardiac monitoring, and (4) 4+ required some aspect of life support other than cardioversion. Illness severity is highly predictive of drug-related QTc interval prolongation and *TdP*, and more predictive than prevalence/incidence studies employing principles of parametric statistics. Of course, illness severity incorporates risk factors, but it seems to be a new way to think about drug-related QTc interval prolongation and *TdP*. Further studies are needed to help understand this possible association.

SPECIAL TOPICS IN PSYCHOSOMATIC MEDICINE AND THE HEART

SSRIs, PREGNANCY, AND CONGENITAL CARDIAC MALFORMATIONS

About 10–15% of women experience depression during pregnancy, and 3–6% of women use SSRIs during pregnancy (Wichman et al., 2009). Untreated depression during pregnancy may link to low birth weight, preterm delivery, and lower Apgar scores; poor prenatal care; not recognizing or reporting signs of labor; and increased risk of fetal abuse, neonatocide, and maternal suicide (Wichman et al., 2009). There has been a flurry of recent interest in the risk of cardiac malformations among women taking SSRIs during pregnancy.

Alwan & Friedman (Alwan & Friedman, 2009) comprehensively reviewed the literature on exposure to SSRIs during the first trimester of pregnancy and fetal malformations. They grouped the available literature into four categories: (1) exposure Cohort (teratogen information service) studies, (2) studies based on linked administrative records, (3) population-based prospective cohort studies, and (4) retrospective case-control

studies. They concluded that that first-trimester maternal paroxetine treatment may increase the risk for cardiac anomalies about 1.5-fold to about 1%, considering a general population incidence of approximately 0.7% for the occurrence of congenital heart defects. The authors noted that it was difficult to determine the magnitude of risk for major malformations more generally or the risks associated with use of other SSRIs, as available data were inconsistent. More recently, Gentile (Gentile, 2011) specifically looked at the methodological quality of the data on the potential teratogenic effects of SSRIs. He identified 16 peer-reviewed studies suggesting an SSRI-associated teratogenic risk. He noted several limitations in the available data and concluded that the hypothesized teratogenicity of SSRIs remains undemonstrated.

Paroxetine

Among the SSRIs, paroxetine has received particular attention. Wurst et al. (Wurst et al., 2009) undertook a meta-analysis with a focus on first-trimester use of paroxetine and the prevalence of congenital, specifically cardiac, defects. The authors found an increased prevalence of aggregated congenital defects (prevalence odds ratio [POR] 1.24; 95% CI, 1.08–1.43) with paroxetine use. However, the increased prevalence of combined cardiac defects (POR 1.46; 95% CI, 1.17–1.82) may best explain this association. The small proportion of studies reporting specific cardiac lesions precluded statistical analysis. However, Wurst et al. (Wurst et al., 2009) tabulated the POR of selected reported specific cardiac defects and first-trimester use of paroxetine. Specific cardiac defects included (1) septal defects (atrial septal defect and ventricular septal defect), (2) bulbus cordis anomalies and anomalies of cardiac septal closure, (3) ventricular septal defect, (4) right ventricular outflow tract obstruction defects, (5) conotruncal defects, and (6) left ventricular outflow obstruction defects.

In a population-based case-control study, Bakker et al. (Bakker et al., 2010) evaluated the association of first-trimester paroxetine use and congenital cardiac defects (678 cases of isolated cardiac defects [first-trimester paroxetine exposure 1.5%] and 615 controls [first-trimester paroxetine exposure 1.0%]). After excluding mothers who used paroxetine outside the first trimester, or were exposed to another SSRI, the authors found no significantly increased risk for cardiac defects overall but did find a significantly increased risk for atrial septal defects (3 exposed cases; adjusted odds ratio, 5.7; 95% CI, 1.4–23.7).

General Comment

Scialli (Scialli, 2010) noted that the U.S. Food and Drug Administration and the manufacturer of paroxetine (brand name Paxil) agreed to classifying this drug as Pregnancy Category D (positive evidence of human fetal risk based on adverse reaction data from investigational or marketing experience or studies in humans, but potential benefits may warrant use of the drug in pregnant women despite potential risks). The package insert stated that epidemiology studies had shown that infants born to women exposed to paroxetine during the first trimester had increased cardiovascular malformations,

particularly atrial septal defects. Scialli (Scialli, 2010) pointed out that septal defects are prone to diagnostic bias. For example, ventricular septal defects may be found in up to 5% of newborns, with the vast majority of the defects representing small muscular defects that close spontaneously without intervention. Scialli (Scialli, 2010) then remarked, based on the evidence reviewed by Wurst et al. (Wurst et al., 2009) and others, that the scientific evidence does not support the conclusion that paroxetine causes cardiac defects.

HOW DO WE MOVE BEYOND QTC INTERVAL PROLONGATION AS THE BEST ESTIMATE OF THE RISK FOR PSYCHOTROPIC DRUG-INDUCED PVT/*TdP*?

By mid-2011, AstraZeneca, in concert with the FDA, altered the package insert for Seroquel (quetiapine) to reflect new concerns about the capacity of this drug to induce QTc interval prolongation. The package insert was changed after the FDA learned of reports of ventricular arrhythmias in 17 patients who took more than the recommended dose of quetiapine. Though QTc interval prolongation should not be problematic at recommended doses, quetiapine should be avoided in combination with at least 12 other medications linked to cardiac arrhythmias associated with SCD. Drugs not to be co-administered with quetiapine include: (a) the antiarrhythmic agents amiodarone, procainamide, quinidine, and sotalol; (b) antimicrobial medications gatifloxacin, moxifloxacin, and pentamidine; (c) synthetic opioids levomethadyl acetate and methadone; and (d) the antipsychotic drugs chlorpromazine, thioridazine, and ziprasidone. The package insert offers a note of caution in administering quetiapine to the elderly and patients with heart disease.

In our earlier section on QTc interval prolongation and PVT/*TdP*, we listed a series of risk factors for these EKG changes: hypokalemia or hypomagnesemia, female sex, old age, presence of congenital QTc interval prolongation, personal history of presyncope or syncope, family history of SCD, and bradycardia. We pointed out that even among drugs known to induce QTc interval prolongation and PVT/*TdP*, one or more of the above risk factors are almost always present when PVT/*TdP* is found. That is, the drug alone is highly unlikely to lead to serious cardiac arrhythmias or SCD when taken as prescribed in an otherwise healthy person.

Concerns about QTc interval prolongation embrace general principles of medicine. That is, the more immediately serious the illness, the more willing we are to try interventions with significant side effects; and the less immediately serious the illness, the less willing we are to use drugs with significant adverse effects. The incidence of drug-induced proarrhythmias with non-cardiovascular drugs is quite low (≤ 1 in 100,000) (Darpo, 2010). A drug at substantive risk to prolong the QTc interval may still be approved by regulatory agencies if the medical condition it treats has immediate life-threatening or life-shortening dimensions. This principle applies to some currently approved antiarrhythmic agents.

Although clinicians are generally most familiar with the Bazett formula ($QTc = QT/RR^{0.5}$, discussed earlier) in estimating the QTc interval, the Fridericia correction

($QTc = QT/RR^{0.33}$) is the method recommended by the FDA in clinical trials of non-antiarrhythmic drugs (FDA, 2005). Our understanding of the cardiac pathophysiology underlying QTc interval prolongation continues to advance. The congenital long QT syndromes represent rare genetic disorders deriving from gene mutations encoding cardiac ion channels and lead to ventricular action potential prolongation and repolarization delay, resulting in great risk for life-threatening PVT/*TdP* (Hedley et al., 2009). Mutations disrupting a variety of ion currents, including I_{Ks} , I_{Kr} , and I_{Na} , cause long congenital QT syndromes. Drug-induced QTc interval prolongation, in contrast, almost always involves I_{Kr} (rapid component of the delayed rectifier potassium current). Drugs with diverse structures block this KCNH2 channel. Those drug classes include antiarrhythmic drugs, antipsychotic medications, antibiotic and antimicrobial drugs, and antihistamines, and can exhibit a phenotype similar to that of carriers of KCNH2 (congenital long QT syndrome 2) (Mohammad et al., 1997; Kannankeril, Roden, & Darbar, 2010). The FDA has emphasized the need to find new methods of recognizing and measuring the QTc interval-prolonging effect of new drugs. Recently, more than 50 prescription drugs have been found to prolong the QTc interval, and more than 30 of them have been associated with PVT/*TdP* (Parvez & Darbar, 2011). Great attention has been given to the QTc interval because it is a surrogate marker of I_{Kr} . Blocking this ion channel may lead to QTc interval prolongation and possibly, progression to PVT/*TdP*. However, the QT interval is a marker for the total duration of ventricular repolarization and ignores abnormalities of the repolarization sequence. Also, the QTc interval requires normalization for heart rate because of the inherent confounding phenomena such as QT lag and hysteresis (Franz et al., 1988; Pueyo et al., 2003).

Digital EKGs have become available in recent years. Using this technology to assess T-wave morphology has become more important in predicting adverse cardiac events among patients with both the congenital and acquired (drug-induced) forms of the long QT syndrome (Couderc, 2009). Recently, Couderc et al. (Couderc et al., 2011) investigated repolarization morphology in both congenital and acquired forms of long QT syndrome and showed that phenotypical expression of *KCNH2* mutations and the effect of I_{Kr} -inhibitory drugs are specific on the surface EKG (model for the LQT2 showed that left slope was associated with the presence of the *KCNH2* mutation). This opens an exciting frontier for clinicians and investigators interested in psychotropic drug-induced or drug-associated PVT/*TdP* to better predict the drugs and circumstances placing psychiatric patients at increased risk for life-threatening cardiac arrhythmias.

DOES AGE ALONE EXPLAIN INCREASED RISK OF SERIOUS ADVERSE CARDIAC EVENTS IN ELDERLY RECEIVING ANTIPSYCHOTIC DRUGS?

In 2005, the FDA issued an advisory stating that atypical (second-generation) antipsychotic drugs, versus placebo, significantly increased the risk of death among the cognitively

impaired elderly (FDA, 2005). Typical (first generation) antipsychotic drugs were subsequently included in this concern.

Wang et al. (Wang et al., 2007) studied a large population of elderly from the Pennsylvania Pharmaceutical Assistance Contract for the Elderly Program using these outcome variables: (1) acute MI, (2) ventricular arrhythmia, (3) cerebrovascular events, (4) CHF, (5) pneumonia, and (6) other serious bacterial infections. The authors sought to determine whether the elderly newly started on typical versus atypical antipsychotic drugs had greater risks of adverse cardiac, cerebrovascular, and infection outcomes. They found that typical antipsychotic drugs had a modestly increased risk of developing ventricular arrhythmias and cerebrovascular events compared with atypical antipsychotic drugs.

In 2008, Setoguchi et al. (Setoguchi et al., 2008) sought to determine potential causes of higher mortality among elderly patients taking typical and atypical antipsychotic drugs among all British Columbia residents aged 65 years and older who started any antipsychotic drug between 1996 and 2004. The authors found that the greater risk of cardiovascular death best explained about half of the excess mortality among those elderly taking typical antipsychotic drugs.

Mehta et al. (Mehta et al., 2011) compared the risk of serious adverse cardiac events in the elderly taking typical and atypical antipsychotic drugs. They found a moderate increased risk of serious adverse cardiac events among elderly adults taking typical antipsychotic drugs compared with those taking atypical agents. The authors emphasized the need for health care professionals to carefully evaluate the risk–benefit ratio of antipsychotic drugs before prescribing these drugs to a vulnerable population. Psychiatry Drug Alerts (Anonymous, 2011) hypothesized that this finding may be explained by the greater risk of QTc interval prolongation and subsequent ventricular arrhythmias of typical compared with atypical antipsychotic drugs.

When asked for inpatient consultation, the referring clinician invariably wants a quick fix and does not want a recommendation to put the patient under one-on-one nursing observation and withhold medications. Medications then narrow down to sedatives (usually benzodiazepines) and antipsychotic drugs (both typical and atypical agents). Surgeons are most familiar with the typical antipsychotic drug haloperidol and hope that will be your recommendation. If sedation is important, haloperidol would be a poor choice since it is one of the less sedating typical antipsychotic agents. This property likely accounts for haloperidol's increased risk, particularly when administered intravenously in high doses, of inducing QTc interval prolongation and PVT/*TdP* (Vieweg et al., 2009).

In the outpatient setting, behavioral problems in the nursing home are a common stimulus for psychiatric consultation. Behavioral psychologists are becoming more available for nursing home consultation, and a behavioral approach to agitation may be the best initial intervention if time permits (Snowden, Sato, & Roy-Byrne, 2003).

PANIC ATTACKS, THE CARDIOLOGIST, AND THE PSYCHIATRIST

An all-too-common problem is to receive a phone call from a patient with known heart disease and/or cardiac arrhythmias complaining of new-onset “panic attacks” with fear or a sense of impending doom, racing heart, and difficulty breathing. The patient may ask the psychiatrist or cardiologist to phone in an antianxiety agent.

Thavendiranathan et al. (Thavendiranathan et al., 2009) systematically reviewed the accuracy of historical features, physician examination, and cardiac testing to identify a cardiac arrhythmia in a patient complaining of palpitations. The authors concluded that even with the presence of a regular rapid-pounding sensation in the neck or visible neck pulsations consistent with atrio-ventricular nodal reentry tachycardia, clinical examination is not sufficiently accurate to exclude clinically significant arrhythmias in most patients. Therefore, in the patient described above, the clinician must either send the patient to the emergency room or examine the patient electrocardiographically and with other tests as appropriate.

In about half of the cases, chest pain is of cardiac origin. Lenfant (Lenfant, 2010) reviewed chest pain of cardiac and non-cardiac origin—either ischemic or nonischemic. Among the non-cardiac causes, primary esophageal disorder rises to the top of the list. Psychological and psychiatric factors may play a significant role in the perception and severity of the chest pain regardless of its cause, with depression and panic attack or disorder commonly present. Careful evaluation is indicated whatever the cause[s] of a sense of impending doom, racing heart, and difficulty breathing.

MITRAL VALVE PROLAPSE (MVP) AND PANIC DISORDER

Perhaps the most representative prevalence study of MVP was conducted by Procacci et al. (Procacci et al., 1976). These investigators were on active duty in the U.S. Air Force during the Vietnam War and were stationed at Edwards Air Force Base in California. Dependent wives ($n = 1,169$) of Air Force personnel were urged to undergo a physical examination that included cardiac auscultation in the supine, left lateral decubitus, standing, and squatting positions as part of a “Women’s Health Week.” All women found to have non-ejection clicks or late systolic murmurs (or both) on cardiac auscultation underwent reexamination and M-mode echocardiography. Of the 1,169 study subjects, 74 (6.3%) were considered to have MVP. Thus, MVP is a very common condition.

There remains interest in how frequently cardiac arrhythmias are associated with MVP, and in the association of MVP, cardiac arrhythmias, and panic attacks. Kramer et al. (Kramer et al., 1984) compared ambulatory arrhythmias in 63 subjects with MP and 28 control subjects with matched symptoms. The authors found no statistically significant difference in atrial and ventricular arrhythmias between study subjects and controls. Alpert, in an accompanying editorial (Alpert, 1984),

made the observation that it was premature to conclude that MVP was not, in and of itself, a cause of cardiac arrhythmias but asked the clinician to avoid raising the specter of SCD in this population. He carefully outlined his clinical approach to these patients.

Margraf et al. (Margraf, Ehlers, & Roth, 1988) undertook an extensive review of MVP and panic disorder, pointing out that the link between these two conditions remains uncertain and that cardiac complaints occur with some frequency among patients with panic disorder. Also, panic attacks are sometimes accompanied by palpitations and rapid heart rate. Panic disorder patients and those with MVP may complain of chest pain, dizziness, dyspnea, fatigue, and presyncope and syncope, raising the question of whether the cardiac condition may be a cause of this anxiety disorder. The authors quote a prevalence of MVP of 4–21% and the prevalence of MVP in patients with panic attacks ranging on the low side 0–8% and on the high side 24–35%, with these variations demonstrating a bimodal distribution. Margraf et al. (Margraf, Ehlers, & Roth, 1988) state that there is no increased prevalence of panic attacks in patients with MVP compared with controls with other cardiac complaints.

Margraf et al. (Margraf, Ehlers, & Roth, 1988) concluded that available information neither supports nor excludes a greater frequency of MVP in patients with panic disorder. If there is an association, it is quite small. Perhaps the best course of action is to borrow Dr. Alpert's recommendations (Alpert, 1984) for patients with MVP and cardiac arrhythmias:

1. Avoid creating an incapacitating anxiety disorder by placing emphasis on SCD among patients with MVP;
2. Carefully assess MVP patients at high risk for significant cardiac arrhythmias, using studies including ambulatory EKG monitoring, exercise stress testing, and invasive electrophysiological studies;
3. Treat high-risk MVP patients who have high-grade, potentially malignant cardiac arrhythmias;
4. After initiating therapy, monitor carefully and accomplish further arrhythmia testing as necessary; and
5. Pursue treatment until cardiac and panic complaints are adequately controlled.

ANXIETY SENSITIVITY, ATRIAL FIBRILLATION, AND HEART FAILURE

Anxiety sensitivity—the tendency to fear bodily sensations associated with anxiety: sweaty palms, shallow breathing, and rapid pulse—is a trait seen in patients with panic disorder. This sensitivity complicates quality of life in patients with atrial fibrillation who may be sensitive to their heartbeats and reactivity. In a large sample of patients with atrial fibrillation and HF, the patients with anxiety sensitivity who were treated with rhythm- rather than rate-control had a better long-term prognosis (Frasure-Smith et al., 2012).

IMPLANTABLE CARDIOVERTER DEFIBRILLATOR

Patients who have severe left ventricular dysfunction or who have survived life-threatening cardiac arrhythmias are currently treated with an implantable device that can deliver electric shock for life-threatening arrhythmias. Most patients adjust to the implantable cardioverter defibrillator (ICD), and the course of anxiety usually improves over the first year (Pedersen et al., 2010; Kapa et al., 2010). The experience of the shock has been compared to getting kicked in the chest by a horse. Sometimes the defibrillator fires inappropriately. At 18 months post-implantation in one Dutch study, 8% of nearly 400 patients qualified for a diagnosis of post-traumatic distress disorder (PTSD). These were patients more anxious at baseline and more apt to have Type D personality (traits of social inhibition and high negative affect). Shocks per se did not predict PTSD (Habibovic et al., 2012). Phantom shocks (the perceptions of a shock when the device has not fired) are most often seen in ICD patients who had prior exposure to traumatic device shocks and are more common in patients with a history of depression, anxiety, and cocaine use (Jacob et al., 2012). CBT has been shown to reduce PTSD symptoms in patients with acute cardiovascular events and high-baseline PTSD, though not specifically with ICDs (Shemesh et al., 2011).

SUMMARY

Antidepressant and antipsychotic drugs represent a remarkable advance in our treatment of various psychiatric conditions, especially depression and psychosis.

We have focused on two main areas of cardiotoxicity: (1) drug-induced weight gain and other metabolic problems, and (2) drug-induced EKG changes, especially life-threatening ventricular arrhythmias. In discussing weight gain and some of its complications, we have not discussed the capacity of several of the second-generation antipsychotic drugs to induce metabolic problems, including DM, without inducing weight gain. That is a topic for another paper and has been discussed by a number of investigators, including Newcomer (Newcomer et al., 2002).

Antidepressant and antipsychotic drug-induced life-threatening ventricular arrhythmias almost invariably occur among patients (especially women) with existing risk factors for QTc interval prolongation. We have not discussed congenital QT interval prolongation or the rare case of comorbid congenital and acquired (drug-induced) QTc interval prolongation. We did cite such an instance in one of our reviews (Vieweg et al., 2009).

As is the case in so many other aspects of medicine, we recognize what we know and tend to use pattern-recognition in both diagnosing and treating various psychiatric conditions. The tables and figures we offer are our attempt to provide a “picture” clinicians may use in their evaluation and treatment of psychiatric patients. Ready consultation with both the primary care physician and the cardiologist will enhance the

cardiac care of patients receiving antidepressant and antipsychotic drugs. However, a burden does fall on the psychiatrist prescribing antidepressant and antipsychotic drugs to identify a cardiology colleague with sufficient expertise and interest in drug-induced QTc interval prolongation and the potential arrhythmias that may follow, given the observation by Viskin et al. (Viskin et al., 2005) that most physicians and many cardiologists fail to accurately calculate a QTc interval or correctly identify a prolonged QTc interval.

Clinicians may overly rely on computerized interpretations of the EKG (Hongo & Goldschlager, 2004), and cardiac electrophysiologists continue to debate whether QT interval prolongation is a reliable predictor of ventricular arrhythmias (Hondegheem, 2008; Roden, 2008). Malik (Malik et al., 2008) argues that the Bazett formula ($QTc = QT/\text{square root of the RR interval}$) is “clearly one of the worst options” to assess QTc interval prolongation. He used the Fridericia formula ($QTc = QT/\text{cube root of the RR interval}$) modified by individually optimized curvature correction as an accurate measurement of the QTc interval throughout the 24-hour cycle (Malik et al., 2008). This method is labor-intensive and unlikely to be adopted on a large scale any time soon. Franz (Franz, 2008), in an editorial comment, noted that in the best of circumstances QTc interval prolongation is a poor predictor of *TdP* unless it is very long.

A guideline useful to the psychiatrist, is that as long as the heart rate is 70 beats per minute or more, the QTc interval will be normal if the QT interval is less than one-half of the RR interval (Phoon, 1998). We should study carefully QT intervals that are one-half or more of the RR interval. We recommend that non-cardiologists prescribing antipsychotic and antidepressant drugs in the elderly that may prolong the QTc interval should obtain a baseline EKG for female patients with additional risk factors such as personal or family history of presyncope or syncope, electrolyte disturbance, and CVD. Elderly male patients with similar risk factors are also at increased risk for QTc interval prolongation and *TdP*. Inspect the EKG yourself using the Phoon shorthand rule (Phoon, 1998).

Familiarity of psychiatrists with cardiometabolic risk factors and close collaboration with other healthcare professionals will facilitate optimal psychiatric and cardiometabolic care of patients with major mental illness. A patient-centered approach that emphasizes coordination between health professionals will improve metabolic and cardiovascular care and outcome of patients suffering from depression or schizophrenia and needing treatment with antidepressant and antipsychotic drugs.

CLINICAL PEARLS

- Depression is about three times more common in patients after MI than the general population.
- Fifteen to 20% of patients after MI meet DSM-IV-TR (American Psychiatric Association, 2000) criteria for

major depressive disorder, and an even larger percentage will manifest depressive symptoms.

- Women are at particularly high risk for depression following acute MI.
- Major depressive disorder and elevated depressive symptoms link to a worse prognosis in patients with CHD in a dose-dependent manner.
- Although it is suggested that ACS patients with first-time and new-onset depression are at particularly increased risk of worse prognosis, there is no consistent evidence to support such statements.
- Somatic symptoms of depression (in particular, sleep disturbances, fatigue, and appetite problems associated with anhedonia) have a stronger association with CHD prognosis than do the cognitive symptoms.
- Depressed patients with comorbid CHD have reduced medication compliance.
- Screening for depression in CHD subjects is recommended (although the authors have argued for additional evidence before implementing such screening [Hasnain et al., 2011]).
- The Patient Health Questionnaire (PHQ-2) (Wooley & Simon, 2000) provides two screening questions and may be followed by the PHQ-9 (Kroenke, Spitzer, & Williams, 2001) if either answer on the PHQ-2 is positive. If the PHQ-9 is consistent with a high probability of depression, the patient should be assessed further for depression.
- Shimizu et al. (Shimizu et al., 2011) recommend targeted treatment of depression in chronic HF as a strategy to improve cardiac function.
- Depression, but not treatment with antidepressant drugs, may be associated with increased mortality in HF patients (O'Connor et al., 2008).
- Conversely, HF is a risk factor for depression among the elderly (Luijendijk et al., 2010).
- ENRICHD tested the hypothesis that, in patients with acute MI and either low social support or depression, CBT would reduce the rates of subsequent deaths and recurrent MIs, compared with patients receiving usual care. With 2,481 patients, including 334 patients with a history of CHF, ENRICHD was the largest trial to date by far in psychosomatic cardiology. While the primary trial hypothesis was not supported—there was no difference in mortality or the composite event rate—there was a small benefit of the CBT intervention regarding depression symptoms.
- In the CREATE trial, which included depressed patients with stable CAD, investigators sought to compare both the effects of citalopram versus placebo and the effects of IPT versus clinical management

(Lespérance et al., 2007). Citalopram was more effective than placebo in reducing depressive symptoms and in achieving response and remission. In contrast, IPT did not separate from clinical management.

- ECT can be safely done in patients with cardiac disease.
- Operationally, obtaining patients' weight and height is the most common practice to determine BMI. Obtaining vital signs, fasting glucose (or HbA1c), fasting lipids, and triglycerides should be routine practice. Measurement of abdominal circumference can also be added.
- Early weight gain may predict long-term weight gain (Kinon et al., 2005).
- Vigilant monitoring of weight gain early during antipsychotic drug treatment and appropriate interventions as indicated can limit long-term obesity and obesity-related complications.
- For patients who gain weight or develop metabolic complications, switch the antipsychotic medication to one with lower metabolic liability.
- Physicians should be aware, not just of the potential cardiac effects of a drug, but also of all non-drug risk factors that are associated with adverse cardiac events, and on-drug risk factors that prolong QTc interval marginally. Citalopram should not be used in patients with congenital long QT syndrome. Hypokalemia and hypomagnesemia should be corrected and periodically monitored. Electrocardiographic monitoring is recommended in patients with HF, bradyarrhythmias, or patients on other medications that prolong the QTc interval.
- In a large sample of patients with atrial fibrillation and HF, those patients with anxiety sensitivity who were treated with rhythm- rather than rate-control had a better long-term prognosis (Frasure-Smith, et al., 2012).

MULTIDIMENSIONAL BEHAVIORAL MEDICINE STRATEGIES

MANAGEMENT OF TOBACCO USE AND OBESITY

Michael G. Goldstein and Margaret Dundon

INTRODUCTION

Behavioral medicine is the interdisciplinary field concerned with the development and integration of behavioral, psychosocial, and biomedical science knowledge and techniques relevant to the understanding of health and illness, and the application of this knowledge and these techniques to prevention, diagnosis, treatment and rehabilitation (Society of Behavioral Medicine, 2012). Behavioral Medicine interventions may be applied at the clinical, population or community level. In this chapter, we will focus on the application of Behavioral Medicine interventions within clinical settings and will emphasize the integration of these interventions within a Patient-Centered Medical Home model. The Patient-Centered Medical Home (PCMH) is an approach to organizing primary care that has been advocated by the Institute of Medicine, the United States Agency for Healthcare Research and Quality (AHRQ), the National Committee on Quality Assurance and a wide range of primary care medical societies and organizations (Carrier, Gourevitch, & Shah, 2009; Rosenthal, 2008). To meet the AHRQ definition of a PCMH, a health care system must: deliver patient-centered, comprehensive and coordinated care; provide superb access; and employ a system-based approach to quality and safety (Agency for Healthcare Research and Quality, 2012).

Delivering evidence-based preventive care is a critical element of a comprehensive PCMH and promoting positive health behaviors is critical to preventing illness and optimizing patient health and wellbeing. Health behaviors accounted for almost 50% of mortality in the United States in 2000 (Mokdad, Marks, Stroup, & Gerberding, 2004). Among all causes of death, the leading causes were tobacco (435,000 deaths; 18.1% of total US deaths) and poor diet and physical inactivity (365,000 deaths; 15.2%) (Mokdad et al., 2004). This chapter focuses on tobacco use and obesity, two conditions that have strong behavioral and psychosocial determinants. In the sections that follow, we will describe how to apply a multi-dimensional behavioral medicine approach to the management of these conditions and will illustrate how to integrate assessment and

treatment of tobacco use and obesity within the emerging Patient-Centered Medical Home model. We will focus our attention on the assessment and treatment of tobacco use and obesity in adults.

TOBACCO USE AND DEPENDENCE

Cigarette smoking remains the single greatest preventable cause of premature death, disability, and unnecessary expense in the United States (U.S. Department of Health and Human Services, 2010). Currently, about 44 million adults, or about 19% of the U.S. adult population, smoke cigarettes (B. A. King, Dube, & Tynan, 2012) and 70% of smokers report wanting to quit (M. Fiore et al., 2008). Cigarette use, along with other forms of tobacco use such as smokeless tobacco and cigars, is responsible for nearly one in five deaths (443,000) annually in the US, and for \$100 billion annually of direct medical costs and \$97 billion in lost productivity (M. C. Fiore & Baker, 2011). Though most smokers want to quit, quitting smoking can be very difficult, especially for the heavily dependent smoker. Data from the 2010 National Health Interview Survey revealed that 52% of adult smokers had made a quit attempt in the past year, but only 6% were able to successfully quit (CDC, 2011). Biological, psychological, behavioral, and socioenvironmental factors all play a role in the development and maintenance of dependence on tobacco products (D. B. Abrams et al., 2003; Benowitz, 2010; U.S. Department of Health and Human Services, 2010). Smoking prevalence is particularly high among several subgroups including those with low educational attainment, low socioeconomic status, and individuals with psychiatric disorders, including substance use disorders (B. A. King et al., 2012; McClave, McKnight-Eily, Davis, & Dube, 2010; Ziedonis et al., 2008).

The 2008 US Public Health Service (PHS) Clinical Practice Guideline for Treating Tobacco Use and Dependence (CPG) (M. Fiore et al., 2008) (available at http://www.ahrq.gov/professionals/clinicians-providers/guidelines-recommendations/tobacco/clinicians/update/treating_tobacco_use08.pdf) identifies multiple effective smoking cessation

To successfully quit tobacco use, consider all of the factors that contribute to your use of tobacco. It can be helpful to group these factors into three main categories: physical factors, habits, and psychological factors (i.e., your thoughts and emotions).

Physically, nicotine is the most addictive substance on the planet. Your medical provider will tell you whether it is appropriate for you to use a nicotine replacement product, such as the patch or gum. Some medications, like Zyban, are very helpful to some people but don't seem to help other people with their nicotine cravings. Sometimes, using two products together can help relieve cravings and withdrawal symptoms better. It is best to work closely with your medical provider to choose the best medication or combination of medications which may be right for you. These products have been proven to help people quit and are often key to success. People who use medication have much higher rates of success in quitting.

Behaviorally, you will need to change your habits and the situations that you typically associate with tobacco. Undoubtedly, you will experience situations that cause you to crave tobacco, but you can learn skills that will help you choose alternatives other than using tobacco. Practical counseling and support are available to help you through this process and can help you recognize situations that tempt you to use tobacco, problem-solve and develop skills to cope with these situations. Even brief counseling greatly increases the success of a quit attempt. Also, if you would find telephone counseling supportive, you can call 1-800-Quit-Now to get connected to your state telephone quit line.

Thoughts and emotions are some of the hardest aspects of tobacco use to change. Changing thoughts to cope with stress and negative emotions is an essential aspect of successful tobacco cessation. One helpful strategy is to list your top 3 reasons for quitting, and remind yourself of them as a way to stay strong if you need a boost along the way. Take a moment to list *your* main reasons for quitting:

Preparing to Quit

Your Quit Date

When is the last day and time that you are going to use tobacco?

Month _____ Day _____ Year _____ Time _____

Preparing Your Surroundings

What are the things that remind you to use tobacco? It is important to change your surroundings so that you won't be reminded about tobacco use as frequently. Before your quit date consider the following:

- Don't buy tobacco in bulk (e.g., don't buy cartons).
- Find all of your hidden stashes of tobacco or supplies (ashtrays etc.) and dispose of them.
- Prepare family and friends. Let them know that you are planning to quit and ask for their help. If you have friends and family who do use tobacco, ask if they would avoid using tobacco around you.
- Prepare and develop a plan for coping with cravings and withdrawal symptoms. Use the combination of strategies that works for you.
- Choose a method to quit. There are several ways to consider quitting, but one of the most important is to use medications and prepare for coping with urges as well as stress.

Quitting is difficult and many people find it to be challenging. Preparing can help you succeed. What do you expect to be the most difficult challenge for you as you quit? Will it be going without a cigarette with your morning coffee? Will it be not smoking when your spouse or friends light up? Anticipating and having a plan for how to handle these challenges will increase your success.

As you prepare to quit there are other things in your life that you can do a little bit differently that will help you to be successful. There may be places you should avoid or things you should do differently.

Figure 53.1 Continued

treatments, including both behavioral and pharmacologic interventions. As we will stress in the discussion below, treatment that combines behavioral and pharmacologic intervention elements is more effective than either behavioral or pharmacologic treatment alone (M. Fiore et al., 2008; M. C. Fiore & Baker, 2011). However, less than a third of smokers will utilize either medication or counseling in their efforts to stop smoking (CDC, 2011). Even a small increase in the percentage of people who use effective treatments during efforts to quit can have a significant impact on smoking cessation rates. Because more than 70% of smokers see a physician or other health care clinician each year, clinicians have multiple opportunities to offer tobacco cessation interventions and encourage patients who want to quit to employ effective treatments (M. Fiore et al., 2008; M. C. Fiore & Baker, 2011; Jamal, Dube, Malarcher, Shaw, & Engstrom, 2012; Rigotti, 2012). The CPG also frames tobacco dependence as a chronic condition, with most smokers experiencing periods of remission and relapse and requiring multiple quit attempts before achieving stable maintenance of abstinence. As with other chronic conditions, such as diabetes and hypertension, clinicians should consider taking a long term view marked by repeated efforts to offer patient education, counseling and intervention.

In the sections that follow, we will first summarize evidence regarding the factors that contribute to tobacco use and dependence that impact treatment decisions. Then, we will outline evidence-based interventions for tobacco use and dependence, emphasizing the recommendations of the US PHS Clinical Practice Guideline (M. Fiore et al., 2008). We will also offer guidance for implementing a patient-centered approach to tobacco use treatment in health care settings, particularly within the context of a PCMH.

GENERAL CONSIDERATIONS FOR TREATMENT

NICOTINE DEPENDENCE AND NICOTINE'S EFFECTS

Nicotine dependence, like other forms of substance use dependence, results from a complex interplay of pharmacology, learned or conditioned factors, genetics, and social and environmental factors (Benowitz, 2010). Nicotine is a powerful pharmacologic agent with a wide variety of stimulant and depressant effects involving the central and peripheral nervous, cardiovascular, endocrine, and other systems (Benowitz, 2010; U.S. Department of Health and Human Services, 1988, 2010). Release of brain dopamine, glutamate, and GABA is particularly important in the development of nicotine dependence (Benowitz, 2010). Reinforcement of nicotine use results from nicotine's "positive" effects, including arousal, increased concentration and enhancement of mood, while negative reinforcement occurs when nicotine use leads to avoidance of withdrawal symptoms after periods of abstinence (Benowitz, 2010). The very rapid speed of nicotine delivery to the lung alveoli and to the brain (7 to 10 seconds post inhalation) contributes to nicotine's reinforcing effects, as well as to behavioral conditioning resulting from the strong association between cues associated with smoking (i.e., situations, taste, smell, handling) and reinforcement (Benowitz, 2010).

Significant nicotine withdrawal symptoms occur among at least 50% of smokers who try to quit (J. R. Hughes, 2007). The signs and symptoms of nicotine withdrawal can appear within 2 to 6 hours after the last use of tobacco, usually peak between 24 and 48 hours after cessation, and last from a few days to a few weeks (Benowitz, 2010; J. Hughes & Hatsukami, 1992). Withdrawal symptoms

include craving or urges to use nicotine, dysphoric or depressed mood, irritability, frustration, anger, anxiety, difficulty concentrating, restlessness, decreased heart rate and increased appetite or weight gain (J. Hughes & Hatsukami, 1992). Some smokers experience episodic response to tobacco cues, and urges to smoke, years after quitting (Ferguson & Shiffman, 2009; R. S. Niaura et al., 1988). There is a continuum of nicotine dependence, from mild to severe, among the population of smokers (R. Niaura & Shadel, 2003). Genetic studies indicate that nicotinic receptor subtypes and the genes involved in neuroplasticity play a role in the development of dependence, while other studies suggest that people with psychiatric or substance-abuse disorders have an increased susceptibility to tobacco dependence (Benowitz, 2010). The experience of serious withdrawal symptoms after quitting, smoking more than 25 cigarettes per day or smoking a cigarette within 15 to 30 minutes after awakening suggest higher levels of nicotine dependence, and more difficulty with unaided quitting (Benowitz, 2010; Rigotti, 2012).

PSYCHIATRIC COMORBIDITY

Individuals with comorbid psychiatric disorders, especially anxiety, mood disorders, other substance abuse disorders, and schizophrenia, are associated with increased prevalence of smoking, higher levels of nicotine dependence and more difficulty achieving abstinence from tobacco use (Hitsman, Moss, Montoya, & George, 2009; Kalman, Morissette, & George, 2005; Ziedonis et al., 2008). Nicotine use in these individuals is impacted by a complex interplay of factors, including increased vulnerability to nicotine's effects, nicotine's effects on psychiatric symptoms, challenges managing craving and nicotine withdrawal symptoms, and interactions between nicotine, psychiatric medications and other psychoactive substances (Hitsman et al., 2009; Kalman et al., 2005; Ziedonis et al., 2008). Therefore, more intensive and tailored interventions are needed for individuals with these comorbid conditions (Kalman et al., 2005; Ziedonis et al., 2008). For example, it may be critical to understand an individual's reasons and triggers for smoking in order to better prepare them for quitting. It may also be important to address underlying issues such as depression or anxiety or alcohol abuse, before, or at least concurrently with tobacco cessation in order to enhance the effectiveness of treatment interventions for these patients (Hitsman et al., 2009; McFall et al., 2007; McFall et al., 2005; Ziedonis et al., 2008).

MEDICAL COMORBIDITY AND NICOTINE DEPENDENCE

There is no safe level of smoking and no safe tobacco product. The scientific evidence of bodily damage from smoking has grown steadily for more than 50 years and is documented in 30 Surgeon General Reports. The 2010 report lists 13 cancers causally linked to smoking and over 12 additional chronic diseases (U.S. Department of Health and Human Services, 2010).

Tobacco inhalation includes over 7,000 chemicals, 69 of which are known carcinogens. The cellular changes related to absorption of these toxic chemicals lead to disease, particularly cancer, cardiovascular and pulmonary diseases. Disease mechanisms include DNA damage, inflammation, and oxidative stress (U.S. Department of Health and Human Services, 2010).

REPRODUCTIVE AND POST-PARTUM EFFECTS

Tobacco smoke exposure has been linked to multiple adverse reproductive outcomes (U.S. Department of Health and Human Services, 2010). They include low birth weight, possible cognitive and neurobehavioral deficits, cleft lip with or without cleft palate, histopathologic changes in the lung and brain of the fetus from maternal smoking, reduced gestation and possible miscarriage (U.S. Department of Health and Human Services, 2010). Maternal smoking is clearly linked to transient increases in heart rate and blood pressure, placental problems, immunosuppressive effects that may lead to miscarriage and preterm delivery, and diminished oviductal functioning which could impair fertilization (U.S. Department of Health and Human Services, 2010). In addition, paternal smoking is linked to DNA damage in sperm and reduced fertility, pregnancy viability issues and anomalies in offspring (U.S. Department of Health and Human Services, 2010).

Utilizing intensive behavioral counseling interventions with pregnant smokers is extremely important and should continue throughout pregnancy and postpartum (M. Fiore et al., 2008) as smoking in households with young children results in significant increases in the prevalence of asthma, upper respiratory and ear infections, and doubles the risk of sudden infant death syndrome (SIDS) (U.S. Department of Health and Human Services, 2010). The safety and effectiveness of nicotine replacement medication and other cessation medications in pregnancy is unclear (M. Fiore et al., 2008). Because of some evidence that nicotine replacement use during pregnancy may be associated with small risks to the fetus, and because trials assessing the effectiveness of NRT among pregnant women are inconclusive, NRT during pregnancy was not recommended by the CPG (M. Fiore et al., 2008). Encouraging pregnant smokers who are reluctant to quit to, at a minimum, reduce their smoking rate, is likely to have beneficial effects, as a dose-response relationship between smoking rate and birth weight has been observed (M. Fiore et al., 2008).

FEAR OF POST-CESSATION WEIGHT GAIN

There is substantial evidence that cigarette smoking is associated with lower body weight on average, and that smoking cessation is associated with weight gain, generally under 10 pounds (M. Fiore et al., 2008). However, as many as 10% of quitters gain as much as 30 pounds and some smokers, especially women, smoke to prevent weight gain despite the risks (Kleiges & Kleiges, 1988). In addition, some data suggest that fear of post-cessation weight gain may decrease rates of smoking cessation (Pomerleau & Saules, 2007). Smoking cessation programs that have added a weight control component have

not been successful at decreasing post-cessation weight gain or enhancing achievement of smoking cessation, though they also do not appear to reduce cessation success (M. Fiore et al., 2008; Spring et al., 2009). Use of 4 mg nicotine gum and lozenge, and Bupropion SR delay but do not prevent post-cessation weight gain (M. Fiore et al., 2008). One promising approach to minimizing the weight gain associated with smoking cessation is to increase physical activity (Marcus et al., 2005). Others have suggested that rather than try to combat post-cessation weight gain, it might be more effective to help ex-smokers accept the weight gain (M. Fiore et al., 2008). A table outlining suggested clinician statements to help a patient prepare for post-cessation weight gain is available in the PHS CPG—(Table 7.9) (M. Fiore et al., 2008).

MOTIVATION

Though 70% of smokers express an interest in quitting smoking, only about 20% of smokers are ready to attempt to quit at any given time (M. C. Fiore & Baker, 2011). Thus, exploration of motivation is a key element of tobacco use cessation efforts (M. Fiore et al., 2008). A variety of factors may contribute to smokers' low motivation or ambivalence regarding quitting, including limited understanding about the risks of smoking or the benefits of quitting, concerns about the effects of quitting (e.g., withdrawal symptoms, dysphoria, and weight gain) and lack of confidence in their ability to quit. Providing advice or admonitions to quit to patients who are not ready is usually not effective and may harden ambivalence or produce discord. In contrast, Motivational Interviewing (MI), a collaborative patient-centered approach that seeks to explore ambivalence and elicit and strengthen the individual's intrinsic motivation, is associated with an increase in both quit attempts and a modest but significant increase in abstinence from smoking (Lai, Cahill, Qin, & Tang, 2010). Several of the strategies described in the MI chapter in this textbook can be used to enhance motivation among ambivalent smokers.

RECOMMENDATIONS FOR INTERVENTIONS IN HEALTH CARE SETTINGS

Based on an extensive review of the research literature, the 2008 update of the US Public Health Service Treating Tobacco Use and Dependence Clinical Practice Guideline (M. Fiore et al., 2008) made the following 10 key findings and recommendations:

1. Tobacco dependence is a chronic disease that often requires repeated intervention and multiple attempts to quit. Effective treatments exist, however, that can significantly increase rates of long-term abstinence.
2. It is essential that clinicians and health care delivery systems consistently identify and document tobacco use status and treat every tobacco user seen in a health care setting.

3. Tobacco dependence treatments are effective across a broad range of populations. Clinicians should encourage every patient willing to make a quit attempt to use the counseling treatments and medications recommended in this Guideline.
4. Brief tobacco dependence treatment is effective. Clinicians should offer every patient who uses tobacco at least the brief treatments shown to be effective in this Guideline (see recommendation #4 as well as the discussion below).
5. Individual, group, and telephone counseling are effective, and their effectiveness increases with treatment intensity. Two components of counseling are especially effective, and clinicians should use these when counseling patients making a quit attempt: (a) practical counseling (problem solving/skills training), and (b) social support delivered as part of treatment.
6. Numerous effective medications are available for tobacco dependence, and clinicians should encourage their use by all patients attempting to quit smoking—except when medically contraindicated or with specific populations for which there is insufficient evidence of effectiveness (i.e., pregnant women, smokeless tobacco users, light smokers, and adolescents). Seven first-line medications (5 nicotine and 2 non-nicotine) reliably increase long-term smoking abstinence rates:

- Bupropion SR
- Nicotine gum
- Nicotine inhaler
- Nicotine lozenge
- Nicotine nasal spray
- Nicotine patch
- Varenicline

Clinicians also should consider the use of certain combinations of medications identified as effective in this Guideline (see discussion below).

7. Counseling and medication are effective when used by themselves for treating tobacco dependence. The combination of counseling and medication, however, is more effective than either alone. Thus, clinicians should encourage all individuals making a quit attempt to use both counseling and medication.
8. Telephone quitline counseling is effective with diverse populations and has broad reach. Therefore, both clinicians and health care delivery systems should ensure patient access to quitlines and promote quitline use.
9. If a tobacco user currently is unwilling to make a quit attempt, clinicians should use the motivational methods shown in this Guideline to be effective in increasing

future quit attempts (see section on Motivation in this chapter and discussion below).

10. Tobacco dependence treatments are both clinically effective and highly cost-effective relative to interventions for other clinical disorders. Providing coverage for these treatments increases quit rates. Insurers and purchasers should ensure that all insurance plans include the counseling and medication identified as effective in this Guideline as covered benefits.

As noted in the CPG, evidence is clear and compelling that health care providers should routinely ask patients about their tobacco use status and document it in the medical record (M. Fiore et al., 2008; M. C. Fiore & Baker, 2011). Clinic-based reminders that prompt clinic staff to ask about smoking status increase rates of screening and intervention and should be implemented in all health care settings (M. Fiore et al., 2008; M. C. Fiore & Baker, 2011). Further, brief clinician intervention increases abstinence rates, even if delivered during an interaction lasting 3 minutes or less (M. Fiore et al., 2008; M. C. Fiore & Baker, 2011). However, because there is a dose-response relationship between intensity of intervention and abstinence rates, more intensive interventions (i.e., at least 4 sessions for a total of at least 20 minutes) should be made available to smokers who want assistance in quitting (M. Fiore et al., 2008; M. C. Fiore & Baker, 2011).

The following section of this chapter outlines core elements for a stepped care, comprehensive, patient-centered approach for tobacco cessation programming that is consistent with the CPG and current evidence. It is designed to take advantage of multiple members of a health care team so no one member is saddled with all the responsibility for assessment and intervention. Readily accessible treatment, at the intensity desired by the patient, promotes patient engagement and is an essential feature of this approach (M. C. Fiore & Baker, 2011).

Despite convincing evidence for the effectiveness of tobacco cessation intervention in health care settings, recent evidence indicates that, although tobacco use screening occurred during the majority of adult visits to outpatient physician offices during 2005–2008 (62.7%), among patients who were identified as current tobacco users, only 20.9% received tobacco cessation counseling (Jamal et al., 2012). The approach outlined in this chapter may help clinicians to overcome barriers to implementation so they might intervene more consistently and effectively.

FIVE STRATEGIES (THE 5 A'S) AND THREE LEVELS OF CARE

The intervention approach described below is based on the “5A’s” approach to addressing tobacco use that is described in detail in the PHS CPG (M. Fiore et al., 2008) and outlined below (Table 53.1). This CPG version of the 5 A’s differs slightly from the subsequent version that was recommended by the Counseling and Behavioral Interventions Work Group of the U.S. Preventive Services Task Force (USPSTF) in 2002 (E. P. Whitlock, Orleans,

Table 53.1 THE 5 A’S MODEL FOR TREATING TOBACCO USE AND DEPENDENCE

Ask about tobacco use	Identify and document tobacco use status for every patient at every visit. (Strategy A1)
Advise to quit	In a clear, strong, and personalized manner, urge every tobacco user to quit (Strategy A2)
Assess willingness to make a quit attempt	Is the tobacco user willing to make a quit attempt at this time? (Strategy A3)
Assist in quit attempt	For the patient willing to make a quit attempt, offer medication and provide or refer for counseling or additional treatment to help the patient quit. (Strategy A4) For patients unwilling to quit at the time, provide interventions designed to increase future quit attempts. (Strategies B1 and B2)
Arrange followup	For the patient willing to make a quit attempt, arrange for followup contacts, beginning within the first week after the quit date. (Strategy A5) For patients unwilling to make a quit attempt at the time, address tobacco dependence and willingness to quit at next clinic visit.

From PHS Treating Tobacco Use and Dependence” is an acknowledgment that table 53.1 was reproduced from the PHS CPG (M. Fiore et al., 2008 (May)

Pender, & Allan, 2002). The USPSTF recommended adoption of the “5 A’s” construct as a unifying conceptual framework for evaluating and describing health behavior counseling interventions in clinical settings (E. P. Whitlock et al., 2002). When we address the 4th A, Assist, we will describe 3 “levels” of intervention (i.e., brief, moderate, intensive) which may applied in a “stepped-care” manner. In the obesity section of this chapter we will specify the minor differences between the USPSTF version of the 5A’s and the version used in the CPG.

A1. Ask about tobacco- Identify and document tobacco use status for every patient at every visit. Structuring a clinic system to systematically identify all tobacco users at every visit is associated with increased tobacco use counseling (M. Fiore et al., 2008). This may be accomplished through electronic clinical reminders or with expanded vital signs documentation to include tobacco use. The responsibility for documenting tobacco status can be shared across the clinic team but should be explicitly determined.

A2. Advise to quit- Offer clear and unambiguous advice to quit, preferably tied to the individual patient’s health concerns. For example, “As your clinician, I must tell you that quitting smoking is one of the most important things you can do to protect your health, now and in the future. Continuing to smoke makes your asthma worse, and quitting will dramatically improve your health”. Before providing advice, it is helpful to ask the patient about their understanding of the impact of smoking on their health. Clinician use of this patient-centered strategy promotes patient engagement, limits unnecessary

information sharing and provides an opportunity for the clinician to reinforce the patient's understanding. When providing information and advice, it is also useful to ask permission first, (e.g., "Would it be ok if I shared some information about the benefits of quitting smoking?"). Asking permission before providing advice is not only respectful, it supports patient autonomy, which is especially important when patients are not ready for taking action (Miller & Rollnick, 2013; S. Rollnick, Mason, & Butler, 1999; G. C. Williams et al., 2006). See below, under A4, for a more extensive discussion of motivational strategies.

A3. Assess willingness to quit—Assessment of the patient's interest in and motivation for quitting is a key step. Simply asking, "What are your thoughts about quitting?" may start a productive conversation that allows the clinician to tailor intervention based on the patient's motivation.

A4. Assist the patient. Assistance is tailored to the patient based on their willingness to quit.

A4.1. For those patients clearly unwilling to pursue quitting at that time, future treatment engagement will be more likely if the clinician offers a non-judgmental, supportive response such as, "It doesn't sound like you are interested in quitting right now. If you decide you want to consider quitting in the future, I will be happy to help you." For those patients who are ambivalent about quitting, use of motivational strategies can be productive and can increase the likelihood of making a quit attempt in the future (M. Fiore et al., 2008). The use of Motivational Interviewing (MI), a specific person-centered clinical method for enhancing motivation by addressing ambivalence about change (Miller & Rollnick, 2013; S. Rollnick et al., 1999), increases tobacco cessation rates more than advice alone (M. C. Fiore & Baker, 2011; Lai et al., 2010). Training is needed for clinicians to develop and effectively apply MI skills (Miller & Rollnick, 2013). However, even without specific training in MI, use of a patient-centered approach that supports patient autonomy, builds trust, affirms existing kernels of motivation and avoids shaming, directing and judging is much more effective at building motivation than more directive or confrontational approaches (Miller & Rollnick, 2013; S. Rollnick et al., 1999; G. C. Williams et al., 2006).

The 5 R's approach described in the PHS CPG is useful for framing brief motivational elements. The 5 R's are: identify personally **R**elevant reasons to quit, review perceived **R**isks of smoking; identify **R**ewards for quitting, explore potential **R**oadblocks to success; and address motivation through **R**epetition at subsequent visits (See also the chapter in this text on Motivational Interviewing) see Table 53.2.

A4.2. For those patients who are willing to make a quit attempt, the clinician should offer a menu of treatment

options that include medication, brief behavioral counseling, or an intensive group program (See below for a discussion about varying the intensity of intervention to accommodate both patient preferences and typical clinic constraints.). For those patients who are willing to consider a quit attempt, asking permission to share treatment options may set a productive and collaborative tone. "Would you be interested in talking about treatment options?" is one such example. The discussion of treatment options should include a range of choices to accommodate patient preferences as well as maximize success.

A4.3. For patients willing to make a quit attempt, we describe three levels of intensity of tobacco cessation treatment (in terms of duration of treatment and number of contacts): brief, intermediate and intensive. The choice among levels of treatment intensity is largely determined by patient preference, though clinical constraints due to limited staffing and lack of resources may also influence the choice of treatment intensity. As emphasized in the PHS CPG, the combination of pharmacological and behavioral interventions produces higher quit rates than either element alone (M. Fiore et al., 2008 (May); M. C. Fiore & Baker, 2011; Rigotti, 2012). Thus, even brief interventions should offer 3 elements: medication, a behavioral component that addresses triggers for smoking and barriers to quitting; and educational resources. According to a meta-analysis of 35 randomized trials, there is a dose-response relationship between the minutes of total counseling contact and 6-month abstinence rates: about 14% for 1 to 3 minutes of counseling, 19% for 4 to 30 minutes of counseling, and 27% for 31 to 90 minutes of counseling, versus 11% for no counseling (M. Fiore et al., 2008 (May)). (Some studies included pharmacotherapy across all counseling conditions, so medication contributed to these success rates.). A 2012 Cochrane review of the benefits of combining behavioral counseling and medication found a 70 to 100% increase in quit rates when pharmacotherapy was combined with intensive behavioral compared to usual care, brief intervention or minimal behavioral counseling (Stead & Lancaster, 2012). Because intensive interventions that offer multiple contacts and more minutes of behavioral counseling produce the best outcomes, all patients who are interested in intensive treatment should have access to this level of treatment (M. Fiore et al., 2008 (May)). Patients with higher degrees of nicotine dependence, those with co-morbid mental health conditions and substance abuse, and those who have struggled to quit using less intensive interventions are likely to derive the greatest benefit from more intensive interventions, though all populations of smokers fare better when receiving intensive vs. briefer treatments (M. Fiore et al., 2008 (May)). However, many patients are not able to commit to intensive intervention or prefer less intensive interventions. As noted in the PHS CPG, even very brief interventions enhance quit rates when compared to no intervention.

Table 53.2 ENHANCING MOTIVATION TO QUIT TOBACCO—THE 5 R’S

Relevance	Encourage the patient to indicate why quitting is personally relevant, being as specific as possible. Motivational information has the greatest impact if it is relevant to a patient’s disease status or risk, family or social situation (e.g., having children in the home), health concerns, age, gender, and other important patient characteristics (e.g., prior quitting experience, personal barriers to cessation).
Risks	<p>The clinician should ask the patient to identify potential negative consequences of tobacco use. The clinician may suggest and highlight those that seem most relevant to the patient. The clinician should emphasize that smoking low-tar/low-nicotine cigarettes or use of other forms of tobacco (e.g., smokeless tobacco, cigars, and pipes) will not eliminate these risks. Examples of risks are:</p> <ul style="list-style-type: none"> • <i>Acute risks:</i> Shortness of breath, exacerbation of asthma, increased risk of respiratory infections, harm to pregnancy, impotence, infertility. • <i>Long-term risks:</i> Heart attacks and strokes, lung and other cancers (e.g., larynx, oral cavity, pharynx, esophagus, pancreas, stomach, kidney, bladder, cervix, and acute myelocytic leukemia), chronic obstructive pulmonary diseases (chronic bronchitis and emphysema), osteoporosis, long-term disability, and need for extended care. • <i>Environmental risk:</i> Increased risk of lung cancer and heart disease in spouses; Increased risk for low birth-weight, sudden infant death syndrome (SIDS), asthma, middle ear disease, and respiratory infections in children of smokers.
Rewards	<p>The clinician should ask the patient to identify potential benefits of stopping tobacco use. The clinician may suggest and highlight those that seem most relevant to the patient. Examples of rewards follow:</p> <ul style="list-style-type: none"> • Improved health • Food will taste better • Improved sense of smell • Saving money • Feeling better about oneself • Home, car, clothing, breath will smell better • Setting a good example for children and decreasing the likelihood that they will smoke • Having healthier babies and children • Feeling better physically • Performing better in physical activities • Improved appearance, including reduced wrinkling/aging of skin and whiter teeth
Roadblocks	<p>The clinician should ask the patient to identify barriers or impediments to quitting and provide treatment (problem solving counseling, medication) that could address barriers. Typical barriers might include:</p> <ul style="list-style-type: none"> • Withdrawal symptoms • Fear of failure • Weight gain • Lack of support • Depression • Enjoyment of tobacco • Being around other tobacco users • Limited knowledge of effective treatment options
Repetition	The motivational intervention should be repeated every time an unmotivated patient visits the clinic setting. Tobacco users who have failed in previous quit attempts should be told that most people make repeated quit attempts before they are successful.

From the PHS CPG (M. Fiore et al., 2008 (May)).

A4.3. Level One: Brief Intervention Brief intervention may be delivered in a single session. As noted previously, all interventions should offer effective tobacco cessation medications plus behavioral strategies as offering both elements together significantly enhances success (M. Fiore et al., 2008 (May); M. C. Fiore & Baker, 2011). Thus, at a minimum, a brief intervention should include identifying a quit date, removing tobacco use cues, choosing a medication (unless the patient does not want medication) and making a referral to other cessation resources that offer behavioral counseling. This very brief approach, which may be delivered with minimum staffing and resources, has been called AAR (Ask, Advise, Refer) (Rigotti, 2012; Schroeder, 2012). The additional resources might include written guides, online resources or telephone or online counseling (see also Level Two section below). The referral process can be simplified further by using templated fax forms or referral cards. Key behavioral strategies include: selecting a quit date, encouraging patients to share quit plans with others to solicit support for quitting; and helping the patient to employ specific strategies to anticipate and prepare for barriers and challenges to quitting. Exploring previous experience with quitting helps patients to identify triggers for smoking and potential relapse situations while also identifying strategies that helped them to successfully cope with urges, triggers and challenges. Brief advice for managing triggers includes 3 simple and practical behavioral strategies: 1) advising *removal* of all nicotine use-related items (cigarettes, lighters etc.) prior to quitting; 2) *avoiding or altering* situations associated with urges or previous lapses; and 3) *problem-solving* to identify possible substitutes for situations or emotions associated with urges or previous lapses. A sample planning sheet is provided in table 53.3. In addition, there is an online guide to quitting available free of charge at www.smokefree.gov.

A4.3 Level Two: Moderate Intervention. This mid-level intervention offers more than brief intervention, and may include up to 3 individual contacts. The contacts may be delivered in a variety of modalities including face-to-face appointments with a trained member of the clinic team, such as a nurse, a behaviorist (most often psychologist or social worker), or a pharmacist. Alternatively, effective counseling may be delivered via telephone (M. Fiore et al., 2008 (May); M. C. Fiore & Baker, 2011) and can be accessed via state quitlines (1-800 QUIT NOW) or through the Tobacco Control Research Branch of the National Cancer Institute (NCI) (1-877-44U-QUIT). The expansion of interactive computer and smart phone technology has great potential to support cessation efforts and reach the 75% of US adults who are on-line (Whittaker et al., 2012) though the evidence for the effectiveness of this modality of intervention is not as strong as for face-to-face

and telephone-based live counseling (M. C. Fiore & Baker, 2011). NCI is currently testing the effectiveness of LiveHelp, an online health program that uses social media and text messaging. Emerging technologies such as smart phone “apps” are also showing promise in supporting cessation success. Currently, there are at least a dozen versions of mobile apps available to support quitting. Many of these electronic approaches are expected to be particularly appealing to young smokers, though their effectiveness still needs to be studied.

A4.3. Level Three—Intensive Intervention: The most intensive level of treatment is face-face individual or group treatment with at least 4 sessions. Group intervention is widely available in a variety of standardized formats through agencies such as The American Lung Association (ALA), the American Cancer Society (ACS) and the proprietary sector. These programs can be offered within the clinic or, patients may be referred to community offerings. As noted previously, key elements of intensive intervention include pharmacotherapy, practical problem-solving behavioral counseling and educational tools and resources. Offering multiple sessions provides an opportunity to deliver tailored treatment across the three phases of treatment: preparation, quitting and maintenance/preventing relapse (Brown, 2003). The behavioral treatment elements included in intensive treatment are discussed in more detail below in section on specific smoking cessation counseling strategies.

A5. Arrange for follow-up contacts, either in person on the phone, or through one of the new technological options such as a smartphone application. While follow-up is a core element of any moderate or intensive program, follow-up contact is also recommended for brief intervention and even after a motivational intervention for patients not ready to quit (M. Fiore et al., 2008 (May); M. C. Fiore & Baker, 2011). If a quit attempt is planned, initial follow-up should occur shortly after quitting tobacco, preferably within 3–7 days. A system for follow-up could include secure e-mail, telephone follow-up with administrative support staff, or, if time permits, a phone call from a clinical team member to inquire about the patient’s experience. Implementing a health system approach that triggers assessment of smoking status at every visit provides opportunities to provide follow-up even when specific encounters for tobacco cessation are not planned. This systems-based approach, together with the chronic, relapsing nature of tobacco dependence, provides multiple opportunities to support abstinence, encourage additional quit attempts or make adjustments to current strategies as needed. For example, if patients who have quit are still struggling with strong urges, or using nicotine replacement months after quitting, the clinician may add additional pharmacological or behavioral interventions to help the patient maintain abstinence.

PHARMACOTHERAPY

Medications for tobacco use cessation reduce withdrawal symptoms and increase achievement of successful abstinence, even when used with minimal counseling (M. Fiore et al., 2008; M. C. Fiore & Baker, 2011; Rigotti, 2012). Medications for smoking cessation have been shown to be effective when used in a variety of health care settings and with smokers with coexisting conditions (e.g., substance abuse and depression) (M. Fiore et al., 2008; M. C. Fiore & Baker, 2011; Rigotti, 2012). Therefore, the PHS CPG recommends medication for all smokers who are willing to commit to quitting, with only some minor exceptions (M. Fiore et al., 2008; M. C. Fiore & Baker, 2011; Rigotti, 2012). See Table 53.3—VHA Tobacco Use Cessation Treatment Guidance—*Part 3: Medications for Tobacco Use Cessation* for an overview of the most commonly used effective medications. Selection of medication should be done collaboratively with the patient, considering past successes, current preferences, and the pros and cons of available options. Because it is not uncommon for patients to misperceive medication use as a sign of weakness, discussion of this concern can be helpful, along with a discussion of the benefits of medication use and a reiteration of the very large health benefits of quitting.

Seven medications have been approved by the FDA including five forms of nicotine replacement, bupropion and varenicline. The evidence reviewed for the PHS CPG strongly shows that abstinence rates are higher among patients using medications than among those who do not (M. Fiore et al., 2008; M. C. Fiore & Baker, 2011; Rigotti, 2012). A meta-analytic study of 83 RCTs studying the effects of various medications on 6 month abstinence rates found that most of them doubled the odds of achieving abstinence compared to placebo and minimal counseling (M. Fiore et al., 2008; M. C. Fiore & Baker, 2011; Rigotti, 2012). Combination therapies (i.e., combining nicotine patch with either lozenge or gum; combining bupropion and nicotine patch) are effective alternatives to monotherapies, though only the combination of nicotine patch plus bupropion is currently approved by the Food and Drug Administration (M. Fiore et al., 2008; M. C. Fiore & Baker, 2011; Rigotti, 2012). Each of the medications has contraindications and potential side effects, which are outlined in Table 53.3—VHA Tobacco Use Cessation Treatment Guidance—*Part 3: Medications for Tobacco Use Cessation*. Additionally, individual factors such as the presence of conditions which may increase the likelihood of adverse effects (e.g., dental conditions, dentures or jaw pain when considering gum; dermatitis when considering the patch; hypertension when considering bupropion; mental health conditions when considering varenicline) should be considered when choosing a specific pharmacologic agent. It is helpful to explore past successes, and identify what, if any, medication was helpful to a patient in the past and what medication they feel most confident about using. Importantly, clear, reading level appropriate patient education materials with instructions for use should be made available to all patients.

Nicotine replacement. The principle of nicotine replacement therapy (NRT) is to provide the patient with a more manageable and safer form of nicotine to ameliorate withdrawal symptoms and allow the patient to gradually reduce and then discontinue use of the drug (Benowitz, 2010; M. Fiore et al., 2008). Replacement therapy also provides an opportunity for the patient to develop and practice strategies to deal with behavioral or learned components of the drug dependence while controlling the physiologic “need” for the drug. Nicotine replacement therapy has been shown to be an effective aid to smoking cessation approximately doubling the quit rate compared with placebo (M. Fiore et al., 2008; M. C. Fiore & Baker, 2011; Rigotti, 2012). The combination of nicotine patches with other forms of NRT, such as gum or lozenge, added on as needed basis for breakthrough urges, further increases effectiveness (M. Fiore et al., 2008; M. C. Fiore & Baker, 2011; Rigotti, 2012). Since publication of the PHS CPG in 2008, evidence is accumulating that novel ways of administering NRT can improve quit rates, including prolonging treatment beyond the standard 12 weeks of treatment, continuing rather than discontinuing NRT use after a lapse and starting NRT 2 weeks before the quit day rather than on the quit day (M. C. Fiore & Baker, 2011; Rigotti, 2012). Preliminary evidence also suggests that offering NRT to smokers who want to cut down but not to quit might increase quitting rates (M. C. Fiore & Baker, 2011; Rigotti, 2012). However, the FDA label for NRT warns smokers against combining products, starting NRT before the quit date, and smoking while using NRT. These restrictions reflect some concerns about causing nicotine overdose or sustaining dependence that appear to be unfounded (Rigotti, 2012). In the United Kingdom, NRT is licensed for combination use and for reducing smoking prior to cessation.

When considering NRT for patients with cardiovascular disease, it is important to be aware of the relative risks of NRT use versus continued smoking in these patients. The PHS CPG notes that systematic study of the use of NRT in patients with cardiovascular disease has not found an association between nicotine patch use and cardiovascular events, even in patients who continue to smoke while using the patch (M. Fiore et al., 2008; Rigotti, 2012). Nicotine replacement is likely to be less dangerous to a patient with cardiovascular disease than smoking because NRT does not produce the peak nicotine levels associated with smoking and does not decrease oxygen-carrying capacity. However, as noted in the CPG, “NRT should be used with caution among particular cardiovascular patient groups: those in the immediate (within 2 weeks) post-myocardial infarction period, those with serious arrhythmias, and those with unstable angina pectoris.” (M. Fiore et al., 2008)

Nicotine patches. The nicotine patch delivers nicotine through the skin in 21, 14 and 7 mg doses. Patch use is recommended for an initial 8–12 weeks after quitting. The highest dose is recommended if the patient smokes 10 or more cigarettes a day. Nicotine patches reduce some but not all nicotine withdrawal symptoms. They are easy to use, are available over-the-counter and are generally well-tolerated. Mild skin rashes and irritation occur in up to 50% of patients.

Table 53.3 VHA TOBACCO USE CESSATION TREATMENT GUIDANCE—PART 3: MEDICATIONS FOR TOBACCO USE CESSATION

DESCRIPTION & EXAMPLES	PROS & CONS	COMMENTS / LIMITATIONS	DOSING RECOMMENDATIONS
<p>Nicotine Patch 24-hour delivery systems 21, 14, 7 mg/24 hr 16-hour delivery systems 15 mg/16 hr (Generic available, over-the-counter (OTC)) Delivers nicotine directly through the skin.</p>	<p>PROS</p> <ul style="list-style-type: none"> • Achieve constant levels of replacement • Easy to use • Only needs to be applied once a day • Few side effects <p>CONS</p> <ul style="list-style-type: none"> • Less-flexible dosing—cannot titrate dose to acutely manage withdrawal symptoms • Slow onset of delivery • Mild skin rashes and irritation 	<ul style="list-style-type: none"> • Patches vary in strengths and the length of time over which nicotine is delivered. • Patches may be placed anywhere on the upper body including arms and back. • Avoid hairy areas. • Rotate the patch site each time a new patch is applied. 	<ul style="list-style-type: none"> • ≥ 10 cigs/day = 21 mg/day \times 4–6 wks, then 14mg/day \times 2–3 wks, then 7mg/day \times 2–3 wks. • < 10 cigs/day = 14 mg/day \times 6wks, then 7mg/day \times 2 wks. • Adjust based on withdrawal symptoms, urges, and comfort. After 4–6 weeks of abstinence, taper every 2–4 weeks in 7–14 mg steps as tolerated. <p>DURATION</p> <ul style="list-style-type: none"> • 8–12 weeks
<p>Nicotine Lozenge 2 mg, 4 mg (OTC) Delivers nicotine through the lining of the mouth while the lozenge dissolves.</p>	<p>PROS</p> <ul style="list-style-type: none"> • Easy to use • Can titrate to manage withdrawal symptoms • May satisfy oral cravings • Delivers doses of nicotine approximately 25% higher than nicotine gum <p>CONS</p> <ul style="list-style-type: none"> • Should not eat or drink 15 minutes before use or during use; avoid acidic beverages • Should not be chewed or swallowed • Need for frequent dosing can compromise compliance • Nausea frequent (12–15%) 	<ul style="list-style-type: none"> • Use at least 8–9 lozenges/day initially. • Instruct patients to allow lozenge to dissolve slowly over 20–30 minutes. • Rotate to different sites of the mouth. • Nicotine release may cause a warm, tingling sensation. • Maximum 20 lozenges/day • Efficacy and frequency of side-effects related to amount used. • Review package directions carefully to maximize benefit of product. 	<ul style="list-style-type: none"> • Based on time to first cigarette of the day: < 30 minutes = 4 mg > 30 minutes = 2 mg • Based on cigarettes/day: > 20 cigs/day = 4 mg < 20 cigs/day = 2 mg • Initial dosing = 1–2 lozenges every 1–2 hours (minimum 9/day) \times 6wks, then 1 q2–4hrs \times 3wks, then 1 q4–8hrs \times 3wks. • Taper as tolerated. <p>DURATION</p> <ul style="list-style-type: none"> • 12 weeks
<p>Nicotine Gum 2mg, 4mg (Generic available, OTC) Delivers nicotine through the lining of the mouth while gum is parked between cheek and gum.</p>	<p>PROS</p> <ul style="list-style-type: none"> • Convenient/flexible dosing that allows for titration to manage withdrawal symptoms • Faster delivery of nicotine than the patches • Might satisfy oral cravings <p>CONS</p> <ul style="list-style-type: none"> • May be inappropriate for people with dental problems and those with temporomandibular joint (TMJ) syndrome • Should not eat or drink 15 minutes before use or during use; avoid acidic beverages • Frequent use during the day required to obtain adequate nicotine levels—may compromise compliance • Requires proper chewing technique for maximum benefit and to minimize adverse effects 	<ul style="list-style-type: none"> • The term “gum” is misleading; it is not chewed like regular gum. • Many people use this medication incorrectly. • Advise patients to chew each piece slowly. • Chew for 15–30 chews and park between cheek and gum when peppery or tingling sensation appears. • Rotate to different sites of the mouth. • Resume chewing when taste or tingle fades. • Repeat chew/park steps until taste or tingle does not return (about 30 minutes). • Review package directions carefully to maximize benefit of product. 	<ul style="list-style-type: none"> • Based on cigarettes/day: > 20 cigs/day = 4 mg gum < 20 cigs/day = 2 mg gum • Based on time to first cigarette of the day: < 30 minutes = 4 mg > 30 minutes = 2 mg • Initial dosing = 1–2 pieces every 1–2 hrs (10–12 pieces/day) \times 6 wks, then 1 piece every 2–4 hours \times 3 wks, then 1 piece every 4–8 hours \times 3 wks. • Taper as tolerated. <p>DURATION</p> <ul style="list-style-type: none"> • Standard duration is up to 12 weeks. Longer durations have been studied and associated with better abstinence rates.

**Combination
Nicotine
Replacement
Therapy
(NRT)**

*Nicotine patch + Nicotine gum
PRN*

*Nicotine patch + Nicotine lozenge
PRN*

PROS

- Permits sustained levels of nicotine (patch) with rapid adjustment for acute cravings and urges (PRN gum or lozenge)
- More efficacious than monotherapy

CONS

- May increase risk of nicotine toxicity
- Added cost of two NRT products versus one

- Providing two types of delivery system, one passive and one active, appears to be more efficacious.
- Should be considered for those who have failed single therapy in the past or those considered highly tobacco dependent.
- Considered a first-line treatment in the 2008 Update USPHS Clinical Practice Guidelines.
- Not a FDA-approved strategy.

- Dose patch as described above.
- Prescribe 2 mg or 4 mg gum or lozenge (according to dose-dependence level described above) on an as-needed basis when acute withdrawal symptoms and urges to use tobacco occur. (Initially most patients require about 6–8 pieces of gum or lozenges/day)
- Nicotine patch dose may be increased if patient is requiring more frequent use of PRN gum or lozenge after patch taper.

DURATION

- Patch: 8–10 weeks (with lozenge) or 8–24 weeks (with gum)
- Gum: 26–52 weeks
- Lozenge: 12 weeks

**NON-NICOTINE
MEDICATION
Bupropion SR
(Generic available)**

PROS

- Easy to use
- Pill form—may be associated with better compliance
- Few side effects
- May be beneficial in patients with depression
- May be used in combination with NRT

CONS

- Contraindicated with certain medical conditions and medications
- Increased seizure risk

- Treatment should be initiated 1 week prior to quit date and titrated.
- Avoid bedtime dosing to minimize insomnia, but allow 8 hours between doses.
- Use with caution in patients with liver disease (dose adjustment necessary).
- A slight risk of seizure (1:1000) is associated with use of this medication.
 - Assess seizure risk and avoid if:
 - Personal history of seizures
 - Significant head trauma/brain injury
 - Anorexia nervosa or bulimia
 - Abrupt discontinuation of alcohol or sedatives
 - Concurrent use of medications that lower the seizure threshold

- Start medication 1 week prior to the quit date:
 - 150 mg QD × 3 days, then
 - 150 mg BID × 4 days, then
- On quit date STOP SMOKING
- Continue at 150 mg BID × 8–12 weeks.
- If patient has been successful at quitting, an additional 12 weeks may be considered.
- May stop abruptly.
- No need to taper.

**COMBINATION
MEDICATION
Bupropion SR +
Nicotine Patch**

PROS

- Easy-to-use combination (FDA approved)
- Uses agents with two different mechanisms of action

CONS

- Does not allow for adjustment of acute cravings or urges
- Added cost of two NRT products versus one
- May be associated with more side effects than monotherapy

- Should be considered for those who have failed single therapy in the past or those considered highly tobacco dependent.
- Considered a first-line treatment in the 2008 Update USPHS Clinical Practice Guidelines.

- Use standard doses and duration.
- Bupropion: See bupropion dosing above; continue for 8–12 weeks.
- If patient has been successful at quitting, an additional 12 weeks may be considered.
- Nicotine patch: Dose patch as described above for total duration of 8–12 weeks.

(continued)

Table 53.3 (CONTINUED)

DESCRIPTION & EXAMPLES	PROS & CONS	COMMENTS / LIMITATIONS	DOSING RECOMMENDATIONS
COMBINATION MEDICATION Bupropion SR + Nicotine Lozenge or Gum	PROS <ul style="list-style-type: none"> • Uses agents with two different mechanisms of action • Allows for rapid adjustment for acute cravings and urges (PRN gum or lozenge) • More efficacious than monotherapy CONS <ul style="list-style-type: none"> • Added cost of two NRT products versus one • May be associated with more side effects than monotherapy 	<ul style="list-style-type: none"> • Providing two types of mechanisms of action, including an active delivery system, appears to be more efficacious. • Should be considered for those who have failed single therapy in the past or those considered highly tobacco dependent. • Though not included in the 2008 Update USPHS Clinical Practice Guidelines, data published after the Update supports this combination. • Not a FDA-approved strategy. 	<ul style="list-style-type: none"> • Use standard doses and duration. • Bupropion: See bupropion dosing above; continue for 8–12 weeks. • If patient has been successful at quitting, an additional 12 weeks may be considered. • Prescribe 2 mg or 4 mg gum or lozenge (according to dose-dependence level described above) on an as-needed basis when acute withdrawal symptoms and urges to use tobacco occur. (Initially, most patients require about 6–8 pieces of gum or lozenges/day)
NON-NICOTINE MEDICATION Varenicline	PROS <ul style="list-style-type: none"> • Easy to use • Pill form—may be associated with better compliance • No known drug interactions • Unique mechanism of action CONS <ul style="list-style-type: none"> • Nausea common in up to 1/3rd of patients • Severe neuropsychiatric symptoms may occur • Safety and efficacy have not been established in patients with serious psychiatric illness 	<ul style="list-style-type: none"> • Treatment should be initiated 1 week prior to quit date and titrated. • Taking the medication with food and titrating the dose as directed may help with nausea. • Take with a full glass of water. • Varenicline should not be used in combination with NRT. • Dose must be adjusted if kidney function is impaired. • VHA-specific varenicline prescribing guidelines at: www.pbm.va.gov/ClinicalGuidance/CriteriaForUse/VareniclineCriteriaforPrescribing.doc 	<ul style="list-style-type: none"> • TAKE WITH FOOD and full glass of water • Start medication one week prior to the quit date: • 0.5 mg QD × 3 days, then • 0.5 mg BID × 4 days, then • On quit date STOP SMOKING and • Take 1.0 mg BID × 11 weeks • If not smoking at the end of twelve weeks, may continue for an additional 12 weeks. • May stop abruptly. • No need to taper.

Reproduced from: “The US Department of Veteran Affairs Office of Public Health and Environmental Hazards (138), Public Health Strategic Health Care Group, July, 2010.

These tend to self-limiting but sometimes worsen and may be treated with hydrocortisone cream (1%) or triamcinolone cream (0.5%) as well as rotating the patch site to minimize irritation. Insomnia and/or vivid dreams also may occur. Dosing guidelines are available in Table 53.3—VHA Tobacco Use Cessation Treatment Guidance—*Part 3: Medications for Tobacco Use Cessation* and most follow a recommended dosage step-down process. Some preparations of patches are effective when used in a single dose.

Nicotine gum. Nicotine gum, which is available in 2 and 4 mg doses, delivers nicotine through the lining of the mouth while the gum is parked between gums and cheek. The 4 mg gum is recommended for more highly dependent smokers (e.g., smoking 25 or more cigarettes per day) (M. Fiore et al., 2008; M. C. Fiore & Baker, 2011; Rigotti, 2012). Gum can be used as a stand-alone medication or as an adjunct to patches. It allows for rapid titration of nicotine withdrawal and can be used flexibly by patients to self-manage control of withdrawal symptoms. Patients must learn a specific technique (chew slowly, park and chew) to achieve successful nicotine replacement and limit side effects. Use of nicotine gum may not be appropriate for denture wearers. Common side effects include mouth soreness, hiccups, dyspepsia, and jaw ache. These tend to be mild and manageable, often improving with guidance about chewing technique. Acidic beverages can interfere with absorption of the nicotine and should be avoided 15 minutes prior to or during chewing. It is common for patients to use insufficient gum to achieve optimal benefit. The CPG recommends a fixed schedule of at least one piece of gum every 1–2 hours for the first 1–3 months after quitting smoking. See Table 53.3—VHA Tobacco Use Cessation Treatment Guidance—*Part 3: Medications for Tobacco Use Cessation* for more detailed guidance.

Nicotine lozenge. Similar to the gum, the nicotine lozenge is available in 4 mg and 2 mg doses, and the higher dose is recommended for more heavily dependent smokers who smoke within 30 minutes after awakening (M. Fiore et al., 2008; M. C. Fiore & Baker, 2011; Rigotti, 2012). Like the gum, the lozenge allows for rapid self-titration. It can be used as a stand-alone medication or in combination with patches. The lozenge should be allowed to dissolve in the mouth rather than be chewed or swallowed. Patients are advised to use at least 9 lozenges per day for the first 6 weeks but no more than 20 per day. Like the gum, under-dosing is common. Common side effects are nausea, hiccups and heartburn as well as headache and coughing. Acidic beverages can interfere and should be avoided 15 minutes prior to and during use. Pattern of use and possible underuse should be explored if patients are struggling to stay quit or have relapsed. See Table 53.3—VHA Tobacco Use Cessation Treatment Guidance—*Part 3: Medications for Tobacco Use Cessation* for more detailed guidance.

Nicotine spray. The nicotine spray is available as an additional NRT option with one 0.5 mg squirt per nostril equaling one dose. The recommendation for use is 1–2 doses per hour with a maximum of 40 doses per day (M. Fiore et al., 2008; M. C. Fiore & Baker, 2011; Rigotti, 2012). Nasal irritation is a very common side effect, with 94% of users reporting

moderate-severe nasal irritation in the first 2 days of use. The frequency of irritation goes down to 81% after 3 weeks and typically becomes mild to moderate over time. Additional concerns include nasal congestion and transient changes in smell or taste. Spray is not recommended for patients with severe reactive airway disease. Dependency is more common with the nasal spray, as it produces higher peak nicotine levels than other forms of NRT. The CPG reports 15–20% of patients use the active spray for longer than 6–12 months and 5% use higher than recommended doses. See Table 53.3—VHA Tobacco Use Cessation Treatment Guidance—*Part 3: Medications for Tobacco Use Cessation* for more details.

Nicotine inhaler. The nicotine inhaler is a cartridge delivery system with each puff or inhalation constituting a dose from the 4 mg device. Each inhaler delivers 80 inhalations and recommended dosing is 6–16 cartridges daily (M. Fiore et al., 2008; M. C. Fiore & Baker, 2011; Rigotti, 2012). Local irritation of the mouth and throat is reported by 40% of patients, followed by coughing (32%) and rhinitis (23%). All generally mild and all remit with continued use. Ambient temperature impacts delivery which declines below 40 degrees. Acidic beverages interfere much like they do with gum or lozenge, and should be avoided 15 minutes prior to or during use. As with gum and lozenges, patients frequently under-utilize the inhaler and do not use enough as needed NRT for optimal effect. At least 6 cartridges daily are recommended. See Table 53.3—VHA Tobacco Use Cessation Treatment Guidance—*Part 3: Medications for Tobacco* for details.

Bupropion Sustained Release (brand name, Zyban) is one of the 2 FDA approved pharmacological alternatives to NRT (M. Fiore et al., 2008; M. C. Fiore & Baker, 2011; Rigotti, 2012). Bupropion is an antidepressant medication that is generally well-tolerated with occasional reports of hypertension. Most common side effects are insomnia (35–40%) and dry mouth (10%). Insomnia may improve by shifting the second daily dose to an earlier time, but still 8 hours after the first dose. Use is contraindicated in patients with a history of seizures or eating disorders. In 2009, the FDA issued a boxed warning in bupropion's packaging insert as a result of many reports of changes in behavior, including hostility, agitation, depressed mood and suicidal ideation (M. C. Fiore & Baker, 2011; Rigotti, 2012). Therefore, caution and careful monitoring is recommended for patients with psychiatric conditions. Patients are instructed to begin use 1–2 weeks prior to quitting. Dosing involves 150 mg each morning for 3 days, then increase to twice daily for a total maximum of 300 mg per day for 7–12 weeks. At times, patients stop or reduce smoking spontaneously, reporting lost desire and pleasure in tobacco. Alcohol should only be used in moderation. Bupropion blunts the weight gain usually seen post smoking cessation attempts, though the difference in weight gain disappears after bupropion is discontinued (Rigotti, 2012). If there are no contraindications or cautions, bupropion can be considered a first-line agent if a patient has a preference for a medication other than nicotine replacement therapy. It may also be considered when (1) patients have concerns about weight gain post quitting;

(2) patients have a history of mild or moderate depression or previous smoking cessation attempts were associated with prominent depressive symptoms; or (3) previous attempts at cessation using behavioral interventions and nicotine replacement agents have failed. However, as noted previously, if used in a patient with a previous psychiatric disorder, close monitoring is required. See Table 53.3—VHA Tobacco Use Cessation Treatment Guidance—*Part 3: Medications for Tobacco* for guidelines for prescribing bupropion.

Varenicline (brand name, Chantix), a partial nicotine receptor agonist, is also FDA approved for treatment of tobacco dependence and is also recommended as a possible first line agent by the CPG (M. Fiore et al., 2008; M. C. Fiore & Baker, 2011; Rigotti, 2012). Varenicline efficacy is the highest of any of the medications when used alone, with 33% of smokers achieving abstinence 6 months post quit attempt (M. Fiore et al., 2008; M. C. Fiore & Baker, 2011; Rigotti, 2012). However, varenicline carries the strongest warnings of any of the medication options, including caution for those with significant kidney disease or who are on dialysis. As with bupropion, reports of depressed mood, agitation, behavior changes, suicidal ideation and suicide behavior have prompted an FDA warning for use since 2009 (M. C. Fiore & Baker, 2011; Rigotti, 2012). Side effects include nausea, sleep difficulty, and abnormal/vivid dreams. Dosing starts 1 week prior to quit date at 0.5 mg in the morning for 3 days followed by 0.5 mg twice daily on days 4–7, and finally 1 mg twice daily from days 8 to end of treatment, which is in 3–6 months. Because of reports of neuropsychiatric adverse effects, a careful psychiatric history should be gathered, and ongoing monitoring for changes in mood or behavior is recommended during and immediately after a course of treatment. One recent RCT evaluating safety and efficacy of varenicline in patients with cardiovascular disease suggested it may be associated with a small increased risk of events including heart attack (M. C. Fiore & Baker, 2011). Providers are encouraged to weigh the costs and potential benefits of varenicline for each individual patient. As noted below, the combination of nicotine patches and supplemental nicotine gum or lozenge achieves a rate of abstinence that compares favorably with varenicline as a monotherapy. See Table 53.3—VHA Tobacco Use Cessation Treatment Guidance—*Part 3: Medications for Tobacco* for further guidance.

Combination Medication Treatment: Improvements in smoking cessation outcomes in recent years have often been due to combined medication approaches. While most all individual medications double the odds of abstinence, compared to placebo, to reach 19–26% abstinence at 6 months post quit date, the combination of nicotine patches and supplemental nicotine gum or lozenge achieve abstinence rates as high as 37% at 6 months (M. Fiore et al., 2008; M. C. Fiore & Baker, 2011; Rigotti, 2012). The patch provides a steady dose of nicotine, limiting withdrawal symptoms, while the as-needed use of gum or lozenge allows the patient to obtain an added bolus of nicotine when needed to address breakthrough withdrawal or craving in response to a trigger. See Table 53.3—VHA Tobacco Use Cessation Treatment Guidance—*Part 3: Medications for Tobacco* for additional guidance on approved combination therapies.

OTHER MEDICATIONS

The PHS CPG identified 2 additional medications as “second-line” pharmacologic agents for smoking cessation, clonidine and nortriptyline (M. Fiore et al., 2008). Though these medications produce enhanced abstinence rates in controlled trials, they are not approved by FDA for a tobacco cessation indication and have relatively high rates of adverse effects (Rigotti, 2012). Therefore, we do not recommend their routine use for treatment of tobacco dependence. A nicotinic receptor partial agonist, cytisine, has shown promise, (West et al., 2011) though more research is needed to determine its place among pharmacologic agents for treating nicotine use and dependence.

COUNSELING ELEMENTS AND STRATEGIES

Behavioral treatment strategies are essential components of tobacco use and dependence treatment (D. B. Abrams et al., 2003; Brown, 2003; M. Fiore et al., 2008). The expert panel that reviewed and synthesized scores of controlled trials of psychosocial and behavioral treatments for tobacco use cessation identified two key components of effective tobacco use counseling programs: a “practical” problem-solving/skills training counseling approach and social support as part of treatment (M. Fiore et al., 2008).

Practical problem-solving/skills training is an integral element of several health behavior change theoretical models, including Social Cognitive Theory, which suggests that behavior change and maintenance are a function of an individual’s learning history, shaped by classical and operant conditioning, as well as the individuals outcome expectations (i.e., beliefs about outcomes that result from engaging in a behavior) and self-efficacy (i.e., beliefs and confidence in one’s capacity to carry out specific behaviors in specific situations) (Bandura, 2004; Brown, 2003). Behavioral counseling provides smokers with opportunities to learn and practice skills to break the learned/automatic chain of events associated with smoking (Antecedent → Behavior → Consequences) and replacing smoking with more adaptive behaviors and coping strategies. Learning and practicing self-control strategies (e.g., goal setting, self-monitoring, self-evaluation and self-correction) and problem-solving and coping strategies (e.g., using a relaxation exercise to manage anxiety as an alternative to smoking) builds small successes which, in turn, builds self-efficacy and positive outcome expectations (Brown, 2003). Removing cues to smoking and avoiding or altering situations that are associated with smoking (e.g., taking a walk instead of a smoking break; having morning coffee in the bedroom rather than the kitchen) break learned links and establishes new routines that are not linked to smoking (Brown, 2003). The environment also exerts an effect on behavior through modeling (Brown, 2003). Thus, repeated exposure to positive role models, such as clinicians who engage in healthy behaviors or peers with effective coping repertoires, may promote adoption and maintenance of healthy behaviors.

The CPG specifies the key problem-solving/skills training elements that should be included in the behavioral counseling components of smoking cessation interventions. These are: 1) recognize danger situations—identify events, internal states or activities that increase the risk of smoking or relapse; 2) develop and practice coping and problem-solving skills to cope with danger situations; 3) provide basic information about the process and course of quitting, including and the risks of having even a single puff, as well as the benefits of reframing slips as a learning experience, rather than a failure (M. Fiore et al., 2008). It is helpful to consider treatment of tobacco dependence as akin to management of a chronic disease, with a need for repeated quit attempts and understandable lapses and relapses before long-term abstinence is achieved. Lapses can actually help to inform treatment needs and can be reframed as learning opportunities that can guide choice of behavioral strategies during subsequent efforts to quit and maintain abstinence.

SPECIFIC ELEMENTS OF PRACTICAL PROBLEM-SOLVING/SKILLS TRAINING (SEE TABLE 53.4—ELEMENTS OF PRACTICAL PROBLEM SOLVING/SKILLS TRAINING)

As noted previously in the discussion of the 5A's approach to intervention, it is useful for patients to establish a *target quit date* that is soon enough to build on motivation to quit while also providing an opportunity for the patient to prepare for quitting. Patients may use the time before the quit date to obtain medication, arrange sources of social support, and learn and practice problem-solving and coping skills to address anticipated barriers and challenges. If an intermediate or intensive form of treatment is chosen, the planning phase may include a period of self-monitoring to identify key smoking triggers and situations that may prompt relapse. The time prior to the target quit date may also be used to reduce nicotine consumption by changing brands or by reducing the number of cigarettes smoked per day.

Behavioral counseling includes developing a *specific plan* to address barriers to quitting and to cope with urges to smoke. As noted previously, the plan should include: removing all nicotine use-related items (cigarettes, lighters etc.) prior to quitting; avoiding or altering situations associated with urges or previous lapses; and 3) specifying possible substitutes or alternative behaviors or coping strategies for situations or emotions associated with urges or previous lapses. General stress management strategies (e.g., relaxation exercises, cognitive reframing, use of a stress ball) may help the patient to cope with common emotional and cognitive triggers. The plan should also include strategies for identifying and managing nicotine withdrawal symptoms and cravings to smoke, which might include use of as needed doses of nicotine gum, lozenge or inhaler.

Management of lapses (relapse prevention) is another key element of behavioral counseling. Because most treated smokers resume smoking within hours or days to several months after quitting, relapse prevention or management is a critical issue in smoking cessation. When lapses occur, patients

Table 53.4 ELEMENTS OF PRACTICAL PROBLEM SOLVING/SKILLS TRAINING

STRATEGY	EXAMPLES
Identify a Specific Quit Day	<ul style="list-style-type: none"> • Soon enough to build upon motivation • Provide opportunity to prepare and practice skills • Consider self-monitoring as a strategy for identifying triggers and barriers
Identify strategies for managing triggers to smoke and relapse situations	<ul style="list-style-type: none"> • Explore past experience to identify strategies that were successful • Remove smoking-related items • Develop plan for avoiding or altering trigger/relapse situations • Identify substitute behaviors to use in place of smoking for triggers and relapse situations • Teach/practice stress management skills
Managing lapses	<ul style="list-style-type: none"> • Reframe lapses as an opportunity for learning and problem-solving • Challenge self-blame, guilt, other negative emotions and cognitive distortions associated with lapses • After lapses occur, develop a revised plan to address lapse/relapse situations • Consider specific therapeutic interventions and coping strategies to address emergent challenges (e.g., anxiety or depressive symptoms, weight gain)

and clinicians need to guard against what has been called the “abstinence violation effect” (e.g., excess guilt, shame, pessimism and reduced confidence for change) (Baer & Marlatt, 1991; Ockene et al., 2000). As noted repeatedly, most successful quitters have made repeated attempts to quit. Health care providers can support a more positive approach by framing lapses and relapses as a normal, expected part of the process of learning to become a nonsmoker. Moreover, treating tobacco dependence is often a complex process that may require sustained and coordinated care, especially if the patient has coexisting medical and psychiatric comorbidity. Slips or full relapses should be met with non-judgmental, supportive problem-solving and an assessment of factors which may be contributing to difficulty quitting, including coexisting depressive or anxiety symptoms, the use or abuse of other psychoactive substances, or concerns about weight gain (Rigotti, 2012).

Supportive elements. The critical value of supportive elements in smoking cessation treatment is consistent with psychotherapy research that has identified “common factors” associated with positive outcomes of a wide variety of psychotherapeutic interventions across a range of conditions (Brown, 2003; M. Fiore et al., 2008; Miller, 2000; Orlinsky, Grawe, & Parks, 1994; Squier, 1990). These factors include a caring, empathic, collaborative, non-judgmental, patient-centered approach that fosters patient engagement, activation and empowerment and supports patient autonomy (Goldstein, DePue, & Kazura, 2008; Miller, 2000; Miller & Rollnick, 2013; Orlinsky et al., 1994; Squier, 1990; Williams et al., 2002). Operationally,

social support in treatment means: eliciting patient concerns and worries as well as reasons for quitting and successes; communicating caring and concern; offering treatment choices and options; engaging in shared decision-making; and encouraging the patient in their efforts to quit (M. Fiore et al., 2008; Goldstein et al., 2008).

As noted previously, there is a dose-response relationship between the intensity of tobacco cessation treatment and treatment outcome (M. Fiore et al., 2008). Evidence from meta-analyses conducted by the PHS CPG indicate that intensive treatment should include the following counseling elements: at least 4 sessions, each at least 10 minutes in duration; individualized assessments of motivation, beliefs, past experience, nicotine dependence, triggers and relapse situations; inclusion of practical problem-solving/skills training and in-treatment support; integration with pharmacotherapy; and ideally, involvement of multiple clinicians and intervention team members from a variety of disciplines (M. Fiore et al., 2008).

OTHER NON-PHARMACOLOGIC TREATMENT APPROACHES

The PHS CPG reviewed a number of additional non-pharmacologic treatment approaches, including acupuncture, hypnosis, exercise, aversive treatments and strategies to prevent weight gain after quitting smoking found there was either no evidence or insufficient evidence to support the use of these interventions (M. Fiore et al., 2008). Subsequent reviews have not revealed sufficient evidence to recommend these treatment modalities (Spring et al., 2009; Ussher, Taylor, & Faulkner, 2012; Barnes et al., 2010; White, Rampes, & Ernst, 2002).

OBESITY

As noted in the introductory section of this chapter, after tobacco, poor diet and decreased activity is the second highest cause of deaths in the United States each year (365 000 deaths) (Mokdad et al., 2004). The development of obesity is closely linked to these 2 behaviors, though obesity, like tobacco use is a biopsychosocial condition that has multiple contributing factors.

Obesity is identified based on measurement of Body Mass Index (BMI), defined as an individual's weight in kilograms divided by the square of their height in meters (kg/m^2). The United States Preventive Services Task Force (USPSTF) and US government health care agencies uses the following terms to define categories of increased BMI: overweight is defined as a BMI of 25 to 29.9 kg/m^2 , and obesity is defined as a BMI of 30 kg/m^2 or higher (Moyer, 2012).

Epidemiological studies have demonstrated links between obesity and increased risk of death, particularly in adults younger than age 65 years. The impact of obesity on mortality is large; obesity reduces life expectancy by 6 to 20 years depending on age and race (Fontaine, Redden,

Wang, Westfall, & Allison, 2003; E. LeBlanc, E. O'Connor, E. P. Whitlock, C. Patnode, & T. Kapka, 2011). The leading causes of death in persons who are obese are ischemic heart disease, diabetes, cancer (especially liver, kidney, breast, endometrial, prostate, and colon), and respiratory diseases (G. Whitlock et al., 2009). It is less clear whether being overweight is associated with an increased mortality risk (E. LeBlanc et al., 2011).

Data from the 2009–2010 National Health and Nutrition Exam Survey indicated that the prevalence of obesity in the United States now exceeds 33% in most age- and sex-specific groups (Flegal, Carroll, Kit, & Ogden, 2012). Thirty-five and one half percent of U.S. adult men and 35.8% of U.S. women were obese and an additional 38% of men and 28% of women were overweight (Flegal et al., 2012). Moreover, about 1 in 20 Americans has a Body Mass Index (BMI) of $>40 \text{ kg}/\text{m}^2$, which is class III obesity (Flegal et al., 2012). Alarming, the prevalence of obesity and overweight has increased by 134 % and 48%, respectively, since 1976 (Stein & Colditz, 2004). If current trends continue, researchers have estimated that, by 2030, 86.3% adults will be overweight or obese; and 51.1%, obese (Wang, Beydoun, Liang, Caballero, & Kumanyika, 2008).

Obesity increases the risk of coronary heart disease by almost 50% even after adjustment for other established risk factors (E. LeBlanc et al., 2011), while obese men and obese women have a 6.7-fold and 12.4-fold greater risk, respectively, of developing type 2 diabetes compared with normal weight men and women (Guh et al., 2009). Other diseases that have been associated with obesity include ischemic stroke, heart failure, dementia, venous thrombosis, gallstones, gastroesophageal reflux disease, renal disease, sleep apnea, osteoarthritis, and adverse pregnancy outcomes (E. LeBlanc et al., 2011).

Though obesity poses great health risks to obese individuals, the good news is that loss of as little as 5–10% of body weight, achievable with multi-component behavioral intervention programs, is associated with numerous health benefits, including reduction in the risk of heart disease and diabetes and better control of chronic conditions (E. LeBlanc et al., 2011; E. S. Leblanc, E. O'Connor, E. P. Whitlock, C. D. Patnode, & T. Kapka, 2011; Wing, 2010; Wing & Gorin, 2003).

FACTORS CONTRIBUTING TO OBESITY

Energy balance. Weight status is largely a function of the amount of calories consumed (intake) and the amount of calories burned (output). Positive energy balance exists when more calories are consumed than are burned, and this imbalance will result in obesity if even a small positive energy balance is maintained over time. As a general rule, an individual will gain one pound whenever they consume 3500 calories more than they burn (D. Abrams et al., 2000; Katz, 2001). Thus, consuming 100 additional calories daily will produce a 1 pound weight gain after 5 weeks, about a 10 pound weight gain after a year, and a 100 pound weight

Background. The Five As were developed by the National Cancer Institute and later adopted by the Canadian Task Force on Preventive Healthcare, as a way to organize a general approach to counseling patients to address health behavior change. The 5As construct has been used in clinical trials for smoking cessation and other primary care-based interventions for a variety of behaviors.

Application: The content of each step in the Five As varies from behavior to behavior, though clinical intervention targeting change in any behavior can be described using these five intervention components.

The Five As

Assess	Ask about—and assess behavioral health risks and factors that affect choice of behavior change goals and methods. <ul style="list-style-type: none"> Assessing behavioral risk factors identifies patients in need of intervention. Assess beliefs, behaviors, knowledge, motivation and past experience.
Advise	Give clear, specific, well-timed and behavior change advice, including personalized information about health harms and benefits. <ul style="list-style-type: none"> Clinician advice establishes behavioral issues as an important part of health care. Advise in a non-coercive, non-judgmental manner that respects readiness for change and patient autonomy. Advice is most powerful when linked to the patient's own health concerns, past experiences, family / social situations, and level of health literacy.
Agree	Collaboratively select appropriate goals and methods based on the patient's interest in and willingness to change the behavior. <ul style="list-style-type: none"> Collaborate to find common ground and to specify behavior change goals and methods. Shared decision-making is especially recommended for interventions that involve significant risk-benefit tradeoffs. Shared decision-making about behavior change results in a greater patient autonomy choices based on patient values, improved patient follow through and time saved in the exam room.
Assist	Using self-help resources and/or counseling, help the patient to achieve goals by enhancing skills, confidence, and social and environmental supports for behavior change. <ul style="list-style-type: none"> Health care staff provide motivational interventions, address barriers to change, and/or secure support needed for successful change. Effective interventions support self-management and enhance problem-solving or coping skills that enable patients to take the next immediate steps toward targeted behavior change. An action plan is developed that lists goals, barriers and strategies, and specifies follow-up.
Arrange	Schedule follow-up (in person or by phone or secure messaging) to provide ongoing assistance and support and to adjust the plan as needed, including referral to more specialized or intensive intervention. <ul style="list-style-type: none"> Consider behavioral risk factors as chronic conditions that ebb and flow over time. Routine follow-up assessment and support is usually necessary to promote and maintain behavior change.

Adapted from Whitlock, P, Orleans, C.T., Pender, N., and Allan, J (2002). *Evaluating Primary Care Behavioral Counseling Interventions: An Evidence-based Approach*, American Journal of Preventive Medicine and reproduced from Goldstein et al., AJPM, 2004.

gain over a decade. To underscore how easily this can happen, consider that 2 cookies, 1 banana, or 6 oz. of juice are examples of foods that contain about 100 calories. Overall caloric intake appears to be a more important factor than macronutrient composition in the development or maintenance of obesity (Wadden et al., 2012). However, it is harder to achieve energy balance on diets that are high in energy-dense foods, such as fats. Low-fat diets that also feature increased plant-based foods (e.g., grains, fruits and vegetables) yield a low-energy-density diet that may improve satiety because of the larger volume of food that may be consumed while still maintaining energy balance (Wadden et al., 2012).

Energy expenditure. Epidemiologic studies have consistently shown that the level of physical activity is inversely related to weight (D. Abrams et al., 2000; Katz, 2001).

However, decreased physical activity may be both a cause and a consequence of obesity. Moreover, the associations between physical activity and weight are confounded by associations between sedentary behavior and increased caloric and fat intake (Katz, 2001). However, physical activity increases energy expenditure both directly (15 minutes of brisk walking burns approximately 100 calories) and indirectly, through physical activity's effect on lean body mass, which increases basal metabolic rate, the largest contributor to daily energy expenditure (Katz, 2001). Increased physical activity is an essential element of successful weight loss and weight maintenance programs, to be discussed below (Thompson, Cook, Clark, Bardia, & Levine, 2007; Wing & Gorin, 2003).

Psychological factors. Depressive symptoms and obesity frequently coexist and there is an increased prevalence of

depressive and anxiety disorders in patients with obesity (Simon et al., 2006). The relationship between depression and obesity appears to be bidirectional (Ball, Burton, & Brown, 2009; Konttinen, Silventoinen, Sarlio-Lahteenkorva, Mannisto, & Haukkala, 2010; Thompson et al., 2007; Zhao et al., 2011). For example, individuals with depressive symptoms are more likely to report emotional eating or binge eating and also are less likely to engage in physical activity, putting them at increased risk of developing obesity (Konttinen et al., 2010). The rates of binge eating in an obese population seeking treatment for weight control is as high as 20% to 50% (Thompson et al., 2007). In cross-sectional studies of overweight and obese adults, waist circumference or abdominal obesity was significantly associated with increased likelihood of having major depressive symptoms or moderate-to-severe depressive symptoms (Zhao et al., 2011). Prospective studies have shown an increased risk of developing depressive symptoms among individuals who are overweight (Ball et al., 2009; Needham, Epel, Adler, & Kiefe, 2010).

Genetic factors. Though heritability of obesity has been estimated to range from 40–70%, (Herrera, Keildson, & Lindgren, 2011) the search for genetic variants contributing to susceptibility has been a challenging task. For example, the candidate gene *Ob* and its product leptin received significant attention when obese *Ob/Ob* mice were found to be deficient in leptin (Mutch & Clement, 2006). However, leptin and melanocortin, previously assumed to be controlled by a single gene appear to be regulated by multiple interacting genetic and environmental elements (Mutch & Clement, 2006). More recently, genome wide association (GWA) studies have identified more than 40 genetic variants that have been associated with obesity and fat distribution, (Herrera et al., 2011) though the effect sizes of the established loci are small, and combined they explain only a fraction of the inter-individual variation in BMI (Day & Loos, 2011). Though their value in guiding clinical interventions will be limited in the short term, genetic variants are likely to provide new insights into body weight regulation (Day & Loos, 2011). Experts, after reviewing the genetic and environmental influences on obesity, have concluded that genetics most likely contribute to the propensity for obesity, while environmental, behavioral, social and psychological factors determine the severity of obesity (D. Abrams et al., 2000).

MANAGEMENT/TREATMENT OF OBESITY

GENERAL CONSIDERATIONS

Like tobacco use, obesity is best viewed as a chronic, relapsing condition. The vast majority of obese individuals have engaged in serious weight loss efforts. Fifty-eight percent of obese adult women and 50% of adult obese men participating in the 1998 National Health Interview Study reported attempts to lose weight within the past year (Kruger, Galuska,

Serdula, & Jones, 2004). Using data from the Behavioral Risk Factor Surveillance System, investigators noted that adults who had a routine physician checkup in the previous year and reported receiving advice to lose weight had a higher prevalence of trying to lose weight (81% of women and 77% of men) when compared with adults who had a health care visit and reported no advice (41% of women and 28% of men, respectively).

Though many are successful at losing weight, recidivism following successful weight loss is extremely high (DePue, Clark, Ruggiero, Medeiros, & Pera, 1995). To learn about factors associated with enhanced maintenance of weight loss, researchers created a National Weight Control Registry (NWCR) of women and 155 men who lost an average of 30 kg and had maintained a weight loss of at least 13.6 kg for at least 5 years (Klem, Wing, McGuire, Seagle, & Hill, 1997). Researchers were interested in identifying the strategies used by successful maintainers. Initial studies indicated that maintainers modified both their dietary intake and physical activity level to lose weight. The three most commonly used strategies to change diet were limiting the intake of certain foods, limiting the quantities of food, and counting calories (Klem et al., 1997).

A prospective study examined behavioral and psychological predictors of weight regain in 261 successful weight losers who completed an 18-month trial of weight regain prevention (Wing et al., 2008). Decreases in physical activity were related to weight regain while increased frequency of self-weighing was protective in the 2 intervention groups, but not in the control group (Wing et al., 2008). This finding is consistent with a prospective study of participants in the NWCR who had lost > 30 pounds and kept it off for at least 1 year (Butryn, Phelan, Hill, & Wing, 2007). Consistent self-weighing in this cohort was associated with decreased weight gain over the subsequent year (Butryn et al., 2007). Investigators hypothesized that self-weighing may help individuals maintain their successful weight loss by allowing them to catch weight gains before they escalate and by making behavior changes to prevent additional weight gain (Butryn et al., 2007). Of note, in another study, increases in self-weighing was associated with increases in dietary restraint, decreases in disinhibition and decreases in depressive symptoms (Wing et al., 2007).

An American College of Sports Medicine (ACSM) Position Statement, published in 2009, reviewed the evidence regarding the role of physical activity as a weight maintenance strategy after weight loss (Donnelly et al., 2009). Both cross-sectional and prospective studies suggest that after weight loss, weight maintenance is improved with more than 250 minutes of physical activity per week, (Donnelly et al., 2009) considerably more than the 150 minutes of moderate physical activity per week recommended by ACSM and other bodies to get health benefits from physical activity (Haskell et al., 2007). However, there is insufficient evidence from well-designed randomized controlled trials to judge the effectiveness of physical activity for prevention of weight regain after weight loss.

Providing some form of long term follow-up contact may also enhance maintenance after a successful weight loss intervention. In a controlled trial of 2 forms of a maintenance intervention after a 6 month weight loss intervention, providing access to monthly personal contact was effective in helping to sustain weight loss, while an interactive technology-based intervention provided only transient benefit (Svetkey et al., 2008).

Obesity researchers and practitioners have also found value in focusing on challenging patients' unrealistic outcome expectations. If individuals are disappointed in their ability to reach their goal weight or discouraged with their new weight, these negative emotions may reduce motivation and trigger overeating episodes that lead to a full relapse (Thompson et al., 2007).

Though long-term maintenance of weight loss is challenging, as noted previously, the good news is that loss of as little as 5–10% of body weight, achievable with multi-component behavioral intervention programs, is associated with numerous health benefits (E. LeBlanc et al., 2011; Wing & Gorin, 2003).

PRIMARY CARE-BASED INTERVENTIONS

As with tobacco use, there is great opportunity to address obesity within health care settings, and in particular within primary care settings that have adopted the Patient-Centered Medical Home (PCMH). However, in most health care organizations, assessment and intervention for obesity is very limited. Despite the ease of determining BMI, surveys of patients have indicated that only 38 to 66% of overweight or obese patients report that they have received diagnoses of overweight or obesity, and less than half of obese patients report that their physicians have advised them to lose weight or provided specific information about how to lose weight (E. LeBlanc et al., 2011). Even among those who suffer from obesity-related comorbidities, only 52% were screened for obesity, 34% were diagnosed with obesity, and 46% were counseled about their obesity (E. LeBlanc et al., 2011). Moreover, only 24% of obese Americans were referred by their physician to a dietician or nutritionist and only 11% received a recommendation to attend a formal weight management program (Ma, Xiao, & Stafford, 2009). Surveys of obese patients indicate that 4–10% of obese adults received a prescription for weight loss medication, though less than half of the patients who were prescribed weight loss medication reported that they received the behavioral counseling and support that should accompany medication management (Shiffman et al., 2009).

The low rates of assessment and intervention for obesity within primary care settings suggests the need for systematic approaches to support clinician use of educational and counseling interventions that enhance patient engagement in weight management and participation in effective obesity treatment programs. The adoption of systematic approaches for addressing tobacco use interventions in health care settings (discussed in the section of this chapter on tobacco use treatments) may serve as a model for interventions to address obesity. For example, the 5 As behavioral counseling approach that was developed for smoking cessation interventions in health care settings, may be adapted to address obesity,

healthy eating, physical activity and other health risk behaviors (Glassgow & Goldstein, 2008; Goldstein, Whitlock, & DePue, 2004; E. P. Whitlock et al., 2002). See Box 53.1 for an adapted version of the 5 As that may be used for this purpose. Note that version of the 5 As (Assess, Advise, Agree, Assist, Arrange) omits the Ask step (actually combined with Assess) and adds the Agree step to emphasize the importance of addressing patient motivation and readiness for making a health behavior change. The collaborative Agree step supports patient autonomy and may contribute to building patient motivation and commitment to taking action, (S Rollnick, Miller, & Butler, 2008; Williams et al., 2002) as specified in the Assist step.

Obesity interventions in primary care settings may be spurred by a change in the United States Preventive Services Task Force's recommendations for management of obesity in health care settings. In 2012, after an extensive review of the impact of screening and weight loss interventions, the USPSTF recommended BMI screening of adult patients and offering or referring patients with a body mass index (BMI) of 30 kg/m² or higher to intensive, multicomponent behavioral interventions (E. S. Leblanc et al., 2011; Moyer, 2012). The USPSTF concluded that "adequate evidence indicates that intensive, multicomponent behavioral interventions for obese adults can lead to weight loss, as well as improved glucose tolerance and other physiologic risk factors for cardiovascular disease." (Moyer, 2012). The USPSTF also concluded that the possible harms of screening and behavioral weight-loss interventions (i.e., decreased bone mineral density and increased fracture risk, injuries from increased physical activity, increased risk of eating disorders) were small (Moyer, 2012). USPSTF rated the strength of evidence supporting this recommendation as "B," indicating "high certainty that the net benefit is moderate or there is moderate certainty that the net benefit is moderate to substantial." (Moyer, 2012). The B rating was provided even though the USPSTF noted that there was inadequate evidence about the effectiveness of behavioral weight loss interventions on long-term health outcomes, including mortality, cardiovascular disease, and hospitalizations (E. S. Leblanc et al., 2011; Moyer, 2012).

The evidence review utilized by the AHRQ for the USPSTF included a total of 58 weight-loss intervention trials with a total of more than 27,000 participants (E. S. Leblanc et al., 2011; Moyer, 2012). All of the trials included a strong behavioral component, while 21 also included a medication for weight management (either orlistat or metformin) (E. S. Leblanc et al., 2011; Moyer, 2012). Behavioral intervention participants lost an average of 6% of their baseline weight (4 to 7 kg), compared with little or no weight loss in control group participants (E. S. Leblanc et al., 2011; Moyer, 2012). A 5% weight loss is considered clinically important by the U.S. Food and Drug Administration (FDA). The Task Force's evidence review also concluded that weight loss outcomes were greatest when interventions involved more sessions (12 to 26 sessions) (E. S. Leblanc et al., 2011; Moyer, 2012).

The Diabetes Prevention Program (DPP) is a particularly strong example of the effectiveness of a multicomponent behavioral intervention program (Diabetes Prevention Program

Research Group, 2002). The DPP was a multi-centered randomized controlled trial that was designed to test whether a behavioral intervention or metformin, a antihyperglycemic agent, could prevent or delay the onset of diabetes among adults at risk for the development of type 2 diabetes (Diabetes Prevention Program Research Group, 2002). The behavioral “lifestyle” intervention consisted of an individualized 16-lesson curriculum addressing diet, weight loss and physical activity, delivered by case managers (Diabetes Prevention Program Research Group, 2002). Over 3,200 individuals were randomized to one of three conditions: lifestyle recommendations plus metformin; lifestyle recommendations plus placebo; or the intensive lifestyle intervention. After an average follow-up of 2.8 years, the lifestyle intervention reduced the incidence of diabetes by 58% compared with placebo, while metformin reduced the incidence of diabetes by 31% (Diabetes Prevention Program Research Group, 2002). Both the intensive behavioral intervention condition and metformin intervention outperformed the placebo control group, and the behavioral intervention was significantly more effective than metformin in preventing diabetes (Diabetes Prevention Program Research Group, 2002). The behavioral intervention also produced significantly greater weight loss and greater increases in physical activity than metformin or placebo (Diabetes Prevention Program Research Group, 2002).

Although the 21 trials in the USPSTF evidence review that combined pharmacologic agents (orlistat or metformin) with behavioral interventions resulted in significant weight loss and improvement in physiologic outcomes, the USPSTF elected to withhold a recommendation for use of medication to treat obesity because of concerns about the safety of orlistat and insufficient data on maintenance of weight loss after discontinuation of medications (E. S. Leblanc et al., 2011; Moyer, 2012). See the section on pharmacotherapy below for more on use of medications to treat obesity.

COMPONENTS OF INTENSIVE MULTICOMPONENT TREATMENT PROGRAMS TO MANAGE OBESITY

Based on their review of the research literature, the USPSTF specified that intensive, multicomponent behavioral interventions for obesity should include the following components:

- Behavioral management activities, such as setting weight-loss goals;
- Improving diet or nutrition and increasing physical activity;
- Addressing barriers to change;
- Self-monitoring; and
- Strategizing how to maintain lifestyle changes (Leblanc et al., 2011; Moyer, 2012).

The basic premise of the behavioral components included in multicomponent programs is that, in order to lose weight

and keep it off, individuals must gradually replace current maladaptive eating behaviors and sedentary behavior with healthy eating behaviors and physical activity habits that can be incorporated into their lifestyles and maintained indefinitely (D. Abrams et al., 2000; Thompson et al., 2007).

Behavioral program elements for weight management include self-monitoring (keeping a daily record of food or calorie intake or both), stimulus control procedures (i.e., rearranging the environment in order to eliminate unhealthy food cues), goal setting, self-reinforcement to help shape new behaviors (e.g., slower eating), cognitive restructuring (e.g., changing maladaptive thinking regarding eating and dieting), an emphasis on a gradual increase and then maintenance of physical activity, assertiveness training focused on weight loss issues (e.g., food refusal), facilitation of social support for weight loss efforts, and relapse prevention training (D. Abrams et al., 2000; Thompson et al., 2007).

ASSESSMENT

When deciding when and how to intervene to treat obesity, several dimensions of patient characteristics may be evaluated: (1) psychological and medical findings; (2) cognitive-behavioral and social factors; and (3) patient motivation and preferences (D. Abrams et al., 2000; Thompson et al., 2007).

Psychological evaluation. Some obese patients have psychiatric comorbidity or psychosocial factors that warrant individualized treatment. Therefore, obese patients should ideally be screened for the presence of a co-morbid psychiatric disorder. Special attention should be placed on assessing the presence of an eating disorder, substance abuse or dependence, body image disturbance, depression, anxiety, binge eating disorder, history of sexual abuse, or a personality disorder (D. Abrams et al., 2000; Thompson et al., 2007).

Patients with an active substance abuse problem or eating disorder are best managed by being offered specific services for these problems. Patients with other co-morbid psychiatric disorders may be appropriate for participation in a weight management program if they are in simultaneous treatment for their comorbid psychiatric disorder, and if their current level of functioning would not prohibit their ability to adhere to weight management interventions (D. Abrams et al., 2000; Thompson et al., 2007).

In addition, we recommend that clinicians inquire about cognitive-behavioral factors specific to treatment planning, such as previous weight loss attempts, current eating habits, motivation for weight loss, body image, positive aspects of their obesity (secondary gain), binge eating, weight goal, expectations, high risk for relapse situations, and willingness to make long-term lifestyle changes (D. Abrams et al., 2000; Thompson et al., 2007). To assess binge eating, patients should be asked about the occurrence of binge episodes (rapid consumption of a large amount of food accompanied by a loss of control), frequency of binge episodes, history of binge eating, cognition during a binge (perceived loss of control of their

eating), physical distress following a binge, negative affect or cognition following a binge episode (D. Abrams et al., 2000; Thompson et al., 2007). (See Chapter on Eating Disorders in this text.)

If a patient has a history of having been sexually abused, the trauma may or may not be related to the patient's current weight status (D. Abrams et al., 2000; Thompson et al., 2007). However, women in a weight management program who reported a history of being the victim of sexual abuse lost less weight and reported more nonadherence compared to women matched on BMI and age who denied a history of abuse (Clark et al., 2007; T. K. King, Clark, & Pera, 1996). For such patients, clinicians should additionally attempt to assess how likely it is that weight loss will: (1) trigger memories of sexual abuse (based on a return to a lower weight, which may coincide with the weight at which the patient was abused); (2) cause problematic disruptions in their relationships secondary to potential increased sexual attention or demands from others; or (3) lead to feelings of vulnerability (D. Abrams et al., 2000; Thompson et al., 2007). These areas are difficult to assess but may affect treatment; therefore, we recommend that clinicians are trained in this area or maintain a close referral relationship with a program and clinicians who specialize in sexual abuse issues (D. Abrams et al., 2000; Thompson et al., 2007).

Increasing physical activity. Engagement in regular physical activity is a key component of successful weight loss interventions (Jakicic & Davis, 2011; Leblanc et al., 2011; Wing & Gorin, 2003). Physical activity includes both structured exercise as well as lifestyle activity. Regular physical activity is useful in a variety of ways: it increases energy expenditure, raises basal metabolic rate, suppresses appetite, counteracts some of the deleterious effects of obesity and sedentary behavior (e.g., improves cardiac efficiency), and minimizes the loss of lean tissue during weight loss (Jakicic & Davis, 2011; Thompson et al., 2007). Researchers have found that both aerobic exercise and strength training are beneficial and that home-based exercise improves long-term adherence compared to on-site exercise programs (Ashworth, Chad, Harrison, Reeder, & Marshall, 2005; Perri, Martin, Leermakers, Sears, & Notelovitz, 1997). The adherence advantages of home based activity may allow unstructured moderate exercise to be used as a viable alternative to structured program. Thus, obese individuals should be encouraged not only to increase their energy expenditure through regular structured exercise (e.g., walking, swimming, aerobics), but also to increase their level of lifestyle activity (e.g., using stairs rather than elevators, walking to the corner store instead of driving). Furthermore, there is evidence that increase in fitness associated with regular physical activity enhances outcomes even when patients remain obese (McAuley & Blair, 2011).

Nutritional education and use of a balanced-deficit diet. It is important to include a nutritional education component in all obesity treatment programs. Though many different diets have been advocated for weight loss, there is little scientific evidence to recommend one diet over another (Katz, 2001; Thompson et al., 2007). A trial that compared 4 approaches,

the Atkins (low carbohydrate), Zone (high protein, low carbohydrate), Ornish (very low fat), and Weight Watchers diets, found no significant difference in weight loss at 1 year (Dansinger, Gleason, Griffith, Selker, & Schaefer, 2005). An ideal nutritionally balanced diet consists of approximately 50% to 60% of calories from carbohydrates, no more than 30% from fat, and 15% to 20% from protein (D. Abrams et al., 2000; Katz, 2001; Thompson et al., 2007).

Long-term weight loss and weight maintenance usually requires both a reduction in energy intake as well as an increase in energy expenditure. A balanced-deficit diet provides nutritionally balanced daily meals with a caloric intake level below the individual's caloric expenditure level. Decreasing daily caloric intake by 500 kcal below that necessary for weight maintenance generally yields a 1 lb weight loss per week. Generally these diets are 1200 kcal per day for women and 1500 kcal per day for men. It is generally recommended that mildly obese individuals lose 1.0 to 1.5 lb per week (Thompson et al., 2007). A useful and practical approach to reducing caloric intake includes a combination of reducing total fat intake, reducing portion size, reducing energy density, and increasing fruit and vegetable intake (Katz, 2001; Thompson et al., 2007).

Low-calorie and very-low-calorie diets. Two more intense levels of caloric restriction are used in some settings to produce more rapid weight loss: the low-calorie diet (LCD) of about 1000 calories per day and the very-low-calorie diet (VLCD) of 800 or fewer calories per day. Both diets may produce adverse side effects, including excessive loss of lean body mass; therefore, prior to participating in one of these diets, patients must undergo a thorough medical evaluation by a trained physician (D. Abrams et al., 2000; Thompson et al., 2007). A review of VLCDs concluded that they did not produce greater long-term weight losses than LCDs (Tsai & Wadden, 2006). The use of liquid meal replacements as part of a 1000 to 1500 kcal/d diet may provide an effective, safer and less expensive alternative to VLCDs (Tsai & Wadden, 2006).

Interactive computer-based programs. A Cochrane review of 14 interactive computer-based interventions to manage obesity found that, when compared to no intervention or minimal interventions (pamphlets, usual care), these interventions are effective for weight loss and weight maintenance. Compared to infrequent in-person interventions, interactive computer-based interventions result in smaller weight losses and lower levels of weight maintenance, though the greater accessibility and convenience of the computer-based interventions make them an attractive alternative, especially for patients unwilling to commit to in-person care (Wieland et al., 2012).

Pharmacotherapy. The role of medications to treat obesity is an area of considerable interest and research (Colman et al., 2012). However, it should be noted that virtually all medications that have been approved by the FDA for the management of obesity must be paired with behavioral and nutritional intervention elements, as medications alone have not been shown to produce long-term weight loss. Moreover, studies have clearly demonstrated that weight is usually regained when pharmacologic agents are discontinued (Katz, 2001).

Unfortunately, several effective pharmacologic aids to treatment obesity drugs have been abandoned or withdrawn from the market because of serious toxicity: fenfluramine and dexfenfluramine (due to valvulopathy); sibutramine (myocardial infarction and stroke); phenylpropanolamine (stroke); aminorex (pulmonary hypertension); and rimonabant (suicidal ideation and behavior) (Colman et al., 2012). By mid-2012, orlistat was the only prescription drug approved for the long-term treatment of obesity.

Orlistat prevents absorption of fats in the gastrointestinal tract by inhibiting lipases. Multiple placebo-controlled trials have demonstrated orlistat's efficacy when combined with nutritional and behavioral counseling and it has been approved by the FDA for treatment of obesity for up to 2 years (Colman et al., 2012). All trials included elements of nutritional or behavioral counseling. Meta-analyses suggest that the mean weight loss with orlistat is 2.89 kg (Li et al., 2005). Patients switched to a weight maintenance diet after weight loss regain less weight if they continue on orlistat compared to placebo (Davidson et al., 1999). Orlistat needs to be taken in advance of meals containing fats and its use is limited by common gastrointestinal side effects (cramping, diarrhea, oily stool) secondary to fat malabsorption. Vitamin supplementation with lipid soluble vitamins is required. As a result, orlistat is most likely to be useful for patients who can follow a low-fat diet and who are willing to tolerate the side effects (D. Abrams et al., 2000).

In late 2012, the FDA approved two new medications for treating obesity: lorcaserin, and phentermine/topiramate combination (Colman et al., 2012). Both are approved as adjuncts to a reduced-calorie diet and increased physical activity for chronic weight management in adults who are either obese (BMI ≥ 30), or overweight (BMI ≥ 27) with at least one weight-related condition (Colman et al., 2012). Both new medications were assessed in placebo-controlled clinical trials in which all participants also received behavioral counseling. It should be noted that both of these new medications were approved despite safety concerns that are noted in the discussion below.

The efficacy of lorcaserin and phentermine/topiramate were demonstrated in placebo-controlled trials. At the end of 1 year, participants in trials of lorcaserin and phentermine/topiramate who were assigned to the active drug conditions were significantly more likely to achieve at least a 5% weight loss than those on placebos (For lorcaserin, the difference in was 38–47% vs. 16–23%; for phentermine/topiramate, 62–70% vs. 16–21%) (Colman et al., 2012).

Lorcaserin is a selective agonist of the serotonin 2C receptor. Serotonin is a neurotransmitter that affects mood and also a number of physiologic drives including food intake and satiety. Because lorcaserin shares a serotonergic mechanism with the withdrawn agents fenfluramine and dexfenfluramine, questions were raised about lorcaserin's effects on heart valves. However, lorcaserin has low affinity for the 2B serotonergic receptor (Colman et al., 2012). Fenfluramine's and dexfenfluramine's affinity for the 2B receptor is believed to be responsible for the toxic heart valve effects that led to the withdrawal of those agents (Colman et al., 2012). Before FDA

approval, lorcaserin's manufacturer completed an echocardiographic safety study that found no significant increase in valvulopathy in patients on lorcaserin (Colman et al., 2012). Though concerns about lorcaserin's propensity to increase tumor types in rats were also identified, these fears were allayed by subsequent studies (Colman et al., 2012). In addition, lorcaserin may increase the risk of psychiatric, cognitive, and serotonergic adverse effects (Colman et al., 2012).

Phentermine, a sympathomimetic, and extended-release topiramate, an anticonvulsant with anorectic properties, are combined in a fixed-dose preparation. Because of the potential for cardiovascular toxicity, the effects of this combination on cardiac function were scrutinized by the FDA (Colman et al., 2012). At doses of 7.5 mg/46 mg and 15 mg/92 mg, phentermine/topiramate was associated with mean increases in heart rate of 0.6 bpm and 1.6 bpm, respectively, as compared with placebo (Colman et al., 2012). However, this effect on heart rate was offset by greater mean reductions in blood pressure on active drug than on placebo (Colman et al., 2012). Taking into account the magnitude of weight loss and the favorable changes in blood pressure, the FDA concluded that the benefit–risk balance was positive and supported the approval (Colman et al., 2012). Because topiramate use during pregnancy is associated with an increased incidence of oral-facial clefts in pregnancy, FDA approval of phentermine/topiramate required a risk evaluation and mitigation strategy (REMS) that includes a training program for prescribers, a medication guide and a patient brochure that stresses the need for women of reproductive potential to use effective forms of contraception (Colman et al., 2012). Phentermine/topiramate may also increase the risk of metabolic acidosis, glaucoma, and psychiatric and cognitive adverse effects (Colman et al., 2012). The REMS also specifies that only specially certified pharmacies will be able to dispense phentermine/topiramate (Colman et al., 2012).

Because these new medications are associated with potentially serious risks and the FDA has stressed that it is important that their use be limited to patients who are obese, or overweight (BMI ≥ 27) with at least one weight-related condition (Colman et al., 2012). Prescribers should also adhere to the recommendations in the labels regarding patients' initial weight loss response to treatment (Colman et al., 2012). If, after 12 weeks of treatment with lorcaserin, a patient has not lost at least 5% of the baseline body weight, use of the drug should be discontinued, since results from the initial trials suggest that it is unlikely that the patient will achieve meaningful weight loss with continued treatment (Colman et al., 2012). Similarly, if after 12 weeks of treatment with phentermine–topiramate at the 7.5 mg/46 mg dose, a patient has not lost at least 3% of the baseline weight, either the drug should be discontinued or the dose increased (Colman et al., 2012). If the latter option is chosen and the patient does not lose at least 5% of the baseline weight during an additional 12 weeks of treatment, the drug should be discontinued, because the patient is unlikely to achieve meaningful weight loss with continued treatment (Colman et al., 2012). Finally,

the FDA is also requiring that the manufacturers of both lorcaserin and phentermine/topiramate conduct a number of postapproval clinical trials, including a “rigorous assessment of long-term cardiovascular safety in overweight and obese patients” (Colman et al., 2012).

In summary, medications have a place in the management of obesity. Three medications, orlistat, lorcaserin and phentermine/topiramate, are efficacious when combined with behavioral and nutritional intervention elements. However, there are questions regarding their long term safety and efficacy. Longer-term studies with large numbers of subjects may be necessary to further define exactly what role medications will play in the treatment of obesity in the future.

SURGERY

Surgery for obesity, also known as bariatric surgery, has been reported to result in substantial 10-year weight loss (Maggard et al., 2005). Currently accepted criteria for consideration of bariatric surgery include a body mass index (calculated as weight in kilograms divided by the square of height in meters) of 40 kg/m² or greater (or >35 kg/m² with obesity-related comorbidities), patient readiness to participate in dietary, physical activity and self-care activities, and acceptable medical and surgical risk (Collazo-Clavell, Clark, McAlpine, & Jensen, 2006). In a 2004 review and meta-analysis of the health benefits of bariatric surgery, investigators reported that diabetes, hyperlipidemia, hypertension, and obstructive sleep apnea resolved or improved in more than half of the patients who had these conditions preoperatively (Buchwald, et al., 2004). A subsequent meta-analysis of bariatric surgery involving over 7,000 patients with diabetes found 78.1% of diabetic patients had complete resolution, and diabetes was improved or resolved in 86.6% of patients (Buchwald et al., 2009). Weight loss and diabetes resolution were greatest for patients undergoing biliopancreatic diversion/duodenal switch, followed by gastric bypass, and least for banding procedures (Buchwald et al., 2009).

A 2005 meta-analysis and review found that common bariatric procedures (gastric bypass, laparoscopic adjustable gastric band, vertical banded gastroplasty, and biliopancreatic diversion and switch) have been performed with an overall mortality rate of less than 1%, and with adverse events occurring in about 20% of cases (Maggard et al., 2005). Though gastric bypass (GBP) procedures result in more weight loss than gastroplasty, laparoscopic approaches result in fewer wound complications than an open approach (Maggard et al., 2005). A systematic review indicated that laparoscopic isolated sleeve gastrectomy (LISG) was more effective than adjustable gastric banding (AGB). GBP and banded GBP led to similar weight loss and results for GBP versus LISG and VBG versus AGB were equivocal (Picot et al., 2009).

An interdisciplinary team approach, including surgeons, primary care clinicians, psychologists and nutritionists, is essential for achieving both good and safe long-term outcomes of bariatric surgery (McMahon et al., 2006). Careful screening of suitable candidates is useful, including a psychological and

Box 53.2 CRITERIA FOR BARIATRIC SURGERY

- Body mass index of 40 kg/m² or more (approximately 45 kg overweight for men and 36 kg for women) *or*
- Body mass index between 35 and 39.9 kg/m² and a serious obesity-related health problem such as type 2 diabetes, heart disease, or severe sleep apnea
- The patient should understand the operation and the lifestyle changes that will be needed
- Be unlikely to lose weight or maintain weight loss long term with nonsurgical measures
- Be well informed about the surgical procedure and the effects of treatment
- Be motivated to lose weight and improve health
- Be aware of how life may change after the operation (e.g., the need to chew food well and the inability to eat large meals)
- Have no psychological contraindications to obesity surgery such as untreated depression or personality disorders
- Be aware of the potential for serious complications, dietary restrictions, and occasional failures
- Be committed to lifelong medical follow-up and vitamin/mineral supplementation
- Realize that no method, including surgery, is guaranteed to produce and maintain weight loss and that success is possible only with long-term commitment to behavioral change and medical follow-up

Adapted from the National Institute of Diabetes and Digestive and Kidney Diseases, National Institutes of Health. *Gastrointestinal Surgery for Severe Obesity*. Bethesda, Md: National Institutes of Health; December 2004. NM Publication No. 04-4006.

behavioral assessment of the patient’s capacity to manage self-care, behavioral change and nutritional needs before and after surgery (See Box 53.2). Understanding of potential vitamin and mineral deficiencies, effects of weight loss on medical comorbid conditions, and common postoperative surgical issues are quite important (McMahon et al., 2006). Educational and behavioral interventions are also essential, as the long-term success of bariatric surgery relies on patients’ ability to make sustained lifestyle changes in nutrition and physical activity (McMahon et al., 2006). Moreover, collaborative longitudinal care allows prompt and frequent adjustment as weight loss occurs and nutritional and behavioral elements are adapted to current needs (McMahon et al., 2006).

SUMMARY—OBESITY ASSESSMENT AND MANAGEMENT

The prevalence of obesity, a major contributor to morbidity and mortality, is increasing at an alarming rate. Obesity is a complex biopsychosocial condition that, like tobacco use, is best considered as a chronic relapsing condition that usually requires multiple treatment courses. Because of the complex interactions of factors that underlie and contribute to obesity,

and the recidivism that commonly occurs after treatment, the management of obesity requires close attention to not only weight loss, but life-long maintenance of weight. Obesity management should include multiple intervention components including caloric restriction and nutritional education, cognitive-behavioral strategies, a physical activity element, and support of maintenance strategies. Pharmacotherapy and surgical interventions are effective, though they must be closely integrated with behavioral, physical activity and nutritional elements to achieve successful long-term outcomes.

SUMMARY

In this chapter, we have described and illustrated behavioral medicine treatment approaches for two critical conditions: tobacco use and obesity. We applied a multidimensional biopsychosocial approach to the assessment and treatment of tobacco use and obesity and illustrated strategies for integrating this approach within the emerging Patient-Centered Medical Home model. We reviewed the evidence-based recommendations of the PHS Clinical Practice Guideline for Treating Tobacco Use and Dependence and recommendations of the US Preventive Services Task Force regarding Screening for and Managing Obesity. These guidelines both emphasize the importance of a multidimensional approach that integrates motivational strategies, cognitive-behavioral interventions, education elements, medication management and, in the case of obesity, surgical approaches. Though intensive multicomponent multisession interventions produce the best outcomes for both tobacco use and obesity, we have also shared strategies for delivering brief and less intensive interventions (e.g., 5As counseling) that are widely applicable in primary care and other medical settings. Since up to 75% of Americans visit a health care provider each year, clinicians in these setting have the potential to play a central role in addressing health behaviors that are critical to preventing illness and promoting health, functioning and wellbeing.

CLINICAL PEARLS

- Less than a third of smokers will utilize either medication or counseling in their efforts to stop smoking (CDC, 2011).
- In tobacco addiction, as with other chronic conditions such as diabetes and hypertension, clinicians should consider taking a long term view marked by repeated efforts to offer patient education, counseling and intervention.
- The signs and symptoms of nicotine withdrawal can appear within 2 to 6 hours after the last use of tobacco, usually peak between 24 and 48 hours later, and last from a few days to a few days to a few weeks (Benowitz, 2010; Hughes & Hatsukami, 1992). Withdrawal symptoms include psychological symptoms of craving or urges to use nicotine, dysphoric or depressed mood, irritability, frustration, anger, anxiety, difficulty concentrating, restlessness, decreased heart rate and increased appetite or weight gain (Hughes & Hatsukami, 1992).
- Encouraging pregnant smokers who are reluctant to quit to, at minimum, reduce their smoking rate is likely to have beneficial effects, as a dose-response relationship between smoking rate and birth weight has been observed (M. Fiore et al., 2008).
- Smoking cessation is generally associated with under 10 pounds of weight gain (Fiore et al., 2008); however, as many as 10% of quitters gain as much as 30 pounds.
- Brief tobacco dependence treatment is effective. Two components of counseling are especially effective and should be used when counseling patients making a quit attempt: practical counseling (problem solving/skills training) and social support delivered as part of treatment.
- Drugs that support nicotine cessation include bupropion SR, nicotine gum, nicotine inhaler, nicotine lozenge, nicotine nasal spray, nicotine patch, and varenicline.
- Nicotine replacement therapy provides an opportunity for the patient to practice strategies to deal with behavioral or learned components of drug dependence while controlling the physiologic “need” for the drug.
- Novel ways of administering nicotine replacement treatment (NRT) that can improve quit rates, include prolonging treatment beyond the standard 12 weeks of treatment; continuing rather than discontinuing NRT use after a lapse; and starting NRT 2 weeks before the quit day rather than on the quit day (Fiore & Baker, 2011; Rigotti, 2012).
- It is common for patients to use insufficient gum to achieve optimal benefit. The CPG recommends a fixed schedule of at least one piece of gum every 1–2 hours for the first 1–3 months after quitting smoking.
- Insomnia with bupropion SR may improve by shifting the second daily dose to an earlier time, but still 8 hours after the first dose.
- Recognize danger situations—identify events, internal states or activities that increase the risk of smoking or relapse.
- When lapses occur, patients and clinicians need to guard against what has been called the “abstinence violation effect” (e.g., excess guilt, shame, pessimism and reduced confidence for change) (Baer & Marlatt, 1991; Ockene et al., 2000).
- Loss of as little as 5–10% of body weight, achievable with multicomponent behavioral intervention programs, is associated with numerous health benefits.
- Ask about previous (a) weight loss attempts, (b) current eating habits, (c) motivation for weight loss, (d) body image, (e) positive aspects of their obesity (secondary gain), (f) binge eating, (g) weight goal, (h) expectations,

(i) high risk for relapse situations, and (j) willingness to make long-term lifestyle changes.

PSYCHIATRIC ASPECTS OF PULMONARY DISEASE

Richard Kradin

INTRODUCTION

Like facial expressions, ventilation can serve as a window into the domain of psychological affects. The physiology of respiration is closely integrated with psychoneurobiological activities (Caruana-Montaldo, Gleeson, & Zwillich, 2000), yielding bidirectional changes. Both conscious and unconscious motivation systems can affect the ventilatory centers of the central nervous system (CNS); in turn, biochemical imbalances that result from abnormal respiration may alter cognitions, mood, and behaviors (Heaton, Grant, McSweeney, & al, 1983; Prigatano, Parson, Wright, & Hawrylak, 1983).

For this reason, conscious attention to the breath has served as a fundamental technique in the meditation practices of many ancient religious traditions (Mijares, 2009). In attending effortlessly to the breath, it is possible to reach profound levels of relaxation and a sense of well-being. Modern secular practices of relaxation, respiratory physical therapy, and behavioral treatments of anxiety, all continue to adopt awareness of breathing as a means of reducing physiological arousal.

PULMONARY PHYSIOLOGY

In order to better appreciate the links between pulmonary and neurophysiology, it is helpful to review some of the basic features of breathing. The respiratory system has evolved primarily in the service of the exchange of the gases that are critical for vital metabolism. Ventilation—the bellows function of the lungs that results in inspiration and expiration—is homeostatically tightly controlled to meet the oxygen requirements required for both basal metabolism and strenuous exercise. The normal resting breath or tidal volume (V_t) is approximately 500 ml of air with a resting respiratory rate (RR) of 12–15/min. This yields minute ventilation (VE) between 6–7.5 L/min.

$$1) \quad (VE = RR \times V_t)$$

The primary controllers of ventilation include arterial pCO_2 and arterial pH, but an arterial pO_2 of less than 65 mm/Hg can also drive ventilation. Ventilatory failure is defined as a pCO_2 greater than 45mm/Hg. Elevation of the alveolar pCO_2 , or alveolar hypoventilation, leads to respiratory acidosis, which, when inadequately compensated by the renal absorption of bicarbonate, can rapidly result in life-threatening peripheral blood acidemia.

$$2) \quad [H^+] = 24 \times pCO_2/[HCO_3^-]$$

Breathing elevated concentrations of pCO_2 normally yields a rapid rise in minute ventilation. However, patients with central nervous system (CNS) abnormalities, hypothyroidism, severe hepatic failure, who are receiving respiratory depressants following carotid endarterectomy, and those who suffer from major vegetative depression, can all show blunted ventilatory responses to breathing elevated concentrations of carbon dioxide (CO_2) (Bone, 1993). On the other hand, patients with panic anxiety frequently exhibit attacks triggered by breathing elevated concentrations of pCO_2 , a finding that prompted Donald Klein and co-workers to postulate that panic anxiety may result from an overly sensitive CNS “suffocation alarm” (Klein, 1999).

Sensors for the control of ventilation are located in the arterial chemoreceptors of the carotid body and in the pontomedullary areas of the brainstem (Caruana-Montaldo et al., 2000). The central respiratory controllers include pneumotaxic, apneustic, and medullary centers, whose roles are to initiate inspiration and to signal the beginning of expiration. The pneumotaxic center is located both in the *nucleus parabrachialis* and in the *Kolliker-Fuse* nucleus of the pons, whereas the apneustic center is found in the lower pons. The medullary center includes the inspiratory dorsal respiratory group (DRG) of *nucleus tractate salivarius* and the expiratory ventral respiratory group (VRG). These groups project axons into the ventrolateral columns of the spinal cord, the phrenic nerves that innervate the diaphragm, and intercostal nerves that supply the muscles of the chest wall.

Changes in $p\text{CO}_2$ and the acid–base balance have marked effects on both cerebral blood flow and neuronal function. An acute elevation in $p\text{CO}_2$ due to ventilatory failure results in cerebral vasodilatation and brain edema, which can compromise levels of consciousness and mental acuity. Acute ventilatory failure always implies the inability of the ventilatory system to meet the demands of elevated levels of CO_2 . This may be due to a cerebrovascular accident, the obesity-hypoventilation (Pickwickian) syndrome, or the absence of primary inspiratory drive (Ondine's curse). More commonly, acute respiratory failure reflects an increase in the work of breathing due to increased airways resistance, as in chronic obstructive pulmonary disease (COPD) or asthma, unmatched ventilatory energy requirements secondary to pulmonary interstitial and vascular disease, or a failure of the mechanical bellows function due to muscle weakness caused by diffuse myopathies, motor neuron disease, peripheral neuropathy, the Guillain-Barré syndrome, or myasthenia gravis.

Chronic respiratory failure is normally compensated for by a metabolic alkalosis, so that in the absence of blood-volume contraction, elevated serum HCO_3^- concentrations are a reliable clue to the presence of underlying ventilatory failure. But despite maintenance of near-normal arterial blood pH, persistent chronic elevations of $p\text{CO}_2$ can produce cerebral vasodilatation and edema with headache and stuporous mental states (Burns & Howell, 1969).

Hypocapnea reflects increased ventilatory rates. It may be due to primary neuropsychiatric disorders or compensatory for a metabolic acidosis, as can be seen in an anion gap acidosis. In addition to lowering the threshold for musculoskeletal tetany, respiratory alkalosis also diminishes cognitive and memoric processes (Posner, 1972).

Hypoxemia is due to decreased levels of arterial $p\text{O}_2$ attributable to one or more of the following four basic mechanisms: (1) hypoventilation; (2) a mismatch of pulmonary ventilation and perfusion (V/Q abnormality); (3) intrapulmonary shunting, in which alveolar blood flow persists despite the absence of oxygenation (V/Q = 0), or when there is shunting of deoxygenated venous blood to the left side of the heart; or (4) alveolar-capillary block due to scarring or infiltration of the alveolar gas-exchange surface, which limits the diffusion of oxygen and carbon monoxide (DLCO) across the air–blood barrier, especially with decreased capillary transit times that are seen with exercise.

DYSPNEA

A cardinal symptom of respiratory disease is dyspnea, which can be defined as the *subjective* apperception of air hunger. For this reason, it is often not possible to accurately assess the appropriateness of an individual's shortness of breath in the absence of detailed physiological testing. Dyspnea occurs when the mechanical work of breathing increases beyond the limits of ventilation, and may be expected when the forced expiratory volume in the first second of exhalation (FEV_1) is reduced to less than 1 liter (Rock & Schwartzstein, 2007). The afferent sensory information that is interpreted centrally

as dyspnea appears to be mediated primarily by neural receptors in the lung and chest wall (Killian & Campbell, 1983).

The normal work of breathing accounts for about 5% of total O_2 consumption, but this can increase dramatically during exercise or in the presence of underlying cardiopulmonary disease. A measure of the work of breathing is the maximum voluntary ventilation (MVV); that is, the maximum amount of air that can be moved in and out of the lungs during a defined interval. This can be empirically approximated from the FEV_1 (Caruana-Montaldo et al., 2000).

$$3) \quad \text{MVV} = \text{FEV}_1 \times 40$$

Ventilation is normally an energy-dependent process only during inspiration, which relies on the pressure-volume work done by the diaphragm and the inspiratory muscles of the chest wall. On the other hand, exhalation results from the passive elastic recoil of the lung. But when airway resistance is increased, as it is in asthma and COPD either due to the accumulation of viscid luminal secretions, or by loss of the tethering function of the airways by pulmonary elastic tissue, then the work of breathing may extend to include the expiratory phase. This increased energy demand is sensed as dyspnea, especially during exercise. It is important to recognize that severe dyspnea can be reported in patients with normal arterial $p\text{O}_2$ levels due to an increase in the work of breathing or may be disproportionate to physiological abnormalities, as is often the case when there is a comorbid contribution by psychogenic dyspnea. In addition to increased work of breathing, marked hypoxemia, abnormal afferent stimulation from an inflamed esophagus due to reflux, mechanical compression of the lungs by increased abdominal pressure due to intra-abdominal tumor or fluid, gastric distention (*magenblase*) due aerophagia in anxious patients, and intense fear can also produce dyspnea. Although efforts have been made to correlate the language used by patients to describe dyspnea with known causes, in practice there is considerable overlap in how dyspnea is communicated (Mahler, Harver, Lentine, Scott, Beck, & Schwartzstein, 1996).

PHYSIOLOGICAL CATEGORIES OF RESPIRATORY DISEASE

Abnormalities in the compartmental anatomy of the lung determine the physiological changes seen in disease and also play a role in the types of psychological changes that accompany them. Diseases of the pulmonary airways result in diminished airflow due to increased resistance and are physiologically referred to as *obstructive lung disease*. These include asthma, defined as reversible airways narrowing; chronic bronchitis, defined by a clinical increase in airway secretions; and emphysema, which is defined as loss of the alveolar elastic tissue that normally tethers small conducting airways, leading to their narrowing; and bronchiectasis, which may reflect a variety of pathologies of the airways that lead to a loss of the normal cartilaginous support and to airway collapse during expiration. With the exception of asthma, all of the above disorders are often grouped generically as COPD.

Patients with COPD often exhibit one of two distinct phenotypes. Patients with Type A COPD have primarily emphysematous changes and are most often asthenic and exhibit purse-lipped breathing; consequently, they are referred to as “pink-puffers.” Type B COPD patients often show truncal obesity, hypoventilation, and are both cyanotic and edematous due to right heart failure or *cor pulmonale*; and they are referred to as “blue bloaters.”

Interstitial disease is due to a variety of conditions that primarily affect the alveolar wall. It produces diminished compliance of the lung with matched reductions in FEV₁ and the forced vital capacity (FVC), so that the ratio of FEV₁/FVC is maintained as near-normal. The chronic interstitial pneumonias produce alveolar scarring and lead to a loss of gas-exchange surface, as evidenced by reduced diffusion capacity (DLCO), although a decreased DLCO is also a hallmark of both emphysema and primary pulmonary vascular disease. Patients with these abnormalities tend to complain of dyspnea on exertion early in the course of their disease that is accompanied by rapid O₂ desaturation of the arterial blood with exercise. Physiologically, patients with chronic interstitial disease also have pulmonary restriction due to a decrease in their total lung capacity (TLC). However, restriction can also result from abnormalities of the pleura, chest wall, and thoracic musculature, although in these cases the DLCO when corrected for alveolar volume DLCO/VA is near normal.

THE NEUROBIOLOGY OF VENTILATION AND AFFECT

Neuronal networks that control the rate and depth of ventilation are integrated with the pontine reticular activating formation, so that CNS arousal increases ventilation. Ventilation varies within the normal sleep cycle, and decreased ventilation during sleep, either related to a central CNS deficit or obstruction of the upper airways, is the *sine qua non* of the sleep apnea syndromes.

The lung is richly innervated by cholinergic fibers from cranial nerve X (vagus), but sympathetic adrenergic nerves, although less plentiful, can also be identified in the pulmonary bronchovascular septa. A variety of neurotransmitters modulates the activity of the CNS respiratory control centers. Cholinergic neurons are the primary excitatory neurons for the effector motor pacemakers of breathing (Burton, Johnson, & Kazemi, 1989). Gamma-aminobutyric acid (GABA)-ergic neurons inhibit firing of the pacemaker center (Hedner, Hedner, Wessberg, & Jonason, 1984), and adrenergic neurotransmitters augment the output of cholinergic neurons. Finally, noradrenergic noncholinergic (NANC) neuropeptides, including the tachykinins, can modulate the activation of ventilatory neurons (Lindfors, Yamamoto, Pantaleo, Lagercrantz, Brodin, & Ungerstedt, 1986). In addition, endocrine hormones, including thyroxine and progesterone (Fadel, Northrop, Misenhimer, & Harp, 1979) can directly increase the firing of respiratory center neurons, and the latter contribute to the hyperventilation that is observed during pregnancy.

PSYCHIATRIC CONTRIBUTIONS TO DYSPNEA

The subjective assessment of the severity of dyspnea affects quality of life and functional status. The apperception of severity correlates with mood, catastrophic cognitions, phobic concerns with respect to dyspnea, and its intrapsychic meaning (Carr, Lehrer, Rausch, & Hochron, 1994; Preter & Klein, 2008). Emotions affect breathing; breathing affects emotion; as such, they are inextricably linked.

EXERCISE TESTING

Many hospital centers provide sophisticated methods of assessing pulmonary and cardiac physiology, both at rest and with exercise (Wassermann, Hansen, Sue, Casaburi, & Whipp, 1999). These can be measured concomitantly with real-time measurements of arterial blood gases, ventilation, and serum lactate during exercise. Pulmonary exercise testing offers an accurate assessment of the functional limitation during exercise and insight into its cause. Normally, with exercise an anaerobic threshold (AT) is achieved based on the cardiopulmonary limit of O₂ delivery to the tissues, which can be correlated with the minute ventilation and heart rate. As a consequence, one can usually determine whether there is a primary pulmonary or cardiac limit to exercise, based on the patient's simultaneous reporting of dyspnea and fatigue. Exercise testing is an invaluable tool for parsing the contributions by heart and lung to dyspnea, and yields insight into the presence of physical deconditioning and underlying psychiatric disorders, in which dyspnea is reported without achieving either an anaerobic threshold or maximum ventilatory effort. These tests vary in their level of invasiveness (Table 54.1); however, a basic non-invasive study, in the appropriate setting, will often suffice in excluding serious underlying pathology.

ASTHMA

Asthma is a syndrome characterized by reversible bronchoconstriction. It is the most common chronic respiratory disease, affecting about 6% of the U.S. population (American Lung Association [ALA], 2012). Asthma generally begins in childhood, with a second peak of incidence later in life. Most cases of asthma are attributable to atopic disease, and related to abnormalities of the T-helper (Th-2) immune system in response to common environmental allergens. However, some cases of asthma, so called “intrinsic” asthma, are unrelated to atopy. In addition, asthma attacks may be triggered by drugs, including aspirin; or by exercise, exposure to cold, isothiocyanates, or strong emotions.

PSYCHOLOGICAL FACTORS IN ASTHMA

French and Alexander considered asthma to be a psychosomatic disorder. They postulated a psychodynamic cause reflecting unconscious dependency on the mother and triggered by separation anxiety (French & Alexander, 1939–1941). It was suggested metaphorically that asthma was also the patient's unconscious wish to “have the last word” in the

Table 54.1 ROLE OF CARDIOPULMONARY EXERCISE TESTING (CPET) IN EVALUATION OF DYSPNEA

CARDIOPULMONARY EXERCISE TESTING (CPET)	
Level 1	Non-invasive basic cardiopulmonary screening test. Consider for dyspnea, fatigue of unknown origin, heart versus lung as cause of symptoms
Level 2	Level 1 with radial arterial line. Consider to confirm non-invasive arterial desaturation, suspected pulmonary vascular disease, hyperventilation syndromes
Level 3	Level 2 plus pulmonary arterial catheterization. Consider to confirm pulmonary arterial hypertension, dynamic congestive heart failure including left ventricular diastolic dysfunction, valvular heart disease, and oxidative myopathies with abnormal systemic oxygen extraction.
First-pass nuclear ventriculography should be part of most CPET studies as it allows differentiation between cardiac dysfunction and detraining.	

CPET studies may vary in their sophistication, depending on the center. The designations above reflect the practice at the Massachusetts General Hospital but are available at most academic medical centers.

struggle for autonomy. While current concepts in both psychiatry and pulmonary medicine do not include a primary psychogenic causative role for most cases of asthma, it is evident that stress and strong affect can trigger or exacerbate episodes of asthma disease. Emotional arousal, anxiety, fear, and anger can yield an increase in bronchomotor tone. Stress can also promote the Th2 immune system response (Cormier, Yuan, Crosby, Protheroe, Dimina, Hines, et al., 2002; Shen, Ochkur, McGarry, Crosby, Hines, Borchers, et al., 2003). Airway reactivity to emotion may be mediated by the vagus nerve (Isenberg, Lehrer, & Hochron, 1992), and there is evidence that emotion may preferentially affect large-caliber airways (Lehrer, Hochron, McCann, Swartzman, & Reba, 1986) innervated by cholinergic neurons.

Both acute and chronic stress have been demonstrated to affect the pathways that mediate asthma (Greenberg & Kradin, 1996). Stress has been correlated with increased levels of atopic cytokines and decreased expression of adrenergic and corticosteroid receptors (Hoshino, Suzuki, Yamauchi, & Inoue, 2008; Wolf, Nicholls, & Chen, 2008). Although emotions are currently not thought to be causative, comorbidity with both anxiety and depressive disorders is high. In one major study at tertiary care centers, comorbid depression was present in almost half of asthma patients (Van Lieshout, Bienenstock, & MacQueen, 2009). There is also an increased prevalence of general anxiety disorder, panic disorder, and phobic disorders in asthmatics (Rosenkranz & Davidson, 2009). Underlying psychopathology may have deleterious consequences on the prognosis in asthma, as it can limit patient compliance with medications, lead to smoking and other risk-taking behaviors, and result in increased utilization of emergency room visits and hospitalizations (Richardson, Russo, Lozano, McCauley, & Katon, 2008; Strine, Mokdad, Balluz, Berry, & Gonzalez, 2008).

The role of anxiety in asthma is both multifactorial and complex (ten Thoren & Petermann, 2000). Anxiety can trigger an acute attack of asthma or exacerbate an established one. In addition, increased anxiety can be fostered by sensations of decreased airflow, and phobic anxieties conditioned

by repeated attacks of breathlessness (Goodwin, Jacobi, & Thfeld, 2003). Some patients with panic attacks are erroneously diagnosed with asthma when dyspnea is a prominent symptom of the attack. Unlike asthma, panic attacks will generally resolve within 30 minutes, and wheezing is generally not present. If doubt persists, once the acute symptoms have resolved, methacholine-challenge testing, which is based on the ability of a cholinergic stimulus to hyperconstrict irritable airways, should be performed (Schmaling, 1999).

Anxiety, depression, and psychosocial factors all contribute to the severity of asthma. Adverse circumstances in childhood appear to be an excellent predictor of the risk of developing adult asthma (Scott, Von Korff, Alonso, Angermeyer, Benjet, Bruffaerts, et al., 2008; Turyk, Hernandez, Wright, Freels, Slezak, Contraras, et al., 2008). Anxiety and depression both increase the severity of attacks, their frequency, and time spent in hospital, and diminish the quality of life (Marsac, Funk, & Nelson, 2007).

Acute traumatic events can exacerbate asthma. In a study of respiratory complaints following the September 11, 2001, terror attacks in New York City, there was a 27% increase in asthmatic symptoms in the ensuing two months (Fagan, Galea, Ahern, Bonner, & Vlahov, 2003). Physical and sexual abuse also were shown to increase the risk of developing asthma in a study of Puerto Rican children (Cohen, Canino, Bird, & Celedon, 2008). Negative and catastrophic cognitions can exacerbate asthma by leading to irritability, panic, and hyperventilation.

TREATMENT OF ASTHMA

The current pharmacological management of asthma is based on the administration of adrenergic and anticholinergic bronchodilators, drugs like salmeterol that tend to stabilize the airways, and inhaled corticosteroids. Most patients can be treated effectively with hand-held nebulizers. Patients with more severe disease may benefit from leukotriene inhibitors. Aminophylline, once a mainstay in the management of

asthma, has largely fallen out of favor due to its toxicities and the need to monitor blood levels.

The vast majority of asthmatics can be managed without hospitalization; however, others will require frequent visits to the emergency room and in-hospital stays. In patients with severe atopic asthma, efforts should be made to identify an offending environmental antigen and to exclude allergic bronchopulmonary aspergillosis due to aspergillus mold colonizing the proximal airways. These patients may benefit from additional antifungal treatment.

The mainstay in the treatment of severe asthma is the judicious use of oral or intravenous corticosteroids. However, corticosteroids have panoply of metabolic side effects and can aggravate underlying mood disorders. The common side effects of anti-asthmatic drugs include jitteriness, palpitations, and insomnia, but more serious side effects can at times be observed (Greenberg & Kradin, 1996). Table 54.2 summarizes the adverse effects of pulmonary medications in patients with psychiatric disorders.

Psychoeducation, relaxation, biofeedback, perception, cognitive-behavioral therapy (CBT), yoga, and family therapy may have a role in the care of asthma patients (Lehrer, Sargunraj, & Hochron, 1992). Weiss (Weiss, 1994) described a detailed behavioral management program for asthma that included a checklist to assess asthma medications, early signs of wheezing, triggers of an attack, individual behavior and behavior of other people during an attack, and the effects of asthma on social development, school, and the family. Asking patients to maintain a daily diary of their symptoms may provide an additional resource for diagnosis and management.

Identifying core psychological issues that might prevent the patient from attending to early warning signals or from taking medication appropriately is an important strategy. These include fear of inadequacy, fear of social rejection, or a drive to excel athletically, all of which can be motives for hiding vulnerability with respect to the severity of asthma, especially in teenagers. Weiss's treatment approach included knowing the facts and fallacies about asthma, identifying emotional and physical factors that precipitate or aggravate attacks, recognizing the early warning signs of an attack and

Table 54.2 NEUROPSYCHIATRIC SIDE EFFECTS OF DRUGS USED IN THE TREATMENT OF PULMONARY DISORDERS

Anticholinergics	Delirium, amnesia, paranoia, hallucinations
Leukotriene antagonists	Anxiety, vasculitis
Beta-agonists	Anxiety, tremulousness
Corticosteroid inhalers	None
Oral corticosteroids	Irritability, depression, mania, paranoia
Theophylline	Anxiety, tremor, irritability, delirium, insomnia

knowing what to do about them, and learning to relax via focusing on abdominal breathing.

Asthma exhibits a spectrum of severity. Whereas most patients can be well controlled with inhaled corticosteroids and the periodic use β -adrenergic inhalers, others suffer from repeated episodes that are difficult to control. Attack severity has been linked to major depression, panic attacks, number of emergency room visits, and self-assessment of risk of death. Boner and colleagues (Boner, Vallone, Chiesa, Spezia, Fambri, & Sette, 1992) found that patients make judgments about their condition, assessments that correlate with objective markers of increased mortality risk and increased severity. Those who become phobic with respect to the dysphoria of dyspnea may overuse bronchodilator inhalers. Alexithymia, the inability to “read interoceptive cues,” may be a prominent cause of excessive inhaled adrenergic use, as in the at-times-fatal error of underrating the severity of status asthmaticus. A role for antidepressants, including selective serotonin-reuptake inhibitors (SSRIs) and bupropion in the absence of underlying comorbid depression or panic disorder has not been demonstrated (Melien, 2005; Brown, Vornik, Khan, & Rush, 2007).

FACTITIOUS ASTHMA

Occasionally, asthma may be a factitious illness. The distinguishing clinical and physiological features were documented in three cases reported by Downing et al. (Downing, Braman, Fox, & Corrao, 1982). These patients, all of whom had a history of underlying psychiatric illness, exhibited frequent emergency room visits for asthma, no clinical response to bronchodilators, no evidence of hypoxemia or hyperinflation on chest radiographs, and no airway dysfunction on pulmonary function testing shortly after the attack. Methacholine-challenge testing, a sensitive method for excluding asthma, should be utilized when the diagnosis is in doubt (Schmaling, 1999).

Self-induced wheezing in factitious cases is loudest over the neck, with transmission to the chest wall on auscultation. Bronchial wheezes can be mimicked by maneuvers that include holding the vocal cords in apposition. However, one must first exclude vocal cord dysfunction and other causes of intrathoracic and extrathoracic upper airway obstruction (Bahrainwala & Simon, 2001). Intentional malingering is rare. However, “asthma” as a feature of panic disorder is well recognized and should be excluded by careful history-taking and auscultation of the chest.

CHRONIC OBSTRUCTIVE PULMONARY DISEASE (COPD)

COPD is the fourth major cause of death in the United States and affects 16 million people, the vast majority having clinical evidence of chronic bronchitis (Lindberg, Jonsson, Ronmark, Lundgren, Larsson, & Lundback, 2005). The definitions of these disorders are based on clinical, anatomical, and physiological criteria. Chronic bronchitis is diagnosed clinically as the presence of increased sputum production for at least three

months of at least two consecutive years, whereas emphysema is diagnosed by evidence of alveolar loss, as reflected by radiographic imaging and decreased DLCO. These diseases develop in a dose-dependent manner with cigarette consumption, and more than 80% of cases of COPD are attributable to cigarette smoking (Tashkin, Kanner, Bailey, Buist, Anderson, Nides, et al., 2001). A subset of patients with emphysema may have an associated deficiency in α -1 antiprotease, which can yield severe panacinar emphysema even with light cigarette consumption.

The disease develops progressively, beginning with inflammation in the small airways less than 2 mm in diameter. In patients with COPD, even mild chronic hypoxia can compromise cognitive capacities, lead to mood lability, and lead to restrictions in daily activities (Lishman, 1987). Patients with COPD have impaired abstracting ability and complex perceptual motor integration. These are impaired more than motor speed, strength, or gross coordination. COPD is associated with a significant decline in cognitive function over time, and cerebral hypoperfusion has been documented in patients with COPD who are also hypoxemic. Morbidity in COPD is complex; and contrary to expectations, patients with mild reductions of FEV1 may show levels of diminished health-related quality of life that are comparable to those in patients with severe deficits.

DEPRESSION IN COPD

Major depression is common in heavy smokers. In one study, almost 50% of smokers met criteria for depression, whereas only 20% were being treated with antidepressants, and a national multidisciplinary workshop concluded that depression remains underdiagnosed and undertreated, particularly in men with COPD. Borson and McDonald (Borson, Claypoole, & McDonald, 1998) suggested that clues to the diagnosis of major depressive disorder in patients with COPD include the perception of activity as effortful, pervasive pessimism, diurnal mood variation with morning worsening, and early-morning awakening. In an autopsy-documented community study of suicide in men older than 65, Horton-Deutsch and colleagues found that 14 of 73 patients had a chief complaint of dyspnea and undiagnosed major depressive disorder (Horton-Deutsch, Clark, & Farran, 1992).

ANXIETY IN COPD

Anxiety is likewise common in COPD. It has been suggested that as many as 44% of patients with severe COPD have comorbid panic disorder, and panic symptoms may be linked to depression (Light, Merrill, Despars, Gordon, & Mutalipassi, 1985). Although the presence of underlying lung disease tends to disqualify this group from a diagnosis of primary panic disorder, it is likely that the experience of panic is similar, particularly with respect to the catastrophic interpretation of interoceptive cues. Whereas both anxiety and depression can produce reports of dyspnea, only depression has been linked to reduced exercise tolerance (Funk, Kirchheiner, Burghuber, & Hartl, 2009).

The treatment of COPD relies primarily on smoking cessation and on the treatment of exacerbations with steroids and antibiotics. Psychoeducation, psychotherapy, physical therapy, and nutritional therapy can be useful in the setting of COPD and may best be delivered in the setting of an established pulmonary rehabilitation program (Coventry & Hind, 2007; Lacasse, Brosseau, Milne, Martin, Wong, Guyatt, et al., 2002). When present, the treatment of concomitant anxiety and mood disorders is indicated.

Supplemental O_2 is required when O_2 saturations fall to less than 88% either at rest or with ambulation. Continuous O_2 supplementation should be prescribed during sleep as O_2 saturations normally decrease during sleep, which can aggravate pulmonary vasoconstriction, cerebral blood flow, and cardiac output. Continuous oxygen treatment improves quality of life, neuropsychiatric function, and longevity better than nocturnal-only treatment (Group, 1980; Prigatano et al., 1983; Group, 1980). Neuropsychiatric changes were documented in a six-center trial of more than 200 patients, in which continuous versus nocturnal supplemental oxygen administration was compared in subjects with a pO_2 of less than 55 mmHg or incipient right heart failure, although no change in mood was documented (Grant, Chittleborough, Taylor, Dal Grande, Wilson, Phillips, et al., 2006).

However, the benefits of supplemental oxygen come with a psychological cost. The use of supplemental oxygen use may be experienced as social embarrassment. Some patients feel that the need for home oxygen marks the beginning of terminal illness, and become depressed and socially withdrawn. Others may become psychologically dependent on the oxygen supply even when it is not physiologically required. Some patients may phobically limit emotional expression in order not to tax their breathing. Sexual dysfunction, inhibited sexual excitement, premature ejaculation, and avoidance of intimacy, have all been noted in patients with chronic lung disease (Thompson, 1982). The consequent deconditioning, and associated anxiety and depression, only serve to compound the already severe shortness of breath reported by patients with COPD. The introduction of portable lightweight O_2 delivery systems that are less conspicuous and may lead to less social anxiety and stigma than in the past has been a great boon for patients who require supplemental oxygen (Stoller, Panos, Krachman, Doherty, & Make, 2010).

The treatment of anxiety and mood disorders in patients with COPD has certain challenges. Benzodiazepines can suppress the respiratory pacemaker, but they can be used effectively in COPD when pCO_2 retention is either absent or mild, and when they are prescribed judiciously. As a rule, they should be avoided during acute exacerbations. Compared to the benzodiazepines, buspirone is a relatively weak anxiolytic. Its use should be limited to cases where benzodiazepines are contraindicated.

SSRIs are useful in the management of both depression and panic disorder. In a pilot study, seven patients with mild to severe COPD that was largely intractable to standard

medical therapies reported substantially diminished dyspnea after receiving sertraline (25–100 mg/day), with no apparent change in pulmonary function (Smoller, Pollack, Otto, Rosenbaum, & Kradin, 1996; Smoller, Pollack, Systrom, & Kradin, 1998). To diminish fear and agitation without risking respiratory suppression, neuroleptic medications can also be beneficial, in low doses.

Protriptyline, a stimulating tricyclic antidepressant, improves diurnal and nocturnal hypoxemia at a dose of 20 mg in a small percentage of patients with COPD. This effect appears to be unrelated to pulmonary mechanics but may correlate with decreased rapid eye movement (REM) sleep (Series, Cormier, & La Forge, 1990). Protriptyline has also been shown to be beneficial in treating patients with sleep apnea; however, its effect on mood has not been clarified. Borson and McDonald (Borson et al., 1998) reported preliminary data from a trial of nortriptyline in patients with COPD and major depressive disorder. There was a notable risk of hypotension, especially when other antihypertensive medications were used concomitantly.

Some patients with COPD benefit clinically from corticosteroids, and the acute treatment of COPD exacerbations includes high-dose steroids together with antibiotics. However, corticosteroids can exacerbate depression, emotional lability, and irritability, especially in patients with a bipolar diathesis. The psychiatric side effects of steroids are dose-related, and agitation and mania can be misattributed to the effects of hypoxemia unrecognized in this acute setting. Steroid side effects may respond acutely to low-dose neuroleptics.

SMOKING AND SMOKING CESSATION

For historical and practical reasons, cigarette smoking was largely unaddressed by members of the psychiatric community, despite considerable evidence that nicotine was addictive. It has been argued that Freud's compulsive cigar-smoking disposed psychotherapists to excuse the smoking habit in their patients. In addition, the extraordinarily high prevalence of cigarette smoking in hospitalized patients with chronic psychosis and substance-related disorders has been tacitly accepted (Goff, Henderson, & Amico, 1992). Although cigarette smoke contains hundreds of bioactive substances, nicotine appears to be the major component that has both central and peripheral neuroactivities. Nicotine, which increases heart rate and blood pressure, acts as an acute stimulus for breathing. Nicotine also increases dopamine release in the prefrontal cortex and nucleus accumbens (Mifsud, Hernandez, & Hoebel, 1989). Other addictive agents such as opiates, amphetamines, and cocaine also release dopamine (Kradin, 2008).

Several large studies (Anda, Williamson, Escobedo, Mast, Giovino, & Remington, 1990; Glassman, Helzer, Covey, Cottler, Stetner, Tipp, et al., 1990) have found that cigarette smoking is associated with a history of major depression and with other negative states. In a review of this subject, Glassman (Glassman, 1993) made a convincing argument that depressive illness is highly correlated with having ever smoked, with

addictive smoking, and with substantial difficulty with smoking cessation. Based on these highly significant correlations, it has been suggested that smokers may share a genetic vulnerability toward both behaviors, because little evidence suggests that smoking alone can predispose to depression. Alcoholism (Covey, Glassman, Stetner, & Becker, 1993), generalized anxiety disorder, and panic disorder all show an increased association with cigarette smoking (Glassman, 1993). Most anxious smokers report that cigarette smoking allays anxiety, despite experimental models that do not support this observation (Frederick, Frerichs, & Clark, 1988).

The association between smoking and depression remains even when the variables of anxiety and alcoholism are controlled. Glassman (Glassman, 1993) pointed out that 75% of heavy cigarette smokers who attempt to quit will experience depressive symptoms. In some patients with severe psychiatric disease in remission, attempts at smoking cessation have led to severe exacerbations of symptoms that remitted with a return to smoking. Nevertheless, reasonable efforts should be made towards smoking abstinence whenever possible, due to the malignant complications of chronic tobacco use.

The effects of nicotine on dopaminergic pathways modulate dysphoric symptoms. Nicotine-induced firing of dopaminergic neurons that project to prefrontal areas may also antagonize the negative symptoms in patients with schizophrenia and could help explain the inordinately high prevalence of cigarette smoking in this population (Goff et al., 1992).

Fiore et al. found that 95% of former smokers who had been abstinent for 1–10 years had made an unassisted last quit attempt (Fiore & Baker, 2011). The most frequent unassisted methods were “going cold turkey” and smoking a “gradually decreased number” of cigarettes. However, only about 4% to 7% of people are able to quit smoking on any given attempt without medicines or other help.

A 2008 meta-analysis estimated that physician advice to quit smoking led to a quit rate of 10.2%, as opposed to a quit rate of 7.9% among patients who did not receive physician advice to quit smoking (Polito, 2008). But one study from Ireland involving vignettes found that physicians' probability of giving smoking cessation advice declines with the patient's age (Cahill & Perera, 2008), and another, from the United States, found that only 81% of smokers over age 50 had received advice on quitting from their physician in the preceding year (Ossip-Klein, McIntosh, Utman, Burton, Spada, & Guido, 2000).

The American Cancer Society estimates that “between about 25% and 33% of smokers who use medicines can stay smoke-free for over six months. Single medications include nicotine replacement therapy (NRT), as transdermal nicotine patches, sprays, and inhalers, but studies suggest that the vast majority of over-the-counter NRT users relapse within six months” (Ossip-Klein & McIntosh, 2003).

Bupropion is FDA-approved and marketed under the brand name Zyban. Bupropion is contraindicated in epilepsy, seizure disorder, anorexia/bulimia, recent monoamine oxidase (MAO) inhibitor use, and in patients undergoing abrupt discontinuation of ethanol or sedatives.

Varenicline tartrate (Chantix) decreases the urge to smoke and reduces withdrawal symptoms (Crain & Bhat, 2010). Varenicline appears to be more effective than either NRT or bupropion (Fiore & Baker, 2011). A 2 mg/day regimen of varenicline leads to the highest abstinence rate (33%) of any single therapy, while a 1 mg/day dosage yielded abstinence in 25%. However, a 2011 review suggests that varenicline also produces adverse cardiac and neuropsychiatric effects, including arrhythmias, suicidal ideation, and suicidal behavior.

VENTILATION IN CLINICAL DEPRESSION

Severe vegetative depression may contribute to respiratory acidosis and cor pulmonale, due to diminished ventilatory drive in response to the inhalation of $p\text{CO}_2$. Depressed and grieving patients manifest lower respiratory rates, lower resting-end tidal volumes, and elevated levels of $p\text{CO}_2$ (Damas-Mora, Souster, & Jenner, 1982). Patients who experience depression or grief do not increase their minute ventilation appropriately when they breathe a mixture of gas with either high $p\text{CO}_2$ or low O_2 , indicating primary depression of the ventilatory neuronal centers (Jellinek, Goldenheim, & Jenike, 1985). Patients with depression who experience sleep disturbance are more vulnerable to CO_2 retention, so patients who have both depression and lung disease are at increased risk for complications of respiratory depression.

VENTILATION IN CLINICAL ANXIETY

Ventilatory patterns in anxiety disorders are characterized by dystaxic breathing. This may include a decreased V_t with rapid rates. Irregular breathing is common, including breath-holding, frequent sighs, and a tendency to breathe at higher lung capacities due to the inability to relax to the normal functional residual capacity (FRC) at end tidal volume. One can get an immediate sense of the psychological effects of dystaxic breathing on affect by grasping their chest and modeling one's own breath on the patients.

Hyperventilation is common in anxiety disorders, affecting as many as 15% in the general population, and it may be part of generalized anxiety or panic disorder (Lachman, Gielis, Thys, Lorimier, & Sergysels, 1992). Rapid respiratory rates can lead to a syndrome of hyperventilation characterized by respiratory alkalosis, dizziness, and syncope. Carpopedal spasms may result from abnormalities of calcium mobilization at high intramuscular pH.

The appearance of anxiety, and in particular panic attacks, can mimic major medical illnesses, such as pulmonary thromboembolic disease, myocardial infarction, diabetic ketoacidosis, carbon monoxide poisoning, vasovagal syncope, and drug overdose.

Hyperventilation can be seen as a secondary phenomenon in all of the above, as well as in CNS injury. A panic attack in the postoperative setting, or in a patient with phlebitis, should lead reflexively to a computerized tomography (CT)-angiogram, in order to exclude thromboembolic disease.

CYSTIC FIBROSIS

Once exclusively a disease of childhood, cystic fibrosis (CF) now includes a sizable number of survivors into adulthood, thanks to improved management of its metabolic and infectious complications. Most cases are due to a mutation of the *CFTR* gene ($\Delta 405$) that regulates chloride channels, but a variety of genetic variants have been reported. CF affects almost 20,000 children in the United States, with a frequency of 1 in 2,500 births. It is the most common autosomal recessive gene amongst Caucasians.

The disease is caused by the production of viscid mucous (mucoviscidosis) that leads to sinus obstruction, chronic cystic bronchiectasis, chronic pancreatitis with endocrine abnormalities, especially insulin-dependent diabetes, and infertility.

Treatment is complicated medically, and its difficulty is compounded by the young age of its victims. Prominent psychiatric issues may emerge related to anxiety, depression, borderline-spectrum behaviors, dependency, and drug addiction (Anderson, Flume, & Hardy, 2001). The incidence of drug addiction in this population has not been adequately addressed and requires more intensive study by addiction specialists.

One study showed that the levels of anxiety and depression did not parallel disease severity as evidenced by pulmonary function, but were more influenced by patient expectation and their perceived level of support (Wargnies, Houze, Vanneste, Perez, & Wallaert, 2002). Adult survivors tend to show less anxiety and depression and are more resilient. It is unclear whether this is due to selection bias or to the psychological effects of the disorder.

Relaxation techniques, biofeedback, and psychoeducation aimed at independent living can be helpful, and it is generally wise to have stable psychiatric input with these patients, especially during their teenage years. Unfortunately, despite improvements in care and the use of lung transplantation as definitive therapy, many patients with the disorder will die at a young age. Dealing with end-of-life issues is an important part of the care of this patient group and should take into account the patient's own wishes with respect to outcome, when it is judged that they are indeed mature enough to make such informed decisions (Chapman, Landy, Lyon, Haworth, & Bilton, 2005).

IDIOPATHIC PULMONARY FIBROSIS

A large number of disorders can produce interstitial disease with restrictive physiology and decreased alveolar gas exchange. Idiopathic pulmonary fibrosis (IPF) is the clinical moniker for a pathological syndrome termed *usual interstitial pneumonitis* (UIP), in which end-stage lung with progressive hypoxemia ensues with high five-year mortality. The incidence is approximated at 3–5 per hundred thousand; however, diagnostic mimics can confound its true prevalence. Unlike the obstructive lung disorders, relatively little emphasis has been directed at the psychiatric comorbidity in IPF (Martinez, Pereira, dos Santos, Ciconelli, Guimaraes, & Martinez, 2000).

Dyspnea is the dominant finding, but anxiety and depression may contribute to a diminished quality of life. Other biosocial factors, including diminished sleep, the inability to work, and diminished sexual activity, all contribute to the impaired quality of life in this disease (Mermigkis, Stagaki, Amfilochiou, Polychronopoulos, Korkonikitas, Mermigkis, et al., 2009).

There is no effective treatment for IPF, although a small percentage of patients do respond favorably to corticosteroids and other immunosuppressant agents. There is an increasing suspicion by pulmonologists that acid aspiration may contribute to the exacerbations of this disorder, at least in some patients. Lung orthotopic transplantation is the known effective treatment, but this intervention is generally not available to the older population in which the disease predominates.

SLEEP APNEA

Sleep apnea has become an increasingly recognized disorder that affects both adults and children. It manifests clinically as loud snoring, weight gain or loss, excessive daytime sleepiness, hypertension, altered cognitions, and difficulties in concentrating. Depression is common in sleep apnea. Ohayon and colleagues, in a study of more than 18,000 European subjects, showed that subjects with depression were five times more likely to have a breathing-related sleep disorder than non-depressed ones, a five-fold increase (Ohayon, 2003).

Sleep apnea may be divided into obstructive, central, and mixed types. During normal sleep, oxygenation falls and $p\text{CO}_2$ rises. In stage 4 sleep, breathing is regular (Cherniack, Mitra, Prabhakar, & Adams, 1988). During REM and stages 1 and 2 non-REM sleep, irregular breathing and apnea, either obstructive, central, or both, may occur.

The diagnosis of obstructive sleep apnea (OSA) is based on clinical symptoms and the results of a formal sleep study or polysomnogram. Testing identifies apnea events per hour of sleep (Apnea Hypopnea Index [AHI]), and events that exceed a formal threshold identify the patient as suffering from sleep apnea. Oximetry, which may be performed overnight in a patient's home, is an alternative to a formal sleep study.

Treatment often is initiated as behavioral therapy. For mild cases, it may include weight loss when obesity is judged to be a factor; or sleeping on one's side, which prevents the tongue and palate from falling backwards and blocking the airway. Patients should be counseled to avoid alcohol and sleeping pills, both of which relax the throat muscles, contributing to the collapse of the upper airway while sleeping.

Continuous positive airway pressure (CPAP) or automatic positive airway pressure (APAP) devices are the standard treatment modality, as they pressurize the patient's airway open during sleep (Kohler, Stoewhas, Ayers, Senn, Bloch, Russi, et al., 2011). CPAP is generally administered via a plastic facial mask, connected by a flexible tube to a small bedside CPAP machine. Advanced models warm and humidify the air to prevent excessive drying of mucosal membranes. Although CPAP therapy is extremely effective in reducing apneas and less expensive than other treatments, many patients find it extremely uncomfortable and either refuse the treatment

or fail to use their CPAP machines on a nightly basis. In a recent study, 57% of patients with OSA met concomitant criteria for major depression that was alleviated with CPAP. The authors concluded that CPAP should be considered as the first modality of treatment for depression in patients with OSA (El-Sherbini, Bediwy, & Et-Mitalli, 2011).

Oral appliance therapy (OAT) includes a custom-made mouthpiece that shifts the lower jaw forward, opening up the airway. It is usually successful in patients with mild to moderate obstructive sleep apnea. OAT is a relatively new treatment option for sleep apnea in the United States, but it is commonly used in Canada and Europe (Lettieri, Paolino, Eliasson, Shah, & Holley, 2011).

The Pillar procedure is a minimally invasive treatment for snoring and obstructive sleep apnea (Randerath, Verbraecken, Andreas, Bettge, Boudewyns, Hamans, et al., 2011). Dacron strips are inserted into the soft palate with a modified syringe and local anesthetic. After this brief outpatient procedure, the soft palate is rendered more rigid, and snoring and sleep apnea are reduced. Other, more-invasive procedures such as uvuloplasty have been administered with mixed success.

ACUTE LUNG INJURY

Acute lung injury (ALI) or the acute respiratory distress syndrome is a devastating disorder that leads to respiratory failure and the need for prolonged mechanical ventilation. Mortality has been markedly reduced due to mechanical ventilation and optimization of ventilator settings. However, with increased survival it has become apparent that there are neuropsychiatric complications attributable to the disease and the treatment setting. Cognitive disturbances are common and in one study led to occupational disability in 41% of affected survivors (Rothenhausler, Ehrentraut, Stoll, Schelling, & Kapfhammer, 2001). Clinical post-traumatic stress disorder (PTSD) occurs in 44% of survivors at the time of hospital discharge and persists in nearly one-quarter at 5–8 years (Davydow, Desai, Needham, & Bienvenu, 2008).

LUNG TRANSPLANTATION

Lung transplantation has become a widely available procedure, limited primarily by acceptable donor graft availability. The most common indication is severe COPD, but orthotopic lung transplantation has been performed in patients with cystic fibrosis, pulmonary hypertension, IPF, and other less common pulmonary disorders. The current one- and five-year survival rates following orthotopic lung transplantation are ~84% and 52%, respectively.

The pre-transplantation testing and post-transplant monitoring and immunosuppression regimens are rigorous and include the exclusion of patients who are judged to be less than optimal candidates for success. This may include patients with serious psychiatric disorders, those who are addicted to smoking or ethanol, non-compliance with treatment regimens, and poor psychosocial support systems.

During the candidate-screening process, mild to moderate depression was identified in over 50% of patients in one study

(Najafizadeh, Ghorbani, Rostami, Fard-Mausavi, Lorgard-Dezfuli-Nejad, Marashian, et al., 2009). Prolonged waiting times for an allograft are associated with increased stress, anxiety, and depression (Vermeulen, Bosma, Bij, Koeter, & Tenvergert, 2005). Complications from chronic hypoxemia are common, including diminished cognitive function and memory loss.

Despite the need for rigorous monitoring, following transplantation most patients report an improved quality of life, associated with diminished anxiety and depression; however, this tends to diminish with the development of chronic rejection after several years (Vermeulen, Ouwers, van der Bij, de Boer, Koeter, & TenVergert, 2003). The incidence of PTSD is also increased post-transplantation (Kollner, Einsle, Schade, Maulhardt, Guliernos, & Joraschky, 2003). Candidates with psychosocial risks may benefit from cognitive behavioral interactions, and increased patient contact with members of the transplant staff (Blumenthal, Babyak, Keefe, Davis, Lacaille, Carney, et al., 2006). One study showed that having a pet increased the quality of life for patients post-transplantation (Irani, Mahler, Goetzmann, Russi, & Boehler, 2006).

SOMATIZATION AND LUNG DISEASE

An undetermined percentage of patients present to outpatient pulmonary clinics with pulmonary symptoms that have no demonstrable etiology. These most commonly include dyspnea, chronic cough, and chest pain. In a preliminary study at Massachusetts General Hospital (MGH), 100 patients who presented with pulmonary-related symptoms were assessed for depression, anxiety, and stress with a validated subjective scale, the Depression Anxiety Stress Scale (DASS) (Lovibond & Lovibond, 1995). The results of subjective reports were correlated with the impression of a psychiatrically trained pulmonary practitioner. Preliminary findings suggest that a substantial number of patients with objective evidence of pulmonary disease are either syndromally or subsyndromally anxious, depressed, or have been subject to nontrivial stressors. However, there is poor correlation with the subjective and objective assessments in more half of cases. The following case reports illustrate the point.

CASE REPORT 1

A 55-year-old woman presented to the MGH Pulmonary Clinic with persistent shortness of breath and a diagnosis of asthma. She had previously been seen in various area emergency departments, and treated for asthma, but without sustained relief.

History revealed evidence of major developmental trauma and familial alcoholism. The patient was tense, guarded, and reticent about answering questions concerning possible ongoing stressors. She reported the sensation of a "lump in my throat," gastroesophageal reflux (GERD), irritable bowel syndrome, and fibromyalgia. Her physical examination was normal except for a resting tachycardia, and her resting pulmonary function tests showed no evidence of airway obstruction. However, she did have a positive methacholine-challenge test, implying an element of irritation in the airways. (The methacholine-challenge test assesses airway responsiveness. The patient has pulmonary function tests evaluated before

and after inhaling an aerosol of different concentrations of methacholine in order to diagnose asthma or evaluate its severity.)

A cardiopulmonary exercise tolerance test (CPET) demonstrated no pulmonary limit to exercise, despite her report of being unable to walk more than several steps without becoming dyspneic. She scored low across all subscales of the DASS. When I suggested that emotional factors might be playing a role in her asthma, she became angered and chose to pursue her care at another hospital center, where she has been treated with combination immunosuppressive therapies, from which she suffered a serious opportunistic infection. There has been essentially no improvement in her pulmonary symptoms.

CASE REPORT 2

A 27-year-old woman presented with a recent exacerbation of her asthma. She had been treated as an outpatient for asthma, although no one had documented wheezing on physical examination. She reported low distress across the DASS subscales, although she appeared both depressed and anxious on interview and reported having difficulty finding employment post-graduation. Her physical examination and detailed pulmonary function tests were normal. She was referred for both a methacholine-challenge test and pulmonary exercise testing. The methacholine challenge test was positive, indicating an element of irritable airways; however, her CPET showed no pulmonary mechanical limit to exercise, but it did demonstrate abnormal hyperventilation. She presented to her follow-up visit with her mother. When I informed her of her results and again wondered whether anxiety and stress might be contributing to her symptoms, she began to cry and admitted that she had been suffering from numerous panic attacks and was very stressed about leaving home. She was treated with a bronchodilator as well as an SSRI and anxiolytic, with excellent response.

The above cases suggest that reliance on self-reporting can fail to identify patients whose symptoms are exacerbated by psychiatric factors. This may be due to alexithymia or reticence to admit psychological symptoms in a medical setting. Unfortunately, failure to address these symptoms may lead to iatrogenic complications when treatment is directed at organic factors exclusively.

The key to the proper identification of this population is better recognition by medical internists and pulmonologists of the role that psychological factors may play in the exacerbation of pulmonary disease, as well as education in how to identify these patients. In many cases, symptoms may have persisted for weeks to years without evidence of deleterious progression, which may be a clue to the psychological basis of symptoms. Poly-symptomatology is the rule in somatization, and a detailed review of systems will generally reveal other functional symptoms. In all cases, a brief developmental history should be elicited and efforts made to assess the patient's current and developmental level of stress. Physical exam often reveals depressed or flat affect, anxious responses, resting tachycardia, altered pupillary tone, dystaxic breathing, frequent sighing, tense musculature, and evidence of bruxism, all of which may point towards a diagnosis of somatization.

Subsequent diagnostic testing must be tailored to the patient's symptoms. For patients with complaints of dyspnea, an aerobic exercise history can help in ascertaining their level of fitness, and observations with respect to weight and body habitus are helpful. As noted, dynamic cardiopulmonary exercise testing (CPET) can determine the limits of exercise and correlated in real-time with symptoms of dyspnea or chest pain. For patients who show no apparent abnormality in pulmonary-function testing, a simple noninvasive exercise study may point to a cardiac or respiratory limit to exercise versus fatigue. Hyperventilation syndromes can be detected with the presence of an arterial line with frequent samplings of pCO₂ during the exam. More complex issues, including diastolic cardiac dysfunction, abnormal blood-shunting myopathy, and mitochondrial disorders, require sampling of central venous as well as arterial blood.

Cough is a complex problem with both anatomical and functional etiologies. Many cases are attributable to chronic post-nasal drip and allergies, but detailed imaging of the sinuses and upper airways should be performed in all cases, together with an otolaryngological examination. CT scans of the neck and chest may occasionally reveal a benign or low-grade neoplasm such as carcinoid as the cause of chronic cough. Asthma and gastroesophageal reflux (GERD) are common causes and should be excluded. Bronchoscopic examination is rarely indicated in the absence of other troublesome or constitutional symptoms. A recent study has demonstrated some efficacy for gabapentin in the treatment of chronic cough. When all reasonable diagnostic options have been excluded, a diagnosis of psychogenic cough can comfortably be established. Treatment is rarely effective.

Treatment of the somatization syndromes has recently been reviewed elsewhere, and there is limited evidence that drugs and targeted psychotherapies may be helpful (Kradin, 2012). But ultimately, treatment must depend on patient preference and their willingness to actively participate in their therapy. Whereas some patients clearly benefit from antidepressant and/or anxiolytic medications, most refuse both psychopharmacological interventions and psychotherapies. However, they may be willing to participate in behavioral modifications such as meditation, yoga, tai chi, and Pilates. Eliciting the patient's cooperation is most critical, but this is directly proportional to their level of insight.

I have elsewhere discussed the substantial overlap between the placebo response and the therapeutic action of psychotherapy (Kradin, 2008). It is evidence that the factors that promote well-being via placebo mechanisms parallel those adopted in optimal interpersonal communications in the therapeutic setting. Active listening, empathy, mirroring attention, and time spent attending to the patient, all foster therapeutic alliances in both somatic and psychological therapies. At the same time, it is important to recognize that nocebo effects and help-rejecting behaviors are commonly seen in patients with somatization, complicating the therapeutic stance.

Somatizing patients represent a substantial challenge to the self-esteem of the medical practitioners, who often find themselves at a loss both with respect to diagnose symptoms or how to effectively alleviate them. Nevertheless, it is critically important to maintain a patient and empathic stance with these patients, who often view the medical practitioner as their only resource and may adamantly refuse any form of psychological counseling.

DRUG INTERACTIONS BETWEEN PSYCHOACTIVE AND PULMONARY DRUGS

Many of the commonly prescribed pulmonary drugs interact adversely with psychiatric medications, and these are listed in Table 54.3. As previously noted, corticosteroids may exacerbate both depression and mania. Psychotic effects of corticosteroids are dose-related, and they are rarely seen in patients receiving less than 40 mg a day of prednisone. However, physicians and family members must carefully monitor untoward psychiatric side effects, as corticosteroid therapy at times may be completely contraindicated in some patients. When immunosuppressant therapy is necessary, other medications, such as methotrexate, cyclophosphamide, or cyclosporine, may be alternative options.

Neuroleptic medications, when prescribed at high dosages, can produce laryngospasm, paradoxical movement of the chest wall musculature, and diaphragmatic tardive dyskinesia.

Table 54.3 POTENTIAL DRUG INTERACTIONS BETWEEN PULMONARY AND PSYCHIATRIC MEDICATIONS

BETA-AGONISTS	TRICYCLICS, MAO INHIBITORS	HYPERTENSIVE CRISIS
Sildenafil	Fluvoxamine	Increased vasodilatation
Theophylline	Alprazolam	Diminished benzodiazepine effect
Theophylline	Clozapine	Increased theophylline level
Theophylline	Fluvoxamine	Increased theophylline level
Theophylline	Lithium	Decreased lithium level
Theophylline	Carbamazepine	Decreased carbamazepine effect

Drugs with diminished incidence of extrapyramidal effects are preferred in chronic respiratory failure.

The β -adrenergic medications can induce anxiety and tremulousness. β_2 selective agents should be routinely prescribed, as they reduce cardiac effects and the incidence of psychosis. Anticholinergics can lead to delirium, hallucinations, amnesia, paranoia, and depersonalization. Anxiety has been reported with leukotriene inhibitors. Theophylline, once a commonly prescribed medication for asthma and COPD, has fallen out of favor, in part due to its side effect profile and because of the need to monitor the patient's blood levels. However, it may still be used in resistant cases of asthma and in COPD at times to improve diaphragmatic function. It can cause anxiety, delirium, and tremors, especially when serum levels are in a toxic range.

Among the SSRIs, short-acting medications and those with a low incidence of interaction with pulmonary medications should be chosen. These include sertraline, citalopram, and escitalopram. The SSRIs have been shown to reduce dyspnea in patients with subsyndromal panic disorder. Tricyclic antidepressants (TCA) are as effective as the SSRIs in the treatment of depression but have a wider side-effect profile, including dry mouth, constipation, and cardiotoxic effects. QT-intervals should be checked by electrocardiogram prior to prescribing a TCA.

Short-acting benzodiazepines are preferred in patients with COPD and the elderly. Buspirone is a weak anxiolytic but can be used safely in patients with COPD and may improve exercise tolerance and dyspnea. β -blockers are relatively contraindicated in patients with asthma and COPD, due to their bronchoconstrictor properties.

Fluvoxamine can unpredictably promote the pulmonary vasodilatory effects of sildenafil and sodium nitroprusside by increasing half-life and venous dilatation.

SUMMARY

Mind and body may be nowhere more inextricably linked than in the physiological interactions between the nervous and respiratory systems. Severe chronic respiratory ailments invariably show neuropsychiatric effects, or may exhibit preexisting psychiatric disorders that require treatment. Conversely, primary psychiatric disorders are frequently complicated by addictions, such as smoking, which is the primary cause of COPD and the fourth most common cause of death in the United States, or they may exacerbate and confound the diagnosis and treatment of pulmonary disorders. There is a need for increased recognition of the complex interactions between mind and lung, as well as a team approach that includes pulmonologists, thoracic surgeons, and psychiatrists, in the optimal care of complex medical problems such as cystic fibrosis and lung transplantation. Drugs prescribed by psychiatrists and their medical counterparts can have complex and adverse interactions, so it is important to be aware of how to administer them in the least potentially toxic combinations. Finally, increased

sensitivity to psychiatric issues in pulmonary disease has been convincingly demonstrated to improve the quality of care of individual patients and to reduce the overall costs of health care.

CLINICAL PEARLS

- Arterial $p\text{CO}_2$ and arterial pH are the primary controllers of ventilation, but an arterial $p\text{O}_2$ of less than 65 mm/Hg can also drive ventilation.
- Blunted ventilatory responses to breathing elevated concentrations of CO_2 are seen in patients who have clinical depression, CNS abnormalities, hypothyroidism, or severe hepatic failure. They also occur after carotid endarterectomy and in patients on respiratory depressants (Bone, 1993).
- In the absence of blood volume contraction, elevated serum HCO_3^- concentrations are a reliable clue to the presence of underlying ventilatory failure.
- In addition to lowering the threshold for musculoskeletal tetany, respiratory alkalosis also diminishes cognitive and memory processes (Posner, 1972).
- Dyspnea occurs when the mechanical work of breathing increases beyond the limits of ventilation and may be expected when the forced expiratory volume in the first second of exhalation (FEV_1) is reduced to less than 1 liter (Rock & Schwartzstein, 2007).
- A measure of the work of breathing is the maximum voluntary ventilation (MVV); that is, the maximum amount of air that can be moved in and out of the lungs during a defined interval. This can be empirically approximated from the FEV_1 (Caruana-Montaldo et al., 2000).
- The chronic interstitial pneumonias produce alveolar scarring and lead to a loss of gas-exchange surface, as evidenced by reduced diffusion capacity (DLCO), although a decreased DLCO is also a hallmark of both emphysema and primary pulmonary vascular disease. Patients with these abnormalities tend to complain of dyspnea on exertion early in the course of their disease that is accompanied by rapid O_2 desaturation of the arterial blood with exercise.
- Normally, with exercise, an anaerobic threshold (AT) is achieved based on the cardiopulmonary limit of O_2 delivery to the tissues, which can be correlated with the minute ventilation and heart rate. Physical deconditioning and psychiatric disorders might cause dyspnea in patients who do not show maximal effort on testing.
- Asthmatics have an increased prevalence of general anxiety disorder, panic disorder, and phobic disorders (Rosenkranz & Davidson, 2009).
- Adverse circumstances in childhood can predict adult asthma, and acute traumatic events can exacerbate asthma.

- Weiss (Weiss, 1994) described a detailed behavioral management program for asthma that included a checklist to assess asthma medications, early signs of wheezing, triggers of an attack, individual behavior and behavior of other people during an attack, and the effects of asthma on social development, school, and the family. Asking patients to maintain a daily diary with respect to symptoms may provide an additional resource for diagnosis and management (p. 13).
- Self-induced wheezing in factitious cases is loudest over the neck, with transmission to the chest wall on auscultation. Bronchial wheezes can be mimicked by maneuvers that include holding the vocal cords in apposition. However, one must first exclude vocal cord dysfunction and other causes of intrathoracic and extrathoracic upper airway obstruction (Bahrainwala & Simon, 2001).
- A panic attack in the postoperative setting, or in a patient with phlebitis, should lead reflexively to a CT-angiogram, in order to exclude thromboembolic disease.
- Symptoms that have persisted for weeks to years without evidence of deleterious progression may be a clue to the psychological basis of symptoms.

DISCLOSURE STATEMENT

Dr. Kradin has no conflicts to disclose.

NEUROPSYCHIATRIC MANIFESTATIONS OF ENDOCRINE DISORDERS

Erin Sterenson, Christopher L. Sola, and Shirlene Sampson

INTRODUCTION

It has long been known that endocrine disorders are associated with neuropsychiatric symptoms. In 1786, Parry described psychotic symptoms associated with hyperthyroidism, and Graves first lectured on the psychiatric complications of hyperthyroidism in 1834. Other remote observations of psychiatric symptoms associated with endocrine disorders include reports by Addison in 1868, Cushing in 1932, and Sheehan in 1939 (Addison, 1868; Cushing, 1932; Sheehan, 1939).

Psychiatric symptoms can precede or present concurrently with the more typical physical symptoms of endocrine disease. These secondary disorders can be impossible to distinguish from primary psychiatric disorders, such as depression, mania, psychosis, anxiety, delirium, or dementia. Thus, testing for endocrine diseases should be routinely performed as part of the medical work up for these neuropsychiatric disorders.

In this chapter, we will review psychiatric syndromes associated with disorders of the thyroid, adrenal, pituitary, and parathyroid glands, as well as those associated with diabetes mellitus, hypoglycemia, and disturbances of gonadal hormones. For information related to the physical clinical presentations, medical evaluation, and management of endocrine disorders, we refer you to Chapter 6. When psychiatric symptoms are thought to be secondary to endocrine disease, the primary treatment focus remains correcting the endocrine disorder. That being said, there are times when the psychiatric symptoms are severe enough to warrant immediate intervention. This is clearly the case for mania, psychosis, and severe depression that could be life-threatening. The treatment intervention of choice for acute mania and psychosis remains the atypical antipsychotics, and antidepressant medications and interventions remain the treatment of choice for depression. When significant anxiety is present, benzodiazepines can be used to get symptoms under control in the short term, followed by serotonergic antidepressants if longer term drug treatment is needed.

THYROID DISORDERS

HYPERTHYROIDISM (THYROTOXICOSIS)

Numerous neuropsychiatric symptoms have been noted in patients with hyperthyroidism and include psychosis,

depression, mania, anxiety, and cognitive dysfunction (Feldman et al., 2013). Neuropsychiatric symptoms can occur with primary hyperthyroidism (Graves disease), as well as with toxic nodular goiter and excessive consumption of exogenous thyroid hormone (Feldman et al., 2013; Brownlie et al., 2000). Brownlie and colleagues (2000) reported a series of 18 patients: seven presented with mania, seven with depression, three with psychosis, and one with delirium. Thus the range of neuropsychiatric symptoms seen with hyperthyroidism is quite broad. Of note, a case of subacute thyroiditis presenting with neuropsychiatric symptoms (acute psychosis) has also been reported (Lee et al., 2013).

The presenting neuropsychiatric symptoms of hyperthyroidism include emotional lability, poor impulse control, crying spells, euphoria, irritability, distractibility, reduced attention, impaired recall, and psychosis (delusions and hallucinations) (Esposito et al., 1997; Brownlie et al., 2000). A minority of patients can present with symptoms of depression, apathy, or lethargy. Treatment includes targeting the cause of hyperthyroidism and addressing the presenting neuropsychiatric symptoms as clinically indicated.

HYPOTHYROIDISM (MYXEDEMA)

Neuropsychiatric symptoms associated with hypothyroidism include cognitive dysfunction, affective disorders, and psychosis (Heinrich & Grahm, 2003). Early descriptions of psychiatric symptoms in hypothyroidism include reports by Gull in 1874 and Ord in 1887. The psychiatric presentation may be indistinguishable from a primary psychiatric disorder, thus reinforcing the importance of ruling out medical causes of psychiatric disorders. The onset of symptoms of hypothyroidism is often gradual, and slow progression is common, especially in the elderly, mimicking the development of a degenerative dementia. Common symptoms include slowed comprehension and impairment in attention, recent memory, and abstract thinking. In contrast to cortical dementias such as Alzheimer's disease and frontotemporal degeneration, the cognitive disorder of myxedema does not present with discrete cortical syndromes like aphasia, anomia, apraxia, and frontal disinhibition.

The most common affective disorder seen with hypothyroidism is depression, manifested most often as reduced

mood, psychomotor retardation, sleep and appetite disturbances, anhedonia, reduced libido, and emotional lability. Suicidal thinking, delusions, and hallucinations can be present in more advanced illness. Thomsen et al. (2005) have reported that patients hospitalized for hypothyroidism had a greater risk of being admitted for the treatment of depression or bipolar disorder, and that this risk was greatest in the first year after index hospitalization.

A meta-analysis of individuals with treatment resistant depression demonstrated that approximately 50% had subclinical hypothyroidism, and the response to antidepressant therapy is known to be reduced if the thyroid disease is not treated (Howland, 1993; Pae et al., 2009). Demartini et al. (2010) found a prevalence of depressive symptoms in 63.5% of their subjects with subclinical hypothyroidism. In contrast, others have found no increase in neuropsychiatric symptoms in patients with subclinical hypothyroidism (Park et al., 2010). Although it is generally believed that treatment of the underlying hypothyroidism will treat the neuropsychiatric symptoms, Demartini et al. (2010) found that thyroid replacement alone was not effective in producing remission of the depressive symptoms. Evidence for benefit from thyroid replacement in depressed patients with subclinical hypothyroidism remains variable; therefore, the use of thyroid replacement in this patient population remains controversial (Feldman et al., 2013).

Compared to depression, mania is a much less common manifestation of hypothyroidism; however, there are a number of reported cases of hypothyroidism presenting with symptoms of mania (Stowell & Barnhill, 2005; Khaldi et al., 2006; Tor, 2007; Sathya et al., 2009). Patients can present with elevated mood and energy, irritability, psychomotor agitation, decreased need for sleep, increased goal-directed behavior, pressured speech, flight of ideas, grandiosity, hallucinations, and delusions.

Hypothyroidism has been associated with psychosis (myxedema madness), and there is no typical presentation of psychotic symptoms (Davis, 1989; Heinrich & Grahm, 2003), which can include delusions (paranoia), auditory and visual hallucinations, perseveration, and thought disorganization. Psychosis has been noted in 5–15% of patients with hypothyroidism (Hall, 1983).

ADRENAL DISORDERS

HYPERCORTISOLEMIA (CUSHING'S SYNDROME)

Psychiatric disturbances are common with Cushing's syndrome. Sonino and Fava (2001) reviewed the prevalence of psychiatric disorders in Cushing's syndrome and reported the presence of major depression was on average 57%, with a range of 50–80% across studies. Depression was significantly associated with older age, female gender, higher pretreatment urinary cortisol levels, a relatively more severe clinical condition, and the absence of pituitary adenoma. Patients with depression appeared to have a more severe clinical presentation and

have higher cortisol levels than patients with increased cortisol without depression.

Mania in Cushing's syndrome presents less commonly than depression, though approximately 30% of patients present with hypomanic or manic symptoms. Sustained elation is rare, with subclinical mood fluctuations being more common. Hypomania or mania may be some of the earliest signs of illness onset.

Anxiety can be commonly associated with Cushing's syndrome. The rate of generalized anxiety disorder has been noted to be as high as 79%, and panic disorder as high as 53%. The association between anxiety and Cushing's syndrome is complex, given that depression is common with Cushing's syndrome (50–80%), and anxiety is a common symptom of depression, even in patients with depression that is not caused by an endocrine disorder.

Cognitive dysfunction has been noted in approximately two-thirds of patients with Cushing's syndrome. Impairments can be seen in nonverbal, visual-ideational, visual-memory, and spatial-constructional abilities, as well as concentration, memory, reasoning ability, comprehension, and processing new information. Neuroimaging studies may reveal cerebral atrophy.

Although the successful control of hypercortisolism can result in a progressive improvement of psychiatric symptoms and cognitive function, this is not always the case. Pereira et al. (2010) describe a Cushing's syndrome cohort comprising 33 patients, with 67% having significant psychopathology (primarily depression). After cure of Cushing's syndrome, the prevalence of diagnosed psychopathology was 54% at three months, 36% at six months, and 24% at one year. They also report a 74-patient cohort that continued to experience impairments in memory and executive function despite long-term cure of the Cushing's disease.

ADRENAL INSUFFICIENCY (ADDISON'S DISEASE)

Compared to the neuropsychiatric effects of Cushing's syndrome, much less is known about the neuropsychiatric effects of Addison's disease, which results in deficiencies in glucocorticoids and mineralocorticoids. Anglin et al. (2006) reviewed the literature on neuropsychiatric symptoms associated with Addison's disease and reported a prevalence of neuropsychiatric symptoms of 64–84% in the four case series examined. Mild disturbances in mood, motivation, and behavior were described as core clinical symptoms. Psychosis and extensive cognitive changes, including delirium, were less common and associated with more severe disease. Catatonia and self-mutilation were still more rarely seen. Neuropsychiatric symptoms were noted before the diagnosis was made. Specific drug treatment of the neuropsychiatric symptoms was started in 80% of the cases.

The diagnosis of Addison's disease is commonly delayed. Bleicken et al. (2010) report a cohort of 216 patients with adrenal insufficiency in which 41% received a false diagnosis of a psychiatric illness. Thus it is important to have a low threshold for screening for Addison's disease, particularly with atypical presentations and treatment-resistant symptoms.

Adrenal insufficiency is generally treated by replacing hydrocortisone. Thomsen et al. (2006) note that patients with adrenal insufficiency may be at risk for developing severe affective disorders, and in particular may be at risk for developing elevated mood symptoms in the context of receiving hormone replacement.

DISORDERS OF THE PARATHYROID GLANDS

HYPERPARATHYROIDISM

Reports of the occurrence of psychiatric symptoms in patients with hyperparathyroidism vary widely and have been reported for decades, including in the medical school mnemonic “stones, bones, groans, and psychiatric overtones,” referring to the renal or biliary stones, bone pain, abdominal discomfort (eliciting groans), and psychiatric sequelae (overtones) of hypercalcemia. Though it has been commonly held that neuropsychiatric symptoms tend to positively correlate with the degree of elevation of serum calcium (Brown, Fischman, & Showalter, 1987; Haden, Stoll, McCormick, Scott, & Fuleihan, 1997), many patients may tolerate significant elevations in serum calcium without any symptoms, and patients with relatively mild elevation of serum calcium may have significant psychiatric sequelae (McAllion & Paterson, 1989).

Historically, it has been suggested that in mild hypercalcemia, personality changes, irritability, decreased spontaneity, and lack of initiative are more commonly noted. Moderate hypercalcemia (12–16 mg/dl), is more likely to result in more frequent depressive symptoms, including dysphoria, anhedonia, apathy, anxiety, increased irritability, impaired concentration and recent memory, and sometimes suicidal ideation. In severe hypercalcemia (16–19 mg/dl)—or following a precipitous rise in serum calcium—psychosis and cognitive symptoms predominate, including auditory and visual hallucinations, delusions, confusion, disorientation, catatonia or agitation, and paranoid ideation. At levels above 19 mg/dl, stupor and coma are common.

However, this may not be the case. Some studies (McAllion, 1989; Hecht, Gershberg, & St. Paul, 1975) demonstrate “no relationship between the overall psychiatric score and serum levels of calcium.” Increasingly, the literature has recognized that many patients may have atypical features, such as fatigue, generalized weakness, sleep disorders, and cognitive deficits leading to decreased ability to complete common tasks (Coker et al., 2005; Walker, Rubin, & Silverberg, 2013). Indeed, “nearly 80% of biochemically identified cases of primary hyperparathyroidism are ‘asymptomatic’ in terms of the classical symptoms” (Benge et al., 2009).

In view of the insidious onset and frequent lack of specific symptomatology, the diagnosis of hyperparathyroidism is often overlooked (Gatewood, Organ, & Mead, 1975; McAllion, 1989; Coker et al., 2005; Benge et al., 2009; Walker et al., 2013). For this reason, and because of its relatively low cost, a screening ionized calcium determination should be obtained for most psychiatric patients during their initial evaluation.

Common misdiagnoses include anxiety disorders, hypochondriasis, mood disorders, schizophrenia, and cognitive impairment disorders of other etiology. Correction of hypercalcemia generally results in rapid reversal of many of the psychiatric manifestations (Borer & Bhanot, 1985). Evidence regarding the reversibility of psychiatric symptoms following parathyroidectomy is conflicting (Heath, 1989; Walker et al., 2013), though there is some support in the literature for surgical intervention. Due to the high proportion of “asymptomatic” patients who are nonetheless suffering, which may be as much as 80% of patients with hyperparathyroidism, surgery can often, though not always, result in a demonstrable decrease in neuropsychiatric (emotional or cognitive) symptom burden (Heath et al., 1980; Joborn et al., 1988; Benge et al., 2009; Coker et al., 2005; Goyal et al., 2001; Solomon, Schaaf, & Smallridge, 1994; Roman et al., 2011; Walker et al., 2013); however, which symptom improves—and how much—is not predictable (Silverberg, 2013; Walker et al., 2013). Younger patients are thought to benefit more than older patients, and tend to tolerate the procedure better (Benge et al., 2009).

LITHIUM AND HYPERPARATHYROIDISM

Patients on chronic lithium therapy, though more likely to present with renal or thyroid dysfunction, may, more rarely, present a clinical picture indistinguishable from that of primary hyperparathyroidism (Mallette & Eichorn, 1986; Rifai, Moles, & Harrington, 2001). Discontinuation of lithium in these patients most often results in return of serum calcium levels to the normal range, though this is not always immediate (Rifai et al., 2001), and simple lithium cessation may not be sufficient in every case. If stopping the medication does not reverse the hypercalcemia, parathyroidectomy may be indicated (Duggal & Singh, 2007). One review highlighted the possibility that lithium “unmasks” native hyperparathyroidism, causes multiglandular parathyroid hyperplasia, or promotes the growth of existing parathyroid adenomas, and noted that women are four times more likely to present with this issue (Szalat, Mazeh, & Freund, 2009). It is vital that serum calcium be checked in delirious patients who are taking lithium, as hypercalcemia would suggest the need to immediately discontinue lithium (Rifai et al., 2001; Duggal & Singh, 2007). The pathophysiological mechanism of lithium-induced hyperparathyroidism is poorly understood. It has been postulated that lithium might directly stimulate parathyroid (PTH) production, that lithium-induced hypercalcemia could be related to hypocalciuria resulting from impaired renal function, or that lithium may interfere with calcium-mediated, transmembrane signal transduction by the calcium-sensing receptor, inducing a reduction in the set-point for PTH secretion. Lithium may magnify the set-point error in patients with primary hyperparathyroidism, may unmask preexisting changes in the parathyroid glands, or may cause mild, clinically insignificant hypercalcemia and hyperparathyroidism. Lithium-associated hypercalcemia can present a clinical dilemma in patients with bipolar disorder because of limitations in treatment options and the potential of hypercalcemia to exacerbate psychopathological symptoms

(McHenry & Lee, 1996). Because it may be difficult to simply discontinue the lithium, and surgical resection of the parathyroid gland is not indicated (Gregoor, 2007), some authors have explored the potential benefits of cinacalcet hydrochloride, an allosteric activator of the calcium-sensing receptor that decreases serum calcium (Sloand & Shelly, 2006; Gregoor, 2007).

HYPOPARATHYROIDISM

Psychiatric findings occur in 30–50% of hypoparathyroid patients (Popkin & Mackenzie, 1980; Wee-Kiat Ang et al., 1995). The rapidity of change in serum calcium and other electrolytes, especially magnesium, as well as vitamin D, seems to be the most important factor in determining the severity of complaints. As with hyperparathyroidism, symptoms may include anxiety, depression, irritability, emotional lability, social withdrawal, phobias, and obsessions; and, in severe cases, delirium with confusion, disorientation, agitation, and paranoia. Auditory and visual hallucinations may be present, especially in the context of delirium. Intellectual deterioration is found in one-third of patients with primary hypoparathyroidism, the result of a long duration of illness prior to diagnosis and treatment. “Up to 80% of cases studied by Denko and Kaelbling had intellectual impairment (IQ 40 to 90) as the sole or major psychiatric finding” (Hossain, 1970). With surgically induced hypoparathyroidism, cognitive changes are rare, as the condition is usually treated promptly and calcium levels are monitored more closely. Symptoms of hypoparathyroidism may be mistaken for anxiety disorders such as generalized anxiety disorder, hypochondriasis, conversion disorders, depression, schizophrenia, dementia, and cognitive impairment disorders. Normalization of serum calcium levels may result in resolution of symptoms, though this is often insufficient until any existing hypomagnesemia is corrected (Wee-Kiat Ang et al., 1995). When intellectual impairment is present, residual cognitive deficits often persist despite calcium and magnesium correction. In severe cases requiring antipsychotics, it is prudent to consider supplementing with both calcium and magnesium to mitigate the risk of extrapyramidal symptoms, a risk increased by hypomagnesemia and hypocalcemia.

DISORDERS OF PITUITARY FUNCTION

There is a significant literature on the influence of the hypothalamic-pituitary-thyroid and hypothalamic-pituitary-adrenal axes on emotional well-being. Discussion of each can be found in the end-organ (i.e., thyroid and adrenal) sections of this chapter, with specific attention here directed toward the effects of altered pituitary function not contained in those reviews.

HYPERPITUITARISM

The most common type of pituitary tumor is a prolactin-secreting adenoma (prolactinoma). Microadenomas

(<1 cm in diameter) are more common in females, and macroadenomas (>1 cm, and more likely to invade or compress surrounding structures) have an equal gender distribution (Ali, Miller, & Freudenreich, 2010). Hyperprolactinemia can result in a wide variety of symptoms, including galactorrhea, gynecomastia, amenorrhea, decreased libido, and sexual dysfunction (Ali et al., 2010). Psychological disturbances including hostility, depression, and anxiety, as well as apathy, are seen often without dysphoric mood irritability and impulsivity (Fava et al., 1981; Cohen et al., 1984; Ali et al., 2010).

Categories of drugs associated with inducing hyperprolactinemia include antipsychotics (phenothiazines, butyrophenones, and risperidone), antidepressants (amitriptyline, imipramine, amoxapine), and dopamine-receptor antagonists (metoclopramide, domperidone, sulpiride). Of the atypical neuroleptics, risperidone has the greatest capacity for stimulating prolactin secretion (Ali et al., 2010). As a class, however, the atypical neuroleptics have less tendency to be associated with prolactin increases in the serum than the typical agents.

A common clinical dilemma is the psychotic patient on a neuroleptic drug who develops menstrual dysfunction, galactorrhea, or (in males) gynecomastia associated with an elevated serum prolactin concentration. Treatment requires a careful balancing act between the decreasing prolactin and maintenance of adequate control of the psychotic disorder. In such cases, it is reasonable to consider a switch to an alternative antipsychotic, such as quetiapine or olanzapine (Kane et al., 1997), which is less likely to exacerbate hyperprolactinemia. Consideration could also be given to the use of aripiprazole, which might actually decrease prolactin due to its mixed dopaminergic antagonism and agonism. However, metabolic syndrome or diabetes each confer a higher long-term risk than hyperprolactinemia, so it may be wise to introduce aripiprazole as an adjunct, and slowly cross-titrate the offending agent—most often risperidone or haloperidol—to optimize control of psychosis and minimize the effects of increased prolactin (Ali et al., 2010). If the serum prolactin level returns to normal when the offending agent is stopped, the possibility of a pituitary tumor is virtually excluded. If there is an adenoma, though, consideration must be given to surgical intervention, though surgery may not be persistently curative (Cohn et al., 1985; Perovich et al., 1989; Ali et al., 2010). The use of a dopamine agonist such as bromocriptine or cabergoline is potentially risky, as these may theoretically—though rarely—lead to worsened psychotic symptoms despite the patient’s remaining on an antipsychotic (Rao, Hiemke, Grasmader, & Baumann, 2001; Konopelska, Quinkler, Strasburger, Ventz, 2008; Ali et al., 2010). In these cases it is useful to systematically track the psychiatric and endocrine symptoms, perhaps with rating scales as well as blood tests, to find the optimal balance of psychiatric and endocrine symptom control. In order for the psychiatrist and endocrinologist to work effectively together, it is helpful to have a common “dashboard” to which both can refer.

Acromegaly is the clinical syndrome that results from sustained hypersecretion of growth hormone, most often the result of a pituitary adenoma (Ezzat, 1997; Furman &

Ezzat, 1998). Personality changes, including apathy, lack of initiative and spontaneity, and mood lability (Bleuler, 1951), often in relationship to patients' altered physical appearance in active disease, have been reported for decades, albeit with little formal investigation. More recently, increased use of structured diagnostic interviews and validated surveys has generated more detailed descriptions of psychiatric disturbances associated with acromegaly, including depression, pathological gambling, psychosis, amotivational syndrome (De Sousa, 2009), harm avoidance, neurosis, anticipatory worry, pessimism, and reduced impulsivity and less novelty-seeking behaviors (Sievers et al., 2009). A relatively recent examination of 81 acromegalic patients revealed "increased lifetime rates of affective disorders," especially major depression and dysthymia, but not anxiety disorders, which persisted even after curative surgery. The same review revealed that radiotherapy, but not biochemical interventions, "was a predictor for an increased risk for DSM-IV mental disorders" (Sievers et al., 2009), supporting earlier work that demonstrated pituitary irradiation sometimes resulting in delayed cerebral radiation necrosis (DCRN), leading to "progressive dementia, blindness, status epilepticus, and stroke-like episodes" (Furman & Ezzat, 1998). Of note, most of the above-described traits have also been found in patients with nonfunctioning pituitary macroadenomas, though to a lesser degree (Sievers et al., 2009). Finally, 68 acromegalic patients "scored significantly worse on virtually all psychopathology questionnaires," including depression and anxiety scales, but did not score worse on cognitive tests when compared to healthy matched controls and patients treated for nonfunctioning pituitary macroadenomas (Tiemensma et al., 2010).

One pharmacological intervention, octreotide, has very few psychiatric side effects, although according to the package insert it may cause depressive symptoms in 1–4% of patients and, in fewer than 1% of patients, may cause anxiety, libido decrease, paranoia, or amnesia (Sandostatin package insert [Novartis—US], Rev., 01/97, Rec 02/23/99).

HYPOPITUITARISM

The infundibular-hypothalamic anatomy is relatively fragile, such that brain pathology, especially traumatic brain injury (TBI), subarachnoid hemorrhage, or brain tumors increase the risk of patients' developing hypopituitarism, including the first and most common sign of pituitary impairment, growth hormone deficiency (Aimaretti, et al., 2005). Regardless of etiology, the primary issue is the decreased hormonal output, and use of psychotropic agents directed at the nature of the presenting symptom (e.g., antidepressants for depression, anxiolytics for anxiety, or antipsychotics for psychosis) is suggested only after correction of the endocrine abnormality. Despite this final common pathway, much of the literature on the psychiatric sequelae of hypopituitarism is focused on the result of TBI, with estimates of post-TBI hypopituitarism as high as 25–50% (Urban, Harris, & Masel, 2005; Lane, 2010). Most references describe increased rates of depression (Rao et al., 2001; Popovic et al., 2004; Popovic,

Aimaretti, Casanueva, & Ghigo, 2005; Bavisetty et al., 2008; Lane, 2010), and at least one suggesting an attempted suicide rate as high as 18% (Simpson et al., 2002) in untreated cases. Others describe amotivation, dysphoria, disturbed sleep pattern, personality change, affective blunting, and auditory and visual hallucinations (Chang, Tsai, & Tseng, 2006), and cognitive impairment, including visual and verbal memory impairment (Rao et al., 2001; Popovic et al., 2004) and decreased quality of life (Battisetty, 2008). In one study, nearly half of patients with post-traumatic hypopituitarism (as measured by hormone-level output) expressed symptoms of mild to moderate depression, and scales reflecting somatization and paranoid ideation were inversely correlated with pituitary hormone levels. Many neuropsychiatric symptoms significantly improved with hormone replacement (Popovic et al., 2004).

DISORDERS OF GLUCOSE METABOLISM

DIABETES MELLITUS

The interface of diabetes mellitus and psychiatric illness is of growing interest to psychiatrists, endocrinologists, and primary care providers alike. The comorbidity, however, is not new, and, in the seventeenth century, it was speculated that diabetes was caused by "long sorrow and other depressions." Likewise, in 1879, Sir Henry Maudsley asserted that "diabetes is a disease which often shows itself in families in which insanity prevails." As the comorbidity is examined in greater detail, it has become apparent that the relationship is bidirectional; both disorders and their treatment influence one another. Balhara suggests the association between the two illnesses is far more complex than previously thought (Balhara, 2011).

In this chapter, we will discuss type I and type II diabetes mellitus together. Only where the relationship to psychopathology is different will we specify the type of diabetes.

It is generally acknowledged that the presence of psychiatric illness in the context of diabetes mellitus can affect patient motivation and compliance with treatment recommendations. As such, psychiatric comorbidity is associated with decreased quality of life, increased cost of care, elevated glycosylated hemoglobin (HbA1c), and greater end organ damage, as well as increased healthcare service utilization, especially of emergency and hospital services. Given the frequency and consequences of the co-occurrence of diabetes and mental illness, many advocate for regular mental health screening measures in the diabetic population (Collins et al., 2009; Campayo et al., 2011; Balhara, 2011).

Diabetes Mellitus and Depression

Depression is nearly twice as common in individuals with diabetes as in those without (Sridhar, 2007; Campayo et al., 2011; Balhara, 2011). This relationship is felt to be bidirectional; having diabetes may increase one's risk of developing depression, and having depression may increase the likelihood

of developing diabetes, especially type II diabetes (Sridhar, 2007; Campayo et al., 2011; Balhara, 2011).

The risk of developing diabetes appears to be greatest when the preexisting depression is non-severe, persistent, and untreated (Campayo et al., 2011; Balhara, 2011). The association involves both health-related behavior and physiological abnormalities in the hypothalamic-pituitary-adrenal and sympathoadrenal systems that increase insulin resistance (Campayo et al., 2011).

Given the consequences of these coexisting illnesses (i.e. increased morbidity, mortality, healthcare costs, and decreased quality of life), screening and treatment are vital (Campayo et al., 2011; Balhara, 2011). Successful detection and treatment of depression may prevent the development of type II diabetes in patients at risk. Patients were considered at risk if they had persistent, non-severe depression (Campayo et al., 2011). A study comparing the Patient Health Questionnaire (PHQ-9) and the Hospital Anxiety and Depression Scale (HADS-D), two common self-administered tests used to assess depression, suggested that both are reliable tools. The latter (HADS-D), however, appears to provide results less influenced by somatic symptoms often seen in patients with diabetes in the absence of depression, specifically fatigue, sleep disturbances, and changes in appetite (Reddy et al., 2010). Diagnosing depression without considering somatic symptoms is, however, controversial.

Treatment of depression in diabetics is much the same as in non-diabetics, though one must be aware that antidepressants may affect appetite and blood glucose. Likewise, once depressive symptoms are treated, the patient may reengage in physical activity, which may further influence glycemic control.

The selective serotonin-reuptake inhibitors (SSRIs) are the preferred treatment for depression in diabetics due to their lack of effect on glucose metabolism, lower incidence of weight gain and carbohydrate craving, as well as the lower, but not absent, risk of anticholinergic and cardiac side effects (Goodnick, 1997). However, SSRIs can suppress appetite, enhance insulin sensitivity, and lead to hypoglycemia if diet and medication (oral hypoglycemics, insulin) are not adjusted accordingly (Sridhar, 2007). Tricyclic antidepressants should be avoided in the treatment of depression in patients with diabetes, as studies show a correlation with impaired fasting glucose as well as increased appetite and carbohydrate craving (Goodnick, 1997; Sridhar, 2007).

Treatment for diabetes in light of mental illness should be considered carefully, recognizing that cognitive disorders and symptoms of depression, including low motivation and suicidal ideation, may affect a patient's ability and willingness to comply with recommendations. Likewise, patients with diabetes are at greater risk for suicide than the general population, raising the question about the safety of insulin or oral hypoglycemics for disease management. The frequency of suicide attempts via insulin overdose is unclear, and consequences range from mild to severe, including encephalopathy and death. Among antidiabetic agents used with lethal intent, sulfonylureas were responsible for the greatest number of

deaths, though this may be related to the larger type II population, rather than to greater lethality. Medications should be monitored carefully in depressed diabetics, and some studies suggest discontinuation of insulin pumps during acute episodes of depression with suicidal ideation (Russell, Stevens, & Stern, 2009).

Diabetes Mellitus and Anxiety

The prevalence of anxiety disorders, specifically generalized anxiety disorder (GAD), in diabetics is two to three times that in non-diabetics (Collins et al., 2009; Balhara, 2011). As with depression, the presence of comorbid anxiety and diabetes mellitus is associated with elevated HbA1c levels (Balhara, 2011). Treatment of anxiety has been found, in some studies, to improve glycemic control (Grigsby, Anderson, Freedland, Clouse, & Lustman, 2002). It is important to note that the symptoms of anxiety disorders and depressive disorders often overlap, making a very distinct differentiation quite difficult. In most cases, though, treatment is very similar.

The relationship between anxiety and diabetes appears to be bidirectional in type II, but not type I diabetes; the risk of developing incident diabetes following a diagnosis of anxiety is far greater in type II diabetes. It is unclear if diagnosis of anxiety or presence of symptoms predicts onset of diabetes independently or through associated risk factors (later onset of illness, high-fat diet, smoking, etc.) (Engum, 2007).

Studies have shown the presence of incident anxiety in diabetic patients is independent of diabetes subtype. Risk factors associated with more severe anxiety in diabetics include: female gender, presence of diabetes complications, insulin use, unemployment, smoking, and past/present misuse of alcohol. Protective factors associated with a lower risk of developing comorbid anxiety include: older age, structured medical care, private medical insurance, and patient perception of adequate glycemic control (Collins et al., 2009).

In general, anxiety is treated much the same in diabetics as it is in non-diabetics, both pharmacologically and with cognitive behavioral therapy. Caution, however, should be used with pharmacotherapy, such as benzodiazepines and beta blockers, as they may mask the physiological symptoms of hypoglycemia, including tachycardia (Balhara, 2011). Studies suggest selective serotonin reuptake inhibitors are used with greatest frequency, owing to their potential synergistic effects; they have been found to provide adequate control of mood and anxiety symptoms while also improving diabetes self-care (Markowitz et al., 2011).

Diabetes, Eating Disorders, and Eating Disordered Behavior

Despite years of research, it remains controversial as to whether eating disorders, as classified by the DSM-III and DSM-IV TR, are more prevalent in diabetics than in non-diabetics (Herpertz et al., 2001). Some studies have found a high

prevalence of eating disorders and subclinical eating disorders in young female diabetic patients (Lloyd et al., 1987; Rosmark et al., 1986; Goodwin, Hoven, & Spitzer, 2003; Larranaga, Docet, & Garcia-Mayor, 2011). A small study focusing on eating disorders and disordered eating habits in young women with type I diabetes showed an incidence of 25% (Peveler et al., 2005). Most studies on the topic focus on young women and adolescents with insulin-dependent diabetes, but more recent work has suggested eating disorders are equally likely in non-insulin-dependent diabetes, though the features of the illness may differ (Herpertz et al., 1998).

In addition to eating disordered behaviors employed by non-diabetics, those with insulin-dependent diabetes frequently turn to insulin omission or underuse as a means to prevent weight gain and/or to promote weight loss. This appears to be the most common disordered eating habit in diabetics, particularly young women with insulin-dependent diabetes (Rodin & Daneman, 1992; Crow et al., 1998; Herpertz et al., 1998, 2001; Peveler et al., 2005). Weight control via this method has been termed *diabulimia* in the literature, though it is not specifically named in the current diagnostic manuals. Some report that this behavior is present in 30% of females with type I diabetes and suggest the initial effect of this behavior is rapid weight loss via glycosuria (Peveler et al., 2005).

Many studies have shown that diabetics engaging in eating disordered behaviors, particularly insulin omission or underuse, are at particularly elevated risk of experiencing physical complications of diabetes. Glycemic control in this population, as measured by HbA1c, is generally poorer than in those without eating disorders or disturbed eating behaviors. Both short-term complications (severe hypoglycemia, diabetic ketoacidosis [DKA]) and long-term complications (growth retardation, neuropathy, nephropathy, cardiovascular disease) are found with higher prevalence in diabetics engaging in eating-disordered behaviors (Rodin & Daneman, 1992; Peveler et al., 2005).

Providers should be suspicious regarding the presence of an eating disorder or disturbance in patients with persistently poor glycemic control, repeated episodes of DKA, and elevated concerns of weight (Larranaga et al., 2011). Screening for eating disorders is difficult in diabetics, as current rating scales generally incorporate items measuring dietary concern that are often prescribed as part of diabetes self-management. Even in the absence of a diagnosed eating disorder or subclinical eating disorder, one would expect these markers to be elevated in diabetics (Crow et al., 1998). There is suspicion that diabetics are at greater risk than non-diabetics of developing eating disorder syndromes secondary to the perceived and actual dietary restraint necessitated by management of their illness. This is particularly true in patients who eat according to a predetermined meal plan rather than in response to hunger and satiety cues. At present, there are no validated screening measures to accurately detect eating disorders in diabetics, though many experts use tools designed for the general population (Larranaga et al., 2011).

There is little in the current literature about prevention of eating disorders in the diabetic population. For those with type I diabetes, particularly young females, some suggest that

less restrictive and intensive dietary regimens may decrease their likelihood of developing disordered eating behaviors or diagnosable eating disorders. Others favor interventions aimed at increasing self-esteem and body acceptance, which are often compromised in those with chronic medical conditions (Larranaga et al., 2011). Treatment of eating disorders in those with diabetics is often complicated and is best delivered using a team approach, including physicians, diabetes educators, nutritionists, and therapists (Crow et al., 1998; Larranaga et al., 2011).

At present, there is no consensus about which—insulin pump therapy or multiple daily injections (MDI)—is more appropriate for those with comorbid diabetes mellitus and eating disorders. Recent studies, however, have shown that insulin pump therapy may decrease eating disordered behaviors and HbA1c, in comparison to MDI (Pinhas-Hamiel et al., 2010; Markowitz et al., 2013).

Diabetes Mellitus and Cognitive Changes

Many studies have shown an association between diabetes, both type I and type II, and the presence of cognitive decline (Christman et al., 2011). Cognitive status, as measured by the Mini Mental Status Examination (MMSE), appears to decline faster and further in diabetics in comparison to their non-diabetic cohorts. The most significant deficits were seen in tests of executive functioning and processing speeds (Ravona-Springer et al., 2010).

The exact cause of these cognitive changes remains unclear, and some studies have failed to reveal an association with HbA1c, the blood test reflective of long-term glucose control. Other studies, however, have found a correlation, but suggest that HbA1c is not the most significant predictor of cognitive decline in diabetic patients (Ravona-Springer et al., 2010). Current studies indicate that any of a number of mechanisms may lead to increased rate of cognitive decline, including rapid accumulation of advanced glycosylated end products (AGEs), which lead to tissue damage and inflammation, often in cerebral vasculature. In addition, it is thought that a state of hyperinsulinemia, seen in type II diabetics, may contribute to microvascular damage and may interfere with amyloid precursor protein metabolism, leading to cerebral beta amyloid deposits.

HYPOGLYCEMIA

Symptoms of hypoglycemia may be broken down into two distinct constellations: autonomic and neuroglycopenic effects. The autonomic effects are typically defined as adrenergic or catecholamine-mediated symptoms, including tachycardia, diaphoresis, tremor, weakness, hunger, irritability, and palpitations (McCrimmon, Frier & Deary, 1999; Frier, 2001; Graveling & Frier, 2009; Barendse, Singh, Frier, & Speight, 2012), and these hyperadrenergic symptoms can mimic a panic attack. An inadequate supply of glucose to the central nervous system (CNS), or neuroglycopenia, may result in faintness, headache, blurred vision, lethargy, confusion, dizziness, weakness, incoordination, bizarre behavior,

reversible focal neurological findings, seizures, and coma, which typically abates with normalization of glucose levels (McCrimmon et al., 1999; Strachan, 2000; Frier, 2001; Barendse et al., 2012). On formal cognitive testing, “accuracy is often preserved at the expense of speed” (Frier, 2001; Graveling & Frier, 2009).

The brains of the young or the elderly are more vulnerable to longer-lasting effects, and the number of hypoglycemic episodes is predictive of more persistent cognitive deficits (Frier, 2008; Bauduceau, 2010). Additionally, chronic hypoglycemia can lead to considerable personal and familial stress, chronic anxiety, sadness, “tense-tiredness,” overt pessimism, irritability, and anger (Frier, 2008). It is now commonly accepted that hypoglycemia is associated with negative mood states, and understood that negative mood states—including anxiety (such as fear of hypoglycemia) or depression—can worsen adherence to a diabetic regimen (Pirraglia & Gupta, 2007; Papelbaum et al., 2011; Rustad, Musselman, & Nemeroff, 2011).

The differential diagnosis of fasting hypoglycemia must include surreptitious administration of either insulin or an oral hypoglycemic agent. Factitious hypoglycemia secondary to one of these agents must be considered prior to pancreatic exploration for an islet cell tumor in any patient with hyperinsulinism. Up to 7% of patients on a sulfonylurea with adequate glycemic control and 25% of patients with type II diabetes on insulin experience one or more episodes of severe hypoglycemia per year (Barendse et al., 2012). The presence of anti-insulin antibodies or low C-peptide levels at the time of hypoglycemia strongly suggests a factitious etiology (Horwitz, 1989). Screening of urine or blood for sulfonylureas is available for patients suspected of surreptitious oral hypoglycemic-agent ingestion.

Historically, there was significant concern regarding the overdiagnosis of hypoglycemia (Cahill & Soeldner, 1974; Gastineau, 1983; Nelson, 1985), as “reactive hypoglycemia” was once a fashionable diagnosis to account for a variety of poorly defined physical and psychological ills (Yager & Young, 1974). The Minnesota Multiphasic Personality Inventory (MMPI) profiles of patients being evaluated for reactive hypoglycemia differed significantly from those of general medical patients, demonstrating the classic “conversion-V” triad (elevated scales Hs and Hy, and relatively lower scale D) suggestive of underlying emotional disturbance as the basis for their somatic complaints (Johnson et al., 1980). In recent years, however, it has become increasingly clear that the major clinical issue with hypoglycemia is the apparently cumulative effect of repeated hypoglycemic episodes, and that “the profound and negative effects of hypoglycemia on mood and emotion are often unrecognized” (Graveling & Frier, 2009). In a recent thorough review of the impact of hypoglycemia on quality of life, it was noted that “the detrimental impact of hypoglycemia extends beyond immediate physical consequences, and may include pervasive cognitive, behavioral, and emotional effects” (Barendse et al., 2012). This same review notes that “chronic mood changes, depression, and even phobia (of hypoglycemia) may be more common in those who have a history of recurrent severe hypoglycemia.” This detrimental

impact on mood and quality of life has been noted repeatedly (Gold, MacLeod, Deary, & Frier, 1995; Merbis, Snoek, Kanc, & Heine, 1996; Gold, Frier, MacLeod, & Deary, 1997; Williams, 2010; Fidler, Elmelund Christensen, & Gillard, 2011; Korczak, Pereira, Koulajian, Matejcek, & Giacca, 2011).

An important issue in the psychopharmacological management of patients with hypoglycemia is the risk of beta-blocker therapy. Early misdiagnosis of hypoglycemia as an anxiety disorder and treatment with agents whose action blocks the normal response to hypoglycemia may prevent the subjective experience of potentially lethal hypoglycemia. This mimics, and can potentially accelerate, the impaired awareness of hypoglycemia that can develop and is more common in elderly patients who have a long history of diabetes. Additionally, there is some suggestion that the use of antidepressants can impair glycemic control (Dijkgraaf, 2008), leading to hyperglycemia or hypoglycemia (Khoza, 2011), so serum glucose levels should be monitored more closely if any medication is added.

DEVIATIONS IN GONADAL HORMONES

MALE HYPOGONADISM

Male hypogonadism of any etiology may cause significant psychological distress and impaired social adjustment. Low self-esteem and self-confidence and feelings of inadequacy, isolation, and alienation are common.

KLINEFELTER’S SYNDROME AND XXY KARYOTYPES

The XXY karyotypes, the most common human chromosomal abnormality, occur in 1 of 500 live male births (DeLisi et al., 2005). Individuals with XXY chromosomes are generally characterized by tall stature, abnormal spermatogenesis, small testes, and breast tissue development (DeLisi et al., 2005; Slim et al., 2009). Klinefelter’s syndrome, and other XXY karyotypes, has been reported in association with a wide variety of psychiatric disorders, including mental retardation, personality disorders, depression, bipolar disorder, sexual deviance, neuroses, alcoholism, paranoid states, and schizophrenia (Caroff, 1978; Swanson & Stipes, 1969; DeLisi et al., 2005).

Studies have shown a four- to five-fold increase in the presence of schizophrenia in men with XXY karyotype in comparison to their XY cohorts. Interestingly, it is thought that auditory hallucinations, more than other psychotic symptoms, have been associated with the presence of a second X chromosome in men (DeLisi et al., 2005). The incidence of Klinefelter’s syndrome is five times higher in males who are in the mental health and penal systems than in males in the general population (Smyth and Bremner, 1998).

The most consistent association is a form of personality disorder characterized by passivity, dependency, and low social drive; it is thought that such traits may be related to androgen deficiency, although the exact mechanism remains

unclear (Swanson & Stipes, 1969). While major depressive disorder is seen in the XXY population, it is often difficult to separate this from personality traits characteristic of these people; namely, social isolation, passivity, and disinterest (Slim et al., 2009). In addition to standard treatment for depression in men with XXY genotypes, including psychotherapy and antidepressant medications, some studies have proven testosterone replacement therapy is effective in not only promoting development of secondary sexual characteristics, but also improving self-esteem, and, as a result, mood and anxiety (Smyth & Bremner, 1998). This remains controversial.

Cognitive and learning difficulties are common in patients with Klinefelter's. The deficits are seen most often in verbal IQ scores, speech and language acquisition and recognition, as well as in memory (DeLisi et al., 2005; Smyth & Bremner, 1998). Some studies have also shown a higher incidence of attention-deficit hyperactivity disorder (ADHD) and dyslexia in these males. The incidence of mental retardation increases with the number of supernumerary X chromosomes (Smyth & Bremner, 1998).

LOW TESTOSTERONE SYNDROME

Depression is often under-recognized and under-treated in the aging male population. It remains a serious problem, though, as evidenced by the increasing rates of suicide among this cohort. In the United States, suicide rates are highest in men over 65 years of age. This phenomenon is not unique to the United States. According to the World Health Organization (WHO), men over the age of 75 years had the highest rate of suicide in all but one country reporting. Experts remain unsure as to what predisposes this population to depression and suicide (Carnahan & Perry, 2004).

It remains controversial whether men, like women, experience "menopause." Literature within the fields of endocrinology, urology, and gerontology suggest that a male equivalent exists and have named it "the male climacteric," "andropause," and "low testosterone syndrome (LTS)" (Sternbach, 1998). For the purposes of this section, we will refer to it as LTS.

In healthy males, testosterone secretion peaks approximately at age 20 and steadily declines thereafter. Levels decrease more significantly after age 50 (Seidman & Walsh, 1999). The serum testosterone level at which one is diagnosed with LTS remains non-standardized, as the decline in hormone levels occurs gradually throughout life (Carnahan & Perry, 2004). Studies have shown up to 20% of males 60 years and older may have testosterone levels considered to be lower than normal (Seidman & Walsh, 1999).

The effect of declining testosterone levels on mood and anxiety continues to be unclear and inconsistent. Some have described a syndrome of depressed mood, increased anxiety, insomnia, irritability, and poor memory (Sternbach, 1998). Because of confounding factors, namely comorbid medical conditions, weight, alcohol, and tobacco use, and external stressors, it remains unclear if hypogonadism or LTS can cause depressed mood, increase stress-related vulnerability, or lead to resistance to standard antidepressant treatments (Carnahan & Perry, 2004).

Anecdotal reports suggest that testosterone replacement, orally, parenterally, or transdermally, can improve mood, energy, libido, sense of well-being, sleep, and appetite, in addition to other physical changes (Seidman & Walsh, 1999; Carnahan & Perry, 2004). There are, however, few long-term, placebo-controlled studies of testosterone replacement in elderly men, and it is important to note the treatment is not without potentially serious side-effects.

Given the overlap of symptoms in depressive syndromes and LTS, there is little evidence to support obtaining serum testosterone levels in all elderly men who present with depressed mood, low libido, and decreased energy (Sternbach, 1998). Testosterone testing and replacement may be reserved for men with treatment-refractory depression and/or dysthymia (Carnahan & Perry, 2004).

POLYCYSTIC OVARIAN SYNDROME

Polycystic ovarian syndrome (PCOS) is the most common reproductive endocrine condition in women and is characterized by chronic anovulation, obesity, insulin resistance, clinical hyperandrogenism, infertility, male-pattern baldness, and hirsutism (Rassi et al., 2010; Cipkala-Gaffin, Talbott, Song, Bromberger, & Wilson, 2012). It can affect 5–10% of women of reproductive age (Kerchner et al., 2009; Rassi et al., 2010; Cipkala-Gaffin et al., 2012).

Psychiatric illness, specifically major depression and bipolar disorder, are seen with high frequency in this population. Studies have shown the prevalence of depression can reach 50% in women with PCOS (Rassi et al., 2010). Additionally, higher rates of anxiety and body dissatisfaction with resultant eating disorders have been demonstrated (Himelein & Thatcher, 2006). Studies suggest that most of the physical manifestations of PCOS lead to anxiety and decreased health-related quality of life but do not, alone, account for the increased incidence of mood disorders in this population (Kerchner et al., 2009). Specifically, hirsutism and infertility were not correlated with increased levels of depression (Himelein & Thatcher, 2006). Increased weight and body mass index associated with PCOS, however, appear to increase a woman's risk of depression (Kerchner et al., 2009; Cipkala-Gaffin et al., 2012).

The comorbidity of bipolar disorder, types I and II, and PCOS is of high interest and may be bidirectional. Medications used to treat bipolar disorder, specifically valproate, may promote polycystic ovaries or lead to other menstrual irregularities (Himelein & Thatcher, 2006; Rassi et al., 2010). Rasgon and his colleagues completed a small outpatient study that suggested the menstrual irregularities and PCO symptoms seen in women with bipolar disorder are a result of hormonal abnormalities intrinsic to the mental illness, rather than of the treatment itself (Rasgon et al., 2000). Most studies to date have been small and inconclusive, and more research is warranted to better understand the complex relationship between bipolar disorder and polycystic ovarian syndrome (Himelein & Thatcher, 2006).

PCOS has also been associated with a higher prevalence of eating disorders, specifically bulimia nervosa and binge-eating

disorder, in comparison to non-PCOS populations (Himelein & Thatcher, 2006; Kerchner et al., 2009). It is believed this is related to higher rates of body dissatisfaction (Himelein & Thatcher, 2006). Given the high rate of mental illness in women with PCOS, it is important to regularly screen for and aggressively treat these diseases in the PCOS population (Kerchner et al., 2009).

PRE-MENSTRUAL DYSPHORIC DISORDER

Pre-menstrual dysphoric disorder (PMDD) was classified as an official mood disorder and added to the appendix of the *Diagnostic and Statistical Manual of Mental Disorders IV* (DSM-IV) in 1994. It is classified as a *Depressive disorder not otherwise specified*, and the diagnosis remains controversial (Di Giulio & Reissing, 2006; Pearlstein & Steiner, 2008; Zukov et al., 2010). PMDD affects less than 10% of women (Zukov et al., 2010).

Diagnosis of PMDD requires five or more of 11 possible symptoms present during the late luteal phase, approximately days 21–28 of the menstrual cycle. At least one of the five symptoms must be depressed mood, anxiety, affective lability, or irritability. Other symptoms include anhedonia, poor concentration, decreased energy, a sense of being overwhelmed, changes in appetite with particular cravings, changes in sleep, headaches, joint/muscle pain, and abdominal bloating. For diagnosis, these symptoms must be of sufficient severity to cause functional impairment (Di Giulio & Reissing, 2006; Pearlstein & Steiner, 2008). In actively menstruating females, symptoms typically remit within one week of menses (Di Giulio & Reissing, 2006; Ptacek et al., 2010). PMDD is absent after menopause, during pregnancy, and in other situations that may interrupt the cycle of ovulation (Di Giulio & Reissing, 2006). The diagnosis and treatment of this disorder are discussed in detail in Chapter 67.

The cause of PMDD is as yet unknown, but research has focused on serotonin, gonadal and other hormones, as well as genetics and environmental stresses (Di Giulio & Reissing, 2006; Pearlstein & Steiner, 2008). Women with PMDD are more likely to have a history of depression and are more likely to develop subsequent depression following a diagnosis of PMDD (Di Giulio & Reissing, 2006).

Thus far, derangements and dysregulation of the serotonergic system are the most probable causes of PMDD. This is not surprising, giving the significant overlap in symptomatology in PMDD and other depressive illnesses. In addition to depressed mood, decreased serotonin levels have been found to be associated with symptoms more specific for PMDD, including mood swings, self-deprecation, poor impulse control, and decreased pain threshold (Di Giulio & Reissing, 2006).

Treatment studies also support the serotonin hypothesis of PMDD causality, as SSRIs have proven efficacious in decreasing symptoms. A systematic review demonstrated a response rate seven times greater in PMDD patients treated with an SSRI in comparison to those treated with placebo.

Improvement of PMDD symptoms with SSRI treatment is far more rapid in comparison to major depressive disorder; women can experience improvements in symptoms within a few days of treatment initiation. As such, some experts opt to use SSRI medications three to seven days before the onset of menses and discontinue use at the onset of menstruation or shortly thereafter. Dosage requirements for women with PMDD are often lower than for those with depression. Studies comparing the efficacy of intermittent versus continuous use of SSRIs in the treatment of PMDD have, thus far, been inconclusive (Di Giulio & Reissing, 2006; Pearlstein & Steiner, 2008; Ptacek et al., 2010).

CONSULTATION BETWEEN ENDOCRINOLOGY AND PSYCHIATRY

Evaluation of endocrine disorders has traditionally occurred only after the demonstration of systemic signs and symptoms, including dermatological changes, electrolyte and metabolic disturbances, and other evidence of hormonal abnormalities, trigger the diagnostic workup. Expanding awareness of cognitive, affective, and behavioral changes associated with endocrinopathies should facilitate earlier recognition of these treatable disorders.

The personal experience of the psychiatrist determines his or her level of comfort and confidence when administering and interpreting endocrine tests. If a psychiatrist chooses not to pursue an endocrine evaluation when clinically indicated, the primary care physician should pursue the endocrine consultation and serve as intermediary between the specialties if necessary. With collaboration, both the psychiatrist and the endocrinologist can define their limits of confidence with the evaluation and treatment of secondary mental disorders due to endocrine dysfunction. Certainly, having a specialist in each facet of the issue involved and communicating with each other would be expected to result in a better, more precise balance being achieved.

SUMMARY

Endocrine disturbances frequently mimic or exacerbate psychiatric disturbances, and psychiatric illness can clearly exacerbate endocrinological disease; if not directly, then as a result of decreased compliance with treatment. “High-risk” groups, which require careful endocrine and psychiatric evaluation, include the following:

- Patients with mood and other unusual behavioral symptoms and coexistent cognitive dysfunction, especially geriatric patients
- Patients with inconsistent or atypical presentations of psychiatric disorders
- Patients with mental symptoms that are refractory to standard psychiatric treatments

- Patients with symptoms of dementia or other cognitive dysfunction syndromes
- Patients with known preexisting endocrine abnormalities
- Patients with affective symptoms after closed-head injury
- Patients with a family history of either psychiatric or endocrine disorders
- Patients on medications known to affect endocrine functioning (amiodarone, lithium, antipsychotics)
- Patients with a history of brain tumor

CLINICAL PEARLS

- The onset of symptoms of hypothyroidism is often gradual and, especially in the elderly, mimics the development of a degenerative dementia.
- In contrast to cortical dementias such as Alzheimer's disease and frontotemporal degeneration, the cognitive disorder of myxedema does not present with discrete cortical syndromes like aphasia, anomia, apraxia, and frontal disinhibition.
- In Cushing's syndrome, depression is extremely common, and persistent elation rare.
- The majority of cases of primary hyperparathyroidism are asymptomatic (Benge et al., 2009).
- The diagnosis of Addison's disease commonly is delayed. In one cohort of 216 patients with adrenal insufficiency, 41% received a false diagnosis of a psychiatric illness (Bleiken et al., 2010).
- Risperidone is the atypical antipsychotic most likely to cause hyperprolactinemia.
- Acromegaly is associated with depression, psychosis, and amotivational syndrome (De Sousa, 2009).
- Those with insulin-dependent diabetes and eating disorders frequently turn to insulin omission or underuse as a means to prevent weight gain and to promote weight loss.
- The presence of anti-insulin antibodies or low C-peptide levels at the time of hypoglycemia strongly suggests a factitious etiology (Horwitz, 1989).
- Beta-blocker therapy may prevent the normal sympathetic response to potentially lethal hypoglycemia in insulin-dependent diabetics.
- In Klinefelter's syndrome, XXY, boys with hypogonadism, cognitive and learning difficulties are seen most often in verbal IQ scores, speech and language acquisition and recognition, as well as in memory (DeLisi et al., 2005; Smyth & Bremner, 1998).

DISCLOSURE STATEMENTS

Dr. Sterenson, Dr. Sola, and Dr. Sampson have no conflicts of interest. Dr. Sampson has research funded by the National Institute of Mental Health (NIMH) and has been involved in research with equipment support from Neuronetics, Inc.

GASTROENTEROLOGY

Donna B. Greenberg

THE BRAIN–GUT AXIS

For Franz Alexander, ulcerative colitis was one of the psychosomatic illnesses with chronic parasympathetic stimulation like asthma, as distinct from the chronic sympathetic stimulation of hypertension, diabetes, rheumatoid arthritis, and thyrotoxicosis. He thought that a specific conflict that could be expressed in overdrive of the parasympathetic or sympathetic nervous system could lead to specific diseases. “First, the functional disturbance of a vegetative organ is caused by chronic emotional disturbance; and second, the chronic functional disturbance gradually leads to tissue changes, and to irreversible organic disease” (Alexander, 1950). Engel pointed to a transient state of helplessness and hopelessness in patients with ulcerative colitis that could be alleviated but not cured with psychotherapy (Engel, 1958, 1961).

Gut feelings of anxiety, anguish, revulsion, or a need to flee—stomach butterflies, the lump in the throat, loss of appetite, nausea, or hyperactive bowels—are part of the human experience. The mind is connected to the gut. Nervous diarrhea was mentioned in nineteenth-century medical texts and reviewed in a 1936 *New England Journal of Medicine* paper (Aronowitz & Spiro, 1988; Sullivan, 1936). Selye (1956) linked stress and ulcers, but the role of *Helicobacter pylori* and the effectiveness of proton pump inhibitors pushed psychic causes of ulcer into the background. Nonetheless, peptic ulcer still has a psychosomatic component: patients with existing ulcers can become more symptomatic when they are under stress (Choung & Talley, 2008), and the questions remain as to why many more patients are infected with *H. pylori* than have ulcers, and how *H. pylori* and emotional factors interact in the production of non-ulcer dyspepsia. Emotion can increase gastric acid production (Wolff & Wolff, 1943; Brady et al., 1958), and animal studies have shown that an unpredictable, uncontrolled environment facilitates the development of ulcers. The availability of behavioral coping strategies can reduce vulnerability (Overmier & Murison, 2013). An epidemiological literature supports the relationship between life stress and peptic ulcer, its severity and tendency to recur. (Levenstein, 2002).

Since the time of Alexander, the neuroanatomy of the interactions between the brain and the enteric nervous system has been more clearly delineated (Mayer et al., 2006; Bonaz & Bernstein, 2013; Mayer et al., 2011). The *brain–gut axis*, better understood through functional neuroimaging studies, refers

to the connection between the autonomous nervous system and circumventricular organs. The sensory circumventricular organs—the area postrema, the subfornical organ, and the organum vasculosum of the lamina terminalis—sense molecules in plasma and pass information to the rest of the brain and autonomic nervous system. The activity of the secretory component of the circumventricular organs (the subcommisural organ, the posterior pituitary, the pineal gland, median eminence and intermediate lobe of the pituitary) is based on feedback from the brain and external stimuli.

The central autonomic system integrates visceral information from the enteric nervous system embedded in the lining of the GI tract with sensory information from other peripheral sites and affective and sensory information from the limbic system. Homeostatic emotions—the motivations and feelings that come with changes in the body’s condition—are associated with autonomic responses and behavior that corrects an imbalance: for instance, low glucose leads to hunger and eating behavior (Mayer et al., 2006). Other typical visceral sensations are thirst, vasomotor flush, satiation, fullness, and urgency. The proposed framework for this process is that homeostatic emotions have a sensory dimension processed in the anterior insula and an affective/motivational dimension processed in the dorsal anterior cingulate cortex. The right anterior insula seems to hold the subjective awareness of homeostatic emotions as well as emotions of anger, fear, disgust, happiness, trust, love, empathy, and social exclusion (Mayer et al., 2008). The sensory signals of hunger or pain usually remain in the background to modulate homeostasis and color the memories of experience. This system provides a context for visceral memories.

The parasympathetic nervous system includes the vagus nerves that innervate the foregut and the sacral nerves that innervate the hindgut. Sacral parasympathetic pelvic nerves and mixed splanchnic nerves with both afferent and efferent fibers communicate between the gut and the thoracolumbar and sacral spinal cord. The vagus nerves are 90% afferent, and vagal afferent neurons respond to both mechanical and chemical signals; for example, distention of the stomach or intestines and differences in the composition of food in the stomach. Vagal cholinergic efferents have anti-inflammatory actions as well as effects on gastrointestinal (GI) motility. The sympathetic nerves are half afferent and half efferent and transmit signals of visceral pain to the central nervous system. The sympathetic nervous system is typically pro-inflammatory.

Autonomic afferent axons, whether traveling through parasympathetic or sympathetic nerves, terminate in the nucleus tractus solitaries in the medulla.

Because the circumventricular organs are outside the blood–brain barrier, they are also sensitive to circulation of emetic stimuli and to the inflammatory cytokines that modulate the hypothalamic-pituitary-adrenal (HPA) axis and the production of glucocorticoids. The prefrontal-amygdaloid complex integrates the balance of sympathetic and parasympathetic activity and the HPA axis. The prefrontal cortex modulates the outflow of vagus nerve efferents. The hypothalamic corticoid releasing factor system adapts to chronic stress. This affects the intestinal response, including the intestinal barrier, luminal microbiota, and the intestinal immune response.

Mayer posits that interoceptive memories of complex homeostatic states with both affective and motivational dimensions like pain, nausea, hunger, and satiation may be encoded during development from infancy so that a child has a value-based map of the world analogous to Damasio's concept of "somatic markers." The somatic markers may be memories of body states encoded as meta-representations in the orbitofrontal cortex (Mayer, 2011). In this way, unconscious visceral memories may color current experience and decision making. These distresses may come to the foreground for functional GI patients who are more attentive, perhaps more able to perceive these signals, and more distressed by them.

FUNCTIONAL GASTROINTESTINAL DISORDERS

The functional gastrointestinal disorders identified by symptoms in the absence of known anatomical and biochemical abnormalities have been defined by consensus of a group of international clinical investigators and the third iteration, the Rome III criteria, were further developed with the hope that the definitions will lead to more clarity in the pathophysiology (Drossman, 2006). Rome III categories for functional gastrointestinal disorders (Tack et al., 2006) include:

1. *Functional esophageal disorders*: functional heartburn, chest pain of presumed esophageal origin, functional dysphagia and globus;
2. *Gastroduodenal disorders*: functional dyspepsia (postprandial distress and epigastric pain); belching disorders: aerophagia, excessive belching, and belching; nausea and vomiting disorders: chronic idiopathic nausea, functional vomiting, and cyclic vomiting syndrome;
3. *Functional bowel disorders*: irritable bowel syndrome, functional bloating, diarrhea, and constipation;
4. *Functional abdominal pain syndrome*;
5. *Functional gallbladder and sphincter of Oddi disorders*: gallbladder dysfunction, biliary sphincter of Oddi disorder, pancreatic sphincter of Oddi disorder; and

6. *Functional anorectal disorders*; fecal incontinence; anorectal pain (chronic proctalga, levator ani syndrome, unspecified anorectal pain); functional defecation disorder (dyssynergic defecation and inadequate defecatory propulsion).

Historically, there has been an overlap between functional GI disorders and gastrointestinal motility disorders (Drossman et al., 2006; Ouyang & Locke, 2007). The functional disorders are contrasted to conditions with clear evidence for GI dysmotility like pelvic floor dyssynergia, Hirschsprung's disease, scleroderma, colonic inertia, and gastroparesis (Ouyang and Locke, 2007). The syndromes of pain in different functional disorders may not be distinct, as a patient may transition from one to another. The pattern of pain is similar to that in diabetic gastroparesis, celiac disease, and inflammatory bowel disease. These chronic GI disorders overlap with anxiety, depression, and somatization, and with other persistent pain disorders like painful bladder syndrome/interstitial cystitis, temporomandibular joint (TMJ) disorder, and fibromyalgia (Mayer & Tillisch, 2011).

The Rome group and others emphasized that effective treatment of patients with functional GI disorders requires an understanding of the psychosocial background against which symptoms occur (Jones et al., 2007). Patients do better who are not suffering from depression, panic, neurasthenia, a history of abuse, and illness worry. Histories of physical or sexual abuse are high (30–56%) in referral populations. A review of the psychosocial aspects of functional gastrointestinal disorders (Levy et al., 2006) highlighted the importance of the physician–patient relationship and a stepped-care approach, educating the patient about the condition, offering symptomatic treatment and simple behavioral or life style changes, and then the opportunity for a psychological assessment and assessment of psychiatric diagnoses. After medical therapies such as lifestyle changes, dietary manipulation, prokinetics, proton pump inhibitors, laxatives, bulking agents, antidiarrheals, and antispasmodics, relaxation therapies can be combined with an antidepressant medication (Jackson et al., 2000) and then more formal psychotherapies. Those with most evidence of depression, panic, history of abuse, and illness worry would benefit from the addition of thoughtful psychological care.

GLOBUS

Globus, the sensation of a lump in the throat, something stuck, or tightness in the throat, has been attributed to esophageal dysfunction. In some patients it may evolve into a fear of swallowing. The symptom is extremely common, mostly in women, and is often seen by otolaryngologists. Direct laryngoscopy and barium studies of swallowing are a critical part of the evaluation to rule out abnormalities, including cancer or other anatomical causes of the lump in the throat. Patients may try to dislodge the "lump" by swallowing repeatedly. Gastroesophageal reflux was noted in about 25% of patients with globus (Clouse et al., 1999), and patients are commonly treated with proton pump inhibitors. The term *globus*

hystericus has evolved to *globus pharyngeus* (Lee & Kim, 2012). Historically, globus has been associated with anxiety, phobia, and grief. It has been the fourth most common symptom in somatization disorder. Antidepressants can be useful if there are other signs of panic disorder or depression (Clouse et al., 1999).

FUNCTIONAL DYSPEPSIA

Proton pump inhibitors and prokinetic drugs are often used for functional dyspepsia with consideration of gastroesophageal reflux disease and the possibility of delayed gastric emptying. Buspirone, the 5HT_{1A}-receptor agonist, has been shown to relax the proximal stomach in healthy subjects and to improve functional dyspepsia better than placebo (Tack et al., 2012). Venlafaxine also enhances gastric accommodation and reduces sensations of distension, but a randomized controlled study of venlafaxine did not find benefit for functional dyspepsia (van Kerkhoven et al., 2008). Particularly in women, tricyclic antidepressants reduce sensations in response to food, including nausea and delayed gastric emptying (Grover et al., 2013).

CYCLIC VOMITING SYNDROME

Cyclic vomiting syndrome (CVS) is a syndrome of three or more recurrent discrete episodes of vomiting, variable intervals of completely normal health between episodes, and stereotyped episodes repetitive in symptom onset and duration, with no laboratory or imaging findings suggesting another diagnosis. By contrast, functional vomiting occurs once or more per week without evidence of an eating disorder, rumination (a gastrointestinal disorder of effortless regurgitation), or another psychiatric diagnosis (Olden & Chepyala, 2008). CVS is mostly seen in children with a history or family history of migraine headaches. In adults, CVS like functional vomiting is rare. Both are associated with migraines. The prevalence of anxiety and depression is not elevated in CVS, but sometimes there is a distinct aura that precedes emesis like an aura often precedes a migraine. Triggers for this syndrome are like the triggers for migraine: menses, infection, motion sickness, sleep deprivation, infection, stress, and foods with high tyramine content such as cured meats, aged cheeses, and pickled meat or fish. Anti-migraine medications like low-dose propranolol, sumatriptan, cyproheptadine, valproic acid, carbamazepine, and phenobarbital have been used, as well as erythromycin as a prokinetic agent. There are no randomized studies of treatment, but low-dose tricyclic antidepressants have led to improvement in small studies. Zonisamide 400 mg/day or levetiracetam have been effective in some cases (Choung et al., 2008; Choung et al., 2013).

In the differential diagnosis of CVS is *cannabis hyperemesis syndrome*. In fact, CVS more than functional vomiting is associated epidemiologically with young men who use cannabis (Choung et al., 2008; Choung et al., 2013). Cannabis hyperemesis syndrome—recurrent episodes of severe nausea

and intractable vomiting with colicky or epigastric pain—is associated with daily heavy cannabis use for years. Patients learn that relief comes with hot baths or showers and may compulsively bathe (Chepyala & Olden, 2008). Episodes last one to several days and may repeat over months. Relief comes with cessation of cannabis use. Patients are often constantly sipping water (Sullivan et al., 2010). The mechanism is unknown (Sontineni et al., 2009).

IRRITABLE BOWEL SYNDROME

Irritable bowel syndrome (IBS) is a condition of chronic abdominal pain and altered bowel habits categorized by the predominant pattern: diarrhea, constipation, or both. The definition suggests that symptoms occur at least three days per month and are associated with change in stool frequency or form and relief with defecation. IBS occurs in 10–15% of the population, 1.5 times as often in women; and only a small proportion of these (15%) seek care. Diarrhea is associated with cramps, urgency, frequent stools while awake, and mucus in the stool (American College of Gastroenterology [ACG] IBS Task Force, 2009).

Mechanisms

IBS is attributed to an interaction between intestinal microbiota, the mucosal barrier, and immune activation, nerve plasticity, visceral hypersensitivity, enteroendocrine factors, and the amplification of these contributors by anxiety and depression. Visceral hypersensitivity is thought to contribute to abdominal pain and reflect altered neurotransmission. Low thresholds to sensory perception have been found in esophagus, stomach, small bowel, and colon; however, only a portion of patients with IBS have such hypersensitivity. Gut enterochromaffin cells contain 90% of human serotonin (Barbara et al., 2011).

Visceral sensation is modulated by the 5-HT₃ receptor and non 5-HT₃ receptor-dependent mechanisms on vagal or spinal sympathetic afferent nerves; and mucosal 5HT may have a role in IBS. Some patients with IBS have an infectious trigger, with IBS following acute infectious enteritis. Abnormal microbiota may activate mucosal innate immune responses that increase epithelial permeability, activate nociceptive sensory pathways, and dysregulate the enteric nervous system (Simren et al., 2013). Some interventions to alter the intestinal microbiome—diet, probiotics, fiber, and non-absorbable antibiotics—have been used clinically; however, the significance of the flora for a particular patient cannot be defined clinically beforehand.

The role of altered motor function in the colon and the pelvic floor has gained importance. The disturbances of colonic motility can be documented by the radiopaque-marker transit time, scintigraphy, or wireless motility capsule (Rao et al., 2011). Pelvic-floor retraining for evacuation disorders can have a role for anismus (the failure of the pelvic floor muscles to relax with defecation), pelvic floor dyssynergia or puborectalis spasm, and descending perineum syndrome, all syndromes that meet criteria for IBS in adults. These may also

cause bloating that worsens throughout the day (Camilleri & DiLorenzo, 2012).

Factors that should set off alarms about the diagnosis of IBS and warrant further workup are older age and male gender, weight loss, nocturnal symptoms, family history of colon cancer, anemia, rectal bleeding, and recent antibiotic use. (Spiller et al., 2007).

Interventions

A sequence of dietary changes is often one aspect of treatment. Food sensitivity—both immune-mediated and pseudo-allergic—can be considered (Bischoff & Crowe, 2005). Food elimination may begin with exclusion of gas-producing foods like onions. The role of dietary fermentable oligosaccharides, disaccharides, monosaccharides, and polyols (FODMAPs) in causing symptoms has led to exclusion of apples, cherries, peaches, nectarines, artificial sweeteners, most lactose-containing foods, legumes, broccoli, Brussels sprouts, cabbage, and peas (Halmos et al., 2013). A trial exclusion of gluten is also a consideration (Boettcher & Crowe, 2013).

The ACG review of the evidence on medications and strategies for treatment of IBS (ACG, 2009) supported short-term benefit of antispasmodics like hyoscyne, cimetropium, pinaverium, and peppermint oil. Loperimide is effective for diarrhea. The benefit of fiber was not clear. Bifidobacteria and some combinations of probiotics have offered benefit, but lactobacilli has not.

Both 5HT₃ antagonists and 5HT₄ agonists have been used for IBS symptoms (Barbara et al., 2011). Of the drugs developed for IBS, alosetron, the 5-HT₃ receptor antagonist, is only used in women with severe IBS and diarrhea who have not responded to other therapies. Lubiprostone, a selective C-2 chloride channel activator, has been useful at 8 mg bid in women with constipation. The 5-HT₄ receptor agonist tegaserod helpful for female patients with constipation was taken off the market due to side effects.

THE PSYCHOLOGICAL DIMENSION

IBS is more common in families, presumably from both genetic and environmental factors. Parents can be role models for sickness behavior; also, parents' responses to a child's illness behavior can reinforce it. Diminishing this reinforcement can reduce recurrent abdominal pain in children (Levy et al., 2006). A history of sexual, physical, and/or emotional abuse is common in patients with functional gastrointestinal disorders as it is in other conditions of chronic pain. A history of trauma and current post-traumatic stress disorder is often found (Irwin et al., 1996). The connection between previous trauma and IBS has been attributed to concurrent psychiatric disorder, psychological distress, the tendency to report many somatic symptoms, increased hypervigilance about symptoms, maladaptive coping styles like catastrophic thinking, lack of social support, amplified sensory signals, and increased sympathetic function with hyperarousal (Levy et al., 2006; Halpert & Drossman, 2005). Many patients are

depressed or anxious. IBS may overlap and co-occur with fibromyalgia or chronic fatigue syndrome and has been seen as one of the functional somatic syndromes with higher than expected psychiatric comorbidity (Barsky & Borus, 1999; Nater et al., 2013).

Gastroenterologists caring for IBS patients are encouraged to interview their patients in a comprehensive way, more typical of a psychiatric evaluation than a typical medical examination (Levy et al., 2006). This acknowledges that those who come for treatment are more chronically distressed, in more chronic pain, and that their nervous system and psychological context affect treatment outcome. Understanding patient's concerns, like fear of cancer, the impact of the disorder on their life, and the psychological context at times of exacerbations makes a difference. Treatment of anxiety and depression improves bowel and other symptoms. (Spiller et al., 2007).

Two recent meta-analyses have concluded that antidepressants are helpful for IBS (Ford et al., 2012; Ruepert et al., 2011). Both tricyclic antidepressants and selective serotonin-reuptake inhibitors (SSRIs) have shown benefit. Tricyclic antidepressants have a better record of treatment for visceral pain, and the analgesic effect occurs at doses below the usual antidepressant range. Most studies with SSRIs have used paroxetine or fluoxetine (Grover & Camilleri, 2013). Since the analgesic benefit of antidepressants comes with lower doses, an effect that may be separate from their effect on mood, clinicians can describe these drugs as central analgesics (Grover & Drossman, 2008).

Some psychotropic medications have been studied for specific effects on the gut. In regard to colonic motility, compliance, and sensation, buspirone had no effect. Venlafaxine increases colonic compliance, relaxes tone, reduces postprandial colonic contraction, and tends to increase thresholds for sensation and gas. It reduces pain-sensation ratings as provoked by graded distension. Venlafaxine does not alter colonic transit time nor does paroxetine or buspirone (Chial et al., 2003). Citalopram has been shown to reduce pain, bloating, and overall symptoms independent of anxiety, depression, and colonic sensorimotor function (Grover, 2013).

For the psychiatrist familiar with the profile of antidepressants, a reasonable strategy would be to use tricyclic antidepressants for their analgesic effects and constipating side effects as well as antidepressant effects in patients with IBS with prominent diarrhea. SSRIs may be neutral in the patients with more prominent constipation (Grover & Drossman, 2008). It is worth noting that a specific SSRI can occasionally make diarrhea worse; sertraline in depression studies caused diarrhea in 18% of subjects, compared to 9% in placebo (Micromedex, 2009). Both venlafaxine and duloxetine have about a 10% rate of constipation as an adverse effect, and paroxetine, although anticholinergic in part, has a similar rate of both constipation and diarrhea. Olanzapine has some benefit for nausea, and quetiapine 25–100 mg has had benefit for augmenting treatment in patients with severely refractory symptoms (Grover & Drossman, 2008).

Focused attention on antidepressant medication adherence, as practiced in collaborative care studies for depression

and titration of medication in the context of the physician–patient relationship, would improve the outcome of IBS patients (Sayuk et al., 2007). One-quarter of outpatients seen by gastroenterologists do not adhere to the antidepressant regimens offered by the gastroenterologist for their IBS.

Interpersonal psychodynamic therapy has been shown to be beneficial in patients with severe IBS, reducing healthcare costs over the following year (Creed et al., 2003). Patients with social inhibition and dependency had a longer disease duration, and improvements in interpersonal difficulties independently predicted better health status (Hyphantis et al., 2009).

Behavioral therapy has also proven more effective than placebo at relieving individual IBS symptoms (Drossman et al., 2003; Spiller et al., 2007). Strategies of cognitive behavioral treatment include reframing maladaptive beliefs, reducing over-responsiveness to stress, changing catastrophizing, reducing anxiety about symptoms, reducing shame or guilt, and changing maladaptive behavior (Grover & Drossman, 2008). Benefits are reported with relaxation therapy, biofeedback, and hypnotherapy, which has shown benefit in otherwise refractory patients (Spiller et al., 2007).

While antidepressants are known to benefit these patients, ameliorating chronic pain and affective syndromes, the way these medications should interplay with other gastrointestinal medications and treatments is not clear (Wald, 2014). The medical psychiatrist and psychologist, watching more closely how the patients care for themselves and how their symptoms interact with the patients' roles and life stresses, have an opportunity to make psychotherapeutic interventions, especially in the most distressed patients.

FECAL INCONTINENCE

Fecal incontinence, the involuntary passage of stool or the inability to prevent expulsion of stool, is a serious cause of embarrassment, social isolation, and narrowing of the patient's world. In the elderly, it is sometimes a reason for nursing home placement. The incontinence may come as *urge incontinence* when the patient actively tries to prevent the stool from being released before reaching the bathroom; or passively as a consequence of involuntary loss without awareness. Sometimes patients' clothes are soiled by fecal seepage after normal evacuation (Shah et al., 2012). Patients may not mention incontinence to their physicians or may talk about it as fecal urgency or incomplete evacuation. Risk factors are history of pelvic radiation, obstetrical trauma, depression, chronic diarrhea, and urinary incontinence. In older patients, anatomical changes in the anorectal unit leading to decreased squeeze pressures come with age, stroke, dementia, and diabetes. Fecal incontinence due to seepage sometimes occurs from fecal impaction due to constipation.

Lactose, fructose, or sorbitol malabsorption can contribute to urgency. Sorbitol is an osmotic laxative found in dietetic foods that diabetics may seek out. Other contributors to incontinence are mental status changes that impair awareness or planning for getting to the bathroom in time. Conditions that impair peripheral nerve pathways like diabetes, polyneuropathies, cauda equina syndrome (compressing

the sacral nerves), toxic neuropathy, and multiple sclerosis explain some of the loss of effective external and sphincter pressure. From the history, the clinician can gather information on stool consistency, urgency, lack of sensation of stool passage, and urinary incontinence. From the rectal examination, resting and squeezing anal sphincter tone, masses, hemorrhoids, prolapse, and intact sensation can be defined. Anorectal manometry and ultrasound are the most common tests if surgery is considered for sphincter injury (Lazarescu et al., 2009).

INFLAMMATORY BOWEL DISEASE

In the modern age, depression or anxiety are not seen simply to be risk factors for the development of ulcerative colitis or Crohn's disease. Perceived psychological stress and depression at the onset of illness, however, are risk factors for relapse of the disease. Patients with higher depressive scores at the time of a flare-up of inflammatory bowel disease were more apt to relapse sooner (Mittermaier et al., 2004). However, at least one study did not find that the diagnosis of major depressive disorder predicted relapse (Vidal et al., 2006).

Careful evaluation of depression and consideration of antidepressants has a key role in the care of patients with inflammatory bowel disease (Tache & Bernstein, 2009). Depressive disorder or generalized anxiety has been noted in 20% of patients with Crohn's disease or ulcerative colitis (van Assche et al., 2013), and depressive symptoms are associated with active disease (Hauser et al., 2011). Lifetime diagnosis of major depressive disorder is higher in IBD patients, and panic disorder is even more common. In one study, those with depression had developed the disease younger and been diagnosed younger. Depression often antedated the inflammatory disease by more than two years (Walker et al., 2008). Furthermore, in Crohn's disease, patients were more apt to achieve remission with infliximab if they did not have major depression (Persoons et al., 2005). While psychosocial treatment thus far has not prevented relapses, one study of psychodynamic psychotherapy and relaxation treatment in patients with Crohn's disease did show a reduction in healthcare utilization after psychological treatment (Deter et al., 2007).

About one-third of patients at a center for IBD feel the need of psychological treatment, especially if they are younger with limited social support. They benefit from relaxation exercises, adjunctive psychotherapy, and antidepressants. A retrospective case-control study suggests that cognitive behavioral therapy and antidepressants may improve the course of IBD, reducing relapse rates, the use of corticosteroids, and endoscopies (Goodhand et al., 2012). However, there has not been a definitive prospective study to show this. Corticosteroids are still used in flares of the disease and may contribute an element of affective instability.

IBS symptoms may also occur in the setting of healed anti-inflammatory disease (Mikocka-Walus et al., 2007), and gastroenterologists commonly use antidepressants to alleviate these symptoms in patients with IBD. The prevalence

of depression in patients with IBD, and the suggestion that depression may interfere with remission or hasten relapse, argues for screening and treatment of depression in those with moderately severe IBD. The medical psychiatrist can contribute by championing multimodal treatment for depression and anxiety, paying attention to sleep and function, and using psychotherapies that facilitate coping.

CELIAC DISEASE AND NON-CELIAC GLUTEN SENSITIVITY

CELIAC DISEASE

In celiac disease, predisposed individuals cannot tolerate gluten, and gluten causes intestinal malabsorption, intestinal villi atrophy, and chronic inflammation of the jejunal mucosa. This is a genetically determined immune-mediated syndrome based on inappropriate response of T-lymphocytes to the gluten antigen. It affects multiple organs, including the skin, thyroid, heart, pancreas, spleen, liver, and nervous system. Patients with malabsorption, weight loss, steatorrhea, postprandial abdominal pain, and bloating should be tested for celiac disease.

Confirmation of a diagnosis of celiac disease should be based on a combination of findings from the medical history, physical examination, serology, and upper endoscopy with histological analysis of multiple biopsies of the duodenum. Both serology and biopsy should be performed while the patient is on a gluten-containing diet. Immunoglobulin-A (IgA) anti-tissue transglutaminase antibody (TTG) is the preferred single test for detection of celiac disease. A total IgA level is often obtained to eliminate the possibility that IgA itself is low. If IgA is low and the TTG is negative, then IgG TTG and deamidated gliadin peptide can be obtained. The test for antibodies against native gliadin is not recommended to detect the diagnosis, as it is less sensitive and is associated with too many false positives.

Patients with a first-degree family member who has a confirmed diagnosis of celiac disease should be tested if they show possible signs or laboratory evidence of celiac disease. Patients with type 1 diabetes who have some digestive symptoms should be tested for celiac disease. *HLA-DQ12/DQ8* genotyping should not be used routinely in the initial diagnosis of celiac disease but can be used to rule out the disease in patients with certain conditions like Down's syndrome. If the genotype is not *HLA-DQ12/DQ8*, then celiac disease in Down's syndrome patients is unlikely. This *HLA-DQ* typing test might also be used to try to exclude celiac disease prior to embarking on a formal gluten challenge (Rubio-Tapia et al., 2013).

Psychiatric symptoms in celiac disease include depression, anxiety, irritability, and apathy. Treatment with a gluten-free diet leads to recovery of the jejunum but may take years. In a cross-sectional survey of 2,265 adult patients with celiac disease in the Netherlands, the lifetime prevalence of self-reported depressive symptoms was 39%. Keeping a gluten-free diet for longer than five years was associated with

a lower risk of current depressive symptoms, compared to the diet for less than two years (van Hees, 2013). Nutritional deficiencies—for instance, iron, folate, and vitamin D deficiency—should be considered as contributors to affective presentations in patients with this cause of malabsorption.

NON-CELIAC GLUTEN SENSITIVITY

A syndrome of gluten sensitivity in patients with IBS who do not have celiac disease has been suggested to cause GI symptoms, including bloating, abdominal pain, and persistent fatigue (Biesiekierski et al., 2011). Gluten sensitivity does not seem to have a familial risk or be associated with autoimmune disorders or intestinal malignancy (Biesiekierski, 2011; Lundin, 2012).

A diagnosis of non-celiac gluten sensitivity should be considered only after celiac disease has been excluded with appropriate testing (Rubio-Tapia, 2013). Non-celiac gluten sensitivity cannot be reliably differentiated from celiac disease, because the two syndromes overlap. Celiac serology (TTG) and small-intestinal histology, both obtained when the patient is consuming a gluten-rich diet, and *HLA-DQ* typing to rule out celiac disease if negative, are needed to differentiate between the two disorders.

The possibility of gluten sensitivity has led to the popularity of gluten-free diet trials; a growing number of people come to gastroenterologists with complaints of gluten intolerance. The cause of the sensitivity is not well understood (Mooney et al., 2013). Fermentable fructans present in wheat rather than gluten itself may provoke symptoms. Some patients who report gluten sensitivity respond to reduction of fermentable, poorly absorbed, short-chain carbohydrates (FODMAPs), or foods that cause gas (Biesiekierski et al., 2013b), rather than specifically to gluten-sparing diets.

The symptoms of non-celiac gluten sensitivity include abdominal discomfort, bloating, pain or diarrhea, and fatigue, and may extend to headaches, foggy mind, depression, musculoskeletal pains, and skin rash (Volta & De Giorgio, 2012; Sapone et al., 2012). As clinicians have been skeptical about the entity, some patients have been referred for psychiatric assessment (Mooney et al., 2013). In one study, somatization or abnormal personality traits were not found to explain symptoms (Brottveit et al., 2012). A gluten-free diet has also been suggested for autism and autism spectrum disorders, but a recent review documented that there is insufficient evidence to support this treatment (Buie, 2013).

One retrospective study found that patients with non-celiac gluten sensitivity were composed of two distinct groups: one with wheat sensitivity alone, and one associated with multiple-food hypersensitivity. The first seemed similar to celiac disease, and the second similar to patients with food allergy. Compared to controls with IBS, the whole group had a higher frequency of anemia, weight loss, self-reported wheat intolerance, and (in infancy) coexistent atopy and food allergy. The main histological feature is eosinophil infiltration of the duodenal and colon mucosa (Carroccio et al., 2012; Sanders & Aziz, 2012). Patients with non-celiac wheat sensitivity were those with IBS-like symptoms, negative TTG and

anti-endomysium IgA antibodies, no villous atrophy on duodenal histology, negative IgE-mediated immuno-allergy tests to wheat, and resolution of symptoms on a gluten-free diet and their reappearance on double-blind placebo-controlled wheat challenge. (This time-consuming double-blind placebo-controlled challenge has been used primarily as a research tool.)

The boundaries of the entity of gluten sensitivity have not been fully clarified. A response to a gluten-free diet or exacerbation of symptoms due to a gluten-containing diet is not sufficient to prove that these symptoms are due to specific effects of gluten (Biesiekierski et al., 2013a). Clarification of the disorder depends on further validation with diagnostic criteria and a better understanding of mechanisms of action.

HEPATIC ENCEPHALOPATHY

For the medical psychiatrist, hepatic encephalopathy (HE) is a diagnosis to consider in the confused patient, especially when asterixis is present and the patient has liver disease. In fact, when the syndrome is overt, there is marked confusion, incoherent speech, and altered consciousness, ranging from lethargy to coma. The mechanism of HE is not fully understood. However, the main explanation is that ammonia produced in the colon by intestinal bacteria gets into the systemic circulation when the liver is impaired and when portal-systemic shunts occur. Ammonia adversely affects neurotransmission, consciousness, and behavior. (Mas et al., 2006).

In the normal condition, ammonia is metabolized to urea by the liver; when the liver is injured, ammonia levels rise. Astrocyte swelling causes low-grade cerebral edema and a neuroinhibitory state related to elevated glutamine. The level of ammonia does not always correlate with the severity of encephalopathy. Elevated ammonia is only one component of the disorder; chronic inflammation and hyponatremia may also play a role.

Precipitants of overt encephalopathy are infection, GI bleeding, dehydration, hyponatremia, hypokalemia, metabolic alkalosis, renal failure, and constipation; benzodiazepines, narcotics, or alcohol; increase of protein intake; portal vein or hepatic vein thrombosis and portal-systemic shunts, the latter either spontaneous or iatrogenic. Treatment of acute HE requires general supportive care and a search for precipitants. Nutritional and metabolic precipitants should be corrected when feasible. Although proteins may be restricted initially, guidelines suggest that this restriction need not be prolonged (Blei et al., 2001).

Lactulose is a first-line treatment, facilitating the passage of ammonia into the colonic lumen. This drug can cause gas, abdominal cramping, and a sweet taste, as well as diarrhea. The dose is first hourly until the first evaluation, and then adjusted to achieve two to three soft bowel movements per day (Blei et al., 2001). Neomycin, a non-absorbable antibiotic, is also FDA-approved for the acute syndrome. Rifaximin has also been used in addition to lactulose for the overt syndrome but is primarily approved for secondary prevention. Percutaneous embolization of large portosystemic shunts has

been finding a place in treatment; and a molecular adsorbent recirculating system (MARS), designed to remove protein and albumin-bound toxins like bilirubin, bile acids, nitrous oxide, and endogenous benzodiazepines, but also removes non-protein-bound ammonia, has also been FDA-approved for overt HE. Probiotics have also been advantageous (McGee et al., 2011; Leise et al., 2014).

To prevent further episodes of HE, lactulose and rifaximin are recommended. How effective the treatment will be at preventing the next episode of encephalopathy is related to the patient's compliance and how well the patient is advised about lactulose and rifaximin. Furthermore, patients at risk for HE should be advised about driving, as some patients have impaired driving skills, and car accidents are common (Leise et al., 2014).

Agitation should not be treated with benzodiazepines, and sedatives are generally avoided. In patients awaiting liver transplantation, those taking SSRIs had better cognitive function and longer latency to encephalopathy (Bajaj et al., 2012). Limited data suggest that antipsychotics slow psychomotor speed but do not hasten encephalopathy (Bajaj et al., 2012).

Flumazenil, which blocks gamma aminobutyric acid (GABA), can bring temporary improvement in a few patients, but its value is to rule out possible previous administration of benzodiazepines. Bromocriptine or L-dopa are restricted to cases of extrapyramidal signs with chronic HE (Mas, 2006). A meta-analysis did not lend much support for the benefit of dopaminergic agents (Als-Nielsen et al., 2003).

COVERT HEPATIC ENCEPHALOPATHY

For the psychiatrist seeing a patient with liver disease in the office who is less ill, it may be more important to consider covert HE (Kappus & Bajaj, 2012). Covert HE combines patients who meet criteria for *minimal hepatic encephalopathy* (MHE) with those that have *Grade 1 hepatic encephalopathy* by West Haven criteria. Clinical recognition of the covert syndrome in patients with mild liver disease can have a significant impact. These patients are those with liver cirrhosis who have mild cognitive and attention deficits, compounded by response disinhibition, impaired working memory, and impaired coordination. The diagnosis requires neuropsychological and neurophysiological testing over and above a routine clinical assessment. These patients have difficulty sleeping, have poor executive function, suffer more falls, have difficulty driving, a poorer quality of life, and are destined to develop overt HE if they are not diagnosed and treated. Fifty-six percent of patients with MHE develop the overt syndrome in three years (Hartmann et al., 2000). Both lactulose and rifaximin have been shown to improve cognitive function in patients with MHE.

A psychometric hepatic encephalopathy score (PHES) has been recommended as a standard for following patients. Deficits in attention and processing speed are central to the diagnosis, with impairment of visuospatial function, attention, response time, and inhibition. The PHES includes the number connection test-A (NCT-A) and the number

connection test–B (NCT-B) (These have also been called Trail Making Tests A and B (Weissenborn et al., 1998)); the digit symbol test (DST), the line-tracing test, and the serial dotting test. When a shorter test is required, the Working Group recommends two of the tests: NCT-A, NCT-B, the DST, and the block design test. The diagnosis is made by evidence of impairment on two of these tests, such that the patient scores two standard deviations below age-matched controls at the same education level (Kappus & Bajaj, 2012). The NCT-A tests psychomotor speed, and the NCT-B tests speed, set shifting, and divided attention. The DST tends to be sensitive and an early indicator of impairment. While these tests take a few minutes, the block design test is for visuospatial reasoning, praxis, and psychomotor speed, and takes 10–20 minutes (Kappus & Bajaj, 2012).

HEPATITIS C

Hepatitis C (HCV) infection is primarily the consequence of injection drug use, especially for the cohort born between 1945 and 1964. HCV is much less likely to be transmitted by sexual activity or transfusion than by drug injection. The prevalence of new infections dropped in the 1990s as drug users modified their behavior to prevent exposure to human immunodeficiency virus (HIV). Of the 1.6% of the U.S. population who had been infected with HCV (anti-HCV-positive), 1.3% were still positive for HCV ribonucleic acid (RNA) between 1999 and 2002. Those who still have active virus are prone to chronic liver disease, cirrhosis, and hepatocellular carcinoma (Armstrong et al., 2000). Chronic HCV is the most common reason for liver transplantation (Dienstag, 2006). In light of this and the evolution of new treatments for hepatitis C, screening is recommended for all patients born between 1945 and 1964.

HCV causes a flu-like syndrome acutely that may last 10–12 weeks. Only 20% of patients clear the infection the vast majority within 8–16 weeks of infection; the other 80% go on to develop chronic HCV lasting more than six months. The chronic phase is generally asymptomatic. Heavy alcohol use accelerates vulnerability to chronic liver disease. Chronic HCV itself has been associated with recurrent brief depression independent of treatment (Carta et al., 2012; Lim et al., 2010). Depression is more common in HCV- than in HBV-infected patients. Fatigue, the most common symptom, remits with antiviral treatment (Schaefer et al., 2012). Cognitive impairment also has a high prevalence in chronic HCV patients and raises the question of whether the virus can infect the central nervous system. Virus in human brain endothelial cells, a major component of the blood–brain barrier, may be a mechanism for entrance into the brain (Fletcher & McKeating, 2012).

The standard regimen for chronic HCV has included pegylated interferon and ribavirin. New protease inhibitors, including sofosbuvir and simeprevir, with ribavirin and with or without pegylated interferon have the potential to shorten treatment from 24 to 12 weeks. Ledipasvir and sofosbuvir have been given as one tablet with or without ribavirin in

regimens as short as 8 weeks, and other direct-acting antiviral agents are on the way. The new agents may elevate the chance of successful treatment from 50% to more than 90%; however, the new drugs are very expensive, and the economic barriers may be the biggest challenge (Hoofnagle & Sherker, 2014). Actually, most patients with HCV have not received treatment (North et al., 2012; Volk, 2010; North et al., 2013), and psychiatric and medical syndromes have often made patients ineligible for treatment. One requirement has been to be sober from substance abuse for six months before starting treatment. In the real world, only 20% started treatment, and many did not finish. Patients with active injection drug use should not be systematically excluded (National Institutes of Health [NIH], 2002). It is worth noting that treatment of HCV, even in active drug users, can be as effective as it is in those in remission from drug use, particularly if there is specific support for psychiatric disorders and substance abuse (Zanini et al., 2010). Extra attention to treatment adherence, psychoeducation, and social support are critical (Grebely et al., 2010).

Patients with serious mental illness have a higher prevalence of HCV; for instance, among veterans the prevalence is 8% in bipolar patients and 7% in patients with schizophrenia (Himelhoch et al., 2009). In stable patients with bipolar disorder, interferon-related depressive disorder can be managed (Kelly et al., 2012).

The standard regimen for hepatitis C has included ribavirin and pegylated interferon alpha over 48 weeks. Interferon can cause malaise, major depressive disorder, anxiety, suicidal ideation, insomnia, anger, and irritability. The first 12 weeks of interferon treatment are the highest risk period for the emergence of suicidal ideation (Sockalingam et al., 2011; Lotrich, 2013). Depression is a cause of interferon dose reduction, and depression wanes after a few weeks off interferon. However, most patients who are depressed respond to SSRIs even as interferon is continued. Guideline suggestions include citalopram (Morasco et al., 2010), escitalopram, paroxetine, mirtazapine, sertraline, and others (Schaefer et al., 2012). Antidepressants given before interferon is started may reduce the psychiatric side effects of interferon given with ribavirin for hepatitis C treatment (Hou et al., 2013); however, the key point is that patients should be educated to report troubling dysphoric symptoms so that antidepressants can be initiated (Wise, 2011). Pre-treatment is recommended for those with chronic HCV infection who are depressed even before treatment begins (Raison et al., 2007) as well as for those with previous interferon-induced depression. Insomnia should be treated early and can be treated with mirtazapine, trazodone, antihistamines, or benzodiazepines. Guidelines suggest continuing antidepressants for 12 weeks after interferon is stopped. Psychosis and mania are rare. Cognitive function, particularly processing and reaction times, may be slowed, particularly with higher doses of interferon.

Thyroid function tests should be followed during interferon treatment. Interferon is associated with autoimmune thyroiditis, so hypothyroidism or hyperthyroidism and their psychiatric symptoms can complicate the psychiatric picture. Furthermore, hypothyroidism and interferon's inhibition of

the P450 system can raise levels of antidepressants and thereby raise the risk of antidepressant drug-induced mania.

The website HCVguidelines.org has up-to-date recommendations for management, treatment, and screening. Resources are found at www.hepc123.org, the American Liver Foundation's dedicated online information center.

WILSON'S DISEASE

Wilson's disease is an autosomal recessive disorder of copper metabolism that presents with neuropsychiatric and/or hepatic symptoms. Three hundred discrete genetic mutations of the gene responsible for synthesis of the protein ATP7B for the transport of copper (Ala et al., 2007) have been found in patients with this disease (Ferenci, 2004).

Psychiatrists take note of the diagnosis in the differential of a new psychosis, especially when the psychosis is accompanied by a movement disorder. This is a critical diagnosis not to miss since the brain injury can improve with treatment, and the identification of vulnerable family members can prevent the disease. The full neurological syndrome of Wilson's disease is characterized by tremor, rigidity, dysarthria, dysphagia, and apraxia; the associated neuropathology includes signs of copper deposition in the basal ganglia, thalamus, and cerebellum. The dysarthria, one of the most common symptoms, can have dystonic (harsh, strained qualities) and ataxic irregularity of word spacing and volume. The tremor can take many forms, looking like essential, postural, or intentional tremor (Lorincz, 2010). Approximately one-third of cases of Wilson's disease present with neuropsychiatric rather than hepatic symptoms; the psychiatric symptoms include depression, labile mood, and functional consequences of impaired executive function (Frota et al., 2013). Cognitive symptoms may be mild, but both frontal syndromes and subcortical dementia can be seen. The onset is most often in patients under 35 years old (Lorincz, 2010).

The presence of liver disease may be the clue to the diagnosis. Of those with a neuropsychiatric presentation, 39% already have hepatic cirrhosis. In addition to cirrhosis, patients can present with fulminant liver failure or chronic hepatitis. One-third of the patients who present with hepatitis or liver failure will also have neuropsychiatric findings at the time of presentation. Sometimes these are misdiagnosed as having hepatic encephalopathy. Liver injury becomes evident in patients between 8 and 18 years old.

Kayser-Fleischer gray-green corneal rings are seen at the time of presentation in 95% of patients with nervous system disease, but only in half of those who present with liver abnormalities. This finding should be sought visually by ophthalmoscope and, if necessary, the patient should be referred to an ophthalmologist for a slit lamp exam. Neuropsychiatric assessment can document impairment, particularly in executive functions that correlate with MRI findings. The most common brain MRI findings are atrophy of the caudate, brainstem, and cerebral and cerebellar hemispheres, and both gray and white signal abnormalities (Frota et al., 2013).

Corneal rings and a low ceruloplasmin can make the diagnosis; however, a low ceruloplasmin level without Kayser-Fleischer rings is not sufficient. Ceruloplasmin may also be low in malnourished states and in autoimmune hepatitis. Some patients with Wilson's disease in the liver will have normal ceruloplasmin as it is an acute phase reactant that increases due to hepatic inflammation. Thus, a normal ceruloplasmin does not rule out the diagnosis.

A 24-hour urine copper test is the most useful screening procedure, and the gold standard for diagnosis is a quantitative measure of copper in a percutaneous liver biopsy.

The chelating agents penicillamine or trientine (the latter if the patient is intolerant to penicillamine) are the first treatment. Zinc is a useful alternative, as it disrupts intestinal absorption of copper and has been used for maintenance treatment and preventive treatment in presymptomatic patients (Lorincz, 2010). Liver transplantation is the treatment for liver failure; in some patients the neurological findings have improved post-transplant. Psychiatric syndromes may improve over the first two years of treatment (Akil & Brewer, 1995).

WHIPPLE'S DISEASE

Whipple's disease is a rare gastrointestinal syndrome of diarrhea, weight loss, and malabsorption, associated with psychiatric symptoms and cognitive impairment in 20%– of patients (Afshar et al., 2010; Fenollar et al., 2007). *Tropheryma whippelii*, a common gram positive bacterium, causes the disease, presumably in patients with special susceptibility. The presentation is associated with a prodrome of polyarticular arthritis after six to seven years of chronic diarrhea. The disease may be identified in the setting of rheumatological treatment with immunosuppressive therapy. (Fenollar et al., 2014). About one quarter of patients present with neurologic involvement, and depression and personality changes are seen in half of these (Lagier et al., 2010; Louis et al., 1996). Patients also can present with dementia, hemiparesis, ophthalmoplegia, Wernicke's encephalopathy, cranial nerve abnormalities, sensorimotor impairment, and cerebellar ataxia. A higher frequency of HLA DRB*13 and DQB *06 has been noted. Diagnosis depends usually on multiple intestinal biopsies and periodic acid-Schiff (PAS) stains with a polymerase chain reaction (PCR) analysis. Even if there are no central nervous system (CNS) findings, the cerebrospinal fluid (CSF) should be evaluated with PCR. Repeat study of CSF should be done after antibiotics. Relapses are common. Based on antibiotic susceptibilities, doxycycline and hydroxy-chloroquine are given for 12 months. Doxycycline may be continued life-long (Fenollar et al., 2014).

CLINICAL PEARLS

- Irritable bowel syndrome is attributed to an interaction between intestinal microbiota, the mucosal barrier, and immune activation, nerve plasticity, visceral

hypersensitivity, enteroendocrine factors, and the amplification of these contributors by anxiety and depression.

- Buspirone 5HT-1A receptor agonist has been shown to relax the proximal stomach in healthy subjects and to improve functional dyspepsia better than placebo.
- In the differential diagnosis of cyclic vomiting is a syndrome associated with heavy and longtime cannabis use. Cessation of cannabis is the treatment.
- Lactose, fructose, or sorbitol malabsorption from dietetic foods may contribute to fecal urgency and incontinence.
- Two recent meta-analyses have concluded that antidepressants are helpful for IBS (Ford et al., 2012; Ruedert, 2011) but how these drugs related to other treatments and how they may be used for maximal benefit have not been fully defined.
- Patients with higher depressive scores at the time of a flare-up of inflammatory bowel disease were more apt to relapse sooner (Mittermaier, 2004).
- Recognizing that a patient with liver disease has covert hepatic encephalopathy can bring them to attention and treatment before they suffer the overt syndrome. They have deficits in attention and processing speed, with impairment of visuospatial function, attention, and response time, and are more prone to motor vehicle accidents.
- Immunoglobulin-A anti-tissue transglutaminase (TTG) antibody is the preferred single test for the detection of celiac disease.
- Antidepressants can prevent depression in the setting of interferon treatment for hepatitis C, and they may be continued for 12 weeks longer than the interferon.
- A diagnosis of non-celiac gluten sensitivity should be considered only after celiac disease has been excluded with appropriate testing (Rubio-Tapia, 2013).
- Wilson's disease is not the only thing that can cause a low ceruloplasmin. It is also low in autoimmune hepatitis and malnourished states.

PSYCHIATRIC CARE OF THE ONCOLOGY PATIENT

Donna B. Greenberg

The cancer patient is drafted into a complex series of diagnostic efforts to clarify his prognosis and medical plan, then a systematic series of upfront treatments, including surgery, radiation, and chemotherapy that may offer the best outcome. As patients comprehend the nature of their illness and adapt psychologically over time, they are moving through a sequence of assignments that also affect their symptoms and psyche. Because of the challenge of the illness and its dark history, individual and group psychosocial interventions have been developed to reduce the suffering of patients and to sustain their morale.

The medical psychiatrist meets the cancer patient where she is, grapples with the patient's requests as he discovers the patient's medical and personal saga. The clinician has a mission to hear the patient out and to support her, to clarify the medical predicament, and to help the patient break down the problem into smaller bits with appropriate priority. The specific course and implications of the cancer diagnosis and treatment interact with the individual psychological course. In consultation, the clinician may stabilize mood, anxiety, and clarity of thought, at the same time as he clarifies which symptoms have medical or psychiatric contributions.

The interview is the psychiatrist's trained method for assessing what is important to the patient, how he tolerates the threat of death, how the patient has begun to cope with the challenges of diagnosis and treatment, what bothers him the most, and what he fears. The medical facts as the clinician understands them are put in the context of the patient's experience of illness. In addition to the personal history, history of psychiatric syndromes, and developmental predicament, the patient may allow assessment of who is close to him, who can be relied upon for support, and who knows what is going on medically with the patient.

COPING WITH CANCER

Weisman (Weisman, 1974) outlined objectives that guided an approach to the patient coping with cancer. These were the objectives that came with the hope of an appropriate death—the death that we would choose if we had a choice. He defined as feasible:

1. Adequate medical care, alleviation of pain and suffering, full use of technical resources, prolongation of life but

not prolongation of dying when recovery is wholly out of the question;

2. Informed collaboration between doctor and patient;
3. Encouragement of conscious, competent control; helping the patient use available, practical, and appropriate coping strategies;
4. Maintenance of behavior on as high a level as seems consistent with physical and psychological limitations;
5. Preservation and, if necessary, enhancement of self-esteem, an essential ingredient of a dignified death [and life];
6. Support of the significant key others, a gesture that helps them help the patient with gradual relinquishment of control to those who have shown themselves to be trustworthy;
7. Safe conduct in sustaining life until it ceases; and
8. Honest communication, designed to support acceptance, reduce bitterness, and replace denial with courage to confront what cannot be changed (pp. 188–189).

These principles can serve as a guide for good care.

In modern cancer treatment, the patient detours fairly abruptly from the preoccupation with her usual concerns to the challenge of diagnosis and biopsy and defining a complex medical plan. In many cases, the patient's ability to follow through with treatment over a long course will affect the outcome. The patient's family and extended supporters facilitate the urgent needs; and often in the emergency, subtler emotional concerns are left until later. The ability of the patient to cope over time and to use her support system strategically becomes critical.

As with any life-threatening illness, the patient faces an existential crisis, recognizing losses and mortality. The psychiatrist encounters the patient at a very vulnerable time, a moment when her relationships to the world are in critical transition. The psychiatrist, with patients and physicians, formulates the salient problems as succinctly as possible during continued patient care. The goal is to help the patient find the most efficient method of coping, with the best use of psychiatric knowledge for optimal oncological care.

It takes time for patients to metabolize the significance of the cancer. The course of acute distress has been described as taking 100 days (Weisman, Worden, 1976–1977); this three-month time frame can serve as a guide to the time course of acute adjustment.

Weisman highlighted the primary paradox that, in confronting a life-threatening illness, a dying man believes in the fact of his own death but hopes that he is an exception (Weisman, 1972, p. 13). In the setting of incurable cancer, clinicians set out a medical plan, standing by the patient as the patient fluctuates between acknowledgement and denial of his predicament. Denial has a social dimension. Patients tend to deny their knowledge of fatal illness to different people at different times; sometimes in order to preserve important relationships (Weisman, 1984, p. 83). The clinician can foster tactful discussion of mortality between a patient and his caretakers so that they may be responsive to each other as long as possible (Weisman, 1972, p. 18). Weisman described *middle knowledge* as the uncertain certainty that is “somewhere between open acknowledgement of death and its utter repudiation; middle knowledge is most evident particularly at serious transition points” (Weisman, 1972, p. 65). This concept of middle knowledge describes how patients often seemed to know and want to know about the gravity of their illness, yet often talked as if they did not know and did not want to be reminded (Weisman, 1972, p. 66). “Patients may deny facts, inferences, or extinction” (Weisman, 1972, p. 66). However, “denial is almost impossible to maintain; and inner perceptions force themselves on the most reluctant patient” (Weisman, 1972, p. 133). The balance between denial and acceptance evolves (Weisman, 1972, p. 112).

HOPE

The will to live is a combination of hope and the ability to put in effort (Weisman, 1972; Khan et al., 2010). Hope is related to a desirable self-image and a belief in one’s personal ability to exert a degree of influence on the world (Weisman, 1972, p. 20), the conviction that a person may do something worth doing (Weisman, 1972, p. 21). That sense of purpose adds value to one’s life regardless of the time frame. The clinician’s respect for the patient sustains authentic hope.

The purpose of the treatment plan in the cancer setting is to facilitate coping. Faced with the conflict between sickness and responsibility, cancer patients by trial and error seek a way forward. Coping is a complicated mixture of cognitive appraisal and reappraisal, “first responses and corrected responses over a long time continuum” (Weisman, 1978, pp. 264–267). Simultaneously, the clinician assesses the contributions of demoralization, malaise, and major depressive disorder to the patient’s presentation and judges how best to use the therapeutic armamentarium.

DEMORALIZATION

At times when the burden of illness is overwhelming and coping is difficult, patients can face existential despair,

hopelessness, helplessness, and loss of meaning and purpose in life. This syndrome of demoralization has been seen as a normal response to the adversity of serious medical illness (Clark & Kissane, 2002) analogous to grief, echoing Frank’s description of demoralization in combat soldiers and Schmale and Engel’s “giving up–given up complex” (Frank, 1993; Schmale, 1972). The demoralized patients feel inhibited to act because they do not know what to do. They feel helpless and incompetent in the face of uncertainty. The focus is subjective incompetence rather than loss of pleasure. A scale of demoralization has distinct dimensions of loss of meaning, dysphoria, disheartenment, helplessness, and a sense of failure (Kissane et al., 2004). Helplessness, despair, or meaninglessness may combine to contribute to the sense of subjective incompetence, positioning a patient to retreat from the existential challenges of illness (Griffith & Gaby, 2005). Demoralization may be difficult to distinguish from clinical depression, as many feel more incompetent when their mood is persistently low. The clinician who recognizes demoralization must work with patients to promote a sense of mastery and return of hope regardless of what decision is made about medication treatments for depressive disorder (Shader, 2005).

In order to treat demoralization, Griffith and Gaby focus questions at the bedside to find the dominant existential theme in the patient’s experience of illness; they then suggest nudging the patient forward with a series of questions oriented to attributes of resilience: coherence, communion, hope, agency, purpose, courage, and gratitude rather than their opposites: confusion, isolation, despair, helplessness, meaninglessness, cowardice, and resentment. They prod patients in interviews, as follows.

Coherence vs. Confusion

How do you make sense of what you are going through?
When you are uncertain how to make sense of it, how do you deal with feeling confused?
Whom do you turn to for help when you feel confused?
[For a religious patient] Do you have a sense that God has a way of making sense of it? Do you sense that God sees meaning in your suffering?

Communion vs. Isolation

Who really understands your situation?
When you have difficult days, whom do you talk with?
In whose presence do you feel a bodily sense of peace?
[For religious patients] Do you feel the presence of God?
How? What does God know about your experience that other people may not understand?

Hope vs. Despair

From what sources do you draw hope?
On difficult days, what keeps you from giving up?
Who have you known in your life who would not be surprised to see you stay hopeful amid adversity? What did this person know about you that other people may not have known?

Purpose vs. Meaninglessness

What keeps you going on difficult days?

For whom, or for what, does it matter that you continue to live?

[For terminally ill patients] What do you hope to contribute in the time you have remaining?

[For religious patients] What does God hope you will do with your life in days to come?

Agency vs. Helplessness

What is your prioritized list of concerns/What concerns you the most? What the next most?

What most helps you stand strong against the challenges of this illness?

What should I know about you as a person that lies beyond your illness?

How have you kept this illness from taking charge of your entire life?

Courage vs. Cowardice

Have there been moments when you felt tempted to give up but didn't?

How did you make a decision to persevere?

If you were to see someone else taking such a step even though feeling afraid, would you consider that an act of courage?

If so, can you imagine viewing yourself as a courageous person? Is that a description of yourself that you would desire?

Can you imagine that others who witness how you cope with this illness might describe you as a courageous person?

Gratitude vs. Resentment

For what are you most deeply grateful?

Are there moments when you can still feel joy despite the sorrow you have been through?

If you could look back on this illness from some future time, what would you say that you took from the experience that added to your life?

Hopelessness and humiliation may be eased by psychotherapeutic interventions that sustain dignity and meaning (Chochinov et al., 2011; McClain et al., 2003). Group therapy for patients with metastatic cancer, a supportive-expressive approach, has reduced distress and facilitated the patients' confrontation with what had to be confronted (Spiegel et al., 2007; Spiegel et al., 2000). When the care of patients depends on spouse or family, the clinician can amplify the caregivers' understanding of the illness and support communication within a couple or family (Zaider & Kissane, 2010). Cognitive behavioral interventions, supportive psychotherapy, relaxation techniques, and mind-body medicine have all been found to reduce distress among cancer patients.

SYNDROMES OF ANXIETY

In the course of cancer treatment, anxiety is common. The medical team makes a plan for patients, informs them at each step what will happen, and pays attention to their comfort and the things that make them anxious.

CONDITIONED ANXIETY

Cancer treatment itself makes certain anxiety syndromes likely. The anticipatory anxiety associated with repeated painful procedures, anxiety about routine visits to oncologists, waits for results of studies redefining the stage of the cancer, and the worry about recurrence are typical elements of the oncology experience. A patient who has been at equilibrium may find that the experience of the first recurrent lesion, the medical event that changes the condition from curable to palliative is an alarm signal that is difficult to quiet. The patient may remain in a state of alarm for an extended period waiting for the next lesion; the patient's medical understanding of his continued vulnerability can perpetuate a chronic level of anxiety and contribute to "battle fatigue."

Historically, cancer chemotherapy has been associated with nausea and vomiting. Because of the power of vomiting as a visceral stimulus, emetic chemotherapy has provided a model for iatrogenic induction of conditioned anxiety. With repeated treatments associated with nausea and vomiting, patients can become conditioned to anticipate and to avoid the next chemotherapy or the sights, smells, and people that come with treatment. With highly emetic treatments, patients may vomit before they receive the treatment. With improvements in effective anti-emetic regimens and lorazepam infusions added to the chemotherapy protocol, conditioning has been reduced, but subclinical nausea may be a marker for this syndrome. With repetition of nauseating treatments, patients begin to have anxiety the day before or several days before treatment. Benzodiazepines used prophylactically as this syndrome evolves may reduce nausea and avoidance (Greenberg et al., 1987).

Keeping down the anxiety as patients go through treatment has a premium value as the best anti-emetic regimen and lessened anxiety help prevent visceral Pavlovian conditioning and subsequent anticipatory vomiting. Those with conditioned anxiety to the treatment are more apt to be reminded later by memories of the treatment, and respond with anticipatory anxiety to triggers of smells or residual symptoms like paresthesias of peripheral neuropathy (Greenberg et al., 1997; Kornblith, 2003). Persistent symptoms among survivors of Hodgkin's disease fitted with an explanatory model based on classical conditioning. Treatment-induced symptoms are less likely to persist if conditioning did not occur initially (Cameron et al., 2001). Younger patients, those with a history of motion sickness, and those with more emetic treatments are more at risk for conditioning (Andrykowski, 1990).

Claustrophobia can interfere with magnetic resonance imaging (MRI) scans and the preparation for radiation treatment. Benzodiazepines and behavioral treatments can be targeted for these procedures. The role of phobia and anxiety disorder in treatment is not always obvious, as embarrassed patients may disguise the degree of their disability. Anxiety about side effects often interferes with adherence to effective treatments. Patients with anxiety disorders are more likely to believe that oncologists would offer futile therapies and not adequately control their symptoms, and may have delayed diagnosis (Spencer et al., 2010). Among advanced cancer patients, those with panic disorder and post-traumatic stress disorder (PTSD) were more likely to report suicidal thoughts (Spencer et al., 2012). This fits with the recognition that patients with anxiety disorders in general have a greater independent risk of suicide (Sareen et al., 2005).

POST-TRAUMATIC STRESS DISORDER

Although the diagnosis of cancer can be traumatic, most cancer patients do not come to psychiatrists with the primary symptoms of flashbacks. They do experience intrusive thoughts and symptoms of acute stress as they go through complex cancer treatment, all the more if they have anxiety and depressive syndromes (Palgi et al., 2011). These symptoms most often ease with time, except in a small subset of patients. In breast cancer patients, post-traumatic stress symptomatology was noted at 18 months in 16% of patients, and those who met criteria for the disorder were more likely to have a history of violent trauma and anxiety disorder (Elklit et al., 2011; Shelby et al., 2009). In lung and head and neck patients, current cancer-related PTSD was noted in 22% six months after diagnosis and in 14% at 12 months (Kangas et al., 2005). Among more than 500 adult survivors of non-Hodgkin's lymphoma at least seven years from diagnosis, half reported no post-trauma symptoms, and 12% reported resolution of post-traumatic symptoms. (Smith et al., 2011).

Among more than 6,500 survivors of childhood cancer compared to sibling controls, Stuber et al. (2010) found only a minority (9%) who reported functional impairment and/or clinical distress and symptoms consistent with a full diagnosis of PTSD. Those most likely to have the full syndrome were more apt to have had more intensive treatment, to be less educated, and to be unemployed.

The concept of PTSD includes the avoidance of reminders of distress. Avoidance is often not immediately visible to the clinician, as patients avoid describing how they have narrowed their life. Psychosocial interventions have a role in enlarging a life constrained by cancer-related anxiety. Interventions like supportive-expressive group therapy (Spiegel et al., 2007) have strengthened patients' ability to confront, and cognitive behavioral therapy interventions activate patients and reduce avoidance.

Some medical problems masquerade as anxiety in cancer patients. Akathisia or restless leg syndrome is seen as an adverse reaction to anti-emetics, prochlorperazine, or perphenazine. Because patients use anti-emetics so commonly, they may even forget to mention the use of this medication. In the setting of chemotherapy, patients often have as-needed prescriptions of lorazepam 1 mg. If benzodiazepines have been used for a long period, patients may experience inter-dose jitteriness without recognizing any physiological dependence. Because pulmonary embolism is more common in cancer patients and may be heralded by obscure symptoms and anxiety, pulmonary embolism should be on the differential with pulmonary edema as a cause of anxiety and dyspnea.

SYNDROMES OF DEPRESSIVE SYMPTOMS

MALAISE

The flu-like syndrome of malaise, most associated with fever and acute illness—listlessness, poor concentration, hypersomnia, social withdrawal, anorexia, loss of interest, and poor grooming—has been described in animal models as “sickness behavior.” This syndrome of fatigue associated with injury and inflammation triggers cytokines and mimics the vegetative somatic symptoms of major depressive disorder (Dantzer et al., 2008). A somatic fatigue syndrome predictably follows procedures like surgery, radiation treatment, and cumulative cycles of chemotherapy. After one year of complex, upfront, multimodal treatment for breast cancer, depressive symptoms were noted in 25% of patients and fatigue in 60%. Fatigue was associated with elevated levels of inflammatory-marker soluble tumor necrosis factor receptor II and with recent chemotherapy treatment. Depressive symptoms were associated with fatigue but not with inflammatory markers. These data support the idea that systemic adjuvant chemotherapy is followed over a year by a somatic fatigue syndrome related to inflammation and distinct from the fatigue of major depressive disorder (Bower et al., 2011). The fatigue of depression is associated with sleep disturbance, a sense of effort, and a dread of the day, rather than the lack of stamina that comes with the fatigue of sickness behavior. However, as the patient takes on pretreatment responsibilities, limited stamina can become a factor that undermines his self-esteem and adds to negative emotions and cognitions.

Clarifying the diagnosis of depression in cancer patients becomes more difficult when the burden of illness is greater and patients come closer to death. To put this in perspective, Lo et al. (2010) followed prospectively 365 patients with advanced gastrointestinal and lung cancer; depressive symptoms were assessed longitudinally every two months. At first, mild depressive symptoms were seen in 35% of patients; 16% had moderate to severe symptoms; and about 5% had persistent moderate to severe depressive symptoms. Compared to patients more than one year before death, the prevalence

of moderate to severe symptoms tripled in the final three months of life. Those who were more apt to have depressive symptoms were younger, had a greater physical burden of disease, and had a closer proximity to death. They were the patients more apt to have been treated with antidepressants before the study and who had lower self-esteem, less sense of spiritual well-being, greater anguish about rejection and abandonment, and greater hopelessness.

The convergence of physical and mental symptoms was ultimately associated with the highest risk of depression (Lo et al., 2010), suggesting that the growing physical symptom burden over time is synergistic and demoralizing. Here depressive symptoms are seen as a final common pathway of distress, particularly in those who have psychosocial vulnerability and worse physical symptoms before death.

Depressive symptoms may reflect tumor-related systemic malaise and overlap clinically with the symptoms of major depressive disorder. The course of major depressive disorder in the normal population threads through symptomatic cancer patients as they are treated. For instance, men treated with androgen blockade were more likely to get depression if they had a history of depressive disorder (Pirl et al., 2008), and the rate of depression in cancer survivors seems to be the same as in the normal population (Pirl et al., 2009).

THE MOST VULNERABLE

The elements of psychosocial vulnerability identified in cancer patients in the 1970s—the characteristics that made some more apt to be distressed and more likely to benefit from psychosocial intervention with cancer treatment—showed a similar pattern to that of those most distressed in Lo’s study (Weisman et al., 1980; Lo et al., 2010). Those at risk for more distress were more likely to have history of anxiety or depressive disorder; to have a greater burden of physical disease; to have the least social support; to be hopeless, despondent, helpless, anxious, exhausted; feeling worthless, with low self-esteem and a perspective that their time is short. They had more history of maladaptive coping, of being truculent and resentful, repudiating significant key others, and having lower ego strength (Weisman, 1984). The goal of treatment is to reduce tumor burden and medical symptoms, to treat psychiatric diagnoses, to minimize the behavior patterns that make coping inefficient, and to increase social support.

SUICIDAL THOUGHTS

The desire for hastened death, death sooner than natural disease progression, or passive or active suicidal wishes in the setting of advanced disease, comes with depressive disorder and hopelessness. Chochinov found 8.5% of those admitted to the hospital for terminal illness wished to die sooner, and most of these patients were clinically depressed (1998). Among 3,000 ambulatory cancer patients in Scotland, 8% reported that they had had thoughts in the previous two weeks that they would be better off dead, or had thoughts of hurting themselves (Walker et al., 2008). Those with suicidal thoughts were more apt to have clinically significant emotional distress,

substantial pain, and to a lesser extent, older age. A similar proportion, 8.9% of 700 advanced cancer patients, acknowledged the thought of suicide. By structured clinical interview, these patients were more apt to have current panic disorder and PTSD and more likely to be sad and to lack a sense of self-efficacy, spirituality, and a sense of being supported (Spencer et al., 2012).

In the setting of a cancer diagnosis, the likelihood of suicide is greatest when the diagnosis is new and when it seems to the patient more likely to be advanced and progressive: and therefore, more overwhelming. The cancers associated with the highest rates of suicide as determined by death certificate are lung, stomach, oral cavity and pharynx, larynx, and pancreatic cancer (Misono et al., 2008). Even with pancreatic cancer, however, suicide is extremely rare (Turaga et al., 2011). The presence of suicidal thoughts should lead directly to further assessment of the diagnosis of depressive disorder, to clarification of the medical predicament, and to attention for pain and other physically distressing symptoms.

HORMONAL CAUSES OF DEPRESSIVE SYMPTOMS

The diagnosis of depressive disorder is complicated by simultaneous hormonal changes.

Induction of Chemical Menopause

Many women in their forties or fifties or younger in the midst of cancer treatment develop temporary or permanent menopause as a side effect of treatment (Walsh et al., 2006). The symptoms of menopause—hot flashes, insomnia, dysphoria, and irritability—add to the psychic stress of coping with cancer and overlap with other depressive symptoms. The psychological adjustment is more difficult if women are younger and if they have rapid estrogen withdrawal. Reasons for estrogen withdrawal during cancer treatment are listed in Box 57.1.

Box 57.1 CAUSES OF ESTROGEN WITHDRAWAL FROM CANCER TREATMENT

1. Surgical oophorectomy.
2. Chemotherapy, particularly alkylating agents, can cause ovarian injury; so that women stop menses temporarily during treatment or come to menopause earlier than they would have otherwise. Permanent menopause is likelier if the woman is older or if the dose of the agent is higher.
3. Radiation treatment in the vicinity of ovaries can also lead to ovarian failure and hasten menopause.
4. Stopping estrogen replacement abruptly, particularly in women with newly diagnosed estrogen-positive breast cancer.
5. For women with estrogen receptor–positive tumors, the treatments with tamoxifen or aromatase inhibitors amplify menopausal symptoms.

Most women without cancer do not get depressed as they go through natural estrogen withdrawal, but some do. Clarification of menopausal symptoms like insomnia and hot flashes in the backdrop of cancer treatment may help women understand what they have been feeling. Risk of major depressive disorder is greater in perimenopause or the late menopausal transition (Schmidt et al., 2009). Estrogen withdrawal is more apt to induce depressive symptoms in women with a past history of perimenopausal depression than in those without such a history. Both tamoxifen and aromatase inhibitors, which suppress estradiol, have a risk of anxiety or depressive symptoms in a minority of women. In a large study comparing tamoxifen and anastrozole, an aromatase inhibitor, for instance, this rate of mood swings and irritability was about 10%, similar in both groups (Howell et al., 2005; Fallowfield et al., 2004). Tamoxifen was associated with more disruptions in sleep and with hot flashes in 40–85% of women. Other menopausal symptoms, like vaginal dryness, low libido, dyspareunia, diarrhea, dizziness, and vaginal discharge, were worse over the first three months; thereafter, menopausal symptoms remained the same or improved.

One clinical strategy is to pay attention to the patient's quality of sleep. The risk of depression may be reduced by preserving the quality of sleep disrupted by estrogen deficiency (Joffe, 2006, 2010, 2011). Many psychotropic medications reduce the vasomotor symptoms of estrogen deficiency that disrupt sleep and may simultaneously treat anxiety or depression. These are gabapentin, venlafaxine, and serotonin reuptake inhibitors, especially citalopram, escitalopram, paroxetine. These have been more effective than sertraline or fluoxetine (Loprinzi, 2009). Escitalopram has also been shown to improve the quality of sleep in healthy menopausal women (Ensrud et al., 2012).

Postmenopausal women with hormone-sensitive breast cancer may have a choice of taking an aromatase inhibitor or tamoxifen; premenopausal women with estrogen-receptor-positive tumors may require tamoxifen as a component of anti-cancer treatment to lower the risk of relapse. Some have thought that the effectiveness of tamoxifen in preventing relapse of breast cancer hinges on the metabolism of tamoxifen to endoxifen by CYP 2D6 enzyme metabolism. Use of drugs that inhibit 2D6 has been discouraged, such as fluoxetine or paroxetine. Bupropion similarly inhibits 2D6 in some patients. Thus far, it has not been clear that the effectiveness of the CYP 2D6 enzyme actually affects the risk of relapse. In fact, there was no difference between rate of relapse compared by genetic CYP 2D profile in two large studies (Regan et al., 2012; Rae, 2010, 2012; Morrow et al., 2012; Lash et al., 2010, 2011). It may be that the other metabolites of tamoxifen are sufficiently anti-estrogen and variable in metabolism regardless of the 2D6 profile. It is cautious to use citalopram, escitalopram, or venlafaxine with tamoxifen to minimize the interaction. When bupropion is the drug of choice, the value of the dose and duration of treatment can be evaluated against the unproven relationship to 2D6 inhibition for tamoxifen.

The luteinizing hormone-releasing hormone (LHRH) agonist leuprolide that causes reversible inhibition of gonadotropin secretion and suppression of testosterone and ovarian function is used in breast cancer patients and prostate cancer patients. In breast cancer patients, it sustains a temporary menopause. Like other drugs that precipitate menopause, this drug can cause hot flashes, disturbed sleep, diminished libido, and poorer quality of orgasms in women, but significant depressive symptoms are less common (Schmidt, 2009; Ben Dor et al., 2013). In prostate cancer patients, this drug aids in androgen blockade. The risk of major depressive disorder in the setting of androgen blockade is related to a history of past depression (Pirl, 2008; Pirl et al., 2002; Roth et al., 1998).

Corticosteroids

Corticosteroids are mood destabilizers and the most common cause of mood lability in the course of cancer treatment. Psychiatric side effects are typically associated with the equivalent of prednisone 60 mg each day, and dexamethasone 9 mg is equivalent to 60 mg prednisone. To prevent vomiting with highly emetic chemotherapy drugs, dexamethasone 12 mg is often added on the day of treatment and in advance. Dexamethasone 8 mg twice daily has had a role in preventing delayed nausea, which occurs with doxorubicin, cisplatin, carboplatin, or oxaliplatin (Roscoe, 2012). Steroids prevent hypersensitivity from taxanes. Prednisone 100 mg per day for five days is a standard regimen in anti-lymphoma treatment, and dexamethasone is a treatment for myeloma. Steroids also prevent vomiting from visceral radiation treatment and reduce edema in the central nervous system.

Psychiatric side effects range from insomnia, jitteriness, and hyperactivity to depressed mood, emotional lability with tearfulness, and irritability, to psychotic and manic-like syndromes. The psychiatric side effects are not predictable from one time to another, but the risk is dose-related. Stopping the steroid may not relieve the psychiatric syndrome immediately, unless the syndrome is treated with psychotropic medication. Mood stabilizers can be used to advantage to minimize insomnia and mood lability, for instance brief use of atypical antipsychotics. Sometimes, a depressive syndrome comes with the cessation of steroids. In the setting of primary care, a history of using glucocorticoids increases the risk of suicidal behavior and neuropsychiatric disorders (Fardet et al., 2012).

Cushing's disease from a pituitary adenoma or adrenal malignancy is more likely to present with a depressive syndrome than hypomania. Ectopic adrenocorticotrophic hormone (ACTH) is a paraneoplastic non-pituitary cause of corticosteroid-induced psychiatric side effects. This condition accounts for about 10% of patients with Cushing's syndrome. About half present with psychiatric disorders. Ectopic ACTH is associated with carcinoid tumors, neuroendocrine tumors, small-cell lung cancer, pheochromocytoma, and medullary thyroid cancer (Ilias et al., 2005).

Hypothyroidism and Hyperthyroidism

Symptoms of hypothyroidism, such as fatigue, weakness, depression, memory loss, cold intolerance, and cardiovascular effects, can appear insidiously in patients with cancer. When hypothyroidism is not recognized, sedating medications can raise the risk of delirium, aspiration, and hypotension. An elevated thyroid stimulating hormone (TSH) will identify a patient with hypothyroidism from thyroidectomy, radiation to the thyroid, or radiation to the neck for lymphoma. However, TSH will be low or normal in patients who had pituitary radiation, and measures of free thyroxine will be required to document secondary hypothyroidism in a patient who has had radiation to the pituitary or brain. Iodinated contrast (from scans of organs for staging) can have acute effects on thyroid, in presence of autonomous nodules or mild Graves' disease, including transient hypothyroidism in patients with Hashimoto's thyroiditis. Hypothyroidism can also develop in patients on newer anti-cancer agents, immune modulators, tyrosine kinase inhibitors (Lodish et al., 2010), and lenalidomide. Thyroid function should be screened periodically in these patients and is an important differential diagnosis for major depressive disorder (Hamnvik et al., 2011).

Adrenal Insufficiency

Adrenal insufficiency may be another mimic of depression in patients with immune-mediated hypophysitis from anti-CTLA4 treatments, like ipilimumab (Dillard et al., 2010; Weber et al., 2007).

Chemotherapy agents implicated in depressive syndromes are listed in Box 57.2.

TREATMENT

The medical psychiatrist's art is to tailor the type and timing of psychosocial interventions based on the diagnosis, the patient's willingness, and the data for the greatest clinical benefit to his psychological predicament and natural course of cancer illness. Since there is no laboratory test for the severity of major depressive disorder, an oncologist may not be evaluating the degree to which the patient's psychological suffering may be untreated, or related, for example, to a previous history of major depressive disorder and distinct from the course of cancer. In addition, patients with depression who also have anxiety syndromes are more difficult to treat, even when cancer is not an issue. It is helpful to use measures like the Patient Health Questionnaire 9 (PHQ9; Fann et al., 2009) as a screen and then to monitor outcome.

Pirl et al. (2012) found that lung cancer patients who met criteria for clinical depression in the two months following diagnosis had a worse prognosis. Patients often responded to clinical treatment for depression, but the data were not sufficient to show if successful antidepressant and psychosocial treatment improved their overall cancer prognosis. It is likely that both major depressive disorder and depressive- or malaise-like symptoms associated with the tumor contribute

Box 57.2 CHEMOTHERAPY AGENTS IMPLICATED IN DEPRESSIVE SYMPTOMS

Alkylating agents, sparse data for depressogenic effects (Celano et al., 2011)

Procarbazine (Deconti, 1971)

Reported side effect of depression or lassitude

Weak monoamine oxidase (MAO) inhibitor, inhibition of P450 enzymes

Disulfiram reaction if patient drinks alcohol

Rare cases of serotonin syndrome, mania

Vincristine and vinblastine—depressive reactions reported

Pemetrexed

Depression reported (Cohen et al., 2005), an antifolate antimetabolite

The drug is given with folate and vitamin B12 supplementation

L-asparaginase

Irritability, depression, hallucination (Haskell et al., 1969; Oettgen et al., 1970)

Paclitaxel fatigue, given with steroids to prevent hypersensitivity

Docetaxel prominent fatigue, given with corticosteroids to prevent hypersensitivity (Thornton et al., 2008)

Imantinib, cetuximab, dasatinib, sorafenib, sunitinib (O'Brien, 2003; Quek, 2009; Pirl, 2009)

Depression uncommon

Consider hypothyroidism

Interleukin-2

Dose-related depression scores (Walker et al., 1997)

Correlated with increased cytokine levels (Capuron et al., 2001)

Interferon (Musselman, 2001; Kirkwood et al., 2002; Hauschild et al., 2008; Greenberg et al., 2000; Islam et al., 2002)

Malaise and major depressive disorder common

Inhibition of P450 enzymes

Autoimmune changes in thyroid function

Manic state has been observed, usually during interferon dose reductions, or pauses in therapy, or as interferon-induced depression is treated with antidepressants

Nearly all patients develop adverse effects on memory after six doses of therapy in the dose used for advanced melanoma

Generally mild to moderate neuropsychiatric symptoms that resolve in 2–3 weeks after interferon discontinuation

Tamoxifen, aromatase inhibitors, LHRH agonists, testosterone, anti-androgens

Clinical depression related to hormonal change, history of depressive episodes, or history of mood vulnerability to hormonal change

Corticosteroids

Affective change is dose related, most likely in equivalent of prednisone 60 mg or higher.

Mood lability varying from anxiety, jitteriness, insomnia to hypomania and depression. Psychosis can occur. Mood stabilizers like atypical anti-psychotics are effective for lability as well as psychosis.

Depression may occur after cessation of these drugs.

to the prognosis (Pirl et al., 2011). In these studies of advanced lung cancer patients, care was a collaboration between an oncology team and palliative care team who kept their eyes on depressive symptoms, provided antidepressants, and focused on other psychosocial issues (Yoong et al., 2013).

Collaborative care programs for psychosocial aspects of cancer treatment have been shown to be effective for treatment of depression in four other randomized controlled trials (Ell et al., 2008; Fann et al., 2012; Sharpe et al., 2004; Kroenke et al., 2010; Fann et al., 2009) in settings as diverse as the California public health sector, a cancer center in Scotland, primary care settings, and at home. These programs are structured with psychiatrists supervising care managers who hold a caseload of patients. The psychiatrists also consult to primary medical providers on the more challenging patients for additional specialty services, and see patients themselves when required. Care managers provide brief evidence-based psychosocial treatment. The emphasis is on a population-based approach to identifying needs, measuring outcomes, sustained follow-up, vigorous outreach, and treatment to remission. Measurement-based care and clinical rating scales identify patients who require treatment or are at risk.

Severity of depression is measured repeatedly, and the treatment is intensified to ensure targeted improvement. Of note, Ell found in a female, predominantly Hispanic population of cancer patients, including 114 with major depression, treated with antidepressant medication and/or problem-solving therapy, a response rate of 70% at six months. At 12 months, 14% relapsed, another 17% had responded, and 13% had not responded (Ell, 2008). Continuing attention to the instrument score measuring depressive symptoms is warranted.

When the rate of depressive disorder is high for specific anti-cancer treatments, antidepressants have prevented depression. Paroxetine given before a protocol of high-dose alpha interferon for melanoma reduced the rate of depression compared to placebo (Musselman et al., 2001). In head and neck cancer patients, escitalopram 10–20 mg compared to placebo given at the outset of multimodality treatment and continued for 16–17 weeks led to a reduction in the risk of depression by more than 50%. Better quality of life was reported for three months after cessation of the antidepressant in the treated group (Lydiatt et al., 2013).

The best treatments would combine protocols for affective psychiatric diagnoses with those that help patients tolerate cancer treatment. One recent trial combined a biobehavioral intervention for stress in cancer patients with cognitive behavioral treatment tailored specifically for depression, in order to treat cancer patients with depressive disorder who were already on antidepressant medication. Concurrent anxiety disorders and high levels of cancer stress were each associated with beginning and ending treatment with more depressive symptoms. The program included progressive muscle-relaxation training, emphasis on coping with the cancer crisis, behavioral activation, communication with healthcare providers, social support, cognitive reappraisal, communicating needs, problem solving, core beliefs, rhythmic walking, review of therapy components, and strategies

for successful maintenance (Brothers et al., 2011). The strategies of mind–body medicine used to foster healing in cancer patients were combined with evidence-based strategies for those with depression (see chapter 17).

Standard protocols for cognitive behavioral therapy for anxiety disorder or depression must be adapted to the realistic worries of the cancer patient who may face real progression toward feared events. Greer and colleagues (2012) have adapted a decisional model to help patients evaluate how much negative thoughts may contain both biased and realistic elements. Adaptive thinking skills may be supplemented with acceptance-oriented coping, like mindfulness for what seems realistic or getting more information when data is missing.

PSYCHOPHARMACOLOGY

Strategic use of pharmacology in cancer patients can make important contributions to their quality of life.

1. If patients have depressive disorder—particularly if they have a history of depressive disorder—the treatment of depression in the setting of cancer should be careful and persistent, with adequate and sequential trials of antidepressants and proactive monitoring for relapse.
2. Some patients undergoing recurrent cancer treatment will develop conditioned anxiety to procedures or traumas associated with treatment. When anxiety becomes chronic, antidepressants also have a role.
3. Anxious patients with depression do not respond as well to pharmacological treatment; multiple modalities of treatment and attention to specific anxiety, avoidance, and adherence may be particularly important.
4. Medications used for nausea with chemotherapy like olanzapine (Navari et al., 2013) or lorazepam may be used to advantage for anxiety or mood stabilization.
5. In the setting of estrogen withdrawal, serotonin reuptake inhibitors can suppress hot flashes as well as treat depression.
6. Gabapentin has benefit for neuropathic pain as well as hot flash suppression and the improvement of sleep or some types of anxiety (Pachman et al., 2012; Loprinzi et al., 2009). Duloxetine is useful both as an antidepressant and analgesic for chemotherapy-induced neuropathic pain (Lavoie-Smith et al., 2013).
7. Akathisia should not be missed when due to prochlorperazine.
8. Serotonin reuptake inhibitors can cause initial nausea and appetite suppression. This can be difficult in the anorectic patient, but ondansetron or another drug that offers 5HT₃ blockade can be used as an antidote for the nausea until initial nausea dissipates and an anti-depressant response occurs.
9. Mirtazapine has an advantage in patients who wish for better sleep and appetite (Riechmann et al., 2010).

10. Psychostimulants methylphenidate and dextroamphetamine have been used in the medically ill to improve concentration and attention, mood, and energy. They have the advantage of a quick effect. Recent meta-analyses have shown marginal improvement for depression or cancer-related fatigue, with more benefit in those more fatigued (Minton et al., 2011). Modafinil has also been useful to alert patients.

CANCER TREATMENT-ASSOCIATED COGNITIVE DECLINE

Since patients often have difficulty concentrating and thinking during chemotherapy treatment, they worry about permanent effects on the brain. The term “chemo-brain” suggests that chemotherapy puts cognitive functions at risk. Only a subset of patients has distress from clinically significant, persistent cognitive consequences.

Patients do not think as well as they face a series of infusions, recurrent inflammation, fatigue, and anemia. Anticholinergic medications, sedatives, corticosteroids, and narcotics that contribute to cognitive impairment are often added to the mix. Systemic illness with associated cytokines brings on a variety of cognitive complaints, fatigue, and low mood. Just as it takes time to recover from the fatigue associated with chemotherapy, it takes time to recover from the marathon of treatment. Breast cancer survivors, particularly those who had adjuvant chemotherapy, show improvement after a year; but markers for chronic inflammation and subjective cognitive complaints can persist (Bower, 2011).

Younger premenopausal women with breast cancer, three to four months after treatment with chemotherapy, had more difficulty with concentration, memory, processing speed, and more self-reported cognitive complaints of distraction, poor memory of names, and searching for words. Common complaints are being easily distracted, having difficulty concentrating and staying on task, and having difficulty recalling recent events or what was just said to them. The late transition to menopause even without cancer treatment is associated with temporary cognitive decrements in verbal memory, processing speed, and working memory (Greendale et al., 2009), and cognitive difficulties may be greater with the use of tamoxifen and chemotherapy compared to chemotherapy alone (Castellon et al., 2004) or tamoxifen compared to exemestane (Schilder et al., 2010; Janelins et al., 2011). These hormonal effects may be more problematic in young patients.

The patients at risk for cognitive impairment from non-hormonal treatments may be older, may already have cognitive decline at cancer diagnosis, or may have genetic risk factors for cognitive impairment in cancer survivors like apolipoprotein E and catechol-0-methyltransferase (COMT) Val-allele genotypes. The more vulnerable patients may have less cognitive reserve, in terms of education, occupational attainment, and lifestyle.

Clinical depression, by itself associated with poor concentration, poor sleep, fatigue, and negative self-image, amplifies

cognitive complaints. Neuropsychiatric testing does not typically document findings that parallel these complaints.

Patients who undergo hematopoietic stem cell transplantation (HCT) often develop delirium or seizures with significant cognitive impairment, gradually recovering after the procedure. About half have mild long-term deficits, and 20–28% have moderate long-term deficits, more than two standard deviations below population norms. The likelihood of persistent cognitive impairment is related to cumulative risk factors over time (Jim et al., 2012). These factors include history of cranial irradiation, intrathecal chemotherapy, total-body irradiation, multiple courses of standard-dose chemotherapy, baseline impairment, allogeneic rather than autologous transplantation, unrelated donor, and length of hospital stay. Hospital-stay duration is a proxy for complications of treatment like graft vs. host disease, or the use of steroids and narcotics. The domains most often impaired are memory and executive functioning, the ability to store and retrieve verbal and visual information, and the ability to plan higher order tasks. Cancer patients who receive standard-dose chemotherapy may have structural changes: for instance, reductions in gray matter, primarily in frontal structures and hippocampus, and white matter integrity (Ahles et al., 2012; Deprez et al., 2012).

The best clinical strategy for cognitive complaints is to simplify medication regimens, improve quality of sleep, and give the best treatment for depressive disorder. More thorough neuropsychological testing can offer objective data, clarifying particular deficits. Practice of compensatory strategies can lead to improvements in the range of 0.5 to 1.0 standard deviation on objective neuropsychological function and subjective description of function (Ferguson, 2007; or Ferguson et al., 2012). Cognitive rehabilitation, particularly in patients with brain tumors, has shown benefit (Langenbahn et al., 2013). Modafinil can make a positive contribution (Kohli, 2009; Lundorff et al., 2009).

Tests for cognitive impairment related to cancer should focus on the frontal subcortical profile, particularly the domains of learning, memory, processing speed, and executive function (more complex attention). A task force has suggested using standard tests: Hopkins Verbal Learning Test–Revised HVLT-R, Trail-Making Test (TMT), and the Controlled Oral Word Association (COWA) of the Multilingual Aphasia Examination. Tests for working memory like the auditory Consonant Trigrams, or Paced Auditory Serial Addition Test, Brief Test of Attention, and WAIS-III Letter-Number Sequencing may be added (Wefel, 2011).

PSYCHOSIS

It is uncommon for a patient to have a psychotic episode with hallucinations, delusions, and thought disorder from cancer alone. Delirium is the most common reason for delusion or hallucination. Corticosteroids given exogenously for treatment would be the most likely reason to see psychosis in cancer patients.

Tumors that produce corticosteroids also can lead to psychosis of Cushing's syndrome, including adrenocortical carcinoma, ACTH-producing tumor of the pituitary, and ectopic ACTH (Ilias, 2005). Antipsychotic medications may have some benefit as the tumor producing high levels of endogenous corticosteroid is treated. If the tumor continues to progress and psychotic symptoms persist, mifepristone can reduce psychiatric symptoms (Johanssen & Allolio, 2007).

There are case reports of psychosis occurring with carcinoid and thymoma. Chemotherapy has rarely led to psychosis; recent literature includes two cases associated with sunitinib, one with ifosfamide neurotoxicity (responsive to methylene blue), and one with 5-fluorouracil (5-FU) neurotoxicity. Neurotoxicity from 5-FU is worse in the setting of a vulnerable blood-brain barrier or dehydropyrimidine dehydrogenase (D6PD) deficiency. Sunitinib can cause cobalamin deficiency and hypothyroidism. An ifosfamide metabolite is thought to be the culprit in ifosfamide-induced encephalopathy.

Psychosis can be a late sequela of brain tumor treated in childhood or adolescence. Late-onset persistent psychosis may occur in survivors of childhood brain tumors at a rate of 2–3%. Many cases are associated with cognitive impairment and imaging showing diffuse, irregular, asymmetrical focal calcifications, glial scars, and multiple small areas of necrosis and infarction (Turkel, 2007). Survivors of cancer in childhood or adolescence ($n = 3700$) in a Danish population-based, retrospective cohort study, had no greater risk for psychiatric hospitalization for any psychiatric disorder; the rate of psychiatric hospitalization was only increased in survivors of brain tumors.

Patients with serious mental illness are more likely to present for care when they already have metastases, and to die of the cancer (Kisely et al., 2013). They do not have a greater incidence of cancer than the general population, and patients with schizophrenia may even have a *lower* risk for cancer (Bushe & Hodgson, 2010). However, once they have cancer they may not be offered treatments that require active compliance, and some refuse care (Hwang et al., 2012).

The key to management of cancer treatment in a patient with schizophrenia is coordinated care between psychiatric and oncology team. Psychotic symptoms should be stabilized before cancer treatment starts. The factors that make it more likely the patient will take psychotropic medications should be maximized. Complicating factors like depression and substance abuse should be considered and treated if possible. Because the patient with psychotic disorder may have cognitive deficits like concrete thinking, clinicians should avoid theoretical and statistical examples in talking to the patient about cancer and stick to basic facts about the specific patient. Attention should be paid to the possibility of delirium rather than psychosis complicating care during the course of the illness. Familiar staff and familiarizing the patient with the settings of radiation or chemotherapy can be helpful. When patients are assumed to have capacity to make decisions about their own care, they may still need extra help to follow up consistently with multiple medical appointments and to call with specific symptoms (Irwin et al., 2014).

USE OF CLOZAPINE

The neutropenia that results from chemotherapy for cancer has a different mechanism than neutropenia caused by clozapine. Clozapine is associated with a rare risk of idiosyncratic agranulocytosis. If a schizophrenic patient has been doing well on clozapine and now faces cancer chemotherapy, there is value in maintaining her clarity of thought and the remission of delusion and hallucination. Clozapine has been used even through the ablation chemotherapy and stem cell transplant for Hodgkin's lymphoma. The risks and benefits can be evaluated in each case (Rosenberg et al., 2007; Rosenstock, 2004; McKnight et al., 2011; Manu, 2012; Andres et al., 2008; Liu et al., 2010).

In practical terms, once started on chemotherapy, the patient will need to have white cell count, hematocrit, and platelets monitored just as with any chemotherapy. If the white count drops below 2000, or the absolute neutrophil count drops below 1000, any physician (oncology or psychiatry or primary care) can contact the clozapine registry and ask for a waiver (to be granted permission to continue clozapine treatment despite the expected granulocytopenia related to chemotherapy). The waiver is normally issued if the following elements are carefully documented:

1. The low absolute neutrophil count is not related to clozapine.
2. Clozapine treatment plus chemotherapy is needed to continue to treat the tumor.
3. There is a plan for the weekly monitoring of white count and absolute neutrophil count.
4. The method of support for the bone marrow has been defined should agranulocytosis develop.

The waiver cannot be issued in advance.

NEUROPSYCHIATRIC SYNDROMES AND SUBACUTE EMERGENCIES

Some emergencies in oncological care present with psychiatric symptoms, and it is useful for psychiatrists to keep in mind the subacute emergencies of the cancer patient.

METABOLIC ABNORMALITIES

Hypercalcemia presents with fatigue, constipation, thirst, cognitive impairment, and delirium. *Hyponatremia* due to the syndrome of inappropriate diuretic hormone (Smith et al., 2000) is a cause of confusion and seizure.

SPINAL CORD COMPRESSION

Spinal cord compression can present with symptoms that are gradual and not readily recognized: weakness in legs, falling, and incontinence associated with back pain. While not strictly psychiatric, the psychiatrist may hear about these embarrassing symptoms first.

BRAIN METASTASES

When a patient has a known cancer diagnosis, changes in mental status may signal brain metastases. The likelihood increases with the stage of cancer at first presentation and more common in some tumors than others. The total incidence proportion percentage of brain metastases was 10% for patients with primary lung, melanoma, breast, renal, or colorectal cancer. The rate was highest for lung (20%), then melanoma (7%), renal 7%, breast 5%, and colorectal cancers (2%) (Barnholtz-Sloan et al., 2004).

LEPTOMENINGEAL METASTASES

Leptomeningeal metastases may present with mental status changes and minimal brain MRI findings. Cancer spreads to the arachnoid and pia mater, the leptomeninges, surrounding the cerebrospinal fluid (CSF) in 5–8% of all patients with cancer. As treatments extend survival, the problem may become more common. Leptomeningeal metastases occur more often in breast cancer, particularly lobular, lung; melanoma, acute lymphoblastic leukemia, non-Hodgkin's lymphoma, and GI malignancies, but any cancer can spread to the leptomeninges (Groves, 2011). Patients usually present with cranial nerve and spinal nerve root dysfunction, but also mental status abnormalities, headache, syncope, seizures, balance problems, and nausea and vomiting. Diplopia, hearing changes and facial weakness may be signs of cranial nerve deficits. Diagnosis requires brain MRI with gadolinium and CSF evaluation for tumor cells. The entire neuraxis needs to be evaluated. Typically, the MRI shows contrast enhancement of the leptomeninges, subependyma, cranial and spinal nerves. It is not uncommon, however, for an MRI to be positive and the CSF negative or for the MRI to be normal in hematological cancers with leptomeningeal disease. Bevacizumab makes it harder to see the typical findings of leptomeningeal enhancement (Keinschmidet-DeMasters & Damek, 2010). If the patient presents with mental status changes deemed psychiatric and more subtle clinical findings, the psychiatrist's role may be to remain suspicious about cancer-related causes of deterioration.

PARANEOPLASTIC LIMBIC ENCEPHALITIS AND ENCEPHALOMYELITIS

A paraneoplastic autoimmune encephalitis in adults and children due to antibodies against neuronal cell surface antigens or immune reactions to intracellular antigens can present with psychiatric symptoms. Disseminated neuronal loss and inflammatory lesions in different parts of the nervous system, especially the hippocampus, the lower brainstem, spinal cord or dorsal root ganglia, characterize this syndrome. About half the patients with the syndrome associated with the onconeural antigen Hu-abs have a subacute sensory neuropathy, and some have cerebellar signs and limbic encephalitis. Most of these patients have small cell lung cancer (SCLC), and the course of the syndrome can improve with tumor treatment and relapse with tumor recurrence. Collapsin response mediator protein type 5 (CV2/CRMP5)-Abs and amphiphysin-abs

are also implicated. Limbic encephalitis is now seen as part of a more disseminated encephalitis as more than the limbic system may be affected (Didelot & Honnorat, 2014).

Limbic encephalitis is characterized by short-term memory loss (an anterograde amnesia), behavioral disturbance, confusion, and seizures (Kayser et al., 2010). Irritability, depression, hallucinations, sleep disturbance, personality disturbances, and short-term memory loss progressing to dementia may be noted. In addition to a mild lymphocytic pleocytosis in the CSF, imaging may show medial temporal lobe hyperintensities on fluid-attenuated inversion recovery (FLAIR) and T2-weighted images with progressive hippocampal gyrus volume loss. The descriptions have ranged from psychosis to obsessive compulsive disorder. Abnormalities are noted in the limbic system and medial temporal lobe on MRI or positron emission tomography (PET). The presence of antibodies does not necessarily indicate that there is an underlying tumor. However, almost all patients with Hu-Abs have cancer after 5 years of follow-up. Ma2-Abs is associated with cancer in the majority of cases, mostly SCLC, but also testicular cancer. Antibodies to gamma aminobutyric acid-b receptor (GABA_BR-ab) lead to limbic encephalitis in Hu-negative SCLC patients presenting with seizures (Boronat et al., 2011). Voltage gated potassium channel/ leucine rich glioma-inactivated 1 protein(VGKC/LGII) antibody-positive limbic encephalitis is associated with tumor in 12% of cases. The presentation includes hyponatremia, autonomic symptoms, and seizures, in addition to amnesia. Malignant thymoma as well as SCLC have been reported. Rarely limbic encephalitis associated with other antibodies have been linked to thymoma, breast cancer, lung cancer, or prostate cancer (Didelot & Honnorat, 2014).

Immunotherapy (intravenous immunoglobulin G (IgG) and/or plasma exchange at presentation for rapid antibody clearance, followed by six months of high-dose corticosteroids) may be helpful. Tumor resection, chemotherapy, or radiotherapy by reducing or removing the tumor can have benefit. Cortical atrophy is associated with persistent cognitive deficits, especially in verbal and visual memory.

Limbic encephalitis from antibodies to N-methyl-D-aspartate receptor (NMDA_R-Abs) is a syndrome that psychiatrists should not miss. The antibody targets the N-terminal extracellular domain of the NR1 subunit of the glutamate receptor NMDA interfering with the glutamatergic pathway. It presents in the psychiatric setting as subacute atypical psychosis, irritability, catatonia, dyskinesia, autonomic instability, and central hypoventilation (Irani, 2011). This syndrome occurring predominantly in women, begins with psychiatric symptoms and seizures and progresses to movement disorders, loss of consciousness, and dysautonomia in one-third. In the first stage CSF lymphocytosis is noted; in the second oligoclonal bands are found in the CSF (Dalmau et al., 2014). It is associated with ovarian teratoma, and removal of the teratoma may be curative. The pertinent examination when this syndrome is suspected is transvaginal ultrasound and/or pelvic MRI. This syndrome has been reported in children in association with teratoma and neuroblastoma (Didelot & Honnorat, 2011).

POSTERIOR REVERSIBLE ENCEPHALOPATHY SYNDROME (PRES)

Posterior reversible encephalopathy syndrome (PRES) is a syndrome of hypertension, headache, speech difficulty, altered consciousness, visual hallucinations, change in mental status, seizures, hallucinations, acute visual changes, and findings of symmetrical white matter lesions in parietal and occipital lobes (Hinchey, 1996).

The angiogenesis inhibitors put patients at risk for hypertension, alteration in the blood–brain barrier, capillary leakage, and vasogenic edema. The effects are more prominent posteriorly because of sparse sympathetic innervations of the vertebrobasilar system. Hypomagnesemia facilitates cortical spreading depression. Non-enhancing, confluent, periventricular white matter lesions, necrosis, ventriculomegaly, and cortical atrophy are seen with delayed onset of several months. An MRI with FLAIR images and diffusion-weighted sequences should be done. Treatment is control of blood pressure and management of seizures with anticonvulsants for three to six months. A specific offending agent should be discontinued. PRES is also one of the immune-related adverse events associated with some tyrosine kinase inhibitors.

CHEMOTHERAPY-INDUCED LEUKOENCEPHALOPATHY

Methotrexate leukoencephalopathy is precipitated in the setting of high-dose or intrathecal treatment, but it occurs later than PRES, resolves more slowly, and is associated with hemiparesis, paraparesis, and choreoathetoid movements. Visual disturbance and change in mental status are less prominent (Filley, 2005). Other chemotherapy agents known to cause leukoencephalopathy are cisplatin, ifosfamide, 5-fluoruracil, cytarabine, and carmustine. Delayed leukoencephalopathy syndrome mimicking stroke is seen mainly with methotrexate, 5-FU, and capecitabine.

Leukoencephalopathy Due to Radiation Treatment with or Without Chemotherapy

The combination of radiation treatment and intrathecal methotrexate increases the risk of cognitive impairment (Duffner, 2004; Crossen et al., 1994). Children treated for acute lymphocytic leukemia or a brain tumor with cranial irradiation are at risk for cognitive decline. Cognitive decline is progressive over at least ten years. A radiation-induced progressive microvasculopathy may account for this progression. Babies are particularly prone to radiotoxicity in the first two years of life because of the rapid growth of the brain and white matter development in those years. Cognitive defects have been seen in verbal comprehension, perceptual organization, distractibility, and memory in survivors of acute lymphocytic leukemia. Visuomotor integration, sequential memory, fine motor coordination, processing speed, and math abilities may also be affected. Risk factors include young age, female gender, and time since radiation. The

volume and dose of radiation are also thought to be factors. Even with a relatively low dose of cranial radiation, deficits can persist, particularly in tasks involving rapid processing of information (Edelstein et al., 2011). Children exposed to cranial irradiation may also suffer hypothyroidism and growth hormone deficiency. Children who have been treated for leukemia or brain tumors should be monitored for cognitive and endocrine dysfunction.

CLINICAL PEARLS

- In confronting a life-threatening illness, the primary paradox is that a dying man believes in the fact of his own death but hopes that he is an exception (Weisman, 1972, p. 13).
- Hope is related to a desirable self-image and a belief in the personal ability to exert a degree of influence on the world (Weisman, 1972, p. 20); the conviction that a person may do something worth doing (p. 21).
- In order to treat demoralization, Griffith and Gaby focus questions at the bedside to find the dominant existential theme in the patient's experience of illness and then suggest nudging the patient forward with a series of questions oriented to attributes of resilience.
- Treatment-induced symptoms are less likely to persist if conditioning did not occur initially (Cameron, 2001). Younger patients, those with a history of motion sickness, and those with more emetic treatments are more at risk for conditioning (Andrykowski, 1990).
- Among more than 6,500 survivors of childhood cancer compared to sibling controls, Stuber et al. (2010) found only a minority (9%) who reported functional impairment and/or clinical distress and symptoms consistent with a full diagnosis of PTSD.
- The cancers most associated with the highest rates of suicide are lung, stomach, oral cavity and pharynx, larynx, and pancreatic cancer (Misono et al., 2008).
- Hypothyroidism can also develop in patients on newer anti-cancer agents, immune modulators, tyrosine kinase inhibitors (Lodish et al., 2010), and lenalidomide.
- Clozapine has been used even through the ablation chemotherapy and stem cell transplant for Hodgkin's lymphoma. The mechanism of agranulocytosis from clozapine is idiosyncratic and distinct from the mechanism of chemotherapy-induced leucopenia.
- Patients with serious mental illness are more likely to present for care when they already have metastases, and to die of the cancer (Kisely, 2013). They do not have a greater incidence of cancer than the general population, and patients with schizophrenia may even have a lower risk for cancer (Bushe et al., 2010); however, they present with more advanced disease.

- Collaborative care programs for psychosocial aspects of cancer treatment have been shown effective for treatment of depression in five randomized controlled trials (Ell, 2008; Fann, 2012; Sharpe, 2004; Kroenke, 2010; Fann, 2009).
- Antibodies against NMDA receptors (NMDA-Abs) are associated with widespread encephalitis and paraneoplastic limbic encephalitis seen as subacute atypical psychosis, catatonia, dyskinesia, autonomic instability, and central hypoventilation. This syndrome is associated with ovarian teratoma, and removal of the teratoma may be curative.

INTRODUCTION

The psychiatric care of the patient with hematological illnesses is the focus of this chapter. This includes patients with anemia; and B12 and folate deficiency, patients with sickle cell disease, thalassemia; patients with clotting disorders and those who feign clotting disorders; and patients whose religion restricts the use of transfusions.

The making of hemoglobin requires iron, folate, and vitamin B12; the deficiency of these nutrients affects not only the blood but mood, cognition, and the development of the nervous system. Genetic disorders of hemoglobin and clotting factors lead to sickle cell anemia's vaso-occlusive crises, thalassemia's organ injury, hemophilia's risk of bleeding, and the psychological challenges for those who suffer with these disorders. The familial enzyme deficiencies of porphyrias that can lead to confusion and abdominal pain evolve from the neurotoxic effects of hepatic overproduction of metabolites in the heme biosynthetic pathway. Thrombocytopenic thrombotic purpura (TTP) and hyperviscosity syndrome are distinct hematological syndromes that can both present with signs of microangiopathic injury in the brain.

We also discuss agranulocytosis associated with clozapine, as well as bleeding risks with selective serotonin reuptake inhibitors (SSRIs). We review how to recognize patients with factitious disorder using anticoagulation as a means to become a patient. Patients who are Jehovah's Witnesses (who restrict the use of blood transfusions) face complex decisions in the setting of medical illness; and medical psychiatrists may be consulted.

IRON DEFICIENCY ANEMIA

David Axelrod

Iron deficiency, the world's most common nutritional deficiency, has a variety of psychiatric implications.

Besides anemia, iron deficiency is associated with pica and restless legs syndrome. Adequate iron, is critical for healthy brain development during gestation and the first months of life.

Iron, a component of hemoglobin, is essential to red blood cell production. Iron deficiency anemia, a hypochromic microcytic anemia, is an advanced state of iron deficiency, characterized by low or absent iron stores in the bone marrow. Laboratory measures show low serum iron concentration, low transferrin saturation, low serum ferritin, low hemoglobin concentration, and an associated elevation of free erythrocyte porphyrin and transferrin (Dorland, 2003).

Impaired iron intake, iron loss, or increased metabolic demand for iron can all lead to deficiency. The most common etiologies of iron deficiency anemia are chronic blood loss and, more rarely, decreased iron absorption. In men and in post-menopausal women, the first suspect is chronic bleeding from the gastrointestinal tract; in adults, the most common causes of gastrointestinal bleeding are peptic ulcer, reflux esophagitis, gastritis, hemorrhoids, vascular anomalies, diverticulitis, and neoplasms (Coban, 2003). In pre-menopausal women, heavy menstrual flow is a common cause of iron loss (Hallberg et al., 1995). The medical etiology for blood loss is always considered before blind iron replacement is prescribed.

In infants, iron deficiency anemia most often results from diets of milk that are not supplemented with adequate iron, or milk from lactating mothers already iron deficient. Most brands of infant formula are supplemented with iron. Premature infants are at even greater risk. For older children and young adults, an iron-poor diet may contribute to deficiency. Good sources of iron include animal-based foods such as beef, pork, poultry, fish, clams, and oysters. Plant sources of iron include leafy green vegetables, legumes, dried fruits, and molasses. Iron-enriched cereals, bread, and rice are other high iron sources. Coffee, tea, and cola may all interfere with iron absorption.

Due to poor nutrition, chronically mentally ill, homeless, and poverty-stricken patients all are at higher risk; as are young men, particularly during growth spurts; and premenopausal women with heavy menstrual flow (Hallberg,

* The following sections were reprinted and adapted with permission from the American Psychiatric Publishing's *Textbook of Psychosomatic Medicine: Psychiatric Care of the Medically Ill* (copyright, 2011).

1995). In pregnant women, iron-deficiency anemia has a high prevalence due to diversion of iron to the fetus and blood loss during delivery.

Daily iron demand dramatically increases during pregnancy and continues through to term. Breastfeeding leads to additional iron diversion to the baby, making iron deficiency common in the postpartum period (Milman, 2006).

Malabsorption of iron is uncommon, except after certain types of gastrointestinal surgery, especially gastrectomy or gastric bypass surgery, as the primary locus of absorption is the duodenum. In malabsorption syndromes, iron deficiency may take years to develop, due to the indolent nature of iron loss. Atrophic gastritis, *H. pylori* gastritis, and celiac disease are associated with iron malabsorption (Annibale et al., 2003; Dickey et al., 1999).

CLINICAL MANIFESTATIONS

Severe iron-deficiency anemia is associated with all of the various symptoms and signs of anemia, resulting from the body's response to hypoxia, including tachycardia with palpitations, pounding in the ears, headache, lightheadedness, and angina pectoris. Clinical symptoms of anemia include fatigue, tiredness, weakness, headache, irritability, and exercise intolerance. Glossal pain, reduced salivary flow with dry mouth and atrophy of tongue papillae, and alopecia may be more specific to iron deficiency (Osaki et al., 1999; Trost et al., 2006). Physical signs also include pallor, glossitis (smooth, red tongue), stomatitis, and angular cheilitis. Retinal hemorrhages and exudates may be seen in severely anemic patients. Koilonychia (dystrophy of the fingernails), a well-known finding in iron deficiency anemia, is uncommon (see Table 58.1).

NEUROPSYCHIATRIC MANIFESTATIONS

A hemoglobin level of less than 10 g/dL puts patients at risk of developing neuropsychiatric symptoms. Neuropsychiatric manifestations include depression, developmental delay, cognitive impairment, restless leg syndrome, and fatigue. Iron

deficiency anemia may impair vision by causing occlusion of the central retinal artery, and can impair auditory function by an unknown mechanism. It has also been demonstrated to lead to decreased work and exercise performance, and to immune system abnormalities (Cook et al., 1989).

Iron is thought to play a crucial role in neurological development. Iron deficiency anemia is associated with both mental and motor developmental delays in infants and young children (Booth & Aukett, 1997). Many studies from all over the world have found that infants with iron deficiency anemia at 6–24 months old had poorer cognitive, motor, and social/emotional functioning. Although a few studies showed dramatic improvement after iron treatment, most have reported persistent deficit seven after three months of treatment (Lozoff, 2006). Children and adolescents with iron deficiency have been shown to have lower standardized math scores compared to children with normal iron status (Halterman et al., 2001). Long-lasting effects noted in the auditory and visual system function as well as memory and behavior have been attributed to iron's role in myelination and neurotransmitter synthesis (Algarin et al., 2003; Congdon et al., 2012). Less well established is the relationship of iron deficiency anemia to developmental deficits in adolescents and young adults.

In adults, iron deficiency anemia may impair cognitive function. In the postpartum period, when there is a high prevalence of iron deficiency, there is a strong association of low iron status with depression, stress, and impaired cognitive functioning in the mother (Beard et al., 2005). Women who have iron deficiency anemia are also more likely to have postpartum fatigue (Lee & Zaffke, 1999). In the elderly, anemic patients demonstrate significantly worse results on almost all measures of cognitive and functional assessments, mood, and quality of life (Lucca et al., 2008).

Patients with iron deficiency anemia may crave both food items and non-food substances. Pica, particularly the compulsive eating of clay, and pagophagia (ingesting extraordinary amounts of ice) are specific symptoms prevalent in patients with iron deficiency anemia (Rector, 1989; Reynolds et al., 1968; Kettaneh et al., 2005). Pica is more common in pregnant women and children. Why iron deficient patients eat ice or clay is not known, but treatment of the anemia seems to reduce the behavior (Coltman, 1969; Woods, 1970; Young, 2010).

Brain iron deficiency is suspected to play a role in restless leg syndrome (Krieger & Schroeder, 2001) by causing dopaminergic dysfunction (Connor et al., 2009). The severity of the syndrome has been demonstrated to correlate with serum ferritin levels (Sun et al., 1998). Some studies find that treatment with iron improves symptoms of restless legs syndrome (Krieger, 2001; O'Keeffe et al., 1994); however, a *Cochrane Review* of six studies found insufficient evidence to support this (Trotti et al., 2012).

DIAGNOSIS AND TREATMENT

Iron deficiency anemia often is discovered incidentally through screening laboratory tests. Plasma iron concentration and serum ferritin concentration are usually both low, and

Table 58.1 MANIFESTATIONS OF IRON DEFICIENCY ANEMIA

NEUROPSYCHIATRIC	NON-NEUROPSYCHIATRIC
Cognitive impairment	Alopecia
Depression	Angina
Developmental delay	Angular cheilitis
Fatigue	Exercise intolerance
Headache	Glossitis
Impaired auditory function	Koilonychia
Impaired vision	Pallor
Irritability	Stomatitis
Restless legs syndrome	Weakness

iron-binding capacity is increased. In inflammatory states, ferritin may be elevated.

All patients should be educated to maintain a diversified diet with adequate iron. Supplemental iron is almost always necessary for recovery. Iron supplementation can be replaced orally, parentally, or as a blood transfusion. The dosage in adults should be enough to provide between 150 mg and 200 mg of iron daily that may be taken in 3–4 doses one hour before meals. The effectiveness of oral iron is compromised by poor absorption, poor compliance, and side effects (e.g., constipation). Side effects, which limit compliance, are dose-dependent and may be ameliorated by choice of preparation. In one study, ferric disglycinate caused the lowest rate of side effects compared to other formulations (Melamed et al., 2007). The elderly are particularly sensitive to side effects. Severe iron deficiency anemia can be treated with combined therapy of erythropoietin and intravenous iron (Breyman et al., 2001).

Symptom improvement is generally rapid after iron repletion. Headaches, fatigue, paresthesias, and pica rapidly resolve (Rector, 1989). There are conflicting data as to whether oral iron improves mental development in infants (Lozoff & Georgieff, 1982, 2006).

B₁₂ AND FOLATE DEFICIENCY

Madeline Becker

Many of the patients who are seen in the medical or psychiatric setting; older, malnourished, those with psychiatric disorders; strict vegans; and those who had gastric surgery are at high risk for both B₁₂ and folic acid deficiency. Both folate and B₁₂ deficiency are a consideration in patients with cognitive impairment, depression, and ataxia.

B₁₂ and folate deficiency lead to megaloblastic anemia. Both B₁₂ and folate are cofactors for the conversion of homocysteine to methionine, and are necessary for DNA synthesis (Andres et al., 2004). Deficiency of either B₁₂ or folate correlates with high homocysteine levels, which is a risk factor for cardiovascular disease, stroke, dementia, and Alzheimer's disease (Carmel et al., 2003; Ravaglia et al., 2005; Reynolds et al., 2006; Seshadri et al., 2002). Elevated homocysteine level and high methylmalonic acid level indicate impairment in the cobalamin metabolic pathway. Both high homocysteine levels and deficiencies of B₁₂ and folate have been associated with depression (Bottiglieri et al., 2000; Kim, 2008a). Multiple studies have shown a significant correlation between low levels of B₁₂ and cognitive impairment and dementia (Vogel, 2009).

VITAMIN B₁₂

B₁₂ is found in meat and dairy products, and in a variety of foods that are fortified with B₁₂, including fortified cereals and fortified nutritional yeast. The most common cause of B₁₂ deficiency is pernicious anemia, an autoimmune disorder that causes loss of gastric parietal cells and an absence of intrinsic factor. Intrinsic factor is necessary for B₁₂ absorption.

Pernicious anemia is often associated with other autoimmune disorders, including Hashimoto's thyroiditis, type 1 diabetes mellitus, Addison's disease, Graves' disease, vitiligo, myasthenia gravis, primary ovarian failure, and hypoparathyroidism (Carmel, 2003; Toh et al., 1997).

The prevalence of B₁₂ deficiency in the elderly is common, about 20% (Andres, 2004; Vogel, 2009); and is often unrecognized because the clinical manifestations can be subtle. In the elderly, B₁₂ deficiency is usually associated with pernicious anemia (20–30%), or food-cobalamin malabsorption (50–70%), mostly due to gastric atrophy (Andres et al., 2009). B₁₂ malabsorption or gastric atrophy may be caused by *H. pylori* infection or intestinal overgrowth due to antibiotics.

Medications, including the chronic use of metformin (Bauman et al., 2000; Liu et al., 2006), antacids, H₂ receptor antagonists, and proton pump inhibitors also can cause B₁₂ deficiency (Valuck et al., 2004). B₁₂ malabsorption also can be caused by alcoholism, pancreatic failure, and Sjogren's syndrome. Vitamin B₁₂ malabsorption also may result from gastrectomy, gastric bypass surgery (Malinowski, 2006), ileal diseases or resection, Crohn's disease, autoimmune deficiency syndrome (AIDS), or parasitic infestation with *Diphyllobothrium latum* (fish tapeworm) (Andres, 2004).

Dietary B₁₂ deficiency is rare, but may occur in strict vegans. B₁₂ deficiency also can occur in children who are exclusively breastfed and whose mothers are vegans (Chalouhi et al., 2008).

Abuse of nitrous oxide—"whippit" abuse—can cause neuropsychiatric signs of vitamin B₁₂ deficiency when used chronically in patients with marginal levels of B₁₂ (Sethi et al., 2006). The anesthetic inactivates cobalamin.

Neuropsychiatric Manifestations

Neurological and psychiatric symptoms are common in B₁₂ deficiency, and may manifest before or without obvious hematological signs (Lindenbaum et al., 1988; Carmel, 2008). Peripheral neuropathy may present with paresthesias and numbness. A less common, but classic neurological manifestation is subacute combined degeneration of the spinal cord (Reynolds, 2006). This results in loss of vibration and position sense and ataxia (caused by posterior column disruption) and weakness, spasticity, and extensor plantar responses (caused by lateral column disruption) (Toh, 1997). Other, less common, manifestations of B₁₂ deficiency include optic neuritis, optic atrophy, and incontinence.

In addition to neurological symptoms of ataxia and paresthesias, psychiatric symptoms may include mood changes, acute psychotic depression (Bar-Shai et al., 2012), psychosis (Rajkumar, 2008; Tufan et al., 2012; Hutto, 1997; Dogan et al., 2012), catatonia (Lewis et al., 2009), and obsessive-compulsive disorder (Sharma et al., 2012). No one symptom of psychosis is more commonly observed (Hutto, 1997).

B₁₂ deficiency and high homocysteine have been associated with cognitive impairments (Selhub et al., 2000) and reversible dementia. B₁₂ deficiency has also been associated with an increased rate of brain atrophy and damage to white matter (Smith et al., 2009). Multiple studies have shown an

association with both B₁₂ deficiency and high plasma homocysteine levels in patients with dementia; however, the relationship between vitamin B₁₂ and dementia remains unclear (Andres, 2004; Reynolds, 2006; Vogel, 2009). In children, B₁₂ deficiency may cause irritability, failure to thrive, apathy, anorexia, abnormal movements, and developmental regression, which are generally responsive to supplementation (Chalouhi, 2008).

Diagnosis and Treatment

A low-normal serum vitamin B₁₂ level in the presence of megaloblastic cells and hypersegmented neutrophils, with or without anemia and/or the typical neuropsychiatric findings, should lead to further investigation for B₁₂ deficiency. There is no “gold standard,” and there are different normal values for cobalamin levels; however, a deficiency is usually defined as a B₁₂ level less than 200 pg/ml (Schreir 2014). Elevated serum methylmalonic acid and elevated serum total homocysteine also can help establish if deficiency exists, as they are markers for functional B₁₂ status (Smith, 2009). These tests should be done when the B₁₂ level is found to be low or borderline. Tests for intrinsic factor antibody, serum gastrin, and a Schilling test may be used for diagnosing pernicious anemia. Identifying the cause of the B₁₂ deficiency, however, yields important clinical information and can guide diagnosis and treatment (Carmel, 2003).

Daily injections of 1000 mcg of cyanocobalamin are recommended for one week, then 1000 mcg every week for four weeks, then maintenance doses every 1–3 months, depending on the severity of the deficiency. Clinical evidence suggests that oral B₁₂ replacement (1000 mcg) also is effective as a second-line therapy (Andres, 2009). Significant improvement of neuropsychiatric function has been shown after B₁₂ administration (Andres 2009); the degree of recovery is correlated with symptom severity before treatment (Reynolds 2006). Neurological recovery is more variable than hematological improvement (Carmel, 2008). Continued maintenance therapy is recommended to fully replenish body stores. Administration of folate, without B₁₂, will reverse the hematological abnormalities, but if there is also an unrecognized B₁₂ deficiency, neurological impairment may progress further, sometimes leading to irreversible deficits (e.g., subacute degeneration of the spinal cord) (Reynolds, 2006).

FOLIC ACID

Folic acid is found in both animal products and leafy green vegetables. Folate is important in mood, cognition, brain growth, and DNA synthesis and repair. These mechanisms are mediated through nucleotide synthesis and DNA transcription and integrity (Carmel, 2003; Duthie, 2011). Adequate folate levels may protect against certain cancers, neural tube defects (Lucock, 2004), and dementia (Ravaglia, 2005; Lushsinger, 2007), presumably by lowering homocysteine.

Inadequate diet, alcoholism, chronic illness, drugs that interfere with folate metabolism (phenytoin, valproic acid, lamotrigine, barbiturates, trimethoprim/sulfamethoxazole,

oral contraceptives, and methotrexate), or malabsorption can cause folate deficiency (Reynolds et al., 2002). Folate deficiency is common in the elderly (Reynolds, 2006). Deficiency has been found to be relatively common in psychiatric patients, especially those with depression (Bottiglieri, 2000). This association is not entirely clear; it may in part be attributed to the use of psychotropic medications, especially anti-epileptic drugs and mood stabilizers, which are known to decrease folate levels, or to poor nutrition (Lerner et al., 2006).

Folate, by promoting conversion of homocysteine to methionine, catalyzes the production of S-adenosylmethionine (SAME), which independently influences the rate of synthesis of serotonin and perhaps other transmitters like norepinephrine and dopamine. Recent research has exploited this benefit, and doctors have given folate in the form of 5-methyltetrahydrofolate (MTHF) and SAME as supplements for treatment-resistant depression (Papakostas et al., 2012).

Clinical Manifestations

Symptoms of folate deficiency are similar to those of B₁₂ deficiency; however, subacute combined degeneration of the spinal cord is specific to B₁₂ deficiency. Depression has been associated with low baseline levels of both folate and B₁₂ (Kim, 2008B), but the association is much more commonly seen with folate deficiency (Reynolds, 2006). The megaloblastic anemia is identical to that seen in B₁₂ deficiency. Folate deficiency invariably is accompanied by an elevated plasma homocysteine level (Bottiglieri, 2000), which is associated with an increased risk of cardiovascular disease, dementia (Kim et al., 2008; Ravaglia, 2005), and depression (Bottiglieri, 2000; Kim, 2008b).

Insufficient folate during conception and early pregnancy results in neural tube defects. Since 1998, the U.S. Food and Drug Administration (FDA) mandated fortification of grains with folate in order to lower the risk of neural tube defects in women of childbearing age. This action led to a reduction in such defects and an improvement of blood folate status and homocysteine levels in adults in the United States (Jacques et al., 1999).

Diagnosis and Treatment

Low red blood cell folate combined with high plasma homocysteine is a good standard marker for the diagnosis of folate deficiency and is more accurate than measuring serum folate alone. Serum folate is quickly responsive to folate intake, but red blood cell folate offers a measure of folate presence over a longer time-average (Galloway, 2003).

If screening test for folate level is low or borderline, a homocysteine level should be checked. As mentioned before, B₁₂ levels should also be checked when screening for folate deficiency so that cobalamin deficiency is not missed.

Full treatment response to folate supplementation takes many months. Although there are no clear guidelines for the dose or duration of folate therapy, treatment is recommended for at least six months (Reynolds, 2006). To treat folate deficiency, prescribing 1 mg daily for one to four months, or until

hematological recovery is generally recommended (Schrier, 2014). For women of childbearing age, recommendations are 0.4 mg–0.8 mg daily (US Preventative Services Task Force, 2009). Higher doses are recommended for women at risk for folate deficiency or who already have had a child with a neural tube defect. Collaboration with an obstetrician is necessary. To lower homocysteine levels, 0.8 mg daily is typically required (Homocysteine Lowering Trialists' Collaboration, 2005). There has been some evidence that higher doses of folate may impair natural killer cell cytotoxicity, and possibly increase cardiac events (Smith, 2008).

B₁₂ AND FOLATE AND LINKS TO DEMENTIA

The relationship between dementia and vitamin deficiency is complex and probably bidirectional. As low B₁₂ levels and elevated homocysteine levels have been linked to cognitive impairment and dementia (Clark et al., 2007), there is controversy on whether supplementation of either folate or B₁₂ (which lower homocysteine levels) has any effect on cognition or the development of dementia. A large, randomized double-blind placebo-controlled study found that memory, information-processing speed, and sensorimotor speed were improved in elderly people getting folic acid supplements (Durga et al., 2007). There is also evidence that B₁₂ and folic acid supplementation can slow brain atrophy in elderly people with mild cognitive decline (Smith et al., 2010). However, findings to date have been inconsistent, and the association remains unclear. Although elevated plasma homocysteine levels are associated with dementia, there is no clear evidence that low B₁₂ or folate vitamin levels are *independently* related to the risk of dementia (Seshadri, 2002). To date, Cochrane Reviews show that supplementation with folic acid, with or without B₁₂, provides no *consistent* evidence of a beneficial effect on cognition or the development of dementia in individuals with either normal or impaired cognitive functioning at baseline (Balk et al., 2007; Malouf et al., 2008; Vogel et al., 2009).

HEMOPHILIA

Dimitri Markov

Hemophilia is a bleeding disorder caused by a deficiency of one of the coagulation factors essential for blood clotting. Hemophilia A (factor VIII deficiency) and hemophilia B (factor IX deficiency) are the most common inherited bleeding disorders. Hemophilia A and B are clinically indistinguishable from each other.

Disease severity is related to the plasma concentrations of the clotting factors. Classification into *mild*, *moderate*, and *severe* hemophilia is useful for predicting prognosis and bleeding propensity (Bolton-Maggs et al., 2003; Casey et al., 2003; Manco-Johnson, 2005). Patients with severe hemophilia (clotting factor concentration less than 1% of normal) may bleed spontaneously into muscles, joints, and body cavities. Patients with moderate hemophilia (concentration of clotting factor 1–5% of normal) are typically diagnosed by the age of

five years and tend to bleed less frequently. Mild hemophilia (>5% of normal concentration) usually is diagnosed following trauma, surgery, or tooth extraction later in life. Patients with mild hemophilia rarely have spontaneous bleeding (Bolton-Maggs, 2003; Manco-Johnson, 2005). Most children with hemophilia are asymptomatic until they start to crawl or walk. These children may bruise easily and bleed after minor injuries. By the age of four years, many children with hemophilia have experienced a bleed into a joint. Families of these children may be inappropriately suspected of child abuse.

Purified factor VIII became commercially available in the 1960s. The use of purified factor VIII allowed for home-based infusions, improved the quality of life, and increased the life expectancy of patients with severe hemophilia. The use of purified factor VIII has reduced the frequency of bleeds into large joints and muscles, resulting in less joint injury and fewer patients with chronic pain. As a result of this advance, patients with severe hemophilia are much less likely to experience bleeding and its complications (Bolton-Maggs, 2003; Manco-Johnson, 2005). In the early 1980s, more than 80% of patients with severe hemophilia who were older than ten years of age were infected with viral illnesses, including hepatitis B, hepatitis C, and human immunodeficiency virus (HIV) from contaminated blood products. Beginning in the 1990s, the use of recombinant clotting factors almost eliminated the risk of acquiring viral infections.

The prevalence of psychiatric disorders in patients with hemophilia is not known. Children and adolescents with hemophilia have been reported to suffer higher rates of anxiety disorders than those with asthma (Bussing & Burket, 1993). Disease-related stressors pose challenges to children with hemophilia as they proceed toward developmental milestones. While facing chronic pain, disability, social ostracism, and job and insurance discrimination, adults living with hemophilia strive for a healthy identity, autonomy, and a good quality of life (Spilsbury, 2004).

Despite the severe pain associated with joint bleeds, some physicians are reluctant to prescribe opiate analgesics due to concerns about inducing opiate dependence; furthermore, some adult patients without opiate dependence report concerns about narcotic addiction (Elander & Barry, 2003). It is important to provide adequate analgesia to patients with hemophilia, and opiate analgesics may be prescribed safely. Healthcare providers should adequately address patient concerns about becoming opiate dependent.

Individual, family, and group psychotherapy are useful psychotherapeutic modalities for helping manage the stressors associated with hemophilia (Casey, 2003; Gerstner et al., 2006).

SICKLE CELL DISEASE

David Axelrod

Sickle cell disease is the most common hemoglobinopathy, presently affecting approximately 100,000 Americans (Hassell, 2010). The disease occurs primarily in those of African descent, but also afflicts people of Mediterranean,

Asian, and Middle Eastern origin. Eight percent of African-Americans in the United States carry the sickle cell trait, and approximately one out of three hundred have the disease. The disease is a classic example of a balanced polymorphism; the asymptomatic sickle cell trait provides a selective advantage against malaria, while the homozygous disease has devastating consequences. Medical advances have transformed the disease from what was once primarily a pediatric illness into a chronic disease of adults. Life expectancy has increased from a mean of 14 years in the 1970s to close to 50 years today (Platt et al., 1994).

The vaso-occlusive crisis is the hallmark event in sickle cell disease (SCD). These recurrent “crises,” or “severe pain episodes,” are the cause of acute episodes of intense pain and represent the most common reason patients seek medical care. Occlusion of macrovasculature and microvasculature produces pain and end-organ damage. All organ systems are potentially affected, but vascular occlusion particularly causes damage to bones, kidneys, lungs, eyes, and the central nervous system. Chronic pain becomes a problem for many patients. Neuropsychiatric manifestations of SCD can be grouped into three main categories:

1. Depression and anxiety resulting from living with a chronic, stigmatizing disease associated with unpredictable painful episodes, chronic pain, and high morbidity and mortality;
2. Problems from living with chronic and acute pain that is often undertreated and when treated with opioids can produce opioid tolerance, including pseudo-addiction and true opioid dependence;
3. Central nervous system damage resulting from cerebrovascular accidents, primarily during childhood.

Psychological and psychiatric complications in patients are common and contribute to impairment in functioning and quality of life. Psychological and psychiatric treatment is believed to improve outcomes, and many comprehensive SCD centers provide psychological and psychiatric care as a component of their treatment. A significant barrier to obtaining proper psychiatric treatment for patients with SCD is that African-Americans are often reluctant to see mental health specialists, attempting to overcome their mental health problems through self-reliance and determination (Snowden, 2001). In addition, lack of psychosocial resources and lower socioeconomic status may make it more difficult to access psychiatric care (Burlew et al., 2000).

Depression and anxiety are common in SCD and correlate with more daily pain and poorer physical and social quality of life (Levenson et al., 2008). The prevalence of any depressive syndrome in SCD approaches 30% (Burlew, 2000; Jenerette et al., 2005; Levenson et al., 2008). Potentially depression-inducing stressors in SCD include living with a chronic illness, chronic pain, developmental problems, and knowledge of a decreased life expectancy. The specific diagnoses of anemia, renal failure, and stroke all are independently associated with depression (Molock et al., 1994).

Children with SCD have a higher prevalence of excessive fatigue, physical complaints, impaired self-esteem, morbid ideation, and feelings of hopelessness (Anie, 2005; Yang, 1994). Adolescents with SCD have high rates of mental disorders; one study found a prevalence of 50% (Benton et al., 2011). The most common diagnoses in Benton’s study were attention deficit disorder (40%), oppositional defiant disorder (22.5%), conduct disorder (17.5%), and major depressive disorder (12.5%). Adolescents with SCD frequently suffer from low self-esteem, heightened self-consciousness, dissatisfaction with body image, and social isolation (Morgan & Jackson, 1986).

CHRONIC AND ACUTE PAIN AND OPIOID USE

The most common reason that patients with SCD seek medical treatment is for management of pain. They have a tremendous pain burden; suffering from both episodes of acute, unpredictable, severe vaso-occlusive pain episodes, and also chronic daily pain. A recent prospective cohort study found that for these patients, pain is the rule rather than the exception. This study found that patients with SCD reported experiencing pain on more than half of the days in a year, and 29% had pain on more than 95% of the days (Smith et al., 2008).

For most cases of severe pain, nonsteroidal pain medications are inadequate. Treatment of sickle cell pain with opioids has now gained mainstream acceptance. Opioids help control pain, improve functional capacity, and decrease hospitalizations (Brookoff & Polomano, 1992; Smith et al., 2008). Chronic opioid use induces pharmacological tolerance and physiological dependence, and may lead to dysfunctional drug dependence and abuse. There is also evidence that chronic opioid use can produce cognitive deficits (Chapman et al., 2002). The few studies that address addiction in SCD report a low prevalence of addiction. Cocaine abuse may occur in up to 10% of patients with SCD who are treated with chronic opioids (Axelrod, 2011). Like patients with other chronically painful conditions, many with SCD use marijuana. In a questionnaire study from Great Britain, 36% of patients with SCD used cannabis in the previous 12 months to relieve symptoms of SCD. The main reasons for cannabis use were to reduce pain, to induce relaxation, or to relieve anxiety and depression (Howard et al., 2005).

Due to skepticism and fear of introducing iatrogenic addiction, many medical practitioners may under-treat pain in these patients (Labbe et al., 2005). Additionally, the medical literature supports the contention that African-Americans suffer from disparities of care in regards to pain management (Shavers et al., 2010). In cases of under-treatment of pain, patients may develop pseudo-addiction, where addiction-like behaviors occur in an attempt to obtain better pain control (Weissman & Haddox, 1989). Some patients seek out illegal narcotics in an attempt to better manage uncontrolled pain, and some patients use opioids to help non-pain symptoms such as depression, insomnia, and anxiety. These behaviors may lead to long-term problems with true addiction and illicit substance abuse (Alao et al., 2003). Careful monitoring with

pain agreements, psychiatric evaluation, and urine drug testing mitigate the risks of opioid treatment.

CENTRAL NERVOUS SYSTEM DAMAGE

Central nervous system (CNS) complications of SCD frequently begin in childhood and often cause cognitive deficits. An estimated 25–33% of these children have CNS effects from the disease (Schatz & McClellan, 2006). Seizures occur in 12–14% of pediatric patients with SCD (Adams, 1994; Liu, 1994). Children suffering from strokes demonstrate intellectual deficits ranging from borderline to moderate mental retardation, reduced language function, and problems with adjustment (Hariman et al., 1991). Cognitive deficits in children with SCD may lead to learning problems, intellectual impairment, verbal problems, attention and concentration deficits, and dementia later in life (Anie, 2005). As early as kindergarten, patients with SCD had lower scores in language skills and auditory discrimination, compared to their peers, scores that could not be attributed to absence from school (Steen et al., 2002). Factors contributing to poorer cognitive function include degree of anemia and older age (Vichinsky et al., 2010).

THALASSEMIA

Keira Chism

Thalassemia is an inherited autosomal recessive disorder that causes changes to the globin chains of hemoglobin. Like sickle cell disease, thalassemia is believed to persist because the heterozygote state confers a selective advantage for survival in malarial areas. Adult hemoglobin consists of a tetramer, with two alpha and two beta chains. In patients with thalassemia, the decreased or absent production of alpha or beta globin chains results in the overproduction of the other chain, and to anemia, which in turn affects patients' development (Messina et al., 2008).

There are various forms of thalassemia, with various clinical consequences. The severest form, beta-thalassemia major, causes the greatest disability. Patients with beta-thalassemia major suffer from the effects of severe and chronic anemia, stigmata of chronic hemolysis, organ damage from transfusional iron overload, and local and systemic effects of rapidly expanding erythroid bone marrow progenitors. Damaged blood cells aggregate in the spleen, leading to splenomegaly, which causes increased red blood cell trapping and worsening anemia. An increase in erythropoiesis, albeit ineffective, leads to bony deformities, with severely disfigured pelvis, spine, and skull; facial deformities; and shortening of the limbs (Cunningham, 2008).

Individuals with severe forms of thalassemia (major and intermedia) require red blood cell transfusions to prevent growth retardation, severe bony defects, congestive heart failure, and endocrinopathies. High-risk periods such as pregnancy, growth spurts, and infection-associated aplastic crises demand more frequent transfusions. Regular blood transfusions lead to iron overload. Iron deposition causes cirrhosis,

diabetes, hypogonadism, secondary amenorrhea, short stature, congestive heart failure, and arrhythmias. To prevent these effects, patients with thalassemias undergo iron chelation therapy, in the form of deferoxamine infusion or oral deferasirox. Infusion is a rather onerous form of treatment, lasting throughout the night (Musallam, 2008). Side effects include neutropenia, shortness of breath, headaches, and dizziness (Abetz et al., 2006). Blood transfusions and chelation therapy have changed thalassemia from a fatal childhood illness to a chronic adult disease. Access to, and compliance with, hematological treatment allows 90% of children born with thalassemia major to survive past 40 years of age (Clarke et al., 2009).

PSYCHOLOGICAL ISSUES

The psychiatric sequelae of thalassemia arise from the chronic nature of the disease, from its association with developmental issues, and from the burden of treatment. Patients struggle with denial, acting out, concerns about body image, and low self-esteem (Messina, 2008). Patients may suffer from bony deformities, delayed or absent sexual development, and/or growth retardation, all of which can affect self-esteem. Children with thalassemia require frequent hospitalizations, transfusions, iron chelator therapy, and sometimes surgery. Given the intensive care needed to manage their disease, these children may suffer from the common psychological disturbances of any pediatric chronic disease: isolation, loss of autonomy, and overdeveloped identification with the sick role as well as with health professionals.

Both psychological problems and psychiatric illnesses are observed to be more common in patients with thalassemia than in the general population. Several studies show a higher incidence of anxiety and depressive disorders in these patients than in age-matched controls (Cakaloz et al., 2009).

Children with thalassemia may demonstrate cognitive dysfunction, including impaired abstract reasoning and deficits in attention and memory. They suffer from problems with visuospatial skills and executive functioning. Adults with thalassemia demonstrate similar deficits, as well as slower attention and processing speed, language skills, memory, and visual-constructional skills (Armstrong, 2008). Intellectual deficits, which include cognitive impairment and lack of access to education, are likely to accrue from a variety of etiologies: chronic anemia; missed schooling from illness and treatment; and complications from treatment itself. Iron deposits in the brain, resulting from transfusions, cause cognitive issues. Patients with thalassemia have a higher risk of transient ischemic attacks and microvascular ischemic disease, which contribute to cognitive deficits (Armstrong, 2008).

The complexity of psychosocial adjustment to the chronic disease, and its impact on individuals and their families throughout the lifespan, demand a multidimensional, multidisciplinary treatment strategy. Family counseling, clear communication between healthcare providers and patients, education, and frequent psychological assessments are crucial to good psychiatric, and therefore, hematological, outcomes in these individuals. In general, patients with psychiatric

disorders have more difficulty adhering to chelation therapy. Finally, transitioning from pediatric to adult medicine also requires careful, multidisciplinary attention to foster ongoing compliance (Musallam, 2008).

PORPHYRIA

Tal Weinberger

The porphyrias are a group of eight rare metabolic disorders characterized by enzyme deficiencies in the heme biosynthesis pathway. Each porphyria is caused by deficiency of a different enzyme in the pathway, resulting in accumulation of specific toxic heme precursors. Heme is synthesized primarily in the erythropoietic cells for the production of hemoglobin, and in hepatic cells for synthesis of cytochromes and other proteins. The neuropsychiatric features of porphyria are thought to be due to neurotoxicity from hepatic overproduction of 5-aminolevulinic acid and other metabolites in this pathway (Puy et al., 2010).

Porphyrias are further categorized into “acute” (neuropsychiatric), cutaneous, and mixed forms. The four acute porphyrias are acute intermittent porphyria (AIP), variegate porphyria (VP), hereditary coproporphyria (HP), and aminolevulinic acid dehydratase deficiency porphyria (ADP). VP and hereditary coproporphyria are “mixed” porphyrias and can thus present with either neuropsychiatric or dermatological symptoms (which are characterized by a bullous or erythematous rash) (Crimlisk, 1997).

Patients with acute porphyria present with sudden, generally infrequent, crises. Clinical characteristics of these acute episodes are highly variable and can include mental status changes such as anxiety, depression, disorientation, hallucinations, and/or paranoia in 20–30% of patients. About 1% of acute attacks are fatal (Thadani et al., 2000). Most acute attacks present with severe abdominal pain (Puy et al., 2010). Muscular weakness is common, generally starting in the proximal muscles (Puy et al., 2010). In some cases, weakness can progress to quadriplegia and respiratory paralysis, resembling Guillain-Barré syndrome. Mild sensory symptoms can co-occur with a predominantly motor neuropathy (Thadani et al., 2000); motor neuropathies are unusual and thus, are a distinguishing feature of this illness. Other common symptoms include nausea, vomiting, constipation, tachycardia, and hypertension. Hyponatremia due to inappropriate antidiuretic hormone secretion occurs in 40% of cases. Seizures may occur secondary to electrolyte imbalances or as a direct manifestation of porphyria (Puy et al., 2010). The combination of acute mental status changes with acute weakness in a proximal greater than distal, neuropathic pattern is strongly suggestive of the diagnosis. AIP is the most common acute porphyria; it is caused by deficiency of porphobilinogen deaminase. It affects approximately 0.01% of the general population (Regan et al., 1999). The classic triad of symptoms in AIP consists of abdominal pain, mental status changes, and peripheral neuropathy; neuropsychiatric symptoms occur in 19–58% of patients during an acute episode (Regan et al., 1999). In addition to more obvious psychiatric symptoms such as psychosis

and agitation, AIP has also been associated with more subtle neuropsychiatric symptoms. Cases of panic attacks (Vgontzas et al., 1991) and obsessive-compulsive symptoms (Hamner, 1992) have been reported in patients with AIP. Increased incidence of generalized anxiety disorder was found in patients with both manifest and latent AIP, and the severity of anxiety symptoms was found to directly correlate with levels of porphyrin metabolites (Patience et al., 1994).

AIP, VP, and hereditary coproporphyria all have an autosomal dominant inheritance pattern with low penetrance. Only 10–15% of gene carriers ever become symptomatic (Thadani et al., 2000). Most symptomatic patients experience a few isolated attacks and then remain asymptomatic for the rest of their lives (Puy et al., 2010). As the disease remains latent in a large percentage of people carrying the gene, a third of patients have no family history. The clinical manifestations of porphyria vary dramatically. Some patients never develop symptoms, even when exposed to precipitating factors, while others have severe, life-threatening attacks without apparent triggers (Thadani et al., 2000). Acute episodes are rare before puberty and after menopause, most commonly occurring in the third decade (Puy et al., 2010). Women are four to five times more likely than men to develop the clinical syndrome (Thadani et al., 2000).

Acute episodes are precipitated by triggers that induce ALA synthase-1, the first enzyme in the heme biosynthesis pathway. As heme is necessary for the production of cytochrome P450 enzymes, the induction of these enzymes increases hepatic heme production. Most drugs that trigger acute attacks do so by inducing cytochrome P450 enzymes; since these enzymes are synthesized from heme, inducing them necessarily triggers heme synthesis. Many lists of medications considered unsafe in acute porphyria are available, but none is universally accepted. Some specific medications are widely regarded as safe, and some are generally accepted to be unsafe; however, for large number of drugs, safety data are unclear (Thadani et al., 2000). Drugs of abuse such as marijuana, Ecstasy (XTC), amphetamines, cocaine, smoking, and alcohol are also common triggers (Thadani et al., 2000). Fasting may induce hepatic amino levulinic acid (ALA) synthase, precipitating an acute attack (Crimlisk, 1997). Infectious and inflammatory processes can aggravate porphyria by inducing production of heme oxygenase 1, which catabolizes heme, thus indirectly stimulating increased heme production (Puy et al., 2010). Estrogen and progesterone can trigger acute attacks; hormone-related attacks most commonly occur during the luteal phase and during pregnancy (Crimlisk, 1997; Thadani et al., 2000). Emotional and physical stress can also induce an acute episode (Thadani et al., 2000), by unknown mechanism.

First-line diagnostic testing for porphyria includes urinalysis looking for increased porphobilinogen (PBG). Urinary 5-aminolevulinic acid (ALA) is also elevated in all three acute porphyrias (AIP, HP, and VP) during acute episodes (Puy et al., 2010). Urine can be dark due to the presence of porphyrins and other pigments. Between attacks, however, urinary concentration of PBG and ALA are often normal (Thadani et al., 2000). Measurement of urinary porphyrins

can be misleading, as they are also elevated in other disorders; thus, this is not recommended as a first-line screening test (Puy et al., 2010). DNA analysis is useful only when the disease-specific mutation in an affected family member is known, as large numbers of mutations have been identified.

The diagnosis of porphyria may be missed for many reasons. As porphyria presents with symptoms that mimic other disorders, it may not even be considered in the differential diagnosis. Additionally, evaluation of the results of screening tests is complicated, and results may be misinterpreted (Crimlisk, 1997). On rare occasions, AIP can present exclusively with psychiatric symptoms. The literature describing this phenomenon consists primarily of case reports and small case series, with a wide variety of psychiatric symptoms (Ellencweig et al., 2006). Abrupt onset and resolution of symptoms, in the context of a known porphyrinogenic trigger, should prompt suspicion of and workup for this diagnosis in the psychiatric patient.

Intravenous hemin administration is the mainstay of treatment for an acute attack, as it inhibits the formation of ALA synthase, the rate-limiting enzyme in the synthesis of heme and the buildup of porphyrins toxic to the tissue. Intravenous glucose or food also reduces synthesis of aminolevulinic acid by shunting metabolism to the carbohydrate pathway, and can improve clinical symptoms; however, experts currently recommend initiating hemin treatment immediately, as it has been found to be more effective in reducing levels of heme precursors during an acute episode. If an attack of any acute porphyria is a consideration, urine urobilinogen can be sent, and distinctions among porphyrias can come later. Urgent use of hemin intravenously and dextrose 10% or food will limit the attack. Fasting state and delay of treatment put the patient at risk for the life-threatening consequences of an acute attack like progressive motor weakness, respiratory failure, and arrhythmias (www.porphyrifoundation.com).

THROMBOTIC THROMBOCYTOPENIC PURPURA (TTP)

Keira Chism

The fluctuating changes in mental status, confusion, or headache associated with microangiopathic injury can be a presenting feature of thrombotic thrombocytopenic purpura. Although the diagnosis of thrombotic thrombocytopenic purpura (TTP) and hemolytic uremic syndrome (TTP-HUS) no longer requires the classic pentad of microangiopathic hemolytic anemia, thrombocytopenia (low platelets with or without purpura), renal insufficiency (elevated creatinine), neurological abnormalities, and fever, some combination of microangiopathic hemolytic anemia and thrombocytopenia along with the other symptoms occurs in all patients. Together, hemolytic anemia and thrombocytopenia lead to a devastating and rapid multisystem coagulopathy, with deposition of platelet thrombi in arterioles and capillaries. These deposits lead to tissue ischemia and infarction. Renal insufficiency and CNS involvement are common; cardiac involvement also occurs (George, 2010).

TTP may be associated with infection, particularly enterohemorrhagic *E. coli*; malignancy; autoimmune diseases,

especially systemic lupus erythematosus; and a history of organ or stem cell transplantation. Exposure to some medications may lead to the development of TTP: chemotherapy; non-steroidal immunosuppressants; quinine products; and some anti-platelet agents (George, 2010). Some case reports also link quetiapine with the development of TTP (Huynh et al., 2005). Up to one quarter of cases of TTP occur during pregnancy or the peripartum. Most cases of TTP are idiopathic. In these cases with no identifiable cause, molecular genetics reveals that the primary pathophysiology is deficiency or inactivity of ADAMTS13, an enzyme involved in the coagulation cascade (Meloni et al., 2001).

Psychiatric symptoms may herald the presentation of TTP. Sixty percent of patients have significant neurological changes at presentation, and up to 90% of patients develop such symptoms over the course of their illness (Meloni, 2001). Psychiatrists should consider workup for TTP in the context of unexplained change in mental status in context of low platelets and anemia. Prior to the use of plasmapheresis, TTP was associated with 95% mortality. Today, the treatment response rate, with attendant survival, reaches 80% (Meloni, 2001).

NEUROPSYCHIATRIC SYMPTOMS

TTP leads to a variety of neuropsychiatric symptoms, which can fluctuate throughout the course of the illness. Mild symptoms include headache and numbness. More serious symptoms include confusion, disorientation, paresis, aphasia, personality changes, mood changes, seizures, and coma. TTP can cause delirium, probably mediated by microvascular dysfunction and by the metabolic derangements associated with organ ischemia and failure (Meloni, 2001). One complication is nonconvulsive status epilepticus, which can occur with subtle or no motor manifestations. An electroencephalogram can be useful to make this diagnosis (Meloni, 2001). Neuroimaging rarely reveals infarct or hemorrhage, but MRI often shows findings consistent with reversible posterior leukoencephalopathy syndrome (PRES) (Burrus et al., 2009). Patients who have recovered from TTP may have subtle persistent cognitive abnormalities. Complaints of memory, concentration, and endurance difficulties may be related to measurable deficits in neuropsychological testing and may reflect the remnant of diffuse subcortical microvascular disease (Kennedy et al., 2009).

TREATMENT

Plasmapheresis is the mainstay of treatment in cases of idiopathic TTP. Cases associated with autoimmune conditions also benefit from brief pulses of high-dose corticosteroids. Testing for ADAMTS13 activity takes time. It is recommended not to wait for test results before making the diagnosis or starting treatment. With treatment, even severe neurological symptoms such as coma do resolve, with concomitant resolution of PRES findings on MRI. Patients with ADAMTS13 deficiency have higher rates of recurrence of TTP, especially during times of physiological stress such as illness or pregnancy.

HYPERVISCOSITY SYNDROME

Howard Field

Excessive blood viscosity is associated with a constellation of findings, together known as *hyperviscosity syndrome* (Sigle & Buser, 2011). These include bleeding diathesis, retinopathy with visual disturbances (Omoti et al., 2007), renal failure, cardiac decompensation (Corrigan, et al., 2010), and neurological symptoms, such as seizures, alteration of consciousness, and coma (*coma paraproteinaemicum*) (Kipps, 2001). Other symptoms, including fatigue, headache, vertigo, and cognitive impairment, are prominent (Stern et al., 1985; Gómez et al., 1999, 2000). Hyperviscosity is found in conditions that greatly increase either serum protein concentration or cell counts, including multiple myeloma (Barlogie et al., 2001), Waldenström's macroglobulinemia (Kipps, 2001), leukemia (Pimental, 1993), polycythemia vera, sickle cell disease, AIDS (Gadaret et al., 2004), rheumatoid conditions, diabetes, and other illnesses (Rampling, 2003). The normal blood viscosity as measured by viscometer is 1.5 to 1.8 cP (centiPoises). A measurement of 4 cP or greater is an indication for further investigation. The neuropsychiatric symptoms like delirium are based on microangiopathic dysfunction. The finding of "sausaging" and retinal venous engorgement on ophthalmic exam can contribute to the diagnosis. Reducing the blood viscosity may be life-saving. Phlebotomy is used in polycythemia. Plasmapheresis (plasma exchange) is recommended for multiple myeloma (Teruya, 2002) and Waldenström's macroglobulinemia (Drew, 2002). Where hyperviscosity is responsible, reduction in blood viscosity produces a prompt improvement in neuropsychiatric symptoms. Ultimately, treatment of the hyperviscosity syndrome is directed at the underlying condition.

HEMATOLOGICAL SIDE EFFECTS OF PSYCHOTROPIC MEDICATIONS

Olu Oyesanmi

AGRANULOCYTOSIS

Agranulocytosis, a life-threatening condition, occurs when the bone marrow stops production of granulocytes, leaving the body vulnerable to bacterial infection. Drug-induced agranulocytosis occurs as a rare idiosyncratic reaction related to the genetic vulnerability of the patient, traditionally thought to be a toxic or immune-mediated suppression of the bone marrow, although the mechanism is hard to pinpoint (Opgen-Rhein & Dettling, 2008; Tesfa et al., 2009; Chowdhury et al., 2011). This reaction is distinct from the low white count seen with direct cytotoxic effects of cancer chemotherapy agents.

Among the psychotropics, clozapine is the drug most often associated with this condition (Becker, 2007). In patients with agranulocytosis, absolute white blood cell (WBC) count is low ($\text{WBC} < 500/\text{mm}^3$), and almost entirely composed of lymphocytes and monocytes. The hematocrit and platelet counts are normal. Patients with agranulocytosis frequently

present with fever, headache, dry cough, sore throat, oral mucosa infection, bleeding gums, or sepsis.

Clozapine-induced agranulocytosis occurs in 1–2% of patients who are receiving clozapine. Total and differential WBC counts must be performed prior to the initiation of clozapine (package insert: see below, Chandrasekaran, 2008). Once clozapine is started, WBC counts must be monitored at least every week for the first 18 weeks, because the risk of agranulocytosis is greatest during this period. Subsequently, WBC counts must be performed at least every month during the entire duration of treatment and continued for one month after stopping treatment. Biweekly counts, however, may be done at total $\text{WBC} < 3500/\text{mm}^3$ and/or absolute neutrophil count (ANC) $< 1500/\text{mm}^3$, or in patients who develop infection. Following stoppage of clozapine, patients may resume treatment, provided that the total $\text{WBC} > 3000/\text{mm}^3$ and $\text{ANC} > 1500/\text{mm}^3$. Immediate withdrawal of clozapine is mandatory at total $\text{WBC} < 3000/\text{mm}^3$ and/or $\text{ANC} < 1500/\text{mm}^3$. Hematology consultation is advisable if, after stopping treatment, the total WBC count drops below $2000/\text{mm}^3$ and/or the ANC drops below $1000/\text{mm}^3$ (Teva Clozapine Monitoring Guidelines, 2008; Chandrasekaran, 2008). Support with hematopoietic growth factors like granulocyte-colony stimulating factor (G-CSF) and antibiotics would be considered.

In patients with clozapine-induced agranulocytosis, discontinuation of clozapine and a hematology consultation are recommended. Patients should be monitored until blood counts return to normal and for at least four weeks from the day the drug is stopped. Recommendations are daily monitoring until $\text{WBC} > 3000/\text{mm}^3$ and $\text{ANC} > 1500/\text{mm}^3$; then twice weekly until $\text{WBC} > 3500/\text{mm}^3$ and $\text{ANC} > 2000/\text{mm}^3$; then weekly after $\text{WBC} > 3500/\text{mm}^3$ (Teva Clozapine Monitoring Guidelines, 2008; Chandrasekaran, 2008). Prior to discontinuing the blood monitoring, patients are educated on the symptoms of agranulocytosis and are advised to notify their medical provider should they experience any of these symptoms (Chandrasekaran, 2008).

Clozapine-induced agranulocytosis is an indication for hospitalization. During hospitalization, reverse isolation and a full septic workup should proceed. The associated risk of mortality is increased in patients who develop infection prior to the discontinuation of clozapine. Treatment of agranulocytosis may include both the use of intravenous antibiotics and transfusion of granulocyte-stimulating factor. Following the exclusion of high-risk, clozapine-induced agranulocytosis patients with genotype HLA-DQB1 6672G>C, physicians may also reconsider clozapine rechallenge in refractory patients who responded to clozapine in the past (Manu et al., 2011; McKnight et al., 2011).

SELECTIVE SEROTONIN REUPTAKE INHIBITORS AND BLEEDING RISK

The SSRIs and serotonin norepinephrine reuptake inhibitors (SNRIs) are associated with increased upper gastrointestinal (GI) bleeding risk in relation to their serotonergic mechanisms (Meijer, 2004). The overall increased risk of upper GI bleeding, however, is low (Carvajal et al., 2011); for instance,

compared to those not taking an SSRI, the risk was 3.1 per 1,000 treatment years in a Danish population study (Dalton et al., 2003). The risk of GI bleeding is greater in older patients taking nonsteroidal anti-inflammatory drugs (NSAIDs), low-dose aspirin, or anti-platelet drugs with SSRIs. Andrade et al. (2010) have suggested that the increase may be related to serotonergic increase in gastric acid production rather than platelet dysfunction. Proton pump inhibitors (PPI) are effective for reducing the risk of GI bleeding in those taking SSRIs. Most patients are restarted on the same antidepressant with a PPI (Dall et al., 2012).

Tendency to bleed had been presumed to be related to the effect on platelet function (Andrade et al., 2010; Wessinger et al., 2006). Patients chronically medicated with SSRIs exhibit lower platelet 5-HT content and reduced serotonergic platelet aggregation by ADP, collagen, and epinephrine (Bismuth-Evenzal et al., 2012). However, clotting parameters for patients on paroxetine, for instance, are not prolonged and do not vary by serotonin transporter polymorphism (Hougardy et al., 2008).

Patients taking warfarin with concomitant SSRIs also have an increased risk of clinically relevant bleeding (Wallerstedt et al., 2009; Cochran et al., 2011). Although not dose-related, an increased risk of bleeding in patients on any type of SSRIs/SNRIs and anticoagulants may be related to the inhibition of cytochrome P₄₅₀2C9 isoenzyme, as warfarin metabolism is principally mediated by this isoenzyme (de Abajo et al., 2006; Mansour et al., 2006). Bleeding may range from ecchymoses and bruising to gastrointestinal bleeding. In patients with a history of bleeding, SSRIs increased the risk of GI bleeding when used concurrently with nonsteroidal anti-inflammatory drugs (Andrade, 2010). SSRIs do not seem to increase the risk of bleeding during procedures (Douglas et al., 2011; de Abajo et al., 2000, Andrade, 2010). In regard to brain hemorrhage, a recent meta-analysis found the absolute risk in those taking SSRIs was very low, although relative risk was slightly increased (Hackam & Mrkobrada, 2012).

SSRIs and SNRIs, then, should be administered with caution in patients receiving NSAIDs, aspirin, clopidogrel, warfarin, and enoxaparin (Kutscher et al., 2010; Hauta-Aho et al., 2009; Monastero et al., 2007; Wessinger, 2006; FDA.gov, 2011). Patients receiving anticoagulant therapy should receive careful coagulation-monitoring when SSRIs are initiated (Hauta-Aho, 2009; Holbrook et al., 2005). Andrade suggests that patients with a history of peptic ulcer disease or liver disease and those with a history of hemorrhages or GI bleeding might be at a higher risk of bleeding and should be monitored during treatment with fecal occult blood testing. Risk of bleeding usually returns to normal when the SSRI/SNRI is eliminated from the body following discontinuation (Andrade, 2010).

ANTICOAGULANTS AND MALINGERING

Howard Field

Confronted with hemorrhage that cannot be explained by medical conditions, clinicians may consider the possibility of self-induced bleeding. In malingering, the motivation is

external (secondary gain); in factitious disorder, patients are motivated to assume the sick role (primary gain). Progress in pharmacology has provided many powerful drugs that can be used to feign a bleeding disorder (Misra et al., 2010; Weitzel et al., 1990). Warfarin and other, more powerful and long-acting warfarin-like anticoagulant agents (the “super-warfarins” brodifacoum or difenacoum) are easily obtained in hardware stores for the purpose of rodent control and at pharmacies by prescription. Elevated prothrombin times will point the clinician in the right direction. A normal factor V points to normal synthetic liver function and vitamin K deficiency. A plasma level for warfarin confirms the diagnosis. Active bleeding requires immediate treatment with vitamin K. In the case of superwarfarins, which also may be used to lace marijuana or crack cocaine, the warfarin level will be negative, and the serum level of the superwarfarin must be sought. Anticoagulation will last much longer and may be associated with thrombotic events as well.

In suspected malingering, a search for external gain factors can provide the clinician with an understanding of the diagnosis. Patients with factitious disorders often have masochistic and histrionic personality traits. Some fantasize about causing bleeding in others. Further exploration may reveal violent accounts of past bleeding episodes in family members or themselves (Feinsilver et al., 1983).

Once bleeding is corrected, the physician should gently discuss the situation with the patient. Initially, one can anticipate denial, rage, or other relatively primitive psychological defenses. It should be remembered that these patients have “selected” a maladaptive and dangerous means for coping with stress and for seeking attention, so a logical, rational response should not be expected. The patient should be encouraged to see a psychiatrist (with the primary physician present, if desired), who can do a comprehensive evaluation, including assessing whether the patient poses a danger to himself/herself or others, and whether psychotropic medication or hospitalization is warranted. Although integrated medical and psychiatric management is not always successful owing to the complexity of these patients, it continues to be the best available course. Factitious disorders by proxy (e.g., Munchausen’s) involving children or frail elders must be reported to legal authorities and will entail the intervention of social service agencies (Meadow, 1977).

APPROACH TO THE JEHOVAH’S WITNESS PATIENT

Lex Denysenko and Chris Marchionni

According to their internal statistics, the Church of Jehovah’s Witnesses has a global following of over 7.2 million people (Worldwide Report, 2010). Patients who are Jehovah’s Witnesses believe eternal salvation comes through a literal interpretation of the Bible. The church’s specific prohibition against blood transfusion is derived from an interpretation of various passages in the Bible prohibiting the “eating of blood,” including Genesis 9:4, Leviticus 17:14, and Acts 15:29 (Hughes et al., 2008). Patients refuse treatment with blood

products based on their religious beliefs, posing a challenge to physicians faced with diseases ordinarily requiring treatment with blood products. For decades, the church had a policy of excommunication, known as “disfellowing,” of any member who accepted prohibited blood products. In 2000, the Watchtower Society, which is the corporation in charge of the church’s legal, publishing, and administrative needs, published the following media statement:

If a baptized member of the faith willfully and without regret accepts blood transfusions, he indicates by his own actions that he no longer wishes to be one of Jehovah’s Witnesses. The individual revokes his own membership by his own actions, rather than the congregation initiating this step. . . . However, if such an individual later changes his mind, he may be accepted back as one of Jehovah’s Witnesses. (Watchtower, Statement to the Media, 2000)

Although the church no longer initiates the judicial proceedings of disfellowing a member who accepts blood products, the current policy ensures that the member who is discovered to have accepted blood products, and who bears no remorse for his actions, will be immediately ostracized by his religious community (Muramoto, 2001).

An article in *The Watchtower*, the official magazine of the Watchtower Society, further explained that it is up to the individual to decide whether to accept or decline blood product fractions (e.g., hemoglobin or albumin, as well as erythropoietin and hemoglobin-based oxygen carriers; see Table 58.1) (Watchtower, Questions from Readers, 2000). In contrast, medical procedures that allow the blood to remain in circulation and do not separate the blood from the body are permitted, including hemodilution, intraoperative blood salvage, use of a heart-lung machine, hemodialysis, and plasmapheresis (Watchtower, October 2000).

A medical psychiatrist may be asked to evaluate a patient who is a Jehovah’s Witness when their medical decision-making capacity is questioned, or if the wishes of the patient are discordant with those of family or hospital staff. The decision by a Jehovah’s Witness to refuse a medical procedure normally meets criteria for rational decision-making if the decision is congruent with the patient’s religious doctrine, and all other criteria are met for demonstrating capacity.

It may be difficult in some cases, however, to determine if the patient is refusing blood products on purely religious grounds, or whether the patient’s decision to refuse life-saving treatment is under duress, fear of ostracism, and/or a desire to remain part of the religious community. Thus, involvement of hospital legal counsel and the hospital ethics committee may be needed in more complicated cases. For example, legal or ethical consultation may be warranted if the patient is believed to be lacking capacity; the patient is a minor; or the patient’s wishes are inconsistent with the known method by which they practice their faith.

In 1964, the Washington, D.C., Appeals Court upheld Georgetown University Hospital’s decision to transfuse blood against the known wishes of a critically ill patient (App. of

Pres and Dir of Georgetown, 1964). The judge determined that the patient’s wishes to not accept a transfusion were overshadowed by her decision to go to the hospital for medical care, an action that expressed a wish not to die, thereby overriding her religious beliefs. Furthermore, as the patient was “little able to competently decide for herself,” the court determined that the hospital had the duty and responsibility to treat.

In an attempt to improve access to medical care for its congregation, the church established hospital liaison committees to assist communication between patients who are Jehovah’s Witnesses and physicians who are willing to perform procedures without the use of blood transfusions. Advances in “bloodless medicine” have provided alternative management options for patients in some cases. The church has also instituted a “durable power of attorney wallet card” that followers can carry with them, listing their specific wishes about transfusion (Remmers et al., 2006).

The governing body of Jehovah’s Witnesses continues to garner criticism from a vocal minority within its community who view themselves as “Reformed” Jehovah’s Witnesses. One organization, the Associated Jehovah’s Witnesses for Reform on Blood, seeks to reform the church’s policy, and also to educate Jehovah’s Witnesses about blood transfusions.

Finally, one should not assume that the personal beliefs of the Jehovah’s Witness patient are the same as official church doctrine. As with all patients, the medical care of a Jehovah’s Witness should be managed on a case-by-case basis, utilizing a multidisciplinary treatment approach, including engaging with the local Jehovah’s Witness hospital liaison committee. Maintaining patient confidentiality is of paramount importance, because the patient may not wish to share their treatment decision with their family or their religious community.

CLINICAL PEARLS

- Iron deficiency is associated with pica and restless legs syndrome.
- Iron is critical for healthy brain development in gestation and the first months of life and prevents persistent emotional and cognitive neurodevelopmental deficits in children.
- In iron-deficiency anemia, plasma iron concentration and serum ferritin concentration are usually both low, and iron-binding capacity is increased. Ferritin is elevated in iron deficiency but also in inflammatory states.
- If the B12 level is found to be low or borderline, elevated serum methylmalonic acid and elevated serum total homocysteine also can help establish if a deficiency exists, as they are markers for functional B₁₂ status (Smith, 2009).
- Administration of folate without B₁₂ will reverse the hematological abnormalities, but if there is an

unrecognized B₁₂ deficiency, neurological impairment may progress further, sometimes leading to irreversible deficits.

- Psychiatric aspects of sickle cell disease can be grouped into: (a) depression and anxiety from living with a chronic, stigmatizing disease associated with unpredictable pain, chronic pain, and high morbidity and mortality; (b) problems from living with chronic and acute pain that is often undertreated and when treated with opioids can produce opioid tolerance, including pseudo-addiction and true opioid dependence; and (c) central nervous system damage resulting from cerebrovascular accidents, primarily during childhood.
- People with thalassemia may demonstrate cognitive dysfunction, including impaired abstract reasoning and deficits in attention and memory. They suffer from problems with visuospatial skills and executive functioning.
- The classic triad of symptoms in acute intermittent porphyria consists of neuropathic severe abdominal pain, mental status changes, and peripheral neuropathy; neuropsychiatric symptoms occurs in 19-58% of patients in an acute episode (Regan et al., 1999).
- If an attack of any acute porphyria is a consideration, urine urobilinogen should be sent, and distinctions among porphyrias can come later. Urgent administration of hemin and dextrose 10%, or food will limit the attack. A fasting state and delay of treatment put the patient at risk for progressive motor weakness and respiratory failure.
- Thrombotic thrombocytopenic purpura (TTP) leads to a variety of neuropsychiatric symptoms that can fluctuate throughout the course of the illness. Mild symptoms include headache and numbness. Severe symptoms include delirium, paresis, aphasia, personality changes, mood changes, seizures, and coma. Treatment for idiopathic TTP is plasmapheresis.
- Hyperviscosity syndrome presents as bleeding diathesis, retinopathy with visual disturbances (Omoti, 2007), renal failure, cardiac decompensation (Corrigan, et al., 2010), and neurological symptoms, such as seizures, alteration of consciousness, and coma.
- Drug-induced agranulocytosis is a rare idiosyncratic reaction related to the genetic vulnerability of the patient, traditionally thought to be a toxic or immune-mediated suppression of the bone marrow (Opge-Rhein, 2008; Tesfa, 2009; Chowdhury, 2011). This reaction is distinct from the low white count seen with the direct cytotoxic effects of cancer chemotherapy agents.
- Among Jehovah's Witnesses, it is up to the individual to decide whether to accept or decline blood product

fractions (e.g., hemoglobin or albumin, as well as erythropoietin and hemoglobin-based oxygen carriers; see Table 58.1) (Watchtower, 2000b). Medical procedures like hemodilution, intraoperative blood salvage, use of a heart-lung machine, hemodialysis, and plasmapheresis that allow the blood to remain in circulation and do not separate the blood from the body are permitted (Watchtower, 2000c).

END-STAGE RENAL DISEASE AND ITS TREATMENT

DIALYSIS AND TRANSPLANTATION

Gregory M. Gressel, Norman B. Levy, Michael J. Germain, and Lewis M. Cohen

INTRODUCTION

The term *psychonephrology* was coined by Levy to refer to the many complex psychiatric and psychological conditions associated with renal disease (Levy, 1978). Over the last three decades, the interaction between kidney failure, psychiatry, bioethics, geriatrics, social work, nursing, and other specialties has continued to challenge clinicians, patients, and families (Levy & Cohen, 2000).

Each year about 111,000 Americans develop end-stage renal disease (ESRD), and by the end of 2008, there were 548,000 people receiving dialysis, for a total national expenditure of \$39.5 billion (Rettig, 2011; United States Renal Data System [USRDS], 2010). The number of patients receiving therapy for ESRD continues to increase at a rate of 5–7% per year (USRDS, 2009). Under a 1972 congressional amendment, Medicare covers the cost of ESRD care for most citizens, and this ranges from \$26,668 per year for transplant recipients to \$77,506 per year for patients receiving dialysis (Iglehart, 2011). The causes of renal failure include systemic illnesses such as diabetes, hypertension, generalized arteriosclerosis, AIDS, and lupus. Primary renal diseases include chronic glomerulonephritis, chronic interstitial nephritis, polycystic kidney disease, and other hereditary and congenital disorders. The national epidemic of obesity and type 2 diabetes has affected renal care and is responsible for the rapidly increasing numbers of patients with ESRD. The elderly (over 75 years of age) now constitute the fastest growing sector of the population (USRDS, 2009). Currently available treatments are kidney transplantation, dialysis, and conservative management (supportive care with no renal replacement therapies) (Murtagh et al., 2007).

DIALYSIS

Dialysis prevents derangements in extracellular volume and the accumulation of organic waste products that would normally be cleared by the kidneys in healthy people. Without dialysis, a patient with ESRD would become uremic and eventually expire.

Dialysis is usually initiated when the prominent symptoms of uremia, most notably lethargy and anorexia, progress to the point that they impair a patient's daily function. This is usually when the glomerular filtration rate approaches 7% of its normal value (Meyer & Hostetter, 2007). The evolution of uremic symptoms, including cognitive impairment, can be quite subtle and easily misdiagnosed as clinical depression.

The two most commonly employed methods of dialysis are peritoneal dialysis and hemodialysis. In peritoneal dialysis, dialysate fluid is introduced and removed from the peritoneal space via an indwelling catheter. The peritoneum serves as a semipermeable membrane through which fluid and wastes pass; they are removed together with dialysate. Peritoneal dialysis may be performed by a machine at home (continuous cycling peritoneal dialysis [CCPD]), or manually at home four to six times a day (continuous ambulatory peritoneal dialysis [CAPD]). Peritoneal dialysis now accounts for only 5–6% of all dialysis; this is a decrease from 13% in the early 1990s, which has taken place despite the fact that peritoneal dialysis is easier to perform at home and less costly than hemodialysis (USRDS, 2009). It is unclear why peritoneal dialysis is done less often than in the past, but it is probably a combination of economic variables and availability.

Hemodialysis may be performed at home or at dialysis units in which there are varying degrees of self-care. In hemodialysis, a fistula is produced by joining an artery and vein together in the arm or forearm. The vein is arterialized and thereby permits multiple venipunctures. Early placement of an arterio-venous (A-V) fistula allows the patient to prepare psychologically for the eventual initiation of dialysis.

If a fistula is not possible, an artificial graft or an indwelling venous catheter is used. This connects the patient's blood supply to a dialysis machine, and blood flows between the person and the mechanical device. Home dialysis can be done daily, three times a week, or during sleep (nocturnal dialysis). The patient can do his or her own treatments, but it is felt to be important that another person is present, for safety reasons.

Peritoneal dialysis can be performed by the patient even when living alone. This can be done nocturnally with an automated cycler or manual exchanges three to four times a day. Patients and their families frequently prefer peritoneal dialysis, as it affords them greater independence and freedom from

hospitalization as well as a more liberal diet and latitude for fluid intake (Fan et al., 2008). Lately, there have been efforts aimed at encouraging nocturnal hemodialysis three to five times per week, either at home or in a dialysis center. Studies have reported improved quality of life ratings as well as better control of patient blood pressure, nutrition, and anemia (Rayment & Bonner, 2008; Pierratos, 2004). These advantages need to be balanced against the greater effort, time, and expense of this treatment approach.

Over the past few years, innovations have improved quality and safety of treatment. Hemodialysis membranes, dialysate buffers, electrolyte concentrations and temperature, prescription monitoring, volume ultrafiltration control, and arteriovenous-access monitoring have all been enhanced. Promising technologies include a wearable bioartificial kidney based on continuous hemofiltration and bioartificial tubules. Hopefully, with these advances, we may see a decrease in the morbidity and mortality associated with ESRD.

STRESS OF DIALYSIS

Chronic intermittent hemodialysis is associated with a low quality of life and high rates of morbidity and mortality. In-center hemodialysis forces patients to be unusually dependent on the technology and on the staff who are responsible for providing the procedure (Reichsmann & Levy, 1972). Treatment changes, such as switching from a dialysis center to home dialysis, or from peritoneal dialysis to hemodialysis (and vice versa), or from dialysis to a renal transplant, can be stressful for patients and their families. Patients who undergo hemodialysis may experience many tangible and symbolic losses secondary to their disease and treatment, including physical strength, employment, and social function. The cognitive and affective grief responses to loss have been collectively termed *kidney-disease-related losses* and have been extensively described (Chan et al., 2009). Applying a psychodynamic model to the somatic and psychological loss experienced by dialysis patients can help one understand the spectrum of reactions, from daily stress to clinical depression.

For example, emotional difficulties can ensue when highly independent patients receive treatment that requires them to be relatively passive (DeNour et al., 1968; Levy, 1976). Difficulties arise as a result of the conflict between the strong characterological need for independence in these people and the treatment modality, which places them in a situation of total dependence on a machine, a procedure, and medical personnel. Since traits such as hyperindependence are often refractory to psychological therapy, especially under the stress of medical illness, the more practical solution is to give such individuals a treatment modality (peritoneal, home hemodialysis, self-care center dialysis, or transplantation) that provides a greater amount of personal control. Conversely, dependent patients can have emotional problems if they are pushed into self-care, and such individuals often cope best when they are provided with ordinary in-center hemodialysis. Although transplantation affords an opportunity for a more independent lifestyle, it has its own set of challenges

and responsibilities. Patients with renal disease should be provided with information about each treatment option by the renal team, and ideally, they should be permitted to choose a treatment modality that is best suited to their medical situation, social circumstances, personal preferences, and personality traits.

Another loss related to kidney disease that causes patients considerable distress is the unrelenting lack of respite from treatment and illness (Levy, 1976). Most other chronic illnesses afford their victims some break from continual awareness of the disease. For example, patients with cardiac conditions often have long periods of being asymptomatic, while patients with metastatic cancer may have substantial periods of remission or breaks in their therapy regimen during which time they do not have pain or require chemotherapy. However, patients with ESRD are constantly reminded of their illness by the need to take multiple medications throughout the day, adhere to a restrictive diet, and attend repetitive dialysis sessions. Furthermore, patients maintained on hemodialysis have to endure frequent hospitalizations and surgery for vascular access complications, while peritoneal dialysis patients often experience recurrent peritonitis.

Dialysis patients are often quite frail (Schell et al., 2010). The etiology of this is multifactorial, including the dialysis procedure itself, the chronic uremia, advanced age, and comorbidities. Although dialysis provides better filtration than the ESRD patient's failing kidneys, the filtration is incomplete, and the patient experiences partial and intermittently (between dialysis runs) treated uremia (Depner, 2001). The constant flux of extracellular fluid volume and exposure to bioincompatible compounds, in addition to the patient's ongoing acidemia and hyperphosphatemia, contribute to malnutrition, immunosuppression, low-grade serositis, impaired vascular function, and general malaise (Meyer & Hostetter, 2007). This overall feeling of low-grade illness may be particularly devastating to previously active individuals. Sleeplessness, fatigue, pain, and pruritis are very common among dialysis patients, and the overall symptom burden is comparable to that of oncological disease.

Patients on dialysis also experience a loss of freedom in what they can and cannot eat and drink, as they are placed on low-sodium, low-potassium, low-phosphate, high protein, and low fluid diets. Patients on peritoneal dialysis usually receive a more lenient diet since this treatment can remove more fluid and phosphate than hemodialysis. Many patients are non-adherent to the dietary regimen, in particular to low fluid intake. This is readily evident to dialysis staff, who can easily monitor and measure serum potassium levels and weight changes between dialysis treatments.

ESRD patients often experience marital tension as a result of their illness. It has been shown that spousal depressive affect correlates strongly with patient Beck Depression Inventory (BDI) scores (Danecker et al., 2001). Marriage can serve as a source of solace and comfort, or it can serve as a source of conflict and emotional stress. Well-adjusted couples negotiate various coping strategies to compensate for the time devoted to treatment and changes in family dynamics, employment, and sexual function. Emotional

support has been correlated with decreased mortality secondary to ESRD (Gee et al., 2008). No major study has looked at divorce rates in the ESRD population compared to the general public. Compounding marital tension, patients on hemodialysis often experience a diminution in their ability to have, or interest in, sex (discussed later) (Finkelstein et al., 2007). When the patient's partner performs the dialysis treatment at home, this can lead to tension related to control issues and anger over complications of the treatment, placement of the needles in the fistula, and other issues.

The psychosocial disturbance experienced by patients extends into the realm of employment (Gutman et al., 1981). Prior to the initiation of dialysis, approximately 42% of patients are employed full- or part-time. This number decreases to 21% at dialysis initiation and to 6.6% at one year after initiation (Tappe et al., 2001). The resulting change in income, the loss of employment benefits, and additional expenses for medications, transportation, and special diets and equipment may have devastating economic effects on the family. For most people, work is not merely a source of income; self-esteem and identity are closely linked to work productivity in Western society (Bruce et al., 2009). Patients who are able to obtain late dialysis appointments, and who are on peritoneal dialysis or home hemodialysis are more likely to remain employed (Kutner et al., 2008). Although many dialysis facilities are attempting vocational rehabilitation, unemployment and its associated depressive symptoms remain an ongoing struggle (Kutner et al., 2010).

Despite the fact that peritoneal dialysis affords patients improved quality of life when compared with hemodialysis, it has special stresses of its own. Treatment distorts the patient's body by distending the abdomen. Patients also face the pain and discomfort of recurrent peritonitis with the ensuing need for hospitalizations. Hemodialysis patients may be similarly embarrassed at the appearance of their vascular access sites and the skin discoloration that is common with chronic treatment.

PSYCHOLOGICAL COMPLICATIONS OF DIALYSIS

Anxiety and depression are the most common psychological symptoms. Anxiety may be present during treatments, particularly in hemodialysis (Cukor et al., 2008). The fear of a medical emergency, such as significant blood loss or a cardiac event, may cause anxiety. Rapid removal of fluid and electrolytes may also produce anxiety, hypotension, nausea, vomiting, and muscular cramps. Anxiety is evident in the uncertainty many patients have about the future, fear about their sexual performance, and apprehension over their ability to cope with the ongoing demands of dialysis and the expectations of staff and family (Levy, 1983).

Evaluation of depression represents a diagnostic challenge, as the symptoms of ESRD along with its treatment may each produce the same somatic signs and symptoms that constitute the criteria of depression. *The Diagnostic and Statistical*

Manual of Mental Disorders (DSM-IV) defines *Major depressive disorder* as a clinical syndrome wherein a patient experiences anhedonia and depression in conjunction with five of nine symptoms, including loss of interest or pleasure, depressed mood, appetite disturbance, sleep disturbance, psychomotor agitation or retardation, fatigue and tiredness, feelings of worthlessness, difficulty with concentration, or recurrent thoughts of death or suicide. These symptoms are not supposed to be attributable to a general medical condition, which complicates the diagnosis in ESRD. The symptoms of uremia, including fatigue, sleep disturbance, and anorexia, are common. "Criterion contamination" (Chilcort et al., 2008) refers to difficulty in assessing whether symptoms are the result of depression, somatic illness, or a combination of both.

Prevalence of major depression in the ESRD population is about 20–30%. The exact prevalence remains an issue of debate, as the literature has reported rates anywhere from 0–100%. This may be due, in part, to the numerous screening methods and diagnostic tools used in researching depression in this population. Self-administered questionnaires are commonly employed as a screening tool for the identification of depressive symptoms in the dialysis population. These tools include the Beck Depression Inventory (BDI), the Patient Health Questionnaire (PHQ), and the Center for Epidemiological Studies Depression Scale (CES-D). Self-screening tools tend to report large numbers of depressive symptoms in ESRD patients (Hedayati et al., 2009a). Structured screening by a physician remains the gold standard, but few studies have assessed the prevalence of clinical major depression using the DSM-IV for establishing the diagnosis.

Cohen's approach (1998) to diagnosing depression in these patients entails describing the criteria for major depression, eliciting patient opinion as to whether they believe they are depressed, and then documenting the existence of associated factors, such as depressive episodes prior to the onset of renal failure, a family history of depression, and past suicide attempts.

DEPRESSION, MORBIDITY, AND MORTALITY

Depressive symptoms as assessed by self-report questionnaires and retrospective analyses of maintenance dialysis patients are associated with increased hazard of death and risk of hospitalization. The formal diagnosis of depression by a DSM-IV-based, structured physician interview is also associated with poor outcomes (Hedayati et al., 2008). Patients on long-term hemodialysis with a clinical diagnosis of depression are twice as likely to die or require hospitalization within a year as those without depression. A depression diagnosis is independently associated with a 30% increase in both cumulative hospital days and the number of hospitalizations (Hedayati et al., 2009b).

Many theories exist as to why depressive symptoms are linked to poor patient outcomes, including decreased adherence to therapy, and metabolic changes in endocrine,

neurological, hemodynamic, and immune functioning, which place a patient at increased risk for comorbidities (Watnick, 2009). Findings in cardiology disorders complement these conclusions (Boulware et al., 2006). It remains to be seen if successful treatment of depression in patients with ESRD will effectively reduce morbidity and mortality.

SUICIDE

When dialysis first became available in the 1960s, suicide mortality rates were calculated by combining data on deaths following dialysis discontinuation, treatment noncompliance, and clinical suicides. The result was an exaggerated conclusion that the risk of suicide was 400 times that of the general population (Cohen & Germain, 2005). The early estimates of suicide risk are no longer applicable, as dialysis withdrawal and treatment noncompliance are now widely believed to be distinctly different phenomena from clinical suicide.

Data from the USRDS indicates that suicide in ESRD occurs at a rate of two deaths per 10,000 patient-years—only a small increase compared with that of the general population. However, a study analyzed a national cohort of patients from 1995 to 2001 and determined the crude suicide rate to be 24.2 suicides per 100,000 patient-years, with a standardized incidence ratio of 1.84 (Kurella et al., 2005). Several independent predictors of suicide were identified, including older age, male gender, white race, substance abuse, and geographic region. Probability of suicidal behavior significantly increases among dialysis recipients who are single or divorced, who have low quality of life indices, and who perceive themselves as lacking friendship and familial support (Soykan et al., 2003). In contrast to patients who withdrew from dialysis, clinically suicidal patients were less malnourished and debilitated. Interestingly, in Western Europe, the dialysis discontinuation rate is a third of that in the United States, but the ESRD suicide rate is twice as high (Eiser, 1996). Lastly, it remains to be seen if the rates of suicide in the population can be decreased by systematic implementation of depression screening at dialysis facilities.

DIALYSIS CESSATION

Over the past twenty years, there has been growing societal awareness of end-of-life issues. Many religions, American jurisprudence, and mainstream medicine are more accepting of clinical practices that hasten death among the terminally ill, including withholding and withdrawal of life-prolonging treatments (Cohen, 2010). Despite improvements in the management of ESRD patients, the annual mortality rate remains high, and dialysis discontinuation is increasingly considered an option for patients by nephrologists (DeFrancisco & Pinera, 2006). Each year, older and sicker patients undergo dialysis; new advances in technology provide patients with extended life but do not necessarily ensure an acceptable quality of life. Accordingly, treatment decisions are increasingly complicated for practitioners and patients (Lowance,

1993). Paternalism is no longer an acceptable way to practice medicine. Physicians are increasingly involving their patients in treatment plans and encouraging them to make their own decisions about living and dying (Cohen et al., 2003).

Currently, the national withdrawal from dialysis accounts for 26% of ESRD deaths, 10% of deaths in patients age 20–26, and 46% of patients over age 85 (USRDS 2009). These patients are generally elderly, white, diabetic, and severely ill with multiple comorbidities (Bostwick & Cohen, 2009).

The decision to withdraw from dialysis is complicated and involves the patient, physicians, family members, and interdisciplinary teams. In a substantial number of these cases, nephrologists welcome psychiatric consultations. Most psychiatrists are unaccustomed to participating in these complex decisions, and the specialty of psychiatry as well as the rest of medicine and society has not yet sorted out the conflict over issues of physician-assisted dying and euthanasia (Cohen, 2010).

Withdrawal from dialysis allows patients who are terminally ill to shorten the time of suffering. Once dialysis is withdrawn, the mean time to death is 8.2 days (median, 6 days) (Cohen, Germain, et al., 2000). Dialysis withdrawal does not usually result in any pain or discomfort. Potentially, fluid gains could result in pulmonary edema and respiratory distress, but this occurs infrequently, and isolated ultrafiltration (fluid removal without toxin clearance) can be performed to treat these symptoms without prolonging the patient's suffering. Narcotics and sedatives can also be administered if the patient experiences respiratory distress.

The seminal study on dialysis withdrawal by Neu et al. (1986) reported withdrawal in 9% of 1,766 patients in a large regional program between 1966 and 1983; this accounted for 22% of all deaths. Although many were surprised at the high incidence of withdrawal reported by this study, these statistics are now validated and have since been exceeded by other reports and national data (USRDS, 2009). In New England over the past several years, over 40% of ESRD deaths are preceded by decisions to terminate dialysis.

An often-overlooked intervention is not starting dialysis in the chronically ill patient whose quality of life would not benefit from treatment (Murtagh et al., 2007). The incidence of “conservative management” is not known, but it is increasingly being employed in the United Kingdom and Europe. In the United States, there is a countervailing trend to give patients a trial of dialysis if there is a question as to whether they will benefit (Moss, 2001; Moss, 2011). This is carried out with the understanding that, if no benefits are apparent after the trial period, dialysis will then be withdrawn.

Dialysis patients and their families often have difficulty with end-of-life issues, such as whether to perform cardiopulmonary resuscitation (CPR), or withdraw from dialysis, and decisions about ventilator and nutritional support. A survey of 121 dialysis patients demonstrated only 6% had advance (End of Life) directives. Seventy-four percent had never thought about the issue of dialysis withdrawal, and 84% had never discussed it with their nephrologist (Cohen et al., 1997). Dialysis patients have considerable denial surrounding these issues, and a minority prefer not to discuss

it (Cohen et al., 1996)—although as many as 97% of some patient samples endorse that they want staff to communicate available prognostic information (Davison, 2010). One factor contributing to the hesitation to have dialysis discontinuation discussions is confusion over whether or not these practices constitute suicide. The renal community now largely sees cessation of dialysis, non-adherence to treatment, and clinical suicide as separate entities. To help physicians and their patients with these distinctions, Bostwick and Cohen (2009) have proposed an algorithm categorizing ESRD deaths based on the patient's intent to die, their acknowledgement of death, and collaboration with the social network (loved ones and staff) in making the decisions (See Figure 59.1).

The Baystate Dialysis Discontinuation Study has been the only prospective investigation analyzing the physical and psychosocial aspects of the dying process in patients who withdraw from dialysis. In the 79 patients from eight sites in the United States and Canada, 38% had “very good,” 47% “good,” and 15% “bad” deaths, as determined by a “quality of dying” score (Cohen et al., 1995). These findings stand in stark contrast to descriptions of families after a true suicide in which the death is overwhelmingly traumatic for everyone involved. In the ESRD discontinuation research, 57% of patients died within one week, and 75% within two weeks after dialysis withdrawal (Cohen & Germain, 2004).

The line between the presence of psychiatric disorders, such as depression, and patient capacity to refuse lifesaving therapies is sometimes blurred. Cohen has found that irrational thought processes rarely prompt requests for cessation of dialysis. In a few cases, psychopathology was obvious, and patients were strongly encouraged to continue dialysis while undergoing psychiatric treatment, including commitment to a hospital unit (Cohen, 1998). On the other hand, three studies have found an association between depression and patients' decisions to refuse or to terminate life-sustaining treatments (Brown et al., 1986; Ganzini et al., 1994; Sullivan & Younger, 1994). If there is concern that clinical depression may be influencing a patient's request to withdraw dialysis, this can usually be ascertained by seeking input from the family and treatment team.

In 2000, the Renal Physicians Association with the American Society of Nephrology published evidence-based guidelines entitled “Shared Decision-Making in the Appropriate Initiation of and Withdrawal from Dialysis” to aid practitioners and patients in their decisions (Moss, 2001). The guidelines were updated in 2010 (Moss, 2011), and they are the standard within the field.

The Renal Palliative Care Initiative (RPCI), a project funded by the Robert Wood Johnson foundation, was established to train a core group of physicians, nurses, and social workers in palliative medicine, and it charged them with the goals of developing and implementing innovative interventions. The RPCI's programs include: symptom-management protocols, advance care planning, and bereavement services for families and staff. The Initiative findings have been summarized by Poppel and associates (2003).

The Robert Wood Johnson ESRD End-Of-Life workgroup website offers information about additional programs, and the Kidney End-Of-Life coalition maintains an active website with useful resources for members of the health care team and patients (www.kidneyeol.org). A nephrology textbook on end-of-life care has now been published to assist clinicians in these efforts (Chambers et al., 2010). It is time for consultation psychiatrists to become further acquainted with the complexities of modern bioethics and master the techniques of compassionate palliative care (Cohen et al., 1995; Cohen et al., 2003).

SYMPTOM MANAGEMENT DURING DIALYSIS WITHDRAWAL

Historically, nephrology has focused on management of laboratory parameters and dialysis adequacy rather than on symptom assessment and quality of life. As the medical community comes to acknowledge the benefits of hospice and palliative medicine, more physicians are addressing the symptom burden in ESRD patients. Studies by Weisbord et al. (2005) and Davison (2003) have demonstrated that the symptoms experienced by dialysis patients are similar to those of other chronic disease states such as cancer. Pain, in particular, has been singled out as common, and recent studies demonstrate approximately 55% of patients experience an unacceptable degree of suffering in the last days of life. The World Health Organization has developed a three-step analgesic ladder that has been shown to adequately control pain symptoms in 96% of patients with ESRD (Barakzoy & Moss, 2006). The algorithm begins with acetaminophen for patients with mild pain and progresses to hydromorphone, methadone, fentanyl, and oxycodone for patients with severe pain. Narcotics are the mainstay of treatment for patients with extreme pain, and most patients on dialysis withdrawal are placed on a continuous drip, which is titrated as necessary. Respiratory failure is rare in most terminally ill patients receiving chronic opioids. Some authors have cautioned against the use of morphine in patients with CKD because of the side-effect profile (Angst et al., 2000; Dean, 2004; Davison, 2003). Dosing can be complicated by the multiple available preparations, and caution

must be used when changing formulations and/or doses. With palliative care intervention, pain prevalence may decrease to 22% in the last 24 hours of life (Germain et al., 2007).

Other side-effects of dialysis-cessation and chronic kidney disease that cause patients discomfort must be anticipated by the physician and treated. As the patient becomes weaker, he or she may retain secretions and develop shortness of breath, which can be alleviated by anticholinergics such as transdermal scopolamine, and also proper positioning. Agitation and involuntary twitching from the buildup of toxins can be addressed with benzodiazepines, haloperidol, and atypical antipsychotics. Nausea, vomiting, and hiccoughs may be treated with traditional antiemetics such as metaclopramide, prochlorperazine and ondansetron. Pruritis from accumulation of bile salts secondary to hepatorenal syndrome responds well to H1 antagonists and ondansetron. Thirst may be palliated with ice chips and mouth swabs. Palliative care principles applied throughout the patient's disease will help patients not only to live well, but also to die well.

SEXUAL DYSFUNCTION

Sexual dysfunction is prevalent in the ESRD population, with 40% of male patients and 55% of female patients reporting difficulty in achieving orgasm (Finkelstein et al., 2007). Men often complain of erectile dysfunction, premature or delayed ejaculation; women frequently report vaginal dryness or dyspareunia (Seethala, et al., 2010). Patients of both sexes have reduced libido, difficulty with sexual arousal, or inability to achieve orgasm. Younger men (under 50 years of age) are less likely to experience sexual dysfunction after the initiation of dialysis than older men (Stewart, 2006). A nationwide questionnaire study of dialysis patients was performed (Levy, 1973) comparing pre-uremic sexual functions of women with that which they experienced after being on dialysis or receiving a kidney transplant. It was found that women receiving dialysis have decreased libido and greater difficulty having orgasms during intercourse. Transplantation improved all of these sexual functions, but it did not bring them back to the level prior to the onset of renal failure.

The etiology of sexual dysfunction in patients with chronic kidney disease is multifactorial. As diabetes is the leading cause of kidney failure in the United States, it is understandable that the sexual dysfunction in these patients may be linked to vascular problems and neuropathy. One study examined ESRD patients using pharmacocavernostometry and pharmacocavernosography, and it found a 78% prevalence of cavernosal arterial occlusive disease (Kaufman et al., 1994). Autonomic neuropathy of pelvic organs also contributes to sexual dysfunction (Campese, 1990).

Uremic patients experience endocrinological derangements in the hypothalamic-pituitary axis (HPA). Male patients have decreased levels of testosterone and elevations in luteinizing hormone, follicular-stimulating hormone, and prolactin; these are accompanied by reductions in testicular size, impaired spermatogenesis, and weight gain. Women have

similar hormone derangements, resulting in decreased libido, vaginal dryness, and inability to achieve orgasm (Finkelstein et al., 2007). Endocrinological changes rarely deviate sufficiently from the normal range to explain reduced sexual function on this basis alone.

Patients with ESRD are frequently placed on drug cocktails that interfere with sexual function. Diuretics, antihypertensives (Bailie et al., 2007), antidepressants, and histamine-receptor blockers may contribute to erectile dysfunction. Other drugs, such as spironolactone, ketoconazole, steroids, and cimetidine, interfere directly with the synthesis of sex hormones (Finkelstein et al., 2007).

Depression contributes to sexual dysfunction; it erodes self-esteem and causes marital difficulties. Patients with higher self-reported depressive symptoms appear to have higher degrees of sexual dysfunction (Peng et al., 2007). The three major physical functions of pre-menopausal women that distinguish them from men are menstruation, gestation, and lactation, and all are impaired in renal failure. Appearance remains an important aspect of femininity and is often compromised by renal failure and dialysis. In men, the actual or nearly total cessation of urination may compromise their sexual identity (Levy et al., 2006). Patients demonstrating pessimistic, anhedonic, or sad affects should be screened for the presence of sexual dysfunction.

There are now numerous treatments for impotence. A device consisting of a cylindrical pump placed over the penis can create a vacuum, which enables the penis to be engorged with blood and thereby become erect, and a rubber band-like instrument placed at the base of the penis prevents the egress of blood during sexual events. Prostaglandin may be inserted into the urethra or directly injected into the corpus cavernosa of the penis to create a temporary erection. Consideration should also be given to surgical approaches to intractable impotence through means of a penile prosthesis. Two systems involve either a silastic rod inserted in the body of the penis, or a hydraulic pump that the patient squeezes. Since these techniques involve destruction of erectile tissue, it is necessary to establish an organic cause prior to surgery by demonstrating the absence of nocturnal penile tumescence.

Less-invasive sexual therapies have demonstrated effectiveness, including in kidney transplantation (Espinoza et al., 2006; Muehrer, 2009; Ozdemir, 2007) where improvement rates are between 20–75% (Shamsa et al., 2005), and the use of medications. The last is the most commonly employed treatment approach, and pharmacotherapy research has largely focused on sildenafil (Viagra). Reported success rates in patients are between 60–80% (Turk et al., 2001; Chen et al., 2001). Studies of sildenafil in renal transplant recipients showed a satisfactory response in 60–81% of transplant patients with erectile dysfunction (Sharma et al., 2006). However, sildenafil is contraindicated in patients receiving medication for angina, and coronary artery disease is common among dialysis patients. Sildenafil and related medications are not covered by Medicare Part D, and the approximate retail cost of a single 100 mg tablet of Viagra is \$18.

Currently, only 33% of dialysis centers have even limited educational programs that address sexual dysfunction

(Stewart, 2006). A more thorough initial evaluation is advisable as a screening tool to address all psychosocial and physiological concerns related to sexuality.

COGNITIVE IMPAIRMENT DISORDERS

The presence of cognitive impairment and its negative outcomes in ESRD have been largely neglected by clinicians and the academic community (Murray & Knopman, 2010). However, several studies now report a high frequency of moderate to severe cognitive impairment in these patients and an association with increased mortality. Even mild to moderate cognitive impairment of younger patients appears to increase the mortality rate (Griva et al., 2010). Dementia in dialysis patients increases the risk of hospitalization almost twofold, and a recent prognostic tool with very good validity to predict the likelihood of six-month mortality found dementia to be one of its five variables (Cohen et al., 2010). Cognitive impairment may lead to decreased medication and dietary adherence, and to increased risk of iatrogenic hospitalizations and death. Screening patients and identifying cognitive impairment may help clinicians and families design treatment plans to supervise medication administration, diet, and care plans, and to hold appropriate discussions regarding initiating and withdrawing from dialysis.

Just as ESRD patients have kidney damage from diabetes, cardiovascular disease, and hypertension, so, too, are their brains affected by microvascular pathological processes. If the brain and kidneys are equally thought of as target-end organs damaged by vascular disease, accelerated vascular cognitive impairment can be analogized to decreased glomerular filtration rate (GFR). It has been shown that as GFR decreases in CKD patients, the rate of global cognitive decline increases, as assessed by mental status examination (Murray, 2009). Patients with low levels of kidney function are more likely to have cognitive dysfunction compared with the general population, independent of prevalent cardiovascular disease and risk factors (Tamura et al., 2008). Furthermore, the incidence of clinically evident stroke is more common as CKD worsens in aging patients (15% per year, vs. 2.5% in the general Medicare population) (USRDS 2009).

Because of the higher incidence of organic brain syndromes and dementia, psychiatric hospitalization is 1.5 to 3 times higher in ESRD than in other chronic illnesses (Kimmel et al., 1998). Patients employed in intellectual occupations will tend to note progressive impairment as their day for dialysis approaches. Immediately after dialysis, they may experience a short period of delirium, termed “disequilibrium syndrome,” caused by the rapid change of fluid and electrolytes that has taken place during the session. This syndrome may last from minutes to hours. Daily nocturnal hemodialysis may help prevent this syndrome (Pierratos, 2004). An electroencephalogram (EEG) can confirm the presence of a transient metabolic encephalopathy, especially if a baseline EEG is available for comparison; the typical finding is diffuse slowing. Computed tomography and magnetic resonance imaging do not help confirm a dialysis-related delirium but may be helpful in screening for opportunistic central nervous

system infections of cerebrovascular events in patients with persistent changes in neurological function.

These acute changes are usually not seen in chronic ambulatory peritoneal dialysis, because this procedure is slow, continuous, and not accompanied by sudden fluxes of fluid and electrolytes. Single-photon emission tomography has been used to compare hemodialysis patients with matched controls, and dialysis patients appear to have reduced cerebral blood flow in the frontal cortex and thalamus (Fazekas et al., 1996).

Among the most serious cognitive disorders is “dialysis encephalopathy.” This often-fatal neurological syndrome may occur in patients who have been on hemodialysis for at least two years. The early signs are dysarthria, stuttering speech, memory impairment, depression, and psychosis. Patients often develop choreoathetotic limb movements, asterixis, and generalized tremulousness. If not successfully treated, the disease is progressive and leads to neurological death. Its cause is not fully understood. Aluminum was at one time believed to be the etiological agent, and it was found in trace amounts in dialysate water and phosphate binding gels (Alfrey, 1986). Aluminum has since been removed from dialysate fluids; the incidence of “dialysis encephalopathy” has dropped significantly and is almost never seen clinically. Uremic encephalopathy is still found in patients with advanced uremia who have not been receiving dialysis. It progresses from subtle cognitive impairment, to seizures, coma, and then death.

TREATMENT OF DIALYSIS-INDUCED ANEMIA

Dialysis patients almost always experience severe anemia as a result of decreased endogenous erythropoietin production, decreased red blood cell survival, resistance to erythropoietin action, and impaired iron utilization. Erythropoietin is a glycoprotein hormone produced in the kidney and the liver that acts by stimulating red blood cell production in the bone marrow. ESRD patients experience profound anemia, which is cited as being an independent risk factor for increased weakness, fatigue, difficulty in concentrating, exercise intolerance, life dissatisfaction, and sexual dysfunction (Shah et al., 2009; Weisbord & Kimmel, 2008).

Recombinant human erythropoietin (rHuEpo) was introduced in 1988 for commercial use, and is now widely prescribed to ameliorate anemia. ESRD patients on rHuEpo have seen a drop in transfusion requirements from 16% to 3% per quarter, with less associated transfusion-related infections (Beusterien et al., 1996). Current guidelines advocate maintaining hematocrit levels between 11 and 12 g/dl (Spiegel, 2006). With relief of anemia, patients experience improvement in a wide variety of life functions and quality of life. The National Cooperative Recombinant Human Erythropoietin study demonstrated increased exercise capacity, decreased fatigue, as well as improvement on visual, conceptual, and auditory-verbal learning in patients on rHuEpo (Beusterien et al., 1996). rHuEpo has also been shown to improve erectile dysfunction in some male patients (Lawrence et al., 1997). Treatment

with erythropoietin is widely prescribed except dialysis patients with polycythemia and some cases of uncontrolled hypertension.

TREATMENT OF HYPERPARATHYROIDISM

Virtually all patients with ESRD develop secondary and tertiary hyperparathyroidism that worsens as their renal function deteriorates. Hyperparathyroidism results from abnormalities in calcium, phosphorus, and vitamin D metabolism; increased parathyroid function prevents serum hypocalcemia. The end result is renal osteodystrophy secondary to bone resorption. Few studies have assessed the relationship between hyperparathyroidism and depression in ESRD; however, it has been shown that patients with cognitive disorders have higher levels of parathyroid hormone than do non-depressive patients (Driessen et al., 1995). Treatment of hyperparathyroidism involves the use of vitamin D and phosphate-binding agents, and the calcimimetic drug cinacalcet (Goodman, 2003). Patients receiving these agents sometimes develop hypo- or hypercalcemia; this can lead to other neuropsychiatric conditions, such as delirium (Tanaka et al., 2007). The relationship between parathyroid hormone, calcium levels, and cognitive dysfunction in dialysis requires further analysis.

RENAL TRANSPLANTATION

In 2007, 17,500 patients with ESRD received kidney transplants, with 72,000 remaining on the waiting list (USRDS, 2009). Renal transplantation is the treatment of choice for many patients. Transplanted patients have improved health-related quality of life and fewer depressive symptoms compared to that of a well-matched sample of wait-listed hemodialysis patients (Kovacs et al., 2010; Szeifert et al., 2010). Kidneys may come from a living donor or be obtained by organ donation following death. Long-term kidney survival is greater with living donors. Most cadaveric kidneys are procured from brain-dead individuals following acute trauma, intracerebral bleeds, and cerebral vascular accidents.

There has been some debate in the transplant community concerning the use of living unrelated donors. Commercially available organs from individuals who were willing to sell their kidneys prompted an outcry, and these sales have been banned by federal statute in the United States and in many other countries. In India, living unrelated donors are not allowed due to past abuses. However, a long-standing critical shortage of cadaveric organs has led most transplant programs to liberalize requirements, and use of kidneys from living unrelated donors, such as a spouse, other relatives, and friends, have become increasingly common. Altruistic donation to an anonymous recipient also occurs, although this practice is controversial and sometimes clearly problematic. Psychiatric consultation is necessary in these latter cases, and psychiatrist and psychologists participate in many transplant programs.

Immunosuppressants are used postoperatively to inhibit rejection of the organ, and patients must remain on

immunosuppressive therapy for the rest of their lives. The principal medications are cyclosporine, tacrolimus, sirolimus, mycophenolate mofetil, and steroids (prednisone). If Medicare is the primary insurance, it covers 80% of immunosuppressant medication costs in the initial 36 months, but this still leaves a substantial economic burden on patients and families.

Renal transplantation relieves many patients from the burdens and stresses that accompany dialysis. Diabetics may fare better with transplantation than dialysis, and one group of researchers has claimed that cognitive brain dysfunction associated with dialysis may be fully reversed by transplantation (Kramer et al., 1996). Children are fewer than 1% of the total number of people with renal failure, and have improved growth, development, independence, and quality of life following transplantation (Karrfelt & Berg, 2008).

Transplantation is certainly not a panacea (Cohen, 1996). In contrast with the prevailing belief, an elegant comparison study of men following transplantation matched with those continuing dialysis could not identify either improved psychological adjustment or vocational rehabilitation (Sayag et al., 1990). Transplant recipients face the same uncertainties about their health and future finances, in addition to medication side effects (Szeifert et al., 2010). Drawbacks of transplantation include the constant risk of rejection, the need to adhere to a complex regimen of medications that are capable of producing pronounced side effects, and the necessity for ongoing medical supervision (Fallon et al., 1997; Jindal et al., 2009; Pinsky et al., 2009). A recent prospective study of 840 renal transplant patients showed that depressive symptoms are an independent predictor of mortality in these people (Novak et al., 2010). Psychiatrists need to be alert to steroid-related changes in mood, as well as post-rejection depressions. Psychiatric screening of potential recipients is of value to avoid problems with post-transplant psychiatric complications and or lack of adherence to the post-transplant regime. A functional and histocompatible kidney for transplantation may become possible someday, given advances in organogenesis and therapeutic cloning (De Francisco & Pinera, 2006).

THE DONOR

Living donor-kidney transplants may come from related donors, or from unrelated living donors paired through a donor registry. The number of related donors has declined 18% from a high in 2001, while the number of unrelated living donors increased 125% between 2006 and 2007 (USRDS, 2009). Overall, living donor-kidney transplantations are increasingly performed and have excellent graft-survival outcomes. From a recipient perspective, it is preferable to receive a living donor-kidney transplant rather than waiting for a cadaveric transplant to materialize. In addition, a living donor allows for a pre-emptive transplant and avoids the need for dialysis with its complications. Wait-times on the transplant list continue to increase, with a median lag from registration to transplant of 2.8 years (USRDS, 2009). Studies are now focusing on the donor's well-being and quality of life after transplantation.

The selection of the donor can become a very complex matter, involving familial tension, personal anxiety, and emotional dilemmas. The patient expects that people will come forward voluntarily and without coaxing. It is uncommon for patients with renal failure to confront relatives with their need for a kidney. An intermediary, such as a family member, nurse, or physician, usually makes such requests. Parents, particularly mothers, often want to donate a kidney to their children. Children frequently wish to donate to their parents or siblings, but parents are often unwilling to accept the gift of a kidney.

Early analyses of psychosocial factors in organ donors claimed that they suffer long-term renal dysfunction, depression, and anger at being coerced to make the decision to donate (Saljiad et al., 2007). These data cause ambivalence among some physicians towards live organ donation. Newer studies refute these claims and demonstrate that donors are generally voluntarily forthcoming with their kidney, and after donation they experience good quality of life (Reimer et al., 2006).

In a study in Spain, 86% of donors voluntarily informed the recipient of their wish to donate a kidney; the other 14% were asked by a family member. Although 25% of patients claimed they suffered financially from the operation and were out of work for a mean of 58 days, 100% of the donors said they would favor donation a second time (Cabrer et al., 2003). A German study determined that most donors have an equal or better quality of life than that of the healthy population (Giessing et al., 2004).

Living related donor-kidney transplantation may also strengthen bonds between family members. Goetzmann et al. determined that 72% of patients feel a sense of responsibility toward the donor and the received organ; only 2.7% reported guilt for receiving the transplant (Goetzmann et al., 2008). Donors often feel a justifiable sense of pride, and families are relieved that their loved one has been spared a lifetime of dialysis. On the other hand, families may have unrealistic expectations of the positive ways donation will influence their relationship with the patient or be disappointed with the care provided to "their" kidney by the recipient.

Post-transplant psychosocial assessment of living kidney transplant donors is not yet the standard of care. Although most donors do not experience post-donation mental distress, many feel that psychiatric follow-up after their donation is inadequate (Giessing et al., 2004). Experts now advocate that transplant centers should monitor donors and perform routine psychosocial follow-ups of both recipients and donors of living kidney transplants while providing counseling to those in need (Saljiad et al., 2007).

PSYCHIATRIC SCREENING FOR ORGAN DONATION

Psychiatrists and social workers are members of many transplant teams, and may play an active role in screening donors and recipients. Although the presence of Axis I disorders (including psychotic disorders and substance abuse) do not represent contraindications to this procedure, they need to

be considered in evaluating people considered for donation. Psychiatric disorders should be identified and managed prior to transplantation. It is our impression that screening by behaviorally trained professionals is a cost-effective method of reducing post-transplant complications. Surgery may need to be postponed until a sufficient period of time for sobriety or symptom control is achieved. Personality disorders pose a greater challenge, and they often require the involvement of the extended family. Transplantation is deferred when patients cannot emotionally or intellectually grasp the risks and responsibilities of surgery (Cohen, 1996). Since transplant organs are a precious resource, it is important that the patient will be adherent to the regimen and has no active psychiatric or abuse issues that could affect adherence.

Acute kidney rejection has fallen sharply, and now occurs in only 10% of patients (USRDS, 2009). Most recipients and donors have uncomplicated hospitalizations. However, renal transplant recipients have the lowest rates of adherence to postoperative immunosuppressive therapy among solid organ transplant recipients, and this has been correlated with graft loss (O'Grady et al., 2010). Like liver transplantation of people with alcoholic cirrhosis, people with kidney failure represent a skewed sample of the total population. They are overrepresented by people who are non-adherent to their diabetic and hypertensive medical regimens, as well as drug addicts with HIV. At least some degree of non-adherence in adult renal transplant recipients is estimated at about 22%, with graft failure increasing sevenfold among non-adherent versus adherent patients (Butler et al., 2004). Psychiatric screening needs to emphasize this risk factor. Surgery must be deferred until compliance is satisfactory, and these patients may require more intensive post-transplant psychiatric and psychotherapeutic treatment management.

In the past, people with a history of psychosis, sociopathy, and substance abuse were excluded from being kidney donors or recipients of renal transplants. Neuropsychiatric disorders are not currently considered contraindications to surgery, as graft survival is similar regardless of cognitive dysfunction. Many patients with major psychoses, depression, or bipolar disorder have undergone successful transplantation (Carrasco et al., 2009).

Psychiatric screening for organ transplantation should ensure that patients are able to give informed consent in order to understand the risks and benefits of the operation. Patient and professional education, reduction of polypharmacy and pill burden, and creating individualized patient adherence plans based on regular interviews starting before transplantation are of value towards optimizing adherence and reducing graft rejection (O'Grady et al., 2010).

POSTOPERATIVE PSYCHOLOGICAL PROBLEMS

Kidney transplant recipients often experience postoperative anxiety about losing their newfound freedom. As time goes on and rejection is not experienced, the recipient feels relatively relieved. The recipient is never, however, completely safe

from the possibility of rejection, and diseases that caused the patient's initial renal failure can recur or affect the transplanted kidney.

Immunosuppressant medications may create difficulties. All transplant recipients must be placed on immunosuppressive therapy in order to reduce the risk of graft rejection. These drugs generally have narrow therapeutic windows, interact with other drugs, and have potentially deleterious physical, neuropsychological, and biochemical effects. The numerous psychiatric complications of steroids are well known. Corticosteroid-free regimens have been used successfully and are becoming increasingly common. Cyclosporine and tacrolimus have been associated with delirium, seizures, and tremors. They may interact with antidepressant medications in transplant recipients (Fireman et al., 2004). Little is known about the psychiatric manifestations of other immunosuppressants such as sirolimus, azathioprine, and mycophenolate, but it is clear that they also interact with other medications and may contribute to cognitive impairment.

New cognitive deficits in transplant recipients indicate the need for a careful workup, especially for infectious diseases. The psychiatrist can play a critical role in initiating the delirium evaluation by identifying the patient's mental symptoms as being of probable organic origin. Patients on prednisone and other immunosuppressants after transplantation are vulnerable to opportunistic pathogens and may have bacterial, fungal, and viral infections with fewer systemic signs than usual. In addition, neoplastic illnesses are slightly more common in these people than in the general population.

PSYCHOTROPIC MEDICATIONS IN RENAL FAILURE

Pharmacokinetics refers to the absorption, distribution, degradation, and excretion of drugs and their metabolites (McIntyre et al., 2008). Several of the factors constituting the pharmacokinetics of psychotropic medications can be altered in renal failure. However, few psychotropics are exclusively excreted by the kidneys; most are metabolized primarily by the liver, eliminated in the bile, and excreted by the gastrointestinal tract (Cohen, Ruthazer, et al., 2010). It is commonly recommended that psychotropic dosing be reduced because of renal failure. This recommendation is based on the fact that protein binding is an important part of the pharmacokinetics of psychotropic medications used in renal failure. People with this disorder have a marked decrease in the ability of their blood to bind protein, which is most likely due to decreased albumin, thereby making available more free medication in their blood for a given dose than in people with normal kidney functioning. Most studies on pharmacokinetics of psychotropics in the ESRD population have been inadequately powered and poorly controlled, and few *in vivo* studies have been performed (Cohen et al., 2004). Levy et al. (1996) performed a small double-blind, crossover study of fluoxetine (Prozac). Clinical evidence suggests that psychotropics are effective and may be safely used. Dosing requires trial and error, but most patients tolerate and require ordinary doses of psychotropic medications.

The bioavailability (drug absorption) of many psychotropics is decreased in patients with renal disease. Although not all psychotropics have been adequately evaluated in patients, it is known that many medications have diminished absorption from the small bowel because uremia results in excess gastric alkalization and decreased gastrin levels (Mirot et al., 2008). Furthermore, dialysis patients frequently experience nausea and vomiting, and diabetic patients often have gastroparesis, all of which alters drug absorption and pharmacokinetics.

The distribution of psychiatric medications is altered in ESRD patients, as they are often malnourished and have less fluid and body mass in which a drug can diffuse. This theoretically decreases the volume of distribution and increases the potency of a single dose compared to that in a healthy person. The primary alteration in drug distribution is related to decreased serum protein binding of psychotropic drugs. Urea competes for plasma protein binding, decreasing binding of the drug, and resulting in elevated serum levels. Patients also usually have proteinuria that results in diminished protein binding and increased free drugs in the plasma. This is particularly important for drugs such as phenytoin and valproic acid, which normally have high levels of plasma protein binding (Cohen et al., 2004).

Patients also experience decreased degradation (breakdown) and clearance (excretion) of drugs from the body. As the GFR decreases, it is assumed that the rate of drug metabolism by the renal brush border will also decrease, leading to elevated levels in the plasma. It has been shown that ESRD patients have decreased levels of chemical reduction by hydrolysis but normal rates of glucuronidation, microsomal oxidation, and sulfate conjugation (Cohen et al., 2004). Finally, excretion is impaired in ESRD, because patients are unable to filter drugs or secrete their inactive metabolites into the renal tubules, thereby eliminating them from the body. Therefore, there are certain drugs that require altered dosing or should be avoided entirely.

ANTIDEPRESSANTS

Virtually all the antidepressants may be tried in renal failure, but some caution is required. Both SSRIs and tricyclic antidepressants (TCAs) have been demonstrated to be beneficial. Fluoxetine is the best studied of the SSRIs and appears to be well tolerated by patients with renal impairment (Levy et al., 1996). It has a very high therapeutic index, and the kinetic profile of single doses of fluoxetine is not changed in anephric patients, attesting to its safety for use in this population (McIntyre et al., 2008). Sertraline and citalopram are metabolized in the liver and are also widely prescribed without dose adjustment. Patients tend to have increased plasma levels of paroxetine, and the recommended initial dose is halved (10 mg) in the context of severe renal dysfunction (Cohen et al., 2004). TCAs should be reserved for treatment-resistant depression, although amitriptyline and imipramine are occasionally used for treatment of neuropathic pain, and trazodone is commonly tried for insomnia. Venlafaxine levels are markedly increased in patients with renal failure and should be

dose-adjusted for ESRD patients. Bupropion may build up and predispose dialysis patients to seizures (Turpeinen et al., 2007), and this medication should be used cautiously. Little is known about nefazodone, and it should also be avoided as a first-line therapy since it may lead to hepatotoxicity (McIntyre et al., 2008).

MOOD STABILIZERS

Lithium has been used for years as the primary mood stabilizer for bipolar affective disorder. It is the only psychotropic medication associated with severe nephrotoxicity. Although there is a current trend to substitute less toxic anticonvulsants such as divalproex and carbamazepine, these drugs may not work as well in some patients as mood stabilizers. Lithium is completely dialyzable, and since it is entirely excreted by the kidneys, a single dose of 600 mg of lithium may be given after each dialysis run in patients with comorbid bipolar disorder and ESRD. After the dialysis session, the lithium level will remain unaltered because of the absence of any renal elimination. Smaller doses of lithium may be employed to augment antidepressant regimens (Mirot et al., 2008).

NEUROLEPTICS

Delirium and agitation are common comorbidities in ESRD patients, and clinicians regularly rely on typical neuroleptics, such as haloperidol (Cohen et al., 2004). The use of atypical neuroleptics is more complicated. Olanzapine is metabolized by the liver but excreted in urine. Studies suggest that special dosing is not required, but olanzapine may aggravate diabetes, a common comorbid disease in ESRD patients. Ziprasidone should probably be avoided because the frequent electrolyte shifts from dialysis may contribute to life-threatening arrhythmias related to QT prolongation. Risperidone clearance is decreased by 60% in patients with renal disease. Thioridazine and mesoridazine are more likely to cause life-threatening arrhythmias and should be avoided.

ANXIOLYTICS AND SEDATIVES

As has already been discussed, anxiety is common in ESRD patients, and pharmacological management is directed either at acute episodes of panic and anxiety or at more generalized nervousness. Benzodiazepines are hepatically metabolized, and dose-reduction is not necessary in ESRD—with the exception of midazolam and chlordiazepoxide, which have high plasma protein binding levels. Lorazepam, diazepam, alprazolam, and clonazepam can be administered in ordinary doses, and are often given at dialysis clinics immediately prior to sessions. The half-life of buspirone is prolonged in patients with renal dysfunction and can worsen dizziness and postural hypotension; the dose should be carefully titrated. Hypnotics such as temazepam or zolpidem may be used in normal doses in conjunction with behavioral management and sleep hygiene education to further prevent sleep disturbances (Cohen et al., 2004).

MEDICATION-RELATED PROBLEMS

ESRD patients have to take many medications several times a day, and they often face difficulties complying with the regimens. Most are elderly and have multiple comorbid conditions, such as diabetes, hypertension, and vascular disease, and this further compounds the medication problems encountered. The average hemodialysis patient is prescribed an average of 12 medications to treat a mean of six comorbid conditions (Manley et al., 2005). A recent retrospective study of 133 patients showed that 98% of patients had problems with medications, and that the number of medication-related problems in an individual patient increased directly with the number of comorbid conditions (Manley et al., 2003). The most frequent medication-related problems encountered are inappropriate laboratory monitoring, patients' not receiving medication for an indicated illness, and dosing errors (Manley et al., 2005). Responsibility to ameliorate these problems falls on physicians and pharmacists, who need to make sure patients are receiving the smallest effective doses, try to avoid polypharmacy, and ensure that medication instructions are clearly communicated.

PROFESSIONALS

Medicare has required all dialysis programs to include psychiatric social workers on their interdisciplinary teams, but only a small number of facilities have formed close working relationships with psychiatric consultants. Behaviorally trained professionals should ideally be involved in evaluating prospective patients for dialysis and transplantation. The data they gather may be useful in determining the modality of treatment that is most feasible each patient. They may give the nephrologist and transplant surgeon valuable information about what might be expected concerning compliance (based on character structure and past adherence), and identify individuals who require closer psychological attention. Professionals are occasionally valuable in managing patient or family requests for dialysis discontinuation. They certainly aid in the early diagnosis and treatment of psychiatric disorders, prevent major disruptions in therapy, and at times forestall hospitalizations. Although its cost-effectiveness has never been systematically studied, it is our impression that greater involvement of psychologically sophisticated clinicians should reduce the cost of caring for this population. Lastly, despite numerous technological advances in renal replacement therapies, treatments have not lived up to expectations that they will allow the majority of patients to return to work or to have satisfactory quality of life (Rettig, 2011). We believe it will require the addition of more behaviorally trained staff and a greater effort to establish more effective collaboration with psychiatric consultants before these important goals can be achieved.

CLINICAL PEARLS

- Dialysis is usually initiated when the prominent symptoms of uremia, most notably lethargy and anorexia,

progress to the point that they impair a patient's daily function. This is usually when the glomerular filtration rate approaches 7% of its normal value (Meyer & Hostetter, 2007).

- The evolution of uremic symptoms, including cognitive impairment, can be quite subtle and easily misdiagnosed as clinical depression.
- Since traits such as hyperindependence are often refractory to psychological therapy, especially under the stress of medical illness, the more practical solution is to give such individuals a treatment modality (peritoneal, home hemodialysis; self-care center dialysis; or transplantation) that provides a greater amount of personal control.
- Conversely, dependent patients averse to being pushed into self-care often cope best when they are provided with ordinary in-center hemodialysis.
- The unrelenting lack of respite from treatment and illness in patients with end-stage kidney disease is a stress (Levy, 1976).
- An overall feeling of low-grade illness with sleeplessness, fatigue, pain, and pruritis is very common among dialysis patients.
- Cohen's approach (1998) to diagnosing depression in these patients entails describing the criteria for major depression, eliciting patients' opinion as to whether they believe they are depressed, and then documenting the existence of associated factors, such as depressive episodes prior to the onset of renal failure, a family history of depression, and past suicide attempts.
- Currently, the national withdrawal from dialysis accounts for 26% of ESRD deaths, 10% of deaths in patients age 20–26, and 46% of patients over age 85 (USRDS 2009). These patients are generally elderly, white, diabetic, and severely ill with multiple comorbidities (Bostwick & Cohen, 2009).
- Once dialysis is withdrawn, the mean time to death is 8.2 days (median, 6 days) (Cohen, Germain, et al., 2000).
- Pruritis from accumulation of bile salts secondary to hepatorenal syndrome responds well to H1 antagonists and ondansetron.
- As GFR decreases in CKD patients, the rate of global cognitive decline increases as assessed by mental status examination (Murray, 2009).
- Patients employed in intellectual occupations will tend to note progressive impairment as their day for dialysis approaches. Immediately after dialysis, they may experience a short period of delirium termed “disequilibrium syndrome,” caused by the rapid change of fluid and electrolytes that has taken place during the session.
- Depressive symptoms are an independent predictor of mortality in renal transplant patients (Novak et al., 2010).

- Many patients with major psychoses, depression, or bipolar disorder have undergone successful transplantation (Carrasco et al., 2009).

INFECTIOUS DISEASES

Scott R. Beach

INTRODUCTION

Infectious processes should be considered in the differential diagnosis of any patient presenting with neuropsychiatric symptoms. While many patients with infections will demonstrate additional signs or symptoms (fever, elevated white blood cell [WBC] count, rash, etc.), psychiatric symptoms may be the earliest or most prominent manifestation. As is the case for all psychiatric presentations, workup begins with a good history and physical. Risk factors leading to a potentially impaired immune response (e.g., human immunodeficiency virus [HIV] infection, immunosuppressant medications, substance abuse, extremes of age) should raise suspicion for infection. Behaviors, including hobbies, occupation, and sexual practices, may also influence risk. Geographic factors are of paramount importance, and birthplace, residence, and travel may represent the most essential components of the history in terms of evaluating an individual patient's risk for a particular infectious illness.

The history and physical should guide subsequent testing. Laboratory testing, including blood and urine cultures as well as serological tests for specific entities, may be indicated. Patients with new-onset psychiatric symptoms in the setting of other objective evidence of infection may require a lumbar puncture (LP) in order to analyze cerebrospinal fluid (CSF). Electroencephalogram (EEG) sometimes aids in localizing disease, while imaging of the brain and/or spinal cord may provide additional useful information. In rare cases, a brain biopsy may be indicated, though with advancing diagnostic techniques over the past decade, this is becoming a rarer necessity.

Many infectious processes have the potential to cause neuropsychiatric symptoms by leading to the development of delirium. Among these entities are typhoid fever, bacterial endocarditis, toxic shock syndrome (TSS), bacteremia, and occult infections (urinary tract infections, sinus infections, etc.). Encephalopathy may result from a variety of pathways, including direct invasion of the central nervous system (CNS) by the infectious organism, release of inflammatory cytokines, hypoxia, or edema. Presentations may include changes in mood, cognition, personality, or behavior, as well as psychosis. Like the canary in the mineshaft, the symptoms of delirium may be the first indication that something is amiss.

Other infectious agents may induce specific neuropsychiatric symptoms via direct invasion of the CNS, leading to meningitis, encephalitis, encephalomyelitis, or abscesses, as in Boxes 60.1 and 60.2. Still others, such as pediatric

autoimmune neuropsychiatric disorders associated with streptococcal infections (PANDAS) are thought to lead to CNS dysfunction by precipitating an immune reaction to natural brain proteins. Some entities, such as those in Box 60.3, may exist in a chronic form, sometimes controversial in nature, which may induce neuropsychiatric symptoms. Others, such as those in Box 60.4, are likely to be missed because they are more common in developing countries and more rarely seen by American physicians.

This chapter is organized by organism type, divided into sections on *bacteria*, *viruses*, *parasites*, and *fungi*. Entities lacking a well-defined subgroup—*prions* and *algae*—are presented towards the end. The chapter concludes with a discussion of some psychiatric concerns relating to the use of antimicrobial medications.

BACTERIAL INFECTIONS

SYPHILIS

Syphilis is a chronic systemic disease caused by the spirochetal bacterium *Treponema pallidum* and spread through contact with infectious lesions or body fluid, usually through

Box 60.1 INFECTIOUS DISEASES ASSOCIATED WITH ENCEPHALITIS

Bacteria:

Lyme Disease
Rocky Mountain Spotted Fever
Typhus Fever
Tuberculosis

Viral:

Herpes Simplex Virus
Arboviruses (West Nile, Eastern Equine, Western Equine, etc.)
Cytomegalovirus
Epstein-Barr Virus
Varicella Zoster Virus

Parasites:

Chagas' Disease
Amoebiasis

Fungal:

Histoplasmosis

**Box 60.2 INFECTIOUS DISEASES ASSOCIATED

Malaria
Trypanosomiasis
Schistosomiasis
Trichinosis
Amoebiasis

sexual contact. Transmissibility is highest in the early stages of disease (Hook et al., 1992). As late as a hundred years ago, syphilis was the leading diagnosis in psychiatric inpatients; the incidence began to decline with the advent of penicillin and continued to decline with the institution of public health-control measures, reaching a nadir in 2000. In the past ten years, however, rates have begun to climb again, owing to a variety of factors such as increasingly unsafe sex practices, particularly among men who have sex with men (MSM), in the wake of available antiretroviral therapy for HIV. Furthermore, HIV-positive patients infected with syphilis are more likely to develop neurosyphilis (Chahine et al., 2011). With current trends, psychiatrists are obliged to relearn this disease.

Primary syphilis develops first as a small papule at the site of inoculation, which progresses to an ulcer or chancre. Secondary syphilis occurs four to ten weeks after the appearance of the chancre and can involve multiple organ systems. Onset of secondary syphilis is heralded by a macular rash in 70% of cases. Other symptoms are constitutional and include malaise, fatigue, anorexia, and weight loss. Secondary syphilis resolves without treatment but may recur in the next few years. If untreated, one-third of individuals develop later sequelae. Tertiary syphilis occurs years to decades after primary infection and can assume a benign (gummatous) form or affect the heart or CNS.

T. pallidum invades the CNS early in the disease course, and neurosyphilis can be seen at any of the three stages of illness. Early neurosyphilis, coexisting with primary or secondary syphilis, generally presents as meningitis or, less commonly, as meningovascular disease or stroke (Golden et al., 2003). Overall, rates of early neurosyphilis have increased in the HIV era. Late neurosyphilis, the most common form of tertiary syphilis, is rare but can affect the meninges, spinal cord, or brain parenchyma. The form best known to psychiatrists is general paresis, a rapidly progressing dementia, which may present with a host of psychiatric symptoms, including irritability, personality change, emotional lability, delirium, mania, or psychosis. A recent retrospective review suggests that a positive sucking reflex, Argyll-Robertson pupils that accommodate but do not react to light, and hyperreflexia are the most common signs (Zheng et al., 2011). Imaging commonly shows atrophy of the frontal and temporal lobes. Tabes dorsalis, marked by Argyll-Robertson pupils, sensory ataxia, and bowel and bladder dysfunction resulting from demyelination of the posterior columns and dorsal roots is the second potential form of late neurosyphilis.

Because *T. pallidum* cannot be cultured, diagnosis relies on serological testing. Workup for primary or secondary syphilis without presumed CNS involvement traditionally begins with a non-treponemal test, such as rapid plasma regain (RPR) or venereal disease research laboratory (VDRL), with positive results or high clinical suspicion leading to a treponemal test, such as *T. pallidum* particle agglutination (TPPA) or fluorescent treponemal antibodies (FTA-abs). Non-treponemal serological tests have a sensitivity of about 80% in primary syphilis, 100% in secondary syphilis, and 95% in latent syphilis. Acute false positives occur with non-treponemal tests after some immunizations, during acute infections, and in pregnancy.

Chronic false positives occur in autoimmune diseases (e.g., systemic lupus erythematosus [SLE]), in patients with leprosy, and in the elderly (Relman & Swartz, 1998). A prozone effect can also be seen, in which RPR is falsely negative because very high levels of antibodies interfere with the antigen–antibody interaction needed to visualize a positive reaction, and more commonly occurs in HIV-positive patients. Infection with HIV can cause false-positive or -negative results in non-treponemal tests. Although non-treponemal tests generally become negative after treatment and treponemal tests generally stay positive for life, this is not always the case. For further comparison of treponemal and non-treponemal tests, see Table 60.1.

As a result of these concerns, some have suggested a shift towards the use of treponemal-specific enzyme immunoassays (EIA) and chemiluminescence immunoassays (CIA) for initial screening, followed by a non-treponemal test in the setting of positive results.

The Centers for Disease Control and Prevention (CDC) has offered the following indications for LP in patients with syphilis: neurological or ocular symptoms, late latent syphilis or syphilis of unknown duration in patients with HIV, active tertiary syphilis (e.g., gumma, aortitis, iritis), or treatment failure for non-neurological syphilis. A positive CSF-VDRL establishes the diagnosis of neurosyphilis but has a sensitivity of 30–70% (Larsen et al., 1990). Conversely, a negative CSF-FTA-abs essentially excludes the diagnosis, but a positive result has low specificity.

Diagnosis of neurosyphilis can be difficult, particularly in its late stages. Current recommendations for the workup of neurosyphilis are summarized in Box 60.5 and begin with a serum treponemal test. Treponemal-specific tests should be positive in all patients with neurosyphilis. If positive, CSF-VDRL should be performed. If the CSF-VDRL is positive, diagnosis is established. If the result is negative, but the patient has a mild mononuclear pleocytosis, HIV-negative patients should be presumed to have neurosyphilis. Because HIV can cause a mild mononuclear pleocytosis as well, diagnosis in this population in the setting of a negative CSF-VDRL is further clarified via a CSF-FTA-abs. Some authors have recommended that asymptomatic patients without HIV be treated for neurosyphilis if they have a positive CSF-FTA-abs and either CSF pleocytosis or elevated

CSF protein, while asymptomatic patients with HIV are treated on the basis of a positive CSF-FTA-abs and CSF pleocytosis.

Guidelines for treatment recommend a single dose of penicillin G for primary, secondary, or early latent syphilis. Late latent syphilis should be treated with a three-week course of penicillin G. Treatment for neurosyphilis involves a 10- to 14-day course of intravenous aqueous penicillin G. Within the first 24 hours of any treatment, an acute febrile illness associated with headache and myalgias, the Jarisch-Herxheimer reaction, may occur. All treated patients should have clinical and serological follow-up at 6 and 12 months, and HIV-positive patients should be followed for two years after treatment. All patients with neurosyphilis should have a repeat LP at three to six months, and then again every six months until the result is normal (Golden, 2003).

In late neurosyphilis, psychiatric symptoms frequently do not remit with antibiotic treatment. There have been case reports suggesting efficacy for most atypical antipsychotics in treating particular manifestations of neurosyphilis, especially in general paresis, though no controlled studies exist. Valproate has also been suggested to have some utility in terms of mood stabilization and controlling agitation in this population.

LYME DISEASE

Lyme disease (LD), caused by the spirochete *Borrellia burgdorferi* and transmitted by deer ticks, is a multisystem illness that can cause a variety of neuropsychiatric symptoms. LD is the most common tick-borne infection in the United States and is increasing in incidence and geographical spread, though risk remains highest in the Northeast. Erythema migrans, a large rash with central clearing, heralds the onset of the disease in over 90% of patients, though the rash may have an atypical appearance in more than half of those cases and may go unnoticed by the patient at the time (Schneider, Robinson & Levenson, 2002). Up to one-fifth of infected individuals have no further symptoms beyond the rash.

Three separate phases of disease progression have been described (acute, subacute, and chronic), and CNS involvement (Lyme neuroborreliosis) can occur in all of them. *B. burgdorferi* is rapidly disseminated in the body over the first month of illness and is known to invade the CNS

Table 60.1 TESTS FOR SYPHILIS

TYPE OF TEST	EXAMPLES	STATES CAUSING FALSE POSITIVE	STATES CAUSING FALSE NEGATIVE	EVOLUTION OF TEST RESULTS
Non-treponemal	RPR, VDRL	<i>Acute:</i> Immunizations, acute infections, pregnancy, HIV <i>Chronic:</i> Autoimmune diseases, leprosy, elderly patients	Prozone effect (more common in patients with HIV)	Generally become negative after treatment
Treponemal	TPPA, FTA-abs	Autoimmune diseases	Unknown	Tend to stay positive for life

**Box 60.5 ALGORITHM FOR THE DIAGNOSIS
OF SYPHILIS**

CNS Involvement Not Suspected

1. Start with non-treponemal test:
 - a. If negative, and clinical suspicion is low, no further testing indicated
 - b. If positive, proceed
 - c. If negative but clinical suspicion high, proceed
2. Follow up with treponemal test:
 - a. Positive result establishes diagnosis

CNS Involvement Suspected

1. Start with treponemal test:
 - a. If negative, no further testing indicated (patient does not have neurosyphilis)
 - b. If positive, proceed
2. If treponemal test positive, follow up with CSF-VDRL:
 - a. If positive, diagnosis of neurosyphilis is established
 - b. If negative, proceed
3. If CSF-VDRL is negative, evaluate CSF for presence of pleocytosis:
 - a. If no pleocytosis, no further testing indicated (patient does not have neurosyphilis)
 - b. If pleocytosis present, proceed
4. If pleocytosis is present, evaluate for HIV status:
 - a. If HIV-negative, diagnosis of neurosyphilis is established
 - b. If HIV-positive, proceed
5. If HIV-positive, perform CSF-FTA-abs:
 - a. If negative, no further testing indicated (patient does not have neurosyphilis)
 - b. If positive, treat presumptively for neurosyphilis

within the first few weeks after initial infection (Fallon et al., 2010). Common symptoms in the acute phase include fatigue, myalgias or arthralgias, headache, fever, and neck stiffness. Untreated LD may progress to subacute disease and affect other organ systems. Neurological symptoms during the subacute phase include Bell's palsy, radiculopathy, and meningitis. This is also the phase during which patients experience arthritis in a limited number of joints, usually including the knee. If patients remain untreated, chronic LD may develop, with further neuropsychiatric symptoms (chronic neuroborreliosis) that include cognitive dysfunction, fatigue, irritability, and depression. Lyme encephalopathy may include impairments in short-term memory, word-finding

difficulties, decreased processing speed, fatigue, and depressed mood. Lyme encephalomyelitis and cerebellitis have also been described. Stroke and hemorrhages are rare complications. Although the neuropsychiatric symptoms of chronic LD are relatively nonspecific, they are almost always preceded by classic early symptoms.

A variety of psychiatric symptoms, including mania, psychosis, catatonia, panic attacks, and personality change, have been described in the setting of LD, though causality has not been established. At least one study suggested no difference in neuropsychological testing between patients with LD at 10- to 20-year follow-up and normal controls, though it was noted that patients who had demonstrated Bell's palsy early in the course and had not received antibiotics were more likely to report sleep disturbances (Kalish et al., 2001). Nonetheless, neuropsychological testing is recommended for patients with chronic neuroborreliosis as a means of evaluating the presence and extent of cognitive dysfunction.

Diagnosis of LD should be made largely on clinical evaluation. If a patient has known exposure to an endemic area, history of a tick bite, history of rash, or symptoms in another involved system, in addition to new-onset or exacerbation of psychiatric symptoms, serological testing should be considered (Tugwell et al., 1997). Serological testing remains unreliable in many cases, with false positives occurring in the setting of other infections and true-positive tests only indicating a history of LD at some time in the past. If pursued, serological testing should involve an initial enzyme-linked immunoassay (ELISA) test, with positive results confirmed by a Western blot. Caveats include the fact that both tests may be negative within the first two to three weeks of infection, and early antibiotic treatment may lead to persistent false negatives (Bunikis & Barbour, 2002). Magnetic resonance imaging (MRI) may demonstrate white matter lesions in up to 25% of patients with chronic neuroborreliosis and may resemble a demyelinating process.

Treatment of LD is accomplished via a two- to four-week course of doxycycline or amoxicillin. Patients' symptoms sometimes worsen during the first few weeks in a phenomenon similar to the Jarisch-Herxheimer reaction seen in syphilis (Fallon et al., 1992). A two- to four-week course of intravenous (IV) ceftriaxone is recommended for neuroborreliosis. Antibiotic prophylaxis is not recommended after a tick bite because of the low risk of contracting LD. A vaccine for LD has been developed and has shown up to 90% protection after the first year (Sigal et al., 1998).

Recent years have seen a drastic increase in cases of post-treatment LD syndrome (PTLDS), colloquially labeled with the misnomer "chronic LD," with patients attributing a myriad of symptoms to LD and some physicians recommending indefinite courses of antibiotics for supposedly ongoing infection. Symptoms such as fatigue, sadness, and chronic nonspecific pain are common in such patients, and the spectrum of complaints overlaps significantly with those seen in chronic fatigue syndrome (CFS) and fibromyalgia. Clinical depression and somatization behavior are also common in this population. Most concerning is that some physicians, often

labeling themselves as “Lyme experts,” diagnose “chronic LD” without any objective evidence or through unvalidated tests such as Lyme urine antigen, and recommend unnecessary courses of antibiotics, which in some cases lead to “Lyme colitis.”

Despite the controversy, the CDC has recognized PTLDS as an entity, though no treatment is recommended. A proposed definition includes established LD diagnosis, conclusion of an appropriate course of antibiotics with resolution or stabilization of objective manifestations of LD, and the presence of symptoms (fatigue, widespread pain, cognitive problems) more than six months after LD diagnosis. Exclusionary criteria include documented co-infection (*Babesia*, *Ehrlichia*), objective evidence of active LD, and preexisting conditions including CFS and fibromyalgia, thyroid disease, and psychiatric conditions (Wormser et al., 2006). It is estimated that up to 10% of patients with erythema migrans will have persistent or intermittent subjective symptoms 12 months after completion of appropriate therapy (Marques, 2008). Some have suggested that ongoing cytokine activation, including elevated interleukin-6 (IL-6), may contribute to persistent symptoms of pain, fatigue, and cognitive dysfunction in patients with prior LD (Fallon, 2010). It is further noted that patients with previously treated well-documented LD have a four-fold greater rate of concurrent depression than patients with medically unexplained symptoms who do not have a clear history for LD (Hassett et al., 2008).

The vast majority of patients who present with a diagnosis of “chronic LD” will have either symptoms of an unknown cause with no evidence of *Borrelia* infection or with a well-defined illness unrelated to *Borrelia* infection. In one study of patients presenting to a tertiary care center with a chief complaint of LD, 57% were found to not have LD and to have symptoms better explained by fibromyalgia and CFS. An additional 20% had evidence of prior LD without the need for further antibiotics (Steere et al., 1993). For psychiatrists who find themselves working with patients claiming to suffer from “chronic LD,” evaluation for other underlying psychiatric and medical conditions is of paramount importance. It is also vital to educate patients that, although some physicians advocate long-term antibiotic treatment, all four randomized controlled trials of prolonged antimicrobial treatment have failed to demonstrate any lasting improvement, and many other open-label trials have failed to separate cases of well-documented LD from those without objective evidence (Halperin, 2008). Furthermore, such treatment carries significant risk in the form of complications related to catheters, biliary disease, *Clostridium difficile* infection, and promotion of antibiotic resistance. In the case of treatment with ceftriaxone, it is hypothesized that transient cognitive improvement seen in some subjects may be the result not of antimicrobial action but of neuroprotective effects involving the reduction of extracellular glutamate (Fallon et al., 2008). Patients may be encouraged by the fact that one-third of patients suffering from symptoms consistent with PTLDS improve regardless of treatment (Auwaerter, 2007).

ROCKY MOUNTAIN SPOTTED FEVER (RMSF)

Rocky Mountain spotted fever (RMSF), caused by *Rickettsia rickettsii*, is a tick-borne disease with a seasonal distribution paralleling human contact with ticks, peaking from May through September. Despite its name, RMSF is seen throughout the United States, with South Atlantic and Central states reporting the highest incidence between 2000 and 2007 (Openshaw et al., 2010). *R. rickettsii* enters the vascular endothelial cells, proliferates and disseminates, causing a diffuse vasculitis in many organ systems, including the CNS, skin, heart, and liver. Incubation period is typically seven days. As the name suggests, RMSF generally presents with fever and a rash characterized by erythematous macules that later progress to maculopapular lesions with central petechiae. The rash is notable in being one of the few diffuse rashes to involve the palms and soles (another being the rash of secondary syphilis). CNS involvement in the form of encephalitis occurs in 25% of all cases, and presents with lethargy, confusion, and occasionally seizures. Subtle changes such as irritability, personality changes, or apathy may occur before the rash, particularly in children.

While *R. rickettsii* may be demonstrated by direct immunofluorescence of skin biopsies, serology is the usual diagnostic method, though confirmation requires convalescent titers. The traditional Weil-Felix agglutination test lacks specificity and sensitivity, and indirect immunofluorescence (IFA), ELISA, or polymerase chain reaction (PCR) are preferred (Gunther & Haglund, 2005). Since mortality is high in untreated patients, a provisional clinical diagnosis (e.g., fever, rash, appropriate season and geographic setting) is sufficient to initiate definitive antimicrobial therapy. Only half of patients remember exposure to ticks. Doxycycline or chloramphenicol are the drugs of choice and are typically administered for two weeks.

OTHER TICK-BORNE ILLNESSES

Other tick-borne illnesses that may mimic LD in early stages include babesiosis and human granulocytic anaplasmosis (HGA), formerly known as *erlichiosis*. Both are transmitted by the same deer tick that transmits LD, and co-infection is possible. The number of reported cases of these illnesses is less than that of LD, though the geographic distribution is similar, with New England being the highest-incident area. Early symptoms of both illnesses may mimic those of LD, though neuropsychiatric symptoms are less common. Chronic babesiosis is not well described, and chronic HGA infection is said to not exist (Wormser, 2006). Diagnosis of babesiosis is based on epidemiological, clinical, and laboratory findings, the latter of which includes microscopic identification of organisms on Giemsa stains of thin blood smears or PCR detection. Diagnosis of HGA is made via identification of characteristic intragranulocytic inclusions on blood smear or by detection of antibodies to the infectious agent. A ten-day course of doxycycline is the recommended treatment for HGA and should treat coexistent LD as well. Treatment for babesiosis, on the other hand, most commonly involves a

combination of atovaquone and azithromycin. Co-infection with LD should be considered in cases of treatment-resistant babesiosis.

PEDIATRIC AUTOIMMUNE NEUROPSYCHIATRIC DISORDERS ASSOCIATED WITH STREPTOCOCCAL INFECTIONS

PANDAS affect a subgroup of patients with obsessive-compulsive disorder (OCD) and tic disorders, including Tourette's disorder. The syndrome is defined by the presence of OCD and/or tic disorder according to DSM-IV (*Diagnostic & Statistical Manual of Mental Disorders-IV*) criteria; onset of symptoms between three years and onset of puberty; an episodic course characterized by abrupt onset of symptoms or by dramatic exacerbations; association with neurological abnormalities (especially tics); and temporal association with group A *b*-hemolytic streptococcal (GABHS) infections (most commonly pharyngitis), with at least two exacerbations occurring shortly after infection (Swedo et al., 1997). Classified in 1998, invocation of the diagnosis has risen dramatically in the past ten years, leading many to conclude that the phenomenon is over-diagnosed, while others question its existence altogether. It is suggested that the syndrome is often misdiagnosed in the community, and unrelated symptoms are inappropriately treated with antibiotics. Psychiatrists should be aware of the controversy and utilize a strict interpretation of criteria for diagnosis.

The age of onset for PANDAS is said to be younger by about three years than that for typical childhood-onset OCD and tic disorders. Including all children, boys outnumber girls by a ratio of 2.6:1; below the age of eight years, the ratio is 4.7:1. Preexisting psychiatric comorbidity is reportedly common (32–42%). Symptom exacerbations are thought to be sudden and dramatic, as distinct from the more gradual waxing and waning pattern of childhood-onset OCD. In addition to OCD symptoms and tics, other described symptoms include separation anxiety, personality changes, rage episodes, oppositional behaviors, cognitive dysfunction, and anorexia. Recently, particular attention has been paid to the presence of motoric hyperactivity, and some have argued that ADHD-like symptoms may be a very common manifestation of the disorder. Typical episodes are generally associated with an increase in anti-streptococcal antibody titers (Swedo et al., 1998). It has become clear recently that not all exacerbations are necessarily associated with GABHS infection, however, and other infectious agents are now being invoked as potential triggers. In cases that do demonstrate elevated titers, diagnosis is further supported by evidence of a decrease in titers with symptom remission.

Studies have suggested enlarged basal ganglia in patients with PANDAS, though neuroimaging is not currently part of the standard diagnostic workup. Pathogenesis has been thought to involve both genetic and environmental factors, with a possible aberrant immune response leading to antibodies against GABHS cross-reacting with basal ganglia

neurons. This hypothesis has been challenged recently, however, by studies that have failed to demonstrate any correlation between clinical exacerbations and autoimmune markers (Singer et al., 2008). Treatment recommendations are not currently specific for this syndrome. Trials involving antibiotics as well as immunomodulatory treatments such as plasmapheresis and intravenous immunoglobulin (IVIG) are continuing, though with inconclusive results at this time. There is very little evidence from controlled trials to support the efficacy of standard psychopharmacological treatment for OCD or tic disorders (e.g., selective serotonin reuptake inhibitors [SSRIs], alpha-2 agonists) in PANDAS, but they are widely used, generally well tolerated, and most experts think they work (Martino et al., 2009).

TUBERCULOSIS

Tuberculosis (TB) remains a major world health problem and is endemic in many developing countries. Groups at high risk for TB include immunosuppressed patients, prisoners, institutionalized patients, immigrants, and the homeless. TB now represents the most common serious HIV-related complication worldwide. CNS TB accounts for 1% of all TB cases and disproportionately affects children and HIV-positive individuals, though alcoholism and immunocompromised states are also risk factors. In some cases, neuropsychiatric manifestations of TB may precede peripheral signs or symptoms. Tuberculous meningitis (TBM) is the most common form of CNS TB. The clinical presentation begins with low-grade fever, generalized malaise, and mild headache. Over the course of a week, symptoms progress to high-grade fever and severe nuchal rigidity. Fatigue, personality changes, and delirium are the most common early psychiatric symptoms. Later findings include vasculitis and cranial nerve involvement. A history of TB is elicited in only 10% of patients with TBM at the time of presentation, and tuberculin skin test may be positive in fewer than 50% of patients (Rock, 2008). CSF classically demonstrates low glucose and markedly elevated protein, with a moderate lymphocytic pleocytosis. Identification of acid-fast bacillus (AFB) in the CSF remains the most important diagnostic test. The presence of active pulmonary tuberculosis in patients with tuberculous meningitis ranges from 30–50%. Diffuse meningeal involvement by TB may be demonstrated on MRI (Gray, 1997). Other forms of CNS TB include tubercular encephalitis, intracranial tuberculoma, and tuberculous brain abscess.

Early treatment of CNS TB is essential, because delayed treatment is associated with higher morbidity and death. Current recommendations involve a two-month induction with isoniazid, rifampin, pyrazinamide, and ethambutol, followed by seven to ten additional months of isoniazid and rifampin (Rock et al., 2008). In many parts of the world, multi-resistant TB is rapidly emerging, requiring development and testing of novel drug combinations.

BACTERIAL CEREBRAL ABSCESS

Although rare in the United States, cerebral abscesses are serious and potentially life-threatening infections. Immunocompromised patients and those with uncontrolled diabetes are at highest risk for death or permanent neurological deficits, while delay in hospitalization and focal deficits on admission are also indicators of a poor prognosis. The pathogenesis of infection for brain abscesses includes hematogenous spread from a remote source, trauma (including neurosurgery), and most commonly, direct extension from another infected site. Non-pneumococcal streptococci account for the majority of cases, while *S. aureus* and anaerobes comprise most of the remaining cases. Other opportunistic pathogens, including *Nocardia*, TB (discussed above), and *Listeria* may affect immunocompromised patients.

The classic triad of headache, fever, and focal neurological deficits occurs in less than half of patients with this condition. Psychiatric symptoms, including personality change and encephalopathy, may be part of the initial presentation, and seizures are also common. Brain abscesses frequently mimic CNS tumors and other space-occupying lesions. Computed tomography scan (CT scan) with contrast is likely to reveal ring-enhancing lesions, though MRI remains the preferred imaging test. Prompt treatment includes empiric antibiotics, though attempts should be made to identify a pathogen prior to initiation (Honda & Warren, 2009). As abscesses are frequently polymicrobial, therapy should cover a range of organisms and is typically continued for six to eight weeks, though with individual variations. Most experts feel that abscesses greater than 2.5 cm in diameter should be surgically treated. Steroids and anticonvulsants are often used as adjuvant treatments.

Following successful treatment, a broad spectrum of psychiatric symptoms may persist, depending on the size and location of the abscess. Affective illness, cognitive dysfunction, psychosis, and aggression are the most common psychiatric complications.

BACTERIAL MENINGITIS

Bacterial meningitis is an acute, serious illness associated with significant morbidity and mortality. Annual incidence in the United States has not changed over the past decade, and *S. pneumoniae*, *N. meningitidis*, and *L. monocytogenes* remain the most common pathogens. The *Haemophilus influenzae* type B vaccine has greatly reduced cases of meningitis caused by this agent (Schuchat et al., 1997). Nuchal rigidity, headache, nausea, vomiting, confusion, lethargy, and apathy may occur. Delirium is the most common psychiatric symptom. Symptom severity generally correlates with the magnitude of the host's immune response, and in elderly or immunocompromised patients the only clinical signs may be irritability or minor changes in mentation or personality (Weinstein, 1985; Segreti & Harris, 1996).

Once clinically suspected, the diagnosis is usually confirmed by examination of the CSF, typically revealing pleocytosis, low

glucose, high protein, and evidence of the offending organism on appropriate staining. Neuroimaging rarely makes the diagnosis of bacterial meningitis. The morbidity and mortality of bacterial meningitis are associated with the time to treatment (Gray, 1997). Initially, antibiotics are chosen to cover a broad range of organisms common to the population in which the patient falls (e.g., age and immune status). Once a pathogen is identified, therapy can be modified. Physicians should be aware of the increasing resistance of *S. pneumoniae* to penicillins and cephalosporins.

VIRAL INFECTIONS

HERPES SIMPLEX VIRUS

Herpes encephalitis is caused by herpes simplex type 1 virus in 90% of cases. A bimodal distribution is seen with one-third of cases between ages 6 months to 20 years, and one-half of cases occurring in patients over 50 years old (Whitley, 2006). Herpes simplex virus (HSV) encephalitis differs from other types of viral meningoencephalitis in its greater likelihood to cause unilateral and focal findings and its predilection for temporoparietal involvement. Fever, headache, confusion, and seizures typically develop rapidly, over a matter of hours to days. Occasionally, onset may be heralded by the presence of olfactory or gustatory hallucinations. Other symptoms may include personality change, dysphasia, autonomic dysfunction, ataxia, and psychosis. Progressive obtundation and focal disturbances develop subsequently, and mortality approaches 70% if untreated. Lower initial level of consciousness and age over 30 are indicators of a poor prognosis. An additional possible, though rare, sequela of HSV encephalitis is Klüver-Bucy syndrome, which includes oral touching compulsions, hypersexuality, amnesia, placidity, agnosia, and bulimia (Thirunavukarasu, 2011).

MRI scans show abnormal signal in the medial temporal lobes and insula earliest on fluid-attenuated inversion recovery (FLAIR) sequences, diffusion-weighted imaging (DWI), and contrast-enhanced imaging, though most MRI scans are abnormal even without contrast or special sequencing once symptoms are apparent (Baringer, 2008). Early HSV encephalitis can be missed on CT scans. CSF typically shows pleocytosis, elevated protein, and normal glucose. PCR detection of HSV deoxyribonucleic acid (DNA) in the CSF has become the diagnostic method of choice, though it may be negative rarely in very early cases. It is widely available, and the time from LP to results is generally 24–72 hours. EEG may demonstrate slowing in frontal and temporal regions, but lacks the specificity of other tests. Brain biopsy is reserved for cases in which diagnostic confusion remains after other workup has been exhausted. Therapeutic decisions must be made within a matter of hours, because only early treatment improves outcome. The current recommendation is to initiate treatment with acyclovir while awaiting laboratory results, given the relatively low risk of the medication. If the PCR result returns negative, a decision regarding discontinuing therapy should be

based on the clinical presentation and other diagnostic tests, with consideration given to repeating the CSF PCR study.

Following recovery from herpes encephalitis, psychiatric sequelae (especially mood disorders) are common and constitute a major cause of disability. Depression, hypomania, irritability, and psychosis have been noted months after recovery (Caparros-Lefebvre et al., 1996). Neuropsychological testing is helpful in fully delineating the extent of cognitive damage. Depressive symptoms often respond to treatment with antidepressants or stimulants, but there are no controlled studies of their efficacy. Hypomania, irritability, and disinhibition have responded to mood stabilizers, and behavior modification may be helpful for aggressive and sexual behaviors (Vallini & Burns, 1987; Boulais et al., 1976).

VIRAL ENCEPHALITIS

Arboviruses are the most common cause of viral encephalitis worldwide, with Japanese encephalitis accounting for the most cases. In the United States, there are five common types: West Nile virus (WNV), St. Louis encephalitis, Eastern equine encephalitis (EEE), Western equine encephalitis, and California encephalitis. All are mosquito-borne, causing illness typically in the summer or fall. Of these, EEE causes the severest illness and has the highest fatality rate (Romero & Newland, 2003). Many survivors of neuroinvasive arboviruses have permanent sequelae.

WNV has been the most common cause of viral encephalitis in the United States over the past decade. Although identified in Uganda in 1937, WNV did not reach the United States until 1999, and between 2002 and 2003, 3,000 confirmed cases of neuroinvasive disease occurred. Despite this figure, neuroinvasive disease is thought to occur in only 1 in 150 individuals, and most cases of WNV are asymptomatic. Patients developing encephalitis are usually older and are often immunosuppressed or suffering from other medical illnesses such as diabetes. One study found a history of hypertension or cardiovascular disease to be associated with development of encephalitis, and the authors speculated that this might be due to increased penetrability of the blood-brain barrier in such states (Murray et al., 2006). The clinical presentation of WNV, like other arboviruses, involves an abrupt onset of fever, headache, nausea, photophobia, and vomiting. Psychiatric symptoms include confusion, cognitive changes, and psychosis. MRI will demonstrate areas of increased signal in the thalamus, basal ganglia, and upper brainstem in up to 75% of patients (Tyler, 2009). Diagnosis is typically based on serology with detection of WNV IgM antibodies in the CSF being diagnostic. Although there is no specific treatment available for viral encephalitis caused by arboviruses, rapid diagnosis is important for the institution of public health measures.

ACUTE DISSEMINATED ENCEPHALOMYELITIS

Acute disseminated encephalomyelitis (ADEM) has been described as occurring in the wake of a number of viral infections, including measles, mumps, rubella, varicella zoster (VZV),

Epstein-Barr virus (EBV), CMV, HSV, hepatitis A or B, Coxsackie virus, and influenza A or B (Huynh et al., 2008). Bacterial agents such as *Mycoplasma pneumoniae* and *Borrelia* have also been implicated. ADEM has additionally been described in the setting of immunization. The presumed mechanism is cell-mediated immunity to myelin basic protein, and clinical symptoms commonly include encephalopathy, fever, seizures, and meningismus. Changes in mood, as well as psychotic symptoms such as delusions and hallucinations, have also been reported in the absence of obviously altered sensorium (Krishnakumar, 2008). MRI is useful in diagnosis, revealing multifocal white matter and deep gray matter lesions, with lesion load typically greater than 50% of the total white matter volume (Menge et al., 2007). Options for treatment include corticosteroids, plasma exchange, and intravenous immunoglobulin.

HEPATITIS

Viruses including hepatitis A, B, C, D, or E; EBV; and CMV all cause hepatitis, an inflammation of the liver (see Chapter X). Hepatitis commonly presents with fatigue, malaise, and anorexia. Chronic forms of hepatitis-B and -C can lead to a secondary depression (Levenson & Fallon, 1993; Sharara, Hunt, & Hamilton, 1996). Treatment of viral hepatitis with interferon may cause a syndrome involving fatigue, apathy, and depressed mood, as well (see GI Chapter). Depression associated with interferon treatment is sometimes responsive to antidepressant therapy, though prophylaxis with antidepressants is not currently recommended.

EPSTEIN-BARR VIRUS

EBV, one of the herpes viruses, causes an acute lymphoproliferative disease called *infectious mononucleosis*, common in adolescents and young adults. The prodromal stage of infectious mononucleosis is characterized by headache, fatigue, and malaise, with progression to fever, sore throat, and lymphadenopathy. Diagnosis may be established on the basis of clinical presentation, the presence of atypical lymphocytes on peripheral blood smear, and a positive heterophile antibody (IgM) test, though the latter remains negative in 25% of patients during the first week of infection and in 5–10% during or after the second week (Luzuriaga & Sullivan, 2010). Definitive diagnosis requires testing for immunoglobulin-M (IgM) and IgG antibodies to viral capsid antigens, early antigens, and EBV nuclear antigen proteins. IgG antibodies to viral capsid antigens persist for life, while IgM antibodies typically disappear or decline significantly within four to eight weeks and are therefore diagnostic of primary EBV infection. Treatment is largely supportive.

Most cases of EBV completely resolve within one month, though the infection can recur in immunocompromised hosts. An entity known as *chronic active EBV* (CAEBV), involving recurrent symptoms of fever, hepatosplenomegaly, and lymphadenopathy, has also been defined in patients without apparent immunodeficiency and is diagnosed on the basis of extremely high titers of IgG antibody to viral capsid antigen and early antigen. Many patients who do not meet criteria for CAEBV, but who have experienced acute EBV infection,

report ongoing symptoms of malaise and fatigue. A prospective study suggested that 9% of patients develop a syndrome of chronic fatigue up to six months after illness onset (White, 1998). A cohort study, however, concluded that, although many patients reported transient distress during acute infection, few subjects met criteria for a psychiatric disorder, and the vast majority demonstrated decreased impairment and distress at two- and six-month follow-ups (Katon et al., 1999).

The role of the psychiatrist in treating patients reporting chronic EBV symptoms is to aid in identifying those with an underlying psychiatric diagnosis, including a mood, anxiety, or somatoform disorder. The absence of any objective physical findings (e.g., significant lymphadenopathy, atypical lymphocytes, lymphocytosis, elevated erythrocyte sedimentation rate [ESR], fever, hepatosplenomegaly) raises suspicion for a primary psychiatric diagnosis but does not exclude the possibility of symptoms' being caused by EBV. Workup for CAEBV is appropriate, with patients failing to meet criteria considered to have CFS, an entity now thought to be unrelated to EBV.

EBV has been rarely associated with encephalitis and meningitis, with the findings indistinguishable from other viral causes. Laboratory diagnosis is enhanced by concomitant use of EBV-specific serology and PCR (Doja et al., 2012), though the pathogenesis may be either immune or viral; antiviral therapy has not shown clinical efficacy; and appropriate preferred diagnostic techniques are unclear, as EBV DNA is often detected in patients without neurological symptoms (Volpi, 2004).

CYTOMEGALOVIRUS

Like EBV, cytomegalovirus (CMV) is a common herpes virus, with infection rates ranging from 40–100% of the population, depending on geographic location. CMV infection occurs in a broad demographic age group. In addition to producing a syndrome similar to EBV mononucleosis, CMV may also cause hepatitis, retinitis, colitis, and pneumonitis. CNS involvement occurs most commonly in the immunocompromised host, particularly in HIV patients and solid-organ transplant recipients. Late-onset disease has also been described following allogeneic stem-cell transplant (Reddy et al., 2010). CMV can cause encephalitis and has been implicated as a cause of depression and dementia in these populations. Diagnosis is most accurately made by PCR testing for viral DNA in the CSF. Treatment with ganciclovir or valganciclovir is preferred, with foscarnet reserved for resistant cases due to its toxicity (Griffiths, 2004). Antidepressant therapy may be needed if the patient develops a post-viral mood disorder.

VARICELLA ZOSTER VIRUS

Varicella zoster virus is the infectious agent that causes chickenpox (primary infection) and herpes zoster (HZ; reactivated virus). Prior to vaccine introduction in 1995, VZV was the most common etiological agent associated with meningitis, encephalitis, and myelitis. VZV continues to be associated with CNS disease despite an overall decrease in incidence. Manifestations in the post-vaccination era include encephalitis, meningitis, and ADEM. Meningitis is now

the most common presentation in younger immunocompetent patients, in contrast to pre-vaccination observations that encephalitis was the typical manifestation in children. Encephalitis is now most common in immunocompromised patients or those over age 60, but it can also occur in younger immunocompetent patients (Pahud et al., 2011). Psychiatric symptoms may include depression, anxiety, or personality changes. CSF most commonly shows a lymphocytic predominance. Imaging is normal in 80% of patients, though some demonstrate diffuse meningeal enhancement. Occasionally, VZV may mimic HSV on imaging, showing abnormal enhancement in the temporal lobes. Classic HZ rash appears to be less commonly seen in recent cases. Six cases of vaccine-associated VZV CNS disease have also been reported in the literature.

Post-herpetic neuralgia, a chronic neuropathic pain that can develop following HZ, can substantially impact sleep and mood. First-line treatments include antidepressant medications such as selective norepinephrine reuptake inhibitors (SNRIs) or tricyclic antidepressants (TCAs), calcium channel α -2- δ ligands like pregabalin or gabapentin, and topical lidocaine (Dworkin et al., 2012).

PROGRESSIVE MULTIFOCAL LEUKOENCEPHALOPATHY

Progressive multifocal leukoencephalopathy (PML) is an often-fatal demyelinating disease of the CNS usually affecting immunosuppressed patients and caused by the John Cunningham (JC) polyomavirus. It is seen in patients with HIV infection or lymphoid malignancies, transplant recipients, and in the context of treatment with monoclonal antibodies. Occasional cases have been reported in patients without overt immunosuppressive risk factors. Classically, clinical presentation varies with disease location and may include muscle weakness, sensory deficit, cognitive dysfunction, aphasia, and occasionally seizures. Multiple lesions are typically detected in the subcortical white matter or cerebral peduncles on CT scan or MRI, and are usually without evidence of edema or mass effect. Lesions may also be seen in the basal ganglia or thalamus. Diagnosis is established by detection of JC virus DNA in CSF via PCR or detection of viral DNA or proteins on brain biopsy sample via *in situ* hybridization or immunohistochemistry. There is currently no specific antiviral medication for PML, and treatment is typically aimed at restoration of host immune defense. Interestingly, mirtazepine is being studied as a possible treatment because the JC virus has been found to enter cultured cells via the 5HT-2a receptor (Tan & Korolnik, 2010). Though still considered a life-threatening disease, positive prognostic factors in PML include a higher CD4+ T-cell count, and contrast enhancement on imaging have been associated with longer-term survival.

PML has also been described in the setting of immune reconstitution inflammatory syndrome (IRIS) following the initiation of therapy for HIV, and this may account for up to one-fourth of PML cases in HIV patients. In addition to PML, JC virus may also cause meningitis or encephalopathy.

RABIES

Rabies is a viral infection of mammals (rarely) transmitted to humans by bite. Bat-variant rabies strains have replaced carnivore-associated strains as the predominant cause of human rabies in the United States (Romero & Newland, 2003). Initial symptoms are nonspecific and include generalized anxiety, fever, melancholia, hyperesthesia, and abnormal sensations at the site of inoculation (e.g., pain, burning, cold, and pruritis). The neurological phase may present as an episodic encephalopathic form (furious rabies), involving agitation, hallucinations, and hydrophobia (an aversion to swallowing liquids secondary to the spasmodic contractions of the muscles of swallowing and respiration, resulting in pain and aspiration). Alternatively, patients may experience a paralytic (dumb rabies) phase, marked by ascending paralysis. The final phase in either case involves coma, usually two weeks after the onset of neurological symptoms, progressing to cardiorespiratory failure and death. Diagnosis is most reliable via either PCR detection from saliva or brain biopsy. However, if a potentially infected animal bites a person, the rabies vaccine should be given as soon as possible, as outcome is correlated with length of time to inoculation (Centers for Disease Control and Prevention, 1998). To date, there have been three reported cases of individuals' surviving symptomatic rabies without receiving the vaccine, though all suffered severe neurological injury. All survivors were treated with the Milwaukee Protocol, which involves placing patients in a medically induced coma and treating with ribavirin and amantadine (Hunter et al., 2010).

VIRAL MENINGITIS

Enteroviruses, mumps, and lymphocytic choriomeningitis primarily affect the meninges. Eighty percent of identifiable viral meningitis is caused by the enteroviruses. The clinical syndrome of viral, or aseptic meningitis includes headache, fever, nuchal rigidity, malaise, drowsiness, nausea, and photophobia. Typically, the CSF shows pleocytosis, elevated protein, and no evidence of an organism. PCR has become the gold standard for diagnosing viral meningitis. Treatment is generally supportive, though antiviral agents are paramount in the treatment of herpes meningitis. Correct early diagnosis is critical to a successful outcome (Deresiewicz et al., 1997).

PARASITIC INFECTIONS

NEUROCYSTICERCOSIS

The larvae (cysticerci) of the tapeworm *Taenia solium* cause an infection known as *cysticercosis*, which may progress to *neurocysticercosis* (NCC). NCC is the most frequent and widely disseminated human neuroparasitosis. It is particularly common in Latin America, Africa, and Asia, but endemic areas exist throughout the world. In the United States, NCC is reported in immigrants from and travelers to endemic areas. The

American Southwest has seen a dramatic increase in reported cases since the mid-1970s. Humans acquire intestinal taeniasis (the tapeworm) by eating uncooked or undercooked pork infected with cysticerci, but only acquire cysticercosis by ingesting the eggs of *T. solium*. Contamination of food with the eggs of *T. solium* may occur indirectly via handling of the food by an infected person (Schneider et al., 2002). Hatched embryos penetrate the intestinal mucosa and enter the circulatory system where they are distributed to extra-enteric sites as cysticerci. In humans, the cysticerci locate primarily in skeletal muscles, but the recognition of disease usually occurs after CNS involvement.

The variable, nonspecific clinical spectrum is determined in part by the number of cysticerci, the location in the CNS (parenchymal, ventricular, subarachnoid, spinal), and the intensity of the host inflammatory response. The initial immune response to the cysticerci is minimal, which explains the potentially long asymptomatic latency period after infection. The inflammatory response is intensified when the cysticercus dies and releases a large number of antigens. The most frequent manifestation of NCC is seizures, commonly of the partial-complex variety, reported as the initial symptom in 66% of patients. Encephalitis, meningitis, and altered mental status are also commonly seen at presentation (Wallin et al., 2004). Dementia, other cognitive dysfunction, and a broad spectrum of other psychiatric manifestations, including depression and psychosis, have also been reported, but the literature consists of largely retrospective reports by non-psychiatric physicians. One study suggested that patients admitted to a chronic inpatient psychiatry unit in Venezuela, particularly those with mental retardation, were more likely to have a positive serology for *T. solium* than were healthy controls in the community (Meza et al., 2005).

Diagnosis is difficult because of the varied and nonspecific clinical presentation, and the only definitive method is biopsy. The diagnosis is often only considered after failed treatment. Diagnosis hinges on a high index of suspicion in a patient with new psychopathology and a history of exposure from an endemic area. MRI is superior to CT in demonstrating some cysticerci, small calcifications, and the inflammatory response. The cysticerci have a characteristic appearance of multiple cystic lesions with a denser central spot containing the scolex, though involvement of the subarachnoid or ventricular spaces may reveal only inflammation or calcification. The preferred test to detect antibodies is the enzyme-linked immunoelectrotransfer blot (EITB), which is more sensitive and specific than ELISA.

Treatment depends on symptoms, location of the cysticerci, stage of development, involution of the cysticerci, and inflammatory response. Surgery, antiepileptic drugs, glucocorticosteroids, and antihelmintic therapy are used with varying degrees of overlap. Although antihelmintics were once considered a key component of treatment, some have questioned their efficacy and potential propensity for side effects like edema and intracranial hypertension. Nonetheless, many experts continue to recommend their use in specific situations (Abba et al., 2010).

MALARIA

Malaria is the leading cause of morbidity in young children and pregnant women worldwide, and the incidence is increasing due to social and environmental changes as well as drug resistance. Co-infection with HIV is a risk factor for developing severe or complicated malaria. In the United States, cases occur in immigrants from and travelers to malarious areas. *Plasmodium* species are transmitted to humans by the bites of female mosquitoes. Erythrocytes infected with late maturing *Plasmodium* disappear from the peripheral blood and localize in the deep vascular beds of vital organs, in a process known as *sequestration*. In the life cycle, merozoites are released from erythrocytes, causing the paroxysms of chills and fever (in excess of 41°C [105°F]) typical of malaria. During the febrile stage, the patient may become encephalopathic. A relapsing pattern of high fever and chills with confusion points towards a diagnosis of malaria.

P. falciparum malaria may lead to a catastrophic complication known as *cerebral malaria*, thought to result from obstruction of the brain microvasculature due to sequestration of parasitized red blood cells. Cerebral malaria may present with disorientation, mild stupor, or even psychosis, within 24 hours of the first symptoms. It rapidly progresses to seizures and coma, sometimes with cranial nerve dysfunction and decerebrate posturing. The severity of the symptoms is correlated with the amount of sequestered parasitized red blood cells in the CNS (Turner, 1997). Definitive diagnosis of cerebral malaria is made by the identification of *Plasmodium* on the blood smear. In the setting of unarousable consciousness, neuroimaging may suggest cerebral edema.

Plasmodium is particularly adept at developing resistance to chemotherapy. Even treated individuals or those on prophylaxis may have active malaria. Antimalarial drugs, particularly mefloquine, also commonly cause psychiatric side effects, as outlined later in this chapter. Following treatment for cerebral malaria, neurological symptoms may resolve slowly, quickly, or not at all, and residual symptoms are described in up to 10% of immunocompetent patients. An entity known as *post-malaria neurological syndrome* has also been described in *P. falciparum* malaria, following or in the absence of cerebral malaria, occurring weeks to months after resolution of acute infection and involving seizures, cognitive dysfunction, and psychiatric manifestations (Walker et al., 2006). Proposed mechanisms for the syndrome include a delayed phenomenon similar to that occurring in cerebral malaria with sequestration of parasitized red blood cells, an immunological response, or perhaps a reaction to mefloquine that has been used earlier in the course for treatment in the majority of cases. Most patients recover from post-malaria neurological syndrome within ten days without specific treatment (Nguyen et al., 1996).

TOXOPLASMOSIS

Toxoplasmosis is caused by *Toxoplasma gondii*, a parasite affecting many mammals (especially cats) and some birds (Yermakov et al., 1982). Many healthy adults carry this

protozoan asymptotically, but immunocompromised individuals can develop serious disease. CNS toxoplasmosis is especially common in patients with AIDS, and may cause diffuse encephalitis or multiple brain abscesses. Toxoplasmosis is in fact the most frequent cause of CNS mass lesions in AIDS. Symptoms are nonspecific and reflect the location and extent of CNS involvement. Cognitive dysfunction, lethargy, confusion, and visual hallucinations are all common. Anxiety and paranoia may progress to delirium and obtundation. MRI is particularly valuable in the diagnosis of CNS toxoplasmosis, with ring-enhancing lesions in the basal ganglia or cerebrum very suggestive of the disease, though transplant recipients may show a variable enhancement pattern as compared to AIDS patients. While brain biopsy provides definitive diagnosis, most clinicians will initiate treatment in patients with suggestive neuroradiological findings and positive serology, reserving biopsy for those who fail to improve with treatment (Iacoangeli et al., 1994). Treatment of active CNS toxoplasmosis involves pyrimethamine, sulfadiazine, and folinic acid, followed by chronic maintenance treatment with any of several medical regimens (Walker & Zunt, 2005).

TRYPANOSOMIASIS

The family of protozoa Trypanosomatidae causes two clinically different syndromes: African trypanosomiasis (sleeping sickness) and American trypanosomiasis (Chagas' disease). African trypanosomiasis occurs in a number of sub-Saharan African countries. Few cases have been reported outside of tropical Africa, though numbers appear to be increasing in the Western hemisphere as a result of travel and migration. The disease is caused by a subspecies of *Trypanosoma brucei* and is transmitted to humans and animals by the bite of the blood-sucking tsetse fly. Early stages of the disease include headache, fever, malaise, weight loss, arthralgias, and myalgias, sometimes accompanied by a chancre at the site of inoculation. CNS symptoms begin in the second stage and may include excessive sleeping or sleep-phase reversal, abnormal gait or speech, and alterations in mood, including depression and mania. Later stages may include seizures or coma. Diagnosis relies on identification of the protozoa. CT is usually normal, but MRI may show hypointensity in the basal ganglia. Traditionally, melarsoprol, which itself is fatal in some cases, was the only treatment available for CNS involvement, though newer evidence suggests that eflornithine and nifurtimox combined with eflornithine may be safer and effective (Lutje et al., 2010).

American trypanosomiasis, or Chagas' disease, is caused by *Trypanosoma cruzi*. *T. cruzi* is carried by Triatomine bugs, commonly called "kissing bugs" or "assassin bugs," which live in rural areas of Central and South America. Years of exposure are required to acquire the infection. CNS involvement is rare in the acute phase (seen mostly in children under two) and somewhat controversial in the chronic phase, though chronic Chagas' disease is thought to be an independent risk factor for vascular ischemic events (Carod-Artal, 2007). CNS involvement is most commonly

seen during reactivation of disease in immunocompromised hosts, where it can involve meningoencephalitis and seizures. On CT scan of the brain, the lesions are indistinguishable from toxoplasmosis, and the organism is not seen on blood smear in chronic Chagas' disease, making diagnosis difficult. Two diagnostic tests based on different antigens or techniques are frequently used in combination (Bern, 2011). Treatment is recommended for chronic disease in patients under 50, but is frequently ineffective and carries significant risk of side effects.

SCHISTOSOMIASIS

Schistosomiasis is an infection caused by blood flukes (trematodes) of the genus *Schistosoma* and affecting 200 million people in 74 countries. Humans can be infected when skin comes in contact with the infective larval stage, usually while swimming in contaminated waters. Adult worms copulate and migrate to the intestines (*S. japonicum*, *S. mansoni*) or bladder (*S. haematobium*). Most infections are asymptomatic. CNS involvement is rare, though it may be more common than previously realized, affecting up to 4% of patients.

Psychiatric symptoms may occur at two distinct phases of infection. Acute toxemic schistosomiasis, seen in previously unexposed people such as travelers, produces symptoms of headache, malaise, and muscle aches several weeks after exposure and can progress to toxemia and associated encephalopathy. In chronically infected individuals, eggs deposited in ectopic locations, such as the CNS, induce a granulomatous reaction. The smaller eggs of *S. japonicum* may travel all the way to the brain, stimulating granuloma formation and leading to symptoms of increased intracranial pressure (e.g., headache, visual changes, nausea, and papilledema), seizures, and cranial nerve abnormalities. Conversely, the larger eggs of *S. mansoni* and *S. haematobium* are retained in the lower spinal cord, causing myelopathy (Ross et al., 2011). Diagnosis is typically based on clinical symptoms and exposure history, coupled with neuroimaging and the detection of schistosomal eggs in the urine or feces. Biopsy or necropsy demonstrating eggs and granulomas are the only definitive diagnostic methods. Drug treatment involving praziquantel and corticosteroids is effective except for rare cases requiring surgery.

TRICHINOSIS

Trichinosis is a worldwide disease caused by the ingestion of larvae encysted in the muscles of infected animals. In the United States and Europe, these parasites are most commonly found in pork, but 150 species of mammals from all latitudes may acquire the infection. Outbreaks of trichinosis are associated with ethnic groups that prefer raw or undercooked pork or horsemeat, or wild animals such as polar bear or walrus. Typical symptoms of infection include a febrile illness with myalgias and diarrhea. Ten to 24% of symptomatic cases have CNS involvement, usually developing three to four weeks after infection, and including headache,

delirium, insomnia, meningeal signs, and seizures (Taratuto & Venturiello, 1997). Some have suggested that there is a chronic form of trichinosis infection, involving persistent formication, numbness, and diaphoresis, but prospective studies have been unresponsive.

In patients with CNS involvement, CT scan shows multiple small, hypodense lesions with ring-like enhancement with contrast (Ellrodt et al., 1987). Diagnosis in humans is frequently based on clinical symptoms, known exposure, and eosinophilia, though ELISA is the most commonly used serodiagnostic method (Gottstein et al., 2009). A muscle biopsy, generally of the deltoid, demonstrating larvae is more definitive though invasive, and sensitivity is dependent on the size of the biopsy sampled. In the early stage of muscle invasion, it can be difficult to differentiate larvae from muscle fibers, though basophilic transformation of muscle cells may be apparent. Treatment in severe cases involves glucocorticosteroids for the inflammation and albendazole or mebendazole to kill the *Trichinella*. A pilot program for trichinella-free pig production has been developed in the United States, resulting in declining rates and changes in recommendations for cooking pork.

AMOEBIASIS

Several amoebas cause human disease, and all are ubiquitous in the environment worldwide. While CNS infection with amoebas remains uncommon in America, it is increasing, due largely to travel and immigration, though cases have also originated from bodies of water in the United States. Primary amoebic meningoencephalitis is produced by *Naegleria fowleri* in healthy, young individuals engaged in freshwater aquatic activities, particularly those in which water may forcibly enter the nasal passages, during the summer months. Its course is acute and fulminant, with headache, nausea, confusion, and a stiff neck, followed by coma and death in days. Treatment involves aggressive amphotericin therapy using intravenous and intrathecal routes, and swift diagnosis via visualization of the amoeba in the CSF is crucial, given that only ten survivors have been reported in the literature (Tuppeny, 2011). Clinical suspicion should be high in those presenting with fulminant meningitis and recent exposure to warm, inland waters.

Granulomatous amoebic encephalitis, caused by *Balamuthia mandrillaris* and some species of *Acanthamoeba*, usually occurs in debilitated, immunosuppressed (especially in AIDS), or malnourished individuals. The course is more chronic, with personality changes, confusion, and irritability, eventually progressing to seizures and death (Martinez & Visvesvara, 1997). Recent development of a multiplex real-time PCR test allows for the rapid detection of all free-living amoebae in a sample, thus potentially enhancing speed of diagnosis. Treatment remains empirical with poor penetration of the blood-brain barrier, though successful treatment following early diagnosis has been reported using fluconazole and sulfadiazine as well as a combination of trimethoprim-sulfamethoxazole, rifampin, and ketoconazole (Visvesvara, 2010).

FUNGAL INFECTIONS

CRYPTOCOCCOSIS

Cryptococcosis is an infection caused by *Cryptococcus* species, a pathogen distributed worldwide and found mainly in bird excreta and soil. *Cryptococcus* may act as a solo pathogen, but in up to 85% of cases, it is associated with another illness, and largely affects immunocompromised patients. In America, rates in AIDS patients have declined with the advent of highly active anti-retroviral therapy (HAART), though IRIS continues to account for many cases. The disease also affects up to 5% of solid-organ transplant recipients, and rates in developing countries remain high, with mortality in 50% of patients within three months (Cannon et al., 2009). The portal of entry is usually the respiratory tract, from which hematogenous spread occurs, though at the time of presentation pulmonary infection may not be evident. This pathogen has a predilection for the subarachnoid space, and *Cryptococcus* is the most common form of fungal meningitis (Sabetta & Andriole, 1985). Illness is typically insidious in onset and slowly progressive. Headache is present in up to 75% of the cases, and other findings include cerebellar signs, cranial nerve deficits, and motor deficits. Besides meningitis, chronic granulomas or cryptococcomas may occur in the parenchyma, and deep cerebral infarcts of the basal ganglia and thalamus may result from small-vessel arteritis.

Psychiatric presentations are broad in scope, ranging from irritability to mania to psychosis, all of which may be present prior to meningeal signs. Periods of remission and relapse are common in undiagnosed and untreated patients. The mean time from symptoms to diagnosis is six weeks. Imaging may be useful if it reveals clusters of pseudocysts in the basal ganglia and thalami, a fairly specific finding. Serological testing of patients with cryptococcal meningoencephalitis reveals cryptococcal antigen in serum, CSF, or both, 90% of the time, though serum testing is less specific in non-AIDS patients. Isolation of the fungi provides definitive diagnosis, and India ink staining is useful in highlighting the organism. Treatment is typically a prolonged course of an antifungal agent, and relapses are frequent. Permanent sequelae include dementia and personality changes (Mitchell et al., 1995). In HIV-negative patients, changes in diffusion tensor imaging in vulnerable brain regions have been shown to correspond to worse cognitive performance (Lu et al., 2011).

CANDIDIASIS

Candida causes limited local infections (cutaneous, vaginal, oral) in immunocompetent hosts, especially after broad-spectrum antibiotics. Disseminated candidiasis occurs only in the immunocompromised host. Psychiatric symptoms occur from the toxic effects of fungemia or from direct invasion of the CNS. Meningitis represents the most common form of CNS involvement, though microabscesses, macroabscesses, and vasculitis are also possible. Meningitis typically develops over several days to weeks, though an acute form resembling bacterial meningitis has been described, and *C. glabrata* may

cause a more insidious form evolving over weeks to months (Rauchway et al., 2010). Symptoms are nonspecific and include confusion, drowsiness, lethargy, and headache. Most diagnoses of CNS candidiasis are made at autopsy. However, CNS symptoms, radiographic changes (hydrocephalus, microabscesses) and isolation of *Candida* from a non-CNS site in an immunocompromised patient should lead to a presumptive diagnosis and prompt treatment with appropriate antifungal agents.

Candida infection has been alleged to be the cause of a wide array of somatic and psychological symptoms, comprising an entity known as *candidiasis hypersensitivity syndrome*. There is no scientific support for this theory or its associated treatments.

OTHER FUNGAL INFECTIONS

The frequency of fungal infection has steadily increased over the last three decades, primarily because of the HIV/AIDS epidemic, the availability of immunosuppressant drugs, and the increasing number of solid-organ transplantations. An aging population, increasing cancer rates, intravenous catheters, use of implantable medical devices, hyperalimentation, illicit drug use, the development of burn units, and the emergence of antifungal-resistant species have all also contributed to the increased frequency of fungal infection (Raman Sharma, 2010). For further details about other fungal infections, please see Table 60.2.

PRION DISEASES

Prion diseases are neurodegenerative diseases that have a broad spectrum of neuropsychiatric clinical manifestations. Human prion diseases include Creutzfeldt-Jakob disease (CJD, or “mad cow disease”), variant Creutzfeldt-Jakob disease (vCJD, also known as “new variant CJD”), Gerstmann-Sträussler-Scheinker syndrome (GSS), kuru, and fatal familial insomnia (FFI). Of these, CJD is the most common. All of the prion diseases are characteristically progressive and uniformly fatal. The incubation period can be months to years. The transmissible pathogen is a proteinaceous infectious particle (PrP) that does not have the structure of a virus, fails to produce an immune response, and is devoid of nucleic acid, and so is resistant to ribonucleic acid (RNA) and DNA destroying enzymes.

CJD can occur sporadically but may also be inherited or transmitted by intracerebral electrodes, dural grafts, corneal transplants, and human-derived growth hormone. It classically presents with confusion and memory loss progressing to a severe cortical dementia, usually accompanied by ataxia and myoclonus. Other symptoms, including rigidity, tremor, alien hand syndrome, and sensory disturbances have also been reported. The EEG pattern is distinctive, showing bilateral periodic discharges of triphasic or sharp wave bursts at 0.5–2Hz. Similar EEG changes can be seen in patients taking lithium, but will remit after discontinuation of the offending agent (Finelli, 1992). Routine CSF

Table 60.2 FUNGAL CENTRAL NERVOUS SYSTEM INFECTIONS

FUNGUS	WHERE IT LIVES	GEOGRAPHY	ROUTE OF TRANSMISSION	WHO IS AFFECTED?	CLINICAL FORMS	CNS SYMPTOMS	DIAGNOSIS	IMAGING	TREATMENT
Coccidioidomycosis	Soil	Southwest U.S., Mexico, Argentina, Paraguay	Inhalation; CNS involvement 1–3 months after initial infection, with insidious and chronic course ¹	Diabetics, Pregnant women, Immunocompromised patients	Meningitis, hydrocephalus, cerebral granulomas, abscesses	Confusion, restlessness, hallucinations, lethargy, and transient neurological signs ²	Neuro-imaging and serological testing; culturing of the CSF; biopsy of infected tissue (usually skin nodules) is definitive	Meningeal enhancement, hydrocephalus	Oral fluconazole or itraconazole; amphotericin B for severe cases ³
Aspergillosis	Soil, decaying vegetation	Worldwide	Infection of lung or GI tract; Extension to CNS via direct invasion from sinuses, hematogenous spread, or embolization	Immunocompromised patients	Meningitis, mycotic aneurysms, cerebritis, abscesses or infarcts	Confusion, headache, lethargy, focal neurological signs, seizures	Brain biopsy ⁴ ; rarely isolated on CSF cultures	Localized edema; hemorrhagic lesions; Aspergillomas as low-density lesions in the cerebral hemisphere, basal ganglia, or thalami with little to no mass effect and no contrast enhancement on CT, often more numerous on MRI ⁵	Voriconazole (response rates 35%); Amphotericin B
Histoplasmosis	Soil contaminated with bird or bat excreta	Worldwide; central and Southeastern U.S.	Inhalation	Immunocompromised; two peaks of distribution—infancy and 5th and 6th decades	Chronic meningitis; parenchymal brain lesions; stroke due to emboli; hydrocephalus; and diffuse encephalitis ³	Extreme nervousness, irritability; lethargy; coma ⁶	CSF can show pleocytosis with an elevated protein; most cultures are negative, though <i>Histoplasma</i> antigen may be detected in the serum, CSF, or urine; Brain biopsy in some cases	Usually normal	LF Amphotericin B for 4–6 weeks +Itraconazole for 1 year
Blastomycosis	Soil	Coincident with Histoplasmosis; central U.S.; parts of India and Africa	Inhalation	Immuno-compromised or –competent	Meningitis, abscesses	Headache, focal neurological deficit, confusion, seizures	Detection of antigen in CSF; Brain biopsy	Dural-based granulomatous lesions; diffuse meningeal enhancement	LF Amphotericin B for 4–6 weeks +Itraconazole for 1 year
Mucormycosis	Common bread and fruit molds	Worldwide	Inhalation; rapid dissemination by attacking contiguous structures; Isolated CNS involvement can occur rarely ⁷	Diabetic ketoacidosis, neutropenia, transplant patients, IV drug use ⁸	Subdural abscesses; cavernous and occasionally sagittal sinus thrombosis; rarely meningitis ⁹	Encephalopathy, facial pain, headache, ophthalmoplegia,	Biopsy, demonstration of mold in tissue	Various patterns; most commonly affects central gray matter	Aggressive debridement; LF Amphotericin B

and other laboratory tests are almost always normal in CJD, but immunoassay detection of fragments 14-3-3, a normal brain protein, or elevated neuron-specific enolase is particularly useful in making the diagnosis. MRI classically shows hyperintensity in the basal ganglia or the so-called cortical ribbon. Cortical gray matter classically displays “spongiform degeneration” or vacuolation, though biopsy is not commonly performed, and most pathological diagnoses are made at autopsy (Brown & Mastrianni, 2010).

Compared to CJD, vCJD more commonly presents with psychiatric symptoms, particularly apathy and depression. Additionally, confusion, agitation, delusions, and hallucinations may be present. As a group, vCJD patients are younger (average age of 27 vs. 60), lack typical EEG findings, and experience a longer average time to death (14 months vs. 4 months) (Haywood, 1997). Variant CJD has been linked to the consumption of beef contaminated with bovine spongiform encephalopathy (BSE).

Kuru is the rarest of the prion diseases, with no new cases described in the past several decades. Kuru occurs only in Papua, New Guinea, and is spread by cannibalistic consumption of dead relatives during mourning rituals. GSS, a familial disease, commonly involves progressive cerebellar ataxia, corticospinal tract signs, dysarthria, nystagmus, and mild dementia. EEG shows diffuse slowing, and the duration of disease is typically much longer than with CJD. Finally, FFI is a genetically determined prion disease with a mutation in codon 178 of the PrP gene in which patients develop progressive insomnia with loss of the normal circadian sleep-activity pattern, which may manifest as a dreamlike confusional state during waking hours. Mental status and behavioral changes include inattention, hallucinations, confusion, and impaired concentration and memory, but overt dementia is rare. EEG shows diffuse slowing, but MRI is usually normal.

HARMFUL ALGAL BLOOM TOXINS

Many harmful algal bloom (HAB) toxins, produced by microalgae, are highly potent neurotoxins. These toxins can lead to massive fish kills, deaths of marine birds and other wildlife, and seafood contamination. Amnesic shellfish poisoning (ASP) involves the release of the toxin domoic acid during red tides, and human ingestion of contaminated shellfish can lead to headaches, memory loss, hemiparesis, seizures, and death (Friedman & Levin, 2005). The hallmark of the illness is a sustained anterograde memory deficit, possibly due to damage to the amygdala and hippocampus by the toxin.

Ciguatera fish poisoning, caused by the consumption of coral reef fish contaminated with ciguatera toxin, is the most frequently reported food-poisoning illness caused by a marine toxin. Acute gastrointestinal symptoms are followed by fatigue, muscle weakness, hot–cold temperature reversal, and sustained memory and mood disturbances. Hallucinations are also frequently reported.

Pfiesteria piscicida, a dinoflagellate, can release a toxin capable of killing large numbers of fish. It occurs along the eastern coast of the United States from the Gulf of Mexico to

Delaware Bay. An entity known as *possible estuary associated syndrome* (PEAS) is associated with exposure to *Pfiesteria*, though the specific toxin has not been identified, nor has it been confirmed that exposure leads to human illness. There have been reports of toxic effects in humans in Maryland and North Carolina, primarily in watermen exposed to large-scale fish kills and in researchers who cultured *Pfiesteria*. Prominent symptoms have included headache, skin lesions, burning sensation on contact with water, as well as reversible memory impairment improving months after cessation of exposure (Grattan et al., 1998).

ANTIMICROBIALS

Antimicrobial medications may cause psychiatric symptoms through a variety of mechanisms. The fluoroquinolones, particularly ciprofloxacin, have been commonly implicated as a cause of delirium. Despite some suggestion that this association has been exaggerated, this class of medications is noted to have a particular affinity for gamma-aminobutyric acid (GABA) and N-methyl D-aspartate (NMDA) receptors. It has been suggested that the mechanism for quinolone-associated delirium may be non-convulsive status epilepticus (NCSE) because of the known ability to lower seizure threshold and reports of abnormal EEGs in patients receiving the medications (Kiangkitiwan et al., 2008). Risk factors for development of neuropsychiatric side effects with quinolones appear to include impaired renal clearance, underlying CNS disease, and increased CNS penetrance due to inflammatory states. Physicians should also be aware of the potential for decreased metabolism of quinolones with certain cytochrome p450 alleles or due to p450-related interactions.

Delirium has also been associated with procaine penicillin, antimalarial drugs, and the antituberculous drug cycloserine. In evaluating the association between delirium and recent initiation of antimicrobial medication, psychiatrists should recall that the Latin dictum *Post hoc ergo propter hoc* (“after this, therefore because of this”) does not always apply. Delirium may be driven instead by the underlying infection, with the temporal association of antibiotic therapy serving as a red herring.

Reports of secondary mania caused by antimicrobial drugs have increased significantly in the past fifteen years, presumably due to the increase in antibiotic prescriptions around the world, as well as the introduction of new classes of antibiotics. Clarithromycin and ciprofloxacin are the medications most commonly implicated (Abouesh et al., 2002). As with all cases of secondary mania, long-term prophylactic treatment may not be required, and overlap with delirium is unclear.

The antimalarial medication mefloquine (structurally related to fluoroquinolones) has been implicated in causing a variety of neuropsychiatric symptoms, including sleep disturbances, anxiety, depression, and frank psychosis. There is some suggestion that females and patients with low body mass index (BMI) are at the highest risk for experiencing adverse effects. Mechanisms may include interference with calcium

homeostasis, acetylcholinesterase inhibition, and enhancement of striatal GABA (Toovey, 2009).

Many medications used to treat infections can prolong the QTc interval and therefore increase the risk of *torsades de pointes*, particularly if used in combination with psychiatric medications that also prolong the QTc interval (antipsychotics, TCAs, some SSRIs). These medications include chloroquine, macrolides (e.g., clarithromycin, erythromycin), pentamidine, and quinolones (Abramson et al., 2008). Macrolides, antifungal agents, chloramphenicol, and norfloxacin may additionally lead to QTc prolongation and predispose to ventricular arrhythmias by inhibiting the metabolism of other QTc-prolonging agents via their action on CYP3A4.

Linezolid, an oxazolidinone antibiotic widely used in hospitals for treatment of methicillin-resistant *Staphylococcus aureus* (MRSA) and vancomycin-resistant *Enterococcus* (VRE), is a mild, reversible, non-selective monoamine oxidase inhibitor (MAOI). If used in combination with serotonergic agents such as SSRIs, there is a small risk of precipitating serotonin syndrome. The standard recommendation is for a two-week washout period for patients taking serotonin agonists prior to initiating treatment with linezolid, but this may not always be prudent, given the potential seriousness of infections requiring linezolid. Most cases of toxicity occur within the first three weeks of treatment. Physicians should conduct a careful risk analysis to determine the relative danger of stopping as opposed to continuing serotonergic agents during linezolid therapy, particularly in patients with tenuous or potentially lethal mental illness (Quinn & Stern, 2009).

Amphotericin B, an antifungal agent, is at times associated with delirium and leukoencephalopathy. Voriconazole, an antifungal agent used for aspergillosis, can commonly (2–16%) cause hallucinations, especially when given intravenously. These are mostly visual and sometimes auditory. Visual hallucinations worsened when the patients' eyes closed to try to sleep, but the patient remained oriented and able to recognize the sensation as unreal (Zonios et al., 2008).

CLINICAL PEARLS

- In the past ten years, rates of syphilis have begun to climb again, owing to a variety of factors such as increasingly unsafe sex practices, particularly among men who have sex with men (MSM), in the wake of available antiretroviral therapy for HIV. HIV-positive patients infected with syphilis are more likely to develop neurosyphilis (Chahine, 2011).
- Secondary syphilis resolves without treatment but may recur in the next few years. If untreated, one-third of individuals develop later sequelae.
- A recent retrospective review of neurosyphilis in the modern age suggests that a positive sucking reflex, Argyll-Robertson pupils that accommodate but do not react to light, and hyperreflexia are the most common signs (Zheng et al., 2011).
- In late neurosyphilis, psychiatric symptoms frequently do not remit with antibiotic treatment.
- The rash of Rocky Mountain spotted fever is notable in being one of the few diffuse rashes to involve the palms and soles (another being the rash of secondary syphilis).
- Serological testing in Lyme disease remains unreliable in many cases, with false positives occurring in the setting of other infections and true-positive tests only indicating a history of LD at some time in the past.
- It is vital to educate patients that, although some physicians advocate long-term antibiotic treatment for post-treatment LD, all four randomized controlled trials of prolonged antimicrobial treatment have failed to demonstrate any lasting improvement, and many other open-label trials have failed to separate cases of well-documented LD from those without objective evidence (Halperin, 2008). Furthermore, such treatment carries significant risk in the form of complications.
- Symptom exacerbations of PANDAS are thought to be sudden and dramatic as opposed to the more gradual waxing and waning pattern of childhood-onset OCD.
- A history of TB is elicited in only 10% of patients with tubercular meningitis at the time of presentation, and the tuberculin skin test may be positive in fewer than 50% of patients (Rock, 2008).
- Herpes simplex virus (HSV) encephalitis differs from other viral meningoencephalitis in its greater likelihood to cause unilateral and focal findings and its predilection for temporoparietal involvement.
- PCR detection of herpes simplex virus DNA in the CSF has become the diagnostic method of choice, though it may be negative rarely in very early cases. It is widely available, and the time from LP to results is generally 24–72 hours.
- The clinical symptoms of acute disseminated encephalomyelitis (ADEM), a cell-mediated immune reaction to myelin basic protein occurring in the wake of many viruses, commonly include encephalopathy, fever, seizures, and meningismus. Changes in mood, as well as psychotic symptoms such as delusions and hallucinations, have also been reported in the absence of obviously altered sensorium (Krishnakumar, 2008).
- The most frequent manifestation of neurocysticercosis is seizures, commonly of the partial-complex variety, reported as the initial symptom in 66% of patients. Encephalitis, meningitis, and altered mental status are also commonly seen at presentation (Wallin, 2004).
- *Plasmodium falciparum* malaria may lead to a catastrophic complication known as *cerebral malaria*, thought to result from obstruction of the brain microvasculature due to sequestration of parasitized red blood cells.

- *Cryptococcus* is the most common form of fungal meningitis and has a predilection for the subarachnoid space (Sabetta & Andriole, 1985). Psychiatric presentations are broad in scope, ranging from irritability to mania to psychosis, all of which may be present prior to meningeal signs.
- Voriconazole, an antifungal agent used for aspergillosis, can commonly (2–16%) cause hallucinations.

RHEUMATIC DISEASE, AUTOIMMUNE DISORDERS, AND ALLERGY

Sherese Ali

INTRODUCTION

Rheumatological disorders are grouped together, as they share an autoimmune basis and typically affect the skin, musculoskeletal system, and connective tissues. Although rheumatological disorders have specific antigens towards the musculoskeletal system, many of them feature multisystem effects, including effects on the central nervous system (CNS). When the CNS becomes affected, the brain effects may manifest as psychiatric symptoms. Secondly, as rheumatological disorders are chronic medical illnesses, these disorders also have a psychological impact on the patient. Thirdly, many of the medications used to treat rheumatological disorders are associated with side effects and adverse reactions that feature psychiatric symptoms. Thus, the psychiatrist managing a patient with rheumatological disorders may consider the etiology of psychiatric symptoms as (1) a direct biological effect of the underlying illness, (2) an indirect effect in terms of the mental health impact of the chronic illness, or (3) a medication effect. Finally, one may consider an independent psychiatric disorder that happens to be comorbid with a rheumatological disorder.

This chapter will focus on the psychiatric effects associated with the more common rheumatological disorders—systemic lupus erythematosus, rheumatoid arthritis, Sjögren's syndrome, and fibromyalgia—in terms of the first three etiologies of psychiatric symptoms in this patient population. (Autoimmune disorders that primarily affect the neurological system are classified as neurological disorders and are not discussed in this chapter.)

SYSTEMIC LUPUS ERYTHEMATOSUS

Systemic lupus erythematosus (SLE) is an inflammatory disorder that affects multiple systems. Its etiology is unknown, but aberrations in immunological function result in the production of certain antibodies that can result in cell damage, immune complex formation, or an inflammatory response. SLE affects women about nine times more frequently than men. It has been found to be three times more prevalent among blacks than among

whites. The diagnosis of SLE is made by a set of criteria, outlined in Table 61.1, according to the American College of Rheumatology (ACR) in 1982 (Tan, 1982) and revised in 1997 (Hochberg, 1997).

There are situations where the importance of knowing these diagnostic criteria is impressed upon the treating psychiatrist. In the author's experience, it is not uncommon to receive consultation requests on patients who have some symptoms not meeting full criteria for the diagnosis of SLE who are then referred for somatoform disorders or otherwise unexplained medical symptoms. Such patients may have subjective complaints without strong support for a diagnosis of SLE from objective tests. For example, a patient may be complaining of diffuse pain, fatigue, general malaise, and low-grade fever over the course of a few months, with a mild anemia, but otherwise normal investigations, including anti-nuclear antibody (ANA) profile and antibody screen. Such a patient would not have been diagnosed with lupus. When one closely examines the criteria, it is important to note that not all symptoms have to be present at the same time, and there is no one criterion that is absolutely essential for diagnosis (like anhedonia or depressed mood in major depression). There is therefore a risk of missing the diagnosis, particularly when objective tests are normal. In this diagnostic schema, a patient can have psychosis as the first presenting sign of lupus, but until other symptoms present over time, the diagnosis does not declare itself (Munoz-Malaga, 1999; Jghaimi, 2009; Simonin, 2004). Indeed, there is known to be a lag time of some years between the onset of the first symptom and the eventual diagnosis of lupus. Often, the significance of previous non-specific symptoms becomes recognized only in retrospect. In such patients, it may be left to the psychiatrist and/or primary care physician to monitor for new symptoms that might reach the threshold for a diagnosis of SLE. In this scenario, the psychiatrist can screen by periodically applying these diagnostic criteria, applying the SLE Disease Activity Index (Bombardier, 1992), and performing investigations including complete blood count (CBC), antibody screen, ANA profile, and urinalysis: every three to six months, at the onset of a worsening or new symptom, or if the psychiatric symptoms are atypical.

NEUROPSYCHIATRIC SLE

DEFINITION

At first, only seizures or psychosis were listed as neuropsychiatric syndromes associated with lupus (criterion 8) in Box 61.1). These criteria were revised by the ACR in 1999 (ACR Ad Hoc Committee, 1999), and the neurological disorders were expanded from two syndromes (seizures and psychosis) to 19 syndromes that define neuropsychiatric SLE (NPSLE), as shown in Box 61.2.

EPIDEMIOLOGY OF NPSLE

Table 61.1 shows available data on the prevalence of some of the neuropsychiatric syndromes. The exact prevalence of psychiatric symptoms in SLE is not known. Prior to the 1999 revised ACR criteria, there was a broad range of prevalence of 14–75%. After the ACR 1999 revised criteria, five large studies (Ainali, 2001; Sibbit Jr., 2002; Brey, 2002; Sanna, 2003; Hanly, 2004) examined the prevalence of NPSLE among patients with SLE and produced an equally broad range of 37–95%. Among the 19 neuropsychiatric syndromes, cognitive impairment, headache, mood disorder, and cerebrovascular disease were the four most common, in descending order of prevalence. Among the psychiatric syndromes, cognitive disorder, mood disorder, anxiety disorder, and psychosis are thought to be the most common, in descending order of prevalence. Other studies were not uniform in their method of attribution of psychiatric symptoms to the direct biological effect of SLE versus an indirect psychological impact of the illness. It remains a clinical challenge to differentiate primary psychiatric from direct lupus-related etiologies of psychiatric syndromes in NPSLE. Of the four psychiatric syndromes, most studies have focused on lupus psychosis. From these epidemiological studies, lupus psychosis has a prevalence estimate of 8% of SLE patients. Prevalence rates for the remaining syndromes are estimated at less than 1%.

Box 61.1 ACR CRITERIA FOR THE DIAGNOSIS OF SLE

1. Malar rash: Fixed erythema, flat or raised, over the malar eminences
2. Discoid rash: Erythematous circular raised patches with adherent keratotic scaling and follicular plugging; atrophic scarring may occur
3. Photosensitivity: Exposure to ultraviolet light causes rash
- 4 Oral ulcers: Includes oral and nasopharyngeal ulcers, observed by physician
5. Arthritis: Non-erosive arthritis of two or more peripheral joints, with tenderness, swelling, or effusion
6. Serositis: Pleuritis or pericarditis documented by electrocardiogram or rub or evidence of effusion
7. Renal disorder: Proteinuria >0.5 g/d or 3+, or cellular casts
8. Neurological disorder: Seizures or psychosis without other causes
9. Hematological disorder: Hemolytic anemia or leukopenia (<4000/L), or lymphopenia (<1500/L), or thrombocytopenia (<100,000/L) in the absence of offending drugs
10. Immunological disorder: Anti-double stranded DNA antibody (Anti-dsDNA), anti-Smith antigen antibody (anti-Sm)), and/or anti-phospholipid antibody
11. Antinuclear antibodies: An abnormal titer of ANA by immunofluorescence or an equivalent assay at any point in time in the absence of drugs known to induce ANAs

Any combination of 4 or more of 11 criteria, well documented at any time during a patient's history, makes it likely that the patient has SLE (specificity and sensitivity are 95% and 75%, respectively).

**Box 61.2 NINETEEN NPSLE SYNDROMES
ACCORDING TO THE 1999 ACR REVISED
CRITERIA FOR SLE**

Central Nervous System

1. Aseptic meningitis
2. Cerebrovascular disease
3. Demyelination syndrome
4. Headache
5. Movement disorder
6. Myelopathy
7. Seizure disorders
8. Acute confusional state

Peripheral Nervous System

9. Guillain-Barré syndrome
10. Mononeuropathy
11. Myasthenia gravis
12. Cranial neuropathy
13. Plexopathy
14. Polyneuropathy

Autonomic Nervous System

15. Autonomic neuropathy

Psychiatric

16. Anxiety disorder
17. Cognitive disorder
18. Mood dysfunction
19. Psychosis

ETIOLOGY AND PATHOGENESIS OF NPSLE

Three basic pathophysiological mechanisms for neuropsychiatric lupus have been purported: (1) autoantibodies, (2) vasculopathy, and (3) inflammation.

Over 150 articles have reported the involvement of several antibodies in the pathogenesis of NPSLE (Colasanti, 2009; Zandman-Goddard, 2006; Valesini, 2006). Some antibodies are CNS-specific, and others are systemic. CNS-specific antibodies are listed in Table 61.2.

Systemic antibodies implicated in NSPLE include anti-phospholipid antibody (anti-cardiolipin antibody and lupus anticoagulant), anti- β 2 microglobulin antibody, anti-ribosomal P antibody, anti-Ro antibody, anti-Smith antibody, anti-endothelial cell antibody, and anti-Nedd 5' antibody, to name a few.

In most cases, small numbers of studies involving small numbers of patients, with varying definitions of NPSLE

and varying assays for detecting antibodies, have been carried out. Thus no single consistent biological marker for NPSLE has yet been found. In the case of NSPLE syndromes of stroke, transient ischemic attacks, seizure, and migraine, anti-phospholipid antibodies (anti-cardiolipin antibody and lupus anticoagulant) are by far the most widely investigated and are most consistently associated with these syndromes via their pro-thrombotic characteristics. There is also a lot of research implicating them in cognitive dysfunction, suggesting a pattern that is probably similar to that of vascular dementia.

Perhaps the most focus has been on anti-ribosomal P and anti-NMDA receptor antibodies for their role in lupus psychosis because of their apoptotic, rather than thrombotic or vasculitic, mechanism of cell death. Apoptosis and subsequent tissue necrosis have been the most common histopathological findings on biopsy (Johnson, 1968). Anti-ribosomal P antibody is the most studied antibody for lupus psychosis, but a meta-analysis (Reichlin, 2006) demonstrated that serum or CNS anti-ribosomal P antibody levels did not differentiate between different NPSLE syndromes or between organic versus primary psychiatric disease. The NMDA receptor antibody is the one most consistently associated with NPSLE (Fragoso-Loyo, 2008; Lauvsnes, 2011). In one study examining serum and CSF levels of five autoantibodies amongst patients with SLE, central NPSLE, peripheral NPSLE, and septic meningitis, only the anti-NMDA receptor antibody showed a distinctive distribution in central NPSLE, although it (and all other antibodies) was also elevated in patients with septic meningitis. The NMDA receptor binds glutamate and plays an important role in learning and memory. The anti-NMDA receptor antibody preferentially binds to the NMDA receptors in the hippocampus, resulting in the loss of hippocampal neurons via apoptosis, and therefore in memory impairment (Kowal, 2004; Kowal, 2006). Consequently, this raises the possibility of using NMDA receptor antagonists such as memantine as therapeutic intervention (Omdal, 2005; Colasanti, 2009), but efficacy studies are lacking.

Vasculopathy has been reported, a non-inflammatory vasculopathy involving the small vessels with vascular hyalinization, perivascular lymphocytosis, obliterative intimal fibrosis thrombosis, and leukagglutination (West, 1996; Pullman, 2004). The most predominant histopathological findings are reported to be multifocal, cerebral cortical micro-infarcts associated with microvascular injury. This vasculopathy causes decreased cerebral blood flow in several areas of the brain, including in the posterior cingulate and thalamus, as seen in psychotic disorders like schizophrenia. It is worth noting that an inflammatory process involving cerebral vessels, or vasculitis, is reported to be an extremely rare finding; therefore, the term "lupus cerebritis" is discouraged.

Some authors have reported increased cerebrospinal fluid (CSF) levels of inflammatory cytokines (Okamoto, 2010); interleukins (IL) 1, 4, 6, 8, and 10; interferon α and γ ; and tumor necrosis factor (TNF)- α ; and chemokines: monocyte chemotactic protein-1 (MCP-1/CCL-2); interferon gamma inducible protein 10 (IP-10/CXCL-10); and Fractalkine (CX3CL1). It is thought that immune complex formation

Table 61.2 CNS-SPECIFIC AUTOANTIBODIES ASSOCIATED WITH NPSLE

CNS-SPECIFIC	NO. OF STUDIES SHOWING POSITIVE ASSOCIATION	CLINICAL SYMPTOMS ASSOCIATED WITH ANTIBODY
Antineuronal antibody	9	Cognitive impairment, non-focal NPSLE, psychosis (1 study, $N = 8$)
Anti-NMDA receptor antibody	4	Mood, cognition (by binding to NMDA receptor targets in hippocampus and causing cell death via apoptosis)
Anti-MAP-2 antibody	1	
Anti-neurofilament antibody	1	
Anti-ganglioside antibody	6 out of 8	Migraine, neuropathy, cognition, depression (1 study, $N = 448$)
Anti-CNS tissue antibody	2	
Anti-GFAP antibody	1	Non-specific NPSLE

NMDA–N-methyl D-aspartate; MAP-2–Microtubule Associated Protein-2; GFAP–Glial Fibrillary Acidic Protein

in the CNS stimulates a cascade of cytokine and chemokine activation, which in turn acts on monocytes, lymphocytes, and neutrophils and specific T cells to bring about CNS pathology resulting in NPSLE. Of the above cytokines implicated in the pathogenesis of NPSLE, IL-6 has the strongest positive correlation with lupus psychosis, in the context of preserved integrity of the blood–brain barrier. The significance of this is that the inflammatory response can occur in the CNS independent of systemic disease activity. Clinically, it aligns with the observation of CNS complaints in patients with otherwise “stable” disease. Such patients are typically referred to the psychiatrist, with a determination that their disease is stable, as serum investigations may also show that the systemic disease is quiescent. Their neuropsychiatric complaints may often get attributed to primary psychiatric illness or illness behavior. Increased levels of IL-6 mRNA have been found in hippocampus and cerebral cortex (Hirohata, 1999). However, not all studies have produced these results.

There is therefore insufficient evidence to support the routine use of lumbar puncture for CSF levels of these cytokines or autoantibodies in clinical practice as diagnostic tools in NPSLE, or of anti-ribosomal P or anti-NMDA receptor antibodies as a diagnostic tool for lupus psychosis.

CLINICAL FEATURES OF NPSLE

There is a significant paucity of studies looking at the phenomenology of psychiatric symptoms in NPSLE as a way of clinically differentiating between organic and non-organic disease in patients with SLE. Some anecdotes indicate that the hallucinations in NPSLE are more commonly visual, although they can certainly be auditory as well. Visual hallucinations have been described by several patients as typically involving faces distorting, animation of faces on wall pictures, or seeing a face or a person at the edge of the bed (observation from clinic population). Patients with stable, inactive SLE in the absence of other signs of NPSLE commonly report seeing nondescript black shadows transiently appearing in their peripheral field that disappear when they turn towards the perception.

There is no one pattern of cognitive impairment that defines SLE. Impairment can occur in one or more cognitive domains, and can be therefore termed *focal* or *multifocal* cognitive impairment. The specific cognitive domains include simple attention, complex attention, memory and learning, visuospatial function, reasoning and problem-solving, psychomotor speed, language (such as verbal fluency), and executive functioning (planning, sequencing, synthesis, drive). Cognitive impairment is defined as two or more standard deviations (SD) below the mean on neuropsychological testing, whereas a deficit of 1.5–1.9 SD below the mean is referred to as *cognitive decline* (Mikdashi, 2007). Cognitive impairment may follow a stepwise decline, with sharp decreases in function associated with acute flares, and an incomplete return to baseline upon flare remission. Thus the impairment becomes chronic, but static in between flares. Several patients describe this chronic, low-grade cognitive impairment as a “brain fog” and find it disabling. Although brain fog can occur in SLE patients with and without NPSLE, those with prior NPSLE are found to have more severe cognitive impairment (Hanly, 1997).

Symptoms of and criteria for depression in NPSLE are the same as those for a major depressive disorder. Symptom attribution becomes the key in differentiating the two, but this is a process riddled with subjectivity, particularly in the absence of a sensitive and specific biological marker for NPSLE. Features such as the presence of a contributory psychosocial history or the presence of a family history of psychiatric illness have not been shown to reliably help to differentiate organic from non-organic disease. In fact, many lupus flares are triggered by psychosocial stressors. There is an entire body of literature on the impact of psychological stress on cytokine activation, oxidative stress, and an inflammatory response. Thus the complex interplay of psychological factors with biological factors in depression in NPSLE makes it difficult to differentiate primary depression from mood disturbance due to a direct biological effect of lupus. An SLE Disease Activity Index (SLEDAI) (Gladman, 2002) can be applied in this circumstance. When there is no other systemic or serological sign of disease activity, it is thought that the symptoms

are more likely to be attributable to a primary mental health problem rather than NPSLE. Thus the symptoms of depression and anxiety in NPSLE are phenomenologically similar to those in primary affective disorders in patients without SLE, and a history elucidating the temporal relationship of mood and anxiety symptoms with clinical and serological SLE disease activity may provide the only clue towards suspicion of NPSLE.

The occurrence of a single generalized seizure in patients with SLE does not necessitate anti-epileptic drug (AED) treatment, and does not necessarily mean that the patient will go on to have a recurrent seizure disorder. If the seizure is generalized and occurs in the context of a lupus flare without neurological localizing signs or focal damage on magnetic resonance imaging (MRI), treatment of the underlying lupus with prednisone and/or immunosuppressants such as intravenous methylprednisolone or intravenous cyclophosphamide is recommended (Barile-Fabris, 2005; Bertsias, 2010). If seizures are recurrent despite recovery from a lupus flare, or if seizures were partial with neurological localizing signs or focal lesions on MRI that raise suspicion of epileptic foci, then AEDs may be indicated.

Movement disorders occur more frequently, but not exclusively, in the subset of SLE patients who test positive for anti-phospholipid antibodies (Orzechowski, 2008) and have thrombotic events. The most commonly reported movement disorder in NPSLE is chorea (Cervera, 1997). It usually occurs as a single episode and subsides within weeks to months. MRI may still appear normal, as in most cases of NPSLE, and other imaging modalities that can detect altered function, such as positron emission tomography (PET) or single-photon emitted computed tomography (SPECT), are more likely to demonstrate changes in the basal ganglia. If generalized SLE activity is present, treatment with prednisone and immunosuppressants is recommended, with the addition of anticoagulation therapy if the patient is anti-phospholipid-antibody positive and other thrombotic manifestations are present (Bertsias, 2010).

IMAGING IN NPSLE

Computed tomography (CT) is of limited value in diagnosing NPSLE, unless an acute cerebral hemorrhage needs to be excluded. MRI is the current gold standard (Peterson, 2005; Stimmler, Coletti, & Quismorio [1993]) and should be done as part of the assessment of NPSLE. The MRI is, however, usually normal in NPSLE, and caution should be taken not to erroneously dismiss a possible diagnosis of NPSLE in the face of a normal MRI. Positive findings include transient, high-intensity, diffuse white matter lesions, more predominant in the frontoparietal area (Ishikawa, 1994; Jacobs, 1988; Chinn, 1997). Periventricular white matter lesions are thought to be associated more with anti-phospholipid-antibody syndrome. None of these findings, however, is specific for NPSLE, and similar findings are seen in other CNS disorders such as multiple sclerosis. They tend to occur early in the course of NPSLE and may resolve within the first 24 hours (Sibbit, 1999), and also resolve rapidly with corticosteroid

therapy (McCune, 1988; Sibbitt, 1989). MRI should therefore be done early in the course of illness, when NPSLE is suspected. The lesions are thought to represent edema and are therefore best visualized on T2-weighted images or fluid attenuated inversion recovery (FLAIR). FLAIR is more sensitive than T2-weighted MRI in NPSLE and is advantageous for use in clinical care (Sibbit, 2003). T1-weighted images will usually appear normal. Chronic lesions such as diffuse white matter disease, periventricular white matter hyperintensities, and focal subcortical lesions occur in about 25–50% of SLE patients without active NPSLE, and are more likely to be seen in patients with a history of more severe disease, in advanced age, and with a history of NPSLE (Jarek, 1994; Brooks, 1997; Rozell, 1998; Friedman, 1998; Hachulla, 1998). Lesion enhancement following gadolinium will help differentiate chronic from acute lesions (Miller, 1992), and radiologists also use certain morphological and intensity criteria of the lesions to help differentiate active NPSLE from non-specific white matter hyperintensities, from chronic SLE without CNS involvement, or from other causes such as hypertension.

Diffusion weighted imaging (DWI) and calculated the apparent diffusion coefficients (ADCs) show significant promise in NPSLE (Moritani, 2004; Welsh, 2007; Zhang, 2007) but are restricted to use in research as the data are limited. There are no studies comparing the sensitivity of FLAIR versus DWI. The same applies for diffusion tensor imaging (DTI), in which there are even fewer studies, but there is hope that it may help in diagnosis of NPSLE and even shed light on its pathogenesis in the future (Hughes, 2007).

Although functional MRI may detect the effects of SLE on cognition and brain function, it does not distinguish between chronic and acute effects, and there is no pattern of cognitive impairment that is specific for or suggestive of acute NPSLE. Serial testing to measure change might be more useful, but the degree of deterioration needed to be considered significant and the acuteness of the decline are not known factors and therefore make any such findings difficult to interpret. Such testing is not used in routine clinical practice and is still restricted to research or used for brain mapping, as in planning for neurosurgery and brain radiotherapy, or for documenting brain and cognitive deficits after traumatic or acquired brain injuries.

Therefore in the clinical setting, T2-weighted MRI is considered the gold standard, with FLAIR enhancing sensitivity and gadolinium enhancement helping to differentiate between acute and chronic lesions. Studies using DWI and DTI are promising but are in infancy stages and not used in routine clinical practice; there are no studies recommending these if MRI with T2, FLAIR, and gadolinium are negative. Functional MRI (fMRI) does not add any further value in the diagnosis of acute NPSLE.

Magnetic resonance spectroscopy (MRS) remains a research tool in NPSLE. It measures the levels of brain metabolites such as N-acetyl aspartate (NAA), total choline, and creatinine, to name a few. Brain NAA levels have been found to be reduced in NPSLE (Peterson, 2005), but again, this finding is not specific and can be seen in other disorders such as dementia of the Alzheimer's type, multiple sclerosis, and

even obstructive sleep apnea (Fuller, 2004). It is also a transient finding, and its reversibility with treatment in cases such as epilepsy suggests reversible neuronal injury (Vermathen, 2002). There are no studies looking at whether NAA levels increase with treatment of NPSLE, and whether, therefore, MRS measuring NAA levels might be potentially useful for early diagnosis and monitoring response to treatment with the aim of preventing and/or predicting chronic CNS effects of NPSLE.

SPECT measures cerebral perfusion by detection of a radio-labelled tracer that is given intravenously prior to the procedure. There are several limitations with the use of SPECT. First of all, the studies are limited, and again, they mostly lack control or comparison groups. Secondly, the findings are variable. Altogether, the studies thus far suggest that SPECT is not very sensitive in detecting minor disease, but it has similar sensitivity to PET in detecting major CNS disease in NPSLE (Kao, 1999). A significant drawback is its high incidence of false positives (Borrelli, 2003). The most common finding is diffuse areas of hypoperfusion (Peterson, 2005). SPECT is, however, easier to administer and is appreciably cheaper than PET. It is often therefore the second modality used in clinical practice after, or in conjunction with, MRI.

PET measures metabolic activity in the brain by measuring glucose uptake and oxygen utilization. The most common observations on resting PET reported in patients with SLE are a higher frequency of gray matter than of white matter lesions, and hypometabolism in any part of the brain, but most frequently in the parieto-occipital and parietal areas (Otte, 1997; Weiner, 2000). Once again, these findings are not specific to NPSLE. PET has been demonstrated to have significantly higher sensitivity than MRI in detecting NPSLE, with several studies documenting normal MRIs where resting PET scans show hypometabolism, when both were done on the same patients at illness onset (Weiner, 2000; Otte, 1997; Kao, 1999), supporting the clinical observation of functional deficits in patients with subjective complaints of cognitive and/or psychiatric symptoms in the absence of structural deficits. Despite its greater sensitivity over MRI and consistent findings of parieto-occipital hypometabolism, there are not enough large studies to provide quantitative estimates of sensitivity and specificity. There are three studies in which resting PET abnormalities resolved with treatment and with clinical improvement of the NPSLE (Carbotte, 1992; Weiner, 2000; Otte, 1998), and a fourth study demonstrated correlation of PET findings with clinical course of the disease on longitudinal resting PET follow-up of 28 patients over a mean of 15 months (Weiner, 2000). Several other studies report resolution of PET findings with corticosteroid therapy or paralleling clinical improvement (Hiraiwa, 1983; Guttman, 1987; Otte, 1998; Meyer, 1989; Stoppe, 1990; Carbotte, 1992).

Although more sensitive than MRI in detecting NPSLE, resting PET has similar utility in helping to differentiate lupus-related from non-organic neuropsychiatric symptoms in patients with SLE (Weiner, 2000; Kao, 1999). Because of cost, invasiveness, and study limitations (such as lack of control groups in most studies), PET is not usually a first choice of imaging in routine clinical practice for evaluating NPSLE.

Its use is reserved for more complicated clinical pictures and clinical dilemmas, where MRI may have been normal or inconclusive and where PET results are likely to have practical implications for important treatment decisions.

In all imaging modalities, the findings of white or gray matter lesions are reported to be transient, and radiological findings on diffusion imaging modalities suggest that they most likely represent edema. Histopathological studies have consistently demonstrated a perivascular lymphocytic infiltration with increased capillary permeability and surrounding microedema, without antibody-complex formation or inflammatory changes. A true vasculitic picture is rarely found. For these reasons, the term "lupus cerebritis" is considered a misnomer, and "NPSLE" is the accepted term as it does not imply an etiopathogenesis, which is still unclear. Apart from the correlation of PET findings with clinical improvement and treatment response, the methodologies among the imaging studies are inconsistent in their reports of association with serology or symptoms, making it difficult to conclude whether the imaging findings correlate with serological activity, antibody type, symptom profile, or treatment response.

Thus MRI is the current gold standard imaging modality in the evaluation for NPSLE, and it should be done early, within 24 hours of suspicion of NPSLE. SPECT or PET may be done afterwards or in conjunction with MRI to further aid with diagnosis, depending on cost and availability.

TREATMENT OF NPSLE

Most psychotropic medications are safe in patients with lupus and the choice of medication should be individually tailored based on side effect profile, medical symptom complex, medication interactions, and phenotype of the psychiatric syndrome. For example, in depression, selective serotonin reuptake inhibitors (SSRIs) and serotonin and norepinephrine reuptake inhibitors (SNRIs) are safe to use, duloxetine may be particularly useful if chronic pain is comorbid, and bupropion may be chosen if fatigue is a prominent, but it may not be the first choice if the patient has symptoms of anxiety or NPSLE with seizures. If bupropion is being considered in a patient with a history of NPSLE, and there has never been a history of seizures, it is safe to use without need for a pre-treatment electroencephalogram (EEG). If there is a history of isolated seizure without focal brain damage, it is helpful to do an EEG prior to starting bupropion. If permanent focal brain damage accounts for the seizures, and if seizures are recurrent, bupropion is better avoided. The same is recommended if tricyclic antidepressants that lower the seizure threshold, such as clomipramine, imipramine, and amitriptyline, are being considered.

Psychosis, if determined to be due to NPSLE, will usually resolve with treatment of the lupus itself, but often adjunctive psychotropic medication is needed to expedite symptom control. The treatment of acute NPSLE with psychosis would assume the same hierarchy as treatment of an acute lupus flare, with preference for certain immunomodulators that have demonstrated specific efficacy for treatment of the psychosis. The hierarchy of treatment is as follows: oral

high-dose prednisone, intravenous methylprednisolone, pulse cyclophosphamide, and rituximab (Trevisani, 2006; Tokunaga, 2007).

When patients are placed on high-dose steroids, a steroid psychosis may develop, which then complicates the clinical picture. A careful history must be taken to determine if the psychosis predated the initiation of steroid treatment, and to determine the temporal relationship between the development of psychotic symptoms and the initiation of steroid treatment. It is worth noting that the incidence of lupus psychosis in the pre-steroid era is not dissimilar to its incidence in the post-steroid era, after 1960 (Stern, 1960). Doses of oral prednisone of less than 40 mg are considered very unlikely to induce psychosis, while oral doses over 80 mg are considered more likely to induce psychosis. The phenomenology of steroid-induced psychosis is most similar to that of an affective psychosis seen in manic episodes. It is usually heralded by a brief period (24–48 hours) of insomnia and marked irritability. Despite these clinical clues, it is often difficult to make the differentiation between NPSLE psychosis and steroid-induced psychosis in the clinical setting, and often the addition of a psychotropic medication is necessary in either circumstance, as the underlying active lupus must be treated.

All neuroleptics are safe in NPSLE; again, paying attention to the individual patient in terms of medical comorbidity when choosing a specific medication. For example, in patients with pericarditis, care must be taken not to complicate the medical illness with psychotropics that have a high tendency to prolong the QTc interval. Risperidone, olanzapine, loxapine, and haloperidol are good first choices due to their higher affinity for the D2 receptor at fairly low doses, and to their tolerability, with predictable and easily manageable side effects. If agitation is an additional issue, a benzodiazepine can be added to the neuroleptic, which also facilitates response to lower doses of neuroleptics and helps reduce the incidence of extrapyramidal side effects. Quetiapine must be used in higher doses, which increases the risks of side effects of over-sedation and orthostatic changes in the blood pressure and heart rate. If insomnia is a prominent feature, however, the sedating side effects of quetiapine can be capitalized upon. Ziprasidone may exacerbate aggression and probably should not be first choice in patients with steroid-induced psychosis. Ziprasidone should be avoided in patients with pericarditis or pleuritis, as it raises the incidence of cardiac arrhythmias. The QTc interval should be monitored in the patient taking a neuroleptic, and patients should be examined for the emergence of extrapyramidal side effects. Dosing of neuroleptics is usually at a lower starting dose than usual, given the multisystem effects of the illness, with slow titration to clinical response tailored to the individual patient. Treatment should not be changed or altered prematurely, and medications should be given adequate time to have an effect while the lupus is also being treated. It usually takes several days to weeks for symptom control, and often the psychiatric symptoms lag behind the medical symptoms.

NPSLE syndromes, such as lupus psychosis, are not considered to be necessarily recurrent (Bertsias, 2010). Thus a patient with lupus psychosis does not require long-term antipsychotic treatment, which should be discontinued after the

patient recovers and a period of stability has been achieved. Similar to seizures in NPSLE, lupus psychosis is not considered to be a chronic disorder, and patients and their families should be informed that full recovery from psychosis is expected (Pego-Reigosa, 2008). This is true for other affected organs as well, so that one episode of pericarditis does not necessarily mean permanent or recurrent cardiac pathology. There are only a few studies on long-term outcome of NPSLE. The available literature suggests that the natural course of SLE in patients with a history of NPSLE is not considered to be any different from the natural course of SLE in patients without such a history, as long as there was good immunosuppressive treatment of the NPSLE (Wang, 2012; Pego-Reigosa, 2008). The presence of NPSLE at presentation or during a lupus flare does not necessarily predict further NPSLE syndromes in subsequent flares. Few predictors of recurrent NPSLE have been found, and so far they are limited to the presence of anti-phospholipid antibodies, baseline severity of the disease, and the presence of permanent brain damage such as infarcts on MRI (Mikdashi, 2004).

OTHER PSYCHIATRIC DISTURBANCES IN SLE

ILLNESS BEHAVIOR AND SOMATIZATION IN SLE

Reaction to chronic illness and illness behavior in SLE reveals a fairly high incidence of somatization tendencies (Goodman, 2005). Most of these studies were in populations of young age, and early age of onset of illness. SLE, being a systemic disease, can affect any body system, any organ; and several symptoms are subjective. Even amongst the 19 NPSLE syndromes, symptoms can be vague and non-specific. The author has observed significant somatization tendencies; overreaction to vague, diffuse non-specific, non-life-threatening symptoms; and an apparently heightened perception of vague physical complaints in this population. A high level of alexithymia, which is commonly seen in patients with somatoform disorders, has been reported in this population (Barbosa, 2010).

Basic psychoeducation may be beneficial in some of these patients (Karlson, 2004). Stress-reduction strategies to target worry, fear, and illness anxiety may help. These include mindfulness-based stress reduction, breathing exercises, and progressive muscle relaxation. Basic support and education about coping with a chronic medical illness may also be helpful. As a general rule, patients with somatization tendencies or somatoform disorders take longer to respond to these treatment modalities, and improvement is even more difficult in a population with a known chronic medical illness. To avoid iatrogenic effects by secondary reinforcement of illness behavior and somatization, limited, regular, but not too frequent visits are suggested, such as once every one or two months, with focus on the above psychotherapeutic interventions and avoidance of over-investigation of multiple diffuse, vague, non-specific complaints. This is best done in a collaborative-care setting with close liaison between psychiatric and rheumatological services.

PSYCHOSOCIAL FACTORS IN SLE

The psychological impact of the illness includes high incidence of incomplete or interrupted education, threat to employability, difficulty securing relationships, difficulty bearing children, changes in physical appearance (moon-like facies, buffalo hump, and abdominal obesity associated with steroids; malar or “butterfly” rash; diffuse body rash with defacement and scarring), chronic fatigue, inability to fulfill life roles, social isolation, and impaired quality of life. These can all contribute to low self-esteem, self-rejection, and nihilism with increased risk of a clinical depression. The need for psychological support for coping with the impact of SLE should therefore always be assessed for these patients.

CHRONIC PAIN

Chronic pain can develop as a long-term sequela of SLE in the absence of active disease. In an acute flare, arthritis in SLE can affect any joint, most often the hands. Joints typically appear hot, red, and swollen. Treatment of the acute flare is often sufficient to treat the arthritis and associated pain. Avascular necrosis should be considered as a cause of acute pain in patients who are on long-term steroid treatment. Patients with SLE who have chronic pain often complain of diffuse muscle as well as joint pain. Some also complain of neuropathic pain. Often psychological factors are judged to be associated, and the presence of depression or maladaptive coping may heighten pain perception or increase the subjective burden and incurred disability of the chronic pain. Many of these patients may be diagnosed with fibromyalgia (discussed later in this chapter).

Chronic pain may be treated with basic analgesics such as acetaminophen or ibuprofen, on an as-needed or regular basis. Duloxetine and gabapentin, which have an effect on neuropathic pain, have also been successfully used. Referral to a pain specialist is frequently required, and many of these patients are often prescribed fentanyl patches, long-acting opioid preparations, and cannabinoids. This then complicates care due to controversies about drug-seeking behavior, dependence, and abuse versus bona fide need and therapeutic benefit. Sorting out the extent to which psychological and physical factors are contributing to the pain can be challenging, regardless of the underlying medical illness. Many patients request “medical marijuana,” raising a lot of questions about the motives underlying these requests. Apart from clinical considerations, some physicians may struggle with moral or ethical issues surrounding this. Hesitation to prescribe can affect the therapeutic relationship and complicate the clinical encounter for both patient and physician. A systematic review of 18 trials of the efficacy of cannabinoids, including smoked cannabis and cannabis-based oral medicine, nabilone, and dronabinol, in patients with neuropathic pain, fibromyalgia (1 trial), rheumatoid arthritis (1 trial), and mixed chronic pain concluded that there is preliminary evidence of modest efficacy in fibromyalgia and rheumatoid arthritis (Lynch, 2011). The study’s limitations were cited as short trial duration, small sample sizes, modest effect sizes, lack of examination of the

potential for abuse, and patient attitudes about whether the modest reduction in pain intensity was clinically meaningful. Another review on the role of cannabinoids on chronic pain suggests that their efficacy and tolerability are still questionable, that they should not be considered first-line therapies where more supported and better-tolerated agents are available, and that they may be considered as adjunctive agents when other available treatments have failed (Turcotte, 2010). The latter is probably best done within a collaborative model with rheumatology and a comprehensive pain program, with one physician as designated prescriber to help monitor for misuse and avoid prescriptions from multiple sources. Mobility should be encouraged, and superimposed psychological factors—for example, coping mechanisms, acceptance of chronic illness, need for cognitive reframing, reactions to socio-occupational losses from the illness, and family support—should be addressed.

CHRONIC FATIGUE

Fatigue is a common complaint in patients with SLE. It can be acute and profound during a lupus flare, often being one of the presenting symptoms of a flare. Although withdrawal of steroid treatment after stabilization of a flare is very gradual, tapering over several months, secondary adrenal suppression during the steroid taper is a second possible cause of significant fatigue. Neither the dosage nor the duration of therapy is a reliable indicator of subsequent adrenal insufficiency, and it has been reported in courses of treatment as short as 14 days (Schlaghecke, 1992; Grinspoon, 1994; Oelkers, 1996; Henzen, 2000). Studies suggest it may take up to six months after steroid taper for the adrenal glands to recover full function (Morkane, 2011) and therefore for fatigue to improve. Also, fatigue can be chronic in patients with inactive disease who are otherwise stable. Individual- or group-graded exercise therapy can be recommended for chronic fatigue (White, 2011). If done in a group setting, the exercise prescription should be individually determined, based on the patient’s exercise tolerance. It should be done by a qualified exercise therapist and planned jointly with the patient, increasing in duration and intensity every one to two weeks. The evidence is best for individual rather than group treatment.

Although stimulants such as modafinil and methylphenidate are not considered first-line treatments for fatigue, they have been safely used in this population. The doses are similar to those used in the psychiatric population, starting low and titrating slowly to clinical response. The author has used both medications in 15 patients, with about 50% of patients responding, as measured by subjective reports of some improvement in motivation and fatigue, coupled directly with improvement in occupational and daily function, as measured by task completion on a patient-generated task inventory (unpublished data). If there is no associated improvement in daily function, the medication is discontinued. Either medication can be chosen first, based on side effect profile and patient symptom complex. For example, if anxiety is comorbid, modafinil might be chosen over methylphenidate, due to the latter’s risk of exacerbating anxiety.

Patients are informed that methylphenidate may suppress appetite, and this may be either an unwanted or a desirable side effect, depending on the individual patient. Modafinil is an inducer of cytochrome p450 3A4, and data on methylphenidate's effect on p450 enzymes are sparse and inconclusive, although it has been cited as an inhibitor of cytochrome p450 2D6 (Cozza, 2001). No drug interactions between either of these drugs with immunosuppressive SLE medications such as mycophenolate mofetil or hydroxychloroquine have been reported, but as in all patients taking multiple medications, caution must be exercised when prescribing, to be alert for potential drug interactions.

RHEUMATOID ARTHRITIS

Rheumatoid arthritis (RA) is a sporadically occurring disease of unknown cause. The strongest factors influencing disease expression are genetic and immunological. It affects women about twice as frequently as men. Although it can occur at any age, it has a peak age of onset in the fourth decade, with a sharp rise in incidence thereafter. It typically has a gradual onset, although both the course and clinical picture can be variable. This means that, despite the availability of diagnostic criteria, time for the evolution of symptoms is required before the diagnosis may actually be captured.

RA is a chronic inflammatory disorder affecting the joints. The process begins with inflammation of the synovium, which proliferates with each recurrence and eventually leads to bone erosion, destruction of joint cartilage, and loss of strength and elasticity of tendons and ligaments. One of the most common clinical features is diffuse, symmetrical joint pain and swelling affecting the small peripheral joints, such as the hands. Other affected joints include ankles, knees, wrists, and elbows. Joints may develop characteristic patterns of deformity (ulnar deviation of the fingers, swan-neck deformity, and boutonnière deformity), with or without subcutaneous nodules, often over the olecranon process and the ulna. This chronic inflammatory process can lead to mild illness with infrequent exacerbations and remissions, or it can follow a rapidly deteriorating course and lead to severe, disabling joint deformity and loss of physical function.

RA features extra-articular manifestations as well, such as fatigue, weight loss, fever, anorexia, and diffuse non-specific aching, and this may precede more characteristic joint symptoms. Some of these patients may be misdiagnosed with depression before the defining features of the illness reveal themselves. The effects of the disease are quite far-reaching, ranging from direct physical effects (from acute pain to chronic disability), to indirect physical and psychosocial effects (such as disturbances of sleep, fatigue, varying degrees of social and occupational impairment, and functional impairment in the instrumental and basic activities of daily living).

RA is a systemic illness, and cardiovascular disease is the leading cause of premature mortality. Cardiac complications include inflammation causing myocarditis and pericarditis, which lead to congestive heart failure, valvular insufficiency, and acceleration of atherosclerotic disease (Moreland, 2009).

Rheumatoid nodules may appear in lung parenchyma and in the airways, resulting in bronchial obstruction. Inflammation of the pleura can lead to pleurisy, and inflammation of lung parenchyma can lead to interstitial disease and progressive fibrosis (Amital, 2011). Gastroenterological manifestations occur usually as a complication of rheumatoid vasculitis, which develops in about 5% of RA patients. When vasculitis affects the intestinal tract, bowel ischemia and infarction may occur. Reduced esophageal motility can lead to dyspepsia and dysphagia. Mild pathological changes in the liver are seen in up to 92% of RA patients at autopsy (Ebert, 2011). Cases of autoimmune pancreatitis have been reported (Mustak, 2011). The eye may also be affected with scleritis and iridocyclitis. The nervous system is less commonly affected. Compression neuropathies can occur following joint deformities in the locale of major nerves, such as the peroneal, ulnar, and median nerves. CNS involvement is considered very rare. There has been one case of rheumatoid meningitis in a 66-year-old patient without a history of RA, but with high titers of rheumatoid factor and anti-cyclic citrullinated peptide antibody (Kim, 2011).

PSYCHIATRIC DISORDERS IN RA

Although RA is a systemic disease, direct neuropsychiatric complications are very rare (Moreland, 2009). More commonly, psychiatric disturbances occur as a consequence of coping with a chronic, disabling, and visibly deforming medical illness.

The prevalence of depression and anxiety in RA has been reported to be similar to that in other chronic medical illness, and is estimated at 21–34% (Creed, 1990; Pincus, 1996). The studies on which this figure is based took into account the somatic symptoms of depression that overlap with symptoms of RA, using an etiological approach, thus providing what is considered a more reliable and accurate estimate. Previous studies, which used an inclusive approach to diagnosing depression based on fulfilling a threshold number of depressive symptoms without consideration of symptom attribution, produced a much wider, and less accurate, range of 22–80% (Pincus, 1996). Psychosis as a consequence of RA is rare.

Most patients with RA will complain of symptoms of depression such as disturbed sleep, appetite, energy, and concentration, and reduced social activity. Sleep disturbance may be due to pain, while fatigue and anorexia may be systemic effects of the illness, and reduced social activity and engagement may be due to limitations imposed by physical disability rather than a low mood. When assessing for depression in patients with RA, therefore, it is helpful to consider the possibility of symptom contamination when applying diagnostic criteria for depression and anxiety. The Hospital Anxiety and Depression Scale (HADS) has attempted to capture depression and anxiety in medical patients while avoiding such symptom contamination, but there is still some debate about its psychometric properties and the advantages of other commonly used questionnaires (Bjelland, 2002). In routine clinical practice, however, symptom attribution, as in the etiological approach to using depression criteria in patients

with medical illness (Koenig, 1997), might be adequate for diagnosis. This approach may be criticized for its subjectivity, but the role of sound clinical judgement and detailed clinical exploration of each depressive symptom in order to determine symptom attribution must not be overlooked. Furthermore, depression in RA may not present in its traditional manner. Patients with RA who are depressed often present to their rheumatologist with excessive complaints of pain and fatigue, anxiety about the disease, hypersensitivity to vague physical symptoms, frequent clinic visits, and increased complaints of disability (Hawley, 1988).

ETIOLOGY AND PATHOGENESIS OF PSYCHIATRIC DISTURBANCES IN RA

The similarity in the incidence of depression and anxiety between RA and other chronic medical illnesses suggests that the etiology of psychiatric symptoms in RA does not directly involve disease-specific factors. Several studies have examined the relationship between depression, anxiety, and various measures of disease activity and severity. In a review of studies examining the relationship of depression with disease severity and duration, there is a consistent finding of lack of direct correlation between measures of disease severity and activity (grip strength, erythrocyte sedimentation rate, total joint score, and duration of morning stiffness) or disease duration, and the presence or severity of depression and anxiety (Creed, 1990). Indeed, the determinants of depression in RA have been found to be the patients' attitude to illness, personality, and socioeconomic factors such as age, education level, marital status, and family income, rather than the disease's activity, duration, or its disabling effects (McFarlane, 1988; Hawley, 1988). These are similar to the determinants of anxiety and depression in patients without RA or a medical illness. Studies have documented that the presence of depression and anxiety in RA is significantly more reflective of lack of social support and experience of social stress, rather than the disabling effects of RA (Murphy, 1988; Creed, 1990). In addition, employment status correlates more with depression than with disease severity or activity. A past history of depression predicts greater complaints of pain in patients with RA. Such patients may receive a secondary diagnosis of fibromyalgia.

Depending on various parameters of personality, such as general response to stress, attitudes towards illness, and coping mechanisms, the patient may or may not react poorly to increasing physical disability. Therefore, these personality factors may shape the disease expression, rather than the disease's having a direct effect on personality, such as in some cases of temporal lobe epilepsy. Therefore, early views of the "rheumatoid personality" are no longer substantiated.

Lipowski wrote on coping mechanisms with regards to medical illness and classified them into "adaptive" and "maladaptive," based on their likelihood to result in psychopathology (Lipowski, 1970). This is shown in Box 61.3.

"Positively reappraising a situation" means to attempt to deliberately perceive it in a way that leads to more positive

Box 61.3 LIPOWSKI'S COPING MECHANISMS IN PATIENTS WITH CHRONIC MEDICAL ILLNESS

Maladaptive Coping Mechanisms

1. Confrontative coping
 - a. Hostile or aggressive efforts to alter a situation
2. Distancing
 - a. Attempting to detach oneself mentally from a situation
 - b. Using escape-avoidance
 - c. Efforts to escape or avoid the problem or situation

Adaptive Coping Mechanisms

1. Seeking social support or information from others
2. Planful problem-solving
3. [†]Conducting positive reappraisal
4. Self-controlling
 - a. Attempting to regulate one's feelings or actions
5. Accepting responsibility for managing the illness—e.g., following treatment strategies, attending medical appointments

[†]Positively re-appraising a situation means to attempt to deliberately perceive it in a way that leads to more positive action. Lipowski wrote about coping with medical illness by identifying perceptions of illness. If we perceive illness for example as a punishment, this is likely to lead to feelings of despair, low self-worth, hopelessness and nihilism. If on the other hand we perceive illness as a challenge, it leads to feelings of wanting to rise above it, to take control and do whatever is necessary to manage it so we can move on with our regular activities as much as possible. Table 6 shows some examples of healthy versus unhealthy responses to illness according to Lipowski.

action. Lipowski wrote about coping with medical illness by identifying perceptions of illness. If we perceive illness (for example) as a punishment, this is likely to lead to feelings of despair, low self-worth, hopelessness, and nihilism. If, on the other hand, we perceive illness as a challenge, it leads to feelings of wanting to rise above it, to take control and do whatever is necessary to manage it so we can move on with our regular activities as much as possible. Box 61.4 shows some examples of healthy versus unhealthy responses to illness, according to Lipowski.

Personality factors such as temperament, tendency towards dependency, and external locus of control may determine whether maladaptive coping mechanisms are utilized and whether unhealthy responses to illness are adopted. These are the factors that correlate with mood disturbance in patients with RA, rather than the disease severity, activity, or disabling consequences.

As in all cases of depression, socioeconomic factors may play a contributing or protective role. Lack of social support, lack of family support, and marginalization from society are important predisposing and perpetuating factors in depression in RA patients. Studies have shown that perceived spousal support plays a big role in depression and

length of hospitalization after acute illness in RA (Creed, 1990). Loss of social function and reduced employability can lead to eroding self-esteem. Coping with fatigue can be emotionally taxing and can limit social engagement. Self-consciousness and negative self-perception from physical changes in joints and from steroid treatment contribute to social withdrawal and depression.

Perhaps because CNS abnormalities are so rare, there are few studies examining brain imaging and function in patients with RA. In a 2012 study (Hamed, 2012), the authors performed a battery of psychological tests, measured P300 amplitude in event-related potentials, and measured serum levels of neuronal cell markers. P300 latency and increased levels of neuronal cell markers correlated with poorer cognitive function, which was reported in 71% of their sample of 55 women. Only seven patients with cognitive dysfunction had MRIs showing white matter hyperintensities. The authors concluded that this was evidence that demyelination or vasculitis—the disease process—was directly affecting cognitive function in patients with RA. However, none of their outcome measures (P300 latency, serum levels of neuronal cell markers) are specific to RA, and cognitive dysfunction did not correlate with disease severity. Several confounding factors could have explained the fairly common finding of mild cognitive impairment and the observed MRI changes in middle age.

As of this writing, there are no reliable studies suggesting direct CNS involvement in patients with RA or outlining consistent CNS neuropathology, and it is still considered a rare entity. No specific pattern of cognitive deficit has been identified. Thus psychiatric CNS symptoms such as depression, anxiety, and cognitive complaints in RA have not been shown to correlate with disease activity or severity and can be thought of as resulting from a complex interplay of indirect consequences of RA, personality factors, psychosocial factors, and, to some extent, medication side effects.

TREATMENT

The treatment of depression and anxiety in patients with RA is similar to that in patients without RA, with a few additional considerations. Although SSRIs are generally safe, most

patients with RA are on non-steroidal anti-inflammatory drug (NSAID) therapy for pain, and care must be taken to monitor for gastrointestinal (GI) bleeding. SSRIs induce increases in gastric acid secretion, causing one of their more common side effects, dyspepsia. It is thought that this, coupled with SSRIs' effects on platelet binding, increases the risk of GI bleeding. Although the absolute risk of GI bleeds with SSRIs is low, this risk increases twofold when SSRIs are combined with NSAIDs, anticoagulants, and antiplatelet agents, and is decreased by concurrent use of proton pump inhibitors (Andrade, 2010).

Drug–drug interactions must be taken into account when prescribing. There are no anti-rheumatic drugs that will be affected by prescription of psychotropics. Some potential interactions might include reduced efficacy of mycophenolate mofetil by CYP 3A4 induction by modafinil; or reduced efficacy of tricyclic antidepressants (TCAs), citalopram, or escitalopram via CYP 2C19 induction by prednisone. The clinical significance of these interactions is not known. One important clinically significant interaction is reduced efficacy of opioid analgesics when co-administered with potent CYP 2D6 inhibitors such as fluoxetine or paroxetine. These analgesics require metabolism by CYP 2D6 for conversion to active metabolites. SSRI-induced sexual dysfunction may add to problems that patients with RA already face in terms of limited sexual activity due to physical consequences of the illness. On the other hand, to the extent that decreased libido exists as a symptom of depression and anxiety, SSRIs may be helpful. Apart from these concerns, SSRIs are generally safe for use in patients with RA. Because patients with depression and anxiety have heightened pain perception, SSRIs may also be helpful in reducing complaints of pain. SSRIs also have a theoretical biological effect on pain as one of the two powerful descending pain-dampening or pain-modulating tracts that affect the ascending lateral spinothalamic tract as they carry pain sensations to the thalamus, is a serotonergic tract. Special consideration can be given to the use of the SNRI duloxetine for treatment of depression and anxiety in RA because of its demonstrated beneficial effects on pain in the clinical setting.

Bupropion may be chosen if fatigue, weight gain, apathy, or sexual dysfunction are prominent features of the depression. Mirtazapine is useful for anxiety and for depression with marked anorexia and insomnia, but weight should be monitored, as weight gain will exacerbate joint pain and instability, and some patients may be on concomitant steroids, already contributing to weight gain.

Patients should be screened for drug dependence before considering use of benzodiazepines, since patients can often be on several controlled narcotic analgesics for refractory pain. As is the case with most patients, benzodiazepines are better used in the short term rather than long-term, because of the risk of physical and psychological tolerance and dependence and risk of abuse.

Psychological therapies for RA include psychoeducation about the illness and its effects. Patients should have a clear understanding of the illness course and expectations of outcome. It is useful for the psychiatrist to be aware of such prognostic information, which is provided to the patient by the rheumatologist, as it would help guide therapy, for

example, in terms of how much emphasis can be placed on acceptance of chronicity of a specific symptom, should that be the illness course in that particular patient. This is probably best facilitated via an educational support group run collaboratively between the rheumatology and psychiatry services. This also helps ensure that the patient is receiving consistent information from all care providers. This would help with their participation in the treatment, so as to avoid a complete external locus of control. In the latter case, such patients frequently complain about symptoms and project helplessness, which contributes significantly to poor social outcome and increased disability regardless of disease severity. Increased participation in their care and “self-regulation” (goal setting, planning, self-monitoring, feedback, and relapse prevention) has been found to be beneficial to many patients with RA and to play a role in reducing symptoms of anxiety and depression (Mulligan, 2003; Knittle, 2010).

Cognitive behavior therapy is useful for depression and anxiety if the patient is able to engage. Psychotherapies for anxiety such as mindfulness-based stress reduction, breathing exercises, and progressive muscle relaxation should be considered and can help with coping with pain as well. Alternative interventions like meditation and tai chi have been found to be helpful in the RA population, as they enhance cardiovascular fitness, muscle strength, balance, and physical function and are associated with reduction in stress, anxiety, and depression, and improved quality of life (Hewlett, 2011; Wang, 2011).

Patients with RA suffer varying degrees of social disadvantage, and RA has been associated with reduced employability. Embarrassment about physical changes in the body can lead to restriction of social activity. These factors can contribute to social isolation. Social support is an important determinant of psychiatric symptomatology and quality of life. While psychotherapy can help with coping, patients should be encouraged to mobilize social and family supports and remain engaged in their family and community. Social support can also occur via support groups or encouraging active participation in community activities. Volunteering has been shown to be very helpful for depression in patients with chronic medical illness (Thoits, 2001). Optimization of function is key. Physical therapy and rehabilitation may be helpful for joint and muscle function and for avoiding accelerated muscle atrophy. Physical exercise can be helpful for the physical effects of the illness (Knittle, 2010) as well as for depression, anxiety, stress, and cognitive function. It should be encouraged in all patients if possible. There are guidelines for prescribing physical exercise in patients with RA, and referral to a multidisciplinary clinic for rheumatological disorders should be considered where available.

SJÖGREN’S SYNDROME

Sjögren’s syndrome (SJS) is an autoimmune illness in which antibodies are produced that target the exocrine glands, most commonly the lacrimal and salivary glands. The most common symptoms are therefore dry eyes and dry mouth. Specific antibodies, anti-Ro and anti-La, are associated with SJS.

Several other systemic manifestations can be present, including dyspepsia, myalgia, arthralgia, Raynaud’s syndrome, dry skin with pruritus and photosensitivity, alopecia, vaginal dryness, and dyspareunia. Associated systemic diseases include pancreatic insufficiency, primary biliary cirrhosis, hypothyroidism, and scleroderma. CNS effects are controversial and are considered uncommon (Brito, Araujo, & Papi, 2002). However, several small studies demonstrate the mental impact of SJS (Gilberto, 2002; Mauch, 1994; Malinow, 1985; Andonopoulos, 1990). The spectrum of its mental impact can vary from strain from coping with a chronic medical illness, to clinical depression, anxiety, or cognitive effects.

PSYCHIATRIC DISORDERS IN SJÖGREN’S SYNDROME

The most common psychiatric complications of SJS have been identified as depression, anxiety, cognitive complaints, sleep disturbance, irritability, and headaches (Malinow, 1985; Gudbjörnsson, 1993; Valtýsdóttir, 2000). With respect to depression, low mood is the most common disturbance and has been found to correlate with fatigue (Rostron, 2002). Fatigue is a very serious problem in primary SJS and may be composed of different elements, including general fatigue, mental fatigue, physical fatigue, reduced activity, and reduced motivation. It may also be related to hypotension, which can develop from autonomic nervous system dysfunction from CNS SJS (Barendregt, 1998). Common symptoms of anxiety reported by patients with SJS include feeling more restless, feeling tense, having more difficulty relaxing, and having feelings of panic (Valtýsdóttir, 2000).

Patients with SJS tend to complain of “brain fog.” The exact frequency of cognitive impairment in SJS is unknown, as the few available studies are limited by sample size and lack of standardized cognitive assessment. From some of the available data (Malinow, 1985; Spezialetti, 1993; Mauch, 1994; Lafitte, 2001; Segal, et al., 2012), the prevalence of cognitive impairment ranges from 20–70% (sample size range of 16–39) of patients with primary SJS without other CNS involvement, and from 27–35% (sample size range of 11–77) of patients with CNS SJS (Lafitte, 2001; Spezialetti, 1993). “Brain fog” in SJS is defined as a mild dysfunction of concentration, short-term memory, and cognitive-processing speed, which is disruptive to the patient’s lifestyle. Patients often complain of having trouble concentrating, being forgetful, or finding that their memory is just not what it used to be, having difficulty finding words during conversation, having difficulty understanding information, feeling that they are just not as sharp as before, needing more time to process information, getting lost more frequently, and feeling the need to repeat things several times before understanding fully. Neuropsychological testing has documented impairment in attention and concentration, impaired associative learning, mild short-term-memory impairment, decreased perceptual speed, and difficulty with names, in the context of preserved generalized intelligence quotient (IQ) without any intellectual decline, except in one study showing mild intellectual decline compared to premorbid intellectual function in four out of 16 patients with primary SJS (Mauch, 1994).

Cognitive impairment can occur at any time during SJS. It has a very insidious onset, and may be chronic, recurrent, and in some cases may spontaneously remit. It is considered very rare that it would deteriorate into progressive memory impairment or dementia. In such progressive cases, it tends to be associated with active symptoms of SJS, and in those cases, treatment of the underlying disorder with prednisone or methylprednisolone usually also treats the cognitive impairment (Caselli, 1991; Alexander, 1992; Kawashima, 1993; Moll, 1993; Cox, 1999; Michel, 2011).

ETIOLOGY AND PATHOGENESIS OF PSYCHIATRIC DISTURBANCES IN SJÖGREN'S SYNDROME

In most cases, the psychosocial impact of the illness is the largest determinant of depression and anxiety. SJS can affect several aspects of life, including physical function, role function, social function, mental health, health perception, pain, and fatigue. These are all determinants of health-related quality of life, and therefore contribute to the overall mental impact of the disease.

Patients with SJS experience an inability to fulfill various role functions: work, family, social, and personal. Social interaction is at risk of being diminished because of issues around eating, swallowing, chewing food, and sustaining prolonged conversation. Fatigue, genitourinary sicca symptoms, and dyspareunia contribute to sexual dysfunction and affect intimate relationships. Lack of support or unsupportive environments can perpetuate low mood and anxiety.

Investigations into the role of biological factors have found inflammatory processes involving cytokines such as IL-6 and interferon- α to be associated with depression (Alexander, 1992). Although their involvement in depression in SJS has been postulated, it has not been empirically proven. One of the most common hypotheses is that neurological involvement in the form of autonomic neuropathy in SJS (Andonopoulos, 1995) leads to decreased levels of plasma norepinephrine. Correlation between decreased plasma norepinephrine levels and general fatigue, physical fatigue, and reduced activity has been reported. (Barendregt, 1998). In this study, there was no correlation between plasma norepinephrine levels and depression, but the patients with depression had added features of mental fatigue and reduced motivation. Based on this study, noradrenergic antidepressants might be chosen first, if medications are being considered.

Although a few antibodies have been reported to be involved, no one antibody has yet been isolated that is consistently associated with, or specific for, CNS symptoms in SJS such as depression, anxiety, or cognitive deficits.

No association has been found between cognitive deficits and anti-Ro or anti-La antibodies (Belin, 1999; Alexander, 1993). One of the more common findings in patients with cognitive deficits is a perivascular mononuclear inflammatory ischemic/hemorrhagic cerebral vasculopathy, causing ischemic damage (Alexander, 1993; Cox, 1999; Belin, 1999). This may be seen on an MRI as transient findings of multiple small areas of hyperintensity. SPECT studies have documented

impairment of flow to certain parts of the brain, consistent with this hypothesis (Belin, 1999). However, such impairment of blood flow has been found to be quite mild.

TREATMENT

Depression, low mood, and anxiety negatively affect disease outcome by affecting compliance with treatment; decreasing physical, social, and mental activity; decreasing motivation; and compounding fatigue. Patients with depression are more likely to report decreased health-related quality of life, increased pain perception, and perception of illness burden. Depression slows recovery from physical illness because of its additive physical effects.

The treatment for depression in SJS is not different from that of depression in patients without medical illness. With respect to the pharmacotherapies, one consideration might be to avoid xerogenic antidepressants. Although most antidepressants have some xerogenic effects, TCAs, paroxetine, and high-dose venlafaxine carry the highest incidence, followed by bupropion and duloxetine. The last two antidepressants might be good choices due to their noradrenergic effects, and a risk-benefit ratio needs to be considered, based on the individual patient's symptoms and their tolerability. Serotonergic antidepressants with superior tolerability such as escitalopram or sertraline might be good first choices.

In cases where cognitive decline has been acute or subacute, progressive, and associated with other physical or neurological symptoms, case reports have reported improvement with corticotherapy, as mentioned above. One study examined the inhibiting effect of hydroxychloroquine on salivary gland cholinesterase and correlated an increase in salivary gland acetylcholine with clinical symptom improvement (Dawson, 2005). Surprisingly, however, there have been no studies examining the effect of cholinesterase inhibitors and other nootropic agents in treating the more common subtle cognitive decline of insidious onset in the absence of other symptoms of active SJS, referred to previously as "brain fog." Intuitively, these agents would seem useful because of their favorable effects on xerostomia and xeroophthalmia, two core symptoms of SJS.

Non-pharmacological intervention may include neuropsychological testing when indicated to document the deficits and explore the potential for cognitive rehabilitation, where strategies for optimizing current brain function can be taught. Physical activity has been associated with increased cerebral blood flow to the brain, including the parts that subserve memory, and it has been shown to be associated with documented improvement in cognitive function (Ratey, 2011). Social activity allows the practice of various cognitive domains such as thoughtful conversation, verbal fluency, comprehension, and cognitive processing. Physical activity and social engagement are also helpful for coexisting anxiety and depression, both of which can affect memory. Exercises such as creative writing, reading, and problem-solving serve to at least maintain brain function. Therefore, patients should be encouraged to keep socially, mentally, and physically active for positive effects on mood, anxiety, and cognitive function.

FIBROMYALGIA

DEFINITION

Fibromyalgia is a syndrome of widespread, diffuse, chronic pain associated with other features such as psychological factors, insomnia, and fatigue, and in which no organic cause for the symptoms can be identified. It affects about 2% of the population, with a female preponderance, and onsets between 30–50 years. The diagnosis has historically been controversial, and although it is gaining more acceptance by the medical community, patients with fibromyalgia still frequently report feeling stigmatized by physicians.

PATHOPHYSIOLOGY

Several factors have been implicated in the pathophysiology of the fibromyalgia syndrome, including (1) genetic factors; (2) altered pain processing at the level of the CNS; (3) altered pain perception at the level of the CNS (the latter two composing the central sensitization hypothesis); (4) viral causes; and (5) psychosocial factors.

Genetic factors are thought to play a role due to observation of familial clustering. First-degree relatives of affected patients are reported to have an eight-fold increase in the risk of expression of the syndrome (Arnold, 2004). Other studies have suggested a link with certain human lymphocyte antigen (HLA) types, (Yunnus, 1999), and others have found variations in genotype of different genes such as the promoter region of the serotonin transporter gene, polymorphisms in the 5HT_{2A} receptor gene, and in the dopamine D₄ gene (Ablin, 2009).

Pain processing has been frequently studied in fibromyalgia. Altered pain processing has been fairly consistently reported. Normally, peripheral nociceptors carrying pain stimuli arrive at the dorsal horn of the spinal cord via two afferent fibers: the small, thinly myelinated A δ fibers and the small, unmyelinated C fibers. Using substance P, they synapse with interneurons that cross to the contralateral side and ascend via the lateral spinothalamic tract. The excitatory neurotransmitter glutamate is also released presynaptically and involved in central pain processing. Descending inhibitory fibers release serotonin at the same synapse before the interneurons cross over and ascend to carry pain signals to the brain. These descending pathways serve to modulate and dampen pain perception before the signal reaches the brain. In patients with chronic pain, both afferent input to the dorsal horn and levels of presynaptic substance P are increased (Bradley, 2009). What is not known is whether this represents cause or effect.

The response to pain in patients with fibromyalgia has been examined using functional MRI. Two major findings have been reported (Gracely, 2002). Firstly, increased signals in pain-responsive cerebral areas with lower pain stimuli were detected compared to controls, suggesting that patients with fibromyalgia have a lower threshold for perceiving pain and greater response to pain. Secondly, in the control groups, some areas of the brain showing increased signals were not active in patients with fibromyalgia. This led to the hypothesis

that these areas may represent reduced activity in the descending inhibitory serotonergic pathways; however, the latter has not been demonstrated. Once again, whether these findings represent the cause of the altered response to pain or the effect of the classic response to pain in fibromyalgia, remains to be determined.

Taken together, the findings of increased central pain processing and increased pain signaling with lower pain stimuli is referred to as “central sensitization.” It is currently the accepted theory accounting for chronic widespread pain in patients with fibromyalgia.

To date, no study has been able to make a direct causal link between viral infection and fibromyalgia. In several cases, patients report a preceding viral infection, but it is thought that this may represent a triggering factor for the expression of symptoms in the context of many other, usually psychosocial, factors, rather than a unifactorial direct cause of the illness. Limited data suggest increased prevalence of fibromyalgia in patients with HIV, HTLV-1, hepatitis B, and hepatitis C infections (Dinerman, 1992; Marquez, 2004; Cruz, 2006; Adak, 2005; Rivera 1007; Buskila, 1997). Even in these cases, associated psychosocial factors are significant and are thought to play an important role in symptom expression.

Psychosocial factors are usually quite prevalent in patients with fibromyalgia, although this history may be not elicited in early assessments. Patients may not be forthcoming about psychosocial factors, as many are aware of stigmatization and already feel rejected by the medical society. By the time they arrive at the liaison psychiatrist's office, they may have undergone various investigations and had some feedback about the diagnosis. Often the diagnosis is not well accepted, and some patients may insist on searching for a single cause. Studies have, however, recorded strong associations between fibromyalgia and a history of abuse, neglect, or a difficult childhood (Walker, 1997a). Fibromyalgia should also raise concern for physical abuse in adulthood, as an association has been demonstrated in one study (Walker, 1997b). Other frequently found external factors include preceding work-related injuries and poor job satisfaction, and a history of preceding motor vehicle accident and/or whiplash injury, although studies have produced mixed results of the prevalence of fibromyalgia in the latter population (Buskila, 1997; Harkness, 2004). Often there is a high incidence of underlying comorbid post-traumatic stress disorder and anxiety in patients with fibromyalgia (Jason, 2002).

Several other factors have been studied, but with limited results, thus their role in fibromyalgia remains unknown. These include levels of ferritin, magnesium, and zinc. The role of oxidative stress might be gaining more popularity.

CLINICAL FEATURES

The 1990 diagnostic criteria from the American College of Rheumatology (Wolfe, 1990) are shown in Box 61.5.

These diagnostic criteria highlight widespread musculoskeletal pain and tenderness, affecting both sides of the body, both

**Box 61.5 ACR 1990 DIAGNOSTIC CRITERIA
FOR FIBROMYALGIA**

1. History of widespread pain for at least three months.
 - a. “Widespread pain” means all of the following:
 - i. Pain in the right and left side of the body
 - ii. Pain above and below the waist
 - iii. Pain in the axial skeleton (cervical spine or anterior chest or thoracic spine or low back)
 - b. Low back pain is considered “lower-segment” pain.
2. Pain on digital palpation must be present in at least 11 of 18 specified tender-point sites. Digital palpation should be performed with an approximate force of 4 kg (until the examiner’s nail bed turns white) at approximately 1 kg/second, with the thumb perpendicular to the site. A tender point means that the palpation was described as “painful,” not just “tender.”
 - a. Occiput—at the suboccipital muscle insertions.
 - b. Low cervical—at the anterior aspects of the intertransverse spaces at C5–C7.
 - c. Trapezius—at the midpoint of the upper border.
 - d. Supraspinatus—at origins, above the scapula spine near the medial border.
 - e. Second rib—upper lateral to the second costochondral junction.
 - f. Lateral epicondyle—2 cm distal to the epicondyles.
 - g. Gluteal—in upper outer quadrants of buttocks in anterior fold of muscle.
 - h. Greater trochanter—posterior to the trochanteric prominence.
 - i. Knee—at the medial fat pad proximal to the joint line.

below and above the hips, and including the axial skeleton as the classic features of fibromyalgia. A recent publication by the ACR (Wolfe, 2010) suggests that the tender-point exam may not be necessary for diagnosis, and provides revised preliminary diagnostic criteria for fibromyalgia that include not just chronic widespread pain as in the 1990 criteria, but also associated features that are commonly reported by patients with fibromyalgia, and a severity scale for those symptoms. These symptoms were so consistently prominent that they have come to be appreciated as key features of fibromyalgia. They include sleep disturbance, low energy, and complaints of memory impairment. The symptom severity scale attempts to address complaints of significant functional impairment and reduced quality of life as a result of these symptoms. Numerous general somatic symptoms with a severity scale are also included in the revised preliminary diagnostic criteria of 2010 (Box 61.6).

There are several studies examining the nature of sleep disturbance in fibromyalgia, and the full range has been reported: from difficulty initiating sleep, difficulty maintaining sleep, and early-morning awakening, to unrefreshing

sleep. The most prominent type of sleep disturbance in fibromyalgia is non-restorative sleep. Although the DSM-IV defines this as “self-reported restless, light or poor quality sleep,” the definition used in fibromyalgia studies is sleep that is subjectively unrefreshing regardless of sleep latency, duration, or continuity. Therefore, the 2010 preliminary diagnostic criteria list this symptom as “waking unrefreshed.” Due to lack of consensus on the definition of non-restorative sleep in fibromyalgia studies, there are no reliable estimates of its prevalence. Non-restorative sleep is prevalent in mood and anxiety disorders—34.2% in one study (Taylor, 2005)—which are common comorbidities in fibromyalgia, and is also common in the general population after a stressful event in the absence of a diagnosable psychiatric disorder (Ohayon, 2005).

Many researchers have looked into the relationship between chronic widespread pain and quality of sleep in fibromyalgia. From the available studies, it is generally agreed that poor sleep predicts greater pain the following day, which negatively affects physical functioning and contributes to depression and worsening fatigue. The bidirectionality of the relationship between sleep quality and pain intensity, however, has not been demonstrated in all studies, so changes in pain intensity did not always correlate with changes in sleep quality in the same patient (Affleck, 1996).

A review of polysomnographic studies in patients with fibromyalgia (Spaeth, 2011) indicated that most studies have captured interruptions of slow wave sleep (SWS) by alpha EEG activity, called “alpha intrusions” or “EEG alpha sleep disorder” (16 studies). None of the polysomnographic findings is specific to or pathognomic for fibromyalgia, but the findings are as follows:

1. Alpha intrusions—pronounced EEG alpha activity during SWS (stages III and IV of non-rapid eye movement [REM] sleep)—corresponding to an increased number of arousals from SWS, characteristic of patients with fibromyalgia (16 studies)
2. Delayed sleep onset on EEG (1 study)
3. Reduced SWS and REM sleep (3 studies)
4. Poorer sleep efficiency (1 study)

Studies have documented certain pathophysiological effects of sleep on pain thresholds:

1. Restorative sleep is attributed to SWS. On a review of sleep in fibromyalgia (Spaeth, 2011), several studies have documented reduced pain threshold and induction of widespread musculoskeletal pain and fatigue upon total sleep-deprivation or experimental disruption of SWS, and one study documented reversal of pain with sleep restoration (Onen, 2001).
2. In line with the CNS sensitization hypothesis underlying pain in fibromyalgia, CNS hypersensitivity, as reflected in fibromyalgia patients by multiple somatic complaints and multiple sensitivities such as to sound or light, can be caused by fragmentation of SWS (Yunnus, 2007).

Criteria

All of the following three are met:

1. Widespread pain index (WPI) ≥ 7 and symptom severity (SS) scale score ≥ 5 or WPI 3–6 and SS scale score ≥ 9
2. Symptoms have been present at a similar level for at least three months
3. Absence of another disorder that would otherwise explain the pain

Ascertainment

1. WPI: Record the number of areas from 0–19 in which the patient has had pain over the past week.

Left and right (2 points maximum for each):

Shoulder girdle, Chest
Upper arm, Abdomen
Lower arm, Upper back
Hip (buttock, trochanter), Lower back
Upper leg, Neck
Lower leg, Jaw

2. SS scale score = severity score for the three key associated symptoms + the extent of somatic symptoms; score range = 0–12

3 key associated symptoms:

Fatigue
Waking unrefreshed
Cognitive symptoms

For each of the three symptoms above, indicate the level of severity over the past week using the scale below:

0 = no problem
1 = slight or mild problems, generally mild or intermittent
2 = moderate, considerable problems, often present and/or at a moderate level
3 = severe: pervasive, continuous, life-disturbing problems

Somatic symptoms:

Muscle pain, irritable bowel syndrome, fatigue/tiredness, thinking or remembering problem, muscle weakness, abdominal pain/cramps, numbness/tingling, dizziness, insomnia, depression, constipation, pain in upper abdomen, nausea, nervousness, chest pain, blurred vision, fever, diarrhea, dry mouth, itching wheezing, Raynaud's phenomenon, hives/welts, ringing in ears, vomiting, heartburn, oral ulcer, loss of/change in taste, seizures, dry eyes, shortness of breath, loss of appetite, rash, photosensitivity, hearing difficulties, easy bruising, hair loss, frequent urination, painful urination, and bladder spasms.

*For the somatic symptoms above, indicate whether the patient has:

0 = No symptoms
1 = Few symptoms
2 = A moderate number of symptoms
3 = A great deal of symptoms

*No numerical cut-off for the somatic symptom scale was indicated for determining "few" versus "moderate number" versus "great deal" of symptoms.

3. More than half of the total daily production of growth hormone (GH) occurs at the onset of SWS. Disruption of SWS is associated with decreased production of GH and insulin-like growth factor-1 (IGF-1).

Several studies have documented decreased GH and IGF-1 levels in patients with fibromyalgia (Bennett, 1997; Leal-Cerro, 1999; Yuen, 2007; Cuatrecasas, 2009; Cuatrecasas, 2010). GH and IGF-1 have an important role in the repair of microtrauma to muscle tissue, which occurs with the normal physical strain

on muscle with daily activity. Thus SWS fragmentation has been found to be associated with chronic widespread pain via reduced muscle repair due to low GH and IGF-1 levels in patients with fibromyalgia, coupled with heightened pain sensitivity. Indeed, some studies have demonstrated improvement in pain with GH-replacement therapy (Bennett, 1998; Cuatrecasas, 2007).

The mechanism for alpha intrusions during SWS in patients with fibromyalgia has not been elucidated, but the roles of some of the same neurotransmitters involved in chronic

widespread pain in fibromyalgia, particularly substance P and serotonin, have been studied. Studies in mice have shown increased sleep latency and an increased number of arousals after ventricular administration of substance P (Andersen, 2006). Animal and human studies have shown that decreased serotonin can induce insomnia (Moldofsky, 2009).

It is therefore recommended that assessment of the patient with fibromyalgia should include a detailed sleep history. The ACR, based on the 2010 revised preliminary diagnostic criteria, developed a visual analog scale as a patient-report measure of sleep disturbance, which may also be helpful in assessment. It is important to assess for other disorders associated with sleep disturbance such as mood disorders, periodic limb movement of sleep, sleep apnea, diabetes, and thyroid disorders, to name a few. Currently, there are insufficient data to suggest routine use of a polysomnogram in clinical practice, but it is recommended if a primary sleep abnormality is suspected. Sleep hygiene education, encouragement of physical activity, dietary contributions to sleep disturbance (caffeine, chocolate, cigarettes, alcohol), medication review, and treatment of comorbid disorders (e.g., depression, thyroid disorders) all are essential elements of assessment and management.

A significant proportion of patients with SLE and RA can meet criteria for fibromyalgia even before those diagnoses are made. Several patients will have symptoms of depression, anxiety (especially generalized anxiety disorder and post-traumatic stress disorder [PTSD]), and somatoform disorders (especially somatization disorder or undifferentiated somatoform disorder). Depending on how the diagnosis is presented, patients can be amenable to treatment by a psychiatrist for the underlying comorbid psychiatric disorders

and associated psychosocial factors, and they may be receptive to taking antidepressants for helping with complaints of pain, sleep, and fatigue as well. Patients may be guarded about sharing their psychosocial history for fear of stigmatization. When job-related or legal factors are foremost, it can complicate case management, and features of malingering should be ruled out.

TREATMENT

Several systematic reviews have recently been undertaken, and some consensus has been reached on treatment recommendations for fibromyalgia (Garcia Campayo et al., 2010). Table 61.3 summarizes its pharmacological treatment, and Table 61.4 summarizes its non-pharmacological treatment.

Based on the proposed pathophysiological theories and the availability of evidence to support or refute them, antivirals, immunosuppressants, and steroid therapy have no role in the treatment of fibromyalgia to date. The aim of pharmacotherapy is control of the core and associated major symptoms, with a goal of improvement in quality of life and restoration of optimal function. The core symptoms that are the targets of pharmacotherapy are pain, sleep disturbance, fatigue, and depression. There is no specific treatment that is approved by the United States Food and Drug Administration (FDA) or the European Medicines Agency for the associated sleep disturbance, but several agents, including amitriptyline, gabapentin, and cyclobenzaprine, have been used off-label with reported benefit in sleep and pain, and trazodone has been used with reported benefit in sleep (Spaeth, 2011). Benzodiazepines carry a risk of tolerance with long-term use and are not associated

Table 61.3 PHARMACOLOGICAL TREATMENT OF FIBROMYALGIA

DRUG	AVAILABLE INFORMATION	RECOMMENDATION
Pregabalin	First medication FDA-approved for fibromyalgia; acts on VGCC in CNS; multiple robust studies (Mease, 2008) show reduction in pain, fatigue, sleep, and QOL; long-term studies (6 months) show efficacy; side effects include dizziness, somnolence, weight gain, and edema. Systematic review (Choy, 2011) confirms its therapeutic efficacy	Pregabalin is efficacious in the treatment of fibromyalgia and has shown improvement in pain, sleep, fatigue, and QOL; also indicated for hyperalgesia
Duloxetine	SNRI; systematic reviews (Choy, 2011) reveal several robust studies and confirm its therapeutic efficacy by measuring pain reduction and reduction in FIQ scores	Duloxetine 60–120 mg/day is the antidepressant of choice in the treatment of fibromyalgia for pain and depression
Milnacipran	SNRI (Europe and USA); studies show improvement in pain, fatigue, cognition, and FIQ scores both in short- and long-term (12 months) studies; well tolerated; headache and nausea are most common side effects (Mease, 2009; Branco, 2010); systematic review (Choy, 2011) confirms its therapeutic efficacy	Milnacipran is efficacious for the treatment of fibromyalgia without depression; it is not approved for the treatment of depression in the USA
SSRIs	increase serotonin at synapse) found helpful for pain regardless of depression (Goldenberg, 1996; Arnold, 2002); efficacy of fluoxetine + amitriptyline > amitriptyline = fluoxetine (Goldenberg, 1996); recent meta-analysis showed 2 out of 2 RCS with citalopram with negative results (Campayo, 2010)	Should be used for depression +/- pain after trying an SNRI; may be combined with a low-dose TCA; avoid citalopram

(continued)

Table 61.3 (CONTINUED)

DRUG	AVAILABLE INFORMATION	RECOMMENDATION
TCAs	Initial drug studied for fibromyalgia; increases levels of serotonin and norepinephrine; limited robust clinical data show short-term improvement in sleep, but long-term studies demonstrate limited efficacy; nortriptyline has the best side effect profile	Low-dose amitriptyline (25 mg – 50 mg) or nortriptyline may improve sleep, pain, fatigue, and QOL; high antidepressant dose limited by tolerability
Cyclobenzaprine	Skeletal muscle relaxant; similar pharmacological properties to TCAs; short-term studies show improvement in pain and fatigue; long-term studies showed no difference from placebo (Carette, 1994)	May be considered as a treatment option for pain in the short term
Gabapentin	Affects VGCC like pregabalin; studies show improvement in pain, sleep, and FIQ score; side effects include dizziness, lightheadedness, and sedation (Saxena & Solitar, 2010)	May be considered as a treatment option for pain in fibromyalgia; indicated in hyperalgesia
Sodium Oxybate	One open-label trial for narcolepsy suggested it was helpful; Three 8-week RCS showed improvement in FIQ score, pain and sleep (Russel, 2009; Saxena, 2010; Moldofsky, 2010)	May be considered as a treatment option for pain and sleep in fibromyalgia
Opiates	There is no evidence to inform the use of short- or long-term use but they are frequently prescribed. Some studies with limitations support use of the dual-action opiate, tramadol, a mu opioid agonist and SNRI (Saxena & Solitar, 2010)	No evidence to inform short- or long-term use. Dual-action tramadol may be considered for pain
NSAIDs and acetaminophen	Commonly prescribed; limited evidence for its use	Should not be prescribed unless other associated diseases justify their use
Oral steroids	One double-blind crossover trial of prednisone versus placebo showed no efficacy (Clark, 1985)	Not recommended
Nabilone	One RCS showed no change in tender points, but improvement in FIQ score, pain, and anxiety was reported (Skrabek, 2008)	Experimental; expert opinion and consensus reports recommend against experimental therapies
Naltrexone	One pilot study of 10 patients reported it was helpful (Younger, 2009)	Experimental; expert opinion and consensus reports recommend against experimental therapies

FDA: Food and Drug Administration; VGCC: voltage-gated calcium channels; QOL: quality of life; FIQ: fibromyalgia impact questionnaire; RCS: randomized controlled study; CNS: central nervous system

with specific benefit on sleep or pain. Zolpidem and zopiclone may lead to subjective reports of improvement in sleep and daytime fatigue but have no effect on pain and no demonstrated impact on the sleep architecture. Currently, pharmacotherapy in fibromyalgia is targeted at pain control via counteraction of central pain processing. The putative mechanism of pharmacotherapy in fibromyalgia, therefore, is by altering the levels of the implicated neurotransmitters; for example, pregabalin inhibiting presynaptic release of substance P and glutamate, and duloxetine and milnacipram, which are SNRIs (Rao, 2009; Hauser, et al., 2008). Duloxetine, milnacipram, and pregabalin, which are all FDA-approved for fibromyalgia, also have beneficial effects on fatigue and quality of sleep as well, but with inconsistent reports on associated changes in sleep architecture (Chalon, 2005; Kluge, 2007; Lemoine, 2004; Hindmarch, 2005).

Complementary and Alternative Medicine Treatments

The use of complementary and alternative medicine (CAM) is very common in fibromyalgia, with one study reporting up to 50% of fibromyalgia patients using some form of CAM therapy (Wahner-Roedler, 2005). Several studies have reported on various CAM modalities. These studies include clinical trials, reviews, and systematic reviews. Many of the studies on CAM therapy focus on just one or a few modalities, have variable response indicators, use different scales for the same outcome measures, use different criteria for diagnosis of fibromyalgia, and include mixed chronic pain populations, with several diagnoses other than fibromyalgia. The most recent systematic review on CAM in fibromyalgia (Terhorst et al., 2011) included only randomized control trials (RCTs) comparing CAM therapy to a control group, in patients with fibromyalgia only (as diagnosed by ACR 1990,

Table 61.4 NON-PHARMACOLOGICAL TREATMENT OF FIBROMYALGIA

INTERVENTION	AVAILABLE INFORMATION	RECOMMENDATION
Education	Meta-analysis and systematic reviews demonstrate increase in self-efficacy, reduced catastrophization, enhancement of QOL (Hauser, 2008)	Provide education about the diagnosis, course, and treatment; encourage patients to actively participate in their treatment
Cognitive Behavioral Therapy	Systematic review and meta-analysis of RCSs shows improvement in coping with pain, reduction of depression, reduction of healthcare-seeking behavior (Bernardy, 2010); Reduces catastrophization, which helps prognosis (Campayo, 2010)	CBT should be used in depressed patients with high levels of catastrophization
Exercise	Well-conducted meta-analysis and several systematic reviews show improvement in sense of well-being, physical performance, and pain (Busch, 2007) 1. Aerobic exercise (weight-bearing such as walking or dancing, and non-weight-bearing such as swimming or biking) 2. Muscle-strengthening exercises (weights or resistance training) 3. Stretching and flexibility exercises have been studied; the best evidence exists for aerobic exercise (Campayo, 2010)	Physical exercise should be one of the most basic treatments; prescribe or refer to supervised exercise program involving weight-bearing (walking) or non-weight-bearing (biking) aerobic activity

QOL: Quality of life; CBT—Cognitive Behavioral Therapy

Yunus, or Smythe criteria), with the specific outcome being the effect on pain, as measured by the Visual Analog Scale, the Fibromyalgia Impact Questionnaire (FIQ), and the McGill Pain Questionnaire. This systematic review also included every type of CAM modality published that met the inclusion criteria. The rating of the RCTs in this systematic review was as follows:

- Good: 4–5 points
- Moderate: 3 points
- Low: 2 points
- Very Low: 0–1 point

Points were awarded as follows:

- One point each was received for (1) specific mention of randomization, (2) single-blinding, (3) intent-to-treat analysis for missing data/attrition, (4) appropriate data analysis for outcome measures, and (5) “other,” i.e., no other methodological concerns.
- No point was allotted if (1) randomization was mentioned but without specific details, (2) blinding was not mentioned at all, (3) there was minimal attrition and brief mention only about missing data, (4) there was a minor flaw in methodology.
- One point each was subtracted for (1) randomization in the title, but not addressed at all in the manuscript, (2) large attrition rates without accounting for missing data, (3) concerns with thoroughness or adequacy of the results, (4) a

major flaw in methodology (e.g., use of prescription pain medication in conjunction with CAM therapy).

A summary of the data from this systematic review is shown in Table 61.5. It yielded findings compatible with previous systematic reviews (Baranowsky, 2009; Schneider, 2009), although not all forms of CAM modalities were reviewed in the latter studies.

The various forms of CAM therapies are as follows:

1. Hydrotherapy
 - a. Balneotherapy—also known as spa therapy, medical hydrology, or thermal therapy—this refers to any type of bath including mineral baths and mud baths.
 - b. Thalassotherapy—refers specifically to salt water baths versus pool water; a recent RCT on thalassotherapy examined the effect of underwater exercise in salt water versus pool water, but no significant difference in pain was found between groups (de Andrade, 2008), using the FIQ and number of tender points as outcome measures.
2. Massage Therapy
 - a. Manipulative—includes osteopathic and chiropractic.
3. Vibration Therapy—this method involves use of a motor, such as in a vibration table, to apply a high-frequency vibration to the whole body or parts of the body.
4. Magnetic Therapy—this involves creation of an electromagnetic field around the person, such as via use of a magnetic pad.

5. Homeopathic/Nutritional Supplements—Homeopathic remedies include the use of highly diluted derivatives of animal, plant, mineral, or synthetic sources. Popular examples of such remedies used in fibromyalgia include *Rhus toxicodendron* (derived from poison ivy), *Lachesis muta* (derived from snake venom), opium, *Arnica montana* (a yellow flowering plant) and *Byronia alba* (a vine from the cucumber family). Nutritional supplements involve the use of several oral or topical compounds. Some of the more commonly utilized ones in fibromyalgia, and those that have been studied, include *Chlorella pyrenoidosa*, S-adenosyl methionine, Myer's cocktail, soy, anthocyanidins, and capsaicin.
6. Mind/Body Therapy—this includes techniques such as meditation, guided imagery, hypnosis, affective self-awareness, and biofeedback.

RHEUMATOLOGICAL MEDICATIONS AND THEIR NEUROPSYCHIATRIC EFFECTS

Medications used to treat the rheumatic diseases can be categorized as follows:

1. NSAIDs—indomethacin, ibuprofen, celecoxib, diclofenac
2. Acetaminophen
3. Opioid analgesics
4. Corticosteroids—prednisone, methylprednisolone
5. Sulfasalazine (5-aminosalicylic acid)

Table 61.5 COMPLEMENTARY AND ALTERNATIVE MEDICINE IN THE TREATMENT OF PAIN IN FIBROMYALGIA

CAM MODALITY	AVAILABLE DATA	CONCLUSION FROM AVAILABLE DATA
HYDROTHERAPIES:		
Balneotherapy	11 RCTS, only 8 with sufficient data to calculate effect size. 8/8 studies with mean effect size favoring the treatment group, but only 3/8 statistically significant. Of those 3 studies, 2 were Good quality ($N = 69$ and 16), although one combined balneotherapy with massage, and one Moderate quality ($N = 40$).	Positive effect based on available data, but paucity of good-quality data; underpowered studies. More studies needed to make a recommendation
Thalassotherapy	One RCT of moderate quality evaluating a combination of thalassotherapy, patient education and exercise on pain and FIQ score. It was included as one of the 8 balneotherapy studies above. Study showed no significant difference between treatment ($n = 58$) and control ($n = 76$) groups.	Insufficient evidence to make any recommendations
MASSAGE:	6 RCTs, 5 with sufficient data to calculate effect size, 3/5 with mean effect size favoring treatment group, only 1/3 statistically significant; Low quality, $N = 23$.	Current limited data show that massage therapy was not effective in reducing pain
<i>Manipulative</i>		
Chiropractic	2 RCTs, 2/2 with effect size favoring treatment group, but none statistically significant. Studies were Moderate and Low quality, $N = 10$ and 11	The limited evidence does not support its usefulness for pain
Osteopathic	1 RCT, insufficient data to calculate effect size; Low quality, $N = 6$	
<i>Vibration</i>	2 RCTs, 1 with effect size favoring treatment group, but only when vibration was done in conjunction with exercise, and effects was not statistically significant; Good quality, $N = 11$; second study with effect size strongly favoring control group, effect statistically significant, Moderate quality, $N = 13$	The limited evidence does not support its usefulness for pain
MAGNETIC THERAPIES:	3 RCTs, 1/3 with statistically significant effect size favoring treatment group (Good quality, $N = 25$). It was the only study using pulsed magnetic field rather than magnetic sleep pads	Insufficient evidence to support its usefulness for pain

(continued)

Table 61.5 (CONTINUED)

CAM MODALITY	AVAILABLE DATA	CONCLUSION FROM AVAILABLE DATA
HOMEOPATHIC AND NUTRITIONAL SUPPLEMENTS:	9 RCTs, 3 in homeopathy group (2 Good quality $N = 26, 20$; 1 Low quality, $N = 15$), 6 in nutritional supplements group (3 Good quality, $N = 15, 29, 12$; 2 Moderate quality, $N = 22, 37$; 1 Low quality, $N = 17$). 2/3 homeopathy studies had data to calculate effect size that showed no difference from control group. 5/6 nutritional supplement studies (including S-adenyl methionine, soy, chlorella, Myer's cocktail) with sufficient data to calculate effect size, none separated from placebo	Current data do not support the usefulness of homeopathic treatment and nutritional supplements for pain in fibromyalgia
MIND/BODY:	11 RCTs:	Positive effect based on available data, but paucity of good quality data; underpowered studies. More studies needed to make a recommendation
Biofeedback (EEG, heart-rate variability)	4 RCTs, 3 with effect size favoring treatment group (2 Moderate quality, 1 Low quality, $N = 15, 27, 38$), only 1 statistically significant (Very Low quality, $N = 6$)	
Hypnosis	2 RCTs (Moderate quality and Very Low quality, $N = 15, 20$), 1 with effect size favoring treatment group, but not statistically significant	
Meditation	2 RCTs, only 1 with sufficient data to calculate effect size (Moderate quality, $N = 51$), effect size favored treatment, but not statistically significant	
Guided Imagery	2 RCTs, both Moderate quality, $N = 17, 24$, both with statistically significant effect sizes favoring treatment group	
Affective Self-Awareness	1 RCT, Good quality, $N = 24$, effect size favors treatment, but not statistically significant	
MOVEMENT THERAPIES:	4 RCTs:	Positive effect based on limited data, but paucity of good quality data; underpowered studies. More studies needed to make a recommendation
Qigong	2 RCTs, 1 with effect size favoring treatment group, Low quality study, $N = 29$	
Tai Chi	2 RCTs, 1 with effect size favoring treatment group, Good quality study, $N = 30$	
ENERGY MEDICINE:	2 RCTs:	Limited evidence does not support the usefulness of energy medicine for pain in fibromyalgia
Reiki	1 RCT, Moderate quality, $N = 23$, no difference from sham Reiki	
Therapeutic Touch	1 RCT, Moderate quality, $N = 21$, no difference from placebo	
ACUPUNCTURE:	7 RCTs, 6 with sufficient data to calculate effect size. 4/6 with effect size favoring treatment, 3/4 statistically significant	Limited data show modest effect on pain; insufficient data to make recommendation. More studies needed
MISCELLANEOUS:		Inconclusive due to low-quality studies with insufficient data
Essential Oils	1 RCT, Low quality, $N = 65$, insufficient data to make calculations on effect size	
Wool Clothing	1 RCT, Low quality, $N = 25$, insufficient data to make calculations on effect size	
6. Disease-modifying anti-rheumatic drugs (DMARDs)		
a. Antimalarials—hydroxychloroquine		i. TNF-alpha blockers—etanercept, adalimumab, infliximab
b. Cytotoxics—mycophenolatemofetil, azathioprine, cyclophosphamide, methotrexate, leflunamide, cyclosporine A		ii. IL-1 blockers—anakinra
c. Biological response modifiers		iii. T cell modifiers—abatacept
		iv. CD20+ B cell modifier—rituximab
	Side effects of anti-rheumatic drugs are outlined in Table 61.6. Any of these drugs can cause delirium, but this is considered	

very rare and would be more common in toxicity. Delirium has never been reported with mycophenolatemofetil, or with leflunamide or any of the biological response modifiers, which are novel treatments and have not been in use for very long. There are rare reports (Van Royen, 2005; Pacchiarotti, 2007) of behavioral abnormalities, psychosis, vague mood alterations, and confusion associated with use of some of the cytotoxic drugs, but reports are extremely rare, and causal relationships were not confirmed. They are generally considered to be safe in terms of neuropsychiatric side effects. Cyclosporine A and

corticosteroids are the drugs most commonly associated with neuropsychiatric side effects. Gold and penicillamine have never been associated with any neuropsychiatric side effects, but are essentially obsolete.

Corticosteroids more commonly cause mild symptoms of hypomania, usually insomnia, nervous tension, and irritability. Less commonly, but not too infrequently, this can take on a more severe form, and the patient may present with a maniform psychosis. The incidence of steroid psychosis is similar in the pre- and post-steroid era, at least in the SLE

Table 61.6 NEUROPSYCHIATRIC SIDE EFFECTS OF ANTI-RHEUMATIC DRUGS

ANTI-RHEUMATIC DRUG	NEUROPSYCHIATRIC SIDE EFFECTS
NSAIDs:	Reports of depression, anxiety, psychosis, hostility, delirium, confusion, and poor concentration at high doses
Acetaminophen	None reported
Opioid analgesics	Dependence, abuse, somnolence, apathy, euphoria
[†] Corticosteroids	Depression, mania with psychosis, hypomania, irritability, insomnia, fatigue, cognitive impairment
Sulfasalazine	Uncommon: mild headache and mood alterations (Amos, 1986)
Antimalarials: Hydroxychloroquine	Lower incidence of hallucinations, confusion, anxiety, nightmares compared to its non-hydroxylated form (http://www.ncbi.nlm.nih.gov/pubmed/15235536 ; Ferraro, 2004)
Cytotoxics:	Rare
Mycophenolatemofetil	None reported
Azathioprine	None reported
Cyclophosphamide	None reported
Methotrexate	
Immunosuppressants:	Anxiety
Leflunamide	Neurotoxicity at therapeutic levels (Telarovic, et al 2007; Gijtenbeek et al. (1999)
[*] Cyclosporine A	
Biological Response Modifiers:	None reported

[†]Corticosteroids more commonly cause mild symptoms of hypomania, usually insomnia, nervous tension and irritability. Less commonly, but not too infrequently, this can take on a more severe form and the patient may present with a maniform psychosis. The incidence of steroid psychosis is similar in the pre- and post-steroid era at least in the SLE population. Steroid psychosis is usually associated with high doses of corticosteroids, such as oral prednisone > 60-80 mg /day. Depression is a more common side effect of corticosteroids and studies have found that the course of the depression in long-term corticosteroid treatment is variable, being influenced by many other psychosocial factors (Brown, 2007). Fatigue may occur from secondary adrenal suppression upon corticosteroid taper. Short-term use of corticosteroids cause cognitive dysfunction, usually noticeable and measurable decline in declarative memory without detectable changes in hippocampal volume (Hajek, 2006). Long-term corticosteroid treatment has been found to be associated with non-progressive declarative memory impairment with smaller amygdala volumes (Brown, 2008) and smaller hippocampal volumes. There is little evidence about the reversibility of these neuroanatomical changes upon steroid withdrawal. However, the memory impairment is thought to be non-progressive without risk of dementia (Brown, 2007).

Indirect effect of steroids on mood involve feelings of low self-esteem, hopelessness and social withdrawal due to physical changes such as the classic buffalo hump, abdominal obesity, moon-like facies, alopecia and complications such as a vascular necrosis leading to physical disability and restricted mobility and independence.

Treatment of steroid-induced mood and memory impairment has been studied with acetaminophen (Brown, 2010), lamotrigine and leviteracetam (Brown, 2007), but none showed benefit. In one small placebo-controlled study of 39 patients phenytoin 300 mg /day was found to be helpful in preventing the hypomanic effects of corticosteroids but had no effect on memory (Brown, 2005).

^{*}There have been some reports of neurotoxicity with cyclosporine A. In one report (Palmer, 1991), 3 cases of cyclosporine A neurotoxicity in otherwise non-immuno compromised renal patients were described. One developed dementia, the second, a Guillain-Barré like syndrome with ascending motor neuropathy and the third, a flaccid hemiparesis. In all cases, levels of cyclosporine A were therapeutic.

One study (Meyer, 2002) used PET to determine the mechanism of cyclosporine A neurotoxicity in a 37-year-old patient with intention tremor and progressive psychiatric change (social withdrawal and flat affect) and found elevated blood glucose metabolism in the basal ganglia. The authors suggested that cyclosporine A neurotoxicity was mediated by metabolic abnormalities in the basal ganglia.

Side effects of cyclosporine A, though not rare, are usually mild, such as fine tremor, anxiety and hallucinations. There have been reports of exacerbation of paranoid schizophrenia, Di Nuzzo (2007) and depressive psychosis (Telarovic, 2007). Complex neurological side effects such as motor spinal cord and cerebellar syndromes are rare and more likely to be observed in the immuno compromised patient.

population. Steroid psychosis is usually associated with high doses of corticosteroids, such as oral prednisone >60–80 mg/day. Depression is a more common side effect of corticosteroids, and studies have found that the course of the depression in long-term corticosteroid treatment is variable, being influenced by many other psychosocial factors (Brown, 2007). Fatigue may occur from secondary adrenal suppression upon corticosteroid taper. Short-term use of corticosteroids causes cognitive dysfunction, usually noticeable and measurable decline in declarative memory, without detectable changes in hippocampal volume (Hajek, 2006). Long-term corticosteroid treatment has been found to be associated with non-progressive declarative memory impairment with smaller amygdala volumes (Brown, 2008) and smaller hippocampal volumes. There is little evidence about the reversibility of these neuroanatomical changes upon steroid withdrawal. However, the memory impairment is thought to be non-progressive and without risk of dementia (Brown, 2007).

Indirect effects of steroids on mood involve feelings of low self-esteem, hopelessness, and social withdrawal due to physical changes such as the classic buffalo hump, abdominal obesity, moon-like facies, alopecia, and complications such as avascular necrosis leading to physical disability and restricted mobility and independence.

Treatment of steroid-induced mood and memory impairment has been studied with acetaminophen (Brown, 2010), lamotrigine, and levetiracetam (Brown, 2007), but none showed benefit. In one small placebo-controlled study of 39 patients, phenytoin 300 mg/day was found to be helpful in preventing the hypomanic effects of corticosteroids, but it had no effect on memory (Brown, 2005).

There have been some reports of neurotoxicity with cyclosporine A. In one report (Palmer, 1991), three cases of cyclosporine A neurotoxicity in otherwise non-immunocompromised renal patients were described. One developed dementia; the second, a Guillain-Barré-like syndrome with ascending motor neuropathy; and the third, a flaccid hemiparesis. In all cases, levels of cyclosporine A were therapeutic.

One study (Meyer, 2002) used PET to determine the mechanism of cyclosporin A neurotoxicity in a 37-year-old patient with intention tremor and progressive psychiatric change (social withdrawal and flat affect) and found elevated blood-glucose metabolism in the basal ganglia. The authors suggested that cyclosporine A neurotoxicity was mediated by metabolic abnormalities in the basal ganglia.

Side effects of cyclosporin A, though not rare, are usually mild, such as fine tremor, anxiety, and hallucinations. There have been reports of exacerbation of paranoid schizophrenia (Di Nuzzo, 2007) and depressive psychosis (Telarovic, 2007). Complex neurological side effects such as motor spinal cord and cerebellar syndromes are rare and more likely to be observed in the immunocompromised patient.

CLINICAL PEARLS

- There is known to be a lag time of some years between onset of the first symptom and the eventual diagnosis of

lupus. Often, the significance of previous non-specific symptoms becomes recognized only in retrospect.

- The psychiatrist can screen for SLE by periodically applying diagnostic criteria, applying the SLEDAI (Gladman, 2002; Bombardier, 1992), and by performing investigations including CBC, antibody screen, ANA profile, and urinalysis every three to six months or at the onset of a worsening or new symptom, or if the psychiatric symptoms are atypical.
- Lupus psychosis has a prevalence estimate of 8% of SLE patients. Prevalence rates for the remaining neuropsychiatric syndromes are estimated at less than 1%.
- No single consistent biological marker for NPSLE has yet been found.
- There is insufficient evidence to support the routine use of lumbar puncture for CSF levels of cytokines or autoantibodies as diagnostic tools for NPSLE, or of anti-ribosomal P or anti-NMDA receptor antibodies as a diagnostic tool for lupus psychosis.
- The occurrence of a single generalized seizure in patients with SLE does not necessitate AED treatment and does not necessarily mean that the patient will go on to have a recurrent seizure disorder.
- When NPSLE is suspected, a brain MRI should be done early in the course of illness.
- In the clinical setting, T2-weighted MRI remains the gold standard for assessing NPSLE, with FLAIR enhancing sensitivity and gadolinium enhancement helping to differentiate between acute and chronic lesions.
- SPECT or PET may be done following or in conjunction with MRI to further aid with diagnosis, depending on cost and availability.
- Psychosis, if determined to be due to NPSLE, will usually resolve with treatment of the lupus itself, but often adjunctive psychotropic medication is needed to expedite symptom control.
- The hierarchy of treatment is as follows: oral high-dose prednisone, intravenous methylprednisolone, pulse cyclophosphamide, and rituximab (Trevisani, 2006; Tokunaga, 2007).
- NPSLE syndromes, such as lupus psychosis, are not considered to be necessarily recurrent (Bertsias, 2010). Thus a patient with lupus psychosis does not require long-term antipsychotic treatment.
- Patients with lupus psychosis and their families should be informed that full recovery from psychosis is expected (Pego-Reigosa, 2008).
- Despite the availability of diagnostic criteria for RA, time for evolution of symptoms is required before the diagnosis may actually be captured.

- Since constitutional symptoms may predate joint symptoms and signs, some patients with RA may be misdiagnosed with depression before the defining features of the illness reveal themselves.
- The nervous system is less commonly affected in RA. Psychosis as a consequence of RA is rare.
- CNS effects are controversial and are considered uncommon in Sjögren's syndrome.
- Cognitive impairment can occur at any time during SJS. It has a very insidious onset; it may be chronic, recurrent, and in some cases may spontaneously remit. It is considered very rare that it would deteriorate into progressive memory impairment or dementia.
- The pain of fibromyalgia has been attributed to central sensitization.
- Based on the proposed pathophysiological theories and the availability of evidence to support or refute them, antivirals, immunosuppressants, and steroid therapy have no role in the treatment of fibromyalgia to date.
- The aim of pharmacotherapy in fibromyalgia is control of the core and associated major symptoms with a goal of improvement in quality of life and restoration of optimal function. Those core symptoms are pain, sleep disturbance, fatigue, and depression.

ADDENDUM

Arbuckle, M. R., McClain, M. T., Rubertone, M. V., Scofield, R. H., et al. (2003). Development of autoantibodies before the clinical onset of systemic lupus erythematosus. *New England Journal of Medicine*, 349, 1526–33.

In 115 of 130 patients with SLE (88%), at least one SLE autoantibody tested was present before the diagnosis (up to 9.4 years earlier; mean 3.3 years). Antinuclear antibodies were present in 78% at dilutions of 1:120 or more, anti-double stranded DNA antibodies in 55%, anti-Ro antibodies in 47%, anti-La antibodies in 34%, anti-Sm antibodies in 32%, antinuclear ribonucleoprotein antibodies in 26%, and anti-phospholipid antibodies in 18%. Antinuclear, anti-phospholipid antibodies, anti-Ro, and anti-La antibodies were present earlier than anti-Sm and antinuclear ribonucleoprotein antibodies (a mean of 3.4 years before the diagnosis vs 1.2 before the diagnosis). Anti-double-stranded DNA antibodies, with a mean onset 2.2 years before the diagnosis, were found later than ANA and earlier than ANRNP ab.

Autoantibodies are typically present many years before the diagnosis of SLE. Furthermore, the appearance of autoantibodies in patients with SLE tends to follow a predictable course, with a progressive accumulation of specific autoantibodies before the onset of SLE, while patients are still asymptomatic.

1. Some autoantibodies (antinuclear, anti-Ro, anti-La, and anti-phospholipid ab) usually precede the onset of SLE by many years.
2. Others (anti-Sm and antinuclear rnp ab) typically appear only months before the diagnosis, in the time of typical clinical manifestations.
3. Anti-Sm and anti-double-stranded DNA antibodies do not present before the clinical diagnosis.
4. Anti-Ro, anti-La, anti-phospholipid, and antinuclear antibodies are in fact relatively common in normal persons who never have clinical symptoms of rheumatic disease.
5. Anti-double-stranded DNA, anti-SM, and antinuclear ribonucleoprotein A/B are very rare in normal persons.
6. The presence of antinuclear antibodies at ratios of 1:120 or more, or anti-ro, anti-La, or anti-phospholipid ab appears to increase the risk by a factor of at least 40; however, their presence does not suggest that the onset of clinical illness is imminent.

Crescendo autoimmunity culminating in clinical illness however their presence alone does not suggest that the onset of clinical illness is imminent. Rather, there is crescendo immunity culminating in clinical illness.

DERMATOLOGY

*Joseph A. Locala**Who has the disease is as important as the disease they have.**—Hippocrates*

INTRODUCTION

Erasmus Wilson published the initial writings in psychodermatology in 1867; he discussed nervous influences on skin function for multiple dermatological diseases. Almost a century elapsed before additional articles were published in the field, highlighted by a pivotal monograph on “psychophysiological aspects of skin diseases” by Whitlock in 1976 (Medansky, 1981). Despite a relative upsurge in research and academic literature over the past 25 years, psychodermatology remains a narrow, subspecialty field with a limited group of clinicians dedicated to its practice worldwide.

With many psychiatric disorders, patients suffer internally, but their affliction is outwardly unrecognized. Patients with psychodermatological disorders face amplified stigma when they suffer both mental concerns and skin disease visible to others. They cannot keep their condition private, and others may remain distant due to fear of infection or just an uncertainty about how to react to their appearance. Indeed, some have theorized that the tendency for people without skin disease to avoid contact with the afflicted person results from transient identification and discomfort with this reminder of their own flaws and vulnerability (Walker, 2005; Updike, 1990). Studies have demonstrated increased prevalence of psychiatric morbidity in patients with lesions on exposed areas of the body. In an assessment of dermatology outpatients in Italy, women with skin lesions on their faces and hands had a greater prevalence of psychiatric disorders than patients with lesions elsewhere (Picardi, 2001). Persons with skin disorders may also develop their own avoidance behaviors, along with a diminished body image and lower self-esteem. Elpern (2010) has quite accurately described psychocutaneous disease as “darkness visible.”

It should be no surprise that the mind affects the body in skin disorders and that the skin alters brain function through feedback loops. The skin is a primary organ for communication with the outside world. It serves as a vital barrier of defense for the organism and a crucial feedback mechanism to protect the body against trauma or external insults. As such, the skin is filled with dense afferent and efferent nervous system connections and is a target for stress hormones and immune modulators; its own feedback modifies the release of these chemicals. Disturbances in this delicately balanced system may morph into a myriad of disease states.

Dermatology is a discipline in which psychosomatic issues play a key role in the understanding of the etiology and progression of skin diseases as well as the determination of appropriate treatments. Psychodermatological disorders may be classified into several categories: primary psychiatric disorders associated with cutaneous symptoms; psychosocial factors affecting dermatological diseases, comorbid psychiatric and skin illnesses, and disorders related to medication use. Box 62.1 provides a list of diagnoses in each group.

This chapter will include discussion of selected psychodermatological disorders, review of psychiatric comorbidities, treatment approaches, medication issues, special areas of clinical concern, and, finally, a model for the establishment of a multidisciplinary care team.

PRIMARY PSYCHIATRIC DISORDERS
MANIFESTED BY CUTANEOUS
SYMPTOMS

Patients consult dermatologists with symptoms related to the hair or skin, but systemic disease or emotional illness actually causes or exacerbates many of these symptoms. This section will discuss a collection of skin disorders caused by a primary psychiatric illness; these run the gamut from frank psychosis, to self-inflicted lesions, to addiction and lifestyle choices.

DELUSIONAL PARASITOSIS

Patients with delusional parasitosis (DP), classified in the *Diagnostic & Statistical Manual of Mental Disorders* (DSM-IV) as a form of delusional disorder, somatic type, commonly presenting to dermatologists first because their skin complaints are the only manifestation of their illness. DP has been known by many names; these include: Ekbom's syndrome, parasitophobia, and Morgellons. As highlighted in a recent editorial in the *British Journal of Dermatology*, Freudenmann and Lepping's use of the name “delusional infestation” is more accurate, because patients believe worms, bacteria, parasites, insects, viruses, particles, fibers, and other agents may be responsible for their symptoms (Bewley, 2010).

This disorder is rare, with a prevalence of 80 cases per million people, and a bimodal age distribution with peaks from age 20–30 and over 50. In younger patients, there is an equal sex

**Box 62.1 CATEGORIES OF
PSYCHODERMATOLOGICAL DISORDERS**

Primary psychiatric disorders manifested by cutaneous symptoms or complaints:

- Delusional parasitosis (infestation)
- Trichotillomania
- Body dysmorphic disorder
- Tanning addiction
- Self-inflicted dermatological lesions
- Dermatitis artefacta
- Acne excoriée
- Hypochondriasis and specific phobias
- Obsessive-compulsive disorder and related dermatitis

Psychosocial factors affecting primary cutaneous disorders:

- Psoriasis
- Atopic dermatitis—Eczema
- Acne
- Rosacea
- Chronic urticaria
- Idiopathic pruritus
- Alopecia areata
- Hyperhidrosis
- Herpes

Comorbid psychiatric disorders in patients with skin disorders:

- Depressive disorders
- Anxiety spectrum disorders
- Social phobia
- Post-traumatic stress disorder
- Substance use disorders

Skin diseases caused or exacerbated by psychotropic medication

Psychiatric effects of dermatological medications

Adapted from Locala, J. A. (2009). Current concepts in psychodermatology. *Current Psychiatry Reports*, 11, 211–218.

distribution, but in those over 50, it is three times more prevalent in women (Lyell, 1983). Five to 15% of persons close to patients with DP develop *folie à deux* (shared psychotic disorder) (Trabert, 1999; Wykoff, 1987). A recent study of 54 patients seen at the Mayo Clinic reported a 28% prevalence of shared psychotic disorder; in this group identified over a seven-year period, another striking finding was that 74% had a comorbid psychiatric disorder (depression, 45%; anxiety, 19%; drug dependence and abuse, 19%). Personality disorders were found to be uncommon (Hylwa, 2012). DP may be a primary delusional disorder or a disorder secondary to dementia, medication side effects (such as amantadine in Parkinson's), or drug intoxication or withdrawal (e.g., methamphetamine, cocaine, alcohol, marijuana) (Bewley, 2010).

Patients with DP have a specific fixed, false belief that they are infested with living organisms, and will offer samples of material as evidence of their disease. They commonly present to their physician collections of lint, skin crusts, and other debris, and the “matchbox sign” refers to the frequent use of small containers to carry this material. With the advent of smoking cessation and the disappearance of matchboxes, this author more commonly has seen patients arrive with plastic bags, bottles, and “specimens” taped to pieces of paper.

Symptoms of Morgellons disease closely match those of DP, with a greater emphasis on the extrusion of fibrous materials from the skin, rather than infestation with frank organisms. Morgellons disease was first described by physician Sir Thomas Browne, in a work posthumously published in 1690. It has been known by many names, and its existence as a genuine medical malady has been controversial. The dermatological community has long argued that Morgellons and delusions of parasitosis are one and the same disorder. The Centers for Disease Control (CDC) embarked on an epidemiological investigation in conjunction with Kaiser Permanente Northern California in 2008. After careful evaluation of 113 case subjects with Morgellons, “no single underlying medical condition or infectious source was identified.” Most of the skin lesions were either arthropod bites or chronic excoriations, and fibers from patients’ skin were identified as cellulose from clothing. No evidence was found for mycobacterial or parasitic infection. Furthermore, this population had significant rates of substance use, cognitive disorders, high somatic complaint scores, and greater functional disability, in line with those with major medical problems or significant psychiatric disorders (Pearson, 2012).

Often patients are very resistant to the notion that this problem is psychiatric in origin and will strongly defend their belief in an infectious etiology. Many refuse psychiatric evaluation, or if they attend one appointment, are often non-adherent with medication and follow-up. A useful approach is to target improvement of symptoms and quality of life as the goal of an initial treatment, without attempting to confront the question of the “infestation” directly. (Murase, Wu, & Koo, 2006).

Pimozide, a first-generation neuroleptic, has been a drug of choice for treating DP, potentially because of anti-pruritic action due to its effect on opioid pathways. However, pimozide has a risk for significant side effects, including QTc prolongation and cardiac arrhythmias. Risperidone, olanzapine, aripiprazole, and quetiapine have all shown efficacy in small studies or case reports in treatment of DP (Sandoz, 2008). Freudenmann (2008) reviewed case reports and identified full remission rates of 37% with atypical antipsychotics versus 51% with older antipsychotics (pimozide); the older antipsychotics were clearly associated with greater side effects. When adding both partial and full remission rates, atypical antipsychotics had better results against older agents (75% vs. 65%). Treatment with an atypical antipsychotic from the list above is a reasonable first-line therapy for DP. Some clinicians opt to initiate treatment without clear patient education about antipsychotics, with the hope that they will more readily accept medication. This approach is not advisable; when patients discover this deception, it will greatly erode the physician–patient alliance. A better approach is to inform patients of documented efficacy for this class of medication and instruct them that these medications will help allay the fears, stress, and anxiety associated with their illness.

TRICHOTILLOMANIA

Trichotillomania (TTM) is a disorder characterized by hair-pulling from regions such as the scalp, eyebrows,

eyelashes, face, or pubic regions. Often hair is then chewed and/or ingested. Two specific subtypes of TTM have been identified: “Focused” hair pulling, which is very conscious and similar to compulsive behaviors, and “automatic,” in which patients pull their hair with a decreased attention to their activity. DSM-IV-TR criteria for TTM include: “Recurrent pulling of one’s hair resulting in noticeable hair loss and an increased sense of tension immediately before pulling...pleasure, gratification, or relief when pulling out the hair” (American Psychiatric Association, 2000). TTM tends to emerge in early childhood or adolescence, with average age of onset at 13 years. Later onset has been associated with greater symptom severity and treatment resistance. The bimodal onset and different characteristics lead some to believe there are “phenomenological differences between early and late onset” TTM (Mansueto, 2012). Prevalence rates vary by the criteria used for assessment. Two studies of different populations (student vs. general adult) both found prevalence rates of 0.6% using full DSM-IV-TR criteria. With expansion of those diagnostic criteria to include “clinically significant” hair-pulling and hair-pulling with noticeable hair loss, those rates increase to 1.2–2.5% (Christenson, 1999; Duke, 2009). As many as 57% of adults with TTM have a comorbid psychiatric disorder; most commonly major depressive disorder, other mood disorders, obsessive-compulsive disorder (OCD), or other mood or anxiety disorders (Flessner, 2012; Vythilingum & Stein, 2005).

The diagnostic criteria for TTM, and even use of the term “trichotillomania,” have been recently debated. DSM-V includes a name change to “hair pulling disorder” and modified criteria to read: “Recurrent pulling out of one’s hair resulting in hair loss; the hair-pulling causes clinically significant distress or impairment in social, occupational or other important areas of functioning.” In DSM-IV-TR, it was classified as an impulse-control disorder. It has been argued that TTM could fit into one of three categories: obsessive-compulsive spectrum disorders, impulse-control disorders, or body-focused repetitive behavior disorders (Stein, 2010). As many as 57% of adults with TTM have a comorbid psychiatric disorder, the most common of which are major depression, other mood disorders, OCD, and other anxiety disorders. (Flessner, 2012) This pattern of comorbidity resembles that of patients with other body-focused repetitive behaviors.

A major hurdle in effective treatment is getting the patient’s acknowledgement of a problem and a request for care; many persons in the population with TTM probably never seek clinical assistance. Psychotherapeutic approaches have been demonstrated to be valuable in TTM. Habit-reversal training (HRT) is a cognitive behavioral therapy (CBT) modality that has three stages: (1) Increase the awareness of pulling behaviors, (2) Engage in competing behavior that prevents pulling, and (3) Recruit a social support person to remind patients of their behavior. Stimulus control is a method by which patients identify situations that trigger hair-pulling and work with the therapist to find interventions that modify the setting or actions for pulling behavior. HRT has been combined with dialectical behavioral therapy, stimulus control

therapy, acceptance and commitment therapy; all had favorable response rates (Woods, 2012).

Pharmacologically, there is limited positive evidence to support use of naltrexone, N-acetylcysteine, and olanzapine. Case reports and open-label studies suggest that other serotonin reuptake inhibitors (SSRIs), lithium, bupropion, topiramate, and other antipsychotics (haloperidol, pimozide, risperidone, quetiapine, and aripiprazole) may also be efficacious (Chamberlain, 2012; White, 2011).

EXCORIATION (SKIN-PICKING) DISORDER

Excoriation (skin-picking) disorder in DSM-V, also known as *neurotic excoriation* or *psychogenic excoriation*, or *pathological skin picking* (PSP), is a repetitive, compulsive picking of skin that causes actual damage. With pathological skin-picking (PSP), the patient is conscious of his/her behavior and will readily admit it. Often patients begin to pick or scratch an area due to initial itch or a perceived lesion or skin defect. Repetitive scratching initiates an itch-scratch cycle and perpetuates the behavior. A special form of skin-picking is acne excoriée, in which minimal acne lesions, typically on the face, are manipulated with fingers or sharp instruments to the point of ulcerations or erosions capable of scarring. PSP has similarities to trichotillomania and onchyphagia (nail-biting) and onchotillomania (peeling of the nail and cuticle); some authors consider these to be a group of pathological grooming behaviors. Another view is that PSP has a common etiology with obsessive-compulsive disorder because of similar clinical characteristics and the high comorbidity of OCD, as well as incidence of OCD in first-order relatives (Grant, 2010).

PSP has quite an extensive degree of psychiatric comorbidity, with lifetime rates of DSM-IV axis I diagnoses occurring with a range from 55% to 100%! The most common disorders identified have been major depressive disorder, bipolar disorder, anxiety disorders, OCD, eating disorders, alcohol abuse, and attention-deficit disorder (Odlaug et al., 2012). PSP occurs with TTM with lifetime prevalence of 38.3%, and with compulsive nail-biting, 31.7%. Patients with body dysmorphic disorder have lifetime rates of 44.9% with point prevalence of 36.9% (Odlaug et al., 2012). The significant overlap of disorders and symptoms paints a confusing clinical picture. Probably multiple different etiologies are involved, and with them, different required treatment modalities.

Small trials and case reports have suggested the efficacy of SSRIs, doxepin, aripiprazole, and olanzapine for PSP (Gupta, 2011). In a careful review of available double-blind, open-label studies and case reports, Chamberlain (2012) has identified fluoxetine as likely to be efficacious for PSP, whereas citalopram, escitalopram, fluvoxamine, and lamotrigine (Grant, 2010) had mixed results. With regard to psychotherapy, HRT alone or in conjunction with CBT, ACT alone or with HRT, may benefit persons with chronic skin-picking (Woods, 2012).

DERMATITIS ARTEFACTA

Dermatitis artefacta is a condition in which patients cause self-inflicted skin lesions, often without conscious

awareness. Patients often deny recall of the event that caused lesions and may have dissociative episodes surrounding them. On interview, patients often are vague about symptoms, omit details, and appear emotionally disconnected as they discuss their illness. Dermatitis artefacta would typically be classified as a factitious disorder unless a clear secondary gain can be identified, in which case it would be malingering. Self-inflicted skin lesions may also occur as a symptom of several psychiatric disorders, such as severe personality disorders, dissociative disorders, and post-traumatic stress disorder (PTSD). Lesions are usually located in areas easily within reach and can imitate most forms of actual dermatological diseases. In order to create lesions, persons will bite, stab, apply pressure, create burns (thermal and chemical), introduce infectious material, and also inject covert medications such as heparin and insulin (Harth, 2009). Nielsen (2005) reported a retrospective analysis of 57 dermatitis artefacta patients seen over the course of 20 years in a dermatology department. Female to male ratio was 2.8:1, and median age was 39, with a range from 18 to 60 years. Two-thirds of patients initially denied self-infliction, and only one patient agreed to psychiatric consultation. Eighteen percent were diagnosed with psychiatric disorders. Multiple lesions were present in 88% of patients; the most common lesions were skin ulcers (72%), excoriations (46%), and erythema (30%).

Initial treatment of dermatitis artefacta consists of management of underlying psychiatric disorders with antidepressants or anxiolytics when appropriate. In a similar fashion to management of Munchausen's or factitious disorder, early intervention is crucial to avoid excessive utilization of medical resources and unnecessary or harmful treatments for the patient. Supportive psychotherapy has value, followed by a shift to behavioral, relaxation, and/or psychodynamic therapy when patients are ready to accept mental health intervention.

BODY DYSMORPHIC DISORDER

Body dysmorphic disorder (BDD) is a preoccupation with an imagined defect in appearance, or when an actual abnormality is present, the person's level of concern is excessive. Although classified as a somatoform disorder, BDD most certainly has characteristics of an obsessive-compulsive spectrum disorder as well. BDD affects approximately 1–2% of the American population. In dermatology clinics, incidence ranges from 12–16%, and in cosmetic dermatology offices, 15–46% (Malick, Howard, & Koo, 2008). Patients with BDD may focus on whole-body concerns such as aging, excessive hair, excessive sweating, or muscle mass; or regional concerns like the shape of specific body parts, scars, genitalia, hair-growth patterns, and so on. Approximately one-third of patients pick their skin to “improve” their physical appearance, sometimes using dangerous implements (Thomas, 2005). This author has cared for a patient who developed and sharpened homemade surgical instruments and spent significant periods of time doing intricate dissection of his face in order to remove perceived “small growths.” He described in vivid detail the removal of pieces that sounded like lymphatic

system, subcutaneous fat, and blood vessels. Resultant poor wound healing led to infections, prolonged inpatient hospital stays, and repeated plastic surgery.

Malick and colleagues (2008) have written an excellent summary that outlines the process of screening for psychiatric issues in cosmetic surgery patients. They advocate screening for BDD, narcissistic personality disorder, and histrionic personality disorder, all of which are seen more commonly in cosmetic surgery populations; they also offer sets of diagnostic screening questions for clinical use. Interestingly, cosmetic dermatology patients have not been shown to have higher prevalence of psychotropic drug use compared to medical dermatology patients (18% vs. 17%), although both groups have much higher rates than the general population and a matched non-cosmetic surgery group (Orringer, 2006).

Treatment for BDD consists of psychotherapeutic and pharmacological interventions. SSRIs are effective, with case reports and open-label studies supporting use of fluvoxamine; a placebo-controlled study with fluoxetine (doses 20–80 mg daily) showed 53% response rate (Mackley, 2005). CBT has been proved efficacious; through a 12-week randomized, controlled study, Veale et al. (1996) demonstrated a 50% reduction in symptoms of BDD. Proper management of this disorder needs to address protection of the patient from unnecessary surgery or treatments for minimal or imagined deficits. It is also critical to screen for suicidal ideation or thoughts of self-harm, as patients with BDD are a high-risk group in dermatology.

TANNING ADDICTION

Despite society's increased awareness of the risks of ultraviolet (UV) exposure, such as premature aging and skin cancer, dermatologists continue to struggle with patients who engage in excessive tanning. Indoor tanning among young adults has increased from 1% to 27% between 1988 and 2007 (Robinson, 2008). Along with increased tanning, rates of skin cancer have increased in parallel. One study has shown an eightfold increase in melanoma rates in women under 40 between the years 1970 and 2009, and a fourfold increase for men under 40 (Reed, 2012). Ferrucci et al. (2011) recently reported a 69% increase in risk of early-onset basal cell carcinoma (under age 40) associated in a dose-dependent fashion with years of use of indoor tanning beds. One might hope that a history of skin cancer in the immediate family would dissuade younger persons from tanning; however, 35% of young adults from families at risk for melanoma use tanning beds. Indoor tanning prevalence is highest in young, white females, particularly those aged 18 to 29 (Heckman, 2008). This age group is at significantly higher risk for skin cancer; ten annual tanning visits per year doubles the risk for melanoma in those over 30, but the risk increases eightfold for those under age 30.

Frequent tanners have demonstrated the ability to discriminate between ultraviolet light (UV) versus non-ultraviolet light in a double-blind study, and chose to receive additional UV light 95% of the time. It is speculated that UV light stimulates production of beta-endorphin and acts as reinforcing stimulus for repeated tanning (Feldman, 2004). Naltrexone,

an opioid antagonist, blocks the effect of UV light in frequent tanners and has caused withdrawal symptoms (nausea) (Kaur et al., 2006). Single photon-emission computed tomography (SPECT) identified regional cortical blood flow increases in the dorsal striatum, anterior insula, and medial orbitofrontal cortex, areas believed to be part of the reward circuits, when subjects were exposed to UV light vs. sham light (Harrington, 2012).

The concept that tanning may be a substance-related disorder is supported by the fact that frequent tanners have difficulty controlling their use, persist despite negative consequences, experience tolerance, and withdrawal, and have psychological dependence (Nolan, 2009). Mosher (2010) evaluated university students in the northeastern United States for prevalence of indoor tanning addiction and comorbidity with psychiatric disorders and substance use. Of these, 39.3% met DSM IV-TR criteria, and 36.6% met CAGE substance abuse screening tool criteria for addiction to indoor tanning, and within that group, scores were higher for drug and alcohol use and anxiety (but not depression). Perception of habitual tanning as an addiction may assist dermatologists in the goal of weaning patients. Mosher's data lend credence to the concept that tanning may be an addictive disorder, but also suggest that successful treatment needs to address substance use and anxiety disorders in this population. The obstacle to care is that most patients fail to understand the hazards of tanning or simply ignore them. Greater public education is necessary, and skin cancer prevention efforts that target school-age children would probably be beneficial. A number of localities worldwide and in the United States have set limits on minimum age for indoor tanning or have made it illegal.

PSYCHOSOCIAL FACTORS AFFECTING DERMATOLOGICAL DISORDERS

Emotional factors appear to significantly influence most skin diseases, and the correlation between stressful life events and disease flares is well recognized in dermatology. The skin is a target for stress hormones and immune modulators and also influences release of these mediators. The neuro-immuno-cutaneous-endocrine (NICE) model (O'Sullivan, 1998) explains the interplay between organ systems, neurotransmitters, hormones, and cytokines and the various feedback loops. Tausk (2008) has elegantly outlined the effects of chronic stress on the immune system, particularly with regard to skin diseases. The nervous system maintains a delicate balance between cell-mediated (Th1) and humoral (Th2) immune responses. When subject to acute stress, the hypothalamus is responsible for the release of corticotrophin-releasing hormone (CRH), adrenocorticotrophic hormone (ACTH), noradrenaline (NE), and eventually cortisol, which result in an increase in immunity. Chronic stress may result in a decrease in overall immunity. The skin appears to have its own version of the hypothalamic-pituitary-axis (HPA), which Slominski (2000) called the "skin stress response system" (SSRS). The skin produces CRH, proopiomelanocortin (POMC)-derived neuropeptides,

alpha-melanocyte stimulating hormone, ACTH, and beta-endorphin, and contains active receptors for CRH and POMC-peptides. The SSRS is believed to perform a "stress neutralizing activity" and limits disruptions of internal homeostasis. A similar localized system appears to be active in the hair follicles as well.

Specific sets of cytokines promote cell-mediated immunity, and other cytokines enhance humoral immunity. Cytokines are frequently regulated in cascades, where earlier cytokines serve to increase the production of later cytokines. Proinflammatory cytokines, such as interleukin-1 (IL-1), interleukin-6 (IL-6), and tumor necrosis factor (TNF) augment the immune response to speed elimination of pathogens and resolve inflammatory challenge, whereas anti-inflammatory cytokines, such as IL-4, IL-10, and IL-13, serve to dampen the immune response (Kronfol, 2000). Stress affects regulation of cytokines and may result in overexpression, a condition believed to be linked to a number of dermatological diseases.

Some studies have linked hyperactivity of the HPA and parallel increases in proinflammatory cytokines to the presence of major depression (Maes, 1995). Sickness behaviors (often associated with infection) include increased sleep, decreased appetite, and decreased sex drive; these may also be attributed to effects of the cytokines (Kronfol, 2000). Maes (2012) has recently reinforced the premise that depression and sickness behavior are "Janus-faced responses to shared inflammatory pathways." And yet, antidepressant therapy, despite effective treatment of depression, has failed to demonstrate decreases in proinflammatory cytokines as a class (although SSRIs as a subclass reduced TNF-alpha and IL-6) (Hannestad, 2011).

PSORIASIS

Psoriasis is a chronic, relapsing disease of the skin that affects approximately 2% of the United States population and 1–4% of people worldwide. It is considered to be an immune-mediated disorder with evidence for genetic risk. The clinical picture consists of papulosquamous plaques that are well delineated from surrounding normal skin. Plaques are red or salmon pink in color and are covered by white scales, with common areas of distribution on extensor aspects of elbows and knees, scalp, lumbosacral region, and umbilicus. Psoriasis has a several medical comorbidities, among them psoriatic arthritis (25%) and cardiovascular disease. Triggers for psoriasis flares include physical trauma or pressure (Koebner phenomenon), bacterial or viral infections, steroid withdrawal, and medications (for example, beta-blockers and lithium).

A well-established relationship exists between stress and exacerbations of psoriasis, and the degree of stress due to anticipation of others' perception of the psoriatic lesions is actually the greatest predictor of disability in these patients. Stress has been linked to onset of the initial episode of psoriasis in 44% of patients, and recurrent flares are attributed to stress in up to 80% of patients; patients who self-report high levels of stress are likely to have more severe skin and

joint symptoms (Jafferany, 2007). A study of 1,580 psoriasis patients in 39 Italian dermatology centers revealed minor psychological distress in 46% of patients, and major distress, to the degree of psychopathology, in 11% (Finzi et al., 2007). Both types of distress were more frequent in women, and there was no correlation between degree of psoriasis severity and distress.

Pietrzak (2008) provides an excellent review of the role for overexpression of proinflammatory cytokines, particularly TNF, interleukins, and interferon gamma, in patients with psoriasis, as well as the utility of cytokines/anticytokines for treatment. TNF antagonists are cited as the most commonly used agents. Research has indicated that patients with psoriasis, particularly those whose disease appears stress-responsive, exhibit an altered HPA response to acute social stress, reflected by a diminished cortisol response. One group hypothesizes that the similarities are so “considerable” between depression and psoriasis—namely, elevated proinflammatory cytokines and acute-phase proteins—that both disorders can be considered immunologically mediated, inflammatory states (Filakovic, 2008). The most recent study to address HPA axis function in psoriasis found no significant correlation with neuroendocrine, psychiatric, and immune parameters in a sophisticated design with tracking of a number of hormonal and immune markers (Karanikas, 2009). Further investigation of the psychoneuroimmunology of psoriasis will be an important area for future research.

ATOPIC DERMATITIS

Atopic dermatitis (AD) is a form of eczema that affects between 5% and 30% of children and 2–3% of the adult population, and causes intense pruritus and inflammation, often complicated by excessive scratching. Most cases arise in childhood prior to age five, and AD may develop into a chronic, relapsing disorder. The itch-scratch cycle often results in excoriations, crusting, and areas of thickened skin (lichenification). Approximately half of all patients with AD will develop allergic asthma and/or allergic rhinitis. The severe itching often leads to sleep disturbance for patients, and in the case of children, for caretakers or family members. Thirty percent of patients notice exacerbations of AD with stress. Life-altering events may elicit itching or reduce the itching threshold. No specific personality type has been identified with AD.

Controlled studies have demonstrated that patients with AD are more anxious and depressed (Hashiro, 1997). Depression may worsen the perception of discomfort experienced with itching and also may be a contributor to the poor adherence to therapy often seen in patients with AD. Schmitt and colleagues (2009) utilized a multidisciplinary outpatient database in Germany to investigate the relationship between AD and multiple psychiatric disorders. AD was independently associated with affective disorders, schizophrenia, “neurotic” and stress-related disorders, somatoform disorders, and personality and “behavior disorders.” Patients with stress-exacerbated AD have affected areas of the skin that contain fewer nerve fibers in the epidermis and an increase

in the epidermal fraction of 5-HT_{1A} receptor and serotonin transporter (SERT) immunoreactivity in the involved skin (Lonne-Rahm, 2008). This research led to the hypothesis that changed innervation and modulation of the serotonergic system are implicated in AD and chronic stress, and future therapies targeting serotonin receptors and SERT may be efficacious.

Alternative therapies such as relaxation techniques and CBT, combined with antipruritics, antihistamines, and antidepressants/anxiolytics (when indicated) have the most value in treating this disorder.

ACNE

Acne is a papulopustular disease of the sebaceous glands with formation of comedones and secondary inflammation. Acne affects 90% of adolescents in puberty, but persistent acne (acne tarda) may continue into the fourth decade of life; 12% of adult women and 3% of adult men are affected. A genetic heritability is present, with an influence by androgen activity. The psychological impact of acne is significant, and emergence occurs at a period in life (adolescence and young adulthood) in which self-esteem, body image, and social functions are in stages of critical development. Significant comorbid depression, high stress levels, anxiety, social impairment, suicidality, and diminished quality of life are associated with acne. These factors may partly explain why acne patients are often poorly compliant with treatment regimens.

Gupta and Gupta (1998) cite a 5.6% prevalence of suicidal ideation, approximately double that of the general population. Compared to other skin disorders, the rates of suicidal ideation and depression were only greater in those with severe psoriasis. The highest rates of suicide in dermatology are in adolescent males with a severe form, acne conglobata. Acne is also associated with BDDs and eating disorders.

A topic for debate is the contribution of the acne treatment, isotretinoin, to the development of depression and suicidal thoughts. Hull et al. (2005) reviewed a number of studies, and concluded that both depression and anxiety occur at higher rates in acne patients without drug therapy. This article scrutinized existing treatment-cohort studies and large-scale population studies and concluded that the low number of cases of depression did not suggest a direct drug effect of isotretinoin. Magin et al. drew similar conclusions in a 2005 review of published database articles. Strahan (2006) published a rigorous review of available case reports, adverse drug event reports, prospective studies, and retrospective studies relating to psychiatric adverse events with isotretinoin. The analysis determined that a lack of solid scientific data “limits any conclusion that can be drawn about causal relationship between isotretinoin and psychiatric adverse events.” Retinoids can influence central nervous system (CNS) functioning through effects on neuronal development and influence on transmitter receptors. Retinoids also cause hippocampal suppression, which is a known risk factor for depression (Strahan, 2006). The current consensus would appear to be that no definite conclusions can be made

regarding risks of isotretinoin with regard to psychiatric side effects or suicidality. Patients should be made aware of potential risks and screened for history of mood or psychotic disorders, suicidal ideation, family psychiatric history, and current psychiatric symptoms prior to initiation of therapy and at each visit. The great value of isotretinoin for many patients with severe acne needs to be weighed against risk of a rare, and perhaps preventable, adverse event.

CHRONIC URTICARIA AND IDIOPATHIC PRURITUS

Idiopathic chronic urticaria (ICU) is defined by recurrent short-lived, itchy wheals and swelling of at least six weeks' duration for which no clear physical factor or cause can be identified. ICU is associated with high levels of anxiety and depression and diminished quality of life. Quality of life (QOL) has been correlated with mood symptoms more than with the extent of skin disease (Engin, 2007). Furthermore, patients with ICU and no comorbid axis I or axis II psychiatric disorder had a QOL similar to that of healthy controls (Uguz, 2008).

Idiopathic pruritus is defined as an itch that cannot be explained by an identified medical disorder and without a primary skin eruption. The presence of itching has been associated with psychosocial stressors, a variety of psychiatric conditions, and psychological features such as lack of emotional maturity, anxiety, and high subjective reaction to stress (Kretzmer et al., 2008). A study in hospitalized psychiatric inpatients revealed high incidence of idiopathic pruritus in 100 subjects (42% overall, 34% of men, 58% of women) and demonstrated higher levels in those without adequate social support and among those without regular employment (Karanikas, 2009). A total of 76% of regular opioid users experienced pruritus. Those treated with tricyclic antidepressants had much lower rates (14%) as opposed to those treated with other antidepressants (48%).

ALOPECIA AREATA

Alopecia areata is an abrupt loss of hair from round or oval patches, typically involving the scalp. Hair loss may occur in other regions, and a patient may present with loss of all scalp hair or all body hair.

Alopecia areata (AA) is presumed to be an autoimmune disease in which T-lymphocytes excrete cytokines that inhibit hair growth at the follicle (Willemssen, 2008). AA occurs in approximately 0.1–0.2% of the population. Up to 10% of patients will experience progression of hair loss, but for the majority, hair grows back after several months. AA has been linked to stressful life events (in the preceding 6 months to a year), higher anxiety and stress levels, alexithymia, avoidance of intimate or attached relationships, and poor social support (Willemssen, 2008). Significant percentages of patients with AA have psychiatric comorbidity. Koo et al. (1994) found rates of major depression, generalized anxiety disorder, social phobia, and paranoid disorders to be higher with AA patients than in the general population. A more recent study found a 66% rate of psychiatric comorbidity in persons with AA;

diagnoses were primarily adjustment disorder, depression, and anxiety (Ruiz Doblado, 2003).

COMORBID PSYCHIATRIC DISORDERS IN PATIENTS WITH SKIN DISEASE

Dermatology patients present with an overall estimated 30% prevalence of comorbid psychiatric and psychological disorders (Gupta, 2003). In outpatients in a dermatology clinic, Picardi et al. (2000) identified psychiatric disease in 25% of patients with vitiligo, 26% with psoriasis, 32% with acne, 34% with urticarial, and 35% with alopecia. Psychiatric comorbidities commonly observed in a dermatology practice include: depressive disorders, anxiety spectrum disorders, post-traumatic stress, BDD, and social anxiety. In a consecutively screened sample of 166 patients who presented to dermatology clinics, 24.7% met DSM-IV criteria for OCD. Only 14.6% of these patients had previously been diagnosed with OCD (Demet, 2005). PTSD, as a form of severe stressor, may be associated with exacerbation of psoriasis, AD, AA, and urticaria (Gupta, 2005). Social anxiety may be diagnosed in patients with disfiguring skin diseases, such as psoriasis or acne, particularly when they have received negative attention or ridicule earlier in life (Gupta, 2005). Patients with social anxiety or severe OCD may not be diagnosed due to their reluctance to leave home to attend doctor's appointments.

General adult dermatology patients were screened using the Patient Health Questionnaire in the clinic and found to have prevalence rates of 14% for anxiety and depressive disorders, and in the hospital setting had prevalence of 20% diagnosed anxiety and depressive disorders by Structural Clinical Interview for DSM disorders (SCID) (Picardi, 2004). This suggests that a higher acuity of skin disease is associated with more significant rates of psychiatric disorders.

Alexithymia is a personality trait that predisposes a person to have problems differentiating and describing feelings. A recent review of publications on alexithymia and dermatology concluded that alexithymia appears to be associated with AA, AD, psoriasis, vitiligo, and chronic urticaria (Willemssen, 2008). Alexithymia has been linked to changes in sympathetic activity, immunity, and brain activity. Alexithymia rates of 33% were found in a study of psoriasis patients using the Toronto Alexithymia Scale–20, equivalent to prevalence found in other severe chronic medical disease states; the researchers believe that alexithymia is not an acute coping strategy but rather a stable character trait (Richards, 2005). Seventy-five patients with chronic skin disorders, the majority hospitalized on a university dermatology inpatient service, were evaluated for depression, alexithymia, and degree of skin lesions. Significant correlations were found between score on the Toronto Alexithymia Scale, Hamilton Depression Scale, and the extent of skin lesions (Asri, 2008). For individual patients, the presence of alexithymia may give psychotherapists a target for treatment.

By and large, comorbid psychiatric disorders in the dermatology patient are treated with a similar array of antidepressants,

anxiolytics, and antipsychotics as solo psychiatric disorders. Medications specifically identified as advantageous in skin disease are discussed later in this chapter. Use caution to avoid drug–drug interactions with dermatology medications, and observe the potential for exacerbation of underlying dermatological disorders by the psychiatric medications (consult Box 62.2). CBT or biofeedback are frequently recommended for patients with anxiety or depression issues. The majority of patients with stress-induced skin disorders would benefit from relaxation training and exercises. Breathing techniques, yoga, tai chi, relaxation tapes, physical exercise, proper nutrition, and so forth may all help to reduce stress levels. Hypnosis has been found to be of value for a number of disorders. Shenefelt (2000) performed a MEDLINE search and identified that hypnosis or alternative

and complementary treatments were beneficial for patients with AD, psoriasis, AA, rosacea, vitiligo, and hyperhidrosis.

MEDICATION-RELATED ISSUES

SKIN DISEASES CAUSED OR EXACERBATED BY PSYCHOTROPIC MEDICATION

Any psychotropic medication may cause an allergic reaction or drug eruption. A myriad of other skin conditions are caused or exacerbated by psychotropics, as outlined in Box 62.2.

Mood stabilizers, including lithium and anticonvulsants, are the most common causes of dermatological conditions in the realm of psychotropics. Lamotrigine, with dosing precautions necessary to prevent rash and concern about potentially life-threatening Stevens-Johnson syndrome, has received the most attention; however, note that severe skin reactions may occur with *any* of the anticonvulsants. Mood stabilizers have the highest incidence of severe dermatological problems out of all of the psychiatric medications (Warnock, 2003). Lithium causes a variety of skin problems, including exacerbation of psoriasis. Lithium-induced psoriasis typically occurs in the first few years of treatment, resists traditional psoriasis regimens, and resolves after discontinuation of lithium (Krahn, 1994). For patients on an established regimen of lithium with good control of mood symptoms, change of psychotropic medications is not always an option. Wachter (2007) reported successful treatment of a patient with recalcitrant psoriasis and the need to continue lithium for control of his suicidality. He was treated with etanercept 50 mg subcutaneously twice weekly and sustained almost complete remission of psoriatic lesions after 12 weeks (Wachter, 2007).

PSYCHIATRIC DISORDERS SECONDARY TO DERMATOLOGICAL MEDICATIONS

Medications used for dermatological disorders may precipitate mania, depression, psychosis, or acute confusional states (delirium). Steroids, particularly when given above the equivalent of 40 mg oral prednisone daily, may cause anxiety, mania, psychosis, delirium, and depression. The link between interferon-alpha and severe depression has been well documented in the literature, and case reports of mania have been presented from interferon as well. Higher doses used for melanoma patients seem especially prone to causing psychiatric side effects. Rapid identification of these side effects is critical for management, and education of patients in advance of potential psychiatric adverse events will prepare them to report promptly. Selected specific medications and side effects are listed in Box 62.2.

PSYCHOTROPIC MEDICATIONS USED AS A PRIMARY TREATMENT FOR DERMATOLOGICAL CONDITIONS

Antidepressants are often used for treatment of skin disorders in the absence of psychiatric symptomatology. Doxepin actually has higher affinity for histamine receptors than classic

Box 62.2 MEDICATION-RELATED ISSUES IN PSYCHODERMATOLOGY

Skin diseases caused or exacerbated by psychotropic medication:

Anticonvulsants—maculopapular eruptions, alopecia, pruritus, pigmentation, erythema multiforme, Stevens-Johnson syndrome, toxic epidermal necrolysis, exfoliative dermatitis, hyperhidrosis, psoriasis, acne eruptions, seborrheic dermatitis, photosensitivity, drug hypersensitivity syndrome (DRESS), alopecia (valproate)

Lithium—psoriasis, acne, alopecia, folliculitis, urticaria, maculopapular eruptions, drug hypersensitivity vasculitis, seborrheic dermatitis, exfoliative dermatitis

Antipsychotics—photosensitivity (particularly phenothiazines) and changes in pigmentation (particularly thioridazine and chlorpromazine), injection-site reactions with depot meds, acne, exfoliative dermatitis, seborrheic dermatitis (phenothiazines), hyperhidrosis, drug hypersensitivity vasculitis (clozapine), alopecia

Antidepressants—hyperhidrosis, bleeding, photosensitivity/hyperpigmentation with exposure (tricyclic antidepressants), acne, exfoliative dermatitis (TCAs), alopecia

Barbiturates and benzodiazepines—drug hypersensitivity vasculitis, porphyria photosensitivity

Any psychotropic medication—risk for allergic reaction and fixed drug eruption

Psychiatric adverse effects of dermatological medications:

Isotretinoin—depression

Interferon-alpha—depression, suicidal ideation, psychosis, cognitive disorders

UV light therapy—mood changes, hypomania

Methotrexate—mood disorders

Dapsone—psychosis

Immunosuppressants (cyclosporine, etc.)—psychosis, delirium

Antihistamines—delirium, CNS depression

Steroids—mood disorders or psychosis

Adapted from Locala, J. A. (2009). Current concepts in psychodermatology. *Current Psychiatry Reports*, 11, 211–218.

antihistamines. It is commonly used to treat acute pruritus or chronic urticaria when other antihistamines have proven ineffective. The long half-life of doxepin allows it to offer relief for a more prolonged period than medications like diphenhydramine or hydroxyzine (Lee et al., 2008). Dose range for therapeutic effect is highly variable and should be adjusted on an individual basis. Often lower doses are effective for pruritus. Tricyclic antidepressants (TCAs) may be employed in skin conditions associated with acute or chronic pain.

Postherpetic neuralgia is a chronic, painful condition that becomes more common with increasing age and produces a burning, lancinating, or stabbing pain. TCAs have been a primary treatment for postherpetic neuralgia, with amitriptyline as a well-documented agent, in average dosage ranges from 25–75 mg daily (Koo, 2002). For patients who cannot tolerate the side effects of tricyclic antidepressants, serotonin-noradrenaline receptor inhibitors (SNRIs) such as venlafaxine or duloxetine may be considered. Gabapentin, an anticonvulsant, is also useful in treatment of postherpetic pain.

TCAs are effective in any dermatological conditions associated with stinging, chafing, or burning sensations (Szepietowski, 2007). One study evaluated efficacy of bupropion slow release (SR) in ten non-depressed patients with AD and ten with psoriasis. Of these, 60% of subjects with AD and 80% of those with psoriasis showed demonstrable improvement in affected body surface area after six weeks of therapy (3 weeks at 150 mg daily and 3 weeks at 300 mg daily). The average reduction in affected surface area was 50%, and patients returned to pre-study baseline after discontinuation of bupropion (Modell et al., 2002). It has been proposed that bupropion may have anti-TNF properties; additional investigation is required (Kast, 2005).

MEDICATIONS USED IN DERMATOLOGY AS POTENTIAL TREATMENTS FOR PSYCHIATRIC DISORDERS

Psoriasis, fatigue, and depression have been linked to proinflammatory cytokines (such as TNF). Etanercept binds and inhibits TNF and is used for plaque psoriasis and psoriatic and rheumatoid arthritis. Krishnan (2007) demonstrated improvement of depression (measured by the Beck Depression Inventory and Hamilton Depression Inventory) as well as fatigue during an initial 12-week therapy with etanercept vs. placebo; additional improvement was seen in both of these symptoms during a 96-week follow-up, and this improvement was also demonstrated in the arm of the study that crossed over from placebo to active drug. It is unclear whether the antagonism of TNF caused improvement in mood and fatigue directly, or whether this occurred via another mechanism of action.

SPECIAL CLINICAL CONSIDERATIONS IN DERMATOLOGICAL DISEASES

SUICIDALITY

The presence of combined psychiatric and dermatological disorders appears to be associated with higher rates of

suicidality, and every encounter in dermatology warrants careful screening for suicidal thoughts, particularly during periods of acute exacerbation of illness. A study of 217 psoriasis patients with depression revealed 9.7% with a passive death wish and 5.5% with active suicidal ideation (Gupta, 1993). Cotterill and Cunliffe (1997) performed a retrospective review of 16 completed suicides over a 20-year period. The overall age range was 16 to 73 years, but in the seven suicides of acne patients, the mean age was 20.4 (range 16–24 years).

Groups at highest risk were patients with BDD, acne, long-standing and debilitating dermatological disease, and a history of severe comorbid psychiatric illness. Case reports have identified persons with certain dermatological disorders to be at higher risk; namely, those with acne, metastatic tumors (particularly melanoma), progressive scleroderma, and BDD (Harth, 2008). The majority of dermatology patients are not under the care of a psychiatrist. Patients seen in a dermatology office may not feel comfortable broaching the topic of self-harm; they need to be asked routinely about suicidal ideation and referred for additional mental health care as indicated (See Box 62.3).

SUBSTANCE USE DISORDERS

Alcohol, drug, and nicotine screening and abstinence education must be standard components of evaluation of patients with skin disease. Substance use accompanies skin disease to a significant degree and may precipitate the onset or worsen the progression of skin pathology.

Alcohol consumption is a risk factor for development of psoriasis, and patients with excessive alcohol intake have more severe psoriasis and a more distinct distribution of plaques on acral surfaces; they are also more likely to be treatment-resistant. Psoriasis patients who consume alcohol have greater levels of anxiety, depression, and psoriasis-associated disability (Kirby, 2007). Individuals who chronically abuse alcohol also have twice the risk for seborrheic dermatitis and increased risk for nummular eczema, tinea versicolor, hyperpigmentation, skin cancer, oral cancer, glossitis, pruritus, spider telangiectasia, and palmar erythema (Smith, 2000; Rao, 2004). Alcohol also causes flushing and may exacerbate rosacea due to vasodilatation.

Box 62.3 GROUPS AT HIGHEST RISK FOR SUICIDE IN DERMATOLOGY

Severe acne (particularly males)
Metastatic melanoma
Progressive scleroderma
Body dysmorphic disorder
Psoriasis

Harth, W. (2008). Psychosomatic dermatology (psychodermatology). *Journal der Deutschen Dermatologischen Gesellschaft* 1, 67–76.

Cotterill, J., & Cunliffe, W. (1997). Suicide in dermatological patients. *British Journal of Dermatology*, 17, 246–250.

Smoking in general is hazardous to the skin, causing premature aging and acceleration of skin damage from other causes. Alcohol-controlled studies suggest that women who smoke have a 3.3-fold increased risk of developing plaque-type psoriasis. Men do not show the same risk for onset; however, men who smoke more than ten cigarettes per day may have more severe psoriasis expression in the extremities (Behnam, 2005).

Cocaine use is associated with numerous cutaneous manifestations, including multiple vasculitides, palpable purpura, Stevens-Johnson syndrome, infections, and non-descript skin eruptions. Cocaine may also cause formication and psychosis; cases of DP have been attributed to cocaine use (Brewer, 2008). Methamphetamine users also experience formication—"crank bugs" or "meth mites"—and may open skin in an endeavor to remove, see, or feel the nonexistent bugs. Intravenous drug users will develop linear scars along their veins ("track marks") or deep round scars due to "skin popping." Skin infections such as cellulitis, impetigo, abscesses, and necrotizing fasciitis develop with high prevalence secondary to drug injection. Pruritus may occur with cocaine, methamphetamine, and opioid use (Liu, 2010). Screening for drug use should be part of the evaluation of any patient with significant dermatological disease; referrals for smoking cessation and substance abuse treatment are an important component for comprehensive care. Skin manifestations of drugs, alcohol, and tobacco may be considered an early warning sign and an opportunity for intervention.

SEXUAL DYSFUNCTION

Issues with sexual dysfunction are a common problem in dermatology patients, but often are not explored on interview or recognized clinically. Sexual dysfunction in both men and women has been described in patients with psoriasis, AD, neurodermatitis, and vitiligo (Ermercan, 2006; Mercan, 2008; Sukan, 2007). Many factors may play a role in sexual issues: body image, confidence, mood, or anxiety disorders and relationship strain due to chronic illness. Diseases with disfigurement may have a greater effect on patients' social, relational, and sexual lives. Much of the research thus far into sexual function has been in psoriasis. Physical discomfort such as itching, burning, and bleeding may disrupt intimacy; lesions in genital areas have been identified as particularly linked to high sexual distress and worsened quality of life (Meeuwis, 2011). Some authors have speculated that depression may be the primary cause for sexual dysfunction in psoriasis (Mercan, 2008). Other studies have demonstrated no effect of depression on sexual dysfunction in psoriasis patients (Ermercan, 2006). Sampogna et al. (2007) identified the combination of psoriasis severity and psychological factors as contributory to sexual impairment.

Ruiz-Villaverde (2011), in a pilot study, determined that treatment of psoriasis for a period of six months with biological agents (etanercept and adalimumab) significantly improved sexual function for both men and women as measured by the International Index of Erectile Function and

Female Sexual Function Index, respectively. Patients with depression and alcohol abuse were excluded from the study. If these data extrapolate to a larger population, it would imply that the sexual dysfunction is significantly related to the physical issues in psoriasis patients.

Sexual dysfunction is most likely to be identified by a specific, structured survey. Quality of life surveys and general health surveys may ask basic questions about sexuality, but gender-specific, sexual function questionnaires are necessary. Ermercan (2009) has proposed that the Female Sexual Function Index (FSFI) be used to screen for sexual dysfunction in females and the International Index of Erectile Function (IIEF) be used for males. Clinicians are not always diligent in asking patients about their sex life, and patients are not apt to spontaneously offer that history. It is critical for caregivers to discuss the impact of dermatological disease on sexual function with their patients.

ITCHING

Regardless of etiology for a specific skin disorder, the battle to combat itching is omnipresent. Itching, or pruritus, is an unpleasant sensation that leads a person to want to scratch, and this is commonly cited as a factor in reduced quality of life, disturbed sleep, inattention, diminished sexual function, and incidence of psychiatric comorbidity in chronic skin disorders. Itching can be a particularly challenging problem to treat and may require multiple trials of medications due to high rates of therapeutic failure. It has been demonstrated that depression appears to worsen pruritus perception, with resultant increased pruritus score in patients with AD, psoriasis, and chronic idiopathic urticaria (Gupta, 1994). This may explain the efficacy seen in treatment of pruritus with antidepressants, even those with less antihistaminic effect. Topical therapies are employed for localized, mild areas of pruritus. For moderate or severe itching and that which covers larger areas of the body, systemic therapy is the choice. Patel (2010) has written a nice review of the management of pruritus that is summarized in Box 62.4.

Use of systemic antihistamines can be approached in a stepwise fashion. First, attempt to obtain relief from non-sedating antihistamines, such as cetirizine, loratidine, and fexofenadine; progress as needed to sedating antihistamines, such as hydroxyzine, diphenhydramine, and clemastine. Finally, advance to psychotropics such as promethazine or doxepin. Phototherapy may also assist in management of severe pruritus (Harth, 2009).

CLINIC MODELS FOR TREATMENT OF THE PATIENT WITH PSYCHIATRIC AND DERMATOLOGICAL ISSUES

Optimal care of the dermatology patient should include careful screening for psychiatric issues and the mechanism for referral either to external mental health providers or to an on-site psychiatric liaison. The best model for care delivery consists of an interdisciplinary clinic in which

Box 62.4 TREATMENTS FOR PRURITUS

Topical preparations:

Barrier cream and moisturizers
Topical calcineurin inhibitors
Doxepin cream
Menthol cream or lotion
Capsaicin cream
Salicylic acid
Local anesthetics

Systemic therapies:

Antihistamines
Antidepressants (SNRIs or SSRIs)
Mu-opioid receptor agonists
Gabapentin
Immunosuppressants (cyclosporine or azathioprine)

patients meet providers from multiple specialties as part of a treatment team, thus reducing the stigma associated with emotional issues. At University Hospitals Case Medical Center, we launched the first interdisciplinary psoriasis clinic in the country, the Murdough Family Center for Psoriasis (Locala, 2009). This clinic provides comprehensive, disease-specific care with a team of dermatologists, psychiatrists, rheumatologist, nutritionists, and nurses. Patients who were previously reluctant to accept psychiatric referral much more readily agreed when the psychiatrist accompanied the dermatologist into the exam room. Patients complete a comprehensive questionnaire prior to their appointment, which includes basic questions regarding emotional coping, psychiatric symptoms, and mental health history. Taken in the context of a request for information about general medical history, the psychiatric review of systems is elicited in a non-threatening fashion. A targeted or comprehensive psychiatric assessment is

Table 62.1 TOP REASONS FOR REFERRAL

PSYCHIATRY TO DERMATOLOGY	DERMATOLOGY TO PSYCHIATRY
Drug-related rash	Delusion of parasitosis
Acne	Neurotic excoriation
Psoriasis	Trichotillomania
Atopic dermatitis	Depression associated with skin disease
Alopecia areata	Skin-related obsessive-compulsive behaviors

Jafferany, M., Stoep, A., Dumitrescu, et al. (2010). The knowledge, awareness, and practice patterns of dermatologists toward psychocutaneous disorders: Results of a survey study. *International Journal of Dermatology*, 49, 784–789.

Jafferany, M., Stoep, A., Dumitrescu, et al. (2010). Psychocutaneous disorders: A survey study of psychiatrists' awareness and treatment patterns. *Southern Medical Journal*, 103, 1199–1203.

performed in the exam room, and treatment initiated as part of the treatment team plan. We recently established a “virtual” psychodermatology clinic for referrals of patients with other skin disorders. Appointments in the psychiatry clinic (in a different building) are reserved for last-minute dermatology referrals, and dermatologists can readily access psychiatry during the workday for curbside consultation and recommendations. This approach has been an effective means of collaborative care at times when a multidisciplinary clinic model is not practical (see Table 62.1).

CONCLUSION

It is critical to identify psychiatric comorbidity and psychosocial factors in patients with dermatological disease. In 2010, Jafferany set out to evaluate the level of awareness of psychocutaneous disorders among practicing psychiatrists and dermatologists via mail-in survey. Both groups concluded that knowledge about diagnosis, treatment, and/or appropriate referrals was lacking. A distinct lack of awareness about resources for patients and families with skin disease was also identified.

Additional education in psychodermatology would be beneficial for both specialties and should ideally be initiated in residency training. Early exposure to the interplay between psychiatric and dermatological diseases would hopefully foster collaborative clinical care and expand interdisciplinary research.

CLINICAL PEARLS

- Risperidone, olanzapine, aripiprazole, and quetiapine have all shown efficacy in small studies or case reports in treatment of delusional parasitosis (Sandoz, 2008). Compared to pimozide, they seem to have fewer side effects.
- The dermatological community has long argued that Morgellons and delusional parasitosis are one and the same disorder.
- Depression, anxiety, and drug dependence and abuse are common comorbid disorders with delusional parasitosis.
- Trichotillomania tends to emerge in early childhood or adolescence, with average age of onset at 13 years; later onset has been associated with greater symptom severity and treatment resistance.
- As many as 57% of adults with trichotillomania have a comorbid psychiatric disorder; the most common are major depression, other mood disorders, OCD, and other anxiety disorders (Flessner, 2012). This pattern of comorbidity resembles that of patients with other body-focused repetitive behaviors.
- Habit-reversal training is a cognitive behavioral therapy modality used for trichotillomania that has three stages: (1) Increase the awareness of pulling behaviors; (2) Engage in competing behavior that prevents pulling;

and (3) Recruit a social support person to remind patients of their behavior.

- Excoriation (skin-picking) disorder has similarities to trichotillomania and onychophagia (nail-biting) and onchotillomania (peeling of nail and cuticle); some authors consider these to be a group of pathological grooming behaviors.
- In a careful review of available double-blind, open-label studies and case reports on pathological skin-picking, Chamberlain (2012) has identified fluoxetine as likely to be efficacious, whereas citalopram, escitalopram, fluvoxamine, and lamotrigene (Grant, 2010) had mixed results.
- The prevalence of indoor tanning is highest in young, white females, particularly those aged 18 to 29 (Heckman, 2008). This age group is at significantly higher risk for skin cancer; ten annual tanning visits per year double the risk for melanoma in those over 30, but the risk increases eightfold for those under age 30.
- Supporting the concept of tanning addiction, it is speculated that UV light stimulates production of beta-endorphin and acts as reinforcing stimulus for repeated tanning (Feldman, 2004).
- The skin appears to have its own version of the hypothalamic-pituitary-axis, which Slominski (2000) calls the “skin stress response system” (SSRS). The skin produces corticotrophin-releasing hormone (CRH), proopiomelanocortin (POMC)-derived neuropeptides, alpha-melanocyte stimulating hormone, ACTH, and beta-endorphin, and contains active receptors for CRH and POMC-peptides.
- Triggers for psoriasis flares include physical trauma or pressure (Koebner phenomenon), bacterial or viral infections, steroid withdrawal, and medications (for example, beta-blockers and lithium).
- Approximately half of all patients with atopic dermatitis will develop allergic asthma and/or allergic rhinitis.
- The highest rates of suicide in dermatology are in adolescent males with a severe form, acne conglobata.
- For the majority with alopecia areata, hair grows back after several months.
- Comorbid psychiatric disorders in the dermatology patient are treated with a similar array of antidepressants, anxiolytics, and antipsychotics as solo psychiatric disorders.
- Lithium-induced psoriasis typically occurs in the first few years of treatment, resists traditional psoriasis regimens, and resolves after discontinuation of lithium (Krahn, 1994).
- Cocaine use is associated with numerous cutaneous manifestations including multiple vasculitides, palpable purpura, Stevens-Johnson syndrome, infections, and nondescript skin eruptions and formication.

HIV AND AIDS

Philip A. Bialer and Joseph Z. Lux

INTRODUCTION

Thirty years and more have now passed since the first case reports of the human immunodeficiency virus (HIV) epidemic. In 1981, the *Morbidity and Mortality Weekly Report* (MMWR) reported the cases of five previously healthy homosexual men in Los Angeles who had developed *Pneumocystis carinii* (now *P. jirovecii*) pneumonia (PCP), a rare pneumonia seen in patients with profound immunodeficiency (Centers for Disease Control [CDC], 1981b). This initial report was soon followed by other published cases of both PCP and the cancer known as Kaposi's sarcoma (KS), an illness not previously seen in healthy men in the United States (CDC, 1981a; Gottlieb et al., 1981; Masur et al., 1981). Soon there were reports of individuals in other groups developing PCP and KS, including people receiving blood transfusions, Haitians, injection drug users, infants of infected mothers, and, eventually, heterosexual partners of infected individuals. Given the nature of the infections and cancer, it was quickly recognized that an epidemic related to some type of immunodeficiency, but with an unknown etiology, was occurring.

Various hypotheses for this immunodeficiency were raised, including environmental exposure, infection, and cancer. Over the next few years, a causative virus was identified, isolated by several groups of scientists and given the name *human immunodeficiency virus* (HIV) (Gallo et al., 1984; Gallo et al., 1983). Patients continued to die, and communities began to be ravaged. Given the uncertainty of transmission and the already existing stigma surrounding some of the groups acquiring the infection, panicked and unsympathetic reactions were not uncommon. People feared that they could acquire the infection from casual contact with HIV-infected persons, and some physicians completely refused to treat patients with the infection. The identification of the virus enabled its further study. Research efforts defined the steps in the life cycle of the virus: attachment, fusion, reverse transcription, integration, and proteolytic cleavage. With increased understanding of the HIV virus, there was hope that a vaccine could be synthesized to prevent new infections.

The first HIV vaccine trials took place in the 1980s, but they were unsuccessful. In 1987, the first antiretroviral medication, azidothymidine (AZT), was shown to be effective against HIV, finally giving cause for optimism. As AZT began to be used, however, patients receiving treatment had

an early increase in their CD4 lymphocyte (CD4) count, followed by what appeared to be drug resistance and drug failure. Several other antiretroviral medications were soon developed, but these showed the same pattern of initial clinical and immunological improvement—then failure. It is now understood that combination antiretroviral treatment with three effective agents is optimal, and the use of one antiretroviral agent or the addition of a single new drug to a previously failing regimen leads to increased HIV drug resistance.

Another clinical milestone was the realization that the incidence of the opportunistic infections associated with HIV such as PCP and *Mycobacterium avium-intracellulare* (MAI) could be reduced with prophylactic antibiotics (CDC, 1989; Nightingale et al., 1993). Since the introduction of AZT, antiretroviral drug development has progressed, and nearly 30 medications (including combination pills) in six classes now exist as therapeutic options for HIV-infected persons. The treatment of HIV has now become largely that of a chronic illness.

EPIDEMIOLOGY

From the onset of the HIV epidemic through 2008, an estimated 617,000 people in the United States have died from AIDS. The CDC estimates that more than one million people in the United States are living with HIV infection, and approximately one-fifth of these are unaware of their HIV-positive status. Despite public health efforts to limit new HIV infections, an estimated 56,300 persons in the United States continue to be newly infected each year. Men who have sex with men (MSM) account for almost half of all people living with HIV, and more than half (53%) of all new infections in the U.S. each year. Individuals infected through heterosexual sex are 28% of the people living with HIV and 31% of those with new infections. Women account for 25% of people living with HIV and 27% of new infections. Injection drug users are 19% of those living with HIV infection and 12% of new HIV infections. African Americans are the most disproportionately affected and account for nearly half of new infections (45%) and nearly half of those living with HIV in the United States. Hispanics/Latinos are also infected at an elevated rate; the infection rate for Hispanic men is more than twice that of white men and Hispanic women acquire infection almost four times more than white women (CDC, 2011).

The HIV epidemic has affected all parts of the world, but particularly sub-Saharan Africa. After the onset of the epidemic in the 1980s, the rate of HIV infection in this region skyrocketed, spread primarily through heterosexual sex and mother-to-child transmission. Average life expectancies in some countries diminished to the mid-40s. For economic reasons, antiretroviral medications were largely unavailable in countries with the highest prevalence of the infection. Further complicating HIV prevention and antiretroviral treatment in Africa were ongoing controversies about the origins of HIV and arguments that HIV infection was not itself the cause of AIDS. Issues related to the rights of women and the women's inability within local cultures to negotiate condom use and safer sex also hampered HIV prevention efforts.

In the 1990s and 2000s, a growing recognition of the devastation that was occurring in other parts of the world led to increased international efforts. Organizations such as the Global Fund and the U.S. President's Emergency Plan for AIDS Relief (PEPFAR) made the global delivery of HIV medications an increasing reality. While these efforts and accomplishments have been significant—some 5 million people internationally are now on antiretroviral drugs (ARVs)—the percentage of people with CD4 counts below 200 who receive ARVs remains limited, and the percentage of those with CD4 counts below 500 receiving ARVs is even smaller (Joint United Nations Programme on HIV/AIDS [UNAIDS], 2010).

The global HIV AIDS epidemic now appears to have stabilized, though much remains to be done. Compared to the peak of the epidemic in the late 1990s, there are fewer new infections and AIDS-related deaths. In 2009, there were an estimated 2.6 million people newly infected with HIV, approximately 20% fewer than at the time of peak incidence of new HIV infection in 1997. In sub-Saharan Africa, an estimated 1.8 million people were newly infected in 2009. In 2008, an estimated 32.8 million people were living with HIV infection worldwide; 52% of them women. An estimated 2.5 million children in 2009 were estimated to be living with HIV infection. (UNAIDS, 2010).

HUMAN IMMUNODEFICIENCY VIRUSES

HIV is now understood to have two variants: HIV-1 and HIV-2. Both variants appear to have originated in West Africa and jumped species from non-human primates: HIV-1 from the chimpanzee and HIV-2 from the sooty mangabey, a monkey found in West Africa (Hahn, Shaw, De Cock, & Sharp, 2000; Keele et al., 2006). The first confirmed cases appear to have occurred in the 1950s, and increased urbanization caused the epidemic to accelerate. HIV-2 is mainly seen in parts of West Africa; it follows a more indolent course than HIV-1 even without ARVs. There are four subtypes of the HIV-1 virus: More than 90% of cases worldwide are from Subtype Group M and other than a handful of cases in Groups N and P, the remainder from Group O, which is mainly limited to west-central Africa.

HIV antibody testing utilizing an enzyme immunoassay (EIA) method was first licensed in the United States in 1985. Successive generations of tests were developed to reduce the time interval between HIV exposure and when HIV testing could detect infection (Perry, Ramskill, Eglin, Barbara, & Parry, 2008). First-generation testing used viral lysate to detect HIV antibodies in a sample of the patient's blood; it had a high false-positive rate so was mainly useful in populations with a high base rate of the disease. Western blot testing was used as a confirmatory tool. Second-generation testing using recombinant HIV antigens was developed, which permitted earlier detection of HIV infection with fewer false positives. Third-generation testing used a "sandwich" technique to detect both Immunoglobulin G (IgG) and Immunoglobulin M (IgM) antibodies, allowing for even earlier detection of HIV infection. In 2010, the FDA approved the first fourth-generation HIV assay which detects IgG and IgM antibodies and as well as p24 viral antigen, reducing the window period sufficiently to pick up to 80% of acute HIV infections that were previously only detectable via HIV RNA assays (Pandori & Branson, 2010). Speeding up the testing process has important implications, as patients may not return for their HIV test results. Current rapid HIV tests can produce preliminary results in as little as one minute, increasing the likelihood that patients will know their HIV status and, if it is positive, receive care. Clinicians should be aware that individuals with acute HIV illness may present with a variety of symptoms, which include a flu-like syndrome, aseptic meningitis, lymphadenopathy, and rash. If there is a high suspicion of acute HIV illness, HIV RNA testing remains indicated.

Current CDC guidelines recommend routine testing of patients in all health care settings for patients age 13–64 years old, and that patients be informed verbally or in writing that they will be tested for HIV unless they decline or "opt out" (Branson et al., 2006). Separate written consent is not recommended by the CDC. The objective is to enhance earlier diagnosis of HIV infection and link patients to care. Patients with acute HIV infection often have extremely high viral loads with increased risk of transmission. Research has shown that most HIV transmission occurs with people who are unaware that they are HIV-positive.

CD4 COUNT

HIV targets CD4 cells resulting in progressive immune dysfunction. Earlier treatment with antiretrovirals may help maintain immune function and prevent the decline of the CD4 count and the emergence of HIV-associated infections and cancers. However, there are reasons to delay treatment with antiretrovirals for a HIV-infected individual, including potential toxicity, issues of drug resistance, uncomfortable side effects from medications, as well as lifestyle adjustments related to the challenges of taking a large numbers of pills. At different times in the epidemic, the recommended CD4

threshold for commencement of antiretroviral therapy for asymptomatic patients has been raised and lowered, based on the available evidence and treatment options. Current U.S. guidelines suggest treatment of all symptomatic patients and asymptomatic patients with CD4 counts less than 500, and consideration of antiretroviral treatment for asymptomatic patients with CD4 counts greater than 500 and treatment of asymptomatic patients at a CD4 count less than or equal to 500 (Department of Health and Human Services [DHHS], 2011a; Thompson et al., 2010). The guidelines further advise that HIV-infected individuals with significant medical conditions, including cardiovascular, hepatic, or renal diseases, and pregnant women, be treated with antiretrovirals at any CD4 count.

VIRAL LOAD

Measurement of the HIV RNA level (viral load) is used as a baseline value for the diagnosis of acute HIV illness, before a patient is treated with ARVs, and it is used to assess the success of ARV therapy. The viral load varies, depending on the point in infection. The viral load of patients with acute HIV infection is often extremely high before settling down to a lower viral set point and generally staying at that level until antiretroviral treatment is begun. The magnitude of this set point is influenced by a number of host and virus factors, and remains a focus of research.

With successful antiretroviral treatment, the CD4 count rises, and the plasma viral load becomes undetectable. Achievement of an undetectable HIV viral load has important implications for health and transmission risk. The sensitivity of assays has increased over time, and the newest assays often measure down to 50 or 20 copies per milliliter (mL) of blood, with some assays even measuring as little as one copy per mL. Despite the ability of successful antiretroviral treatment to lower HIV viral load below 50 copies, continued HIV viremia in the range of 1–50 copies is found in a majority of patients on highly active anti-retroviral therapy (HAART) (Chun et al., 2011). This very low level of HIV plasma viral load generally does not appear to cause viral load rebound and drug failure. However, even low-level viral loads in the range of 1–50 copies may be associated with a chronic inflammatory process that is linked to cardiovascular disease and other signs of accelerated aging (Kuller et al., 2008; Triant, Meigs, & Grinspoon, 2009). Additionally, antiretroviral therapy penetrates poorly into the central nervous system (CNS), and ongoing CNS HIV replication and neurocognitive effects may persist despite viral load suppression in other parts of the body.

Transmission risk is reduced as plasma viral load decreases. Studies have shown that serodiscordant couples with a HIV-positive partner and a high viral load transmit HIV to their HIV-negative partners at a much greater rate as compared to those in which the HIV-positive partner has a low viral load. Although more controversial, some studies looking at the average viral load of a community have found

that new HIV infections decrease as the community viral load is reduced. Mathematical models also support the use of aggressive testing and treatment of HIV-infected persons as HIV prevention (Granich, Gilks, Dye, De Cock, & Williams, 2009). Based on this evidence, a potential prevention strategy is to implement an aggressive “test and treat strategy” in which all adults are offered testing, linked to care, and immediately offered ARV treatment as a means of reducing community viral load and curtailing the HIV epidemic.

HIV AND INFLAMMATION

Contributing to the current emphasis on earlier antiretroviral treatment is a growing recognition that untreated HIV-infected patients, even those with a high CD4 count, suffer ill effects of HIV replication, including immune dysregulation and associated inflammation. The presence of elevated levels of immune markers such as interleukin-6 (IL-6) and C-reactive protein (CRP) (Kuller, et al., 2008) support that patients with ongoing HIV viral replication have an ongoing inflammatory process associated with endothelial inflammation and increased end-organ damage. For instance, comorbid infections such as hepatitis B and hepatic C appear to progress more quickly with accelerated development of cirrhosis and hepatocellular cancer when patients with HIV are not treated with antiretroviral medications (Sulkowski, 2008; Thein, Yi, Dore, & Krahn, 2008; Thio et al., 2002).

HIV LATENCY AND CURE

Studies have shown that, despite suppression of HIV by successful ARV treatment, a small proportion of CD4 cells remain latently infected with the HIV virus, leading to viral load rebound and progression of HIV-associated illness in patients who stop their antiretrovirals (Chun, et al., 2011; Finzi et al., 1999). This HIV reservoir decays very slowly, even for patients treated with combination antiretrovirals for long periods of time, and effectively is never eradicated. A current research focus is on how to safely activate these resting cells so that antiretroviral treatment can eradicate these infected cells without causing excessive systemic immune activation. HIV vaccine efforts have generally been disappointing, with the exception of one modest positive result (Rerks-Ngarm et al., 2009). A case study in Germany, with still unclear implications, has rekindled excitement about a future cure (Allers et al., 2011). In this case, a patient who was HIV-positive for more than ten years developed acute myeloid leukemia and required a bone marrow transplant after relapse following chemotherapy. The patient was transplanted with stem cells from a donor screened for homozygosity for the *CCR5* homozygous deletion (HIV predominantly uses *CCR5* as a co-receptor for entry into CD4 cells). In four years since the transplant occurred, the patient has remained off antiretrovirals, and no sign of active replicating HIV virus has yet been detected.

ANTIRETROVIRALS

There are almost 30 approved antiretroviral medications (including combination pills) in six drug classes: nucleoside/nucleotide reverse transcriptase inhibitors (NRTI), non-nucleoside reverse transcriptase inhibitors (NNRTI), protease inhibitors (PI), CCR5-receptor antagonists, integrase inhibitors, and fusion inhibitors. During the 1990s, a number of large randomized, controlled trials showed that patients on combination antiretroviral therapy did better, with more durable clinical improvement (Hammer et al., 1996; Hammer et al., 1997). The current strategy is to choose a regimen with at least two, and preferably three, potent antiretroviral medications.

The use of these medications is complicated and may have serious adverse effects, and it is recommended that they be used and monitored by experienced HIV clinicians. Side effects of the NRTIs can range from lactic acidosis and lipodystrophy to bone loss, renal failure, and a potentially lethal hypersensitivity reaction. The class of NNRTIs includes delavirdine, nevirapine, efavirenz, etravirine, and rilpivirine. Efavirenz is associated with neuropsychiatric side effects, which generally occur early in treatment and are time-limited. Common side effects of efavirenz may include dizziness, bad dreams, and anxiety, and there have been case reports of severe depression, mania, and psychosis (Arendt, de Nocker, von Giesen, & Nolting, 2007; Tozzi et al., 2007). The protease inhibitors are often co-administered with low doses of the PI ritonavir. Ritonavir, one of the early protease inhibitors, is now rarely used for its antiviral effect, but is used for its drug-boosting effect. It is a potent P450 inhibitor, particularly of 3A4, and many of the protease inhibitors use this isoenzyme pathway. The co-formulation increases the drug levels of the PIs, decreasing the likelihood that resistance will develop and allowing dosing schedules that are less frequent and onerous. The PIs are associated with hyperlipidemia (though less so with atazanavir), and some studies have shown an association with protease inhibitor use and increased cardiovascular events. The CCR5 antagonist maraviroc is the only antiretroviral medication that targets, not the HIV virus, but a human cell receptor. HIV uses either the coreceptor CCR5 or CXCR4 to gain entry into target cells, and maraviroc is a CCR5 antagonist. Most patients with early HIV infection have a virus that preferentially uses a CCR5 co-receptor rather than CXCR4. As HIV infection progresses and CD4 count declines, the HIV virus may mutate to a virus that uses the CXCR4 receptor, and maraviroc is therefore ineffective. A commercially available assay can determine the type of co-receptor used by an individual patient's virus. The integrase inhibitor raltegravir is generally well tolerated, and minimal long-term problems have been identified to date. The fusion inhibitor enfuvirtide, the only injectable antiretroviral, is a twice-daily medication that causes local skin reactions at the injection and is poorly tolerated. It is often used only as an antiretroviral medication of last resort for patients with broad class resistance. For a comprehensive table of currently available

antiretrovirals with dosing recommendations, common side effects, and potential drug interactions, the reader is referred to the AIDS Meds website, http://www.aidsmeds.com/articles/DrugChart_10632.shtml.

It is important to realize that, even in the current antiretroviral era, not every HIV-infected patient receives care or adheres to antiretroviral therapy. Patients may poorly tolerate or decline treatment with ARVs; have active mental illness, cognitive deficits, or substance use complicating adherence; or continue to have limited access to HIV care if living in resource-limited settings.

GENOTYPE AND PHENOTYPE TESTING

Genotype testing is a technique that screens for HIV virus polymorphisms associated with antiretroviral drug resistance. Genotype testing is generally performed before a patient starts on antiretroviral therapy and when a patient on treatment has viral load rebound. Genotype testing usually requires a viral load of about 500–1000 copies/mL for the test to be accurate. Antiretrovirals have different resistance patterns. In some instances, a single mutation, such as the *M184V* mutation with the NRTIs lamivudine and emtricitabine, and the *K103N* mutation with the NNRTIs nevirapine and efavirenz, can render a single medication or multiple medications within a drug class ineffective. By contrast, the newer protease inhibitor medications have a higher resistance barrier and may remain active even with a number of mutations in the protease enzymes. Deciphering a genotype can be complicated, and to aid interpretation, a virtual phenotype, which predicts drug susceptibility based on a resistance pattern databank, can assist clinicians and guide clinical decision making.

A phenotype test may also be ordered for patients with significant treatment experience and complicated genotypes. This entails, not HIV genetic testing, but a more traditional approach of culturing the virus with various antiretrovirals and determining the concentration of drug needed to inhibit HIV virus growth. Whatever test is used, one important consideration is that different HIV subpopulations may coexist in a certain individual—both “wild type” virus and subpopulations of HIV with drug resistance. A genotype or phenotype may not detect a resistant HIV virus subpopulation that is not currently under drug pressure, but will emerge in the presence of antiretroviral therapy.

PRE- AND POST-EXPOSURE PROPHYLAXIS

A major success in combating the HIV epidemic has been the reduction of perinatal HIV transmission. In 1994, the Pediatric Aids Clinical Trial Group (PACTG 076) trial showed a two-thirds reduction in mother-to-infant transmission, from 25.5% in the placebo-treated group to 8.3% in the AZT-treated group (Connor et al., 1994). The use of HIV screening for pregnant women, antiretroviral therapy, elective

Caesarian delivery for women with suboptimal HIV viral suppression, and exclusive bottle-feeding has reduced the rates of vertical transmission to less than 2% in the United States and Europe (DHHS, 2011b).

Sexually transmitted infections (STIs) such as herpes simplex appear to increase HIV transmission. To date, randomized clinical trials using STI treatment as a means of HIV prevention have not generally demonstrated significant results, but further research is ongoing (Padian, McCoy, Balkus, & Wasserheit, 2010). Conversely, clinical trials have shown that circumcision can reduce the HIV acquisition rates of heterosexual men by up to 60% (Auvert et al., 2005; Bailey et al., 2007; Gray et al., 2007). Despite the dramatic reduction of HIV rates in heterosexual men who are circumcised, increasing circumcision rates as a means of reducing HIV risk in endemic regions has been a challenge.

Women may have difficulty negotiating condom use. As a means of addressing this obstacle, numerous trials have looked at the use of non-specific vaginal microbicides, including chemical surfactants, as a means of preventing the acquisition of HIV. The trials have generally been disappointing, but a recent placebo-controlled trial in a high-HIV prevalence area of South Africa was encouraging, and showed that the use of tenofovir intravaginal gel inserted within 12 hours before or after sex reduced HIV acquisition by 54% in “high adherers” and 39% reduction in the overall group (Abdool Karim et al., 2010).

The use of antiretrovirals for occupational post-exposure HIV prophylaxis has reduced HIV transmission rates in the workplace. In the absence of post-exposure antiretroviral prophylaxis, the estimated HIV transmission risk for percutaneous exposure is 0.3%, and after a mucous membrane exposure, 0.09%. Only a handful of cases due to occupational exposure have been reported since the introduction of the first occupational exposure guidelines (Panlilio, Cardo, Grohskopf, Heneine, & Ross, 2005). Antiretroviral post-exposure prophylaxis may also be used for high-risk sexual and injection drug-use exposures with a 28-day course of HAART administered within 72 hours of exposure (Smith et al., 2005).

As antiretrovirals have become more tolerable and less toxic, there has been increasing interest in using ARVs for sexual pre-exposure prophylaxis in high-risk groups. A recent placebo-controlled, double-blind randomized trial involving men who have sex with men (MSM) and transgender women (genetic male) engaging in high-risk behaviors suggested that once-daily prophylactic use of tenofovir and emtricitabine (Truvada) can reduce the likelihood of HIV acquisition (Grant et al., 2010). Enrollment in the treatment arm of the trial provided a 44% reduction in the incidence of HIV acquisition. Based on this single study, the CDC issued interim guidelines on the use of pre-exposure prophylaxis with antiretrovirals (CDC, 2011). The CDC interim guideline suggests that providers might consider use of tenofovir-emtricitabine for high-risk MSM and transgender women in combination with other prevention strategies. It is important to recognize that this

use of antiretrovirals for pre-exposure HIV prophylaxis remains off-label, and the emergence of drug resistance and long-term toxicity remains a real concern. There is emerging, but not unanimous, new evidence that pre-exposure prophylaxis may be also be helpful in reducing HIV infection among high-risk heterosexual men and women, but expert guidelines have not yet been established to guide this antiretroviral indication.

ANTIRETROVIRAL DRUG INTERACTIONS WITH PSYCHOTROPIC MEDICATIONS

The protease inhibitor ritonavir has significant CYP P450 interactions, and is an extremely potent cytochrome 3A4 inhibitor, but it also inhibits the cytochrome isoenzyme 2D6 and induces 2B6, 1A2, and glucuronyl transferase. Benzodiazepines that undergo metabolism through the 3A4 enzyme pathway, notably alprazolam, midazolam, and triazolam (the latter two have absolute contraindications), can have markedly elevated plasma levels with ritonavir use. Many selective serotonin-reuptake inhibitors (SSRIs) and tricyclic antidepressants undergo metabolism through the 2D6 pathway and may require a dose decrease when used with ritonavir. There have been case reports of serotonin syndrome with fluoxetine- and ritonavir-containing regimens due to P450 inhibition with ritonavir (DeSilva et al., 2001). Trazodone plasma levels may be markedly increased through 3A4 inhibition on ritonavir-containing regimens. Drug levels of bupropion may initially be increased when used with ritonavir and also with efavirenz because of an initial 2B6 inhibition that precedes 2B6 induction; in the longer term, bupropion levels may decrease (Park Wyllie & Antoniou, 2003). Most antipsychotics are CYP 2D6 and/or 3A4 substrates and may require a lower dose of, for example, risperidone, perphenazine, and thioridazine, if used with ritonavir-containing regimens; olanzapine is one exception, as its plasma levels are decreased through induction of 1A2. Ritonavir may lower plasma drug levels of the anticonvulsant/mood stabilizers valproic acid and lamotrigine.

Pharmacotherapy for opioid dependence may be affected by the use of antiretroviral therapy. Methadone serum levels may be decreased by the antiretrovirals ritonavir, efavirenz, and nevirapine. Treatment with buprenorphine and atazanavir or atazanavir/ritonavir may increase buprenorphine drug levels and cause sedation, possibly through 3A4 inhibition and phase II metabolism of buprenorphine by atazanavir, requiring a reduction in buprenorphine dose; but a 2007 observational trial suggested the combination can be safely used (Bruce & Altice, 2006; McCance-Katz et al., 2007) (see Table 63.1). Due to the large number of drugs prescribed to patients with HIV/AIDS, we recommend consulting with comprehensive websites such as the University of Liverpool's <http://www.hiv-druginteractions.org/> to check for potential drug interactions when recommending the addition of a psychotropic to the medication regimen.

Table 63.1 PHARMACOKINETIC EFFECTS OF SOME HIV AND PSYCHOTROPIC MEDICATIONS THAT CAN POTENTIALLY LEAD TO DRUG-DRUG INTERACTIONS

PROTEASE INHIBITORS	CYP 3A4 ^a	CYP 2D6 ^b	COMMENTS
Ritonavir	Potent Inhibition Induction	Potent Inhibition	Midazolam, triazolam contraindicated Alprazolam—use with extreme caution Tricyclic antidepressants—blood levels may increase due to inhibition; monitor carefully Clozapine—use with extreme caution Pimozide—contraindicated Methadone—serum levels may decrease Thioridazine—avoid use SSRIs—monitor for increased side effects Trazodone—plasma levels may increase Olanzapine—blood levels may decrease secondary to 1A2 induction Antipsychotics (non-olanzapine)—monitor for increased side effects Valproic acid—plasma levels may decrease; monitor serum levels Lamotrigine—plasma levels may decrease
Amprenavir	Moderate Inhibition		Midazolam, triazolam, alprazolam—use with caution
Indinavir	Moderate Inhibition	Mild Inhibition	Midazolam, triazolam, alprazolam—use with caution
Nelfinavir	Moderate Inhibition	Mild Inhibition	Midazolam, triazolam, alprazolam—use with caution
Atazanavir	Moderate Inhibition		
NNRTIs			
Nevirapine	Induction		Methadone—serum levels may decrease
Efavirenz	Moderate Inhibition Induction		Methadone—serum levels may decrease
Etravirine	Induction		
PSYCHOTROPICS			
Nefazodone	Moderate Inhibition		May cause protease inhibitor levels to increase
Phenytoin Carbamazepine Phenobarbital	Induction		May <i>decrease</i> serum levels of protease inhibitors and lead to viral resistance
St. John's Wort	Induction		May <i>decrease</i> serum levels of protease inhibitors and lead to viral resistance
Modafinil	Induction (High Doses)		May <i>decrease</i> serum levels of protease inhibitors and lead to viral resistance

^b Cytochrome P450 2D6 metabolic enzyme

MANAGEMENT OF HIV AND PRIMARY CARE

As options for the treatment of HIV and the prophylaxis of opportunistic infections have improved, HIV-infected individuals are dying less frequently from AIDS, and also living longer (Hogg et al., 2008). Most HIV-infected patients on combination antiretroviral therapy can now achieve an undetectable viral load (Moore, Keruly, Gebo, & Lucas, 2005) and increased CD4 count, lowering the risk of acquiring AIDS-related opportunistic infections, such as PCP, MAI, toxoplasmosis, and cytomegalovirus, and cancers, such as invasive cervical cancer, KS, and non-Hodgkin's lymphoma (El-Sadr et al., 2006). As the clinical management of HIV has changed into that of a chronic illness, the HIV population is aging. HIV-infected patients may develop diabetes mellitus (Palacios, Santos, Ruiz, Gonzalez, & Marquez, 2003), hypertension, and age-related cancers, and there is increasing evidence that patients with HIV may have an increased risk of bone loss (Brown & Qaqish, 2006), cardiovascular disease (El-Sadr, et al., 2006), renal disease (Gupta et al., 2004), cognitive changes and dementia, liver disease (Sulkowski, 2008; Thein, et al., 2008; Thio, et al., 2002), and a frailty phenotype (Desquilbet et al., 2007). As a result of these changes, the management of HIV patients requires expertise in general medicine beyond just antiretroviral management.

NEUROPSYCHIATRY OF HIV INFECTION

HIV-ASSOCIATED NEUROCOGNITIVE DISORDERS

Neurocognitive disorders and subtle cognitive impairment are seen throughout the spectrum of HIV infection. Formal neuropsychological testing combined with clinical examination, lumbar puncture, and radiographic imaging provides the most useful means for evaluating cognitive decline (Box 63.1). Some of the earliest reports about HIV/AIDS indicated that the virus entered the central nervous system during initial infection and that this was a neurocognitive disease as much as it was an immunological disease. In 1991, the American Academy of Neurology published criteria to be used in the diagnosis of HIV-associated dementia (HAD) and the minor cognitive motor disorder (MCMD). These criteria indicated that HAD was an acquired abnormality in at least two cognitive areas, causing impairment in work or activities of daily living (ADLs), and that there was abnormality in motor function or abnormality in neuropsychiatric or psychosocial functioning leading to behavioral change. These criteria have been updated to cover a slightly broader range of HIV-associated neurocognitive disorders (HAND), which places a greater emphasis on cognitive impairment and behavioral abnormalities without any requirement of motor impairment. Suggestions are given for age- and education-appropriate normed neuropsychological testing of eight cognitive domains as well as psychosocial evaluation that must be performed in order to make a HAND diagnosis.

Box 63.1 EVALUATION OF ALTERED MENTAL STATUS IN PATIENTS WITH HIV/AIDS

Physical Neurological Exam

- Focal deficits may indicate space-occupying lesion; e.g., CNS lymphoma, toxoplasmosis, PML*
- Ataxia or changes in gait may indicate myelopathy associated with HAD
- Sensory changes indicative of peripheral neuropathy

Labs

- Complete blood count with differential
- Serum chemistries
- Arterial blood gas in patients with pneumonia
- Venereal Disease Research Laboratory (VDRL), Fluorescent Treponemal Antibody (FTA)
- B₁₂, folate

Neuroradiology

- MRI to rule out space-occupying lesion, Progressive Multifocal Leukoencephalopathy PML

Lumbar Puncture

- To rule out acute infection; e.g., herpes, cryptococcal meningitis, syphilis, toxoplasmosis

Review of Medications

- Neuropsychiatric side effects of AIDS meds; drug interactions, especially with protease inhibitors

Neuropsychological Testing

- AIDS Dementia Rating Scale**
- Finger Tapping Test
- Trail Making Test

EEG

*PML—progressive multifocal leukoencephalopathy

**See Power et al. (1995) to obtain the AIDS Dementia Rating Scale

Three categories of HAND are defined:

1. Asymptomatic neurocognitive impairment (ANI), in which the patient scores one standard deviation below the mean in two cognitive areas, with no subjective or objective signs of impairment in functioning;
2. Mild neurocognitive disorder (MND), again scoring one standard deviation below the mean in two or more areas, but with some mild impairment; and
3. HIV-associated dementia (HAD), in which the patient scores two standard deviations below the mean on

normative neuropsychiatric tests and has moderate to severe impairment in functioning (Antinori et al., 2007).

HAD is most commonly seen in more advanced stages of HIV disease. In the pre-HAART era, some degree of cognitive impairment was reported to be found in up to 60–90% of individuals with advanced-stage disease, and HAD was diagnosed in 15–20% patients. The annual incidence of HAD was reported to be 7% (McArthur et al., 1993). Since the introduction of HAART, several studies have shown the yearly incidence of HAD to have dropped to approximately 1% (d'Arminio Monforte et al., 2004; McArthur & Brew, 2010; Sacktor et al., 2001). However, as patients live longer with HIV, and with the inclusion of asymptomatic states, the overall prevalence of HAND has increased. For patients stabilized on a HAART regimen with no detectable viral load, the current prevalence estimates of ANI ranges from 32–50%; for MND, 12–17%; and for HAD, approximately 2–3% (Heaton et al., 2010; Simioni et al., 2010). The prevalence rates of HAND rise in patients with poor immunological control, as seen particularly in resource-poor countries (Robertson et al., 2007).

The precise pathophysiology of HAND remains unclear, but it appears to be related to neurotoxins secreted by mononuclear phagocytes. Some of the cytokines implicated include tumor necrosis factor (TNF), interleukin 1 (IL-1) and the N-methyl-D-aspartate (NMDA) agonists quinolinic acid and arachidonic acid. The immune cascade hypothesis supposes that inflammation at the blood–brain barrier (BBB) allows more HIV to enter the CNS, which provokes primed and immune activate macrophages to secrete neurotoxins that affect neuronal functioning and cause CNS inflammation, leading to further breakdown of the BBB and perpetuation of the inflammatory cascade. This hypothesis also emphasizes the importance of maintaining good immunological control peripherally to minimize CNS malfunction.

The early symptoms of HAD are subtle, typically with subcortical brain dysfunction and overlapping with the cognitive impairment associated with depression. Common early features include apathy, memory loss, cognitive slowing, impaired concentration, psychomotor slowing and slowed information processing, social withdrawal, and dyscoordination (Ferrando & Lyketsos, 2008). Later features include psychosis, severe memory loss with attention-deficit disorder, gross ataxia, seizures, and mutism (Price & Spudich, 2008).

The diagnosis of HAD is basically one of exclusion, and the evaluation will involve ruling out other primary causes of cognitive dysfunction, such as opportunistic CNS infections or neoplasms. Since the introduction of HAART, confounding factors such as increased age, co-infection with hepatitis C, substance use disorders, endocrinological disorders, and mental illness play a greater role in causing cognitive impairment in long-term survivors of HIV/AIDS. Computed tomography (CT) and magnetic resonance imaging (MRI), although not diagnostic, usually show some degree of cortical atrophy, and subcortical or periventricular white matter changes. Lumbar

puncture often reveals a mild increase in protein and mononuclear pleocytosis, and while not diagnostic of HAD, examination of the cerebrospinal fluid (CSF) is helpful in excluding opportunistic CNS infections such as cryptococcal meningitis and toxoplasmosis.

The HIV Dementia Rating Scale assesses psychomotor processing speed, verbal memory, constructional ability, and executive function, and is a useful instrument for screening cognitive impairment in HIV-positive patients. It is more sensitive than the Mini-Mental Status Exam (MMSE; Power, Selnes, Grim, & McArthur, 1995). A recent study indicates that a cutoff score of less than 14 is a good predictor that HAND will be diagnosed on full clinical assessment (Simioni, et al., 2010). Formal neuropsychological testing can provide detailed information on deficits in specific domains and can be very helpful in differentiating self-reports of cognitive impairment seen in depressed patients. Corroborative history from family and friends is extremely important in accurately characterizing functional impairment. Risk factors for HAD have been reported to include: increased viral load, decreased CD4, anemia, older age, decreased body mass, a history of persistent physical symptoms, anemia, female sex, and injection drug use (McArthur & Brew, 2010).

The primary choice of treatment for HAD, and possibly all HAND, is a regimen of HAART. One the earliest clinical trials looking at the treatment of HIV/AIDS found that high-dose AZT led to significant neuropsychological improvement (Schmitt et al., 1988). However, because these patients were receiving monotherapy, the physical and neurocognitive improvements were short-lived. Since these early studies, HAART regimens have been shown to lead to neuropsychiatric improvement, radiological improvement, and decreased CSF viral load, despite concerns about variable BBB penetrance of the antiretrovirals (Ferrando, Rabkin, van Gorp, Lin, & McElhiney, 2003; Filippi, Sze, Farber, Shahmanesh, & Selwyn, 1998; Price & Spudich, 2008). Some authors recommend using a regimen of four agents, with at least two that have relatively high BBB penetrance, such as zidovudine, nevirapine, atazanavir, inidnavir, and lopinavir, in order to maximize treatment of CNS infection; while others emphasize the importance of systemic immunological control to minimize the neurotoxic immune cascade.

Psychostimulant medications such as methylphenidate have been studied extensively in HIV-positive patients and have been found to be well tolerated and to lead to a decrease in cognitive dysfunction and depressive symptoms associated with dementia (Fernandez, Levy, & Ruiz, 1994). More recently, modafinil was shown to increase cognitive performance in HIV patients with complaints of fatigue (Rabkin, McElhiney, Rabkin, & McGrath, 2010). Other agents, such as memantine, selegiline, nimodipine, and peptide T, thought to have neuroprotective effects, have been studied but none have been found to significantly ameliorate HAND (Turchan, Sacktor, Wojna, Conant, & Nath, 2003).

With current treatment regimens, the course of HAND has become more variable over time, with fluctuations and at times nearly complete remission of symptoms.

DELIRIUM

Delirium occurs frequently among hospitalized HIV-infected patients, with reported prevalence rates ranging from 29% to 57% (Bialer, Wallack, Prenzlauer, Bogdonoff, & Wilets, 1996; Fernandez, Levy, & Mansell, 1989). AIDS patients may be especially susceptible to the development of delirium in the context of underlying HIV brain infection, the common use of multiple drugs, and the frequency of multiple medical complications. The etiology of delirium in this population is usually multifactorial, and while the causes of delirium are similar to those of any medically ill patient, some are more specific to the patient with AIDS (Box 63.2).

Evaluation and correction of the underlying medical cause of delirium is of primary importance, since there may be significant morbidity and mortality associated with this diagnosis (Uldall, Harris, & Lalonde, 2000; Uldall, Ryan, Berghuis, & Harris, 2000). Repeated mental status exams, a careful review of medications, thorough physical and neurological exams, a search for infections or metabolic abnormalities, neuroradiological exams, lumbar puncture, and electroencephalograms

Box 63.2 ETIOLOGIES OF DELIRIUM IN HIV/AIDS PATIENTS

Intracranial

Seizures and postictal states

Infections

Cryptococcal meningitis

Encephalitis due to HIV, herpes, Cytomegalovirus (CMV)

Progressive multifocal leukoencephalopathy (PML)

Mass lesions

Lymphoma

Toxoplasmosis

Extracranial

Medications and drugs (not exhaustive):

Amphotericin B: Sedative/hypnotics

Acyclovir: Cycloserine

Ganciclovir: Opiate analgesics

Ethambutol: Isoniazid

Trimethoprim/sulfamethoxazole: Rifampin

Pentamidine: Zidovudine, Didanosine

Foscarnet: Vincristine

Ketoconazole: Dapsone

Drug or alcohol withdrawal

Infections/sepsis

Endocrine dysfunction/metabolic abnormality

Hypoglycemia due to pentamidine, protease inhibitors

Liver failure due to comorbid hepatitis, medication toxicities

Nutritional deficiencies

Wasting syndrome

Failure to replace trace elements or vitamins in total parenteral nutrition

(EEG) are all essential in the evaluation of the delirious AIDS patient (Table 63.1).

Prompt management of agitation due to delirium is extremely important because of the distress caused to the patient and families, the potential for self-harm, as well the potential for exposure of HIV to others. Neuroleptics are the mainstay of treatment of the agitated delirious patient, and low-dose haloperidol is often effective in the AIDS population. Intravenous haloperidol may be necessary in very agitated patients where the risk of needle-stick injury is high. However, patients with HIV/AIDS may be more susceptible to severe, extrapyramidal and sedative side effects, and extreme caution must be exercised (Breitbart, Marotta, & Call, 1988; Fernandez et al., 1989). Cardiac arrhythmias and lengthening of the Q-T interval on electrocardiogram (EKG) have also been reported with the use of high-dose intravenous haloperidol (Metzger & Friedman, 1993). Medically ill patients receiving intravenous haloperidol at any dose should be monitored with frequent EKGs.

In a double-blind study, Breitbart (Breitbart, Marotta, et al., 1996) demonstrated the usefulness of low-dose oral haloperidol or chlorpromazine in the treatment of delirious AIDS patients. Although chlorpromazine is generally not recommended for the management of agitated, delirious patients, low doses that should have relatively mild anticholinergic effects may be useful for HIV patients who are very sensitive to the extra-pyramidal symptoms EPS caused by high-potency neuroleptics. The use of lorazepam in this study appeared to make many patients worse and had to be discontinued.

Atypical neuroleptics such as aripiprazole, quetiapine, risperidone, and olanzapine have been shown to be useful in the management of delirium (Breitbart, Tremblay, & Gibson, 2002; Schwartz & Masand, 2002; Straker, Shapiro, & Muskin, 2006) and may also be helpful in managing AIDS patients who are not highly agitated. Clinical experience indicates that patients with HIV/AIDS may tolerate these medications with fewer side effects and less EPS than they have with high-potency neuroleptics.

MOOD DISORDERS

DEPRESSION

Depressive disorders are the most frequently diagnosed mental disorder among patients with HIV/AIDS, with prevalence rates ranging from 35–85% depending upon sampling criteria such as hospitalization status, HIV disease stage, and comorbid risk behaviors (Bing et al., 2001; Ickovics et al., 2001; Morrison et al., 2002; Rabkin, 2008). One of the largest surveys of mental disorders among HIV patients found a rate of 36% for major depressive disorder and 26.5% for dysthymia (Bing et al., 2001) and a meta-analysis of published studies about depressive disorders among HIV patients demonstrated that seropositive compared to seronegative subjects were twice as likely to be diagnosed with major depression (Ciesla & Roberts, 2001). Although depression has been described as

a component of HAD, individuals are more likely to present with apathy as a component of cognitive decline, which may be typical of frontal lobe and subcortical dementias, misdiagnosed as major depression (Price & Spudich, 2008).

As HIV disease progresses, depressive symptoms are more likely to arise (Lyketsos et al., 1996). Many investigators have found an association between the severity of HIV-related physical symptoms and the severity of depressive symptoms (Belkin, Fleishman, Stein, Piette, & Mor, 1992; Burack et al., 1993); however, other studies have reported no such association (Ciesla & Roberts, 2001; Lyketsos et al., 1993). In another investigation, Mayne et al. (Mayne, Vittinghoff, Chesney, Barrett, & Coates, 1996) found that while depression was independent of physical symptoms, depressed mood was associated with higher mortality risk. Mayne and colleagues hypothesized that behaviors associated with depression (treatment nonadherence, substance abuse) may speed the progression of HIV disease. A more recent study indicated that women diagnosed with dysthymia were less likely to receive HAART (Turner & Fleishman, 2006). These findings underscore the critical importance of diagnosis and treatment of depression in this population.

A thorough evaluation for suicide risk should be part of the assessment of all depressed individuals with HIV infection. Although occasional, transient thoughts of suicide are not uncommon among individuals with HIV disease—pervasive suicidal ideation often accompanies HIV-related depressive syndromes and may be particularly prevalent among individuals who have recently tested positive for HIV (Perry, Jacobsberg, & Fishman, 1990).

Although HIV/AIDS may be more commonly viewed as a treatable disease in the age of HAART, some studies have shown suicidal ideation to still be highly prevalent, in the range of 17–38% (Goggin et al., 2000; Heckman et al., 2002; Kalichman, Heckman, Kochman, Sikkema, & Bergholte, 2000). Completed suicides appear to occur at a significantly increased rate among persons with HIV infection compared to age-matched controls (Cote, Biggar, & Dannenberg, 1992; Kizer, Green, Perkins, Doebbert, & Hughes, 1988; Marzuk et al., 1988), a phenomenon that has continued even after the introduction of HAART (Haller & Miles, 2003; Keiser et al., 2010).

Bereavement has taken on community-wide proportions among those affected by HIV and should be aggressively treated when symptoms suggest pathological grief reactions. Bereavement support groups have not only been shown to be effective in improving the psychological outcomes of those affected, but they have also been associated with improvement in viral load measurements for intervention subjects (Goodkin et al., 1999; Goodkin et al., 2001; Sikkema, Hansen, Kochman, Tate, & DiFranceisco, 2004). Goodkin and colleagues postulate immunological and neuroendocrine benefits from the support group and recommend such interventions be used as an adjunct to HAART in bereaved HIV patients.

When medical comorbidity (brain infections, medication side effects) is determined to be the primary cause of depression, initial treatment should be aimed at correcting the

underlying problem. Otherwise, treatment regimens include typical pharmacological and psychological strategies for the treatment of major depression in medical illness.

Numerous antidepressant agents have been found to be well tolerated and efficacious in the management of depression in patients with HIV disease. Research utilizing randomized, placebo-controlled designs reveals that SSRIs such as fluoxetine, paroxetine, citalopram, and escitalopram may be particularly useful in treating HIV-related major depression; this is especially true for patients with more advanced HIV disease and comorbid disorders such as hepatitis C (Currier, Molina, & Kato, 2004; Elliott et al., 1998; Laguno et al., 2004; Rabkin, Wagner, & Rabkin, 1999a). Other antidepressants such as venlafaxine, duloxetine, and mirtazapine have not been as well studied in the HIV population, but clinical experience indicates these agents may also be successfully used. Bupropion is usually avoided in patients receiving HAART due to concerns about drug interactions, although some have indicated that it can be used safely in this group (Park Wyllie & Antoniou, 2003). Psychostimulants have been shown to have a beneficial effect on depressive symptoms, especially when depression is accompanied by cognitive impairment (Fernandez, Levy, & Ruiz, 1994; White, Christensen, & Singer, 1992). Newer agents such as modafinil and armodafinil have also been shown to improve mood among patients being treated for HIV-related fatigue (Rabkin, McElhiney, & Rabkin, 2011; Rabkin et al., 2010); testosterone replacement therapy has also been shown to be helpful when fatigue is pronounced (Rabkin, 2008; Rabkin, Wagner, & Rabkin, 1999b). Although not specifically studied in this population, there is no specific contraindication to using electro-convulsive therapy (ECT) or repetitive transcranial magnetic stimulation (rTMS) and may be considered in patients with treatment-resistant depression.

Most psychotherapeutic interventions reported in HIV-positive individuals have aimed at reducing risk behaviors or lowering distress. Nonetheless, research data and clinical experience suggest that various modes of psychotherapy are beneficial in the management of HIV-related depression. Investigators have reported the successful use of interpersonal therapy (Markowitz et al., 1995), cognitive behavioral therapy (Kelly et al., 1993), supportive therapy (Markowitz et al., 1998), structured group therapy, and combined structured group therapy and antidepressant pharmacotherapy (Targ et al., 1994).

MANIA

Prevalence rates of manic syndromes in HIV patients have respectively been reported as 2.4% (Halman, Worth, Sanders, Renshaw, & Murray, 1993), 8% (Lyketsos, Schwartz, Fishman, & Treisman, 1997), and 30% (Boccellari, Dille, & Shore, 1988) in selected series of patients. Mania in the HIV patient may be due to preexisting psychiatric illness, the CNS effects of HIV-related opportunistic infections or tumors, HAD, or side effects of medications.

Some authors have noted differences between patients presenting with mania early or late in the course of HIV disease (Halman, et al., 1993; Lyketsos, et al., 1997). Early-onset

mania was more likely in patients with a personal or family history of mood disorders, and these patients more often presented with increased talking as a symptom. Late-onset mania was more often associated with a diagnosis of HAD, and irritability was a more frequent symptom.

Evaluation of HIV patients with mania should first rule out a secondary mania and include, at a minimum, a personal and family psychiatric history, a review of medications and any temporal relationship to the onset of symptoms, determination of CD4 count and viral load, and a neuroradiological exam. In patients with evidence of late-onset mania, examination of the CSF and neuropsychological evaluation for HAD are also indicated (Table 63.1).

Given the risk for impaired judgement, the potential for hyperactive sexual behavior, and poor impulse control, the clinician must aggressively treat the acutely manic patient with HIV/AIDS. Those with asymptomatic HIV infection and a premorbid history of bipolar disorder may be managed with standard lithium treatment, although patients with advanced HIV disease appear at increased risk for lithium-induced side effects, including neurotoxicity, delirium, diarrhea, polyuria, and polydipsia (Adler Cohen & Jacobson, 2000). Antiepileptic drugs are better treatment choices in patients with AIDS-related mania (Halman et al., 1993). Due to the greater risk of myelosuppression by carbamazepine, sodium valproate is preferred, with careful monitoring of hepatic enzymes, coagulation factors, and complete blood-count including platelets, being carefully monitored especially in patients with hepatitis C co-infection. Anticonvulsants such as lamotrigine may also prove to be effective and well tolerated in this population.

High-potency neuroleptics, such as haloperidol in low doses, may be useful in the acute management of manic HIV patients. However, increased sensitivity to extrapyramidal side effects of neuroleptics has been well documented. Some have reported the safe and effective use of risperidone in the management of mania in AIDS patients (Singh, Golledge, & Catalan, 1997), but while other atypical neuroleptics have indications for the treatment of mania, none have been well-studied in this population. Lorazepam or clonazepam have also been shown to be effective in the treatment of the acutely manic HIV patient (Budman & Vandersall, 1990) but act therapeutically primarily as sedatives.

ANXIETY DISORDERS

Treatment of anxiety disorders in persons with HIV/AIDS follows the general guidelines for other medical patients. For chronic generalized anxiety, buspirone has been shown to be effective in this population (Batki, 1990). A benzodiazepine may be the drug of choice for acute anxiety, but it should be used cautiously in patients with multiple medical complications and in those with a history of substance use disorder. Agents that are primarily glucuronidated and bypass the P450 enzyme system (e.g., lorazepam, oxazepam) are preferred due to decreased metabolite accumulation and decreased potential for interactions with

antiretrovirals. Other agents with varying efficacy in the treatment of anxiety in the setting of HIV infection include β -adrenergic blockers, antihistamines, and sedating antidepressants. The antidepressant venlafaxine is approved by the US Food and Drug Administration (FDA) for Generalized Anxiety disorder (GAD) and should be considered as a first-line drug as well.

Psychotherapies play an important treatment option for many patients with anxiety, particularly if the anxiety is less severe or if patients cannot take anti-anxiety medications. In most settings, the preferred treatment combines pharmacotherapy and methods of anxiety self-regulation. Numerous techniques for self-regulation have been shown to be effective in treating HIV-related anxiety, including muscle relaxation therapies, electromyographic biofeedback, behavioral techniques, acupuncture, self-hypnosis, and aerobic exercise training.

SUBSTANCE USE DISORDERS (SUD)

While men who have sex with men continue to compose the largest proportion of people with HIV/AIDS, injection drug use (IDU) remains a significant transmission category. IDU accounts for 15% of new HIV infections and 22% of cumulative cases of AIDS among women (CDC, 2009). Non-injecting SUD is also related to higher rates of HIV transmission (Chesney, Barrett, & Stall, 1998; Ferrando & Batki, 2000; Woody et al., 1999). A high lifetime prevalence of psychiatric disorders among those with SUD, in the range of 50–80%, has been reported, and several studies have demonstrated high rates of psychiatric disorders among HIV patients with SUD: the “triple diagnosis” patient (Bialer, Hoffman, & Ditzell, 2008; Klinkenberg & Sacks, 2004; Lipsitz et al., 1994).

Methamphetamine use has increased greatly among gay men in urban centers and is often associated with both needle-sharing and unsafe sexual behavior (Halkitis, Parsons, & Stirratt, 2001; Molitor, Truax, Ruiz, & Sun, 1998; Shoptaw, Reback, & Freese, 2002). There is also a high prevalence of methamphetamine use among heterosexual men and women in the West and Midwest, and studies have demonstrated increased risk behaviors associated with HIV transmission among these populations (Molitor et al., 1999). Thus, methamphetamine abuse may be playing a larger role in the HIV epidemic in the coming years.

Psychiatric management of the HIV patient with a SUD has become increasingly important for several reasons:

1. Continued substance use may lead to an increase in unsafe behaviors such as needle-sharing or unprotected sex (Chesney, et al., 1998; Vanable et al., 2004; Woody, et al., 1999);
2. Adherence to medical treatment may be impaired (Ferrando, Wall, Batki, & Sorensen, 1996; Freeman, Rodriguez, & French, 1996; Klinkenberg & Sacks, 2004);
3. The mental and physical changes resulting from SUD can negatively affect the patients' quality of life.

The most helpful treatment approach is to determine whether SUD is a primary diagnosis. This can be difficult, either because of a patient's poor reliability or because of a mixed picture, such as a sleep disorder and alcohol abuse presenting simultaneously. If SUD is the primary diagnosis, then specific drug abuse treatment and abstinence should be required before further psychiatric treatment can continue. Treatment options include brief inpatient detoxification for patients with physiological dependence on substances such as heroin or alcohol, followed by inpatient rehabilitation; outpatient rehabilitation or therapeutic communities for longer-term intensive treatment; methadone maintenance for heroin users (Cooper, 1989); and 12 Step programs such as Alcoholics Anonymous (AA) or Narcotics Anonymous (NA). All of these modalities offer a group setting, which addresses the difficulties in interpersonal relationships so common among these patients. They also offer the support and advice of others who are further along in their recovery, so that patients have role models who can offer concrete advice. It is important to have referrals to these programs readily available, since patients tend to have brief windows of opportunity when they are willing to accept these services.

Various types of therapies have been recommended for treating HIV patients with SUD, including cognitive, interpersonal, and supportive/exploratory (Markowitz, et al., 1995), as well as motivational interviewing. Harm-reduction strategies that acknowledge that not all patients will achieve or maintain abstinence are especially applicable to HIV patients with SUD (Ferrando & Batki, 2000). Studies have shown that counseling and education regarding risk behaviors and corresponding precautions should be incorporated into the treatment and can have beneficial effects (Gibson, McCusker, & Chesney, 1998; Semaan et al., 2002). The clinician must be prepared to be flexible, and to incorporate whichever form of treatment (or combination of treatments) is most useful for a particular patient at a particular time.

PAIN

Studies have shown that pain may be undertreated in AIDS patients, as it is in most medical and surgical patients (Breitbart, Rosenfeld, et al., 1996). Non-psychiatrists often do not recognize pain as a common symptom among patients with HIV/AIDS. Psychiatrists may be consulted to evaluate for psychological causes of pain complaints. The prevalence of pain in this population has been estimated to range from 30–80%, however, and can be due to HIV infection itself and its related complications, therapies used to treat AIDS, or to non-HIV-related causes (Breitbart, McDonald, et al., 1996; Dobalian, Tsao, & Duncan, 2004). Although neuropathic pains occur frequently, pains of a somatic and visceral nature are actually more common (Breitbart, 1996) (Box 63.3).

Pain in the AIDS patient can be managed according to the same guidelines for cancer pain management. This involves a complete physical, neurological, and psychiatric evaluation for correctable causes of pain. Analgesic medications can then be prescribed according to the level of pain: non-opioid medications (e.g., acetaminophen or non-steroidal anti-inflammatory

drugs [NSAIDs]) for mild pain, weak opioids (e.g., codeine or oxycodone) for moderate pain, and strong opioids (morphine, hydromorphone) for severe pain. For continuous or recurring pain, analgesics should be given around the clock.

Psychotropic medications play an important role in the management of pain in AIDS patients. In addition to their direct effects on associated syndromes such as depression or anxiety, antidepressants, neuroleptics, and stimulants have been shown to be useful adjuvants in pain management by potentiating the effect of analgesics. Duloxetine, gabapentin, and pregabalin are all approved for patients with postherpetic and diabetic neuropathies, and may offer particular benefit to patients with HIV-related, painful neuropathies. Lidocaine patches can also be used to treat localized neuropathic pain.

The management of pain in AIDS patients with a history of substance abuse can be problematic. As there is no objective way to measure pain, one must rely on the patient's report of pain and its severity. Although a certain number of patients with a substance use disorder may mangle in order to obtain drugs, complaints of pain should be taken seriously and fully evaluated. Pain management guidelines, including the use of around-the-clock opioid analgesics for moderate to severe pain, should be similar to that of patients without a history of substance abuse. Correction of medical causes of pain and the use of adjuvant medications and non-pharmacological treatments may lessen the need for opioid analgesics.

Box 63.3 PAIN SYNDROMES IN AIDS PATIENTS

Pain Related to HIV/AIDS

- HIV neuropathy
- HIV myelopathy
- Kaposi's sarcoma
- Opportunistic infections (intestines, skin)
- Organomegaly
- Arthritis/vasculitis
- Myopathy/myositis

Pain Related to HIV/AIDS Therapy

- Antiretrovirals, antivirals
- Antimycobacterials, PCP prophylaxis
- Chemotherapy (vincristine)
- Radiation
- Surgery
- Procedures (bronchoscopy, biopsies)

Pain Unrelated to AIDS

- Spinal disc disease
- Diabetic neuropathy

From: Breitbart, W. (1996), *Pharmacotherapy of pain in AIDS*. In G. Wormser (Ed.), *A clinical guide to AIDS and HIV*. Philadelphia, PA: Lippincott-Raven. Permission to reprint being requested.

Early in the AIDS epidemic, little attention was paid to the mentally ill as a possible risk group for HIV infection. Perhaps this reflected a lack of knowledge regarding the sexual behaviors of this population or inadequate awareness of the frequency of comorbid conditions or behaviors that might increase risk. In 1989, the first published reports appeared regarding HIV infection among patients with major psychiatric illnesses in state hospitals (Cournos, Empfield, Horwath, & Kramer, 1989). Interest in the seroprevalence of HIV and risk behaviors of the mentally ill grew, and several important studies began to appear in the literature. Rates of HIV seroprevalence among the severely mentally ill have been reported to range from 4.0–22.9% (Cournos & McKinnon, 1997; McKinnon, Cournos, & Herman, 2002). The highest rates of infection were found in settings that treated dual-diagnosis patients with both severe mental illness and comorbid substance use disorder (Dausey & Desai, 2003). Both injection drug use and sexual activity were predictors of HIV seropositivity. When risk factors were identified, the highest seroprevalence was found among those with a history of prostitution (37.9%), sex with a drug injector (37.5%), male–male sex (25.4%), or drug injection (21.6%). Of interest was the finding that, among patients with *non*-injected drug use, the seroprevalence rate was still quite high, at 11.4%. In the majority of these studies, women were as likely to be infected as men. However, across studies, the rates of seropositivity were 9.8% among African Americans, 9.6% among Hispanic patients, and 3.1% among Caucasian and Asian patients combined. The likelihood of seropositivity did not seem to vary with psychiatric diagnosis: 9.2% among schizophrenics and 10% among other Axis I diagnoses. These data suggest that the rates for HIV infection among the severely mentally ill are elevated when compared to the general population. The findings of these studies underscore the important role for the psychiatrist in advocating for improved substance-abuse treatment strategies for the mentally ill and in the promotion of AIDS education and prevention for our patients. HIV testing should be strongly encouraged for all chronically mentally ill patients, and HIV infection should be considered in the differential diagnosis of acute medical illness in this population.

CONCLUSION

While great strides have been made in the management of HIV/AIDS, it remains a complex disease with profound neuropsychiatric as well as psychosocial implications. For patients with a dual and sometimes triple diagnosis of medical, psychiatric, and substance use disorders, treatment would ideally occur in an integrated setting with medical specialists, nursing, and mental health providers. Such integrated settings have been developed in urban centers in the United States and elsewhere with large numbers of patients with HIV. When such settings are not available, we would recommend that patients with dual and triple diagnoses be managed at a minimum by HIV specialists.

- The fourth-generation HIV assay test picks up 80% of acute HIV infections with a 5% false positive rate.
- The assay test can be used for other fluids but approved only for blood.
- Viral load (RNA) not diagnostic but high viral load in acute HIV may be picked up in 10 days, slightly earlier than by fourth-generation assay.
- Clinicians should be aware that individuals with acute HIV illness may present with a variety of symptoms, which include a flu-like syndrome, aseptic meningitis, lymphadenopathy, and rash. If there is a high suspicion of acute HIV illness, HIV RNA testing remains indicated.
- P9 antiretroviral therapy penetrates poorly into the central nervous system (CNS), and ongoing CNS HIV replication and neurocognitive effects may persist despite viral load suppression in other parts of the body.
- Transmission risk is reduced as plasma viral load decreases.
- Contributing to the current emphasis on earlier antiretroviral treatment is a growing recognition that untreated HIV-infected patients, even those with a high CD4 count, suffer ill effects of HIV replication, including immune dysregulation and associated inflammation.
- The current strategy is to choose a regimen with at least two, and preferably three, potent antiretroviral medications.
- Efavirenz is associated with neuropsychiatric side effects, which generally occur early in treatment and are time-limited. Common side effects of efavirenz may include dizziness, bad dreams, or anxiety, and there have been case reports of severe depression, mania, and psychosis (Arendt, de Nocker, von Giesen, & Nolting, 2007; Tozzi et al., 2007).
- Ritonavir, one of the early protease inhibitors, is now rarely used for its antiviral effect, but is used for its drug-boosting effect. It is a potent P450 inhibitor, particularly of 3A4, and many of the protease inhibitors use this isoenzyme pathway.
- The use of HIV screening for pregnant women, antiretroviral therapy, elective Caesarian delivery for women with suboptimal HIV viral suppression, and exclusive bottle-feeding has reduced the rates of vertical transmission to less than 2% in the United States and Europe (DHHS, 2011b, p. 12).
- The use of antiretrovirals for occupational post-exposure HIV prophylaxis has reduced HIV transmission rates in the workplace. In the absence of post-exposure antiretroviral prophylaxis, the estimated HIV transmission risk for percutaneous exposure is 0.3%, and after a mucous

membrane exposure, 0.09%. Only a handful of cases due to occupational exposure have been reported since the introduction of the first occupational exposure guidelines (Panlilio, Cardo, Grohskopf, Heneine, & Ross, 2005). Antiretroviral post-exposure prophylaxis may also be used for high-risk sexual and injection drug-use exposures, with a 28-day course of HAART administered within 72 hours of exposure p 13.

- Benzodiazepines that undergo metabolism through the 3A4 enzyme pathway, notably alprazolam, midazolam, and triazolam (the latter two have absolute contraindications), can have markedly elevated plasma levels with ritonavir use. Many SSRIs and tricyclic antidepressants undergo metabolism through the 2D6 pathway and may require a dose decrease when used with ritonavir. There have been case reports of serotonin syndrome with fluoxetine- and ritonavir-containing regimens due to P450 inhibition with ritonavir (DeSilva et al., 2001). Trazodone plasma levels may be markedly increased through 3A4 inhibition on ritonavir-containing regimens.
- Methadone serum levels may be decreased by the antiretrovirals ritonavir, efavirenz, and nevirapine.
- The precise pathophysiology of HAND remains unclear, but it appears to be related to neurotoxins secreted by mononuclear phagocytes.
- CT and MRI, although not diagnostic, usually show some degree of cortical atrophy, and subcortical or periventricular white matter changes. Lumbar puncture often reveals a mild increase in protein and mononuclear pleocytosis and, while not diagnostic of HAD, examination of the CSF is helpful in excluding CNS opportunistic infections such as cryptococcal meningitis and toxoplasmosis.
- The HIV Dementia Rating Scale assesses psychomotor processing speed, verbal memory, constructional ability, and executive function and is a useful instrument to screen cognitive impairment in HIV-positive patients.
- Risk factors for HAD have been reported to include: increased viral load, decreased CD4, anemia, older age, decreased body mass, a history of persistent physical symptoms, anemia, female sex, and injection drug use (McArthur & Brew, 2010).
- Some authors recommend using a regimen of four agents with at least two that have relatively high BBB penetrance, such as zidovudine, nevirapine, atazanavir, indinavir, and lopinavir, in order to maximize treatment of CNS infection; while others emphasize the importance of systemic immunological control to minimize the neurotoxic immune cascade. P 19.
- Psychostimulants have been shown to have a beneficial effect on depressive symptoms especially when depression is accompanied by cognitive impairment. (F. Fernandez, Levy, JK., Ruiz, P., 1994). More recently, modafinil was shown to increase cognitive performance in HIV patients with complaints of fatigue (J. Rabkin, McElhiney, Rabkin, & McGrath, 2010).
- Other agents such as memantine, selegiline, nimodipine, and peptide T, thought to have neuroprotective effects, have been studied; but none have been found to significantly ameliorate HAND (Turchan, Sacktor, Wojna, Conant, & Nath, 2003) p 20.
- Although depression has been described as a component of HAD, individuals are more likely to present with apathy as a component of cognitive decline, which may be typical of frontal lobe and subcortical dementias, misdiagnosed as major depression (Price & Spudich, 2008).
- Women diagnosed with dysthymia were less likely to receive HAART (Turner & Fleishman, 2006).
- Bereavement support groups have not only been shown to be effective in improving the psychological outcomes of those affected but have also been associated with improvement in viral load measurements for intervention subjects (Goodkin et al., 1999; Goodkin et al., 2001; Sikkema, Hansen, Kochman, Tate, & Difranceisco, 2004) p23.
- Research utilizing randomized, placebo-controlled designs reveals that SSRIs such as fluoxetine, paroxetine, citalopram, and escitalopram may be particularly useful in treating HIV-related major depression; this is especially true for patients with more advanced HIV disease and comorbid disorders such as hepatitis C (Currier, Molina, & Kato, 2004; Elliott et al., 1998; Laguno et al., 2004; Rabkin, Wagner, & Rabkin, 1999a).
- Bupropion is usually avoided in patients receiving HAART due to concerns about drug interactions, although some have indicated that it can be used safely in this group (Park Wyllie & Antoniou, 2003) p24.
- Early-onset mania was more likely in patients with a personal or family history of mood disorders, and these patients more often presented with increased talking as a symptom. Late-onset mania was more often associated with a diagnosis of HAD, and irritability was a more frequent symptom. P25.
- Many of the medications used in the treatment of HIV/AIDS have been reported to cause anxiety as a possible side effect, including antiretrovirals, isoniazid, acyclovir, and pentamidine.p27.
- While men who have sex with men continue to comprise the largest proportion of people with HIV/AIDS, injecting drug use (IDU) remains a significant transmission category. IDU accounts for 15% of new HIV infections and 22% of cumulative cases of AIDS among women.

- If SUD is the primary diagnosis, then specific drug treatment and abstinence should be required before further psychiatric treatment can continue.
- (Breitbart, Rosenfeld, et al., 1996). Non-psychiatrists often do not recognize pain as a common symptom among patients with HIV/AIDS.
- Rates of HIV seroprevalence among the severely mentally ill have been reported to range from 4.0–22.9% (Cournos & McKinnon, 1997; McKinnon, Cournos, & Herman, 2002).
- When risk factors were identified, the highest seroprevalence was found among those with a history of prostitution (37.9%), sex with a drug injector (37.5%), male-male sex (25.4%), or drug injection (21.6%). 9.2% among schizophrenics and 10% among other Axis I diagnoses.

MEDICAL GENETICS

Kristen M. Shannon and Gayun Chan-Smutko

INTRODUCTION

Genetics and genomics are now a well-established part of mainstream medicine. The understanding of the genetic causes of disease makes it possible for individuals to undergo genetic testing that can diagnose them with a specific genetic condition. This genetic condition may exhibit symptoms in the present or future, and gives the individual information that he or she may transmit the genetic condition to her children. The psychiatric care of individuals with genetic conditions is unique, and mental health professionals are often called on to consult during the diagnostic process. In addition, mental health professionals are often necessary health-care providers for the long-term care of individuals with genetic disease. This chapter will focus on genetic counseling and testing, and will provide the mental health professional with a framework in which to work with individuals with genetic disease.

PRINCIPLES OF GENETIC COUNSELING

GENETIC COUNSELORS

Genetic counselors are health professionals with specialized graduate degrees and experience in the areas of medical genetics and counseling. Genetic counselors work as members of a healthcare team, providing information and support to families who have members with birth defects or genetic disorders and to families who may be at risk for a variety of inherited conditions. They identify families at risk, investigate the problem present in the family, interpret information about the disorder, analyze inheritance patterns and risks of recurrence, and review available options with the family (National Society of Genetic Counselors NSGC, 1983).

Genetic counselors also provide supportive counseling to families, serve as patient advocates, and refer individuals and families to community or state support services. They serve as educators and resource people for other healthcare professionals and for the general public. Some counselors also work in administrative capacities. Many engage in research activities related to the field of medical genetics and genetic counseling (NSGC, 1983).

Genetic counselors work in both clinical and non-patient contact settings. Most genetic counselors work in a clinic or

hospital setting and specialize in general genetics, prenatal care and family planning, pediatrics, oncology, cardiology, neurology, or many other areas of specialized medical care. Some genetic counselors work in related areas such as laboratories, research, education, public health settings, and corporate environments.

GENETIC COUNSELING PROCESS

Genetic counseling is the process of helping people understand and adapt to the medical, psychological, and familial implications of genetic contributions to disease (Resta, Biesecker, et al., 2006). This process integrates:

- Interpretation of family and medical histories to assess the chance of disease occurrence or recurrence
- Education about inheritance, testing, management, prevention, resources, and research
- Counseling to promote informed choices and adaptation to the risk or condition (NSGC, 2005)

The practice is specifically aimed at assessing a patient's personal and family history to determine whether there is an underlying genetic cause for the medical condition in the individual or family. Ascertaining and communicating this information helps patients and their healthcare providers better understand an individual's risk of developing specific associated diseases. This information is then used to help establish the best medical management for a patient with respect to medical surveillance and/or risk reduction (Trepanier, Ahrens, et al., 2004).

The process of genetic counseling can be divided into distinct components that include contracting, obtaining medical information, risk assessment, education, genetic testing, informed consent, and psychosocial support. These seven components are outlined in the following text.

Contracting

Contracting is the term used to describe the beginning of the genetic counseling encounter, when both the genetic counselor and counselee share their intentions for the session. Contracting provides the opportunity to communicate the expectations of what will occur during the genetic counseling

appointment. Patients are sometimes unaware of what a genetic counseling session entails (Bernhardt, Biesecker, et al., 2000) and may have conflicting expectations for the visit. Contracting also provides the genetic counselor with the opportunity to describe his/her role in the genetic assessment process. Another important task accomplished by contracting is that it provides the genetic counselor the opportunity to assess the patient's baseline knowledge of genetics and comfort level with genetics information. Assessing the comfort level is particularly important, as some patients are ambivalent about pursuing genetic counseling due to underlying anxiety (Tessaro, Borstelmann, et al., 1997; McDaniel, 2005; Dorval, Bouchard, et al., 2008). It is believed that contracting may actually shorten the length of a genetic counseling session, as it can potentially prevent the "doorknob syndrome." The phenomenon of "doorknob syndrome" is common and occurs when patients are not given the opportunity to share their thoughts and concerns with providers and choose to do so only near the end of the session, as the provider's hand is "on the doorknob" to leave (Jackson, 2005). The process of contracting allows for the organization of a session that best meets the patient's needs, while allowing the genetic counselor to be most efficient.

The Personal and Medical Family History

After the brief contracting, the genetics professional will most often begin the assessment with gathering a detailed personal medical and family medical history. Typically, a detailed three-generation family history is constructed in the form of a pedigree (Bennett, Steinhaus, et al., 1995; Bennett, French, et al., 2008).

When taking the family history, it is important to document each individual's age or age at death as well as his/her personal medical history. Depending on the disease suspected in the individual/family, the information requested on the relatives will be tailored. For example, if hereditary breast and ovarian cancer syndrome (HBOCS) is suspected, the genetic counselor will ask about cancer diagnoses in the family as well as determine if the women in the family have their ovaries intact, as this affects risk assessment (prophylactic bilateral salpingo-oophorectomy has been shown to reduce the risk of developing breast cancer in HBOCS patients [Rebbeck, Levin, et al., 1999; Olopade & Artioli, 2004]).

Patients may feel anxious during this information gathering portion of the session because their level of knowledge about their own diagnosis as well as other family members' diagnoses may not be high. For example, many patients with a diagnosis of cancer will not be aware of the specific pathology or histology of their tumor, and in some cases, confirming the diagnosis with medical records is essential (Trepanier, Ahrens, et al., 2004). Many factors can influence an individual's knowledge of the family history (Schneider, 2002). Information on relatives may not be available because of estrangement, adoption, or simply because the patient has lost contact with his or her family members. The information provided can be incorrect because the patient is mistaken or confused about the diagnosis. A recent study of the accuracy

of family history in a cancer genetic counseling practice, for example, indicates that individuals are often confident that a family member has had cancer, but are typically unsure of the details surrounding that diagnosis (Jefferies, Goldgar, et al., 2008; Reid, Walter, et al., 2009). Reports of breast cancer tend to be accurate, while reports of ovarian cancer are less trustworthy (Murff, Spigel, et al., 2004; Chang, Smedby, et al., 2006). It is also important to note that family histories can change over time, with new diagnoses arising in family members as time passes. All of these factors must be considered during the consultation, as the risk assessment and differential diagnosis are based primarily on this information.

Risk Assessment

Risk assessment is an important part of the genetic counseling encounter. The genetic counselor will use his/her expertise and experience to determine the likelihood that an individual has a genetic disease. Many guidelines exist that can assist the genetic counselor in determining this likelihood.

The patient's reaction to the genetic counselor's risk assessment can vary greatly, depending on their personal and family history as well as their underlying emotional well-being (Schneider, 2002). If an individual is confronted with a potential diagnosis of genetic disease, he or she may feel validated that their concerns regarding their personal and family history are real. Others who have lived in denial may react with disbelief, anger, and fear. The individual's experience with disease in the family will also be a factor in their reaction. Those who have lost many family members to a specific medical condition are more likely to be anxious, while those whose family members have survived the medical condition may be less worried about the mortality associated with the disease.

There are times when a genetic counselor feels that an individual's personal and family history is not consistent with a genetic diagnosis. In these instances, the patient can react in a variety of ways. Patients can react with relief, surprise, and sometimes anger (Schneider, 2002). The genetic counselor will address these emotions, and typically, through the education process, these emotions will subside in the patient.

Education About Genes and Genetic Disease

The education portion of the genetic counseling session includes the provision of information about the role of genes in genetic conditions and their inheritance patterns, possible results of genetic testing, risk reduction options, and the benefits, risks, and limitations of genetic testing. The role of the genetic counselor in this component of the session is to effectively communicate scientific information to meet the patient's level of understanding (Bennett, Hampel, et al., 2003). As patients have diverse learning styles, it is important to be able to communicate the same information in different ways to accommodate a patient's specific learning method. The education portion is typically the longest portion of a genetic counseling session.

Most genetic diseases are due to mutations in Mendelian genes. Genetic disorders are inherited in autosomal dominant,

autosomal recessive, and sex-linked manners. It is not imperative that a patient understand the differences in the types of genes that give rise to genetic disease; however, the manner in which these genes are inherited in families is essential to understanding the familial implications of genetic testing. Autosomal dominant disorders result in a 50% risk to siblings and offspring. Autosomal recessive disorders typically result in a 25% risk to siblings and varying risks to offspring as they are dependent on the genetic status of the individual's partner. Sex-linked diseases are only passed to specific genders. It is important to note that many genetic diseases are a result of a *de novo* mutation in an individual. If a disease is truly *de novo* in nature, the risks in the relatives are limited to offspring.

The education portion of the genetic counseling encounter extends into a thorough discussion of the disease that is suspected in the family. This will include a discussion of the risks of clinical symptoms associated with the disease as well as symptom screening and prevention options. Risk reduction options for individuals—including surgery, medications, avoidance of specific foods, habits, exposures—are often discussed. Typically, the genetic counselor's role is to introduce these concepts, allowing a detailed discussion to be provided by physician specialists (geneticists, surgeons, oncologists, gastroenterologists, etc.).

Education About Genetic Testing

Finally, the education process will often include a detailed discussion of genetic testing that lays the foundation for informed consent. Genetic testing is often not straightforward. When performing germline genetic testing, there are four possible test results.

Mutation detected (i.e., “Positive”): The individual is diagnosed with a genetic disease. The individual can pass this gene mutation on to his or her children.

No mutation detected, and a gene mutation has previously been found in another family member (i.e., “True Negative”): The individual does not have the genetic disease known to be in the family. In addition, the individual cannot pass it on to his or her children.

No mutation detected, and a mutation has *not* been found in another family member (i.e., “Inconclusive Negative”): The test has provided little new information about the underlying etiology of the individual's symptoms. He or she may still have a genetic disease because:

- The individual may still have a mutation in the gene being tested, but it was not detectable with testing technology that was used, or
- The individual may have a gene mutation in another gene that was not analyzed in the test.

A mutation is found, but its meaning is unknown (i.e., it is a variant of uncertain significance [VUS]): This is considered an inconclusive result and is typically a missense mutation in a gene. In this case, there are insufficient

data to classify whether the variant is deleterious to gene function or is a benign polymorphism that has no bearing on gene function. A VUS result should not be used to guide medical management, and clinicians should defer to the family history to determine the best management protocol for the patient and their family.

A thorough discussion of the benefits, risks, and limitations to genetic testing is essential to the informed-consent process. Benefits include relieving uncertainty associated with having a set of medical symptoms in the family history, as well as providing additional information in assessing the patient's personal risk of developing a specific medical symptom. This information may help the individual and healthcare providers determine the best plan for medical management with regard to early detection, risk reduction, or prevention of disease. Another benefit of genetic testing is that results may give other family members information about their chance of having inherited a mutation and chance of developing certain symptoms. Finally, if an individual learns that he or she is a true negative, it means there is no increased risk of developing certain symptoms due to their family history. Their risk of developing certain symptoms is that of the general population.

Risks associated with the genetic testing process include increased stress, anxiety, and depression. Sharing information about a positive genetic diagnosis may affect relationships with family members. This information may be upsetting to family members and strain relationships. There is a possibility of learning sensitive information about the family. For instance, if more than one family member is tested, there is a chance of learning about misattributed paternity of a child, or an unknown adoption. It is possible that testing will reveal a variant of uncertain significance, which can be disconcerting to patients as it is unknown if this variant is associated with disease. Feelings of guilt, distress and uncertainty are discussed further in the later section, “Genetic Testing over the Lifespan.”

One common question that is encountered during the genetic counseling consultation is regarding negative use of genetic information. Genetic discrimination occurs when a genetic test result is used as a preexisting condition by insurance providers and employers. This is less of an issue for patients who already have a medical diagnosis (i.e., are already exhibiting symptoms of the genetic disease). However, those who are currently not exhibiting symptoms of disease should know that most are protected by law with respect to discrimination by their health insurance company or employer. However, no legislation exists to protect individuals from life insurance or disability insurance companies' use of this information.

The limitations of genetic testing must be explored with patients, as the uncertainties underlying any result (positive, uninformative negative, etc.) are often unsatisfying and difficult for patients to grasp. Test results provide risk information, but they cannot predict if an individual will actually develop a specific clinical manifestation of the disease. If an individual is a true negative for a known familial mutation, it does not mean that they will never develop a symptom associated with the disease. For example, if an individual tests negative for a

known mutation in the gene responsible for familial hypercholesterolemia, it is possible that the individual might still develop high cholesterol.

Psychosocial Assessment and Support

The psychosocial implications of genetic testing for patients and their families can be substantial. Psychosocial assessment should be provided throughout the entire genetic counseling and testing process.

INITIAL SUPPORT

During the genetic counseling session, the genetics professional should help the patient understand the information regarding their disease and the genetic cause of it. In addition, the psychosocial impact of the disease must be addressed. Living with a genetic disease or as a member of a family with a genetic disease can be very challenging psychologically. Often, individuals with genetic disorders require frequent medical visits and a battery of medical tests. Some individuals with genetic disorders are afforded the ability to participate in dedicated follow-up clinics that are specialized for their individual disease and symptoms. Many of these specialized programs are located in larger academic medical centers, and some also include psychological care of the patients. However, many individuals with a genetic disease are managed by a menagerie of healthcare providers, and their psychological care is often neglected.

When genetic testing is available and offered, the genetic counselor must support the patient's decision to proceed or not proceed with the genetic testing. Although there have been no studies that formally address whether genetic counseling leads to genetic testing decisions that are consistent with patient preferences (Braithwaite, Emery, et al., 2004), the role of the healthcare professional is to provide emotional support and empathy. Patient-perceived provider empathy has been shown to increase patient satisfaction and compliance by way of the mediating factors of information exchange, perceived expertise, interpersonal trust, and partnership (Kim, Kaplowitz, et al., 2004). In order for the full benefit of genetic testing to be realized, patients must ultimately be compliant with the recommendations for treatment, screening, and prevention of clinical symptoms.

It is important that the patient's support system be identified and addressed. If the patient is considering genetic testing, identifying this support system prior to the genetic test initiation is essential, as waiting for genetic test results can require emotional support. It is also important for the genetic counselor to gather more information about family dynamics. Whether an individual wants it to be or not, genetic testing is a family affair, and there are family issues that will be brought forth. It is important to determine if a patient will be comfortable doing this; and if not, to provide guidance and support. Identifying individuals with insufficient sources of support and addressing family communication concerning genetic disease may help the patient adjust better to genetic testing (van Oostrom, Meijers-Heijboer, et al., 2007a).

When genetic testing is performed, it is important to consider the anticipation of test results. Waiting for test results can be stressful for some patients. It is important to offer a reliable estimate of when the results will be available, as anxiety tends to heighten around the end of this timeline.

ONGOING SUPPORT

It is important to recognize that living with a genetic disease is a lifelong process. The psychosocial impact of living with disease is likely to change over time—and throughout the lifespan. Individuals, for example, with a predisposition to adult-onset conditions will probably change their psychological assessment of living with the disease as they age. Individuals with genetic disease also will have to face sometimes-difficult decisions during their reproductive years. It is imperative that the psychological well-being of these patients be addressed over their lifespan.

When genetic testing is performed, it is noted that most individuals cope well with the results of genetic testing, but that some will require additional support after the test results are given. Studies have indicated that there are factors, such as high anxiety at time of blood draw for genetic testing, that predict who will be distressed six months after receiving a test result (Dorval, Patenaude, et al., 2000; van Oostrom, Meijers-Heijboer, et al., 2007b). Healthcare providers should be aware of these factors and identify the individuals who will need additional support, so as to maximize opportunities for prevention, early detection, and healthy coping (Vadaparampil, Miree, et al., 2006). Support groups for people found to have cancer-predisposition gene mutations can be helpful, and some have suggested that such support groups should be a priority (Di Prospero, Seminsky, et al., 2001).

GENETIC TESTING OVER THE LIFESPAN

Over the last several decades, genetic testing has evolved to touch many areas of medicine. In the late 1950s, medical geneticists used chromosome analysis techniques to support what was still largely a phenotype-based diagnosis for syndromes such as Down syndrome. Genetic testing, which began as primarily a diagnostic tool, now includes carrier screening for recessive diseases like cystic fibrosis, newborn screening for diseases like phenylketonuria, and presymptomatic testing for diseases like hereditary breast or ovarian cancer syndrome. Clinical genetic testing is now available for over 2,500 diseases (Gene Tests, 2011), many of which are single-gene, Mendelian inherited disorders (Table 64.1).

Genetic testing now encompasses other diseases that are not classically defined as “genetic” disorders. Tissue samples such as malignant tumor specimens routinely undergo genetic testing for non-hereditary genetic markers that create a genetic profile of the tumor to guide diagnosis and treatment. With the varied ways that DNA analysis has become integrated in nearly all areas of medicine, the medical patient is likely to experience genetic counseling or encounter complex genetic information at some point in their lifetime, whether it

Table 64.1 DEFINITIONS OF DIFFERENT TYPES OF GENETIC TESTS.

GENETIC TEST	PURPOSE	EXAMPLES
Diagnostic	Genetic testing reveals underlying cause for a particular phenotype	Down syndrome (Trisomy 21)
Carrier screening	Testing to reveal carrier status of a recessive trait	Cystic fibrosis, Tay-Sachs disease
Newborn screening	Testing in newborns for diseases for whom early treatment can reduce severity of phenotype	Phenylketonuria
Presymptomatic	Testing in healthy individuals for disease that may present later in life	Huntington's disease, hereditary breast and ovarian cancer syndrome

is in regard to their own health or to that of a family member (frequently both).

GRAPPLING WITH A NEW DIAGNOSIS

A new diagnosis of a genetic condition can be a very isolating experience for the medical patient. This can be due to the rarity of the condition and therefore unfamiliarity on the part of the patient, their family, their friends, and very often their healthcare providers. A couple with a child diagnosed with Down syndrome, for example, can gain access to a strong and diverse social network on which to rely for information and advice on special-needs services for their child from birth into adulthood (Down Syndrome Congress, 2012). In contrast, parents of a child diagnosed with Pena-Shokeir syndrome may have fewer disease-specific information resources readily available.

LIFELONG IMPLICATIONS

Many patients diagnosed with a genetic disorder are faced with a myriad of struggles for both themselves and their family members throughout the course of their life. Take, for example, a 24-year-old single woman with a new diagnosis of von Hippel-Lindau (VHL) disease. VHL affects 1 in 36,000 live births and is inherited in an autosomal dominant manner, in that each person with VHL has a 50% chance of passing the condition to each offspring. Approximately 20% of individuals represent *de novo* cases, where there are no family members affected with the disease (Maher, Iselius, et al., 1991). It is a multisystem disorder associated with an increased risk for developing specific tumors, including hemangioblastomas of the brain, spine, and retina; renal cell carcinoma; pheochromocytoma; pancreatic neuroendocrine tumors; and other lesions. An individual with VHL requires close monitoring for signs and symptoms of the disease, and the probability of developing at least one component tumor is 100%. Monitoring for retinal lesions and pheochromocytoma begins in childhood and continues into adulthood with additional imaging of the brain, spine, and abdomen added to the surveillance protocol during adolescence.

This 24-year-old single woman with no children receives a new diagnosis of VHL based on the detection of a hemangioblastoma of the cerebellum and bilateral renal cell carcinoma. She faces the struggles of understanding and coping with the

medical implications of the diagnosis, including treatment and lifelong surveillance. After genetic testing confirms that she carries a deleterious mutation in the *VHL* gene, she must grapple with the genetic implications of the diagnosis. She weighs the implications of sharing the information with her at-risk family members (parents, siblings, etc.): How will the family react? Will they reject her or accept her? Will she have to deal with a parent's guilt if one parent carries the mutation as well? With they reject or accept the information and its implications for them?

The young woman with VHL has the hopes and dreams of one day entering a lifelong relationship with a partner and starting a family. As in any relationship, disclosing private matters is par for the course, but a medical condition such as VHL means that she has the potential to become ill, placing an emotional and financial burden on a marriage. She must ponder the questions of when to disclose, how to disclose, and what to disclose. The desire to have or not to have children is a common discussion in any relationship, but when a transmissible genetic condition is involved, she faces the added dilemma of whether or not to embark on genetic testing of a future pregnancy prior to birth (Klitzman & Sweeney, 2010).

TIMING OF GENETIC TESTING

Genetic testing for genetic disease can be done as early as pre-conception (i.e., in developing embryos) or at any other point in the lifetime. In some cases, informative genetic testing can be done post-mortem on a tissue sample.

Preimplantation Genetic Diagnosis

One recent development in medical genetics, known as *pre-implantation genetic diagnosis* (PGD), is diagnostic testing of fertilized embryos prior to conception (Adiga, Kalthur, et al., 2010). A couple must first undergo *in vitro* fertilization (IVF); then developing embryos are tested for genetic conditions such as chromosome aneuploidy, chromosome rearrangement, or single-gene (Mendelian) disorders such as cystic fibrosis or Tay-Sachs disease. Embryo biopsy consists of sampling one cell from a blastocyst without compromising or damaging the embryo. Couples can select embryos unaffected for the genetic condition for transfer to the woman's uterus, optimizing the chances of an unaffected pregnancy.

Prenatal Genetic Diagnosis

Diagnostic testing of a fetus can be achieved through various techniques. Amniocentesis can be performed at 14–16 weeks' gestation, and for many pregnancies, testing can be performed earlier, at 10–12 weeks' gestation, through chorionic villus sampling (CVS). Couples may wish to know the genetic status of the fetus in order to make special preparations for the birth and antenatal period. This type of couple may also feel they need the information to emotionally prepare themselves for caring for a child with special needs or medical needs. Other couples may choose to know the genetic status with the option of potentially terminating an affected pregnancy.

Genetic Testing in Minors

As mentioned in the example of VHL, medical surveillance beginning in early childhood and very often beginning within the first year of life is recommended for genetic conditions in which signs or symptoms present at an early age. When the genetic condition is known, as in the prior example of the young woman with VHL disease, genetic testing provides a clear-cut answer as to whether her child is affected or not. An unaffected child is spared unnecessary screening; an affected child must begin annual retinal exams within the first year of life, with additional imaging exams of the abdomen and brain around the onset of puberty. Although the genetic test is clear, it has no predictive power. A parent of a child with VHL can be certain that their child will develop at least one tumor in their lifetime. At the same time, the parent must cope with the uncertainty of not knowing what type of tumor could present itself, when it would happen, and what the consequences might be. Inherent to most genetic conditions such as VHL is the observation of variable expressivity, where a condition has a spectrum of severity and even each person within the same family (and therefore carrying the same causative mutation) has different manifestations of the disease. The uncertainty can be overwhelming for both the affected parent and the unaffected parent, and can be difficult in different ways as well.

Also at issue with the testing of minors is the age at which the parents decide to pursue testing for their children. Parents can be guided by their healthcare providers as to the best age range by which a positive test result will begin to impact medical management. Parents can include the child on the decision to test or to wait, depending on the age of the child and their emotional maturity. This can help maintain trust between the child and parent and ease the way towards understanding the test result, whether it is positive or negative. Not including a child in the decision to undergo genetic testing is also the parents' prerogative. The healthcare provider or genetic counselor working with the family should help the parents consider when and how they would disclose the results to their child in an age-appropriate way. However, consider a teenaged minor who is intellectually capable of giving assent for genetic testing. The process of establishing assent involves the healthcare professional, who, together with the parents, provides age-appropriate information about the genetic disease, what

is involved in carrying out the test, and how results will be disclosed. Parents may wish to test their teenaged minor without his or her knowledge primarily because they are hoping for a “good news” scenario where the child will test negative for the condition and the child can be worry-free. When parents ask a healthcare professional to test their teenaged child without the child's knowledge, the provider should help parents anticipate that they may be putting their child's trust in them (and the medical community) at risk, particularly if the test results in a positive diagnosis.

Presymptomatic Genetic Testing and Carrier Screening

An individual's genetic diagnosis weighs heavily on decision-making for offspring and future offspring and affects other family members as well. Consider the case of a recessive genetic condition such as cystic fibrosis. This necessitates that both parents of an affected child are carriers of a mutation in the *CFTR* gene, which means each of their siblings could be a carrier and should be offered testing. However, unless the sibling's spouse also is a carrier, any risk to the sibling's offspring is negligible. Contrast this with an autosomal dominant condition with onset in adulthood such as Lynch syndrome. The siblings of an affected individual (and parents) are considered at risk. Any at-risk relative must weigh the implications of *presymptomatic genetic testing*, where a person undergoes genetic testing without signs or symptoms of the disease.

The role of a genetic counselor is to help an unaffected patient understand the disease and understand the medical implications of a positive result that establishes the diagnosis, or a negative result that rules the condition out completely. A genetic counselor can also become a sounding board for patients grappling with the decision of whether to know or not know their genetic status.

Qualitative studies in patients undergoing presymptomatic genetic testing for Huntington's disease and autosomal dominant amyotrophic lateral sclerosis, both adult-onset neurodegenerative conditions, have reported that patients undergo mixed reactions to a negative result, feeling both joy and relief for themselves and their offspring but in some cases also a form of “survivor guilt” over being spared, unlike their affected sibling or parent (Fanos, Gronka, et al., 2011; Williams, Schutte, et al., 2000). These patients have seen generations of family members decline as a result of the disease and knew they could eventually develop symptoms and suffer a shortened lifespan like their affected relatives. A negative result brings a new sense of hope and optimism, and patients find themselves redefining their sense of self, and their place within their family and within society as a whole (Williams, Schutte, et al., 2000).

Similarly, patients testing positive through predictive testing will experience a mix of emotions. Although it may be initially devastating to receive the news, some patients experience a sense of relief at finally knowing they are positive and that they do not have to go on questioning “Do I have the condition? Am I starting to develop symptoms?” Increased anxiety and depression has been reported in some conditions such as Huntington's disease, while some studies of patients

undergoing testing for neuromuscular diseases and hereditary ataxias have not demonstrated an increase in depression (Smith, Lipe, et al., 2004; Graceffa, Russo, et al., 2009). It should be noted that studies of this nature involve a very small sample size and limited follow-up period and therefore cannot be generalized across different diseases or populations. Offering long-term psychological support is warranted for all patients seeking presymptomatic testing.

SUMMARY

For many patients, their first and only encounter with a genetic counselor is in the setting of prenatal diagnosis, and most of these pregnancies result in healthy babies without a genetic condition. But for the individual who is diagnosed with a genetic disease, the psychosocial and medical implications evolve over time. Patients with chronic genetic conditions have reported a need for more psychosocial support in coping with the day-to-day challenges that comes with a physical disability. A genetic diagnosis affects a patient's interactions with her family members and with her peers in terms of friendship, dating, and marriage. It affects his or her reproductive choices and can influence other major milestones such as pursuing an education or choosing a career. In conditions with shortened life-expectancy, a patient is faced with planning for illness, physical disability, or mental incapacitation at a much younger age than normal. As the patients of the twenty-first century are presented with more genetic information, clinicians need to consider the evolving psychosocial needs that come with that knowledge and refer to specialty services such as genetic counseling for clarification and psychotherapy if that would help the patient cope emotionally with the implications of the knowledge and the effect on the family.

CLINICAL PEARLS

- Genetic counselors identify families at risk, investigate the problem present in the family, interpret information about the disorder, analyze inheritance patterns and risks of recurrence, and review available options with the family (NSGC, 1983).
- This counseling can be divided into distinct components that include contracting, obtaining medical information, risk assessment, education, genetic testing, informed consent, and psychosocial support.
- When taking the family history, it is important to document each individual's age or age at death as well as his/her personal medical history.
- Reports of breast cancer tend to be accurate, while reports of ovarian cancer are less trustworthy (Murff, Spigel, et al., 2004; Chang, Smedby, et al., 2006).
- Family histories can change over time, with new diagnoses arising in family members as time passes.

- Risk assessment here means "What is the likelihood that a patient has a genetic disease?"
- The counselor educates about the implications: Autosomal dominant disorders typically result in a 50% risk to siblings and offspring. Autosomal recessive disorders typically result in a 25% risk to siblings and varying risks to offspring, as they are dependent on the genetic status of the individual's partner. Sex-linked diseases are only passed to specific genders.
- If a disease is truly *de novo* in nature, the risks in the relatives are limited to offspring.
- If an individual learns that he/she is a true negative, it means there is no increased risk of developing specific symptoms due to their family history. Their risk of developing specific symptoms is that of the general population.
- If more than one family member is tested, there is a chance of learning about misattributed paternity or a hitherto unknown adoption.
- Those who are currently not exhibiting symptoms of disease should know that most are protected by law with respect to genetic discrimination by their health insurance company or employer. However, no legislation exists to protect individuals from use of this genetic information by life insurance or disability insurance companies.
- Identifying the patient's support system prior to the genetic test initiation is essential.
- Information about family dynamics will be important to helping the patient cope with the implications of genetic counseling and testing.
- The psychosocial impact of living with a genetic condition will change over time—and throughout the lifespan.
- The patient weighs the implications of sharing the information with his or her at-risk family members (parents, siblings, etc.) and the implications for having children.
- The age at which a positive test result will begin to affect medical management serves as a guide for parents to judge when to pursue testing for their children.
- One recent development in medical genetics known as preimplantation genetic diagnosis (PGD) is diagnostic testing of fertilized embryos prior to conception (Adiga, Kalthur, et al., 2010) to identify those who carry a genetic risk.
- When parents ask a healthcare professional to test their teenaged child without the child's knowledge, the provider should help parents anticipate that they may be risking their child's trust in them (and in the medical community), particularly if the test results in a positive diagnosis.

PART VII

WOMEN'S HEALTH

GYNECOLOGICAL SURGERY, PELVIC PAIN, AND OTHER RELEVANT ISSUES

Gail Erlick Robinson and Diane de Camps Meschino

INTRODUCTION

Obstetricians and gynecologists have a complex task. They must deal with the fear, anxiety, and depression that may accompany any physical illness. In addition, issues that involve a woman's reproductive health are highly emotionally charged and closely linked to her sense of femininity, sexuality, attractiveness, and value. The gynecologist often acts as the woman's primary care provider and, therefore, may be the only one in a position to detect ongoing concerns such as relationship problems, domestic violence, sexual dysfunctions, or histories of abuse. Psychological conflicts related to femininity, sexuality, or abuse may present as aversion to physical examination, pelvic pain, or attitudes toward pregnancy or sexuality. Healthcare professionals involved with patients undergoing gynecological surgery must recognize that patients are dealing not only with the reason for the surgery, but also with the specific meanings of surgery on female sexual and reproductive organs.

GYNECOLOGICAL SURGERY

HYSTERECTOMY

Total hysterectomy refers to the removal of the entire uterus, including the cervix; while *subtotal hysterectomy* leaves the cervix in place. This operation may or may not be accompanied by a bilateral salpingo-oophorectomy, which includes removal of the ovaries. Gynecologists disagree about the added benefits of removing healthy ovaries at the time of hysterectomy. Some argue that this reduces the risk of subsequent ovarian cancer, while others feel that the risk in most women is too low to warrant this additional surgery. Indications for hysterectomy range from abnormal or excessive bleeding and pain, to cancer of the uterus. A decline in hysterectomy rates since 1970 may be related to a number of factors, including alternatives to hysterectomy such as endometrial ablation, as well as an increased understanding on the part of physicians that women do not necessarily view their uterus as a useless organ just because they have passed the childbearing stage.

Hysterectomy may be performed abdominally, vaginally, or via laparoscopy. The latter procedure takes longer,

but results in shorter inpatient stays. A six-month follow-up of women who underwent these two different types of procedures showed an overall improvement in psychological well-being, with no significant differences in scores between the two groups (Thakar et al., 2004; Persson, Wijma, Hammar, & Kjolhede, 2006).

Although it was previously thought that post-hysterectomy depression was a common phenomenon, more recent studies have found no evidence that hysterectomy causes depression (Baldaro et al., 2003; Lambden et al., 1997); indeed, Yen et al. (2008) reported an improvement in depressive symptoms, anxiety symptoms, body image, and subjective gynecological symptoms. Women with a history of multiple surgeries and those with chronic pelvic pain are a high-risk group for post-surgical distress. Psychological reactions to hysterectomy vary with the reason for the operation, the type of procedure, the woman's previous medical history, her age, her understanding of the consequences, her past psychiatric history, and her current supports and relationships (Cooper, Mishra, Hardy, & Kuh, 2009). Women who had undergone hysterectomy before age 40 had significantly higher anxiety and depressive scores at age 53 than women who had not undergone the procedure. Women who had undergone hysterectomy for cancer also had significantly higher scores. Women may feel fearful of hysterectomy because of myths they believe about the procedure.

In some women, removal of the ovaries may raise issues about loss of femininity, fears of aging, and concerns about the symptoms of menopause or the safety of hormone replacement treatment. However, research has found that women whose ovaries are removed do not, as a group, have more psychological distress than women with ovary-sparing operations. Women who are younger at the time of the hysterectomy may be at increased risk for psychological distress if they have not started or finished their childbearing. For some women, even though they never wanted or no longer wish to have children, the idea of ending their childbearing potential represents a loss of femininity and can cause psychiatric distress. Others may fear the loss of the familiar menstrual periods, which they may feel cleanse the body.

Women and their partners may mistakenly believe that after hysterectomy they will have no interest in or ability to have sexual activity, or that there will be a decrease in their sexual attractiveness (Flory, Bissonnette, & Binik, 2005). There are

many possible physical explanations for post-hysterectomy sexual problems, including: disturbed vaginal blood flow; changes in nerve supply, or loss of the cervix and its mucus-producing glands, leading to decreased vaginal lubrication; reduction of sensitive tissue from the upper vagina; or the loss of uterine contractions. However, reduction in preoperative pain or bleeding may result in improved postoperative sexual functioning. Women with preexisting pelvic pain and depression do not do so well as those with only one or neither of these conditions; however, their quality of life and sexual functioning still improve over baseline. Sexual functioning postoperatively is highly related to their preoperative sexual activity, enjoyment, and relationship to their partner. Women who do not have good support systems may be at a disadvantage, as they would be in dealing with any other type of stress.

Preoperatively, the clinician should thoroughly discuss the reasons for the recommended hysterectomy and the consequences of the surgery, including allaying unreasonable fears and addressing mistaken beliefs, such as that she will immediately begin aging rapidly. The clinician should also dispel myths about the dangers of hormone replacement, such as that they automatically cause breast cancer or strokes (see Chapter 67, Hormones and Mood). It is helpful to discuss the flaws in the Women's Health Initiative studies (Writing Group for the Women's Health Initiative Investigators, 2002) and explain the misconceptions that came out of that work (Klaiber, Vogel, & Rako, 2005).

In the case of an emergency hysterectomy, there is obviously little time for preparation; however, in elective hysterectomies, the woman should be a key participant in the decision-making process so that she may consider the various quality-of-life issues involved in such a choice. Post-hysterectomy, women can benefit from clear explanations about what has happened. Perhaps because hysterectomy is a fairly common procedure, many women do not think of it as major surgery and are unprepared for the weakness and fatigue that may follow this procedure. They may need reassurance that they do require some time to recover (Table 65.1). Recovery after vaginal or laparoscopic surgery takes three to four weeks, while women who have had abdominal hysterectomies take about four to six weeks to recuperate. Women should gradually regain strength over these periods. If weakness, fatigue, and apathy continue or become worse, the patient should be reevaluated for physical complications or signs of depression.

In terms of sexual functioning, if an oophorectomy has been performed, attention must be paid to symptoms of

vaginal dryness, which may lead to dyspareunia. Estrogen replacement therapy (ERT) should be considered in oophorectomized premenopausal women to alleviate menopausal symptoms such as hot flashes, night sweats, and genital-urinary problems (see Chapter 67, Hormones and Mood).

For women who do suffer from psychological distress or depression post-hysterectomy, antidepressant medication or individual or couple psychotherapy may be required to help them deal with their personal concerns about loss of femininity, loss of sexual interest, discord in the relationship, or fears about the outcome of a malignant disease. Preoperative counseling that includes the partner can help prevent relationship problems related to these concerns.

FEMALE STERILIZATION

Female sterilization, used by 10.3 million American women, is the second most common method of birth control in the United States and the leading method among women age 35 and older (Chandra, Martinez, Mosher, Abma, & Jones, 2005). Female sterilization involves the occlusion of the fallopian tubes via cutting, clipping, or cauterizing. The procedure itself is fairly simple, and the average recovery time is short. Women may seek this as a dependable, trouble-free method of permanent birth control. For many women, this is a straightforward and trouble-free decision. However, in cases in which a woman chooses sterilization because her spouse or partner is pressuring her to do so, or in which the man has been asked to have a vasectomy and has refused, there may be a great deal of ambivalence and resentment. Women who freely choose this procedure and understand its consequences tend to have very low rates of regret (5.9%), while regret and later psychological distress are more common (20.3%) in women who are younger, ambivalent about the sterilization, were pressured into the decision, or who made the decision for financial reasons (Hillis, Marchbanks, Tylor, & Peterson, 1999). Curtis, Mohllajee, and Peterson (2006) reviewed all existing studies and found that the younger women are at the time of sterilization, the more likely they are to report regretting that decision. Women undergoing sterilization at the age of 30 or younger are almost twice as likely as those over the age of 30 to express regret; 3.5 to 18 times as likely to request information about reversing the procedure; and about eight times as likely to actually undergo reversal or an evaluation for *in vitro* fertilization (IVF) (Curtis et al., 2006). Two years after tubal ligation, 80% of women reported that their sexual interest and pleasure had not changed (Costello et al., 2002). For the

Table 65.1 ABDOMINAL VS. LAPAROSCOPIC HYSTERECTOMIES

PROCEDURE	SURGERY TIME (MIN.)	HOSPITAL STAY (DAYS)	TIME OFF WORK (DAYS)	TIME TO FULL ACTIVITY (WKS)
Abdominal hysterectomy	64–98	3–4.9	33.5	10.7
Vaginal or laparoscopic hysterectomy	99–162	2–3.1	26	5.8

SOURCES: Perrson et al., 2006.

20% of women who noticed a change, 18.3 reported increased interest and 17.2% increased pleasure, while 1.7% reported decreased interest and 1.1% decreased pleasure.

Preoperatively, it should be stressed that tubal ligation is a permanent procedure. Women who are not ready to make this decision should be encouraged to try temporary types of contraception. A woman who seems highly anxious about the procedure or who appears to be in conflict with her partner about having the procedure should receive counseling before proceeding. Although about 50% of tubal ligations take place postpartum, it is not generally advisable to carry out the procedure immediately after a birth or an induced abortion. A woman who has sterilization immediately postpartum may experience enormous regret if the baby does not survive. Post-abortion may be a time of increased distress during which decision making is affected.

At times, childless women seek permanent sterilization. Many gynecologists are reluctant to carry out this procedure, believing that this must be evidence of great emotional instability. The reasons for this choice should be thoroughly explored. If the decision appears to be based on current psychological distress or a troubled relationship, attempts should be made to improve these situations before the procedure is considered. Administering a brief psychological test such as the Beck Depressive Inventory (Beck, 2006) may indicate if the woman is depressed. If the gynecologist has concerns about the woman's mental state because she is showing signs of depression or anxiety or seems to be being pressured into this decision, it may be wise to suggest a referral for a psychological assessment. For women in whom the decision is made as a result of a thoughtful analysis of their previous life experience and future expectations, their autonomy and wishes should be respected.

GYNECOLOGICAL PAIN

VULVAR PAIN

The vulvar area includes the labia majora, labia minora, clitoris, and vaginal introitus (area around vaginal opening). Vaginal pain, which occurs farther interior to the introitus, is not included in this section. Chronic vulvar pain lasting three to six months is estimated to affect 16–28% of women (Harlow & Stewart, 2003). It may occur in all age groups, with onset most frequently between 18 and 25 years. Surveys suggest 40% of women with vulvar pain do not seek treatment (Goldstein & Burrows, 2008). Typical presenting symptoms are continuous or intermittent burning, pain, itching, or irritation. Vulvar pain is divided into pains caused by specific disorders and those with no known etiology, referred to as *vulvodynia*. Known causes include: infections such as candidiasis or herpes simplex; inflammation such as lichen sclerosis; neoplasms; and neurological problems such as pudendal nerve entrapment or multiple sclerosis (Danby & Margesson, 2010).

Vulvar pain has a serious impact on one's quality of life, including decreased enjoyment, impaired sexual pleasure,

guilt due to impaired sexual relationships, and depression and anxiety from living with chronic pain. The clinician's basic understanding of biomedical facts and theories not only permits communication with other specialists, but provides a foundation of trust with patients.

VULVODYNIA

Vulvodynia is defined as chronic (3–6 months) vulvar discomfort most often involving burning pain, in the absence of a relevant specific disorder. Visual examination may reveal erythema, easily missed small ulcers and fissures, or nothing abnormal. Vulvodynia is classified as *localized* (affecting part of the vulva) or *generalized* (affecting the entire vulva), with further subclassification into *provoked* (sexual, nonsexual, both), *unprovoked*, or *mixed* (both provoked and unprovoked). Furthermore, localized vulvodynia may be described according to the local area affected (e.g., *vestibulodynia*), and whether it is primary or secondary. *Primary* vestibulodynia is provoked localized vulvodynia, which occurs with first attempts at penetration (tampon or sexual), and *secondary* vestibulodynia is that which occurs after a period of pain-free sexual intercourse (Danby & Margesson, 2010).

Numerous factors, including embryonic abnormalities, urinary oxalates, genetic factors, hormonal factors, inflammation, infection, and neurological factors, are theorized as etiological. Oxalates found in many of our foods (greens, chocolate, berries, beer) are both excreted in the urine and a component of many renal calculi. They have been studied as possible factors in making urine more irritating, thus worsening vulvar pain. Previous infections seem to increase susceptibility to vulvodynia. There are conflicting studies regarding whether prior use of oral contraceptives increases the risk of vulvodynia. Assumptions that sexual trauma is the cause are unwarranted, although such a history may play a role in amplifying anxiety in response to physical distress or in determining coping responses.

Dyspareunia is frequent in women with vulvodynia. Women anticipating painful intercourse may have resultant difficulty with arousal and lubrication, causing added pain and muscle spasms resulting in vaginismus. Depression and anxiety are common comorbidities of chronic pain from any source, and both can negatively interfere with pain-regulation mechanisms. Women with primary localized vulvodynia are reported to have more psychological distress, anxiety, and somatization than those with secondary vulvodynia. Women with vulvodynia often suffer frustration, frequently seeing several healthcare practitioners before a diagnosis is made. In the absence of visible abnormality, women may be labelled as having a psychological disorder. Mandal et al. (2010) have set out guidelines for the medical and surgical management of vulvodynia (Table 65.2).

BLADDER PAIN SYNDROME (INTERSTITIAL CYSTITIS)

Bladder pain syndrome (BPS) has been suggested as preferred nomenclature over *interstitial cystitis* (IC) by several professional bodies (Hanno et al., 2010). BPS/IC is defined as an

Table 65.2 VULVODYNIA TREATMENT RECOMMENDATIONS

RECOMMENDATIONS	DETAILS
Pain history	Degree of symptoms: visual analogue scale, pain diaries, assessment tools, e.g., McGill Pain Questionnaire Impact of pain ISSVD classification
Sexual history if sexual pain is present	Sexual interest, arousal, lubrication, anorgasmia, vaginismus, partner problems, psychosexual comorbidity
Clinical history and physical is basis for diagnosis	Biopsy is unnecessary Review history and physical during treatment to rule out new diagnostic possibilities requiring biopsy/MRI
Multidisciplinary team approach	Individually tailored, e.g., pain specialist/clinic, CBT or supportive psychotherapy, physiotherapy
Combining treatments	Combining is appropriate if various treatments manage different facets of pain, e.g., physiotherapy, dietary, and psychotherapy
Explanation and education	Explanation of diagnosis and allay fears regarding infectious disorders and cancer Information sheet regarding self management: e.g., Sources Vulvar Pain Society, British Pain Foundation
Topical agents	Use with caution re irritancy Topical lidocaine gels/ointments to allow penetrative sex for provoked vulvodynia warn re: irritancy, penile numbness (condoms may help), oral contact 5% lidocaine ointment to affected area plus cotton wool soaked in 5% lidocaine inserted into the vestibule every night for 7 days. Overnight 5% lidocaine ointment for treatment of vulvar vestibulitis Alternatives: capsaicin cream, ketoconazole cream, oestrogen creams, steroid creams interferon, nifedipine—all with mixed results
Tricyclic Agents	Amitriptyline and nortriptyline Start with low dose (e.g., 10 mg amitriptyline) and titrate up weekly according to response and tolerability Gabapentin (start 300 mg increase to max 3600 mg every 3 days; pregabalin
Surgical excision	Modified vestibulectomy in selected patients with provoked vestibulodynia Vestibuloplasty is not recommended Laser vapourization of vestibule is not recommended
Pelvic floor dysfunction intervention	For those with vaginismus response in sex related pain, e.g., pelvic floor exercises, external and internal soft tissue self massage trigger pint pressure, biofeedback, vaginal trainers, vaginal TENS Unknown results of physiotherapy for unprovoked vulvodynia
Acupuncture	Trial recommended for unprovoked vulvodynia Unknown value for provoked vulvodynia
Intralesional injections	Methylprednisolone acetate and lidocaine in saline subcutaneously into vestibule for vestibulodynia Betamethasone and lidocaine infiltration of vestibule for vestibulodynia Botox for allodynia

Mandal, D. et al. (2010). Guidelines for the management of vulvodynia. *British Journal of Dermatology*, 162, 1180–1185; Petersen, C. D. (2008). Vulvodynia. Definition, diagnosis and treatment. *Acta Obstetrica et Gynecologica*, 87, 893–901.

unpleasant sensation (pain, pressure, and discomfort) perceived to be related to urinary bladder filling, associated with lower urinary tract symptoms of more than six weeks' duration, in the absence of infection or other identifiable causes. Sensations may also be felt in the urethra, vulva, vagina, pelvis, rectum, lower abdomen, and lower back. Marked urinary urgency, frequency (up to 60 times per day), nocturia, and dyspareunia are extremely common and distressing, but they may also indicate other disorders. At its worst, the impact of

this condition is devastating, leading to a severely impaired quality of life. The condition tends to progress upon onset for 12–18 months, then stabilize with chronic symptoms (mild, moderate, or severe), but exacerbations and remissions are common. BPS/IC can be difficult to differentiate from recurrent urinary tract infection, endometriosis, chronic pelvic pain, vulvodynia, and overactive bladder. Carcinoma, carcinoma *in situ*, eosinophilic cystitis, and tuberculous cystitis must be ruled out. Medical history to establish the onset,

frequency, pattern, triggers, and location of pain will aid in diagnosis. The pain from BPS/IC usually occurs as the bladder fills and is relieved upon voiding. Premenstrual worsening of pain is typical, differentiating BPS/IC from endometriosis, which is most painful during menses. Vaginitis, vulvar lesions, and urethral diverticula are ruled out by physical examination. Urinalysis and urine culture are necessary investigations, with biopsy or cystoscopy as indicated.

The prevalence rate of BPS/IC is unknown, with reported ranges from 0.067–6.53%. It is more common in women and thought to be under-diagnosed and under-treated (Berry et al., 2011). The median age at diagnosis is 40 years old, but patients typically suffer for many years, consulting several physicians before a diagnosis is made. Women frequently experience their healthcare providers as blaming and unhelpful. Urinary tract infections (UTIs) are frequently diagnosed, even in the absence of a positive urine culture, whereas BPS/IC may be the correct diagnosis. Furthermore, UTIs may be the initiating event for the development of BPS/IC and are a frequent complication of BPS/IC, suggesting the need for ongoing clinical vigilance. Since BPS/IC and endometriosis often coexist, both diagnoses must be considered. In addition, many patients report being told their symptoms could be not accounted for by organic pathology, with the implication that the cause is psychological, but no treatment is offered.

One theory of causation is that increased permeability of the bladder epithelium allows potassium ions to pass the endothelial lining and initiate inappropriate stimulation of both neurons and immune pathways, but the cause of this permeability is unknown. Studies have revealed an increased prevalence of antecedent nonbladder syndromes (NBS) among IC patients, including: chronic pelvic pain (CPP), chronic fatigue syndrome, fibromyalgia, irritable bowel syndrome, sicca syndrome, migraine, depression, panic disorder, allergies, asthma, and vulvodynia (Warren et al., 2009; Warren, Wesselmann, Morozov, & Langenberg, 2011). Some studies suggest a history of current sexual abuse, but not childhood sexual or physical abuse.

The American Urological Association has detailed guidelines for the medical and surgical treatment of IC and of symptom management (Hanno et al., 2011). Support and education for families and partners may help maintain the patient's support network intact. Patients may obtain assistance and support from self-help groups and organizations such as the Interstitial Cystitis Association. Treatment recommendations are summarized in Table 65.3. The response to treatment for most specific IC interventions is individual and unpredictable.

CHRONIC PELVIC PAIN

Chronic pelvic pain (CPP) is defined as pain in the pelvis for six months or more, with incomplete relief with most treatments, significantly impaired function at home or work, signs of depression, and altered family roles. The term of six months is arbitrary, and caution is advised not to delay treatment in clinical situations. Symptoms may be cyclical (either menstrual or non-menstrual) or noncyclical.

CPP in women is a devastating and extremely difficult clinical issue to manage due to its complexity in presentation, the challenges in treating it adequately, and its significant impact on patients' lives. Prevalence estimates vary from 16% in the United States, to over 25% in the United Kingdom, New Zealand, and Australia. A recent study revealed that just over one third of women reporting CPP had sought help from a health professional (Pitts et al., 2008). This frequency is similar to that reported in a 1996 study in spite of increased awareness (Mathias, Kuppermann, Liberman, Lipschutz, & Steege, 1996). CPP is responsible for 15% to 40% of laparoscopies and 12% of hysterectomies in the United States (Reiter, 1990).

Physiological causes of CPP pain include *Mittelschmerz* pain and primary dysmenorrhea. The latter is reported by 60% of adult women (12–14% with severe symptoms) and 72% of adolescents (17% with severe symptoms). Many different disorders, such as endometriosis, adenomyosis, fibroids, cervical stenosis, tumors, intraperitoneal adhesions, and pelvic inflammatory disease, can result in CPP. Pathology in other systems, including neurological, urological, gastrointestinal, musculoskeletal, and psychological, while less common, may also be causative. Primary and secondary co-occurrence of pathological conditions is frequent, suggesting the need for rigorous investigation.

Due to the typically lengthy delay between pain onset and diagnosis, the treating psychiatrist should be aware of the approach to diagnosis and investigations to ensure that the patient has received optimal care. The medical history should include a chronological pain inventory: with details of timing (cyclical, noncyclical, and relationship to menses), onset, quality, location, radiation, and precipitating and relieving factors, as well as symptoms associated with the gastrointestinal, urinary, and musculoskeletal systems. Menstrual, obstetrical (including physical trauma from delivery), and sexual histories (especially deep dyspareunia) are critical components. Prior investigations, treatment and response, self-care, impact on functioning and quality of life, and desire for fertility will guide treatment decisions. The physical exam should be conducted while the patient is symptomatic and should include an assessment of the dermatological, musculoskeletal, gastrointestinal, urinary, and neurological systems, in addition to meticulous gynecological and abdominal exams. Initial laboratory investigations should include a complete blood count (CBC), C-reactive protein, CA-125 (when indicated), urinalysis, urine microscopy and culture, and vaginal swabs. Ultrasound is performed to look for structural abnormalities and is helpful in distinguishing between cystic and solid masses. For endometriosis, only deeply infiltrating lesions and ovarian involvement are detectable by ultrasound, suggesting that 80% of endometriosis will not be visualized. Computerized tomography (CT) may be used when assessing the organs associated with the gastrointestinal tract, and magnetic resonance imaging (MRI) is useful for pelvic masses, adenomyosis, and endometriosis (Won & Abbott, 2010).

Many other conditions are commonly associated with CPP. Endometriosis, a condition defined by the presence of endometrial tissue outside of the endometrial cavity, is the

Table 65.3 TREATMENT RECOMMENDATIONS AND PRIORITIES FOR INTERSTITIAL CYSTITIS

PRIORITY	INTERVENTION	DETAILS	LEVEL OF EVIDENCE
First Line	Education	Benefits vs risks/burdens of the available treatment alternatives	Clinical Principle
	Self care and Behavioural modifications	Altering the concentration and/or volume of urine (fluid restriction or hydration) Avoidance of known food irritants, e.g., coffee or citrus; assessing other food or fluid irritants by using an elimination diet Avoid aggravating pelvic floor exercises, sexual intercourse, tight clothing and constipation use of local heat or cold over the bladder Perineum pain reduction via application of heat or cold over trigger points Bladder training Pelvic floor muscle relaxation Over the Counter preparations: quercetin, calcium glycerophosphates, pyridium (commonly used by patients and some report effectiveness) Coping strategies for flares: e.g., meditation, imagery	
	Mental Health	Validation; empathy Counselling re stigma Prevention of exacerbations by overwhelming stress: meditation and imagery Empowering regarding self care Assessment and treatment of co-morbid depression and anxiety disorders: antidepressants, CBT, mindfulness based stress reduction Assess, treat for ongoing abuse Support and education for families and partners Self-help groups and organizations: Interstitial Cystitis Association	Clinical Principle
Second Line	Manual physical therapy	Maneuvers to resolve pelvic, abdominal and/or hip muscular trigger points, lengthen muscle contractures, and release painful scars and other connective tissue restrictions: avoid pelvic floor exercises	Clinical Principle
	Pain management	Pharmacological, stress management, manual therapy if available	Clinical Principle
	Oral medication	Amitriptyline, cimetidine, hydroxyzine or pentosan polysulfate	Optional Grade B and C
	Intravesical medication	Dimethyl sulfoxide, heparin or lidocaine	Optional Grade B and C
Third line	Cystoscopy	With short duration, low pressure hydrodistension	Optional Grade C
		Treat Hunner's lesions	Recommended Grade C
Fourth Line	Neurostimulation	A trial of neurostimulation; if successful, implantation of permanent neurostimulation device	Optional Grade C
Fifth line	Oral Cyclosporine A		Optional Grade C
	Intradetrusor botulinum toxin A	Possibility that intermittent self-catheterization may be necessary after treatment.	Optional Grade C
Sixth line	Major surgery in carefully selected patients	Substitution cystoplasty Urinary diversion with or without cystectomy Pain can persist even after cystectomy, especially in nonulcer IC/BPS.	Optional Grade C

The AUA categories of evidence strength:

Grade A: Well-conducted RCTs; exceptionally strong observational studies

Grade B: RCTs with some weaknesses of procedure or generalizability; generally strong observational studies

Grade C: Observational studies with inconsistencies/small sample sizes/confounders

most common gynecological pathology of CPP. Its incidence is estimated to be 1% to 7% in the United States (Barbieri, 1990). Pain is typically cyclical, with worsening during menses (75% of those with symptomatic endometriosis), but non-cyclical pain is common with abdominal-wall endometriosis. The severity of symptoms does not correlate with the severity of pathology; however, deep dyspareunia and painful defecation may suggest infiltrating disease.

In laparoscopic investigations of CPP, 30% of these women are found to have endometriosis, yet endometriosis appears to be asymptomatic in 45% of women who have it (Rawson, 1991). Neither the etiology nor the pathophysiology is understood. Treatment may include an estrogen and progestin combination, progestin alone, danazol, or a gonadotropin-releasing hormone (GnRH) agonist, with the option of adding a non-steroidal anti-inflammatory drug (NSAID). Randomized controlled trials (RCTs) reveal symptom improvement with surgery and excision of endometriosis. The most effective treatment for women not trying to preserve their fertility is a hysterectomy with bilateral oophorectomy (Jarrell et al., 2005a). Women suffering from endometriosis may have to endure recurrent pain in order to try to preserve their chance to have children.

Intraperitoneal adhesions are found in 25% to 50% of women with CPP, but their role in causation is unclear. They are a well-known result of surgery and may also be seen in patients who have endometriosis or have had abdominal and pelvic infections or inflammation. It is unclear what relationship adhesions have to CPP, and whether lysis of adhesions is helpful. While Peters' RCT on adhesionolysis in patients with CPP did not reveal clear benefits, many uncontrolled studies support the procedure. It is theorized by some that adhesions have re-formed in those for whom adhesionolysis fails to relieve pain. Women may undergo this procedure only to discover their pain persists.

Adenomyosis (the presence of endometrial glands and stroma with the uterine myometrium) is present in 20% of reproductive women, and while the most common presentation is menorrhagia, about 25% present with cyclical CPP associated with menses. Ultrasound is a good investigational tool, but MRI has increased sensitivity and specificity. Continuous OCP (oral contraceptive pill), levonorgestrel-releasing intra-uterine devices (IUDs), endometrial ablation, and hysterectomy are treatment choices.

Uterine leiomyoma (fibroids), found in 20% of reproductive-age women, may present clinically with CPP, abnormal bleeding, and deep dyspareunia. They are investigated with ultrasound and treated with variable success and side effects, using continuous OCP, levonorgestrel-releasing IUDs, GnRH analogs, fibroid resection, uterine artery embolization, and hysterectomy.

The prevalence of pelvic inflammatory disease (PID) among women with CPP is difficult to estimate, as the presentation of PID varies from severe acute pelvic or abdominal pain (4%) to asymptomatic infections (60%). PID should be suspected in any patient with CPP, and in any sexually active woman with otherwise unexplained abdominal or pelvic pain. Recognition and early treatment of PID may prevent

its long-term complications, particularly tubal scarring with ectopic pregnancy or infertility. PID is caused by sexually transmitted microorganisms, which lead to fallopian tube inflammation, potentially resulting in infertility and ectopic pregnancy. Sexually transmitted microorganisms, including *Chlamydia trachomatis*, *Neisseria gonorrhoeae*, *Mycoplasma genitalium*, and bacterial vaginosis-associated microbes, are causative agents. Ness and colleagues report CPP as a long-term consequence after an episode of PID in 18% to 33% of women, regardless of treatment (Ness et al., 2002). Condom use will assist with the reduction in transmission of some organisms and reduces the development of CPP after an incidence of PID. Adhesions are the suspected etiology of CPP after PID, but some uncertainty about this remains. Women with CPP after PID not only deal with chronic pain, but also may suffer from guilt or anger related to the cause of the infection.

Myofascial pain may be the most common cause (30%) of CPP in women with a negative laparoscopy and frequently is a secondary development of many of the aforementioned conditions. Lower abdominal scars and myofascial trigger points are common. A *trigger point* is defined as a focus of hyper-irritability in a muscle or its fascia, with a pattern of pain-referral specific to that muscle. Trigger points are thought to develop as a result of injury or micro-trauma with mechanical and postural stressors causing prolonged contraction of muscles. Treatment of trigger points has a significant impact on reducing pain from a number of primary initiating disorders (Jarrell et al., 2005b). Techniques used include pelvic floor exercises and biofeedback, pelvic muscle massage, trigger-point injection (local anesthetics, steroids, or botulinum toxin), sacral nerve neuromodulation (electrical stimulation), and acupuncture. Anderson et al. (Anderson, Wise, Sawyer, & Nathanson, 2011) used self-treatment with a wand designed to deliver measured pressure to internal myofascial trigger points and found it able to reduce trigger-point sensitivity by 25% in a pilot study.

IC (see above) is a very common co-occurrence with CPP (84%) in general and with endometriosis specifically. Irritable bowel syndrome (IBS) is present in one third of women with CPP, and 10–20% of the adult population. Menses can exacerbate IBS, including symptoms of dyspareunia and dysmenorrhea. Colonoscopy is performed if indicated, and treatment is primarily with diet. Inflammatory bowel disease must be ruled out.

Pudendal neuralgia (PN) is a less common cause of CPP, but the pain is often severe and sharp in the area of pelvic organs and structures. It may be exacerbated by sexual intercourse and by prolonged sitting, with relief upon standing. It is treated with physical therapy and nerve blocks.

CPP is frequently comorbid with depression, sleep disturbance, previous or current physical or sexual abuse, psychological stress, and substance abuse (Jarrell et al., 2005a). As visible causes of pain are frequently absent, or pain reports are greater than would be suggested by visible findings, psychological theories of causation have been suggested. Theories of stress, psychologically caused pelvic congestion, feminine identity issues, personality disorders, and conflicts about sexuality

and intimacy as causative have been suggested (Lee & Slade, 1996) but have not been proven. Childhood emotional, physical, and sexual abuse is associated with higher levels of negative mental health and negative health trajectories in general. There are numerous physical and psychological adaptations to abuse, such as changes in epigenetic expression or neuroendocrine functioning that may play a role in the development of CPP. Psychological or physical abuse has not been shown to be causally related to CPP, but coping with pain requires robust psychological resources, which can be impaired by victimization. Sexual abuse, however, has been significantly associated with CPP in some studies with a recent meta-analysis, revealing an odds ratio (OR) of 2.7, with subgroup analysis revealing no significant impact regarding the age of the occurrence of the abuse (OR 3.03 for adult sexual abuse and 2.61 for childhood sexual abuse) (Paras et al., 2009).

PSYCHOLOGICAL ASSESSMENT AND TREATMENT OF GYNECOLOGICAL PAIN

Although the above conditions are slightly different, the psychological approach to assessment and treatment is similar. Multidisciplinary teams are most effective at treating chronic pain. The mental health specialist may need to play a role in educating other practitioners about the complex relationship between pain and the psyche. Treatment of comorbid anxiety and depression will improve both the mood symptoms and the pain, as it does in other painful conditions.

The standard psychiatric and psychological assessment should include questions about: the patient's understanding of her condition; fears regarding the meaning of her symptoms, both medically and for her future; attempts at and results of self-care; experiences with healthcare providers; outcomes of previous treatments; expectations of current treatment; past and current physical, psychological, and/or sexual abuse; coping style, and support systems. Fear of pain and catastrophizing responses should be assessed and can further be quantified using standardized measures.

Structured psychotherapy should include: education about the relationship between affective, cognitive, and somatic reactions to pain that may worsen pain and quality of life; identification and modification of individual cognitive and affective reactions to pain symptoms; practice of somatic techniques, such as relaxation to counteract physical reactions to pain; identification and modification of behaviors that potentiate pain; enhancement of behaviors that reduce pain; and improvement of communication and other behaviors that impede relationships and intimacy. Cognitive behavioral therapy (CBT) can address overly negative life and personal appraisals, catastrophic thoughts, and stress responses that amplify pain. CBT has been shown to be effective in randomized control trials in pain research in general and with gynecological and pelvic pain specifically. Masheb and colleagues report clinically significant improvement in pain severity (self- and physician-report), sexual function, and emotional function with both CBT and supportive psychotherapy (Masheb, Kerns, Lozano, Minkin, & Richman, 2009). The CBT treatment arm was superior with respect to

rates of patient satisfaction, decreased pain with vulvar examination, and overall improved sexual functioning. These findings reinforce the importance of support, empathy, treatment of anxiety and depression, education, and specific behavioral interventions in routine practice. Meditation, imagery, and mindfulness-based stress-reduction techniques have also been used to help patients cope with chronic pain and disease; even if pain is not altered, the capacity to live with it can be improved.

GYNECOLOGICAL ONCOLOGY

The reproductive organs are the fourth most common site of cancer in American women, with gynecological cancers affecting one of every 20 women (American Cancer Society, 2007). All patients diagnosed with cancer have to deal with a number of emotional issues, including a sense of helplessness, fear of pain, anticipation of treatment, and fears of death. These reactions are moderated by the individual's typical style of coping with crises, the specific diagnosis, the seriousness of the illness, and the magnitude of the treatment. Gynecological cancers may have an especially strong impact on women because of their relationship to issues of fertility, sexuality, attractiveness, and value.

Removal of the uterus or ovaries in a younger woman leads to a loss of fertility, which may be particularly upsetting. Not only may she personally grieve the loss of potential children, she may feel she has lost value in her culture and, therefore, will never find or maintain a relationship. Even if the woman is not interested in childbearing, loss of her reproductive organs may affect her sense of femininity.

By the time they are diagnosed, 80% of women with ovarian cancer have an advanced stage of the disease. Clinical depression was reported in 21% of patients, while 29% scored above the 75th percentile for anxiety (Grzankowski & Carney, 2011). Not only is it important to assess for depression and anxiety, the individual's quality of life must be considered (Grzankowski & Carney, 2011). Patients often must make a difficult choice between aggressive treatments and their quality of life. This is an individual decision that must be discussed with the patient and respected by the clinician.

Operations that are especially disfiguring, such as complete pelvic exenteration or vulvectomy, may be particularly damaging to a woman's self-esteem. A sense of being disfigured, as well as such physical changes as shortening of the vagina or loss of the clitoris, vaginal bleeding, or dryness may interfere with sexual functioning. The extent of sexual dysfunction tends to be related to the severity of the disease and the magnitude of treatment. While 30–40% of patients with early cervical cancer have sexual problems, up to 90% of patients with pelvic exenteration stop having vaginal sex (Andersen, Anderson, & de Prose, 1989). This may lead to problems in the woman's current relationship or make her avoid any future relationships out of fear of rejection. Previous successful sexual relationships and ongoing support from a caring partner may help the woman adjust to changes in her sexual functioning. Couples may benefit from counseling

aimed at broadening their view of sexuality and discovering other ways of giving and obtaining sexual pleasure. Although some couples may find it difficult, if not impossible, to make this transition, others may be willing to convert to a more flexible and open view of sexuality. Recent advances in reconstructive surgery have led to increased post-operation quality of life with better body image, sexual functioning, and relationships (Hawighorst-Knapstein, Schonefussers, Hoffman, & Knapstein, 1997). Women still have to deal with ongoing fears about the return of cancer.

Treatment of gynecological cancer may revive past traumas such as incest or rape, or stir up guilt for previous behaviors such as induced abortion. Therefore, in addition to the general approach to treatment of individuals with cancer, women with gynecological cancer may need specific attention to these issues.

LESBIAN AND TRANSGENDER WOMEN'S HEALTH ISSUES

A lesbian sexual orientation does not denote psychopathology. However, several large studies found significantly higher levels of depression (Case et al., 2004; Valanis et al., 2000) and suicide attempts (Bradford et al., 1994) in lesbians than in heterosexual women. Lesbians may suffer from depression, anxiety, and poor self-esteem based on the stress of living in a society in which they face prejudice and homophobia. Although, especially in larger centers, lesbians may feel more comfortable seeking out health care, they may still encounter biases that may affect the relationship between the healthcare provider and the lesbian patient. Patients may hesitate to report their sexual orientation to the physician out of fear of a negative reaction. The use of non-gendered language can encourage the patient to feel more comfortable.

Hostility or lack of understanding of specific health risks on the part of healthcare providers may decrease the likelihood of lesbians' receiving standard screening tests such as Pap smears. Lesbians may have increased rates of known risk factors for breast cancer, such as increased body mass, high alcohol intake, and nulliparity. As nulliparity or delayed parity is a significant risk factor in the development of certain disorders of the reproductive system, lesbians who do not have children may be at increased risk for conditions such as endometriosis, ovarian cancer, and endometrial cancer. Therefore, although routine screening is not recommended in the general population, it is important that lesbians be regularly screened for these problems using such tools as measurement of cancer antigen 125 (CA-125) (>35 U/ml) or transvaginal ultrasounds. Lesbians may have elevated rates of cardiovascular problems due to an increase in risk factors such as obesity and smoking (Roberts, 2006). They have higher rates of drinking and binge drinking than do heterosexual women (Roberts, 2006).

Lesbians may also encounter prejudice when seeking artificial insemination, even though they may have considered very carefully the impact of having a child in a nontraditional household. Lesbians who wish to get pregnant may be denied

use of registered sperm banks in which the sperm has been assessed for the presence of sexually transmitted diseases. This issue is highly charged from political, legal, and religious viewpoints.

Lesbians may also be at high risk for having experienced violence from heterosexual males as well as from their lesbian partners. They may suffer from the same kind of psychological, emotional, and physical injuries experienced by any female victims of violence.

The psychiatric consultant may have a role in dispelling prejudices and false assumptions about psychopathology in lesbians. The healthcare providers should be aware of the external stresses and lack of family support often experienced by lesbians. A lesbian partner or spouse should be treated in the same way as any heterosexual partner or spouse and included in discussions when the patient so wishes. Some homosexual patients may prefer treatment by homosexual physicians and therapists, who they feel will be more empathetic and more accepting of their choices. McNair (2010) has a comprehensive list of resource of documents about lesbian healthcare published in countries around the world.

The management of men with gender dysphoria (transgender) who wish to become women is very complicated (Gooren, 2011). They must live for one year as a woman before surgical reassignment is performed. Many healthcare providers are reluctant to treat these patients after surgery or are unfamiliar with their particular needs, including the issues of hormone use, HIV prevention, or gynecological needs. Ideally, the healthcare provider must treat the individual in a respectful, nonjudgmental fashion and not assume the patient will have serious mental health problems.

VIOLENCE

Violence against women takes many forms, including homicide, battering, rape, child abuse, incest, harassment, and boundary violations such as sexual contact between a healthcare worker and a patient. Women may see physicians because of the physical and psychological consequences of such violence. More than one million American women a year seek treatment for injuries caused by battering. Studies have found that 22% to 35% of women who attended hospital emergency departments have injuries or symptoms related to physical abuse (Daugherty & Houry, 2008). Despite this, there continues to be under-reporting by victims and under-detection by physicians (Flury, Nyberg, & Riecher-Rossler, 2010). Violence may be the undetected underlying cause of many gynecological complaints. A history of violence may also influence a woman's behavior in the physician's office, causing her to fail to keep appointments or to avoid or react dramatically during physical examinations.

Prevalence studies show that 20% of adult women and 12% of adolescent girls in North America have experienced a variety of sexual abuses, which may include forcible rape, during their lifetime. These estimates are even higher in the case of immigrant, Native American, or African-American women (Hammett, Powell, O'Carroll, & Clanton, 1992). The reasons

for the high rates of violence against women are complex (Stewart & Robinson, 1995). Substance abuse may precipitate a violent incident, but it is not in itself a sufficient explanation for violence (Anonymous, 1992). Society's view of women as less valuable than men, as well as traditional views of marriage in which the husband, as the head of the household, has a "right" to treat his wife as his property, are important factors. Modeling is also an important component of violence. Women who have grown up in situations of domestic violence are more likely to become victims, and men from violent households are more likely to be violent toward their spouses (Hotaling & Sugarman, 1986). Individual perpetrators may be men who feel powerless or vulnerable in their day-to-day lives and bolster their egos by having power over vulnerable women. In cases of rape, exercising power may more often be the motivation than the gratification of sexual desires.

The victim of violence may present with a variety of injuries, such as bruises, bites, lacerations, fractures, burns, or damaged organs. In pregnant women, violence may result in miscarriage or premature delivery. Victims of violence may also exhibit a variety of stress-related phenomena such as headaches, insomnia, and other somatic symptoms. Childhood sexual abuse or rape may result in various sexual or reproductive consequences, including genital trauma, sexually transmitted disease, CPP, sexual dysfunction, UTIs, or unwanted pregnancy.

Immediate emotional reactions to violence range from shock and fear to emotional numbness and withdrawal. There may be numerous long-term behavioral and psychological effects (Rees et al., 2011). Women may demonstrate either sexual aversion or promiscuity, or show a range of self-harming behaviors such as substance abuse, self-mutilation, and suicide attempts. They may suffer from ongoing low self-esteem, guilt, self-blame, and problems in forming relationships, or may exhibit symptoms of depression, anxiety disorders, dissociative identity disorders, borderline personality disorders, or post-traumatic stress disorders. Although not yet listed in the formal *Diagnostic and Statistical Manual of Mental Disorders* (DSM), a syndrome of "complex post-traumatic stress disorder (PTSD)" has been described in adult patients who suffered from severe and prolonged childhood sexual abuse (Cloitre, Miranda, Stovall-McClough, & Han, 2005). As well as typical PTSD symptoms, this syndrome includes problems in attachment, affect regulation, dissociation,

behavioral control, and self-concept. Victims of childhood or adult violence may be extremely reluctant to have physical examinations and become acutely anxious if breast or pelvic examination is attempted (Weitlauf et al., 2008).

All healthcare workers need to be aware of the high prevalence of violence against women. Questions about violence and past abuse should be a routine part of the assessment of female patients. There are several domestic violence screening tools that can be used (Rabin, Jennings, Campbell, & Bair-Merritt, 2009). The HITS scale uses four key questions, rated from "never" to "frequently," to elicit information (Sherin, Sinacore, Li, Zitter, & Shakil, 1998) (Table 65.4).

Although information may not be immediately forthcoming, an attitude of nonjudgemental acceptance may make it easier for the woman to talk about her experiences at some time.

In emergency situations, such as immediately after a sexual assault, the woman's physical concerns must be dealt with in a caring and empathic manner. It is important that the physical examination not feel like a repeat of the previous assault. Also, attention must be paid to the woman's safety and her practical and psychological needs. She may need assistance in dealing with her immediate emotional reaction as well as in finding a shelter, locating a rape crisis center, dealing with police or family members, or just finding clothes to go home. The woman should be educated about the anticipated impact of the trauma on her, her family, and her friends.

A variety of treatment approaches, including psychodynamic psychotherapy (Schottenbauer, Glass, Arnkoff, & Gray, 2008), CBT (Vickerman & Margolin, 2009), pharmacotherapy (Stein, Ipser, & Seedat, 2006), group therapy (Kessler, White, & Nelson, 2003), and self-help organizations have all been found to be helpful. Specific treatments for complex PTSD have also been described (Cloitre et al., 2010). The prognosis for the individual woman will be influenced by her previous personality and coping style, ego strength, and social supports. Work may also need to be done with her family to deal with their shame, rejection of the victim, or excess anger. Readers are referred to Rose (1991 and 1993) for a more detailed overview of the psychodynamic treatment of women who have been the victims of violence. Women who come from cultures where it is customary to blame the victim may hesitate to even come for counseling. It is important to be patient and not push her to stand up to her family,

Table 65.4 HITS TOOL FOR INTIMATE PARTNER VIOLENCE SCREENING

Please read each of the following activities and fill in circle that best indicates the frequency with which you partner acts in the way depicted. How often does your partner —					
	Never 1	Rarely 2	Sometimes 3	Fairly often 4	Frequently 5
Physically hurt you?					
Insult or talk down to you?					
Threaten you with harm?					
Scream or curse at you?					

Each item is scored from 1–5. Thus, scores for this inventory range from 4–20. A score of greater than 10 is considered positive for intimate partner violence.

while continuing to clearly reinforce the view that she is not to blame for what happened. Counselors should be alert to the possibility that the woman may be in physical danger in families who fear their honor has been impugned by the rape. In these cases, the counselor needs to be aware of community resources such as help lines and women's shelters so the client has a safe exit route if required.

PHYSICIAN–PATIENT ABUSE

Power is a factor in physician–patient abuse. Patients usually come to physicians because they are in emotional or physical distress. They may feel frightened and vulnerable. The physician is viewed as an idealized authority figure who is wise, kind and will have solutions for the patient's problems. This power imbalance in the relationship is further exaggerated by the physician's right to ask the most personal information about the patient's life, without revealing any of his or her own background. Patients assume that physicians are trustworthy and are motivated by a wish to help others. They do not know the correct psychotherapeutic or physical examination techniques and procedures, and must trust that what the physician is doing is ethical and proper. All of these factors can make the patient vulnerable to sexual abuse by an exploitive physician or physical or emotional abuse by a careless or inept physician.

Even after being sexually exploited by a physician, a patient may hesitate to report these activities, as she may doubt her own instincts and deny that any abuse took place, feel ashamed and guilty, or fear that no one would believe her. Patients who have been abused by physicians may avoid any kind of medical care or specific examinations such as of the breast and pelvic areas. They may demonstrate signs of tension whenever the physician begins a medical examination or be very reluctant to divulge any personal information. Physicians must be aware of reporting requirements in their particular area. In a number of states, abuse by a healthcare professional is a crime. Warning a patient not to reveal the name of the abuser if she is not ready to report the offense will allow her to get support from the therapist until she is ready to come forward.

CLINICAL PEARLS

- Although it was previously thought that post-hysterectomy depression was a common phenomenon, more recent studies have found no evidence that hysterectomy causes depression.
- Assumptions that sexual trauma is the cause of vulvodynia are unwarranted, although such a history may play a role in amplifying anxiety in response to physical distress or in determining coping responses.
- The pain from BPS/IC usually occurs as the bladder fills and is relieved upon voiding. Premenstrual worsening of pain is typical, differentiating BPS/IC from endometriosis, which is most painful during menses.

- History of chronic pelvic pain (CPP) should include a chronological pain inventory: with details of timing (cyclical, non-cyclical; relationship to menses), onset, quality, location, radiation, precipitating and relieving factors, as well as symptoms associated with the gastrointestinal, urinary, and musculoskeletal systems. Menstrual, obstetrical (including physical trauma from delivery), and sexual histories (especially deep dyspareunia) are critical components.
- For endometriosis, only deeply infiltrating lesions and ovarian involvement are detectable by ultrasound, suggesting that 80% of endometriosis will not be visualized.
- Noncyclic pain is common with abdominal wall endometriosis.
- Myofascial pain may be the most common cause (30%) of CPP in women with a negative laparoscopy and frequently is a secondary development.
- Prevalence studies show that 20% of adult women and 12% of adolescent girls have experienced a variety of sexual abuses.

INFERTILITY, PREGNANCY LOSS, AND ABORTION

Gail Erlick Robinson

INTRODUCTION

Women may choose not to get pregnant for a variety of reasons. Women who have done a lot of childcare while helping raise younger siblings may feel they have already done enough child-rearing. Other women may not have found a partner who they think will be a good parent. Yet others may have a career or lifestyle that seems to be incompatible with having a family. In all of these situations, the woman may be comfortable with her decision and feel no less feminine. It appears that an important element in feeling like an adequate female is the woman's ability to choose what she wants to do concerning pregnancy. When a woman wishes to get pregnant and either cannot achieve or maintain a pregnancy, the psychological impact may be devastating. Consistent with the concept of the importance of choice, a woman having an induced abortion who has made a free and un-coerced decision does not suffer from any lasting negative emotional consequences.

INFERTILITY

Approximately 10% of couples will suffer from primary or secondary infertility, diagnosed after 12 months of focused attempts to conceive in women 34 years old and under, or after six months in women 35 years old and older. Accepted causes of infertility related to psychiatric conditions include absent or infrequent vaginal intercourse, infrequent or absent menstrual periods due to eating disorders, and medications such as neuroleptics, which inhibit ovulation by increasing serum prolactin levels. Depression is likely to influence the outcome of infertility treatment, but there is less consistent evidence for the effects of anxiety (Wischmann, 2003). Studies have shown higher pregnancy rates in both women with low levels of trait anxiety and those in the highest quartile of anxiety (Sanders & Bruce, 1999). Research is being conducted to determine whether stress can cause infertility via influencing the actions of hypothalamic, pituitary, or adrenal hormones on the reproductive system (Wischmann, 2003). There are no convincing studies showing stress as the sole cause of infertility in women.

The experience of infertility can cause a great deal of psychological distress (Cousineau & Downar, 2007). As most women spend many years protecting themselves against pregnancy, they are shocked when they discover they are

infertile. They experience a sense of loss of control. Their self-esteem and self-worth may diminish if they feel defective and unfeminine. Infertile women have been found to have higher levels of depression and anxiety compared to fertile women and women in general outpatient clinics. Women often feel guilty, seeing their infertility as punishment for real or imagined past "sins." They may feel envious of women with children and find it difficult to attend child-centered events such as showers and new-baby celebrations. Marriages may be either stressed or strengthened as couples blame each other or work together to come to a resolution. If they tell others they are infertile, they may elicit feelings of pity or, in some societies, diminished status and isolation. If they do not tell, others may assume they do not want children and view them as selfish and unwilling to spoil their lifestyle by having children.

Not all couples who are infertile proceed to treatment. This may be due to lack of knowledge or funds, or merely acceptance of whatever fate hands out. For those who do seek answers, the investigation and treatment can be extremely stressful. Their lives may become fertility-focused, with schedules revolving around appointments and clinic visits. Work gets interrupted and vacations put on hold. Their sexual life changes from a pleasurable activity to a mandatory, scheduled procedure. Choosing a fertility clinic is also stressful. The Fertility Clinic Success Rate and Certification Act (FCSRCA) of 1992 mandates that clinics performing artificial reproductive technologies (ART) annually provide data for all procedures performed to the Centers for Disease Control and Prevention (CDC) (Table 66.1). The CDC is required to use these data to report and publish clinic-specific success rates (CDC, 2011). It is important to distinguish between pregnancy rates and live birth rates. Also, rates vary with age and the cause of the infertility.

The first step in infertility treatment is to ensure that couples are having adequate intercourse at times of ovulation. The use of small doses of clomiphene may allow couples to more accurately predict ovulation. Clomiphene is started between days 3 and 5 of the cycle and continued for five days. It is an anti-estrogen that lowers the levels of circulating estrogen. This then causes the hypothalamus to produce gonadotropin-releasing hormone (GRH), which, in turn acts on the pituitary to produce more follicle-stimulating hormone (FSH) and luteinizing hormone (LH). Ovulation occurs between cycle days 14 and 19, allowing the couple

Table 66.1 FERTILITY TREATMENT LIVE BIRTH RATES

PROCEDURE	SUCCESS RATES		
	Combined	<35 yrs.	43–44 yrs.
Intrauterine Insemination:			
Without fertility drugs	5–7%		
Plus infertility drugs	20%		
Intrusive Procedures:			
Non-donor fresh embryos		41.2%	4.9%
Non-donor frozen embryos		35.2%	15.1%
Donor fresh embryos	55.1%		
Donor frozen embryos	34%		

Figures from Centers from Disease Control and Protection, *ART Reports*, Dec. 2, 2011.

to plan intercourse for when it would be most successful. Narrowing the precise time of ovulation can also be assisted by the use of an ovulation predictor kit that uses a urine sample to predict when ovulation is about to occur by measuring the LH level; these are available without a prescription in most pharmacies. Basal thermometers are also useful in detecting ovulation. For the first part of the cycle, women's temperatures at rest are in the 97 to 97.5°F degree range. Just prior to ovulation, the temperature increases to be in the 97.5 to 98.6°F degree range, where it remains for the rest of the cycle. Basal thermometers measure changes as small as one tenth of a degree. Measuring across several cycles allows women to discover their patterns of changes and predict the timing of ovulation.

If these simple steps do not solve the problem, next steps would include hormonal assessments, semen analysis, and ultrasound. Couples who are still unsuccessful may go on to more invasive investigations such as hysterosalpingogram, laparoscopy, hysteroscopy, or testicular biopsy.

Although men and women are equally likely to be the cause of the infertility (30–50% of infertility is attributable to female factors, 30–40% to male factors, and 20–30% to both members of the couple), women have to endure the bulk of the procedures designed to correct infertility. In artificial insemination using partner sperm, the male sperm are washed, concentrated, and injected into the uterus at the time of ovulation. Success rates are high, and psychological effects on the woman may be minimal, although the male partner may have to deal with some feelings of inadequacy. When the insemination is done using donor sperm, the issues may become more complicated (Leiblum & Aviv, 1997). The man may feel jealous or threatened; 47–92% of couples intend to keep the nature of the conception secret. Although some couples may have difficulty, research has failed to reveal psychological problems in couples who have donor insemination. They appear to be well adjusted, have

stable marriages and healthy relationships with the children (Brewaeys, 1996).

Other types of infertility treatments are more invasive for the woman. Gamete intrafallopian transfer, intracytoplasmic sperm injection (ICSI), and *in vitro* fertilization (IVF) all require that the woman take heavy doses of fertility drugs and undergo ova retrieval by laparoscopy. Drugs used to treat infertility, such as clomiphene citrate, human menopausal gonadotropin, and Gonadotropin Releasing Hormone (GnRH) analogues have been associated with depressive side effects (Daniluk & Fluker, 1995). Often these side effects are overlooked, as people assume that the woman's anxiety or depressive symptoms are related to the psychological stress of the infertility program. Fertility drugs may also cause bloating or weight gain, which can affect body image, self-esteem, and mood. In rare cases, they may cause ovarian hyperstimulation, which causes a buildup of fluid in the chest and abdomen, resulting in abdominal pain, nausea, shortness of breath, bloating, and a weight gain of up to 10 lbs. in 3–5 days.

IN VITRO FERTILIZATION (IVF)

At initial presentation, IVF candidates do not differ from non-IVF couples with respect to depression, although they may demonstrate some anxiety (Verhaak et al., 2007). Couples seeking IVF may be worried about being refused treatment if they appear to be too emotional. It may also be that only the strongest survivors of years of infertility treatments continue on to this stage.

Infertility treatments put couples on a rollercoaster of optimism, hope, and disappointment, with a slight increase in anxiety at the time of egg retrieval and pregnancy testing, and an increase in depression scores after one or more unsuccessful treatment cycles. When IVF results in pregnancy, the negative emotions disappear, indicating that treatment-induced stress is considerably related to threats of failure. Dropout rates from IVF are quite high, even when the treatments are free (Van den Broeck et al., 2009). Generally, the psychological burden appears to be the most frequently named reason to discontinue infertility treatments. Some couples feel that after one or two cycles they can quit, knowing they have done everything they could to have a child. Couples who continue with the program but do not conceive after several cycles must decide whether to continue with the treatment, think about adoption, or come to terms with childlessness. The women for whom IVF is ultimately unsuccessful face not merely the loss of a pregnancy, but the loss of the ability to become pregnant. Although there are few longitudinal studies of follow-up after failure of IVF, so far there is no compelling evidence for significant negative emotional consequences of unsuccessful treatment, although a considerable number show subclinical emotional problems. However, although an individual or couple may seem to successfully resign themselves to the lack of success of IVF, there are many who would immediately jump at the chance were a new fertility treatment to present itself.

Counseling may be required if the woman or couple display significant negative affects during the IVF cycle or react with considerable despair to the news that the cycles have been unsuccessful. Counseling is best done by someone familiar with the specific techniques and emotional challenges of infertility treatments and should include discussion of healthy coping techniques. The couple may need help in deciding when to stop the IVF. This is a very individual decision that is based on many factors, including psychological stress, physical burden, financial burden, age, the importance of having a child with their own genetic makeup, pressure from relatives, and stresses between the partners.

OOCYTE DONATION

The procedure of using oocytes donated by young, healthy women as a treatment for infertility has expanded the number of infertile women who can get pregnant. Egg donation has the highest success rate (47–50%) of any fertility treatment. Eggs may be donated anonymously (residual healthy eggs from women undergoing IVF) or openly by a relative giving altruistically, or a stranger who is paid. There has been limited research on the psychological impact of women who receive these donations. These women have already experienced the mental health consequences of infertility and many have gone through the full range of treatments. On one hand, they are grateful that ovum donation may allow them to become pregnant, but they must come to terms with the loss of making a biological contribution to their offspring. If the partner's sperm is used, it may be difficult to accept that he has a closer biological tie to the child than she does (Carter et al., 2011). For most women, however, experiencing the pregnancy makes her feel that she is the mother of this child. She also must begin to think about what and to whom she will disclose about the nature of the pregnancy. Over the last several years, as ovum donation has become more common, families appear to be becoming more open to talking about how they conceived (Greenfeld, 2002). The couple and the donor must decide what degree of contact they will have. This can become more complicated when the donor is a relative. Counseling may be required to help the woman accept the child as her own, deal with any residual sense of inadequacy, and decide how she will deal with disclosure.

PREGNANCY LOSS

MISCARRIAGE

Spontaneous abortion or miscarriage is defined as an unintended termination of pregnancy resulting in fetal death prior to 20 weeks of gestation. Between 12% and 24% of clinically recognized pregnancies end in miscarriage, mostly within the first trimester. Most studies agree that many women experience sad feelings or very intense grief in the first days following the loss, while some have found anxiety and depression still present even after one to two years (Brier, 2008). As well as sadness and depression, women may suffer from shock,

disbelief, guilt, helplessness, and anger. They may have insomnia, loss of appetite, loss of interest in usual activities, and poor concentration. Many have feelings of failure and suffer from repetitive thoughts and dreams of the baby. They often have doubts about their own femininity and competence as women and fear infertility. As many miscarriages are due to unknown causes, women commonly blame themselves and conceptualize the loss as punishment for real or imagined things they did or did not do in the past or during the pregnancy (Robinson, Stirtzinger, Stewart, & Ralevski, 1994; Nikcevic, Tunkel, Kuczmierczyk, & Nicolaides, 1999).

A significant number of women report elevated levels of anxiety up to six months post-miscarriage and are at increased risk for obsessive-compulsive disorder (OCD) and post-traumatic stress disorder (PTSD; Brier, 2004). Robinson et al. (1994) found that the anxiety experienced often seemed worse than the depression, with 77.6% finding this was as great as any previously experienced stressor. Women with a history of miscarriages suffer more from pregnancy-specific anxieties in the first trimester of a new pregnancy than women with no history of miscarriage (Bergner, Beyer, Klapp, & Rauchfuss, 2008). Blackmore et al. (2011) found that anxiety and depression continued even after the birth of a subsequent healthy child.

Factors predictive of an increased risk of adverse psychological sequelae after miscarriage include: previous experience of the death of a loved one; a history of major depression; childlessness; high investment in the pregnancy; concerns regarding infertility; and lack of support from a partner, family, or friends (Lok & Neugebauer, 2007; Janssen, Cuisinier, de Graauw, & Hoogduin, 1997; Stirtzinger, Robinson, Stewart, & Ralevski, 1999). No clear relationship has been found between emotional adjustment after miscarriage and marital status, age, occupational status, social class, the duration of gestation, and a past history of miscarriage or previous therapeutic abortion (Neugebauer et al., 1997).

Each member of a couple may grieve differently, with the woman showing her emotions while her partner tries to help her and manage his own grief by burying his feelings and becoming involved in work and other activities (Kong, Chung, Lai, & Lok, 2010). The woman needs to be reassured that her grief is normal and will take some months to resolve. She should be warned that the date of the anniversary of the loss and the anticipated birth date may be times of increased distress. Grieving over a miscarriage is often complicated by the fact that there is no visible child, memories, or shared life experiences to mourn. Even if it is unofficial, the couple may wish to name the baby and have some sort of memorial service. As there are often no tangible mementos, they may buy something such as a charm for a bracelet to give a greater sense of identity to this child.

If the level of the woman's depression is excessively high or the length of her depression very prolonged, her grieving may have evolved into a major depressive episode that might benefit from medication and psychotherapy. Unjustified or excessive feelings of guilt and responsibility for the loss should be explored. She may need to be reassured that her wish to avoid other women who are pregnant or have new babies is

normal and will eventually resolve. Couple therapy might be indicated to reinforce to the couple that they are both sharing in this sad event.

Women often complain that medical staff appear to be insensitive and unsympathetic, viewing the miscarriage as a minor medical event. Most women would benefit from a follow-up medical appointment in which they are given whatever information is known about the cause of the loss and their chances of becoming pregnant again (Nikcevic, Kuczmierczyk, & Nicolaides, 2007).

STILLBIRTH

Stillbirth is the death of a fetus after 20 weeks' gestation or after the fetus has reached 14 oz. in weight. As almost one-half of stillbirths occur after apparently uncomplicated pregnancies, most parents are unprepared for the death of the infant. This news may come in two ways: prenatal examinations may show the baby has died, forcing the woman to go through the induced delivery of a dead baby; or the baby may die in the process of the delivery. However the stillbirth comes about, anticipation and joy are suddenly replaced by despair. This loss of a desired child may lead to loss of confidence in the ability to produce a healthy child, and "traumatic grief," a syndrome differentiated from depression by the meaning and significance of the attachment that was lost (Bennett, Litz, Lee, & Maguen, 2005). In some cultures, this grief is enhanced by beliefs that such losses are caused by the mother's "sins" or "evil spirits" (Froen et al., 2011).

Common response protocols involve telling the parents (with little supporting evidence) that looking at and holding the baby will help them mourn and speed up the recovery from grief. Although holding the baby is supposed to be optional, well-meaning staff can subtly pressure the couple into complying. Hughes, Turton, Hopper, & Evans (2002) raised questions about this protocol after finding that mothers who held their stillborn babies had higher rates of depression (39%) than women who had just seen their babies (21%) or those who had had no contact (6%). Women who saw their babies also had higher rates of anxiety and PTSD, persisting up to seven years post-stillbirth (Turton, Evans, & Hughes, 2009) and were more likely to have experienced partnership breakdown. However, numerous methodological problems in these studies suggest caution about accepting these conclusions.

The best current approach allows parents to choose whether or not to see or hold the stillborn child. Parents need to hear any available information about the reason for the loss. Counselors can help the couple deal with practical issues such as funeral plans, as well as presenting options such as naming the child, taking a picture, and keeping mementos. The counselor can also give information about the grieving process and supports available. Assuming that all bereaved parents require intense crisis interventions may be at best unnecessary and at worst intrusive, potentially creating more distress. Follow-up therapy should be available for those who require it.

There is also controversy about the timing of future pregnancies. Turton, Hughes, Evans, and Fainman (2001) found

that a perceived low level of support during the stillbirth, as well as conceiving within a year of the loss, increases the risk of PTSD (lifetime prevalence rates of 29% and 21% in the third trimester of the pregnancy following the stillbirth) and results in higher rates of depression both during the third trimester and one year after the follow-up pregnancy. In contrast, Franche (2001) found that increased time between loss and subsequent conception was predictive of increased grief. The conclusion can only be that there is no universal approach that works for all couples.

TERMINATION FOR GENETIC INDICATIONS

Genetic terminations or terminations for genetic indications are highly stressful events. Some women choose to become pregnant knowing that they are carriers of a genetic defect and worry they will pass this defect along to the fetus. They therefore anxiously await the results of prenatal diagnostic testing. In other cases, the woman encounters a problem during pregnancy, such as being exposed to German measles, and then must decide whether or not to terminate the pregnancy (Statham, Solomou, & Chitty, 2000). In the third instance, a woman over the age of 35 might discover that the fetus has an abnormality associated with maternal age after routine prenatal diagnostic testing.

Once an abnormality is detected, the woman or couple must make a decision about whether or not to terminate the pregnancy (Sandelowski & Barroso, 2005). The couple might decide to use the genetic information obtained in order to plan and prepare for the birth of a child with potential difficulties. Factors contributing to a couples' decision to terminate the pregnancy after a positive finding on prenatal diagnostic testing include: the prognosis for the child, their beliefs about having an abortion, concerns about the child's welfare, and feelings about the potential disruption to other children and their own marriage and family life.

In an elective termination following the detection of a genetic disorder, the couple must not only face the loss of a wanted pregnancy but must make a conscious decision to end a pregnancy for a problem that is not necessarily going to result in fetal death. Even in the case of severe abnormalities, the decision to terminate is a difficult one and may be associated with ambivalence, guilt, and grief (Rillstone & Hutchinson, 2001). As genetic testing technology grows, couples are more often being confronted with the news of mosaicism or chromosomal disorders in which the outcome is unclear, forcing them to make a decision based on limited information. In these cases, there may be heightened ambivalence, doubt, and grief. Couples who know they are carriers of a genetic abnormality may feel an excess of guilt, knowing that they caused their fetus to have problems. They may also struggle with the concern that they will never be able to produce a healthy baby.

There is usually little time between the revelation of the abnormality and the termination. A woman terminating a pregnancy after genetic amniocentesis, which occurs in the second trimester, must go through a very difficult procedure. She requires an induction and goes through an actual labor knowing she will deliver a dead infant. She may not be given

necessary medication to help ease her discomfort, and delivery may take place in her bed when she is alone. All of this adds to the stress of the termination (Robinson, 2011). Women have identified this loss to be equal to or more stressful than any previous trauma in their lives (Robinson, Carr, Olmsted, & Wright, 1991). Couples may be supportive or direct their anger and frustration toward each other.

This negative experience can be moderated in many ways. Couples going for amniocentesis should be encouraged to think about what their decision would be if an abnormality is found; counseling should be available for couples who find it difficult to think this through. If an abnormality is discovered, genetic counseling should provide as much information as possible about the risks and outcome of any defect. Couples undergoing a termination should be treated with dignity and respect, including being given detailed information about the process, not being placed on a maternity ward, receiving appropriate pain relief, and being checked on regularly.

Many couples hesitate to inform others of their decision to terminate the pregnancy, fearing negative judgements. This, however, can leave them feeling isolated and alone in dealing with their grief. Pretending that the woman just miscarried may allow some support, but does not encompass the ambivalence and grief that is inherent in making this kind of decision. Medical staff can also have negative attitudes toward a couple if they feel the couple is terminating the pregnancy for what they regard is an insufficient reason, such as the detection of Turner's syndrome.

Management of a possible loss should begin with counseling before prenatal testing (Robinson, 2011). Couples who are known carriers should discuss the probability of passing on a problem to the fetus and carefully think about the choices they would like to make. The woman, individually or with her partner, may benefit from counseling and support at the time of the termination. They should be given opportunities but not be forced to view the baby after delivery. Getting a view of any deformities could give the couple confirmation that they had made the correct decision but also may be extremely traumatic for them. For the couple who do not choose to see the baby after delivery, the hospital staff should, with the parent's permission, take pictures of the appropriately draped baby so that, should they regret their initial decision, the couple may view the images in the future. This visualization of the baby may aid in the grieving process. Although the option of burial or officially naming the baby will vary according to the birth weight and the couple's religion, they may be encouraged to personally give the baby a name or hold some sort of memorial service.

For some women and their partners, the grieving is a normal response to loss. In other cases, past and current issues and conflicts, including guilt about passing on a genetic defect, feelings of inadequacy as a woman, concern about being punished for past events, marital problems, and social and family pressures to have a child, may complicate the grieving and require further psychological intervention. Parents sometimes forget about the need to give an explanation to pre-existing children so they will not be left with fears that their parents will take them to the hospital and "leave them there."

Groups for women or couples who have had genetic terminations can be a helpful way of sharing the pain and resolving the grief.

INDUCED ABORTION

Induced abortion is a common but highly charged religious and political topic with dissenting groups expressing their feelings very passionately, sometimes to the point of violence. And yet, it is a very common procedure. The World Health Organization (2005) estimates that of the approximately 211 million pregnancies that occur worldwide each year, 46 million end in induced abortion. The decision to terminate a pregnancy is seldom made lightly. The consequences of such a decision are influenced not only by the woman's previous level of coping and life circumstances, but also by her interpersonal relationships, the social and religious context, and the access to safe procedures carried out in a nonjudgmental atmosphere.

It is difficult to differentiate the consequences of induced abortion from the effects of the distress caused by the pregnancy itself. An unwanted pregnancy may be the result of a sexual assault or incest or the unintentional consequence of contraceptive failure. A woman may desire a child, but the nature of her current life circumstances, poor or absent partner relationships, social pressures, or future plans cause her to believe it is currently problematic. Women who consider abortion are, therefore, already under stress.

Anti-choice/anti-abortion groups have tried to bolster their position by asserting that abortion causes permanent, serious physical and psychological damage. These groups continue to maintain that abortion increases the risk of developing breast cancer despite the 2009 position statement by the American Congress of Obstetricians and Gynaecologists (Committee on Gynecologic Practice, 2009) that a review of methodologically sound studies demonstrated no causal relationship between induced abortion and a subsequent increase in breast cancer risk.

Anti-choice groups also claimed to have identified an "abortion trauma syndrome" that includes depression (Reardon & Cougle, 2002), anxiety (Cougle, Reardon, & Coleman, 2005), and an increased risk of suicide (Reardon et al., 2003), hospitalization (Reardon et al., 2003) and substance abuse (Reardon & Ney, 2000). These studies have been shown to be methodologically very flawed (Robinson, Stotland, Russo, Lang, & Occhiogrosso, 2009). Research using sound methodology has shown that, although most women having an induced abortion have transient feelings of ambivalence, guilt, and sadness, the majority of women tend to feel increasingly relieved and comfortable with their decisions and, in many cases, have an improvement in life satisfaction and success (Schmiege & Russo, 2005; Robinson et al., 2009; Major et al., 2000; Munk-Olsen, Laursen, Pedersen, Lidegaard, & Mortensen, 2011).

Past psychiatric history is the most consistent predictor of psychiatric disorders following abortion (Dagg, 1991; Stotland, 1992; Gilchrist, Hannaford, Frank, & Kay, 1995). Outcome may also be affected by the attitudes of picketers

at abortion clinics (Cozzarelli, Major, Karrasch, & Fuegen, 2000) or medical staff who may appear hostile. Religious factors may be extremely important to consider, particularly for women associated with religious groups that condemn abortion as a sin.

Women who lack access to safe and legal abortions are under enormous stress. They may be forced to stay in abusive relationships or may undergo illegal or unsafe abortions that could lead to permanent physical or psychological trauma (Stotland, 1992). Children born after the mother was denied an abortion are more likely to drop out of school, be less satisfied with their jobs and relationships, be in treatment for mental health conditions, be sent to prison, or have parenting difficulties (David, 2011). “Denial of abortion lays the foundation for an environment in which children are poorly reared, which subsequently leads to mental health and psychosocial problems for the unwanted child” (David, 2011).

Most women who are seeking an abortion have already decided to go ahead with the procedure. Although they can benefit from a sensitive, supportive atmosphere, they do not usually require psychiatric consultation. Women should be referred prior to abortion if they have a major psychiatric disorder, have marked ambivalence about terminating the pregnancy, are being subjected to marked external pressure to end or keep the pregnancy, or if the pregnancy is the result of sexual assault. Consultants who feel their own personal beliefs interfere with their giving nonjudgmental information and support should refer the patient to a therapist capable of neutrality.

The presence of a current or previous major psychiatric disorder is not necessarily a reason for terminating the pregnancy. In the case of a current major mental illness, the patient should be evaluated for suicidal or homicidal ideation and competency to make a decision about pregnancy termination. Adequate treatment, support, and, if necessary, hospitalization should be arranged. Ideally, the decision to terminate can be postponed until the woman’s current psychiatric problems improve so that she is able to make a decision about termination. Although many women with a history of major psychiatric illnesses can adequately parent, in the case of a woman with chronic and severe mental illness, one must consider her ability to mother and the risk of bearing a child only to have to give up custody. All options should be discussed, including continuing with the pregnancy and giving the child up for adoption. This may be possible if the woman has enough insight into her illness to be very compliant with treatment during the pregnancy while, at the same time, would not be too heart-broken by bearing a child only to give it up.

Women who are highly ambivalent about the pregnancy should be encouraged to delay decision making as long as safely possible, to allow time to explore the decision. When the ambivalence appears irresolvable, it probably indicates either a strong wish to have the child or obsessive personality traits. The patient should consider the option of continuing with the pregnancy and deciding at birth whether or not to keep the child. If the pregnant woman is being pressured by her partner or family to terminate or alternately to keep the pregnancy, the psychiatrist should help her clarify her own

wishes and reinforce her right to make a responsible personal decision. It may be helpful to meet with the couple or family to try to help resolve the differences. Women whose religion forbids abortion may feel extremely conflicted. Some rigid pastors may only reinforce their guilt, while others may be more understanding in helping them balance their religious beliefs with their current needs. A religious woman who is considering abortion has already felt overwhelmed by the idea of having a child at this time. The psychiatrist cannot make a decision for her but may be able to frame the decision in a different light; i.e., viewing the abortion not a selfish act but as the act of someone who cares about the welfare of this unwanted child.

Most women do not require psychiatric intervention post-abortion. Those few women who continue to have or develop a major psychiatric disorder should receive the appropriate combination of support, psychotherapy, medication, and/or hospitalization. Psychotherapy may focus on themes of grief, loss, guilt, and the situations and conflicts that led to the unwanted pregnancy and the need to abort.

In summary, not all women who suffer from infertility or pregnancy loss require counseling (Robinson, 2014). They should not automatically be referred for counseling but offered the opportunity for support should they need it. For some women, support groups of other women dealing with infertility or pregnancy loss may help them express feelings, have their grief acknowledged, and discover their reactions are normal. These losses happen to individuals with personal histories and specific current stressors and supports. Some women or couples may be more likely to develop major depressive disorders or PTSD. These people may also require a referral to a mental health professional for psychotherapy and medication (Van den Broeck, Emery, Wischmann & Thorn, 2010).

CLINICAL PEARLS

- Generally, psychological burden appears to be the most frequently named reason to discontinue infertility treatments.
- Egg donation has the highest success rate (47–50%) of any fertility treatment.
- Between 12% and 24% of clinically recognized pregnancies end in miscarriage, mostly within the first trimester.
- Post-miscarriage women are at increased risk for OCD and PTSD.
- Anxiety experienced after miscarriage often seems worse than the depression.
- Most women who have had a miscarriage would benefit from a follow-up medical appointment in which they are given whatever information is known about the cause of the loss and the chances of becoming pregnant again.
- The best current approach allows parents to choose whether or not to see or hold the stillborn child.

- For women who terminate pregnancy because of a genetic finding, guilt about passing on a genetic defect, feelings of inadequacy as a woman, concern about being punished for past events, marital problems and social and family pressures to have a child, may complicate the grieving.
- Groups for women or couples who have had genetic terminations can be helpful.
- Although most women having an induced abortion have transient feelings of ambivalence, guilt, and sadness, the majority tend to feel increasingly relieved and comfortable with their decisions.

HORMONES AND MOOD

Gail Erlick Robinson and Sophie Grigoriadis

INTRODUCTION

The reproductive hormones, estrogen and progesterone, play a vital role in women's lives. When they function smoothly, menses are initiated, women have regular, non-painful periods, are fertile and pass into menopause easily. Under or over-production of endogenous hormones can lead to problems such as infertility or dysfunctional bleeding. As the reproductive hormones also affect the production and transportation of neurotransmitters responsible for mood, they may also be implicated in mood changes in premenstrual dysphoric disorders and during peri-menopause.

Women also take many types of exogenous reproductive hormones including oral contraceptives, drugs which affect ovarian function and fertility and hormone replacement therapy. Each of these exogenous uses come with benefits and risks.

EXOGENOUS HORMONES

ORAL CONTRACEPTIVES

Although many early studies found that women taking oral contraceptives (OCs) had incidences of depression ranging from 5–30% (Editor, *Drug Facts and Comparisons*, 1993), current research has determined that OC users experience less variability in affect across the entire menstrual cycle and less negative affect during menstruation (Oinonen & Mazmanian, 2002). In the Harvard Study of Moods and Cycles (Joffe, Cohen, & Harlow, 2003), researchers found that 16.3% of women noticed worsening of their moods while on OCs, 12.3% had an improvement, and 71.4% had no change. This discrepancy may be at least in part related to the fact that current OCs contain much lower doses of hormones than earlier versions. The subgroup of women who did experience negative moods when taking OCs were found to be more likely to: have a history of depression, psychiatric symptoms, dysmenorrhea, and premenstrual or pregnancy-related mood symptoms prior to OC use; have a family history of OC-related mood complaints; be in the postpartum period; or be under age 20.

Opinion is divided as to whether it is the estrogen or progesterone component of the OC that causes the most psychological side effects (Jensvold, 1996). Possible explanations for negative mood changes include: an estrogen-induced

pyridoxine (vitamin B6) deficiency resulting in decreased serotonin and gamma-Aminobutyric acid (GABA); progesterone and estrogen mediated GABA-induced inhibition and suppression of glutamate excitation; and progesterone-mediated increase in monoamine oxidase, leading to decreased serotonin (Oinonen & Mazmanian, 2002). Studies have been inconclusive, with some suggesting that OCs with higher doses of progesterone or higher ratios of progesterone to estrogen cause more depression, while others have found just the opposite. It may be that another variable is involved. For example, a lower ratio of progesterone to estrogen is associated with more negative mood changes in women with a history of premenstrual emotional symptoms, while higher progesterone to estrogen ratios are associated with increased negative mood effects in women without such a history. Monophasic OCs have a greater stabilizing effect on mood than triphasic OCs.

If a woman taking OCs becomes depressed, the best approach is to stop the medication and see if the depression is alleviated. Pyridoxine (25–50 micrograms) has been recommended as a treatment for OC-related depression, but there have been no controlled trials. Similarly, there have been no controlled trials of the use of antidepressants to treat OC-generated depression, but, as they are effective in treating premenstrual dysphoric disorder, it is reasonable to assume they could also treat this kind of depression. Because of the controversy about the contribution of estrogen versus progesterone and the ideal combination for mood regulation, it is difficult to recommend appropriate oral contraceptives; but, generally, one should try an OC with a lower progesterone dose, a less androgenic progesterone, and/or eliminate estrogen altogether.

HORMONE REPLACEMENT THERAPY AND ESTROGEN REPLACEMENT THERAPY

Hormone replacement therapy (HRT) refers to a number of drugs, all of which have in common the presence of both an estrogen and progestin. The short-term benefit of HRT involves the minimization or elimination of menopausal changes such as hot flashes and genito-urinary atrophy. HRT used only for the treatment of hot flashes should be continued for approximately two to three years.

For many years, HRT was recommended for long-term use, not only to keep women looking younger (Wilson,

1968), but to prevent osteoporosis, cardiac problems, and dementia. The Women's Health Initiative (WHI) studies put an end to this idea (Rossouw et al., 2002). The results of their estrogen plus progestin study indicated that this combination resulted in a reduced risk of colorectal cancer and fewer fractures, but an increased risk of heart attack, stroke, blood clots, and dementia, with no protection against mild cognitive impairment. Estrogen alone resulted in a reduced risk of fracture, no differences in the risk for heart attack or colorectal cancer, an increased risk of stroke and blood clots, and an uncertain effect for breast cancer. Hundreds of thousands of women ceased taking HRT, and prescriptions dropped dramatically. After the initial shock, criticisms of the study's methodology began to be reported. Goodman, Goldzieher, and Ayala (2003); Klaiber, Vogel, and Rako (2005), and others noted that: the absolute rates of coronary heart disease (CHD), stroke, breast cancer, and pulmonary embolus, based on endpoints per 10,000 women-years, were marginally significant at best; the study did not last long enough to see beneficial effects; and there was a substantial dropout rate. Most important, they felt the population was not representative of the typical patient presenting to her physician for menopausal management of quality-of-life symptoms in early menopause; many of the women in the study were at least ten years post-menopause and already had evidence for underlying CHD, such as previous heart attack, angina, coronary artery bypass or graft, or coronary angioplasty.

A review of the current state of knowledge concerning the use of HRT summarizes the complicated risk and benefit issues (Taylor & Manson, 2011). Some of the confusion concerning HRT may be due to the timing of its use. Protection from atherosclerosis is evident only when hormone therapy is initiated proximal to the onset of menopause and before the development of advanced atherosclerosis. Greater distance from menopause, adverse lipid profiles, other cardiovascular disease risk, and family history may increase the risks of CHD with HRT use.

The risk of breast cancer varies according to the timing of treatment initiation. When HRT treatment was initiated within a three-year period from the onset of menopause, the detection of tumors increased, whereas it was not elevated when treatment was initiated after a greater than three-year absence from sex steroid exposure. It is likely that HRT exerts a promotional effect on preexisting, undetected, less aggressive, estrogen-responsive tumors, rather than initiating new tumors.

Unopposed estrogen use will cause endometrial hyperplasia or cancer in nearly half of women users within three years, although either continuous or sequential progestin administration largely negates the increased risk. There also appears to be a small but significantly increased risk of epithelial ovarian cancer in current and recent users of estrogen therapy.

The risk of dementia was shown to be increased by HRT in the WHI Memory Study. The effect of HRT and estrogen replacement therapy (ERT) on cognitive function in the same population was examined in the WHI Study of Cognitive Aging. Initiation of HRT close to menopause was

not associated with improved cognition, and HRT did not significantly reduce dementia risk over the course of this study (Ryan et al., 2009). ERT did not appear to have an enduring helpful effect on cognitive function in older women.

The WHI also did not look at different types or routes of application of HRT. New information suggests that the risk of stroke (odds ratio [OR] 1.29) can be reduced by the use of transdermal HRT (Brown, 2010). The odds ratio of first-time venous thromboembolism in current users of oral estrogen therapy was significantly elevated. Although the thromboembolism risk was also elevated in users of transdermal estrogen preparations, the risk did not reach statistical significance. Oral regimens provide superior benefits on lipids, showing greater reductions in total cholesterol and low-density lipoprotein (LDL) and increases in high-density lipoprotein (HDL) than do transdermal preparations. However, clotting factors and triglycerides are raised to a greater degree by the use of oral preparations.

Hormone therapy remains an appropriate strategy for management of menopausal symptoms during the menopausal transition. Although there is an increased risk of certain cardiovascular outcomes and cancer, the absolute risk for these events is low, especially in the age group most in need of symptom relief. Symptomatic women will receive quality-of-life benefit from the use of hormone therapy, with minimal risk over the short term. Initiation of hormone therapy is not appropriate for women more than ten years from their last menstrual period or for those at high-baseline risk of cardiovascular disease. Assessing the risk-benefit ratio of HRT is very complicated. For example, the optimal time of estrogen initiation in regard to breast cancer is far different than for CHD. The timing hypothesis and the gap-time hypothesis do not allow for simultaneous optimization of breast and CHD risk reduction. Therefore, HRT or ERT should not be used for long-term disease prevention.

Bioidentical hormones are estradiol or progesterone compounded locally in pharmacies, allegedly in specific formulas suitable to the individual. The Food and Drug Administration (FDA) has noted that there is no evidence demonstrating superior efficacy or safety of estradiol administered in a compounded fashion to standard pharmaceutical HRT.

DRUGS THAT AFFECT OVARIAN FUNCTION

A number of drugs used to treat infertility, such as clomiphene citrate, human menopausal gonadotropin, and Gonadotropin Releasing Hormone (GnRH) analogues have also been associated with depressive side effects (Daniluk & Fluker, 1995). Often these side effects are overlooked, as people assume that the woman's anxiety or depressive symptoms are related to the psychological stress of the infertility program. Also, drugs such as danazol, used to treat endometriosis or premenstrual syndrome (PMS) by eliminating the ovarian cycle, have been found to have depressive side effects in themselves.

INTERACTIONS WITH PSYCHOTROPIC MEDICATION

It is important for the clinician to be aware that there may be an interaction between OCs and psychotropic medication (Jensvold, 1996). Ethinyl estradiol is metabolized by *UGT1A1*, *CYP1A2*, *CYP3A*, and inhibits *CPY1A2*, *CPY2C9*, *CPY2C19*, *CPY2B6*, and *CPY3A*. Progestin is metabolized by *CPY2C9*, *CPY2C19*, and *CPY3A*; and some progestins inhibit *CPY2C9*, *CPY2C19*, and *CPY3A*. Mood stabilizers such as carbamazepine, lamotrigine, and topiramate may increase the metabolism of OCs, leading to insufficient hormonal levels to suppress ovulation and an increased risk of contraceptive failure. This may be managed by increasing the dose of the oral contraceptive or switching to a drug such as valproate. OCs increase the levels of chlorpromazine and clozapine and may decrease levels of lamotrigine and valproic acid. There is some evidence to suggest that OCs inhibit the metabolism of tricyclic antidepressants in women, with a resultant increase in serum levels of the antidepressant. Imipramine blood levels should be regularly monitored and the antidepressant reduced if there are serious side effects. OCs may also interfere with the metabolism of some benzodiazepines, leading to decreased circulating levels of such drugs as lorazepam and temazepam, and increased levels of alprazolam and diazepam.

HORMONES AND MOOD

Estrogens have actions on the brain and the neurotransmitters. They affect neurite growth, neural survival, and synapse formation, and interact with brain-derived neurotrophic factor. They modulate many neurotransmitter systems, including dopamine, serotonin, norepinephrine, acetylcholine, and glutamate; but their main effect on mood more than likely has to do with their effect on the serotonergic system. Estrogen increases the availability, concentration, and utilization of serotonin by increasing the degradation of MAO; regulating free tryptophan available in the brain; enhancing transportation of serotonin; and increasing the density of 5-hydroxytryptamine (5HT)-binding sites in the areas of the brain that control mood and cognition. The decrease in monoamine oxidase (MAO) also results in increased availability of norepinephrine, dopamine, and GABA at neuronal synapses by increasing their release, reuptake, and enzymatic inactivation. The antidepressant effect of estrogen is purportedly related to estradiol-mediated normalization of hormonally sensitive neural circuits of depression activated in hormone-related depressions such as postpartum depression and menopause. It may also have a role in modulating feedback regulation of the hypothalamic-pituitary-adrenal (HPA) axis (Moses-Kolko, Berga, Kalro, Sit, & Wisner, 2009). Stress leads to activation of the hypothalamic-pituitary-adrenal (HPA) axis, which in turn leads to suppression of hypothalamic-pituitary-gonadal (HPG) activity through inhibition of gonadotropin-releasing hormone (GnRH) secretion. The functional effects of stress on reproduction

can be seen with the suppression of luteinizing hormone (LH) release from the pituitary and suppression of sexual behavior. The stress effect on HPG function appears to be mediated by the adrenal stress hormones, glucocorticoids.

Studies about the effect of HRT on mood have shown that women who are not or are only mildly depressed may have an increased sense of well-being following the introduction of HRTs (Zweifel & O'Brien, 1997). However, although physiological doses of estrogen improve mood in non-psychiatric populations of symptomatic menopausal women, women who are given estrogen plus progesterone may experience a dampening of mood, compared with women who are given estrogen alone. The depressive effects of adding progesterone may be attenuated by a higher estrogen to progesterone dose ratio. There is no good evidence, however, to suggest that HRTs alone are effective in the treatment of a major depressive episode post-menopause. These women require the use of antidepressant medication, although the antidepressant effect may be enhanced by giving HRT. Whether this is related to a true augmentation effect of estrogen (Grigoriadis & Kennedy, 2002; Stoppe & Doren, 2002) or to the relief of troublesome menopausal symptoms is not clear. Moses-Kolko, Berga, Kalro, Sit, and Wisner (2009) have investigated the use of HRT or ERT for postpartum depressions and concluded that estradiol cannot as yet be considered as a first-line antidepressant.

Estrogen has been proposed as a treatment for schizophrenia because of the latter's high likelihood of presenting at times of hormonal change. A 2008 study found that giving 100 micrograms of transdermal estrogen to schizophrenic women significantly reduced positive and general psychopathological symptoms (Kulkarni et al., 2008). However, a Cochrane Review, updated in 2009, concluded that adjunctive estrogen, with or without progesterone, does not appear to offer convincing advantages over placebo in the treatment of schizophrenia (Chua, de Izquierdo, Kulkarni, & Mortimer, 2005).

ANDROGENS

Androgens play a role in female sexual functions. Women who undergo natural menopause continue to produce some androgen from cells in the ovary as well as the adrenals. Women with bilateral oophorectomies have a profound decrease in the levels of testosterone in the body. Decreased androgen has been related to a decrease in sexual desire in women. Giving combined estrogen-testosterone preparations to women who have experienced a decrease in libido after either natural or surgical menopause appears to enhance their sexual desire and interest (de Paula, Soares, Haidar, de Lima, & Baracat, 2007). The use of testosterone, 2.5 mg orally or 10 mg gel, either on its own or added to HRT, improves sexual desire, sexual function, and increases a sense of well-being in menopausal women. Possible adverse effects include hirsutism, acne, and a significant decrease in HDL cholesterol levels. At this time, testosterone therapy should be limited to short-term use (less than six months), as long-term studies are not available (Somboonporn, Bell, & Davis, 2011).

HYPERANDROGENISM

Disorders resulting in excess androgen may present as abnormal menstrual patterns, hirsutism, weight changes, and fatigue. Symptoms may also include virilization, including deepening of the voice, frontal balding, and clitoromegaly. Excess androgen can be found in polycystic ovarian syndrome (PCOS), adrenal hyperplasia, virilizing adrenal and ovarian tumors, Cushing's syndrome, and hyperprolactinemia.

POLYCYSTIC OVARY SYNDROME

PCOS is a condition characterized by abnormal regulation of reproductive hormones, including estrogens, progesterone, and androgen. Physical symptoms include weight gain, anovulatory or infrequent cycles resulting in impaired fertility, hirsutism, absent or abnormal menses, acne, ovarian cysts, and hypertension. It is also frequently accompanied by mood disorders. Between 5% and 10% of women of childbearing age have PCOS.

PCOS probably has a genetic basis, as there is often a positive family history in women as well as associated metabolic abnormalities in male family members. Although numerous genes are being explored, no genes are universally accepted as important in PCOS pathogenesis; thus there is no specific genetic test for vulnerability for this disorder (Goodarzi, 2008.) Dysregulation of the androgen-forming enzyme CYP17 results in increased androgen production by the theca cells of the ovary and in the adrenals, and lowered conversion of testosterone into estrogen. In some women, problems begin at puberty; while in others, PCOS may be precipitated by pregnancy, or excessive weight gain may result in insulinemia and insulin resistance. Hyperinsulinemia increases GnRH pulse frequency, LH over follicle-stimulating hormone (FSH) dominance, increased ovarian androgen production, and decreased follicular maturation, all contributing to the development of PCOS. Also, adipose tissue possesses an enzyme that converts androstenedione to estrone and testosterone to estradiol. Therefore, obese patients may have both excess androgens, resulting in hirsutism and virilization, and estrogens that inhibit FSH via negative feedback.

Some anti-epileptic medications that many bipolar women take as mood stabilizers can cause polycystic ovaries (O'Donovan, Kusumakar, Graves, & Bird, 2002). Valproic acid, lamotrigine, and oxcarbazepine all inhibit CYP17, leading to higher testosterone levels (Chiarelli, Coppola, D'Egidio, Parisi, & Verotti, 2009). Valproic acid appears to be the worst offender, but PCOS also happens more often to women with epilepsy taking this medication than to those being treated for bipolar disorder, suggesting that other interactions may be taking place (Bilo & Meo, 2008).

Disturbed ovarian function results in the failure of many primordial follicles to mature, resulting in multiple immature follicles that look like cysts. Ovulation becomes irregular, with resultant possible fertility problems. Although 90–95% of women attending infertility clinics with anovulation have PCOS, 60% will conceive, although it may take them longer.

These women also have a high risk of developing type II diabetes and cardiovascular disease (Guzick, 1998), endometrial hyperplasia, and endometrial cancer. Diagnosis can be made by physical examination, an ovarian ultrasound, and measuring various endocrine levels. The ratio of LH to FSH is greater than 1:1. Free testosterone is elevated, but generally no higher than 160 ng/dl—twice the normal level. Hyperinsulemia can be diagnosed by a peak insulin level of 150 mmol/l on the glucose tolerance test.

Women with PCOS have a higher rate of depressive symptoms than controls (Himelein & Thatcher, 2006). The factors that contribute to this elevated rate of depression are unclear. It appears to be unrelated to androgen levels (Rasgon et al., 2003) or hirsutism (Keegan, Liao, & Boyle, 2003). The presence of higher body mass plays some role but is not the only contributor (Weiner, Primeau, & Ehrmann, 2004). Tan et al. (2008) studied the impact of infertility on women with PCOS. They found that the PCOS group placed a greater priority on current unfulfilled wishes to have a child than other infertile women did. In addition, the self-esteem and emotional stability of the women in the PCOS group depended more on their ability to conceive than in the other infertile group. However, there was no direct link between the presence of infertility and the occurrence of depression, although, in cultures that emphasize having children, infertility plays a stronger role.

Weiner et al. (2004) have found that the greater anxiety experience by some PCOS women was attributable to a generally negative mood rather than an independent problem. There has been some discussion about the relationship between bipolar disorder and PCOS. Women with PCOS can experience profound feelings of despair (Kitzinger & Wilmot, 2002). They may feel unattractive or ugly if they are overweight, very hirsute, or have severe acne. They may worry about dating or finding a partner. Body dissatisfaction may lead to bingeing behavior, which, in turn may exacerbate the polycystic disease (Himelein & Thatcher, 2006). Not surprisingly, these women have less satisfactory sex lives and view themselves as less sexually attractive (Elsenbruch et al., 2003). Sexual problems appear to be related to their perception of their attractiveness, and no relationship has been found between their sexual functioning and androgen levels.

Appearance plays a role in their overall quality of life, especially in cultures where being thin is the ideal (McCook, Reame, & Thatcher, 2005). Barnard et al. (2007) found that women with PCOS had a lowered quality of life in all seven measures on the modified PCOS Quality of Life Scale (emotional disturbance, weight, infertility, acne, menstrual symptoms, menstrual predictability, and hirsutism). Weight was the largest contributor. Women taking anti-androgen medications generally had a better quality of life than those not taking them.

The management of PCOS should involve physical and psychological approaches (Teede, Deeks, & Moran, 2010). The goals include lowering insulin levels, restoring normal periods and preventing endometrial cancer, restoring fertility, and treating hirsutism and acne. There is no single approach that treats all of the clinical features. Weight loss is a difficult

but essential component of management. Weight loss may improve abnormal glucose metabolism as well as decrease hyperandrogenism and improve ovarian function.

Fertility may be restored simply by losing weight. Treatment with an insulin sensitizer such as Metformin (500 mg t.i.d.) may reduce insulin resistance and improve ovulation, but it does not seem to improve fertility. Clomiphene citrate can increase the ovulation rate and improve chances for fertility. Ovarian drilling may be used for women whose cycles do not improve. This involves a laparoscope procedure to destroy, either by electrical impulses or laser, small areas of the ovary thought to be the centers of androgen production. With this procedure, approximately 80% of women have restored cycles, and 50% of these become pregnant. Women who conceive have a higher risk of miscarriage, gestational diabetes, preeclampsia, or preterm delivery, but this may be secondary to insulin resistance or weight problems.

Any type of combination oral contraceptive can decrease ovarian and adrenal production of androgen, reduce hair growth in hirsute patients, and also improve acne. Progesterone-only contraceptives may control the menstrual cycle and reduce the risk of endometrial cancer, but they will not help with hirsutism or acne.

Any of the treatments that reduce androgens have a beneficial effect on both hirsutism and acne. These include medroxyprogesterone acetate (20–40 mg daily or 150 mg intramuscularly [IM] every 6 weeks), GnRH agonists such as leuprolide acetate, and spironolactone 100–200 mg daily. Spironolactone seems particularly beneficial for the reduction of acne.

Patients should be screened for the presence of depression, anxiety, body dissatisfaction, and overall quality of life. If an antidepressant is required, avoid those that cause weight gain, such as mirtazapine. Concerns about appearance should be handled sensitively and not be dismissed as superficial. Information about nutrition, weight loss programs, exercise, depilatories or laser treatment for hirsutism, and acne treatment and prevention should be given. Counseling may be needed if the patient has problems changing her lifestyle to include exercise and weight control and/or has problems dealing with infertility.

PREMENSTRUAL SYNDROME AND PREMENSTRUAL DYSPHORIC DISORDER

The only distinctive thing about the over 150 symptoms that have been attributed to PMS is their relationship to the timing of a woman's menstrual cycle. Symptoms should start in the luteal phase, causing significant impairment in a woman's functioning, and disappear within the first few days of the menses. There must also be at least one symptom-free week during the woman's cycle. Of all the symptoms ascribed to PMS, the ones that most often bring women to their physicians for help are those of depression, anxiety, or irritability (Parry, 1999).

The American Psychiatric Association has devised a diagnostic category of *Premenstrual dysphoric disorder* (PMDD)

to focus on the cases of PMS in which marked mood disturbance and a clinically significant impairment of functioning are the predominant symptoms (American Psychiatric Association, 1994). These symptoms must not be merely a premenstrual exacerbation of an ongoing psychiatric disorder. Approximately 1–5% of women meet criteria for PMDD. This disorder can lead to disrupted relationships, lowered productivity at work or school, and increased use of prescription and over-the-counter medications.

Various theories have been proposed to account for the relationship between PMS/PMDD and the menstrual cycle. Despite extensive investigations, researchers have been unable to find any relationship to the levels, ratios, or rates of change of progesterone or estrogen. It may be that either PMS/PMDD sufferers have an abnormal response to normal endocrine changes or that our current technology is not sophisticated enough to detect the relationship (Schmidt, Nieman, Danaceau, Adamas, & Rubinow, 1998). Similarly, researchers have been unable to find consistent proof of abnormalities in vitamin B₆ metabolism, prolactin levels, levels of prostaglandin, glucose tolerance, or the renin-angiotensin-aldosterone system. The most current theory is that, in some women, changes in hormonal levels in the HPG axis trigger changes in the 5-hydroxytryptamine (5-HT) system, resulting in decreased serotonin and the symptoms of depression (Severino, 1994). This theory is supported by the fact that 65% of patients with unipolar mood disorder experience PMS, while PMS patients have been found to have a lifetime prevalence of major depression of 60%. Women who develop PMS/PMDD tend to have detectable abnormalities in serotonin regulation, with less serotonin uptake by platelets than in control subjects during both the follicular and the luteal phases (Severino, 1994). While no evidence has been found to substantiate a purely psychological basis for PMS (Gannon, 1981), there is evidence that women's expectations about their menstrual cycle may be a factor in their experiencing symptoms, as women who have been misled into believing they are in the luteal phase of their cycle experience "premenstrual symptoms" (Schmidt et al., 1991).

Although some groups still criticize the concept of PMDD as being a "gender-based" diagnosis that fails to consider the sociocultural and biological context of the symptoms, the recent findings of ongoing vulnerabilities in the 5HT system in women who develop PMS/PMDD has convinced many that this is a genuine physiological disorder. Use of strict *Diagnostic & Statistical Manual of Mental Disorders* (DSM) criteria can distinguish those women who genuinely experience PMS/PMDD from those for whom the diagnosis is merely a pejorative label.

Diagnosis of PMS/PMDD requires a detailed history with specific attention to the type, severity, timing, and impact of the woman's symptoms, as well as information on past psychiatric history and current stressors. As some women may self-medicate, it is very important to check whether they are taking vitamin B supplements, as 250 mg a day of B₆ can cause peripheral neuropathies. Many women present with self-diagnosed PMS/PMDD. They may be influenced by magazines or prefer a "hormonal" rather than a psychological

explanation for their problems. Studies have shown that, in 50% of cases, retrospective diagnoses of PMS turn out to be erroneous (Rubinow & Schmidt, 1989). Therefore, an essential component of making the diagnosis is prospective charting of moods over at least a two-cycle period.

This charting can be simply done using a standard calendar on which, on a daily basis, the woman rates her chief symptoms on a scale from 1 to 5. She is also asked to chart the beginning and end of her menses as well as any particular stressful events that occur during the month. After two months of charting, examination of this scale by the physician should reveal a very clear pattern of symptoms. If the woman does not fit this pattern, she, by definition, does not suffer from PMS/PMDD but may very well require attention for other physical or emotional problems. Women who are suffering from a major depressive episode or anxiety disorder may have a premenstrual exacerbation of mood symptoms (Hsiao, Hsiao, & Liu, 2004) that may be related to the hormonal changes or to a dilution effect on their antidepressant medication. Increasing the medication for 7–10 days prior to menses may address this problem. As only antidepressants that increase levels of serotonin are effective in treating PMDD, changing to this type of antidepressant may be tried if merely increasing the dose of the previous antidepressant is ineffective. Luteal phase increases of medication may still be required.

As no specific hormonal imbalances have been related to PMS/PMDD, there is no value in routinely assessing hormone levels. Other laboratory tests such as Thyroid Stimulating Hormone (TSH) or an oral glucose-tolerance test to rule out possible physical causes of somatic and emotional distress should be done, when clinically indicated.

Supportive or general health measures may be helpful in relieving distressing symptoms. These include: education of the patient about the nature of this disorder; lifestyle changes to avoid or reduce stressful activities in the premenstrual period; a healthy diet, avoiding salty foods, which may exacerbate a tendency for fluid retention, or caffeine, which may increase irritability; and a regular exercise routine. Cognitive behavioral approaches and relaxation are of some benefit (Pearlstein & Steiner, 2008).

Calcium 600 mg b.i.d. has been shown to be of some benefit in mild to moderate PMS, but the studies were limited, as they did not use diagnostic criteria for PMDD (Thys-Jacob et al., 1998). There is no evidence of magnesium deficiency in women with PMDD compared with control subjects, and magnesium was not found to be superior to placebo in the mitigation of mood symptoms in women with PMDD (Khine et al., 2006). Chasteberry appears to be more useful for physical symptoms in PMS (Schellenberg, 2001). Controlled studies have debunked the use of progesterone, vitamin B, or gamma-linolenic acid (efamol or evening oil of primrose) to treat mood symptoms (Rivera-Tovar, Rhodes, Pearlstein, & Frank, 1994). While mefenamic acid (a prostaglandin synthetase inhibitor) has been found to reduce mood symptoms in some women who also have dysmenorrhea, it probably only acts to decrease negative expectancy by relieving painful menstrual symptoms (Wood & Jakubowicz, 1980).

Fortunately, research in the last several years has confirmed the benefits of using antidepressant therapy for both the mental and the physical symptoms of the luteal phase. Studies so far have found that the use of a SSRI antidepressant such as fluoxetine, sertraline, or paroxetine in the usual therapeutic dose for depression has been highly successful at decreasing or eliminating the symptoms of PMS/PMDD (Shah et al., 2008). For many women, SSRIs may be given in an intermittent manner, starting at day 15 of the menstrual cycle (the start of the late luteal phase) and discontinuing the drug several days after menses commence (Steiner, Korzekwa, Lamont, & Wilkins, 1997). Results of using only symptom-onset treatment with selective serotonin re-uptake inhibitors (SSRIs) have been variable. Serotonin–norepinephrine reuptake inhibitors (SNRIs) such as venlafaxine and duloxetine have also been found useful for the treatment of both physical and mood symptoms.

Inhibiting ovulation has been found to be effective in eliminating PMS/PMDD symptoms. Studies of mono-phasic and tri-phasic OCs did not find any consistent benefit for mood symptoms. Recent studies using an oral contraceptive containing ethinyl estradiol 20 micrograms and a unique progesterone, drospirenone 3mg, administered for 24 days followed by only a four-day break, showed marked reductions in both mood and physical symptoms. It is not clear whether this is due to unique anti-mineralcorticoid and anti-androgenic properties, or to the 24/4 regimen, which results in greater suppression of pituitary and ovarian hormones (Lopez, Kaptein, & Helmerhorst, 2010).

Gonadotropin-releasing hormone analogues (GnRHs) such as goserelin or leuprolide can treat PMS by suppressing ovulation but are not as effective for behavioral and mood symptoms as they are for physical symptoms (Wyatt, Dimmock, Ismail, Jones, & O'Brien, 2004). They also tend to cause uncomfortable, menopausal-like side effects as well as serious bone loss, and, therefore, may be unsafe to use for longer than six months. Adding back HRT may reduce side effects but may also trigger the return of PMS symptoms if cyclical progesterone is used. Other ovulation suppressants such as danazol and high-dose continuous estrogen are effective but cause significant negative side effects such as weight gain, masculinization, or endometrial hyperplasia (Pearlstein & Steiner, 2008). Hysterectomy and oophorectomy are obviously very extreme ways of alleviating these symptoms and may have their own negative physical and emotional consequences (Cronje, Vashisht, & Studd, 2004). In summary, the majority of women with PMDD will respond to a combination of psycho-education, support, a healthy lifestyle (balanced diet and moderate exercise), stress reduction (especially in the late luteal phase), and treatment with intermittent or continuous SSRIs; therefore, more drastic endocrine therapies of PMS/PMDD would be indicated only in cases in which there is extreme disruption of the woman's life and other, more conservative, therapies have been ineffective. Though the ovulation-suppressing therapies have many drawbacks, they are certain to work at least partially. The medical psychiatrist considering such therapies should involve both a gynecologist and the patient in order to facilitate well-informed decision-making.

PERIMENOPAUSE AND MENOPAUSE

The perimenopause is the transition time from premenopause to post-menopause during which menstrual periods become irregular and women experience vasomotor symptoms such as hot flushes in addition to mood, sleep, sexual, and cognitive disturbances (Dennerstein, Dudley, Hopper, Guthrie, & Burger, 2000; Schmidt, 2005; Freedman, 2005). Menopause is defined as occurring when it has been 12 months since the last menstrual period, and the post-menopause is the time thereafter (Soules et al., 2001). The transition can take many years, but the median age at menopause is 52 years (Proceedings from the NIH State-of-the-Science Conference on Management of Menopause-Related Symptoms, 2005). Methodological issues, such as research being based on clinic-based surveys (e.g., from gynecology clinics) without rigorous assessment, resulted in controversy as to whether women are at an increased risk for developing depressive symptoms or a depressive disorder during the perimenopause. Recent research, based on rigorously conducted community samples, has demonstrated that this time is a period of increased risk. In a prospective study of eight years' duration, Freeman, Samuel, Lin, and Nelson (2006) found women in the menopausal transition were at four-fold greater risk for developing depressive symptoms than during the premenopausal phase, and that entering menopause was associated with double the risk of receiving a depressive disorder diagnosis. Schmidt, Haq, and Rubinow (2004) also followed women prospectively for five years and found that, in the 24 months around the final menstrual period, women were at 14 times greater risk for the development of depression compared to the premenopausal women. Cohen, Soares, Vitonis, Otto, and Harlow (2006) also found an increased risk for the development of depressive symptoms in addition to major mood disorders in the perimenopause. It is therefore well established that perimenopausal women not only have a higher likelihood of reporting depressive symptoms, they are also at an increased risk for developing a mood disorder.

Several mechanisms have been proposed to explain the depressive symptoms, such as fluctuations in estradiol (Prior, 1998); the consequences of the sleep disturbance resulting from the vasomotor symptoms (Campbell & Whitehead, 1977); psychosocial changes such as those encountered in changing roles or family circumstances, decreased physical activity, or change in health status; as well as cultural factors regarding menopause (Avis, 2003; Lock & Kaufert, 2001; Gyllstrom et al., 2007). Although the relationship is not well understood, in a subpopulation of vulnerable women (perhaps more so in those with a history of depression) (Avis, Brambilla, McKinlay, & Vass, 1994), there appears to be a link between the development of depressive disorders and estrogen depletion or deficiency (Steiner, Dunn, & Born, 2003; Daly, Danaceau, Rubinow, & Schmidt, 2003; Payne, 2003). Recent research has suggested other contributing endocrine mechanisms, although not consistently. Harlow, Wise, Otto, Soares, and Cohen (2003) reported that women with a history of depression were more likely to have an earlier transition with higher FSH and LH levels and lower estradiol. Freeman et al.

(2004) found a relationship between FSH and estradiol levels and depression. Subsequently, Freeman et al. (2006) found women with no prior history of depression in perimenopause had increased levels of FSH and LH with increased depression ratings and more variability in FSH, LH, and estradiol levels. Taken together, the changing hormonal environment was hypothesized to contribute to the development of depression. However, Schmidt and colleagues (2002 and 2004) did not find a relationship between basal FSH or LH levels and other hormones in perimenopausal woman with depression. Others also did not find consistent relationships between hormone levels and mood (Woods et al., 2008). Clearly, more work is needed to understand the causal mechanisms. Moreover, it is important to recognize that, although some women may be at an increased risk for developing depression (and perhaps other psychiatric disorders) during the perimenopause, most women will not (Soares & Taylor, 2007).

Physicians must also pay attention to psychological and cultural considerations (Gise, 1997). Perimenopause and post-menopause may be seen as a time of rapid aging and decreased attractiveness. Social roles change, and some women may fear the loss of the ability to have children, or that they will have less valuable roles post-menopausally. Other psychological stressors can include children leaving (or returning) home; difficulties in finding new, fulfilling roles; loss of a partner; health problems; responsibilities for aging parents; and the deaths of relatives or friends (Deeks, 2003).

Most women pass through menopause without serious difficulty, however. The Massachusetts Women's Health Study (Avis & McKinlay, 1991) found that most women in their middle years report relief or neutral feelings about their periods' stopping. Negative attitudes towards menopause usually change once the individual is in menopause and realizes her fears about what will happen to her do not materialize. Employment, better health, and higher education were associated with more positive attitudes, while depression and higher symptom reporting were associated with negative views. The survey by the North American Menopause Society found that 52% of participants saw menopause as the beginning of a new and fulfilling stage of life (Kaufert, Boggs, Ettinger, Woods, & Utian, 1998).

Although in menopausal women, FSH levels exceed 40 mIU/ml (Soules et al., 2001), the determination of perimenopause or menopause is generally made clinically rather than based on laboratory evaluation. Treatment of symptoms of depression at menopause requires an assessment of the contribution of the different etiological factors. The hormonal profile of elevated concentrations of FSH and LH with decreased concentrations of estradiol and progesterone are not clearly different in women who do or do not become clinically depressed; therefore, this profile cannot be used to direct treatment. At this time, there is little value in routinely performing these assessments. As thyroid disease and diabetes are common in women of this age, thyroid function and glucose tolerance should be assessed to rule out any abnormality in these systems. HRT, clonidine, low-dose SSRIs, SNRIs, and gabapentin may decrease distressing symptoms related to estrogen withdrawal (Proceedings from the

NIH State-of-the-Science Conference on Management of Menopause-Related Symptoms, 2005).

Education of women, individually or in groups, to dispel myths and fears about impending unattractiveness or loss of femininity can help avert or minimize their distress (Robinson & Stirtzinger, 1997). Women with specific conflicts or concerns associated with past or current problems may benefit from individual or marital therapy. Self-help groups may provide support and advice in dealing with the physiological and psychological changes at this time, and there is also some evidence for cognitive behavioral approaches for menopausal issues (Hunter & Rendall, 2007). The use of 17 β -estradiol for treating perimenopausally depressed women does have some research support, although the risks need to be weighed against the potential benefits, as the use of estrogen is not recommended for long-term use; moreover, the trials did not assess 17 β -estradiol exclusively in women with major depression, and included less severe forms of depression (Schmidt et al., 2000; Soares, Almeida, Joffe, & Cohen, 2001). For women who meet criteria for a major depressive episode, antidepressant medication is indicated (Lam et al., 2009). HRT can also be used to augment antidepressant therapy, especially SSRIs, for a synergistic effect, especially in women with less-than-optimal response to antidepressants or HRT. For example, if a woman does not respond to an SSRI and is perimenopausal and complaining of hot flashes or other perimenopausal symptoms, augmentation of the SSRI with HRT can be an option prior to switching to another antidepressant, although current clinical guidelines do not exist. Short-term HRT use is recommended for perimenopausal symptoms (Canadian Consensus Conference on Menopause, 2006).

CLINICAL PEARLS

- Initiation of HRT close to menopause was not associated with improved cognition, and HRT did not significantly reduce dementia risk over the course of this study (Ryan et al., 2009). ERT did not appear to have an enduring helpful effect on cognitive functioning in older women.
- New information suggests that the risk of stroke (odds ratio 1.29) can be reduced by the use of transdermal HRT (Brown, 2010).
- Mood stabilizers such as carbamazepine, lamotrigine, and topiramate may increase metabolism of oral contraceptives, leading to insufficient hormonal levels to suppress ovulation and an increased risk of contraceptive failure.
- Although 90–95% of women attending infertility clinics with anovulation have PCOS, 60% will conceive, although it may take them longer.
- PCOS also happens more often to women with epilepsy taking valproate than to those being treated for bipolar disorder; suggesting that other interactions may be taking place (Bilo & Meo, 2008).
- In women with PCOS, excess weight was the largest contributor to poorer quality of life. Women taking

anti-androgen medications generally had a better quality of life than those not taking them.

- Approximately 1–5% of women meet criteria for PMDD.
- Despite extensive investigations of PMDD, researchers have been unable to find any relationship to the levels, ratios, or rates of change of progesterone or estrogen.
- It is well established that perimenopausal women not only have a higher likelihood of reporting depressive symptoms, they are also at an increased risk for developing a mood disorder.
- Although in menopausal women, FSH levels exceed 40 mIU/ml (Soules et al., 2001), the determination of perimenopause or menopause is generally made clinically, rather than based on laboratory evaluation.
- For women who meet criteria for a major depressive episode, antidepressant medication is indicated (Lam et al., 2009). HRT can also be used to augment antidepressant therapy, especially SSRIs, for a synergistic effect, especially in women with less-than-optimal response to antidepressants or HRT.

DISCLOSURE STATEMENTS

Dr. Robinson is an employee of the University of Toronto and works at the University Health Network in Toronto, Canada. She has no ties to any pharmaceutical companies. She has no conflicts to disclose.

Dr. Grigoriadis has a New Investigator Award in Women's Health Research from Canadian Institutes of Health Research (CIHR) in partnership with the Ontario Women's Health Council. She has received honoraria as a consultant, member of an advisory committee, or for lectures over the last five years, from Wyeth Pharmaceuticals, GlaxoSmithKline, Pfizer, Servier, Eli Lilly Canada, and Lundbeck. Her research grant support over the last five years has included the CIHR, the Ontario Ministry of Health, the Ontario Mental Health Foundation, and the C. R. Younger Foundation.

PREGNANCY AND POSTPARTUM

Diane de Camps Meschino, Ariel Dalfen, and Gail Erlick Robinson

INTRODUCTION

Pregnancy and the postpartum period have been idealistically viewed as times of happiness and joy. When a pregnancy is wanted and planned, women are expected to “bloom” and enjoy this state as one of satisfaction and fulfillment. Postpartum, society expects women to be blissfully happy and devoted to the interests of their new baby. The reality is that, even in the case of wanted and planned pregnancies, women may suffer from a variety of problems ranging from simple adaption to this new experience to depression, anxiety, psychotic disorders and substance abuse. Pregnancy and postpartum are times of enormous physiological, psychological and sociocultural changes which can cause enormous stress. As well, women with pre-existing mental illnesses can become pregnant or vulnerabilities to illness may be activated by all of the stressors that accompany this phase in women’s lives.

PREGNANCY

NORMAL PREGNANCY

Pregnancy is a time of enormous biological, psychological, and sociocultural changes, all of which may result in the increased sensitivity and emotional lability that many women experience during pregnancy. During this time, there are major changes in estrogen and progesterone and significant changes in prolactin, corticotrophin-releasing hormone, and oxytocin, among others. There are also many practical and lifestyle changes that may add stress. The couple may have to move or buy a new car. Maternity leave may result in financial difficulties. Women must decide how much leave they will take, whether they will return to work, or, if they do return, whether they will alter their ambitions or work goals.

The immense changes a woman experiences in a relatively short time create both an opportunity for personal growth and the potential for intrapsychic conflict with the need for professional intervention. The greatest psychological changes occur during the first pregnancy. Women must make the psychological transition to being a parent. This may either feel frightening or feel like the final step to becoming an adult. Ideally, a woman chooses to become pregnant because she feels mature enough for the

responsibility of looking after a child and has a balanced view of the joys and stresses involved. In reality, many pregnancies are unplanned, and reasons for becoming pregnant are varied, including: seeing it as a way to feel like an adult, acting on a wish to have someone to love, making an attempt to keep a relationship, or responding to expectations from one’s family or community.

Prior to and during the pregnancy, the woman must reassess her partner and decide whether he will be a good parent. The couple begins to sort out whether their relationship will assume more traditional roles postpartum. Pregnancy may strengthen a couple’s intimate bond and be integrative of maturity, resulting in a more securely attached marriage. The woman also may emotionally revisit her relationship with her own mother, deciding whether she wants to parent in a similar way or develop a different parenting style. Ideally, pregnant women (and their partners) are able to appreciate and identify with the positive aspects of their own parents and consequently experience enhanced independence and self-determination.

For many years, pregnancy was thought of as a protected state, immune to any serious mental health disorders. However, not only can anxiety and depression present during pregnancy, even “normal” planned pregnancies can be accompanied by mood changes and psychological conflict. A woman who expects she should be blissfully happy during pregnancy may find it difficult to tell anyone about these common feelings. Over the course of the pregnancy, as her body changes, she may feel beautiful and confident, or unattractive and fat. Some women feel more sexual during pregnancy, while others may have no interest in sex; and their interest or lack of it may be at odds with the feelings of their partners. Women may initially feel anxious about miscarrying and later about delivering a healthy baby.

Stressful life events (Paykel Emms, Fletcher, & Rassaby, 1980; Bernazzani, Saucier, David, & Borgeat, 1997a), together with the quality and support of marital relationships (Cowan & Cowan, 1988; Bernazzani et al., 1997b) are important factors in adaptation to pregnancy. Recent life adversity, including life events and chronic stressors, has been confirmed to contribute to the development of poor adaptation and depression in pregnancy. In less optimal situations, the demands of pregnancy and the transition of roles and relationships increase stress, which may result in conflict with significant others, depression, or anxiety.

HYPEREMESIS GRAVIDARUM

Nausea and vomiting are common symptoms during the first trimester of pregnancy. Approximately 0.5% of women experience severe, intractable vomiting, or hyperemesis gravidarum (HG) that generally resolves around week 20, but may continue throughout the pregnancy, resulting in dehydration and metabolic and electrolyte disturbances. Despite investigations of hormonal, immunological, infectious, metabolic, and anatomical facts, the cause of HG remains unknown (Verberg, Gillott, Al-Fardan, & Grudzinskas, 2005).

Historically, women with HG have been accused of being ambivalent about the pregnancy or rejecting the idea of motherhood. HG has been labeled as a sign of hysteria, neurosis, depression, stress, or marital conflict; however, there is no evidence that this is true. Women, already feeling miserable because of the symptoms of HG, should not have added stress placed on them by medical staff making these kinds of assumptions.

Initial treatment of HG involves appropriate parenteral fluid and electrolyte replacement. Various antiemetics may be given with vitamin supplementation. The standard treatment in most of the world is Benedictin (also sold under the trademark name Diclectin), a combination of doxylamine succinate and vitamin B₆, although ginger has been found to diminish or eliminate the symptoms without any side effects (Kuscu & Koyuncu, 2002).

PERINATAL DISORDERS

Depression in Pregnancy

Depressive symptoms in the perinatal period are extremely common, with symptoms ranging from enhanced emotionality and sadness to major depressive disorder (MDD). As many as 14.5% of women have a new episode of major or minor depression that begins during pregnancy (Gavin et al., 2005). As many as 18.4% of pregnant women are depressed during their pregnancy, with 12.7% developing a major depression. Bennett, Einarson, Taddio, Koren, and Einarson (2004) found prevalence rates of 7.4%, 12.8%, and 12.0% in the first, second, and third trimesters, respectively; while Gavin et al. (2005) determined point prevalences to be 11.0%, 8.5%, and 8.5%. One-third of these will be first episodes. Rates of depression in pregnancy do not differ from those in non-pregnant women.

Prenatal depression has a similar symptom profile to that of depressive syndromes during other life stages, although it may be associated with greater anxiety, irritability, and severe insomnia. Mood may fluctuate, particularly with the amount of sleep obtained. Anxiety is focused on the baby's health, potential breastfeeding issues, financial issues, relationships, and the mother's appearance or her own health. Depressed mothers often feel no love or bonding with their baby while pregnant, worry they will be inadequate as mothers, and express associated guilt. They may have escape fantasies, wish they had never become pregnant, and worry that the rest of their lives will be joyless and/or that they will feel entrapped or imprisoned. In more severe depressive episodes, mothers

may have suicidal ruminations or thoughts of harming their baby *in utero*. Although they feel ashamed of such thoughts, women are relieved to be asked about them and to be reassured that thoughts of harming one's baby have been experienced by other depressed women. Patients, healthcare providers, family, and friends may dismiss symptoms of depression in pregnancy due to the normal occurrence of insomnia, fatigue, change of appetite, and loss of energy seen during this period.

Risk Factors for Depression in Pregnancy

New-onset or recurrent depressive disorders in the perinatal period have a multifactorial etiology. A personal or family history of mood or anxiety disorders (including premenstrual dysphoric disorder [PMDD]) is associated with increased perinatal risk (Altshuler, Hendrick, & Cohen, 1998; Robertson, Jones, Haque, Holder, & Craddock, 2005). Other factors include ambivalence about pregnancy, insecure attachment style (Bifulco et al., 2004), limited social support, unintended pregnancy, marital conflict, poor relationship quality (Lancaster et al., 2010), and a history of childhood sexual abuse (Bronwyn & Milgrom, 2008). Depressive or anxiety symptoms during pregnancy may be the greatest risk for postpartum disorders (PPD). Women being treated for anxiety or depression frequently discontinue medication in preparation for, or upon discovery of, pregnancy. Cohen et al. (2004) found that discontinuation of medication led to a relapse in 68% of women during pregnancy.

Bipolar Disorder in Pregnancy

Pregnancy appears to neither decrease nor increase the risk of bipolar episodes. Viguera et al. (2000) found relapse rates with lithium discontinuation to be similar during pregnant and non-pregnant states. Pre-conception education allows opportunities to change medications, such as valproic acid, which may cause fetal damage; and to explain the risks of discontinuing medication during pregnancy.

Anxiety Disorders

All anxiety disorders have been reported to be more common in women, with peak incidence in the reproductive years (Kessler et al., 1994; Kessler, Sonnega, Bromet, Hughes, & Nelson, 1995). In addition to the usual symptoms of generalized anxiety disorder (GAD), pregnant women may find themselves checking their fetus more frequently than necessary. Domains of worry often include financial security, personal appearance, household responsibilities, and hygiene (Wenzel, Haugen, Jackson, & Robinson, 2003). To distinguish anxiety from normal perinatal concerns, "anxiety" must be widespread, excessive, and interfere with day-to-day functioning. The *Diagnostic and Statistical Manual of Mental Disorders*, 5th edition DSM-V criteria of six months' duration may not be met at initial presentation. Preexisting anxiety or antenatal anxiety may be a greater risk factor for PPD than a history of depression (Matthey, Barnett, Howie, & Kavanagh, 2003).

Panic Disorder

The rate of panic disorder during pregnancy is consistent with its rates at other times. The course of panic through pregnancy is unpredictable. Women may interpret panic as an indication of fetal abnormality, and require both education and reassurance in addition to treatment.

Post-traumatic Stress Disorder

Trauma related to a past sexual abuse or previous traumatic birth experiences may cause post-traumatic stress disorder (PTSD) symptoms to recur, especially relating to labor and delivery due to anticipated pain, sexual exposure, and lack of control. Re-experiencing (flashbacks, nightmares); avoidance (dissociation, numbing); and hyperarousal (difficulty sleeping, severe anticipatory anxiety) occur.

Obsessive-Compulsive Disorder

Obsessive-compulsive disorder (OCD) is an anxiety disorder that may have its onset in pregnancy (Altshuler et al., 1998). Intrusive, frightening, ego-dystonic thoughts of harm coming to their fetus or of doing harm to their fetus are reported phenomena. Typically, pregnant women with OCD do not act on these thoughts, but one must make a careful assessment of impulsivity and co-occurring depression or irritability, which may increase the risk. Explaining, in a calm, nonjudgemental manner, that these thoughts are signs of an illness rather than negative feelings towards the baby, helps women feel more contained and in control.

Risks of Untreated Mood and Anxiety Disorders

The risks for the mother include poor self-care, inadequate nutrition, weight gain, sleep disturbance, illicit drug use, smoking, alcohol abuse, emotional deterioration, and increased anxiety. Interpersonal and family conflict may escalate, especially if irritability is one of the symptoms. Depression in pregnancy increases the risk of PPD, which imparts independent risks for the child.

There are some reports of an increased risk of preeclampsia (Kurki, Hiilesmaa, Raitasalo, Mattila, & Ylikorkala, 2000; Bansil et al., 2010), Cesarean delivery, epidurals (Chung, Lau, Yip, Chiu, & Lee, 2001), preterm birth, low birth weight (Grote et al., 2010) and poor neonatal adaptation (Misri et al., 2004). This may be a consequence of the lifestyle changes described above. Biological mechanisms thought to be involved include increased cortisol and dysregulation of the hypothalamic-pituitary-adrenocortical axis, which may result in placental hypoperfusion.

There are many reports regarding the neurobiological impact of fetal exposure to severe anxiety and MDD. Although the numbers are small, research suggests a possibility of increased risk of the baby's developing a fearful temperament, attention-deficit hyperactivity disorder (ADHD), autism, or childhood anxiety (Hollins, 2007). There is evidence to suggest that at least some of these effects relate to the impact of MDD during pregnancy, rather than inheritance.

Intervention for Antenatal Depression and Anxiety Disorders

Preexisting and new-onset medical disorders such as anemia, thyroid disorders, or other autoimmune disorders must be ruled out as the cause of the anxiety or depression. Treatment should include validation of the woman's experience and education about the nature of depression or anxiety during pregnancy. Many women are relieved to find out they have an illness, rather than that they are bad or uncaring future mothers. Education of partners and family is essential, as they may feel helpless and overwhelmed or defensively dismissive. Recruitment of family and partners for assistance provides the woman with extra support at home. Respite care, visiting home assistance, public health, mental health nursing, and other community agencies can also be employed with great benefit. Reduction of stressors such as the care of other children, housework, and other domestic chores should be addressed. Ensuring adequate sleep is an important preventive and treatment measure.

Treatment with psychotherapy, facilitated support groups, and supportive counseling may be effective in mild or moderate syndromes and is usually preferred to medication by both mothers and healthcare professionals. An understanding of the psychological development during pregnancy provides a framework for education and psychotherapy. Supportive, psychodynamic, intrapersonal, and cognitive behavior therapy have all been used with good results.

In more severe situations—in which the anxiety and/or depression is disabling and has a profoundly negative impact on the mother, other children, and the marriage—medication should be offered. The clinician should summarize the research on the safety of psychotropic medication in pregnancy and discuss the risk–benefit ratio (Robinson, 2012a). Most patients are not aware that there are risks to the fetus of *not* taking medication for severe depression or anxiety. This type of discussion helps mothers make an informed decision.

Schizophrenia in Pregnancy

The incidence of schizophrenia in women is 1–2%, with the most common age of initial onset during the childbearing years. Women with schizophrenia may become pregnant, although those who are chronically psychotic are more likely to have unplanned pregnancies (Barkla et al., 2000). In these cases, pregnancies may be unwanted and end in terminations. Severely ill women who are non-compliant with medication may fail to seek adequate prenatal care, have poor diets, smoke, or abuse other substances. They may become delusional and try to harm the baby *in utero* or at birth, or develop anxiety or delusions about the obstetrician or the delivery. These women are often at risk of having the newborn removed from them due to their inability to care for the child.

With greater understanding of the benefits of continuous antipsychotic medication, many schizophrenic women continue to lead active lives, enter into relationships, and experience the desire to conceive. For these women, “prenatal care” needs to start prior to pregnancy. Contraceptive needs

should be discussed so the woman can plan her pregnancy. It is important to discuss the dangers of decompensating if she discontinues medication during pregnancy. The clinician needs to help her plan to have appropriate supports in place both during and after the pregnancy.

Schizophrenic mothers have been said to have significantly more obstetrical complications than non-psychotic women. Bennedsen, Mortensen, Olesen, and Henriksen (2001) found a marginally significant increase in congenital abnormalities, but no increase in stillbirths or neonatal deaths. However, Nilsson, Lichtenstein, Cnattinguis, Murray, and Hultman (2002) found the risks for adverse pregnancy outcomes such as low birth weight, preterm delivery, and stillbirth were generally doubled for women with an episode of schizophrenia during pregnancy, compared to women in the control group. Jablensky, Morgan, Zubrick, Bower, and Yellachich (2005) found women with schizophrenia were significantly more likely to have placental abruption, low birth weight infants, and children with cardiovascular anomalies. There was an increased rate of sudden infant death syndrome (SIDS) in the offspring of these women. It is unclear whether these problems are due to some intrinsic biological factors, medication during pregnancy, or maternal lifestyle.

During pregnancy, close monitoring is important as the physiological changes in pregnancy may require an increase in medication doses as the pregnancy progresses (Robinson, 2012b). The clinician needs to watch carefully for any signs of poor eating habits, substance abuse, or delusional ideas, especially concerning the pregnancy. The mental health clinician should work closely with the obstetrician, first to ensure that he/she does not tell the woman to discontinue her psychiatric medication, and then to make sure he/she is aware of possible risks during the pregnancy and delivery. If the woman becomes very delusional prior to or at the time of the delivery, she may require psychiatric admission.

SUBSTANCE ABUSE IN PREGNANCY

Substance abuse during pregnancy is an immense public health concern. Best estimates for pregnant American women in the 15 to 44 age group are: illicit drug use, 3.4%; tobacco use, 17.6%; and alcohol use, 13.8%; with many using all three (Lester, Andreozzi, & Appiah, 2004). It is estimated that approximately 1 million children in the United States each year are exposed to legal or illegal substances during gestation (Chasnoff, Anson, Hatcher, & Stenson, 1998). Rates of substance use and abuse in pregnancy are thought to be significantly under-reported due to fear, stigma, and most recently, the debate over whether to consider such an activity a criminal offense.

Screening for substance use in pregnancy using open-ended and nonjudgemental questioning is more likely to result in disclosure. Inquire by starting with the use of over-the-counter (OTC) and prescription medications (their own and from others), then moving to alcohol and illicit drugs, including questions about the method of administration and any sharing of drug paraphernalia. Information regarding the context of drug use, life impact, and willingness to change will permit

the development of an individualized treatment plan. Urine drug-screening can be done to increase detection of problematic substance use, assist with monitoring and motivation, and provide documentation for child protection services.

Substance use can cause direct toxicity to the fetus, but it can also have indirect effects due to poor nutrition, inadequate housing, and lack of prenatal care. The potential impact of substance abuse in pregnancy includes obstetrical complications, exacerbation of comorbid psychiatric illness, and effects on the fetus, neonate, and child.

Alcohol is the most teratogenic substance of abuse in pregnancy, with rates of abuse highest in the first trimester. It is of particular concern due to its neurotoxic impact, which begins by the third week post-conception. As 50% of pregnancies are unplanned, the potential for early damage is substantial. Fetal effects are dependent on dose, drinking pattern, gestational age, and both maternal and fetal genetic metabolic factors. Fetal alcohol exposure affects the neurodevelopment of nearly 1% of babies, with the full fetal alcohol syndrome (FAS) affecting approximately 1 in 1,000 babies. FAS is the result of heavy drinking and results in prenatal and postnatal growth retardation, facial dysmorphism, and neurodevelopmental abnormalities resulting in a complex pattern of behavioral and cognitive dysfunction. Long-term consequences include mental health problems such as mood and anxiety disorders, ADHD, substance abuse, and suicide (O'Connor & Paley, 2009), as well as a range of behavioral problems (Jones, 2011).

Marijuana causes exacerbation of maternal mood and anxiety disorders and has (inconsistent) effects on the length of gestation. Use in pregnancy can lead to problems for the neonate such as transient sleep disturbances and difficulties in self-soothing. Long-term behavioral problems for the child include hyperactivity, impulsivity, inattention, delinquency, and poor executive function.

Nicotine increases the risk of placenta previa, abruption, miscarriage, intrauterine growth restriction, prematurity, perinatal mortality, and SIDS.

Opioid abuse increases risks of preeclampsia, placental abruption, intrauterine growth restriction, miscarriage, prematurity, fetal distress, and stillbirth.

Management of drug abuse in pregnancy must first focus on engaging and motivating the woman to engage in treatment (Milligan et al., 2010). Education about the impact on the mother and the fetus may help motivate the woman. The choice of medical detoxification or supportive therapy is substance-specific. The second trimester is the safest time for drug withdrawal, as this can induce miscarriage in the first trimester and fetal distress or demise and premature labor in third trimester. Treatment of comorbid psychiatric illnesses is essential. Relapse prevention includes pharmacotherapy and counseling to reinforce her motivation and help the woman recognize and avoid triggers. Multidisciplinary teams are most effective.

EATING DISORDERS

The rates of eating disorders in pregnancy have been estimated as 0.2% for bulimia nervosa and 4.8% for binge-eating

disorder (Bulik et al., 2007). Eating disorders may be exacerbated or remit during pregnancy. They are associated with comorbid depression and higher rates of miscarriage, low birth weight, obstetrical complications, and postpartum depression (Franko et al., 2001). As the potential negative consequences are significant, a high index of suspicion is required when a woman with a history of eating disorders shows poor weight gain. Assertive treatment is required.

POSTPARTUM

Although the postpartum period can be a very happy and exciting time, it is also complex and overwhelming on multiple levels. There are dramatic physical and biological alterations, as levels of progesterone and estrogen drop, and prolactin surges for lactation. A new mother has to cope with physical changes after pregnancy, which may include significant weight gain or complications from labor and delivery such as lacerations or Caesarean section wounds that are not healing. If breastfeeding, she also may be confronted by challenges such as difficulty with initiating or sustaining breastfeeding, painful nipples, or mastitis. During this time, an abundance of new experiences require navigation and adaptation, such as learning to care for the physical needs of a newborn, bonding with one's baby, and incorporating one's new maternal identity into one's previous self-image and lifestyle. There may also be financial and career challenges, as a new mother must coordinate and integrate her work life with her family life. The woman may still be processing memories of her own parent-child experiences. Also, having a baby may strain the new mother's relationship with her partner. Older children may also place additional demands on the new mother.

Because of these myriad transitions, challenges, and changes, the postpartum period is a time of heightened risk for developing psychiatric problems or for the recurrence of preexisting illnesses. During the first three months postpartum, women are at the highest lifetime risk of needing psychiatric care (Kendell, Chalmers, & Platz, 1987). Because postpartum mental illnesses place a tremendous burden on a new mother, her family, and the baby, these illnesses need to be identified early and treated effectively.

POSTPARTUM PSYCHIATRIC DISORDERS

Psychiatric disorders of the postpartum period include "the baby blues," postpartum depression, postpartum anxiety disorders, and postpartum psychosis. These disorders are not separately or specifically described in the DSM-V, but mood disorders (major depressive, manic or mixed episodes in MDD, bipolar I disorder, or bipolar II disorder) and brief psychotic disorder can receive the specifier *with peripartum onset*, if they begin within the first four weeks after delivery.

Baby Blues

Baby blues occur in 50–80% of new mothers, beginning within three to five days after the baby is born. Symptoms last

a few hours to a few days, and remit within two weeks. Baby blues are not widely considered a psychiatric illness, but they are an intense emotional state that occurs in the early postpartum period (O'Hara, Schlechte, Lewis, & Wright, 1991). Despite symptoms of feeling overwhelmed, increased anxiety, tearfulness, and heightened sensitivity, the new mother is likely to be able to function well and care for her baby. It is postulated that baby blues are caused by the dramatic shift in hormones that occurs during delivery and in the early postpartum period. It has also been associated with sleep disruption in late pregnancy (Wilkie & Shapiro, 1992) and may be triggered by the significant psychosocial and lifestyle transition that accompanies having a baby (O'Hara et al., 1991).

Sufficient interventions include education about caring for a newborn, discussions about the importance of getting enough sleep, development of a support network, and emotional support and reassurance for a new mother and her partner. However, for women who are at risk of developing postpartum depression, baby blues symptoms should be monitored closely, with follow-up arranged, as these symptoms may be the early signs of postpartum depression. Up to 25% of new mothers who have the baby blues later develop postpartum depression (O'Hara & Swain, 1996).

Postpartum Depression

Postpartum depression (PPD) affects between 10 to 15% of new mothers (Halbreich, 2005). The official *DSM-IV* diagnosis for this illness is *Major depressive disorder with peripartum onset*, if it begins within four weeks postpartum. However, there are data to show that PPD can begin any time within the first 12 months postpartum (Cooper, Campbell, Day, Kennerley, & Bond, 1988). Generally, symptoms begin within the first 12 weeks after the baby is born, and most resolve within three months (Cox, Murray, & Chapman, 1993); but, in more severe cases, symptoms may persist for up to one year postpartum (Cooper et al., 1988).

Because of the shame, fear, and embarrassment experienced by many depressed new mothers, there is often a lag between the time a woman begins to feel unwell and when she seeks psychiatric care. Because of the overlap between some of the somatic symptoms of depression and regular postpartum recovery or medical illnesses, many clinicians also fail to identify postpartum illnesses.

A formal PPD diagnosis can be made if a woman meets DSM-V criteria for a major depressive episode (MDE), including low mood, anhedonia, changes in sleeping (severe insomnia is prominent in PPD), changes in appetite, physical retardation or agitation, decreased concentration and memory, feelings of guilt or worthlessness, as well as thoughts of death or suicide. For the symptoms to be defined as a disorder, they need to persist for two weeks and have a significant impact on a woman's ability to function and care for herself and her baby.

While PPD often appears clinically similar to MDE, the concerns are usually related to parenting and infant issues. There may also be prominent symptoms of anxiety, irritability, guilt about being unwell and being an inadequate

mother, fears about being unable to care for one's baby, regret about having had a baby, and unrealistic worries about the infant's health and welfare. Forty to 57% of women with PPD may also have some ego-dystonic, intrusive thoughts about harming their baby. In the context of PPD, these thoughts are very frightening to the woman, but her judgement and insight are fully preserved (Brandes, Soares, & Cohen, 2004).

The precise etiology of postpartum depression has yet to be determined. On a biological level, it appears that a sensitivity to changes in gonadal steroid levels make some women susceptible to PPD (Bloch et al., 2000). The absolute levels of these biological markers are not abnormal in women affected by PPD, but the fluctuation of these levels has a pathological impact on some women, perhaps related to the effects of gonadal hormones on the neurotransmitters responsible for mood.

The most significant risk factor for postpartum depression is having a history of depression or anxiety during pregnancy (O'Hara & Swain, 1996; Beck, 2001). Cohen et al. (2006) demonstrated a 68% relapse rate when women who were being treated for depression with antidepressants stopped their medication during pregnancy. A prior history of depression, unrelated to pregnancy, is also a strong risk factor, as is having a family history of depression or postpartum depression (O'Hara & Swain, 1996; Beck, 2001). Recent stressful life events and limited social and personal supports increase the risk of PPD (O'Hara & Swain, 1996; Beck, 2001). Moderate risk factors include neurotic maternal personality, low self-esteem, and negative cognitive styles. Weaker risk factors include obstetrical complications, low income, unemployment and financial strain, difficult infant temperament, breastfeeding problems, the discontinuation of breastfeeding, and young maternal age.

It is important to rule out underlying medical issues, such as thyroid disorders and anemia, that may contribute to the woman's presentation. Women who have mild to moderate postpartum depression often benefit from psychotherapy and improved social supports. Two short-term psychotherapies, interpersonal therapy (O'Hara, Stuart, Gromen, & Wenzel, 2000) and cognitive behavioral therapy (Appleby, Warner, Whitton, & Faragher, 1997), have been studied and found to reduce symptom burden, improve social functioning, and increase coping skills. Group therapy and support groups may also be effective components of treatment.

Improving support from a woman's partner, family, and friends is also an important part of treatment. Partners can be essential in nurturing recovery and in providing various forms of support, from understanding and empathy, to instrumental support. Implementing a sleep plan so that a new mother is able to increase her sleeping hours is another important part of a comprehensive treatment plan. Moderate exercise and a healthy diet may also be beneficial. More research needs to be done to determine exactly what types of social supports and psychological and psychosocial interventions are most beneficial for women suffering from PPD. Interventions and strategies need to be accessible to new mothers and sensitive to their time constraints, resources, and child care needs.

Internet and telephone services and therapies are therefore being investigated.

Women who have more severe postpartum depression may also need antidepressant medication. Treatment decisions and management of medication are ideally shared between the patient and her psychiatrist, mental healthcare provider, obstetrician, and pediatrician.

Many antidepressants and other psychotropic medications are compatible with breastfeeding. Treatment providers should seek up-to-date knowledge about medication use during breastfeeding, as all medications enter the breast milk. However, most are found at very low levels and do not harm the baby. For new mothers who are severely ill (acutely suicidal or psychotic) or who do not respond to medications or cannot tolerate medications, a hospital admission may be required, and electroconvulsive therapy (ECT) may be an option.

Estrogen therapy for postpartum depression has been studied but has not been conclusively shown to be effective or safe (Gregoire, Kumar, Everitt, Henderson, & Studd, 1996; Ahokas, Kaukoranta, Wahlbeck, & Aito, 2001). Progesterone supplements have been shown to exacerbate postpartum depression and should be avoided (Lawrie et al., 1998). Bright light therapy has been proposed as a PPD treatment, but more research is required (Corral, Kuan, & Kostaras, 2000). Although women who have a history of severe depression may take longer to treat, the rate of recovery from PPD is high, and women who receive treatment early do particularly well (Wisner et al., 2004).

Once a woman has experienced an episode of postpartum depression, risk of a recurrence following subsequent pregnancies is increased to 50%. Ideally, a woman who is at risk of postpartum depression should meet with her healthcare providers prior to or during pregnancy to discuss ways to manage some risk factors and thereby limit the recurrence of postpartum depression.

Postpartum Psychosis

Postpartum psychosis (PPP) is the rarest and severest of the postpartum psychiatric disorders, occurring in 0.1–0.2% of new mothers. This psychiatric emergency often begins within 2–14 days postpartum. One study showed that 73% of patients had symptoms begin by the third day postpartum (Heron, McGuinness, Blackmore, Craddock, & Jones, 2008). Initial symptoms often mimic a delirium, with marked confusion, bizarre behavior, disorganized thoughts, agitation, and pronounced insomnia. As the psychosis develops, the woman may display prominent mood lability with severe depression or euphoria. The episode may begin to look like a manic psychosis with hallucinations and delusions, often related to the child or motherhood. One study showed that 53% of women with PPP experience persecutory delusions such as beliefs that the police want to apprehend her child (Chandra, Bhargavaraman, Raghunandan, & Shaligram, 2006). She may experience auditory hallucinations "commanding" her to harm her child or herself, thought broadcasting, or delusions of being controlled by external forces. Women who have PPP exhibit poor insight and impaired judgement, thereby posing

a significant risk to their child and themselves. About 4% of women with PPP commit infanticide (Spinelli, 2009).

In the DSM-V (American Psychiatric Association, 2013), postpartum psychosis is listed as a *Brief psychotic disorder* with postpartum onset if it begins within four weeks postpartum, or as an *Other Psychotic disorder*. Current thinking is that the majority of these women meet criteria for *Bipolar disorder* (Sit, Rothschild, & Wisner, 2006).

A personal history of PPP or bipolar disorder confers an increased risk of postpartum psychosis (Stewart, Klompenhouwer, Kendell, & van Hulst, 1991). Women with a history of bipolar disorder or schizoaffective disorder have a 50% risk for another episode of PPP. It appears that postpartum psychosis also clusters in families that have high rates of bipolar disorder and postpartum psychosis (Jones & Craddock, 2001). A diagnosis of schizophrenia or schizoaffective disorder also increases the risk of postpartum psychosis.

There is some research to show that estrogen may influence circadian rhythms and influence sleep loss. Sleep loss, in turn, has been implicated in the onset of postpartum psychosis (Sharma & Mazmanian, 2003). It is believed that rapid hormonal withdrawal after delivery may precipitate PPP, particularly in women with a history of bipolar disorder (Spinelli, 2009).

PPP is a psychiatric emergency and usually requires inpatient hospitalization to stabilize and protect the mother as well as ensure the safety of the baby. Antipsychotic medications, both typicals (e.g., haloperidol) and atypicals (e.g., olanzapine), are frequently used in the acute phase of treatment. Benzodiazepines may also be required to treat insomnia or for additional sedation. Any underlying mood disorder needs to be treated as well. Lithium is commonly used if there is an underlying bipolar disorder. Antidepressants should be avoided, as they may exacerbate the underlying problem. ECT is another treatment option that has been used with great success for severe cases of PPP.

Once treatment is initiated, the recovery rate from PPP is good and relatively rapid. Most women improve within two or three months. Since there seems to be a link between postpartum psychosis and bipolar disorder, between 18–37% of women have a further postpartum psychosis, while 39–81% of women have a non-pregnancy related episode (Chaudron & Pies, 2003). Studies have shown that initiating prophylactic lithium in the third trimester or immediately after delivery reduces the risk of PPP in at-risk women. In contrast, among subjects who discontinued lithium prior to pregnancy, even those who remained stable over the first 40 weeks, postpartum recurrences were 2.9 times more frequent than recurrences in non-pregnant women during weeks 41–64 (70% versus 24%) (Viguera et al., 2000). For women with schizophrenia, 50% remain well after one episode of PPP, 33% have recurrent PPP, and 5% have a refractory illness with numerous puerperal and non-puerperal recurrences (Sit, Rothschild, & Wisner, 2006).

Ensuring adequate sleep near delivery is also helpful in reducing risk (Spinelli, 2009). A four- to five-day postpartum hospital stay to ensure adequate sleep after the baby is born may also be useful in preventing a severe depression or psychotic episode (Steiner, Fairman, Jansen, & Casey, 2002). As

with postpartum depression, early identification of women at risk of PPP, and early, aggressive treatment of PPP symptoms is essential and limits the impact of this serious illness on a mother and her child.

Postpartum Anxiety Disorders

Postpartum anxiety disorders have received limited research attention to date, but they are common. Rates between 4% and 15% have been demonstrated (Heron et al., 2004; Stuart, Couser, Schilder, O'Hara, & Gorman, 1998). It may be that a history of an anxiety disorder confers a higher risk of postpartum depression and anxiety than a history of depression. Women who have had anxiety disorders or even anxiety symptoms in the past or during pregnancy are at high risk of developing postpartum anxiety disorders. The physiological changes postpartum, as well as the intense stress and responsibility inherent in having a baby and being a new mother, are additional precipitants of postpartum anxiety disorders. Anxiety disorders may also develop *de novo* in the postpartum period.

Panic disorder occurs in 1–2% of new mothers in the postpartum period (Ross & McLean, 2006). There may be a recurrence of previous illness or new onset of panic disorder. Symptoms are similar to those in non-postpartum panic disorder. Avoidance of situations due to anticipatory anxiety makes it difficult for a mother to care for her child or to be alone with her child for fear of having a panic attack.

Two to 3% of new mothers experience postpartum obsessive-compulsive disorder (PPOCD). PPOCD is often characterized by intrusive, unwanted, frightening thoughts about harming one's baby, either inadvertently or intentionally. Compulsions are less common in the postpartum population. There is no record of a woman with PPOCD harming her child. Women with a history of OCD, MDD, or premenstrual dysphoric disorder (PMDD) are at risk of developing PPOCD. Thirty percent of women with PPOCD have a new onset in the postpartum period (Ross & McLean, 2006). Situations in which the mother fears she will act on her thoughts are actively avoided. The avoidance behaviors can become problematic if the woman fears she cannot be alone with her baby and refuses to care for her child. Although women with postpartum depression may have similar thoughts and behaviors, in PPOCD the obsessive thoughts and avoidance are more extreme and more intense. Secondary depression may develop due to intense feelings of guilt and self-hatred for experiencing such frightening symptoms. Women with PPOCD have preserved insight and judgement and require reassurance that they are not at risk of actually harming their babies, despite their thoughts. There is a high relapse rate in subsequent pregnancies of PPOCD, and it may take longer to treat than other postpartum anxiety disorders (Sichel, Cohen, Rosenbaum, & Driscoll, 1993).

Postpartum generalized anxiety disorder (PPGAD) is experienced by 4–8% of new mothers (Wenzel et al., 2005; Wenzel, Haugen, Jackson, & Robinson, 2003). Symptoms are similar to those in GAD at other life stages, but the excessive and uncontrollable worries are usually related to motherhood

and the newborn. Few studies have examined PPGAD specifically.

Postpartum PTSD has also been reported. It may follow a traumatic labor and delivery or be triggered by medical interventions during labor and delivery in women who have previously suffered from sexual abuse. Rates between 1% and 6% have been reported (Wijma, Soderquist, & Wijma, 1997; Creedy, Schochet, & Horsfall, 2000).

Postpartum anxiety disorders are treated similarly to anxiety disorders at other stages of the life cycle. Medical disorders, including thyroid dysfunction and anemia, should be ruled out. Antidepressant medications, particularly selective serotonin-reuptake inhibitors (SSRIs), are commonly used to treat anxiety disorders. Benzodiazepines are also commonly used. The same principles described for the use of medication in PPD treatment should be applied. Cognitive behavioral therapy (CBT) is also an evidence-based and effective treatment for most anxiety disorders. Timpano, Abramowitz, Mahaffey, Mitchell, and Schmidt (2011) have found that integrating a CBT-based obsessive-compulsive symptom program into traditional prenatal classes can significantly reduce the occurrence of PPOCD.

IMPACT ON THE FAMILY OF POSTPARTUM MENTAL HEALTH PROBLEMS

Postpartum psychiatric illness affects not only the life and well-being of a new mother, but also that of her partner, family, and of course, her newborn. Research has shown that partners of women with PPD experience high rates of depression. A recent study concluded that 10% of new fathers experience some major or minor depression in the first three to six months postpartum, and that men whose partners were depressed were more likely to become depressed (Paulson & Bazemore, 2010).

Maternal depression in the first year of a child's life has been associated with significant child psychopathology (Bagner, Pettit, Lewinsohn, & Seeley, 2010). Cognitive, behavioral, and social problems have been widely reported in infants and children of depressed new mothers (Grace, Evindar, & Stewart, 2003). When a mother is severely depressed, anxious, or psychotic, the mother-infant dyad is affected. Infants of mothers with psychiatric illness are more likely to have avoidant and disorganized attachment, which can have long-lasting effects on the child (Martins & Gaffan, 2000).

Most research in this area has examined the impact of severe, prolonged postpartum disorders and does not account for less severe and treated postpartum illnesses. It is important not to use the impact statistics to increase fear and guilt in mothers who are suffering. Several studies have demonstrated that early identification and treatment of a mother's mental illness has a very positive effect on the child and may prevent or reverse some or all of the above-mentioned ill effects (Birmaher, 2011). By providing evidence, reassurance, and hope that early and effective treatment leads to positive outcomes for a woman and her child, clinicians can motivate and support patients suffering with postpartum psychiatric illnesses.

CLINICAL PEARLS

- Hyperemesis gravidarum has been labeled as a sign of hysteria, neurosis, depression, stress, or marital conflict; however, there is no evidence that this is true.
- Up to 25% of new mothers who have the baby blues later develop postpartum depression (O'Hara & Swain, 1996).
- Postpartum depression can begin any time within the first 12 months postpartum.
- Forty to 57% of women with postpartum depression may also have some ego-dystonic, intrusive thoughts about harming their baby.
- The most significant risk factor for postpartum depression is having a history of depression or anxiety during pregnancy.
- Postpartum, it is important to rule out underlying medical issues such as thyroid disorders and anemia.
- Anxiety disorders may develop *de novo* in the postpartum period.
- A history of anxiety disorder may confer a higher risk of postpartum depression and anxiety than a risk of depression.
- There is a link between postpartum psychosis and bipolar disorder.
- Women with postpartum OCD have preserved insight and judgement and require reassurance that they are not at risk of actually harming their babies, despite their thoughts.
- Most psychotropic medication is safe for use during pregnancy and postpartum.

PART VIII

SURGICAL SPECIALTIES

GENERAL SURGERY

BASIC PRINCIPLES

*Frederick J. Stoddard, Jr., Robert L. Sheridan, Jeevendra Martyn, Lawrence F. Selter, and
Donna B. Greenberg*

INTRODUCTION

Innovations in surgery and anesthesia have increased the power of the surgeon to save lives, limbs, and organs. Innovations in psychiatry have enhanced the capacity of the surgical team to reduce suffering and improve outcomes. These innovations affect routine care in hospitals and urgent care for patients and their families after disasters (Stoddard, Katz, & Merlino, 2010; Stoddard et al., 2010; Stoddard, Pandya, & Katz, 2011). To ask for and consent to surgery and anesthesia requires that the patient have enormous trust or desperation, or both. Surgical patients come from varied cultural, racial, and language backgrounds and require culturally sensitive care in a language that they and their families understand. Also, surgical patients vary from being very disadvantaged to very advantaged, and recognition of differing needs for those from backgrounds of poverty or wealth is critical. How patients pay for their expensive surgical care may add significant burdens.

The patient's expectations of the surgeon may vary from realistic to delusional. Patient desire for information about their disease, management options, and recommendations also varies enormously. The surgeon may be respected, idealized as a savior, feared, or demonized by patients and their families for failing to fulfill expectations. The patients who are more likely to have difficulties in the relationship with the surgeon are those with difficulties in previous relationships (i.e., personality disorders or those with traits of these disorders). Their style of relating to authority and pattern of establishing appropriate boundaries affect the relationship to the surgical and anesthesia staff. Psychiatrists can help clarify the patient's distortions as well as respond with empathy to the patient's anger and disappointment if their expectations are not fulfilled. Psychiatrists may also help the surgeons and the surgical and anesthesia staff set appropriate limits on "acting out" by patients, and other types of inappropriate behavior.

PSYCHIATRIC CONSULTATION TO SURGICAL PATIENTS

The surgeon moves rapidly to diagnose surgical conditions and perform operative procedures, using sophisticated tools

in the process. The anesthesiologist also works rapidly with the surgeon to assure optimal management of anesthesia before, during, and after procedures. Working in the surgical setting, the psychiatric consultant must match this pace with efficient diagnostic assessment and treatment. The role of psychiatric consultation in surgical care acknowledges the importance of treating comorbid psychiatric diagnoses to improve surgical outcomes and enhance patient care (Moore et al., 2013; Findley, Sanders, & Groves, 2003; Abrams et al., 2010). The medical psychiatrist will be alert to the history of alcohol or other substance use, the risk of acute withdrawal, and the ways the burden of addiction will complicate post-surgical care. Psychiatrists are often called upon to diagnose and treat delirium, and they support principles that prevent delirium in surgical patients (Ely et al., 2004; Lat et al., 2009). For patients with schizophrenia psychiatrists bring their ability to titrate anti-psychotic treatment through the hospitalization, to communicate with a patient in spite of delusions and concrete thinking and to better understand opposition to care (Irwin et al., 2014). Furthermore, they may be charged with identification of the rare patients with factitious disorder, who amplify symptoms and seek surgery as a way of life.

BODY IMAGE

Body image is a major psychological dimension often affected by surgery. Schilder (1950) described body image as the intra-psychic picture or schema of our own body, including interpersonal, environmental, and temporal factors. Shontz (1974) expanded the concept of body image to include the sensory, motor, and expressive functions that the body serves, as well as the experience of the "self" and the developmental levels at which the self operates, beginning as early as *in utero*. Different meanings are invested in different organ systems, either personally or by social convention; for example, the brain with wit, emotion, and self; the face with beauty and character; sexual organs with reproductive capacity and sexual identity; muscle and bone structure with dexterity, grace, power, and skill. For women in Western industrialized cultures, the breasts may have come to represent femininity, a measure of attractiveness, and even personal worth.

Pain and disfigurement to any body part are long remembered and can have lasting effects on the patient's body image and self-esteem (Freud, 1952). Fear of "shots" or injections and fear of surgery, often stemming from prior experiences, are common in both children and adults. Visible disfigurement to the face is particularly traumatic (Warner et al., 2012; MacGregor, 1990; Berscheid & Gangestad, 1982), as is trauma to the head, scalp, and hands. In addition, breast and genital injury or disfigurement affect sexual dimensions of the body image.

Individuals' assessment of their own physical integrity or beauty is independent of the actual physical presentation of their body. A person may appear conventionally beautiful but subjectively perceive and experience the body as ugly, and vice versa. Young children suffering from a congenital disorder, disease, disfiguring injury, or undergoing an amputation, can incorporate the disfigurement into their body image, whereas older children or adults must grieve the loss of their previously acquired body image and attempt to adapt to scarring or functional loss (Stoddard, 2002). Severe distortions of body image occur in patients with anorexia nervosa or body dysmorphic disorder.

Occasionally patients will refuse life-saving mastectomy or amputation because they have such an aversion to the idea of physical deformity. For most patients these losses are emotionally challenging, but adjustment can and does occur. Patients can be characterized by how invested they are in their own appearance on one dimension and by how much they perceive a discrepancy between their own body image and what they desire, on another dimension. In the surgical setting, these concerns can be thought of on a normal continuum (Fingeret et al., 2014).

THE NEED TO DEVELOP THE RELATIONSHIP WITH THE PATIENT

Although the time for psychiatrists to fully assess clinical situations is often limited in surgical settings, the major diagnostic strategy at their disposal is the human relationship that can be established with the patient and family. Clarification of the psychological component of the case and complex and potential issues of secondary gain depend on obtaining as thorough a past history as possible, the mental status examination, and evaluation of the patient's personality traits and coping strategies under stress. Rapid, complex modern surgical treatment and the time needed for electronic medical record-keeping and procedure coding for reimbursement may inhibit the gathering of records as completely as in the past and limit the time allowed to establish trust with patient and family. Psychiatrists' abilities to discuss the case with the attending surgeon, communicate succinctly to the surgeon what they know, what they do not know, and how they would proceed are critical to arriving at a definitive diagnosis and treatment plan.

The nature of contracts for mental health care in the United States can constrict the relationship between psychiatric and surgical care. Policies for mental health coverage are usually established without the medically ill in mind. The insurer may limit where and by whom services can be performed. Social workers are included in the mental health

networks, usually in much greater numbers than psychiatrists. Psychiatrists are thereby distanced from the medically ill, and surgeons can have difficulty referring patients to psychiatrists for evaluation and treatment.

In some settings, psychiatric services cannot be performed at the same location as the surgical procedure or consultation. As day surgery increases and the duration of hospital stays shortens, preoperative evaluations and postoperative psychiatric evaluations cannot occur as easily in the hospital. Preoperative psychiatric evaluation must be planned in advance for patients vulnerable to psychiatric illness, and postoperative evaluation of cognitive impairment, for instance, may suddenly fall as an unexpected burden on the family at home because the diagnosis was missed due to pressure to discharge the patient rapidly. Inadequate pre- and post-operative attention to mental status assessment can delay recovery and increase the likelihood of complications. Rapid personal telephone or telemedicine contact with psychiatrists and surgeons (remote video, Skype or iPhone) is a potential substitute for on-site preoperative psychiatric triage and screening, as has been done in the Navy aboard ships far from land for years. Education of surgeons and their staffs greatly assists such a screening and triage process.

THE CONSULTATIVE REQUEST

The request for a psychiatric consultation usually occurs in three circumstances: (1) the presence of acute psychiatric symptoms (depression, psychosis, delirium, suicidal risk); (2) family or nursing staff requesting help; and (3) diagnostic dilemmas—for instance, whether a symptom is "functional" or "organic." In some surgical settings, psychiatric consultation occurs routinely, such as in transplantation (see Chapter 74); and in others quite rarely, such as ophthalmology and urology. It may occur pre-, peri- or post-operatively.

Psychiatric consultation is necessary when:

1. The surgeon recognizes that jointly talking with a patient and a psychiatrist is likely to improve the patient's psychological preparation for the postoperative requirements and effects of surgery.
2. Previously known psychiatric conditions can potentially complicate surgery or recovery. For instance, panic disorder, severe anticipatory anxiety, or alcoholism may prevent the patient from following through with a series of surgical treatments, but a proactive behavioral management plan or psychotropic drug regimen may make the surgical plan much easier to accomplish and result in a better outcome.
3. The stability of the patient's psychiatric condition can be jeopardized by the stress of surgery. For instance, a patient with bipolar disorder on lithium will be likely to experience changes in hydration associated with surgery, risking lithium toxicity, or a relapse if the medication is abruptly discontinued.

4. The patient or family requests special attention to the psychological state or needs of the patient.
5. The patient does not understand the surgery to be performed in order to give informed consent—due to age as with an adolescent, to cognitive impairment, or to other factors.
6. The patient is very fearful and refuses to consent to emergency surgery or surgery essential to the patient's well-being.
7. The patient is very anxious or ambivalent about surgery due to prior complications of anesthesia such as respiratory arrest or awareness under anesthesia.
8. The surgeon recognizes psychological issues or potential problems in the patient–doctor relationship or when nurses report difficulties in behavior that complicate nursing care (such as with borderline personality or antisocial patients).
9. The patient's experience of pain or other symptoms brings about excessive requests for analgesia, or the pain behavior of the patient raises questions about the psychological suffering, depression, addiction, or interpersonal conflicts of the patient.
10. There is concern about patient or staff safety.
11. The patient is regressed, confused, agitated, suicidal, or mentally deteriorating.
12. The use of maintenance psychotropic drugs may potentially complicate surgery because of side-effects or drug interactions (e.g., monoamine oxidase [MAO] inhibitors limiting narcotic options, or concerns about QT prolongation with certain agents).
13. The use of medications for surgical care may complicate psychiatric care.
14. The patient has a known or suspected history of alcohol or other type of chemical dependency or abuse.
15. Religious, cultural, or family conflicts exist that may complicate normal surgical and recovery techniques (e.g., the use of blood products that is prohibited by some religious sects).
16. End-of-life issues may benefit from a psychiatric perspective.

This is only a partial list of reasons for psychiatric consultation to surgical patients.

Communication between the surgeon requesting the consultation and the psychiatrist is key, but often fraught with difficulty. The psychiatric evaluation frequently depends on information in the chart, from the family, and the nursing staff, and not directly from the surgeon. It is sometimes necessary, when it is urgent to discuss a case, to even scrub in and talk with the surgeon in the operating room. If at all possible, one may also regularly attend surgical morning work rounds and surgical case conferences.

In those settings, the psychiatrist may gain important practical knowledge about the details of what surgery and its sequelae entail for patients and their families, explain to the clinical staff the findings from psychiatric diagnosis and treatment, and contribute to planning ongoing care, including disposition planning. This psychiatric participation in rounds and meetings demonstrates the psychiatrist's willingness to learn about the complexities of surgical treatment from the team, which then helps the psychiatrist better help the patient and educates the surgical team about psychiatric aspects of surgical care.

PSYCHIATRIC ASSESSMENT OF THE SURGICAL PATIENT

All patients with preexisting severe psychopathology, substance abuse, or who for some reason are at psychiatric risk should have psychiatric assessment prior to admission for elective surgery. This is more likely to be feasible in settings with established and well-staffed psychiatric consultation services. When psychiatric assessment and any needed treatment do not occur before elective surgery, surgical and psychiatric complications are more likely to occur postoperatively. Patients with old and recent brain injuries are more likely to have delirium or cognitive impairment after anesthesia. The psychiatrist must understand the medical rationale, the predicted surgical outcome, and, optimally, know the patient preoperatively. Psychiatric syndromes that can be treated should be defined, and personality traits that will interfere with recovery and coping assessed and a management plan prepared in advance. An ideal standard psychiatric assessment of the surgical patient would include the following elements at a minimum:

- Review of the reason for psychiatric referral at this point in time
- Accurate understanding, with explanation from the surgeon, of the surgical issues (proposed or completed), details of the surgical procedure(s), and prognosis
- Review of the chart and laboratory/radiographic examinations
- History of present illness, including its impact on the patient and family at this stage of the patient's life cycle. This is supplemented with history from family, past medical records, other mental health professionals, or friends when necessary
- Psychiatric history, including substance use, domestic violence, and previous or current treatment, especially any active use of psychotropic medications
- Complete medical/surgical history, especially current and prior medications and *evidence of or the possibility of*, withdrawal from medications, illicit drugs, or alcohol
- Social history, including language and ethnic background, religious beliefs, advance directives, legal issues

- Family psychiatric history
- Mental status examination
- Succinct case summary/formulation
- Problems, diagnoses
- Practical treatment recommendations—thoughtful, responsive to specific questions, clear goals and parameters to monitor
- Follow-up report post-surgery and discussion with the surgeon; mutual agreement on length of post-surgical follow-up care and psychiatric disposition

The basic mental status examination of the surgical patient should include:

- Attempting to establish a positive therapeutic relationship by expressing interest in the patient and family, using developmentally appropriate communication in language understood by the patient and family
- Observing the patient's appearance, including surgical dressings; medical apparatus; behavior, with particular focus on signs of pain, depression, anxiety, impulsivity, delirium, or dementia
- Asking if the patient understands the reason for referral and their surgical status
- Evaluating risk to self or others
- Observing speech and language
- Assessing cognitive function
- Assessing psychotic thinking and hallucinations
- Assessing mood symptoms, such as anger, sadness, anxiety or panic, depression or mania
- Alcohol and drug history; likelihood of post-surgical withdrawal
- Evaluating judgement and decision-making capacity

The psychiatric diagnoses should focus on the problem, diagnosis, or diagnoses most relevant to the referral; for example, adjustment disorder, delirium, post-traumatic stress disorder (PTSD), bereavement, major depression, acute pain syndrome, or substance abuse. Identify both comorbid psychiatric and medical diagnoses.

The treatment plan should respond to the referral question briefly, clearly, and most of all, practically. The psychiatrist's note should summarize the case without psychiatric jargon, with the goal of assisting the patient's surgical progress and recovery from surgery. It seeks to explain symptoms in common-sense language, integrating both the medical/surgical status and the psychobiological status of the patient. Psychiatric treatment plans for surgical patients are usually short-term, aimed at stabilizing the patient and relieving symptoms. They are problem-oriented and outline definite and clearly defined plans for close follow-up by a psychiatrist

who is available to the patient geographically and accessible financially.

THE DEVELOPMENTAL PERSPECTIVE

A classic model of the psychological stages of the life cycle was introduced by Erik Erikson (1980) to describe the phases of human development from birth to death. It is helpful in making sense of patients' responses to surgery. Emotional meanings, personal temperament, and cognitive skills for coping differ widely across the life cycle. For example, surgical care for children should integrate an understanding of normal developmental aspects of early childhood such as maternal–infant attachment and separation, temperament, cognitive and motor development, play, and responsiveness to transitional objects. Transient regressive behavior, in response to surgery, to emotional states typical of earlier stages of development may occur at any developmental stage, including adulthood, and is especially common in children and adolescents. Recovery to the previous level of functioning occurs rapidly with postoperative recovery. Most surgeons caring for children benefit from child psychiatric consultation (Kurtz, Muriel, & Abrams, 2010). Issues of pain and risk of medical traumatization are essential considerations in the surgical care of children.

INFANCY AND TODDLERHOOD

Infants and toddlers are vulnerable to overwhelming fears when subjected to “shots,” restraint, or intubation, or the threat of abandonment, especially when mothers are not nearby. Since many infants and toddlers are nonverbal, their emotional needs are often ignored and left largely to the parents or nurses. While this may be appropriate for those who do well, infants requiring surgery may have significant post-traumatic or depressive reactions that could have a lasting impact on personality development. At a minimum, psychiatric consultation is indicated for infants who suffer intractable pain, attachment or developmental disorders, hyperactivity, depression, PTSD, and anxiety. Even without such diagnoses, most children undergoing surgery and their families benefit from collaborative psychiatric care with the surgeon.

Close contact with a mother or surrogate is central to the development of a sense of safety (Zeanah, 2000), which has a neural basis in the amygdala and dorsal striatum (Rogan et al., 2006). Winnicott (1965) suggested that the mother metaphorically creates a “holding environment” that allows the child to develop a sense of self. He also introduced the concept of the “transitional object,” which allows the infant to tolerate separations from the mother without undue anxiety (Winnicott, 1951). A treasured blanket, toy, book, or song may take that role in the hospital. Nurturing holding by staff who do not have pain-inducing responsibilities and who serve as maternal surrogates reduces pain, distress, and protest in the sick infant, particularly in those whose mother is absent. Chapters 17 and 18 discuss object-relations theory as it relates to the stresses and fears of medical-surgical illness and the role of spiritual

and religious factors in sustaining attachment. In the United States prior to the mid-1980s, parental visitation in intensive care units was very limited. Their right to be present continuously, as they are now, occurred through parental advocacy leading to laws requiring hospitals to comply.

CHILDHOOD

Preschool and school-age children generally have sufficient language skills for use in preoperative preparation. Children master elimination; use age-appropriate play as an expressive modality to enhance coping; and rapidly progress through phases of emotional, interpersonal, cognitive, and motor development to better cope with pain and stress. Formation of their core body image should be complete, but the child is vulnerable to bodily threats or loss, and any bodily injury or probe is long remembered. When overwhelmed, the vulnerable child dramatically regresses, with loss (usually transient) of recently acquired developmental skills; for example, speech or urinary continence. The sensory holding interventions by the staff remain essential, but now can also include verbal communication for these older children. Choices about surgery and other aspects of medical care should involve children as young as six or seven. Children with physical, emotional, or cognitive disabilities, or chronic illness should have formal child psychiatric interventions well in advance of elective surgery. Even those admitted for minor surgical procedures are often much more vulnerable than they might appear. While some literature suggests that adverse psychological effects of general anesthesia, surgery, and hospitalization for injuries and other conditions are transient and reversible (Caldas et al., 2004), others point to risks of persistent post-traumatic and other developmental sequelae (Saxe et al., 2005; Stoddard et al., 2006; Stuber, 2011).

ADOLESCENCE

Early adolescents act more like children, despite their often awkward attempts at seeming more mature; they benefit from the involvement of parents, parent surrogates, or friends. Familiar activities, objects, or people allow regressed adolescents to tolerate surgery, loneliness, and suffering. Consistent nursing care, regular visits by family or friends, and familiar photos, clothing, or favorite music nearby can help as well. Adolescents may be quite irritable or moody, and often fear the violation of their personal privacy and “space.” They may become easily self-conscious or embarrassed, and inhibited or guilty about expressing feelings.

Mid-adolescents in the process of puberty vary in their cognitive and emotional states, levels of understanding, and capacities for self-management. They tend to be more adult-like in their understanding and behavior but are given to emotional regression under stress, which makes them seem “in between” childhood and adulthood. Surgical care should consider their new pride and appreciate their independence, attractiveness, and physical prowess. They require clear direction and sometimes limit-setting of anxious, sexual, and aggressive feelings, coupled with appropriate psychotherapeutic interventions.

Late adolescents are often less competent and mature than they appear. They are in the process of separating from their families, and the associated fears, sadness, guilt, and rebellion may be either quite open, hidden, or not yet occurring. Surgery can even represent a useful experience in the adolescent’s growth and maturation toward autonomy. In most states, after age 16, adolescents must consent to surgery along with their parents.

YOUNG ADULTHOOD

Young adulthood extends through major psychological decisions and tasks such as completing one’s education, choosing an occupation, consolidating sexual identity, marrying or remaining single, childbearing, raising a family, and working toward occupational and economic security. Like the adolescent, young adults may feel very vulnerable in the surgical setting, since the need for surgery challenges feelings of invulnerability. Psychiatrists will take note of prior developmental strengths and vulnerabilities as they talk about surgery. Conflicted needs for dependency will coexist with their own independent adult responsibilities to education, work, or family.

MIDLIFE

Midlife is, ideally, a time when achievements are consolidated and a time when some individuals make changes in work, intimate relationships, or even their own bodies in order to fulfill unmet yearnings. Feelings of virility and femininity, competence and incompetence, are loaded with meaning at this time. Surgery and disease may be a threat to the adult’s livelihood, family roles, and recreation. They may try to deny or postpone the emerging realities of aging. Adjustment to surgery should incorporate the patient’s relationships with family and loved ones, the central place of work, and the available skills for self-care.

LATE ADULTHOOD

By this period of life, the patient has experienced most of life and may or may not have adapted well to achievements and the inevitable disappointments they have encountered along the way. For some, with full faculties and highly developed skills intact, it is a time of new creativity and contributions to family or to society, made possible by retirement from the tasks of parenting or their occupation. For many, adapting to reduced physical or mental vigor, injury, or multiple diseases, multiple medications, and infirmity, increasingly becomes the task, together with coping with the deaths of spouses or loved ones and friends. It can be a period of savoring the young and one’s own past while determining what to leave behind for others. Talking with patients about these aspects of late life can be helpful, especially when the physician demonstrates awareness of patients’ fear of pain or other complications of illness, of dying in the hospital, and of specific aspects of care at the end of life.

Family characteristics have a strong impact on the quality and trajectory of recovery from physical trauma (Sheridan et al., 2012). When confronting the prospect of surgery for a family member, families, like individuals, represent a spectrum from resilient to vulnerable. The absence of support from family or friends usually will affect surgical evaluation, the course of treatment, and long-term outcome. The parents', siblings', family's, or friends' feelings of fear, anger, relief, suffering, or grief often mirror that of the patient. Today's typical family is no longer a couple and their children (it is the exception rather than the rule). Rather, those who support the patient are as likely to be a single mother, an extended family, a social worker, an elderly parent, a "significant other," a gay partner, a group of friends, church members, or family of distant relatives. It can be a challenge for the surgical staff to obtain operative consents and also to manage patients' complications or death when family involvement is marginal or ambiguous. Even as individuals develop through the life cycle, the family's tasks and functions evolve in overlapping stages from the task of infant and child care, to coping with the behavior of adolescents, to "letting go" of young adults as they mature, to partnering and family building, to midlife adjustments and preparing to approach death. It is worth considering with a patient who is planning for surgery who is most trusted, how the family will be able to function, and what strategies would be helpful to sustain this support.

PREEXISTING PSYCHIATRIC RISK FACTORS FOR SURGICAL COMPLICATIONS

Preexisting psychiatric disorders increase the risks associated with surgery and postoperative care, and the prevalence of preexisting disorders may include up to half of all surgical patients, many with disorders of substance dependency or abuse (Powers & Santana, 2010).

MOOD DISORDERS

Mood disorders may affect an individual's clinical presentation, response to surgical treatment, and outcome. If the patient's mood disorder is stable on an antidepressant, then attention should be paid to the continuation of the drug during the surgical hospitalization and recovery. If the period of no oral intake will be prolonged, an SSRI with a long half-life (two weeks) like fluoxetine replacing one with a shorter half-life like citalopram might be used to advantage. Prophylactic antidepressants have been used when the likelihood of treatment-associated depression is high. In patients undergoing treatment for head and neck cancer who are not depressed, the likelihood of their developing depression is greater than 50 percent. In a randomized controlled study, prophylactic escitalopram reduced the risk of developing depression by more than 50%, and treated patients had a better quality of life over the following 3 months of multi-modal treatments (Lydiatt et al., 2013).

All patients, children and adults, experience some degree of anxiety prior to surgery, but anxiety may be worse for those with preexisting anxiety disorders. For someone who has experienced a prior trauma, the prospect of surgery may elicit the re-experiencing of a previous trauma, with a dramatic increase in anxiety, including panic; some patients may shut down emotionally, with avoidance or numbing symptoms that may provide false reassurance to staff that the patient is resilient and doing well. Anxiety disorders are frequently associated with somatic complaints such as headaches, cardiac and respiratory symptoms, and, most commonly, gastrointestinal symptoms. The treatment of an anxiety disorder can include mobilization of social supports, cognitive behavior therapy, hypnosis, relaxation techniques, and psychopharmacological agents. For severe preoperative anxiety, unrelieved by psychological interventions, reassurance that anxiolytics such as benzodiazepines will be given prior to surgery may effectively relieve it. A few patients who have had prior surgery and are very anxious may be aware that they experienced an adverse event in previous surgery (e.g., respiratory arrest) and require psychotherapy before proceeding with elective surgery.

BODY DYSMORPHIC DISORDER

Body dysmorphic disorder (BDD) is a preoccupation with an imagined or slight deformity of the body associated with significant impairment. It overlaps with obsessive-compulsive disorder and anxiety disorders. Patients with BDD have a distorted body image and may be preoccupied with reexamining, improving or hiding the defect. They may avoid mirrors and social activities. At the extreme, they may be delusional, suicidal, and present with self-injury. They generally present to maxillofacial, cosmetic surgeons, and cosmetic dermatologists. These patients are aesthetically very sensitive, and the practical question is whether they will be satisfied with the procedure sought. Those who have more psychopathology tend to have more dissatisfaction. Some questions for assessment include queries about how ugly the patient feels, how much work or social disability results from the deformity, how much checking is done, how noticeable the feature is to other people, and whether family or friends discouraged the cosmetic procedure (Veale, 2004). A screening instrument for a cosmetic clinic has been developed (Veale et al., 2012). Psychiatric treatment included high doses of SSRIs for 12–16 weeks and cognitive behavioral treatment. (Veale, 2004a; Veale, 2004b; Phillips & Hollander, 2007; Wilhelm et al., 2014).

SOMATIC SYMPTOM DISORDERS

The psychiatrist should be alert to patients with a history of somatic symptom disorders who may amplify or be overly focused on somatic symptoms. The psychological component of the symptoms may color surgical decision making, moving surgeons to action on the one hand; or on the other hand, the

history of the patient “crying wolf” may bias surgical judgment such that new symptoms are not taken seriously.

FACTITIOUS DISORDER

Surgery is also extremely risky for those with factitious disorders or factitious disorder by proxy (Masterson, 1995; Acarturk et al., 2014; Burton et al., 2014), where the symptoms are intentionally produced or feigned in order to assume the sick role. In some difficult cases, surgical treatment is unavoidable but must be carefully focused to limit manipulation and contain regressive behavior.

ATTENTION DEFICIT DISORDER

Attention-deficit hyperactivity disorder (ADHD) is the most common disorder for which children and young adults are referred to mental health professionals. A patient, adult or child, with ADHD may not retain information and may have a harder time tolerating holding still. If surgery is performed, a child with ADHD may play with the intravenous apparatus, bandages, and have difficulty tolerating postoperative procedures. The pharmacological treatment of ADHD includes, stimulants, tricyclic antidepressants (TCAs), clonidine, and bupropion. While discontinuation of medications for ADHD may often be judicious preoperatively, pediatric anesthesiologists can usually adjust their treatment perioperatively. Hyperactive children are sometimes at risk of disrupting postoperative wound care. Methylphenidate or dextroamphetamine have the benefit of enhancing the analgesic effect of opiates. Side-effects such as inhibition of appetite with stimulants, or cardiovascular effects of TCAs should be considered (Wilens & Spencer, 2010). (See Chapter 50 on ADHD.)

ALCOHOL AND DRUG ABUSE

Prior to elective surgery, the history or physical or laboratory signs of substance abuse should be sought. Urine and serum toxic screening may be critical in identifying the degree of substance abuse, prescribed medications, and likelihood of overdose or withdrawal. Since substance abuse is a factor so many acute-trauma surgical admissions, screening is essential. However in a national survey of Level 1 trauma centers, only 39% of admissions had screening questions for alcohol abuse, and only 25% received a brief intervention (Terrell et al., 2008). Most children and adolescents have not yet developed the long-term medical complications of drug or alcohol addiction seen in adults, but they can be addicted to alcohol or drugs and must carefully be assessed, just as adults should be. Since denial is part of the disease of chemical dependency, the examiner should be appropriately skeptical and critical of both the patient and family during this part of the assessment. (See also Chapter 38.)

SCHIZOPHRENIA

Clarification of the diagnosis of chronic psychotic disorder offers an opportunity to identify who the patient trusts, who

the regular psychiatrist is, the nature of maintenance medications, whether preoperative medications offer the best possible mental status, and to build an interdisciplinary support team. Often the fracture between the mental health system and the medical hospital make this particularly important. The medical psychiatrist offers the ability to communicate directly with the patient taking cognitive deficits and concrete thinking into consideration. Not all morbidity may be related to schizophrenia, and the often comorbid conditions of depression and substance abuse must be elucidated (Irwin et al., 2014).

BORDERLINE PERSONALITY DISORDER

Patients with borderline personality disorder come to surgical attention when they are treated for self-mutilation: burning, skin-picking or cutting. Compared to patients with body dysmorphic disorder, they seek plastic surgery for different parts of the body rather than focusing on one part (Napoleon, 1993; Morioka & Ohkubo, 2014). The psychiatrist's diagnosis alerts the surgeon to a higher risk of complications and to the more difficult doctor-patient relationship. Because of the patients' unstable relationships, tendency to see others as all good or all bad, and their sensitivity to abandonment, surgeons are more likely to be seduced into operating against their better judgment to rescue patients from their anguish, more likely to be idealized and more apt to disappoint. Firm professional boundaries and sound surgical judgment become all the more important when these patients need surgery. The psychiatric consultant can help to clarify the patient's past history, unrealistic expectations and to support more caution in high-risk procedures.

If acute PTSD, current major depression, suicidal ideation, psychosis, or active substance dependency or abuse is diagnosed, elective surgical care may need to be postponed, unless there is an emergency. Following emergency surgery, patients with these disorders require continuous psychiatric monitoring, evaluation, and treatment to prevent or reduce the risk of surgical and psychiatric complications, including suicide.

PSYCHOPHARMACOLOGY FOR SURGICAL PATIENTS: BASIC PRINCIPLES

The anesthesiologist and surgeon must be informed of all psychotropic medications that the patient has been or is taking. Drug treatment in adults and children (Lorberg & Prince et al., 2010; Stevens et al., 2010) is based on assessment and monitoring of target symptoms of diagnosed psychiatric conditions.

Many patients are already using psychotropic medications at the time of surgery. Although most psychiatric medications are safe during and after surgery, monoamine oxidase inhibitors (MAOIs), lithium carbonate, TCAs, clozapine, and other drugs may pose special problems (Huyse et al., 2006).

For patients on clozapine having surgery, attention should be paid to bowel function. Clozapine is associated with

colonic hypomotility, constipation, and rarely ischemic colitis or toxic megacolon. As patients receiving narcotics are often put on regimens that prevent constipation, so should patients who are receiving clozapine. Factors that raise the level of clozapine like higher doses, fever, drugs that inhibit cytochrome P-450, or other drugs that make constipation worse like opiates and anticholinergic medications can cause additional risk (Alam et al., 2009). If the patient smoked outside the hospital, inducing CYP 1A2 by a carbon-based mechanism, levels of clozapine may rise when the patient is placed on nicotine or abstinence in the hospital. Similarly if smoking begins again after hospitalization, clozapine levels may fall compared to the levels that maintained the patient in the hospital (Lowe & Ackman, 2010). Measured clozapine levels may be helpful over a long hospital course.

Lithium must also be followed with levels as higher plasma levels are associated with toxicity, and older patients are more sensitive to higher levels. In the setting of illness and surgery, dehydration and renal dysfunction risk toxicity. Nonsteroidal anti-inflammatory drugs and thiazides should be avoided. In the setting of urgent surgery, the regular dose of lithium can be held. However, the course of bipolar illness is favored by gradual and not sudden disruptions in lithium treatment, so the importance of restarting lithium postoperatively should be considered postoperatively in patients whose bipolar disorder is responsive to lithium (Baldessarini et al., 1996).

Irreversible MAOIs and the reversible MAOI meclizemide present the risk of hypertensive crisis with certain perioperative drugs: meperidine, dextromethorphan, and epinephrine, but fentanyl and morphine can be used. Irreversible MAOIs like phenelzine and tranylcypromine should be stopped for 2 weeks before a planned surgery if possible (Huyse et al., 2006).

TCAs like imipramine, amitriptyline, and nortriptyline tend to prolong the QT interval and to be associated with anticholinergic and alpha-adrenergic blockade.

Particular attention should be given to drugs that must be restarted after surgery to prevent withdrawal. Abrupt withdrawal from chronic benzodiazepines has caused seizures or delirium in surgical patients. Since patients may be temporarily unable to take oral medicines, options like parenteral or sublingual lorazepam should be considered. Antidepressants and mood stabilizers might be briefly held during the time the patient cannot take medications orally, without appreciable loss of therapeutic effect. Short-acting antidepressants like paroxetine or venlafaxine are associated with a withdrawal syndrome of malaise and paresthesias, which is not life-threatening.

Comorbid medical disorders, hepatic or renal impairment, and brain injury must be considered. Dosing for children is usually adjusted on a milligram/kilogram basis. While neonates metabolize slowly, children metabolize most drugs more rapidly, leading them to usually require higher dosing for equivalent therapeutic effects, depending on their medical status (Stoddard, Usher, & Abrams, 2006). In the elderly, due to reduced rates of metabolism and excretion, lower dosing is often indicated for an equivalent effect. Metabolic rates may be increased in a variety of conditions (e.g., burns), or decreased (e.g., liver disease), requiring adjustments in dosing.

Drugs that were stopped preoperatively should be considered in evaluation of drug interactions (DeVane, 2010). Drugs with a long half-life like fluoxetine or diazepam may interact with drugs started in the hospital, even if they are not continued. Children may develop a paradoxical disinhibition in response to a benzodiazepine. High plasma levels of sedatives may cause unexpected over-sedation, and respiratory or cardiac arrest.

Ongoing monitoring of medications and behavioral target symptoms, cognition, and mood is essential because multiple doctors, nurse practitioners, and physician's assistants often prescribe to the same complex patient and because psychiatric medications may not be taken as seriously as other medications. Often staff who have known the patient only one shift make decisions about psychological symptoms, as well as rapid "ad hoc" decisions about medications (PRN, "as needed") for anxiety, sleep, or pain. The consultant will put into context how long and how consistently an antidepressant has been taken at a specific dose in order to judge the likelihood of its efficacy and will take note of pharmacokinetics, whether an analgesic or anti-anxiety medication has been prescribed long enough to reach steady state.

There is increased surgical attention to reducing the dosages of opiates and benzodiazepines as early as is feasible in order to reduce pulmonary risks and withdrawal and improve outcomes. In order to facilitate this, medications such as methadone and dexmedetomidine (Maldonado et al., 2009) are prescribed more commonly to facilitate weaning from high-dose opiates and anxiolytics.

If a patient does not benefit from the prescribed psychotropic medication, the psychiatric diagnosis, cause of the symptoms, and dosage must be reevaluated. It is helpful for the psychiatric consultant to state in the chart the number of days the patient has been taking an antidepressant at a specific dose so that response to the medication will not be evaluated prematurely. An antipsychotic that was started for delirium in the hospital may be misunderstood to be a post-operative maintenance medication and therefore, continued inappropriately at home. The benefits and risks of discontinuation of psychotropic medications should be weighed carefully.

PSYCHOLOGICAL PREPARATION FOR SURGERY

Every person facing surgery will experience anxiety. The anxiety may be a result of fear of the surgery itself, fear of pain, fear of possible diagnoses, or a general fear of loss of control. Patients may be afraid of not waking up from the anesthesia or afraid of lethal complications following surgery. For patients with a history of an anxiety disorder or of prior trauma, the prospect of surgery may intensify preoperative symptoms. Children and the elderly may have difficulty expressing their anxiety. Unspoken fears and fantasies often intensify anxiety. To reduce preoperative anxiety, it is important to provide as much information as seems appropriate, to allow patients to ask questions, and to express their fears, and possibly to meet others who have experienced the same disease and treatment.

Speaking to children in language geared to their developmental stage and cultural background is key. Children respond positively to reassurance that pain will be relieved with medication, and older children and adolescents may benefit from patient-controlled analgesia (PCA). Preparing children with burns for dressing changes and giving them the sense that they have some degree of control reduces protestations, pain, anxiety and fosters cooperation (Kavanaugh et al., 1991).

Communication opens, for good or ill, with the first contact with the surgeon. Nevertheless, studies indicate that most health care professionals talk to the parents, not to the children, regarding health problems. The education of children regarding health problems is just beginning, so most children have little understanding before surgery.

The five dimensions of the surgical experience that provoke anxiety in children summarize as well the primitive concerns of adults. These are a) pain and mutilation, b) separation from parents or other trusted adults c) fear of the unknown and unfamiliar, d) uncertainty about normative behavior in a hospital setting, and e) loss of control, autonomy and competence (Visintainer & Wolfer, 1975). Behavioral methods to prepare children for hospitalization and surgery have been developed, and similar principles apply for adults (Rasnake & Lindsheid, 1989). Speaking to adults directly in plain language, preparing them step by step with attention to their natural fears should be the rule. Preoperative teaching and psychological preparation for surgery improve postoperative outcomes. "Preoperative teaching" means providing concrete information to patients about postoperative procedures, about treatment-related pain and discomfort, and a thorough psychological exploration of the patient's fears, anxieties, and expectations. One program to prepare children and families for surgery includes tours of the places they will see on the day of surgery, films about surgery or anesthesia, slide presentations, coloring books, photographs chronicling other children's experiences, puppet shows, medical play utilizing real hospital equipment, popular children's books about going to the hospital, drawings or collages, and relaxation and coping exercises (Justus et al., 2006).

Patients benefit from recognition of the personal meanings of the particular operation; for example, an episiotomy, a meningioma, a facial burn, a heart transplant, or uterine cancer. These personal meanings related to illness, the body parts affected, functions of the body that are affected, and the need to seek surgical assistance will partly shape the patient's emotional course before, during, and while recovering from surgery. For those who do not fully recover, continuing interest and compassion from the surgeon will diminish the perception that the surgeon's only interest is in the procedure and not the patient.

Guiding a patient who is preparing for surgery, the medical psychiatrist would encourage the best coping strategies to maximize the best outcome. Comorbid medical conditions should be under the best control. Patients can commit to their own physical fitness, smoking cessation, cutting down on alcohol, and learning methods that have the potential to reduce anxiety before, during and after the operation.

Mind-body interventions (Chapter 17), some similar to natural childbirth methods, which may be learned preoperatively, include meditation, self-hypnosis, guided imagery, yoga, tai chi, massage, therapeutic touch, and others.

Feeling mentally prepared, a positive attitude, motivation and will power have been linked to better surgical outcomes (Frankel, 2012). With elective surgery, the medical psychiatrist has the opportunity to watch the steps that patients go through to decide if they will have surgery; i.e., how they come to a state of readiness (Conner-Spady et al., 2014). The decision for surgery is linked to the personal assessment that the benefit outweighs perceived risks. Indecisive patients may lack information about alternatives or may be unable to make a decision because of anxiety, depression, or paralyzing ambivalence. Those that avoid the decision may also avoid finding out the best timing for surgery in the course of the illness. The adept surgeon who must do sequential surgeries makes a relationship with a patient that resonates with the patient's readiness for the next surgery. The psychiatrist's role is to make clear where there is lack of information, to support information seeking, and to facilitate appropriate risk taking and coping with uncertainty, allowing the patient to go forward with the best sense of control and self-esteem.

In some cases, patients' worry about recurrent cancer outweighs their desire for less surgery despite reassuring data. Breast-conserving surgery developed as an alternative to mastectomy, offering the same likelihood of survival in many cases. Since 2004, the rates of elective mastectomy and contralateral prophylactic surgery among candidates for breast conservation in conjunction with immediate reconstruction and contralateral prophylactic mastectomy have increased (Dragun et al., 2012). Perceived survival benefit and fear of recurrence are primary motivators for both older and younger women in this setting (Fisher et al., 2012). The long-term consistency of satisfaction after surgery is related to the woman's sense of having made an informed decision herself (Frost et al., 2011).

Psychiatric consultations provide opinions about patients' decision-making capacity to give informed consent (Applebaum & Grisso, 1988; Marson et al., 1995; Burrows & Hodgson, 1997). Patients must be mentally competent to give informed consent to be treated. It is an important principle of surgery and the law that patients must give informed consent prior to being treated, unless it is an imminent, life-threatening emergency. To perform a surgical procedure (Giesen, 1993) or anesthesia (White & Baldwin, 2003) without obtaining proper informed consent is considered assault and battery under every state's law.

There are several situations with unique aspects that occur repetitively: surgical consent in the elective patient, the emergency patient, the impaired patient, the research setting, and the pediatric patient. Although it seems counterintuitive, in many ways, obtaining proper informed consent from a patient for the elective surgery is more difficult, especially with day surgical procedures (Wadey & Frank, 1997; Kikuchi & Hara, 1996).

With telecommunication, the surgeon can use timely close cellphone and other electronic communication to inform the

family as important medical and surgical events occur, so that relatives or guardians do not feel uninformed when they are in the role of giving consent.

“Informed” consent implies that the patient has a complete understanding of the indications for surgery, the medically reasonable alternatives to the planned procedure, the consequences that follow from the options offered, and all potential risks and complications associated with each. To truly achieve this in the average lay person can be extraordinarily difficult (Waisel & Truog, 1995); however, this is the law in all U.S. jurisdictions.

Consent for elective operations in pediatric patients and in impaired adults is obtained through a discussion with the parent or legal guardian. It is clearly important that family be involved whenever possible. It is also important to obtain “assent” for research from school-age children (Weithorn, 1983), and there is no reason to think they are incapable of assent for procedures and surgery (Levine, 1996). Children seven and older should assent, along with parental consent, to elective surgical procedures, and they are likely to benefit, even if it elicits anxiety, from preparatory explanation in language they can understand about a forthcoming operation, even for non-elective urgent operations. Children’s assent and consent for surgery is a developing area involving autonomy vs. best interest, family, legal or ethical, and measurement dilemmas (Miller et al., 2004). If a child seven or older does not assent to elective surgery, it is advisable to delay the surgery until the child matures and is able to understand and choose to proceed with it. In a survey of 453 of 852 American anesthesiologists, for a 57% response rate (Lewis et al., 2007), children’s refusal of surgery was not rare, with 9% of respondents reporting at least one case in the past year, and 45% having canceled one or more cases during their entire careers. Forty-four percent used restraint on most children under one year of age, whereas only 2% did so in children over eleven years of age. Respondents were uncomfortable with restraint in older children and less likely to proceed with induction. Twelve years of age was the median age when respondents would respect the child’s refusal to proceed.

Not surprisingly, psychiatric complications with children and mentally impaired adults are reduced when they and their family understand the procedure and choose to proceed with it. In complicated cases, particularly where protracted hospitalization and multiple interventions are required, it is ideal if a family spokesperson and a hospital spokesperson can be identified early to communicate with each other. This facilitates the rapid exchange and dissemination of information and facilitates the creation of a trusting relationship between the extended family and an extended patient-care team. Informed consent is extensively discussed in Chapter 85.

PERIOPERATIVE COMPLICATIONS

PSYCHOLOGICAL REACTIONS RELATED TO SURGICAL ANESTHESIA

There are four major categories of psychological reactions to surgery and anesthesia: phobia in anticipation of anesthesia

and surgery, psychotic-like reactions during induction, post-operative recall of awareness during anesthesia and surgery, and cognitive dysfunction after anesthesia.

Phobias

Phobias may relate to an unrealistic fear or misunderstanding of the surgical procedure and are more likely in patients with a preexisting anxiety disorder. Some fearful reactions are not phobias at all, but realistic fears related to an accurate understanding of the planned surgery. Phobias may also relate to a fear of needles, to an induction-mask phobia (which may be reduced by giving the patient control over choice of “smell” of the agent), to unrecognized prior traumatic experiences under anesthesia, including cardiac or respiratory arrest, or to witnessing another patient’s injury or death after surgery. Some patients are phobic because the choice for surgery is not their own, but rather that of a relative or the surgeon, and they are reluctant participants in the process. A few patients become phobic or anxious because of preoperative discontinuation of their regular psychotropic medications. Brief psychiatric assessment can sometimes readily clarify the problem, provide reassurance, and may invoke the judicious use of a hypnotic or sedative medication, often a benzodiazepine. Distraction, combined cognitive-behavioral interventions and hypnosis have been helpful for needle-related procedural pain (Uman et al., 2006). Some patients, including some children, require cancellation of elective surgery and better preparation or psychiatric evaluation and treatment of the phobia, if that is the problem. Once they are prepared and willing to proceed, surgery may be rescheduled.

Reactions Similar to Psychosis During Induction

Parental presence during induction of anesthesia is available at some hospitals, but children are not necessarily less anxious when parents are there, especially if the parent is anxious (Chundamala et al., 2009; Yip, 2009). The best plan is to advocate for a plan that works best for their family (American Academy of Pediatrics, 2014). Induction may be difficult for children 2–5 years old and those who have been in the operating room before. After surgery, behavioral difficulties are more likely if the child is anxious before surgery. (Kain et al., 1999); those children who were anxious have more pain and sleep difficulties post-surgery (Kain et al., 2006).

Reactions similar to psychosis during induction, like an amygdala interview, may result from anesthetic-induced disinhibition with expression of intense emotions of anger, sadness, fear, and sometimes even hallucinatory experiences; reactions may include violent outbursts requiring restraint. In children this has been described as emergence delirium (Vlajkovic & Sindjelic, 2006; Malarbi et al., 2011). A child is incoherent, inconsolable, kicking and thrashing, unable to recognize people with eyes averted, staring or closed. Paranoid delusions have also been seen. The syndrome lasts less than 30 minutes and sometimes transitions into a tantrum or evidence of pain. While such reactions are generally managed effectively with sedatives and anesthetic agents, they may signal a need for psychiatric assessment.

Unintended Awareness During Anesthesia

Most patients are worried that they will not wake up from anesthesia (McCleane & Cooper, 1990). However, being awake and aware during surgery is also a concern. Awareness is more common than generally known, and has been reported to affect about 0.1–0.2% of the population (Sandin et al., 2000; Sebels et al., 2004). Reports of awareness have been documented in children also (Davidson et al., 2005). Awareness during surgery is defined as the unexpected and explicit recall of intraoperative events during surgery. Although most cases of awareness are inconsequential, some patients do experience long-term sequelae, including PTSD, depression, nightmares, anxiety, and flashbacks (Samuelsson et al., 2007).

The causes of intraoperative awareness can be multifactorial. Genetic and drug-induced factors can alter the pharmacokinetics and pharmacodynamics of drugs administered to induce anesthesia (Kim et al., 1997; Ezri et al., 1997). Polymorphism in γ -aminobutyric acid A receptor $\alpha 5$ gene with at least three different forms of messenger RNA has been reported (Kim et al., 1997). Because of diminished cardiopulmonary function and reserve, anesthetic drugs are purposefully administered in lower concentrations to avoid negative hemodynamic and pulmonary consequences. Concomitantly administered drugs can mask the surrogate markers of awareness. For example, patients on β -adrenoceptor blockers will not have the tachycardiac and hypertensive responses usually seen in light anesthesia. Co-administration of muscle relaxants with light anesthesia will result in a paralyzed, immobile, awake patient unable to express awareness or move in response to pain. The incidence of awareness during Caesarian section under general anesthesia is high because of the deliberate attempt to reduce the anesthetic concentrations in the mother to reduce the side-effects on the fetus. Incidental lack of delivery of anesthetic is another common event, caused by lack of anesthetic in the vaporizer or by pump failure with intravenous anesthetics.

Patients become aware while under anesthesia due to our inability to accurately measure the depth of anesthesia with precision. Most often, surrogate markers (heart rate, blood pressure, lacrimation, and movement) are used. All of these are very nonspecific and can be masked by drugs inhibiting the responses. Bispectral Index devices have been advocated as a useful monitor of consciousness. Two studies, however, found no differences between control and Bispectral Index monitors in the incidence of awareness (Sandin et al., 2000; Avidan et al., 2008). Thus, the American Society of Anesthesiology (ASA) has indicated that brain function monitoring is not routinely indicated (ASA American Society of Anesthesiologists Task Force on Intra-operative Awareness Practice Advisory, 2006).

Cognitive Dysfunction After Anesthesia

It has long been assumed that anesthetic drugs are rapidly metabolized or eliminated from the body and

therefore have minimal long-term effects. Several studies have questioned this assumption and documented that elderly patients experience changes in brain function even months after anesthesia combined with surgery. Post-operative cognitive dysfunction (POCD), persistent difficulties in memory, attention, or executive function that occur commonly post-surgery in older patients, is transient, usually but not always resolving by 3 months (Johnson et al., 2002). In a meta-analysis, general anesthesia compared to regional anesthesia contributed only marginally to the likelihood of POCD. (Mason, Noel-Storr, & Ritchie, 2010; Rasmussen et al., 2003). POCD did not predict dementia in a cohort followed for 11 years (Steinmetz et al., 2013). Older patients with POCD were most likely to die within in the year after non-cardiac surgery (Monk, et al., 2008). In contrast to these reports, a recent study suggests that elderly people undergoing surgery have no reason to worry (Avidan et al., 2009).

A growing body of evidence in animal studies also indicates that anesthesia exposure in the early stages of life has neurocognitive effects (Brambrink et al., 2010; Slikker, 2007). Retrospective studies performed in young children exposed to anesthesia at less than three years of age indicated twice the incidence of developmental or behavioral disorders (DiMaggio et al., 2009). The learning disabilities increased with greater cumulative exposure to anesthesia (Wilder et al., 2009). The possibility of negative effects of general anesthesia on neurological development has led to a standard of limiting exposure for children younger than 2 years (Flick et al., 2011; Loepke et al., 2008; Sun, 2010). The long term effects of anesthesia on the brain are still unclear (American Academy of Pediatrics, 2014).

Conversely, there is also evidence that certain anesthetics (e.g., ketamine and dexmedetomidine) may attenuate the neuronal changes associated with brain insults. Contradicting the retrospective studies in human newborns, two recent studies in the pediatric population reported no significant differences in educational outcomes of twins discordant for anesthesia (Bartels et al., 2009; Hansen et al., 2011). Ongoing prospective studies may settle this dispute, but the outcome data may take several years. Prospective randomized studies cannot be performed, as not many would volunteer for surgery without anesthesia. There are no specific drugs available for brain protection. It seems that regional anesthesia may be preferable to general anesthesia. Every surgery and the type of anesthetic should be evaluated for risks and benefits until evidence for or against neurocognitive effects of anesthesia become available.

POSTOPERATIVE COURSE

A patient's reaction to surgery is dependent on preoperative preparation, the type of surgery, the patient's resilience and stage of development, the diagnosis, speed of recovery, complications encountered, and the patient's preoperative mental status. In relatively uncomplicated surgeries with good prognoses, there is a sense of relief that the individuals have survived and can go on with their lives. However,

for patients with a chronic diagnosis such as incurable cancer, or in whom the surgery meant alteration in their body functioning or lifestyle, the reaction can be one of anger, grief, or depression. All three feelings may occur almost simultaneously.

Often patients enter into surgery with some degree of hope that all will be “okay” or that they do not have a serious disease. After their operation, their ability to use denial is much reduced, and they have to adjust to the realistic ramifications of the diagnosis and treatment. If the postoperative course has unexpected complications, some patients become depressed and hopeless, wondering why they chose to have surgery in the first place, or blaming others for their misfortune. Sometimes anger can lead to legal action against the staff or hospital.

Postoperative regressive behavior is very common and not usually pathological, although it may quickly become so. Children may temporarily lose previously acquired skills such as feeding themselves, speech, self-care, and bladder or bowel control; and their return to normal development generally corresponds with their recovery from surgery and its sequelae. Adults, too, regress after surgery. They may refuse to eat, become uncharacteristically truculent and demanding with nurses, and may cooperate with physical therapists and other caretakers much more slowly than their medical condition merits. Regression may mimic depressive symptoms, with tearfulness, emotional withdrawal, weight loss, sleep disturbances, and irritability. Post-surgical regressive behavior is generally transient, although it may be extended with chronic illness and in psychiatric patients with dependent personality traits. Education of nursing staff regarding regression reduces conflicts and clarifies for them the meaning of patients’ behavior.

A powerful antidepressant for patients recovering from surgery is rapid ambulation and resocialization, which often results in reversal of regressive symptoms and the expedited recovery of more normal psychological functioning. Postoperative regression is usually very responsive to psychiatric interventions, including brief supportive psychotherapy and judicious use of anxiolytics, analgesics, or antidepressants when indicated. Benzodiazepines or analgesics may contribute to regressive behavior, and dosage reduction may be effective in reducing regression and encouraging patients to resume more normal functioning. On the other hand, inadequate pain control can reverse progress and lead again to regression as well as agitation.

PSYCHIATRIC COMPLICATIONS OF SURGERY

Depression and delirium are the two common complications in the surgical setting.

Delirium is common (Fricchione et al., 2008), especially in older patients and many acutely hospitalized children (Schieveld et al., 2007). Risk factors include mild preoperative cognitive deficits and vascular disease (Rudolph et al., 2007). The incidence is greater after major vascular operations like abdominal aortic

aneurysm repair and coronary artery bypass surgery than abdominal, orthopedic, or head and neck operations (Fann, 2000). The possibility of alcohol withdrawal adds a risk of delirium tremens. Good management requires prevention of dehydration and hypoxia, simplification of other medications, strengthening the patient’s sensory abilities with hearing aids and eyeglasses (Inouye et al., 1999). The psychiatrist has a role in educating the family or friends to recognize confusion, report it and not be frightened by it. Efforts have been made to shorten time on mechanical ventilation, the need for prolonged sedation and to hasten exercise. The Mini-Mental State Examination (MMSE) is useful as an initial screen to rule out delirium (Mitchel et al., 2014). The Confusion Assessment Method (CAM) is one of the most widely used screens, and the CAM-S can be used to follow severity of delirium (Inouye et al., 2014). A delirium screening method for children, the Cornell Assessment for Pediatric Delirium, has been anchored in child development (Silver et al., 2014). (See Chapter 41 for a fuller discussion of delirium and its management.)

Depression occurs as patients cope with pain, many setbacks, and the recognition of the challenge of recovery. Suicides can and do occur occasionally on surgical units, sometimes because of delirium, and sometimes depression.

Attention to symptoms of anxiety in surgical patients provides an early clue to surgical complications (e.g., infection, pulmonary embolus, pulmonary edema), psychiatric disorders (e.g., delirium), or reactions such as fear of dying. Repeated painful procedures commonly trigger acute stress disorder with intrusive, dissociative arousal and avoidance symptoms, and require intervention.

PTSD is commonly recognized in surgical patients by clinicians caring for them, but the symptoms are often discovered to be preexisting, from traumatic exposures including abuse or rape, accidents, combat, illness or injury, medical treatment, disasters, and war or genocide (Stoddard et al., 2014). Trauma in childhood and adolescence affects development and may enhance resilience or exacerbate psychopathology throughout the life cycle (Stoddard, 2014). Early interventions, medical or psychosocial, to prevent traumatic exposure in medical-surgical settings are being investigated. The rates of PTSD vary from under 10% for children undergoing bone marrow transplant, to 20–50% for severely burned children and adults (Stoddard, Sheridan et al., 2011), and other physically traumatized patients have similarly high rates of PTSD (Stevens et al., 2010; Zatzick et al., 2004a). SSRIs have the best record of benefit in treatment of PTSD and its associated depression and disability (Stein et al., 2006) and cognitive behavioral therapy has contributed (Bisson & Andrew, 2006).

Under-treatment of pain is a common problem in children and adults, contributing to mental and physical morbidity, and mortality, in some cases, due to pain-related stress (Schechter et al., 1993; Weisman, 1997; Stoddard et al., 2011). The psychiatrist should be alert to undetected pain and inadequate psychological (e.g., relaxation/hypnosis) and pharmacological (e.g., opiates) methods of pain relief. Concern about causing addiction is largely unfounded with acute pain management, and patients with preexisting addiction often require higher doses of analgesics for equivalent effect. For the patient with a history of addiction, the surgery itself and reexposure to

narcotics may foster a relapse in addictive behavior. The psychiatrist, paying more attention to social history, may be the one to hear out the patient about inadequate pain relief, recognize neuralgic components of pain, dimensions of depression and anxiety and the vulnerability of the patient to addictive medications. Sleep disorders are common in the general population, but are even more of a problem surgically, since sleep deprivation often results in regression and behavioral complications. In the surgical patient, sleep disorders are often due to pain, drug side-effects, or excess iatrogenic environmental stimuli. Insomnia may be the initial warning symptom of delirium or acute stress disorder. (Chapters 9 and 33 discuss the diagnosis and treatment of sleep disorders in detail.)

A principal cause of postoperative psychosis, distinct from depression or delirium, is the failure to continue antipsychotic medication previously prescribed.

FACILITATING ADAPTATION TO SURGERY

After surgery, there are changes in the body, and the patient will need time to adapt to such changes.

CASE HISTORY

Alex is a 13-year-old boy with congenital liver disease that worsened, and he underwent a liver transplant. He experienced a complicated postoperative course that included rejection and infection. During his hospital stay, he met with a child psychiatrist, and as he began to feel better, he started talking about what it meant to have a transplant. He was concerned about how he would change, when he would begin to consider the liver his own, and what it might mean to feel healthy after a long period of feeling so sick. During this period, Alex began asking if he could find out about who the donor was. When the therapist explored this question with him, he stated that the main reason he wanted to know was to find out how much the liver transplant would change him. When asked what he meant, he stated that he wanted to know if the person from whom he received the liver liked pizza, because prior to the transplant he never liked to eat pizza, and now he had a craving for it. The case of Alex illustrates well how a patient was helped to express his individual and unique responses to surgery, including sensory experiences, in the process of grieving the illness and loss, and was curious about his relationship to the donor, beginning to “own” the “new” body, and integrating body image transformations into himself.

Inquiry about pain is a useful beginning to consultation with surgical patients (Stoddard et al., 2011; Nejad & Alpay, 2010), and often allows an easy transition to inquiry about the affected body part. In the immediate post-operative period a patient with fear of looking at parts of the body can be coaxed gradually and gently to more direct confrontation. The need for confrontation is directly related to the need for the patients to care for themselves and how fast this must be accomplished. Nurses facilitate encounters with wounds and drains. Mirrors, first small hand-held and later full body mirrors for gradual confrontation and control have been used in nursing settings to foster control and recovery (Freysteinson, 2014).

As patients recover, they may understate their discomfort with their own body image because they are ashamed. Clues to body image difficulties in the setting of surgery are unrealistic expectations about the procedures, difficulties making treatment decisions due to concerns about appearance, the tendency to avoid viewing oneself after treatment, preoccupation with physical flaws, and avoidance of social situations. The practical question is whether concerns about body image prevent them from engaging in social activities or having the confidence to move forward (Fingeret, 2014).

A compassionate clinician can broach questions about their comfort with their physical appearance and find an opening for interventions. After letting a patient know that concerns about body image are common, exploration can begin with asking specifically what concerns the patient may have about the way the body appears and then what are the consequences of their fears or discomfort (Fingeret et al., 2014).

For breast cancer patients, most concerns about body image occur in the immediate postoperative period and soon after completing chemotherapy or radiation (Fobair et al., 2006; Hawighorst-Knapstein et al., 2004). The impact of surgery type on body image within the first year of definitive surgical treatment is related to the severity of surgical side-effects; body image problems differ minimally after two years (Collins, et al., 2011). These preoccupations tend to diminish thereafter and stay relatively stable over 2 years (Falk Dahl et al., 2010; Parker et al., 2007).

Treatments for body image difficulties include cognitive behavioral treatment that changes cognitions about body image and include education, stress management, problem-solving, cognitive reframing and communication skills training (Cash, 2011). Sexual therapy may be particularly appropriate when the issues prevent the patient from being open to sexual encounters. Education about cosmetics and services for hairdressing and makeup provide another avenue to reduce self-consciousness. Exercise and strength training can add to the patient's sense of well being and looking good (Fingeret et al., 2014).

Facial disfigurement is often due to trauma, burns, or cancer and its effects are significantly greater than that affecting other parts of the body (Warner et al., 2012). It often leads to shame and embarrassment (“loss of face”); realistic fears of social stigmatization by family, friends, and strangers; and disability. Some developmental stages and occupations are more critical than others: junior high school students commonly taunt facially disfigured boys and girls with epithets such as “French fry” or “Freddie Kruger”; actors or salesmen may lose their jobs. It is essential for the clinician to provide cognitive preparation for the surgical outcome, to facilitate the grieving for the lost facial features and new “ugliness,” and to actively support patients as they seek reentry into their family, social, and occupational lives. Social skills interaction training (SSIT) for those with facial disfigurement from various causes, a cognitive behavior therapy approach, has been shown to be an effective method in most studies of reducing the effects of social stigmatization on self-esteem (Lansdown et al., 1997; Newell, 2000; Kleve et al., 2002; Blakeney et al., 2005). Face IT for adults and YP Face IT for youth is an easily accessible online program that teaches skills to cope with disfigurement (Bessell & Moss, 2007; Bessell, et al.,

2012; www.ypfaceit.co.uk). Some isolated patients may be at risk of suicide, for which they should be assessed and treated. (Burn trauma is discussed in Chapter 75.)

Like the option of replantation surgery for severed hands and fingers, facial transplantation surgery now offers (a very few) facially disfigured patients an option not previously possible (Siemionow & Gordon, 2010; Bueno et al., 2011). It is being done by multidisciplinary surgical teams in a few select centers for patients with facial disfigurement due to traumatic injuries like burns, as well as due to cancer and other causes. It is not a standard treatment but is increasing very slowly. Psychiatric collaboration is essential in the assessment protocols to judge whether a patient is suitable for such extensive surgery. While the hope is that facial transplantation, similar to other types of reconstructive facial surgery, may reduce stigma and functional losses even for those with massive facial disfigurement, it remains to be determined to what extent it will be available for more than a select few patients. In the meantime, facial reconstruction of specific facial features with grafting, flaps, and microsurgical procedures, remains the common treatment. It is important to add that many patients have adapted to their facial disfigurement and have dealt with the associated stigma, even when severe, and do not want facial transplantation surgery for themselves, nor favor it for others.

Bariatric surgery provides an opportunity for treatment of obesity and for patients to acquire an improved body image. Psychiatric screening is commonly a part of the process of identifying the patients who are at less or greater risk from the procedures and who will follow through postoperatively. Candidates for bariatric surgery have high rates of lifetime affective disorder; psychopathology is greater in patients with more severe obesity and lower socioeconomic status (Malik et al., 2014). A 4-year prospective study of psychiatric outcome of patients who had restrictive bariatric surgery found an improvement in mood and self esteem (Burgmer et al., 2014); improvements in cognitive function has also been seen (Alosco et al., 2014). In a retrospective study of 148 patients, outcomes correlated significantly with surgeon follow-up, attendance at postoperative support groups, physical activity, single or divorced marital status, self-esteem, and binge eating (Livhits et al., 2010). Optimal treatment of depression is also important over time; the suicide rate is higher in these patients (Peterhansel et al., 2013).

Whether small or large, severe traumatic injuries, including burns, are painful, emotionally stressful, and may be disfiguring and functionally disabling (Stoddard & Saxe, 2001; Stoddard, Levine, & Lund, 2006). Severely burned children challenge the emotions and skills of the multidisciplinary burn team (Stoddard, 2002). Most, but not all, adult burn patients have preexisting psychopathology, substance abuse, or medical illness. Suicide attempt by burning is one cause of hospitalization for adult burn patients, and less common among adolescents admitted to pediatric burn units; these patients who have attempted suicide require close collaborative surgical and psychiatric treatment and, due to their severe injuries, often have extended, expensive lengths of stay. Psychiatric care of burn patients is usually needed to manage

and support their coping with delirium, pain, PTSD, depression, and personality disorders (Stoddard, 2002; Stoddard, Sheridan, et al., 2011). (See Chapter 40.)

Amputations usually represent a massive psychic trauma. In children, they are a massive trauma to the parents as well as the child (Stoddard & Saxe, 2001). In the young child, grieving the loss of a leg is complicated by the child's need to relearn how to walk. In the elderly, depression has been reported to correlate with poor prognosis in rehabilitation. There are several psychiatric issues: depression with unresolved grief and denial; pain at the site of amputation; phantom limb sensations and pain; acute and post-traumatic stress disorder (Parkes, 1973).

Amputations are one of the first surgical procedures recorded in ancient history. Since they have been and still are performed in some Middle Eastern countries as punishment or torture (Shukla et al., 1982), we tend to view amputation consciously and unconsciously as punishment or a form of castration. War increases the numbers of children and adults with amputations, as in the Civil War in the United States, the two World Wars, and recent wars in Vietnam, Cambodia, Iraq, Afghanistan, the Balkans, and Africa. An international effort is increasing to ban land mines, which are major causes of amputation and death for children and adults. These efforts to date have been largely unsuccessful.

Loss of a limb is both cosmetically and functionally disabling, at least for a time, even with effective prostheses. Replantation surgery, nerve grafts, free flaps, and other innovative procedures may offer great hope, but should they fail, severe disappointment or depression may occur. The psychiatric consultant may facilitate adequate preparation, but preoperative teaching is often not feasible in emergencies, and there is often an abrupt damage to body integrity. Without preparation, patients may be overwhelmed and have great difficulty coping with their loss. Their families may suffer even more severe and chronic stress. Optimally, the patient should be assessed preoperatively for ego strengths and preexisting psychopathology, and the family, too, should be assessed. The psychiatrist can assist with managing acute pain, stress, and sleep disorders, and may assist with breaking the news that the limb will be lost to the patient and family, perhaps by reflecting with the patient on pain sensations, pain relief, and response to dressing changes as an entry to the grief process. Traumatic amputations tend to affect active children more greatly than they do retired, sedentary individuals.

CASE HISTORY: ACUTE GRIEF IN A 12-YEAR-OLD BOY

A handsome Puerto Rican boy suffered electrical injuries requiring amputation of his right arm, with additional injuries to his left hand and arm. Once morphine and lorazepam were tapered, he was reported to be withdrawn and having sleep difficulty, but was becoming more able to talk about his awareness of his injuries. After initial introductions, an empathic medical student, in the presence of the boy's worried mother, inquired in Spanish about his condition, what he recalled, and what he had enjoyed prior to his injuries. The boy replied that he liked baseball and played second base, at which point he suddenly realized that he would never be able to play again. He

broke down in tears, together with others in the room, and cried disconsolately for a time. Eventually, in the same interview, he was able to accept some consolation that being fitted for and learning to use a prosthetic arm in the future might offer hope of some restored right arm function.

A goal is to facilitate both grieving the personal meanings of the loss, in this case symbolized by the boy's prowess as a second baseman, and the nurturance of a hopeful, realistic attitude. Children, adolescents, and even adults (especially males) may learn to regard their amputation in a "warrior motif" as a "red badge of courage," responding with resilience or "hardiness" even to terrible losses.

Regardless of age, there are always issues of incorporating a new body image, and dealing with grief and loss for the amputated limb. Exploration of the exact precipitating circumstances, the details of the accident or disease, and associated feelings of embarrassment or guilt assists with emotional processing of the traumatic experiences. There often are multiple traumas with which the amputation is associated, perhaps an accident, urban violence, or chronic illness, deaths of others, pain, and acute surgical treatment. The stigma of the amputation may actually be furthest from the patient's mind. PTSD may accompany amputations in civil life, but combat-related amputations are associated with the greatest amount of psychological trauma.

Recovery of maximal function and return to one's usual social and occupational functioning are goals, but not always attainable. Complications such as regression, depression, and noncompliance are common and respond best to early interventions. Some patients—for instance, elderly patients with vascular disease and non-healing ulcers, or teenagers unable to walk due to leg deformities—may welcome amputation as relief from pain or the inability to ambulate. However, even when the limb is painful or nonfunctional, the patient may be ambivalent about the disappearance of this body part. Optimism before surgery may be replaced by normal, grief-related anger, despair, and negativity postoperatively. The patient may have difficulty adjusting to the stump and become resigned to disability and nonfunction rather than active rehabilitation unless vigorous and positive rehabilitation is started promptly by a well-trained, multidisciplinary staff.

"Phantom limb phenomena" commonly occur following amputation in both children and adults. Kolb (1975) noted that the earliest accounts of body image disturbance date back to the sixteenth century, when Paré noted the frequent occurrence of phantom limb sensations following amputation. Phantom limb phenomena are the persistence of pain or sensation as if the limb were still present. The "phantom" phenomena may persist to some degree for a lifetime. "Phantom" symptoms are often missed if not asked about; they may also evoke anxiety and confusion. These phenomena may decrease over time, or be persistent. We and others (Krane & Heller, 1995) have found phantom pain in nearly every child with an amputation, except those with a congenital deformity.

Psychotherapeutically for the young child, "nonverbal and metaphorical 'safe' alternatives via play modalities," such as dolls and drawing (Billig & Weaver, 1996), "and active facilitation of coping skills are useful to impart information, decrease anxiety and enhance mastery" (Atalar & Carter, 1992, p. 128).

An ostomy is a surgically created opening of the intestine, colon, or ureter brought to the surface of the abdomen; for instance, ileostomy, colostomy, or urostomy. The United Ostomy Associations of America and the American Cancer Society provide practical guides for patients (www.ostomy.org). Ostomy surgery is performed to treat a variety of diseases such as congenital malformations, inflammatory bowel disease, diverticulitis, trauma, and cancer. An ostomy may be temporary or permanent. Psychologically, it may evoke even greater emotional stress than loss of reproductive function, both because of its chronic nature, and because of involuntary embarrassment and shame evoked by reduction or loss of excretory function and control present since early childhood.

Initially, patients may experience the ostomy as a form of bodily mutilation, with all of the shock, revulsion, and sense of victimization that that implies. Body odors, gases, fluids, or feces may leak out in public settings or soil clothing, resulting in fear of or actual social stigmatization and interference with activities of daily living. Reinstating normal social and sexual relationships may require patience and understanding by all parties. The ostomy or ostomy apparatus may be painful, or require periodic emptying and attention. Patients with a colostomy or ileostomy have to deal with effects on absorption of food, excretion, stool leakage, and passing flatus; worry regarding sexual attractiveness and function. They are helped by specialized ostomy nurse therapists, resumption of school or work, utilization of practical guidelines and self-help groups.

The threat to virility or femininity associated with urogenital symptoms and urological diagnoses cannot be overestimated; nor can the relief experienced when effective treatment is provided. Depending on the individual's personality and the condition, the psychophysiological issues may include fears of loss of potency (erection and/or ejaculation), orgasm, libidinal or genital sensation, virility or femininity, attractiveness, reproductive capacity, sexual desirability or continence. Certain of these fears may or may not be realistic. As illustrated by the case below, there can be a risk that the fears engendered may lead to denial, depression, indecision, inappropriate interventions, and adverse outcomes, despite rapid advances that have been made in effective clinical treatment options.

CASE HISTORY: SURGERY DELAYED BY PATIENT SEEKING ALTERNATIVE THERAPIES

A 50-year-old obese novelist, the father of a nine-year-old son, presented with abdominal pain and dysuria to his physician and was referred to a urologist. Cystoscopic surgery revealed an aggressive bladder tumor without metastasis, and prompt resection of the tumor was advised. After some delay, he sought continent diversion

surgery from another urologist to preserve sexual functioning and to avoid an ileostomy. At the same time, terrified of losing sexual functioning and distrusting his urologist, he and his wife, both well educated, sought out alternative therapists who introduced them to a man who was allegedly cured of bladder cancer by nonsurgical means; they began a "positive" program with mystical spirituality, dietary and herbal remedies, massage, and use of visual imagery including "channeling", in the belief that by "imaging" cancer remission, it would remit. A 20-pound weight loss, reduced anxiety, and improved mood, and no change on a computerized tomography (CT) scan confirmed for them the effectiveness of these therapies. He canceled his surgery, emphasizing his need to make his own decisions and complaining about each urologist who had gravely broken bad news. Despite confrontation of his denial, depressive signs including irritability, and a severe behavioral regression, he avoided "conventional" medical treatment, including psychiatric care.

After two more months, pain and then blood in the urine signaled further tumor spread. Having by then found a homeopathic physician, he was referred to another urologist who commented with a touch of humor that pleased the patient, "You can't have sex if you're dead." The patient consented to and had continent diversion surgery. Chemotherapy was necessary for possible metastases, and his prognosis was guarded. The urologist referred him for treatment of depression, which responded to combined antidepressant and family and individual psychotherapy, despite the guarded prognosis and chemotherapy.

He chose to continue with some of the alternative therapies, which, while of questionable therapeutic value, did not interfere with his regular medical care.

BREAKING BAD NEWS; LISTENING; PROVIDING HOPE

All people need to maintain some degree of hope. It is hope that allows us to face the traumas of our lives and find the coping skills to move forward in the face of bad news. The psychiatrist seeks to communicate supportively, diagnose, and participate constructively in the treatment of the surgical patient. It is difficult to be the surgeon or psychiatrist breaking bad news, and it can be painful to observe the recipient's reaction to this news. Patients need to know that their physicians can help them to bear it. For most patients, it is important to hear honest answers to their questions, framed in simple and concise terms throughout the course of treatment, and then for the physicians to listen carefully to the responses of the patient and family over time.

Hope is a universal mechanism in facing all of life's travails, and its maintenance is crucial even if an illness will end in death. The maintenance of hope can come from a variety of places, and it is important for clinicians to try to assess what individuals do to create hope for themselves, including discussing with them their belief systems such as religion and knowing which people are important to them during a crisis.

At the beginning of an illness, people hope for a cure. Even in situations in which there is no hope for a cure or survival, it is important to maintain hope. This can be done by looking at

short-term goals such as having a good morning, or sitting in a chair, or having a discussion about the next possible course of treatment. In the face of death, many people maintain hope based upon their religious beliefs, social supports, and planning for those they will leave behind.

COLLABORATION OF SURGEON AND PSYCHIATRIST

Surgeons uncover and create problems and must be equipped to inform patients and loved ones of unfavorable findings and untoward events. Many operations have as their goal, or their side effect, a major change in body image, appearance, or function. Patients benefit from frank discussions of these issues. Unfortunately, surgeons, who are best equipped to discuss these alterations, may not always have the time or feel comfortable listening, providing the information, and responding to the patient's concerns.

Death evokes fear in everyone. It is during the process of death and dying that it is most important for patients to know that their physician will continue to be available to them and that people will answer their questions. It often is difficult to sit with the person who is dying, and family, friends, and caregivers may avoid the dying patient. This unplanned conspiracy of avoidance says to the patient that no one can or wants to hear their thoughts and ideas, and isolates the patient. Cecily Saunders (1998) explains that "No one should have information forced upon them, but any continuing communication with a patient is likely to open up the subject sooner or later." Physicians who overcome their own fears of the subject will learn how and when and what to tell.

As Kübler-Ross (1969) wrote, individuals who know they are going to die will proceed through a series of stages, ending in a state of acceptance. Patients should be given the opportunity to discuss their fears, hopes, anger, and frustrations. They need to know that there are people who will consistently listen with a compassionate and even manner. It is also important to remember that the dying patient may want to talk about other things than dying, including things that may seem minor or frivolous (such as favorite sport teams, politics, etc.). Chapter 18 discusses the roles of religion and spiritual issues in the context of dying patients. Chapter 57 on palliative care also discusses the care of patients with a limited life span.

Children and adolescents can be included in discussion about death, whether this concerns a parent or themselves. The discussion needs to be adapted to a child's understanding of death, and this understanding changes with the child's age. In children under about six years old, death is understood as a magical event and not as a permanent state. The older child and adolescent will have a better understanding of death. The school-age child and adolescent understand death as permanent and irreversible and can discuss their fears and anxieties as well as any preparations they might want to make.

Following a death, the surgeon's and the hospital's continued interest in the grieving family is important (Weisman, 1998; Parkes, 1998). Some surgeons ask the family in the last

meeting after the death of a loved one, including infants, to schedule a return appointment after about six months have passed, to ask any lingering questions, and to discuss the death and their feelings about it with the surgeon (see Chapter 81). Attentive medical social workers keep track of the anniversary dates of deaths and are in touch with the families as those dates approach. The pediatric service at Massachusetts General Hospital serves the families of children who have died by offering an annual Pediatric Memorial Service to which surviving families are invited—it is very well attended.

PSYCHIATRIC CARE, REFERRALS, AND RECOVERY AFTER DISCHARGE

Most patients recover from surgery uneventfully. Those with preexisting or new mental illnesses are at risk, and outpatient psychiatric referral is essential. Collaborative follow-up consultation with visiting nurses, physical therapists, social workers, psychologists, and psychiatrists and other rehabilitative team members may make the difference between whether long-term rehabilitation fails or succeeds. Zatzick et al. (2004; 2011) have successfully developed a protocol for stepped, collaborative care of trauma victims before and after discharge that connects these patients to outside resources—for example, for PTSD, depression, and alcohol abuse—and reduces future risk. Some patients after major surgery, such as transplants, require lifelong psychiatric and surgical outpatient monitoring and care to manage complications of surgical treatment.

SUMMARY

Psychiatrists and surgeons working together reduce patient suffering, strengthen the team, usually shorten lengths of stay, and improve outcomes. That alliance takes several forms, which interact, such as clinical care, planning and implementing care improvements (like protocols pain management and alcohol abuse); sharing clinical case conferences, writing in areas of common interest, and making efforts to fund psychiatric care and research in surgical settings. Table 69.1 describes a 10-point plan for psychiatric care of the surgical patient.

CLINICAL PEARLS

- The surgeon may be respected, idealized as a savior, feared, or demonized by patients and their families for failing to fulfill expectations.
- The patients who are more likely to have difficulties in the relationship with the surgeon are those with difficulties in previous relationships.
- Psychiatrists can help clarify the patient's distortions as well as respond with empathy to the patient's anger and disappointment if his expectations are not fulfilled.
- Psychiatrists may also help the surgeons and the surgical and anesthesia staff set appropriate limits on "acting out" by patients and other types of inappropriate behavior.

Table 69.1 TEN-POINT PLAN FOR PSYCHIATRIC CARE OF THE SURGICAL PATIENT

1. *Speak* with the patient in his or her language, listen carefully, and ensure the patient's safety. After surgery, inquire as to whether or not the patient is in pain.
2. *Consult* with the surgical team about the patient, clarifying the psychiatrist's time availability and role. Within psychiatry if a psychiatrist, or surgery if a surgeon, arrange supervision, peer consultation, and departmental support.
3. *Obtain the history* of the surgical condition, disease, or trauma, psychopathology, or substance abuse, and social and family functioning.
4. *Diagnose* the mental disorder(s): Assess stage of life, stage of illness, mental status (including pain, stress, memory), psychiatric risk (delirium, suicide, domestic abuse), prognosis, medical and surgical issues including medications and their interactions, alcohol or drug withdrawal, risk factors, cultural factors, legal status, and family or staff concerns. Recommend precautions, studies, or consultations as indicated.
5. *Treat* the patient psychotherapeutically and/or psychopharmacologically for pain, delirium, stress, insomnia, depression, and other symptoms or disorders. *Evaluate and monitor* drug selection, interactions, effects, and side-effects. *Provide* staff support, and, for complex cases, plan a team conference.
6. *Communicate* with the child or adult with advanced progressive illness with limited prognosis so as to learn how and when and what truth to tell, in support of their and their family's growth toward the end of life. Assess, treat, and support the dying patient, and assist the clarification and the resolution of ethical dilemmas.
7. *Progress* to treating residual mental disorders, substance abuse, and other problems, when the patient has survived the acute phase.
8. *Facilitate* grieving and adaptation of the patient and family to cosmetic or functional losses, and foster hope.
9. *Collaborate in planning surgical follow-up and communicate psychiatric findings* and recommendations to the surgeon and primary care physician. Support reentry to school or work, including special education and rehabilitation services.
10. *Remain available for follow-up* consultation to the patient, family, and care givers, and *assist* them in *referrals* for needed services.

- Pain and disfigurement to any body part are long remembered and can have lasting effects on the patient's body image and self-esteem (Freud, 1952). Fear of "shots" or injections and fear of surgery, often related to prior experiences, are common in both children and in adults.
- Inquiry about pain is a useful beginning to consultation with surgical patients (Stoddard et al., 2011), and often allows an easy transition to inquiry about the affected body part.
- A treasured blanket, toy, book, or song may take the role of a transitional object for an infant or toddler in the hospital.
- Choices about surgery and other aspects of medical care should involve children as young as six or seven.
- Patients can be characterized by how invested they are in their own appearance on one dimension and by how much they perceive a discrepancy between their own body image and what they desire, on another dimension. In the surgical setting, these concerns can be thought of on a normal continuum (Fingeret et al., 2014).
- Often staff who have known the patient only one shift make decisions about psychological symptoms, as well as rapid *ad hoc* decisions about as needed medications for anxiety, sleep, or pain.
- A powerful antidepressant for patients recovering from surgery is rapid ambulation and resocialization, which often results in reversal of regressive symptoms and expedited recovery of more normal psychological functioning.
- Parental presence during induction of anesthesia is available at some hospitals, but children are not necessarily less anxious when parents are there, especially if the parent is anxious (Chundamala et al., 2009; Yip, 2009).
- For patients on clozapine having surgery, attention should be paid to bowel function. Changes in smoking may affect clozapine levels.
- Attention to symptoms of anxiety in surgical patients provides an early clue to surgical complications (e.g., infection, pulmonary embolus, pulmonary edema), psychiatric disorders (e.g., delirium), or reactions such as fear of dying.
- Clarification of the diagnosis of chronic psychotic disorder offers an opportunity to identify who the patient trusts, who the regular psychiatrist is, the nature of maintenance medications, whether preoperative medications offer the best possible mental status, and to build an interdisciplinary support team (Irwin et al., 2014).
- The five dimensions of the surgical experience that provoke anxiety in children summarize as well the primitive

concerns of adults. These are a) pain and mutilation, b) separation from parents or other trusted adults c) fear of the unknown and unfamiliar, d) uncertainty about normative behavior in a hospital setting, and e) loss of control, autonomy and competence (Visintainer & Wolfer, 1975).

- The adept surgeon who must do sequential surgeries makes a relationship with a patient that resonates with the patient's readiness for the next surgery.

PSYCHIATRIC MANAGEMENT OF BEHAVIORAL SYNDROMES IN INTENSIVE CARE UNITS

Robert J. Boland, Michael G. Goldstein, Scott D. Haltzman, and Tracey M. Guthrie

INTRODUCTION

To outsiders, it seems strange that a psychiatrist would ever be called into the intensive care unit (ICU). In a world where the patients often seem almost like another machine, connected to the many other machines through webs of tubes and wires, what place is there for the psychiatrist's unique skills? However, in this life-and-death setting, each facet of the biopsychosocial model is stressed to its limit. No matter what perspective we examine—the direct effects of life-threatening diseases and procedures on the brain, the psychological adjustments to such illness, or the social effects it has on the patient's world—all are important and relevant in this setting, and the psychiatrist is best able to evaluate the interaction of all these variables.

Nearly all patients in the intensive care setting are experiencing the psychological and physical stresses of having a life-threatening serious illness. Such stress is then compounded by the environmental stresses of the intensive care setting. Weakness, fatigue, impairment of cognitive function, restrictions on mobility, and barriers to communication are ubiquitous in the ICU.

Beyond psychological stress, many psychiatric symptoms can be a result of the illnesses or the medications found in this setting. Although psychological complications are common in the ICU, practically speaking, only a small fraction of these patients will ever be seen by a psychiatrist, as the acuteness of the situation demands that the ICU staff focus on only the most critical aspects of a patient's illness or injury. In our experience, consultation to the ICU is most likely when psychiatric factors are inhibiting a patient's medical progress in some specific way. We have found the following to be the most common reasons for an ICU team to request psychiatric consultation:

1. Management of delirium and agitation
2. Treatment of anxiety, including cases in which the anxiety is inhibiting weaning from mechanical ventilation
3. Evaluation of depressive symptoms—usually when depression may be inhibiting medical recovery
4. Assessment of suicidal patients

5. Assistance with ethical dilemmas, particularly when a patient (or the family) chooses to end life-sustaining treatment

These issues are the focus of this chapter.

DELIRIUM

Reports of the rate of delirium vary greatly. Delirium is certainly more common than reported in the ICU setting. Most ICUs will tolerate a certain degree of confusion as part of the "normal" ICU experience, and are only likely to seek specific intervention when the patient's behavior becomes problematic. Actual rates of delirium in the ICU may be as high as 80% of the patient population (Bledowski & Trutia, 2012).

The use of the term "delirium" to describe all forms of confusion is somewhat specific to the specialty of psychiatry; other disciplines may use other words to describe variations of confusion, such as "acute confusional state," "metabolic encephalopathy," or some other variation. In either case, the term is a general one that characterizes a diffuse pathological state. Part of the difficulty in agreeing on the nature of this syndrome rests in the many possible presentations of delirium: the "clouding of consciousness" that psychiatrists consider the hallmark of delirium can range from an almost stuporous state to a highly agitated one. The symptoms can involve primarily perceptual disturbances, attentional deficits, confusion, or some combination of these.

The course of delirium is dependent on the etiology. As the underlying pathophysiology improves, so will the delirium. The presence of delirium, however, suggests significant pathology, and it is a predictor of morbidity and mortality.

ETIOLOGY OF DELIRIUM

By definition, delirium is the result of some alteration in normal brain function. Although the environment can play a role in adding to confusion, it is rarely, if ever, the sole cause of a delirium. Such terms as "ICU psychosis," which seem to imply that the very nature of the ICU can cause confusion,

are misleading, and delay proper medical attention. As the primary treatment for delirium is to identify and then treat the underlying cause, understanding what the likely causes are is important.

Medications

Medications are the most common cause of delirium. The list of medications that may be associated with neuropsychological side effects is virtually endless. Although such lists can be helpful, their length and breadth raise several questions: Of these different medications, which are most likely to cause psychiatric side effects? Moreover, if there is an absolute medical necessity for a certain medication in spite of its confusional side effects, what can be done?

Several medications seem particularly likely to cause delirium. Special attention should be paid to anticholinergic medications; one must also be aware which medications have these properties. Antiarrhythmics, corticosteroids, antihistamines, narcotics, and sedatives (including the benzodiazepines) are other likely offending agents.

If a medication is required, several options should be considered. First, a switch to a medication that is less lipophilic (therefore less penetrating into the brain) can help. For example, among the beta-blocking agents, propranolol is particularly lipophilic, and another agent, which is more hydrophilic, such as atenolol, should be considered. If there is no reasonable alternative, a medication should be given at its minimal effective dose. This dose can be estimated through either clinical titration or serum drug levels. Drug levels are particularly important for measuring drugs that have a narrow therapeutic range, such as digitalis. In the face of medical illness, a previously appropriate dose may cause toxic drug levels. Even normal levels can cause delirium in an otherwise debilitated patient, and serum levels can be used to determine the minimum effective dose.

Medical Illnesses

Most illnesses severe enough to require an ICU admission are likely to have systemic manifestations; however, we may forget that the brain is one of these systems. Even seemingly minor illnesses, such as urinary tract infections, can have devastating neuropsychological effects on the fragile elderly patient. Of most concern are the effects of acute cardiac illnesses, which may include hypoxia, hypotension, congestive heart failure, and embolic stroke.

Although some studies have found little evidence of neurological sequelae after cardiac arrest with prompt resuscitation, careful assessments of cognitive and psychological status have shown that these patients may develop subtle signs of persistent cognitive impairment. In addition, some patients experience changes in mood and behavior, which may be overlooked on routine examination and can only be fully appreciated when the patient is more stable. Recognition and memory may be relatively spared, and cognitive impairment may occur more preferentially in subcortical areas (those affecting motivation and attention, for example). As such, these symptoms may be mistaken for depression or the effects of medication.

Surgical and Procedural Complications

Cardiac surgery is responsible for more neurological and neuropsychological complications than other common types of surgery; however, the rates of confusion after cardiac surgery vary widely across studies.

Several factors may predispose the surgical patient to delirium, particularly older age and preexisting cardiac impairment. It is not clear to what degree interoperative factors such as length of time under anesthesia contribute to delirium, but they probably play some role. However, in cases of postoperative delirium, one should always investigate for typical causes of delirium, including infections and medication effects.

Withdrawal Syndromes

Withdrawal from alcohol and sedatives or hypnotics may cause delirium as well. The presence of autonomic arousal (including tachycardia, hypertension, and pupillary dilatation), or seizures should alert the physician to this possibility. Withdrawal states are often overlooked, as complete alcohol and drug histories are frequently omitted or difficult or impossible to obtain. Even if they are obtained, patients may underestimate their dependence on medications that they are using therapeutically.

“Multifactorial” Causes

Often, no single factor can be identified, and a precise etiology might not be determined. In such cases, it is likely that several factors, although not singly causative, are contributing to the overall syndrome. In particular, the side effects of pharmacological agents may be additive or synergistic. Patients in the ICU are likely to have impairments of several organ systems. Hypoxia, hypercapnia, and hypotension, common in the critically ill, can also add to the clinical picture of delirium.

RISK FACTORS FOR DELIRIUM

Although not all are causative, several factors have been identified as being independent risk factors for delirium. A number of baseline factors may predispose to delirium, including dementia, advanced age, comorbidity, depression, hypertension, smoking, and alcoholism. Precipitating factors include hypoxia, metabolic disturbances, electrolyte imbalances, withdrawal symptoms, acute infections, seizures, dehydration, hyperthermia, head trauma, vascular disorders, immobilization, sleep deficiencies, psychiatric medications, and intracranial space-occupying lesions (Pun et al., 2007).

Some risk factors may predispose to certain types of delirium. For example, Jaber and colleagues identified seven independent risks for agitation in a medical-surgical ICU: sepsis, alcohol abuse, use of sedatives in the two days prior to ICU admission, body temperature more than 38°C, history of long-term psychoactive drug use, and hypo- or hypernatremia (Jaber et al., 2005). Of these various risk factors, the most important is probably dementia, and it is important to ascertain whether there is a history of preexisting cognitive impairment whenever possible (Lee et al., 2008).

ASSESSMENT OF DELIRIUM IN THE ICU SETTING

As with all assessments, a good assessment of delirium begins with a complete history and physical examination. The psychiatrist should personally review all data, and attempt to obtain a complete history. It may be necessary for the psychiatric consultant to recommend or initiate further assessment of physiological or metabolic status if the treating staff has not pursued all potential physiological derangements that may be contributing to delirium.

Screening for Delirium

Standard screening instruments that have been validated in ICU populations have been developed and should be used. Of these, one of the most commonly used is the Confusion Assessment Method for the ICU (CAM-ICU) (Ely et al., 2001), an instrument that was adapted from the Confusion Assessment Method (CAM) (Inouye et al., 1990) for nonverbal ICU patients. It is an eight-item checklist that can be completed in less than two minutes and requires minimal training. The instrument, along with training materials, is available to the public without cost at the website www.icudelirium.org. Another scale, the Delirium Observation Screening Scale (Scheffer et al., 2011), is designed to be administered by nursing staff, is brief and simple to use, and has been validated as a measure of delirium severity.

Other Tests

Neuroimaging has a low yield and is unlikely to help the clinician determine the etiology of most causes of delirium. However, it may be necessary for ruling out potential emergencies, such as intracranial bleeds. It is most likely to be helpful in the case of focal neurological signs that would suggest an anatomical abnormality, although some brain lesions can present without focal findings. That said, in the experience of the authors, brain imaging is probably overvalued for the workup of delirium: a normal magnetic resonance imaging scan (MRI) does not imply normal brain functioning, nor does an abnormal MRI necessarily correlate to the clinical presentation. There are some preliminary studies looking at the role of functional imaging; currently results are equivocal, but this remains a potential area for investigation (Hipp & Ely, 2012).

Another promising, albeit preliminary, area is the use of biomarkers to detect delirium. Numerous derangements in potential cerebrospinal fluid biomarkers have been implicated (Hipp & Ely, 2012; Hall et al., 2011). Currently results are inconsistent, but this remains an encouraging area of research.

Electrophysiological studies may be of particular use in perplexing cases, as the electroencephalogram (EEG) invariably shows diffuse slowing in delirium. It can be useful in differentiating “functional” psychiatric presentations (such as an acute psychotic episode associated with schizophrenia, or a catatonic depression) from delirium. An EEG is also obviously useful in more specific cases when seizure activity is suspected. Except in such cases, the EEG is generally

non-specific; however, generalized slowing would imply a diffuse neurophysiological impairment and can focus the workup on potential causes of delirium.

In our experience, it appears that clinicians over-rely on neuroimaging in the workup of delirium and related syndromes, and underuse relatively simple neurophysiological tests such as the bedside EEG testing.

TREATMENT

The primary treatment for delirium is to treat the underlying cause. Although many agents have had anecdotal success as “mind-organizing” or “anti-delirium” agents, there is no consistent support for the actual existence of such an agent. Most of the symptomatic treatments are aimed not at the delirium itself, but at behaviors associated with the delirium, such as anxiety or agitation.

Sensory Stimulation and Sleep in Delirium

Both sensory deprivation and sensory overload may lead to the exacerbation of confusion in the ICU. Excessive noise levels, for example, may lead to sleep deprivation, irritability, and impaired cognitive performance.

Management of Behaviors Associated with Delirium

Nonpharmacological interventions that are particularly useful in the prevention and management of delirium in the intensive care setting are listed in Table 70.1. They are directed at enhancing patients’ cognitive function, facilitating communication (among patients, families, and staff), preventing harm (to self or others), minimizing environmental stresses, maximizing comfort, and providing support and reassurance.

In cases of significant agitation or physically aggressive behavior, most patients will receive a medication to control these harmful symptoms. Currently there are no drugs that are federally approved for the treatment of delirium. However, a number of drugs have some evidence to support their use. Some typical medications used are discussed next.

Antipsychotics

With few exceptions, antipsychotics remain the drugs of choice for management of the agitated intensive care patient with delirium. A recent retrospective study of 71 medical centers found that antipsychotics were administered to 11% of ICU patients (Swan et al., 2012). This is for several reasons, including that they do not produce significant respiratory depression, and they are less likely to increase cognitive impairment. Although they have several potentially serious side effects, including cardiac arrhythmias and neuroleptic malignant syndrome, these are generally rare side effects.

Haloperidol probably remains the most commonly used neuroleptic for the treatment of delirium (Ely et al., 2004), given its fast onset of action, ease of administration, and predictable pharmacokinetics (Wang et al., 2012). It is recommended as first-line treatment by the Society of Critical

Table 70.1 NONPHARMACOLOGIC MANAGEMENT OF DELIRIUM IN THE INTENSIVE CARE SETTING

GOAL OF INTERVENTION	METHODS
Enhance cognitive function	Reorient frequently Clock, calendar, radio, television in room Provide explanations, education
Enhance communication between family and staff	Encourage writing if unable to speak; use letter board, communication devices, hand or blink signals if unable to speak or write Encourage family visitation
Prevent harm to patient or staff	Use soft mittens and restrain, using the least restraint necessary
Minimize Environmental Stresses	Provide sensory stimulation but limit noise from alarms and equipment Maintain semblance of day-night (diurnal) cycle (i.e., dim lights at night) Engage in nonessential care (baths, dressing changes) during the day Preoperative orientation and visit, when possible
Maximize patient comfort	Control pain adequately Mobilize (i.e., bed to chair) Permit rest, limit unnecessary awakenings Invite family to stay with the patient to reduce suspiciousness and paranoia
Provide support and reassurance	Empathy, opportunity to ventilate, support, reassurance

Care Medicine (Jacobi et al., 2002). One survey of health professionals found that 86% reported using haloperidol to treat delirium, compared to 40% who reported using atypical antipsychotics (Patel et al., 2009). A more recent retrospective cohort study of U.S. academic medical centers still found haloperidol to be, by far, the most commonly used antipsychotic for delirium (Swan et al., 2012). It is considered to be relatively safe, and its most common side effect of extrapyramidal symptoms are thought uncommon and are less of a concern in an ICU setting; the most common extrapyramidal symptoms are bradykinesia and a resting tremor; both of these are usually tolerable and transient for the usually short durations of treatment required in the ICU setting (obviously, one should be aware of more serious extrapyramidal side effects that could be disruptive, such as akathisia or acute dystonias, both of which would require treatment or a medication change). In addition, it can be given through parenteral routes: although not approved by the U.S. Food and Drug Administration (FDA) for intravenous use, such administration does appear to be safe and it is frequently administered this way in the ICU setting. It has been rarely studied systematically; one study compared the use of haloperidol to placebo for the prevention of postoperative delirium in 430 patients (Kalisvaart et al., 2005). This study found the incidence of delirium to be similar across groups, but the haloperidol group had a lesser severity and a shorter time to recovery than the placebo group; it should be noted that this was a prevention rather than a treatment study. More recently, a different team used haloperidol to prevent delirium in a 457 critically ill elderly patients who underwent noncardiac surgery: they found that the group treated with low-dose, prophylactic haloperidol had a much lower incidence of delirium (15%, versus 23% in the control group) (Wang et al., 2012).

Low-potency phenothiazines, such as chlorpromazine or thioridazine, are inferior to haloperidol in the intensive care setting for several reasons. They have anticholinergic effects (which can worsen confusion), quinidine-like effects (similar to that of tricyclic antidepressants), and alpha-adrenergic-receptor blocking effects (which can cause hypotension and exacerbate the effects of concurrently administered antihypertensive medications).

The atypical antipsychotics are becoming more popular in the ICU, mirroring the general preference for them over older antipsychotics. Anecdotal reports suggest that they can be as effective as haloperidol (Patel et al., 2009), but they have rarely been studied in this setting.

Han and Kim compared risperidone and haloperidol in the treatment of delirium, and found no difference in response between the two drugs (Han et al., 2004).

Two studies compared olanzapine with haloperidol: Skrobik and colleagues compared the use of haloperidol with olanzapine in about 70 delirious patients admitted to an ICU and randomized to one or the other drug. They found that clinical improvement was similar in both groups, but the haloperidol group had more (mainly extrapyramidal) side effects (Skrobik et al., 2004). Hu similarly compared olanzapine and haloperidol, but also added a placebo group (for a total of 175 patients) and found that both haloperidol and olanzapine were preferable to placebo and not significantly different from each other (Hu et al., 2004).

Similarly, quetiapine has been studied in 36 ICU patients who were randomized to a comparison of it with a placebo (Devlin et al., 2010). The quetiapine group had a similar length of stay as the placebo group; however, there were fewer periods of agitation. This study was complicated by the fact

that both groups received as-needed haloperidol, but the quetiapine group required less.

Ziprasidone was also compared to haloperidol and placebo in the Modifying the Incidence of Delirium (MIND) Trial (Girard et al., 2010), which examined 100 mechanically ventilated ICU patients at six American tertiary care centers. The authors found that both antipsychotics did not improve the primary or secondary outcome measures; however, it was intended as a feasibility study, and a larger study is currently underway.

An open-label study of paliperidone gave preliminary evidence for the suggestion that it is safe and effective for treating delirium (Yoon et al., 2011).

A 2009 Cochrane Review concluded that haloperidol, olanzapine, and risperidone (the only three drugs for which it found sufficient data) were equally effective for the treatment of delirium, although it noted the paucity of literature on the subject (Lonergan et al., 2007). These data are even more lacking when one looks at older adults, presumably the most common group of patients likely to get delirium in the ICU setting. One meta-analysis subsequent to the Cochrane Review restricted its analyses to studies in which the mean subject age was 60 or older and concluded that the data were too limited to support the use of any antipsychotic for elderly patients (Flaherty et al., 2011).

When one makes a clinical decision to use antipsychotics for delirious patients in the ICU, there is little guidance as to dose, and treatment is usually empirical. Among the possible routes, intermittent intravenous (IV) administration is the approach of choice (Wang et al., 2012), given the rapid onset and avoidance of absorption and first-pass effects. Continuous infusion may be considered for patients not responding to intermittent boluses (Wang et al., 2012). Although many clinical settings in the past employed rapidly escalating doses (e.g., doubling the dose of haloperidol every half hour until the behavior was controlled), there is little evidence to support these potentially large doses, and following the general principle of careful titration to find the lowest effective dose is advised.

Although the antipsychotics are usually considered safe when treating intensive care patients, there are caveats. In 2005, the FDA issued an alert warning that atypical antipsychotics are associated with an increased mortality risk in elderly patients (FDA, 2008), and subsequent investigations have suggested that the mortality risk with typical antipsychotics is even higher (Wang et al., 2005). Although the exact mechanism of this mortality is not clear, cardiovascular risks are likely to account for a large part of this risk. These warnings were based on meta-analytic data that were not specific to ICU patients, but should be taken into account when considering the risks and benefits of using these drugs in the ICU, particularly in patients with cardiovascular disease.

Benzodiazepines

In some cases, antipsychotics may be ineffective or limited by side effects. Benzodiazepines may be administered parenterally as alternatives to antipsychotics for managing agitation

associated with delirium in the ICU. Some experts and many clinicians actually prefer benzodiazepines to haloperidol because they do not exacerbate seizures or produce extrapyramidal side effects. However, this reasoning may be misguided, as it has long been noted by many psychopharmacologists that benzodiazepines can worsen confusion, and some investigators have found benzodiazepines to be an independent risk factor for delirium (Pandharipande et al., 2006). In situations where they are deemed necessary, lorazepam is the benzodiazepine of choice. It may be useful, not only singly, but in combination with haloperidol, and it may help lessen the amount of haloperidol needed for management of agitation. Advantages include a relatively short half-life, an absence of active metabolites, and elimination mechanisms (conjugation and renal excretion) that are not significantly affected by age or liver disease. Lorazepam is also available in parenteral form and is one of the few benzodiazepines (along with midazolam) with reliable intramuscular absorption.

Midazolam is a parenteral benzodiazepine promoted for intravenous sedation during short diagnostic or endoscopic procedures and as an adjunct to anesthesia regimens. Because of its rapidity of action, high lipophilic nature, short half-life (elimination half-life of 1–4 hours in healthy individuals), and decreased local irritation, it has several advantages for the treatment of delirium in the ICU. However, midazolam's metabolism is affected by acute liver dysfunction and systemic illness, and the potential for iatrogenic overdose is greater for midazolam than for lorazepam. This is the primary reason that we prefer lorazepam to midazolam for management of delirium and agitation in the ICU, especially in patients who are not intubated.

Benzodiazepines are the agents of choice for treating alcohol or benzodiazepine withdrawal and should be considered in the setting of agitation that is associated (or coincident) with status epilepticus, neuroleptic malignant syndrome, and severe Parkinson's disease, primarily for their safety in not exacerbating those syndromes and their relative compatibility with other medications that may be used to treat these disorders.

When dosing patients with these and other sedatives, some experts recommend the use of "daily awakening trials" in which all sedating medications are discontinued, the patient is assessed, and when a target level of arousal is reached, the sedation is restarted at 50% of the previously used dose and titrated to effect. The purpose of this is to ensure the lowest possible dose of sedation. This use of interrupted sedation is associated with better psychological functioning and shorter ICU stays (Banh, 2012).

Other Sedatives

Dexmedetomidine, a selective alpha-2 agonist, has recently received a good deal of attention as an alternative agent for treating agitation in the ICU. It has both sedative and analgesic effects, but is thought to be less likely to cause confusion than standard sedatives. When used as a sedative, it is less associated with delirium than either midazolam (Riker et al., 2009; Maldonado et al., 2009) or lorazepam (Pandharipande

et al., 2007). For example, the Maximizing Efficacy of Targeted Sedation and Reducing Neurological Dysfunctions (MENDS) Trial (Pandharipande et al., 2007) compared the use of dexmedetomidine with lorazepam in 106 mechanically ventilated patients and found that patients treated with dexmedetomidine experienced more days alive without delirium or coma, and a lower prevalence of coma. The Safety and Efficacy of Dexmedetomidine Compared with Midazolam (SEDCOM) trial (Riker et al., 2009) compared dexmedetomidine to midazolam in 375 mechanically ventilated patients and found a lower incidence of delirium while achieving similar sedation. Dexmedetomidine has also compared favorably to morphine (Shehabi et al., 2009) and propofol (Mirski et al., 2010). Perhaps most significantly, dexmedetomidine was found preferable to haloperidol in one study, in that mechanically ventilated patients treated with dexmedetomidine had a shorter time to extubation and needed less adjunctive propofol during their ICU stay (Reade et al., 2009). In considering the weight of the data, and the difference in side effect profiles, dexmedetomidine may be an acceptable and potentially preferable sedative for use in the ICU, given the lesser risk for delirium and respiratory depression (Hipp & Ely, 2012). When using it, patients should be monitored for bradycardia and hypotension.

Benzodiazepine Antagonists

Flumazenil is a competitive antagonist that binds directly to the benzodiazepine receptor. It reverses the effects of benzodiazepines, such as respiratory depression, and is useful in cases of benzodiazepine toxicity. It has a short half-life (30–90 minutes), and repeat dosing of the drug may be required—even then, reversal of respiratory depression is not always complete. Side effects include nausea, vomiting, and agitation. In benzodiazepine-dependent patients, flumazenil may induce withdrawal and seizures, and it should be avoided in all but life-threatening cases.

Opioids

In situations where pain complicates the clinical presentation, further control may be obtained by using intravenous opioids. It is especially difficult in the ICU to distinguish between agitation associated with pain and agitation due to delirium. Although narcotic analgesics may contribute to the development or persistence of delirium, analgesia should not be withheld when pain is known to be present or likely. It is best to continue to treat such patients with a moderate dose of an opioid on a regular fixed schedule. Certain opioids, particularly meperidine, are considered cerebrotoxic and should be avoided altogether.

Cholinesterase Inhibitors

Delirium or coma associated with anticholinergic toxicity may be reversed with physostigmine, a cholinesterase inhibitor. However, because its effects are short-lived and its use is associated with toxicity (i.e., bradycardia, hypotension,

seizures, vomiting, and asystole), we do not recommend its use except in emergency situations. There are limited data to support the use of longer acting cholinesterase inhibitors, such as those used for Alzheimer's disease (donepezil, galantamine, and rivastigmine) for delirium; however, these are primarily limited to case studies. The largest prospective study to date examined the use of rivastigmine as an adjunct to haloperidol (van Eijk et al., 2010). This study did not support the use of cholinesterase inhibitors and, in fact, had to be prematurely terminated when it became apparent that patients in the rivastigmine group had increased mortality as well as longer duration of delirium.

Anesthetic Agents

When patients have not responded to other approaches and their agitation is significantly interfering with critical treatments, it may become necessary to resort to the use of anesthetic or paralytic agents. These agents should be considered only when other methods have failed. The role of the psychiatrist in such cases will most likely be strategic—in helping to determine when other methods are unlikely to be beneficial and when anesthesia should be considered; the specifics of treatment should be established in collaboration with an anesthesiologist.

ANXIETY

Anxiety is ubiquitous in the ICU. Most cases of anxiety arising in the ICU will be secondary to some aspect of the patient's medical illness, medications, or the ICU setting itself.

Many biological factors can influence the experience of anxiety in the ICU. Medical conditions can cause anxiety, including an evolving myocardial infarction (MI), hypoglycemia, and hypoxia. Patients who are treated with sympathomimetic drugs such as theophylline for concomitant pulmonary disease, or with isoproterenol for cardiac rhythm disturbances, may develop anxiety as an adverse reaction to these drugs. Anxiety might be particularly common in patients on mechanical ventilation who are having difficulty weaning from the ventilation.

Anxiety may also be a manifestation of alcohol, sedative, opiate, nicotine, or antidepressant withdrawal, and the issues accompanying the recognition of withdrawal syndromes in this group are similar to those discussed for delirium in this chapter. Because nicotine dependence is more prevalent than other psychoactive substance use disorders, especially among a population of patients with cardiovascular disease, nicotine withdrawal is probably the most common withdrawal syndrome encountered in the ICU.

Many factors contribute to the experience of anxiety. Fears of death or disability, misconceptions about the meaning of an illness and prognosis, misinterpretation of the displays and alarms from the monitors in the room, and restriction of usual activities, all may contribute (Cassem et al., 1971). Patients are also concerned about the life problems they were confronting before admission and the effects that the illness and hospitalization will have on their ability to handle these problems.

Anxiety usually diminishes as patients feel more secure with the knowledge that they are being closely monitored. After an MI, for example, simply having survived the first hours usually reduces panic. Some degree of denial, which can be hazardous during the pre-hospital phase of unstable angina or MI, may protect the patient during the ICU phase, as it may serve to reduce anxiety and associated cardiovascular stimulation. However, transfer from the unit to a general medical or intermediate care floor may be accompanied by a marked increase in anxiety.

Idiopathic, or “primary,” anxiety may also exist in the ICU, and many of the symptoms of panic disorder and other anxiety syndromes overlap with other common syndromes such as cardiac disease. Many cases of preexisting anxiety disorders can be discerned with a complete history.

Post-traumatic stress disorder (PTSD) is particularly prevalent during or after an ICU experience; one review estimated that 22% of patients admitted to an ICU went on to have symptoms suggestive of PTSD. Factors predisposing to this included prior psychopathology, greater benzodiazepine administration, and post-ICU memories of frightening or psychotic experiences (Davydow et al., 2008). Some case-comparison studies suggest that manipulation of the hypothalamic-pituitary-adrenal (HPA) axis at the time of trauma, such as through the use of hydrocortisone or beta-blockers, may decrease the incidence of PTSD in this setting (Girard et al., 2007).

MANAGEMENT OF ANXIETY

Nonpharmacological approaches to treating anxiety include providing accurate medical information, having supportive family members nearby, explaining the roles and meaning of the monitoring equipment, providing emotional support and reassurance, and reinforcing the *appropriate* use of denial. The latter can seem counterintuitive to other staff members, and occasionally a psychiatrist may be called to help a patient who is “not coming to terms” with their disease. In such cases, the psychiatrist should assess the patient and judge whether the use of denial represents an effective coping mechanism for the patient. In most such cases, the patient is using “suppression” in that the patient is aware of the life-threatening issues at stake, but choosing to “put them aside for the moment.” In such cases an appropriate intervention may be to simply reassure the patient and the staff that such a strategy is acceptable and not in itself “pathological.”

Teaching patients relaxation techniques may also be an effective strategy to reduce anxiety and enhance self-control and self-efficacy. In cases in which patients are awake, alert, and cognitively intact, they can find such techniques both useful and distracting. Brief psychotherapies, including such modalities as psychoeducation, crisis intervention, short-term therapy, supportive therapy, cognitive behavioral therapy, and hypnosis, have all been found to be helpful, although our experience is that they are mainly useful when they are focused on a specific problem or stress. Family interventions may be helpful as well, particularly if family members appear to be “transmitting” their own anxiety to the patient.

Pharmacological Approaches

Benzodiazepines have long been thought to be effective in reducing or eliminating autonomic reactivity associated with stress. Although benzodiazepines are commonly used, the concerns already expressed in the prior section should be noted, and the previously stated preference for lorazepam as the benzodiazepine of choice would apply here as well. Although specific dosing recommendations would depend on the specific clinical situation, the general recommendation would again be to use the lowest effective dose. In cases of withdrawal syndromes, appropriate treatment of the specific type of withdrawal would be indicated.

DEPRESSION

Depressive symptoms in the intensive care setting may result from a variety of possible causes. An acute illness may directly cause depressive symptoms or produce symptoms that mimic some aspects of depression. Additionally, the patient may experience an emotional reaction to an acute illness. Medications may cause depressive symptoms. A patient may have an independent major depressive disorder.

Therefore, diagnosing depression in the ICU setting is very difficult. When evaluating for depression, the usual admonition to exclude symptoms that are due to other causes can be difficult to follow. We believe it is best to take an inclusive approach, as the risk of missing a potential depression in the ICU setting seems to outweigh any danger of overdiagnosing the disorder.

Post-ICU depression may be a common phenomenon as well, with one review estimating that about 28% of ICU survivors report clinically significant depressive symptoms. Some of the usual depression risk factors (gender, age) do not seem to be relevant in this population, and the strongest risk factors appear to be early onset post-ICU depressive symptoms (Davydow et al., 2009).

TREATMENT OF DEPRESSION

For most patients, dysphoria in the setting of an illness is time-limited and does not require aggressive pharmacological intervention. Patients with prolonged stays in the ICU may develop an adjustment disorder with a depressed mood. This disorder usually responds to psychotherapy or to the initiation of formal rehabilitation efforts. Some patients, however, develop a major depressive episode.

If feasible, medications that may contribute to a depression should be discontinued or changed. Lists of such medications are common, although sometimes overinclusive. For example, beta-blockers are a frequently cited cause of depression; however, multiple studies and meta-analyses suggest that beta-blockers do not significantly increase the risk for depression and only slightly increase the risk for fatigue and sexual dysfunction (Ko et al., 2002).

When an antidepressant is indicated, the selective serotonin-reuptake inhibitors (SSRIs) are probably the treatment of choice, as they are largely safe to use in this population.

However, they can have significant drug–drug interactions, which is important as most ICU patients are on multiple agents. SSRIs are potent inhibitors of oxidative metabolism. A wide variety of other agents, therefore, can be potentiated by these antidepressants by having their serum levels elevated. This is of most concern with other agents that have low therapeutic indices, such as warfarin, phenytoin, or digoxin. Should an antidepressant be indicated in patients on such agents, SSRIs are not contraindicated; however, the blood levels of medical drugs with low therapeutic indices should be monitored closely after introduction of the SSRI. Some SSRIs, such as sertraline and citalopram, have a lower likelihood of causing drug–drug interactions. Furthermore, the SSRIs and most of the newer agents (except venlafaxine and its metabolite, desvenlafaxine) are highly protein-bound, and may potentiate other medications through this mechanism as well. As patients in the ICU are frequently on multiple medications, it can be difficult to be sure which drug is interacting with which, but a reasonably high index of suspicion and monitoring should be used when SSRIs are initiated in the ICU.

Agents such as venlafaxine may cause an increase in mean blood pressure at higher dosages and should be monitored for such effects in cardiac patients. Alternately, venlafaxine has minimal protein binding and few effects on CYP450-2D6 and CYP450-3A4 isoenzymes. Bupropion has dopaminergic properties; the effect of this on patients who are receiving other dopaminergic agents is not known. Bupropion can also lower the seizure threshold, and is not recommended in patients considered at risk for seizures.

Psychostimulants may be useful agents for the treatment of depression in the medically ill. We do not recommend the use of psychostimulants for the routine treatment of major depressive episodes in the ICU. They may be considered in cases in which a rapid effect is critical or standard antidepressants are not adequate. When they are used, the treatment team should watch for adverse effects on heart rate and blood pressure; fortunately, these are uncommon.

Suicidality in the ICU

Most ICU admissions for suicidality are the result of self-poisoning. Many self-poisonings are done with psychotropic medication. Fortunately, most ICU staffs are well trained in the acute treatment of these potentially lethal overdoses, and consultation is more likely to be for evaluation of the patient's continued potential for suicide.

Although, by definition, any overdose sufficient to justify an ICU admission is serious, it does not imply that the suicidal intent is as serious. Many patients are unaware of the potential toxicity of their medication. Sometimes the overdose may be entirely accidental, a sudden impulse without suicidal intent, or part of a "gesture" that went awry. Patients may express surprise at the seriousness of their act and may be relieved that they were not successful. In short, the possibilities are similar to the evaluation of suicide in any situation, and the seriousness of the act does not change the need for an open-minded evaluation.

The management of the suicidal behavior is usually straightforward in the ICU. Most patients are being

monitored very closely as a matter of routine. Most of the decisions regarding the appropriate level of observation become applicable only when the patient is discharged from the ICU, as patients are generally sufficiently observed as part of the normal ICU routine. In cases in which a patient is acutely and determinedly suicidal, additional supervision including one-on-one observation may become necessary; fortunately, this is rarely the case.

The psychiatrist should be aware of subtle (and not so subtle) hostile staff reactions to the suicidal patient. In this setting, where staff must work hard to treat critically ill patients, some may find it difficult to empathize with patients who "did this to themselves." Expressing anger to a patient for that patient's medical condition is, obviously, unprofessional. However, staff hostility is often unconscious and thus may be insidious, interfering with patient care. The psychiatrist may be in a unique position to help staff members give voice to ambivalent feelings, and to reassure them that such feelings are normal. Open (but private) acknowledgement of angry and negative feelings can help reduce "acting out" that could result from repressing these feelings.

ETHICAL DILEMMAS

No ethical issues are more important than those that surround life-and-death decisions. The ICU is a natural focal point for such issues. The ICU team must negotiate a compromise between reacting to an urgent situation and understanding the larger issues involved. Such a compromise involves balancing many factors and principles. Patient autonomy must be weighed against best-interest issues. Similarly, one must balance the hope engendered by medical uncertainty against the possibility that aggressive treatment will be useless and only cause more pain and suffering to a patient and family. Inevitably, economic issues and the enormous expense of possibly futile care are considerations as well.

In the case of patient (or family) decisions to end treatment, the psychiatrist may be consulted as the "ethical expert" to help negotiate such issues. This can be a thorny problem: although most agree that all competent patients have the right to decide their own treatment—including when to end it—in practice, this decision is strongly influenced by the opinions of others, including physicians, staff, and family members. Although the principles involved may seem straightforward, the dynamics of the situation are rarely so. Psychiatrists must intrude carefully on this potential hornet's nest. However, at the same time, psychiatrists must acknowledge that they are the perceived experts in this area, and should not avoid playing a critical role in coordinating the decision-making process. This requires a solid understanding of the relevant medical, ethical, and legal issues associated with end-of-life decisions.

STAFF ISSUES

Staff working in intensive care settings are exposed to multiple stresses. Such stresses include the high volume and rapid pace of the work, the high level of clinical responsibility, the

severity and high mortality of patients' illnesses, understaffing, and such environmental stresses as noise and overcrowding. Interpersonal conflicts: with administration, within hierarchies (e.g., nurse–doctor conflicts) and among peers can also add to stress. Nursing staff members have few opportunities to rest or escape from the ICU for relief. In modern ICUs, nurses are called on to attend to multiple and diverse tasks simultaneously. They must become familiar with an ever-expanding array of technical equipment developed for the treatment of critically ill patients. Strong feelings about patients and grief over their deaths provide constant sources of stress. Dealing with prolonged care of poor-prognosis patients and having to help families cope with their grief are particularly stressful.

Support groups can be helpful, and certain features seem to distinguish successful ICU support groups. They should be initiated in response to a felt need, should be highly structured, and should discourage premature discharge of intense negative feelings. Furthermore, support groups should center on interpersonal rather than environmental or administrative problems. Open-ended, unstructured “gripe groups” are generally not helpful and may be detrimental.

The psychiatric consultant can play a valuable role by providing house staff and attending physicians with emotional support while performing consultations on patients in the intensive care setting. The level of support will probably vary at different times. In times of high distress or after a particular crisis, the psychiatrist may be asked to provide intensive, structured support. At other times, the support may be more informal and simply a matter of “checking in” with staff while performing patient consultations. In either case, it is helpful to use a multidisciplinary psychiatry team—as the ICU team is also multidisciplinary. A psychiatric nurse is particularly valuable, as nurses in the ICU may be more likely to trust and accept another nurse when discussing difficult issues of stress and their own feelings and reactions.

Numerous innovative strategies have been used to help deal with stress in the ICU. For example, the Medical ICU at the Massachusetts General Hospital conducts “autognosis” (self-awareness) rounds on a weekly basis (Stern et al., 1993), and journal entries based on these rounds are used to prepare incoming housestaff for the particular challenges of the ICU (Sekeres et al., 2002).

CLINICAL PEARLS

- Benzodiazepines are an independent risk factor for delirium (Pandharipande et al., 2006).
- Where benzodiazepines are deemed necessary, lorazepam is the benzodiazepine of choice.
- Nonpharmacological approaches to reduce anxiety include providing accurate medical information, having supportive family members nearby, explaining the roles and meaning of the monitoring equipment, providing emotional support and reassurance, and reinforcing the appropriate use of denial.

- Brief psychotherapies, including such modalities as psychoeducation, crisis intervention, short-term therapy, supportive therapy, cognitive behavioral therapy, relaxation therapies, and hypnosis, can all be helpful, although our experience is that they are mainly useful when they are focused on a specific problem or stress.
- Family interventions may be helpful as well, particularly if family members appear to be “transmitting” their own anxiety to the patient.
- The psychiatrist should be aware of subtle (and not so subtle) hostile staff reactions to the suicidal patient. In this setting, where staff must work hard to treat critically ill patients, some may find it difficult to empathize with patients who “did this to themselves.”

OPHTHALMOLOGY

Mary Lou Jackson and Jennifer Wallis

INTRODUCTION

Vision is a crucial sense that allows us to gain information about our environment; and vision loss, from moderate to severe degrees, impacts the ability to read, gain employment, remain independent, and ambulate safely (Owsley, McGwin, et al., 2009). The adjustment to vision loss often goes beyond such functional impacts to affect the person's emotional well-being. A significant number of individuals who lose vision experience depression, anxiety, and poor quality of life (Horowitz, Reinhardt, et al., 2005; Hassell, Lamoureux, et al., 2006). Vision loss also affects the family and social networks of those who have reduced vision (Friedman & Nason, 2000; Bambara, Wadley, et al., 2009).

THE MOST COMMON CAUSES OF VISION LOSS

The most common cause of vision loss in adults in developed countries is age-related macular degeneration, which causes loss of central vision, but typically allows preserved peripheral vision (Klein, Chou, et al., 2011). Loss of central vision is noted by patients as it interferes with tasks such as reading. Glaucoma typically affects peripheral vision, and diabetic retinopathy can affect both peripheral and central vision. Early peripheral vision loss from glaucoma is often not recognized by patients, and this can delay treatment that can prevent further vision loss. Peripheral vision loss impacts mobility and orientation.

THE MEANING OF "LEGALLY BLIND"

While it is estimated that more than 4.2 million adults in the United States have *legal* blindness or low vision (2012), only a small proportion of these individuals are blind and have no, or very limited vision (Congdon, O'Colmain, et al., 2004). A larger group has legal blindness, determined in the United States as visual acuity with corrective lenses if needed, that is equal to or less than 20/200, or a visual field less than 20 degrees in diameter. The designation as "legally blind" is an arbitrary level of vision loss used historically in the United States to determine eligibility for disability benefits. In 2006, the U.S. Social Security Administration (SSA) expanded the definition of legal blindness to include testing with charts specifically designed to measure visual acuity in patients with low vision. Using these charts, a person is considered legally blind if they cannot see any letters on the 1/5

line. At this time the SSA also outlined how the criteria of legal blindness as a visual field of less than 20 degrees could be calculated using automated visual field assessment. The World Health Organization's (WHO) definition of legal blindness is an acuity less than 20/400 (6/120), and the definition of low vision is acuity less than 20/60 (6/18) (WHO, 2014). Legally blind individuals may still have considerable usable vision and be able to use magnifiers, computers, or other devices. The largest proportion of those with vision loss have partial vision loss and are neither blind nor legally blind (Table 71.1).

ADULTS AND THE ELDERLY

Worldwide, it is estimated that 45 million have blindness and 135 million have low vision (2003). The greatest burden of vision loss is borne by the elderly, as the risk of vision loss increases with age (Congdon, O'Colmain, et al., 2004; Iliffe, Kharicha, et al., 2005). Prevalence of vision loss in those over 65 is estimated to be 15%; rising as high as 30% in those over 75. With the increased longevity of our population, many elderly patients will live with vision loss for the last 20 or 30 years of their life.

CHILDREN

Although visual impairment and blindness are rare among pediatric populations, the needs of this group are unique, change with development, and are often modified by comorbidities (Ferrell, 2010). The most common causes of pediatric vision loss vary in different areas of the world; however, in the developed world, cortical disease, optic nerve disease, and retinopathy of prematurity are significant causes (Gilbert & Foster, 2001). It is estimated that 12.2 per 1,000 children under the age of 18 have low vision. Legal blindness occurs much less commonly, 0.06 per 1,000 (<http://nichcy.org>). Severely visually impaired or multi-handicapped children are more easily identified than children with less severe vision impairment. If vision loss, especially at a moderate level, is the only impairment, however, the handicap may not be readily identified, so these children often "fall through the cracks" of the vision rehabilitation system. Clinicians need to be aware of a range of psychiatric issues in the pediatric, adult, and geriatric patients who experience vision loss or eye disease, including depression, adjustment issues, hallucinations, and psychiatric effects of ocular medications.

Table 71.1 DEFINITIONS OF LOW VISION AND LEGAL BLINDNESS

WORLD HEALTH ORGANIZATION			UNITED STATES		
	Meters	Feet		Meters	Feet
Low vision	<6/18 = or >6/120	<20/60 = or >20/400	Low vision	<6/12 >6/60	<20/40 >20/200
Blindness	<6/120	<20/400	Legal blindness	= or <6/60	= or <20/200

ADJUSTMENT TO VISION LOSS

The diagnosis of vision loss, as well as the potential functional impairments associated with vision loss, confronts an individual with significant challenges (Brennan & Cardinali, 2000; Friedman & Nason, 2000; Brody, Gamst, et al., 2001; Girdler, Boldy, et al., 2010). Poor adjustment to vision loss is associated with compromised quality of life and greater risk of depression (Rees, Tee, et al., 2010). Addressing a patient's ability to adjust emotionally to the challenges posed by vision loss should therefore be an essential part of these patients' clinical care. For instance, due to vision loss, a person may not be able to drive anymore. Thus, the individual may feel that getting to a supermarket or visiting friends is now beyond her or his personal resources. This dilemma would pose a stressful situation for which new coping strategies are required.

For the purpose of the current discussion, we define *adjustment* as the goal of a continuous series of coping responses (Skinner, Edge, et al., 2003). Whether vision loss is partial or total, fluctuating, progressive, or sudden, people will continue to encounter challenges, and new coping strategies may be required.

COPING STRATEGIES

The individual with loss of vision must adjust not only to the functional impairments, but also to psychological challenges. Patients may experience changes in (gender) roles, mobility, communication, social interactions, occupations, leisure activities, and overall independence (Owsley, McGwin, et al., 2009). Both coping approaches suggested by Lazarus and Folkman's stress and coping model—problem-focused actions to counter the stressor, and responses to alter one's internal state or emotions (Lazarus & Folkman, 1984)—are important. Problem-focused actions are effective if the person has control over the situation; and if that is not the case, then modifying one's emotional response to the stressor or one's internal state (accommodating self-concept and goals to the restrictions imposed by vision loss) is the better strategy. Similarly, both assimilative (goal pursuit) and accommodative coping (flexible goal adaptation), as suggested in the model of Brandtstaedter and Renner, have a role (Brandtstaedter & Renner, 1990). Assimilative coping may require learning new strategies to reach a set goal despite vision loss (e.g., using public transport instead of driving to visit a friend), whereas accommodative coping would entail a change in goals (e.g., listening to audio books rather than

reading). Using both coping strategies is most successful in maintaining an optimistic emotional state when dealing with vision loss (Mollenkopf, Wahl, et al., 2007; Rovner, Casten, et al., 2007).

The question is, however, how people with vision loss actually do attempt to cope with the impairment. A recent study analyzed narrative data obtained from interviews with 507 visually impaired individuals to assess prevalent constellations of stressors and coping style (Lee & Brennan, 2006). Individuals' attempts to cope mostly relied on personal resources; for instance, their beliefs in self-reliance and independence. The authors identified five groups of coping constellations; main coping strategies were: (group 1) reliance on own capability with a focus on psychological coping; (group 2) similar reliance on self, but with relatively high acceptance of vision loss; (group 3) use of residual vision with support by devices and rehabilitation; and (group 4) social avoidance. The most prevalent constellation (group 5) involved no distinctive coping strategies except for some reporting self-reliance and reliance on informal support persons.

Self-reliance is an important but not sufficient coping strategy. O'Donnell (2005) also reported that older adults, those now suffering from the highest rate of age-related vision loss, "rolled up their sleeves and went to work. They want to act. They want their eyes back. They find it hard to understand that their ophthalmologist... can do nothing to restore their vision" (O'Donnell, 2005). When using this coping style of self-reliance alone, individuals may hesitate to ask for help or look for and use rehabilitation services that require learning to do tasks in new ways.

A nationwide census of vision rehabilitation services in the United States found that nearly half of the patients (45%) were rated as having emotional or psychological problems with adjusting to their impairment (Owsley, McGwin, et al., 2009). Attitudes towards blindness and fear of stigma may impact one's ability to cope (Horowitz & Reinhardt, 2000). Rates of depression (including major depression and subthreshold depressive symptoms) are relatively high among people with vision impairments (Crews & Campbell, 2004; Horowitz, Reinhardt, et al., 2005; Iliffe, Kharicha, et al., 2005; Hayman, Kerse, et al., 2007). In the elderly, reported depression rates range from 7–39%, compared to 5–8% for elders living in the community (Renaud & Bedard, 2013). Most studies of individuals with age-related macular degeneration show greater depression rates than those found in the general population of older people, comparable with rates observed in individuals with other chronic and disabling diseases (Iliffe, Kharicha,

et al., 2005; Casten & Rovner, 2008; Huang, Dong, et al., 2010). Augustin et al. found that the prevalence of depression increased as visual impairment became more severe, while other authors have linked the rate of depression to loss of function (Augustin, Sahel, et al., 2007; Evans, Fletcher, et al., 2007; Zhang, Bullard, et al., 2013). It is not clear whether individuals with vision loss have an increased risk of depression, or whether individuals with depression have a higher risk of chronic diseases such as vision loss, or both. Undoubtedly, functional losses resulting from vision loss can lead to feelings of loss of independence and lack of control, social isolation, and cessation of activities previously enjoyed—all factors that may facilitate depressive moods; however, depression may in turn affect disease course as well. For instance, individuals with depression are more likely to report poor vision (Huang, Dong, et al., 2010) and show worse performance on tasks requiring vision than those without depression, even controlling for visual acuity (Brody, Gamst, et al., 2001; Rovner & Casten, 2001; Rovner, Casten, et al., 2006). The prevalence of vision loss increases with age and, therefore, elders with vision loss often have other chronic diseases with physical limitations that may contribute to their risk of depressive symptoms (Goldstein, 2011).

Early recognition of depressive symptoms in individuals with vision loss may prevent further impact of their depression on their functioning and increase adherence to medical treatment and rehabilitation outcome. The American Academy of Ophthalmology's SmartSight model outlines how comprehensive vision rehabilitation can be part of the continuum of eye care, and in this model it is recommended that the ophthalmologist notify the patient's primary care provider of possible depression (2012). In cases of dysthymia or sadness, the ophthalmologist can assist in assuring the patient that sad moods are a common and understandable reaction to vision loss. While major depression requires antidepressant drugs or psychotherapy, vision rehabilitation can improve discouragement and sadness by teaching the patient new strategies and behaviors to maintain independence.

There are many barriers to attaining vision rehabilitation. Patients may not be aware of the services available, perhaps because their treating physicians have not advised them of rehabilitation options. Patients may not believe that such services are beneficial for them, or they may have difficulty accessing services due to other health problems or lack of transportation. It is estimated that only one-quarter to one-third of those who could benefit from rehabilitation obtain services. While there are limited reports showing that an individual confronted with vision loss may create novel strategies to cope (Bittner, Edwards, et al., 2010; Riazi, Dain, Boon, & Bridge, 2011), in general, individuals with vision loss will benefit from formal and informal support to identify both psychosocial services such as support groups, and vision rehabilitation resources (access to devices and training). Rehabilitation should be available to any individual whose vision loss impacts their life beyond simply the ability to read fine print. Medicare and most insurers in the United States cover the cost of occupational therapy for patients with vision loss, just as rehabilitation is covered for stroke or orthopedic problems. State agencies exist in all states to provide some

services, although the nature of services provided and eligibility criteria vary. Vision rehabilitation services are provided by the Veteran Administration network, and in addition, agencies, optometrists, and ophthalmologists provide various levels of service. A directory of services is maintained online (see visionaware.org).

SOCIAL SUPPORT AND FAMILY ADJUSTMENT

Adjustment to vision loss takes place in the context of a social network (Horowitz, Reinhardt, et al., 2003; Orr & Rogers, 2006). Family members often function as caregivers and provide emotional and instrumental support to the visually impaired individual (Cimarolli & Boerner, 2005). Both traditional and nontraditional families should be considered in this discussion. Both paid and informal caregivers can be part of the picture. These individuals can provide day-to-day assistance, reassure, motivate, support compliance with rehabilitation and medication, negotiate support and services, help the physician understand what the disease means to the patient, and remind the patient how they have coped with other stressors in the past.

Vision loss, like many other diseases, however, can pose a challenge for family members or caregivers. The family may struggle with finding a balance between supporting and assuring the safety of the visually impaired person and allowing the patient to be self-sufficient. Overprotection can lead to learned helplessness and thus increased dependency, as well as feelings of anger towards the caregiver. Higher levels of perceived overprotection, such as offering assistance that is not required, are associated with less optimal adjustment (Cimarolli & Boerner, 2005; Cimarolli, Reinhardt, et al., 2006). Furthermore, the challenge of providing support to a visually impaired person, often with no or little training, can result in distress for the caregiver. Caregivers may have difficulties attending to their own as well as the visually impaired person's needs and goals. Most literature has focused on the function of families or caregivers as support for the visually impaired individual, and little attention has been paid to the caregiver's adjustment process (Bambara, Wadley, et al., 2009).

Recently, Bambara et al. (2009) found that a substantial number of family caregivers suffered from psychosocial distress (Bambara, Owsley, et al., 2009). Caregivers with low problem-solving skills are more likely to experience distress, anxiety, depression, and poor health. Bambara et al. suggested that interventions to increase problem-solving abilities may support quality of life in caregivers and so eventually facilitate rehabilitation outcomes for the patient.

Including key support persons in the care process is one way to facilitate ideal conditions for the successful adjustment of both patients and caregivers. A family-centered approach to vision care allows everyone involved to understand and cope with the disease and the challenges it may pose. Key support persons can encourage discussion of how the vision impairment affects family members' functioning and goals, emotions, resources, and "how to separate the illness from the family's sense of itself" (Friedman & Nason, 2000). The process can decrease caregivers' sense of burden and support the visually impaired persons' sense of self-reliance.

VISION REHABILITATION AS A RESOURCE

Vision rehabilitation aims to maximize functioning despite an individual's loss of vision (Trauzettel-Klosinski, 2010). Patients whose vision cannot be fully corrected with ordinary spectacles, or medical or surgical treatment are provided with comprehensive assessment of visual function, the opportunity to obtain appropriate devices, and subsequent training, often by an occupational therapist. An individualized rehabilitation plan is established considering the patient's goals. Devices go beyond traditional glasses or optical magnifiers to include magnification with a video camera in either desk or portable formats, magnification on iPads or eReaders, text-to-speech technology, and computer and cellphone accessibility options. Vision rehabilitation assists in developing new coping strategies or enhancing existing productive behaviors to master tasks that are meaningful to the individual. Maintaining independence is encouraged, with the overall aim of increasing quality of life. Vision rehabilitation has been shown to improve quality of life and reduce depressive symptoms (Stelmack, Tang, et al., 2008; Girdler, Boldy, et al., 2010) and thus ought to be considered as a resource that can be offered by the physician to individuals with vision loss.

PRACTICE IMPLICATIONS

The physician can assist by supporting both problem- and emotion-focused coping strategies in various ways:

- Ensure that patients are referred to comprehensive vision rehabilitation services that address not only acquiring devices, but also other impacts of vision loss and draw on multidisciplinary services. A guideline outlining how vision rehabilitation can be incorporated into ophthalmic care is available (see <http://one.aao.org/smart-sight-low-vision>) with patient information and resources for audio digital books, large-print books or newspapers, computer accessibility information, and other resources.
- Identify key support persons and involve them in the care process, if the patient agrees.
- Provide information to the patient as well as the key support persons. Education is a key component of rehabilitation.
- Negative comments can be rephrased to point out positive components. Talking about what is most important, and what they do well, allows patients and their families to regain strength and control (Friedman & Nason, 2000; Buckman, 2005). Patients with central field loss from AMD can be encouraged that peripheral vision is typically maintained, and that, with appropriate training and devices, individuals can use this vision to maintain independence.

HALLUCINATIONS IN VISION LOSS

Many individuals who lose vision report a peculiar symptom of recurrent, vivid hallucinations known as the Charles Bonnet syndrome (CBS; Menon, Rahman, et al., 2003;

Rovner, 2006; Jackson & Bassett, 2010). Physicians often do not recognize the syndrome, in part because patients do not commonly report the symptom. Patients often fear that they will be considered mentally ill if they report such a symptom. Four criteria have been proposed for the diagnosis: (1) the patient reports vivid, recurrent visual hallucinations; (2) there is some degree of vision loss; (3) the patient has insight into the unreal nature of what they see; and (4) there is no other neurological or psychiatric diagnosis to explain the hallucinations (Jackson & Ferencz, 2009). It is now appreciated that such visual hallucinations are not uncommon in patients seeking ophthalmic care and that such hallucinations can occur even with moderate loss of vision.

The first description of hallucinations in a cognitively intact, visually impaired individual was by Charles Bonnet, a Swiss naturalist. In 1769, he wrote clear, elaborate descriptions of hallucinations experienced by his grandfather. This 18-page document describing the visual sensations predated the term *hallucination* (Ffytche, 2005). The eponym was coined in the next century by a neurologist, George de Morsier (de Morsier, 1967).

In *The Diagnostic and Statistical Manual of Mental Disorders* (DSM), a hallucination is defined as "a sensory perception that has the compelling sense of reality of a true perception, but occurs without external stimulation of the relevant sensory organ" (DSM, 2000). Many patients with vision loss can misinterpret an object in their environment, such as thinking that a person is sitting in a chair when a coat is draped on the chair. Such an illusion should be differentiated on history-taking from a true hallucination.

The images that are reported by patients vary a great deal, most often having content that is unfamiliar to the patient. Many individuals describe "seeing" people, faces, or animals, while others "see" repeating patterns of flowers or vegetation that can resemble wallpaper. There is no agreement as to whether images of bright lights or diffuse colors are part of the syndrome; however, a history of a very clear image that recurs and is present with the eyes open or closed is suggestive of the CBS.

Insight into the unreality of the images is required to make a diagnosis of CBS, but it is common that patients do not have full insight when they first experience the hallucinations. Patients may be confused about what they are experiencing, unwilling to disclose them to family or physicians, and, in some cases, very anxious that the symptom is an ominous sign of mental decline or neurological illness. They may act on their hallucinations when they fit into the environment; e.g., they may step over an object that appears to be in their way. To make a diagnosis of CBS, the individuals must have full insight after the nature of the syndrome has been explained. Lack of insight despite explanation would raise consideration of other diagnoses. Little research has addressed the link between cognitive loss and CBS.

The following case histories of patients' descriptions of hallucinations as part of the Charles Bonnet syndrome are reprinted here with permission from *Macular Degeneration: The Complete Guide to Saving and Maximizing Your Sight* (Mogk & Mogk, 2010).
